Whenever treatment is instituted for a rhythm disturbance, an underlying cause should be sought. This course of action is especially important in the treatment of bradycardias that occur in the intensive care setting, where airway compromise and respiratory insufficiency probably are the most common

causes of acute bradycardias. Increased intracranial pressure, hypothermia, or iatrogenic causes also may produce bradycardias that require specific interventions beyond those outlined here. Emergency interventions for AV nodal and sinus nodal dysfunction are essentially identical.

Pharmacologic Treatment of Bradycardias

After appropriate confirmation or restoration of airway integrity and ventilatory function, initial treatment of symptomatic bradycardias usually is pharmacologic, whether the cause is sinus node slowing or AV nodal block. Atropine (0.01-0.04 mg/kg intravenously or, if necessary, intramuscularly or via endotracheal tube) may transiently ameliorate the bradycardic effects of hypoxia (or other vagal stimulants), digoxin, intracranial hypertension, or AV block as a result of Lyme disease. Atropine is less likely to reverse bradycardic effects of β-blocking agents or other antiarrhythmic drugs, particularly in the setting of underlying sinus node disease. Epinephrine (0.1 μg/kg) can be administered by various routes to accelerate the heart rate. Continuous infusions of epinephrine (0.05-0.5 μg/kg/min) or isoproterenol (0.02-0.2 μg/ kg/min) may be instituted. In general, high-dose epinephrine or isoproterenol infusions should be replaced by temporary pacing as soon as feasible. Even if lower doses of these agents prove adequate, temporary pacing should be available as backup. Occasionally, methylxanthines are useful as an alternative to pacing for nonlethal bradycardias. Glycopyrrolate and ketamine may help augment rates in bradycardic patients requiring sedation or anesthesia.

Temporary and Permanent Pacing for Bradycardias

Pacing is an essential adjunct to medical management of arrhythmias in the ICU. Several reviews of pacing in children are available.[19-21] Pacing can be accomplished using a permanently implanted pacemaker and lead systems, temporary leads attached to the heart at the time of cardiac surgery or passed through the venous system to the heart, a lead passed into the esophagus to stimulate the atrium, or through use of transcutaneous patches to stimulate the ventricle. Most pacing is performed for bradyarrhythmias, although temporary pacing may be used to terminate reentrant tachyarrhythmias. Examination of atrial electrograms obtained from epicardial, transvenous, or esophageal pacing leads can be helpful in diagnosing arrhythmias.

Principles of Pacing

All pacing requires a complete circuit with at least one lead on or near each chamber that is to be paced. Often two leads are placed on each chamber (bipolar leads), although sometimes only the cathode is attached to the heart (unipolar leads), with a subcutaneous electrode acting as the anode. The metal can of a permanent pacemaker also can serve as the anode. The intensity of the pacing stimulus is related to the stimulus duration (pulse width) and its amplitude, which can be expressed either as current (mA) or voltage (V). Energy is proportional to the pulse width and the square of the amplitude. Most temporary pacemakers provide a fixed pulse width, with an adjustable current output (mA). Permanent pacemakers generally have both an adjustable pulse width and an adjustable amplitude.

Sensing of intrinsic activity of the heart is important to prevent pacing at inappropriate times. The sensitivity of permanent and temporary pacers is adjustable. The sensitivity setting (mV) actually refers to a sensing threshold for detection of spontaneous cardiac activity. The spontaneous activity must exceed that threshold to be detected. Thus a lower numeric sensitivity setting makes the pacemaker more sensitive to both spontaneous activity of the atrium or ventricle (appropriate sensing) and other electrical signals (oversensing).

The timing circuits of the pacemaker determine when the pacemaker fires and its response to sensed events. A simplification of the North American Society of Pacing and Electrophysiology/British Pacing and Electrophysiology Group (NASPE/BPEG) pacing code uses three letters to describe pacing modes.[22] The first two letters refer to the chamber(s) paced and chamber(s) sensed, respectively (A, atrium; V, ventricle; D, dual). The third letter refers to the response to sensed events (I, inhibit; T, trigger; D, dual). Thus a single-chamber atrial or ventricular pacing demand mode is AAI or VVI mode, whereas dual-chamber pacing is generally DDD mode. In evaluating and adjusting pacemakers, it is helpful to think in terms of intervals rather than rates. Because there are 60,000 ms in 1 minute, to convert a rate (bpm) to an interval (ms) you must divide 60,000 by the rate. For example, a rate of 100 bpm corresponds to an interval of 600 ms. Thus for a ventricular demand (VVI) pacemaker programmed to pace at a rate of 100, the pacemaker stimulates the ventricle 600 ms after the previous paced or sensed ventricular beat unless there is another sensed ventricular beat. If there is another sensed ventricular beat, the pacemaker output is inhibited and another interval of 600 ms is started. Similarly, for dual-chamber pacing with an AV interval of 150 ms, the ventricle is paced 150 ms after an atrial paced or sensed beat unless a ventricular sensed beat occurs during that interval.

Temporary Pacing

In the pediatric ICU, temporary pacing is most commonly used in patients after surgical treatment of CHD. Temporary epicardial pacing wires are usually placed on the atria and ventricles, allowing pacing of either chamber. As previously noted, direct atrial recording (by attaching the wire to an ECG lead) also may aid in the diagnosis of tachyarrhythmias such as JET. Atrial burst pacing can be used to terminate reentrant supraventricular arrhythmias such as IART, AVNRT, and ORT. Pace termination of ORT is shown in Figure 28-9. Although JET generally cannot be terminated with burst pacing, atrial pacing at a rate faster than the JET rate often improves hemodynamics by allowing AV synchrony until the JET resolves or is pharmacologically controlled (see Figure 28-8).

In bradycardic patients who do not have temporary epicardial pacing wires, transcutaneous pacing can be performed.

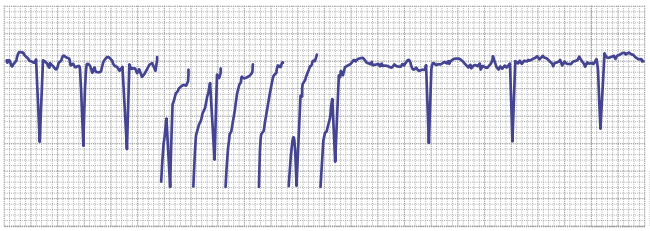

Figure 28–9. Pace termination of orthodromic reciprocating tachycardia with a burst of atrial pacing.

It is important that electrodes and output are appropriate for the patient size, and positioning may be critical to maintaining capture. In general, transcutaneous pacing is used only for a short time while a temporary transvenous pacing lead is placed. At the bedside, placement of a balloon-tipped temporary transvenous lead is best accomplished via the internal jugular or subclavian vein, because the catheter often can be directed to the ventricle "blindly." When fluoroscopy is available, a temporary active fixation may be preferred, allowing more secure positioning and the choice of pacing the atrium, the ventricle, or both (in dual-chamber mode).

Setting Temporary Pacing Parameters

For AAI or VVI demand pacing, the pacemaker usually is initially set at a rate higher than the patient's intrinsic atrial or ventricular rate. The pacemaker's output expressed in mA (current) or V (voltage) is gradually reduced until there is loss of capture and then is increased again. The lowest output that captures the chamber being paced is known as the pacing threshold. Usually the output is set at twice the threshold output. The pacemaker rate is lowered to a rate below the intrinsic rate of the chamber being paced, unless the patient is hemodynamically unstable at that rate. The pacemaker should indicate that it is sensing the intrinsic atrial or ventricular activity, usually with a blinking indicator light. The sensitivity of the pacemaker is adjusted to higher numeric settings (less sensitive) until the pacemaker stops sensing the intrinsic activity. The sensitivity then is reduced to a lower numeric value (more sensitive). The highest numeric value at which the pacemaker senses appropriately is known as the sensing threshold. Ideally, the sensitivity is set to a numeric value that is half the sensing threshold, but this is not always possible, especially for temporary atrial leads. Failure to sense can result in inappropriate pacing, which can induce tachyarrhythmias. Figure 28-10 shows a single inappropriate atrial stimulus initiating sustained ORT.

Dual-chamber pacing is more complex. The atrial and ventricular sensitivity and output are set using basically the same process described for single-chamber pacing. In addition to setting the low rate of the pacemaker, several other timing parameters must be set, including the upper tracking limit (UTL), the AV delay, and the postventricular atrial refractory period (PVARP). UTL defines the fastest rate at which the pacemaker will pace the ventricle. PVARP refers to a period after a ventricular paced event during which the pacemaker is refractory to atrial sensed events and ignores any spontaneous atrial beats. The pacemaker is also refractory to spontaneous atrial events during the AV interval. Thus the total atrial refractory period (TARP) includes both the AV interval and the PVARP. Although TARP is not a programmable parameter (it is the sum of the programmed AV interval and the programmed PVARP), it is an important concept for understanding high rate behavior.

If the spontaneous atrial cycle length (60,000 ms/min divided by the spontaneous atrial rate in bpm) is less than the TARP, only half of the spontaneous atrial beats will be sensed, resulting in 2:1 block. The point at which this occurs is known as the 2:1 block rate. Because abrupt 2:1 block is generally an undesirable situation, most temporary pacemakers will not allow the UTL to be set above the 2:1 block rate. Thus before increasing the UTL, it often is necessary to shorten the AV interval or the PVARP. If the atrial rate exceeds the UTL, the ventricular output will be delayed, producing a rhythm that resembles Wenckebach AV conduction, known as pacemaker Wenckebach. It is important to remember that pacemaker Wenckebach is a desirable response to high atrial rates. The alternatives, tracking rapid atrial rates 1:1 and abrupt 2:1 ventricular tracking of the atrium, are more likely to cause hemodynamic compromise. Occasionally appropriate pacemaker Wenckebach is mistaken for failure to sense the atrium or failure to pace the ventricle. Figure 28-11 shows 1:1 conduction, 2:1 block, and pacemaker Wenckebach at different pacemaker settings in a patient with a dual-chamber pacemaker for high-grade AV block.

When initiating dual-chamber pacing, it is important to be sure that the atrial lead senses appropriately and that the rates, intervals, and refractory periods are set appropriately to allow the pacemaker to track the spontaneous atrial rate. If the intrinsic atrial activity is not appropriately sensed and the dual-chamber temporary pacemaker's low rate is lower than the patient's intrinsic atrial rate, you may falsely assume that dual-chamber pacing is occurring when it is not. The presence of cannon A waves on the central venous pressure tracing may provide a clue that AV synchrony is not occurring. Reversing the atrial leads, lowering the numeric atrial sensitivity, or adjusting the AV interval, UTL, or PVARP may remedy this situation. If the atrium still cannot be sensed appropriately, setting the pacemaker's low rate higher than the patient's own

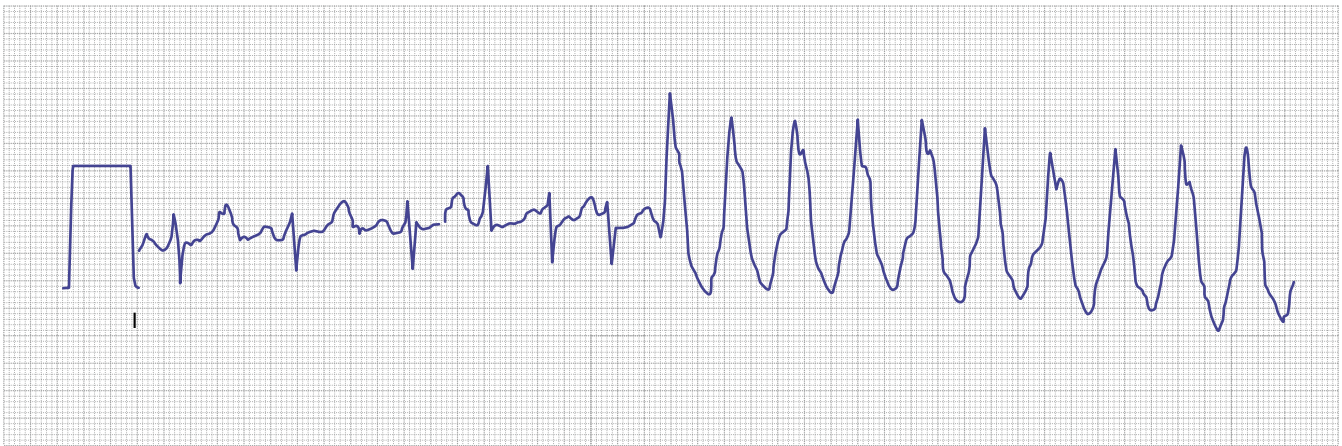

Figure 28–10. Initiation of orthodromic reciprocating tachycardia with a single atrial paced beat that falls at a vulnerable time. After several narrow-complex beats, bundle branch block in tachycardia results in a wide-complex rhythm.

Figure 28–11. Examples of pacemaker high-rate behavior. Each panel shows a surface electrocardiogram with the simultaneous atrial electrogram below. *Top,* 1:1 Atrioventricular conduction. Each sensed atrial event falls outside the total atrial refractory period, resulting in a corresponding paced ventricular event. *Middle,* 2:1 Block occurs when the total atrial refractory period exceeds the spontaneous atrial cycle length. Every other atrial beat falls within the refractory period and fails to trigger a ventricular pacing stimulus. *Bottom,* "Pacemaker Wenckebach" operation occurs when the atrial rate reaches the upper tracking rate. Gradual lengthening of the AV delay ensures that the ventricular pacing does not occur above the upper tracking rate. Eventually, an atrial sensed event falls within the refractory period so that a ventricular pacing stimulus is not triggered. All three recordings were obtained in the same patient over a short period by adjusting the programmable pacemaker parameters. *(From Sliz NB Jr, Johns JA: Cardiac pacing in infants and children,* Cardiol Rev *8:223-239, 2000.)*

atrial rate will allow AV synchrony. In effect, you are pacing in DVI mode, pacing atrium and ventricle, sensing the ventricle, and inhibiting pacemaker output when spontaneous ventricular beats occur. Older temporary dual-chamber pacemakers offered only DVI mode; newer devices allow true DDD pacing as long as atrial sensing can occur.

Occasionally, a reentrant arrhythmia known as pacemaker-mediated tachycardia (PMT) may be seen, in which a DDD pacemaker senses the atrium and paces the ventricle, with the patient's own AV node conducting the impulse up from the ventricle to the atrium and the cycle repeating again. Thus the pacemaker acts as the antegrade limb of the reentrant circuit, while the patient's own AV node acts as the retrograde limb. Usually, PMT can be avoided with careful adjustment of the pacemaker's AV interval and PVARP. Acutely, PMT usually can be terminated by placing a magnet over the pacemaker, which makes the pacemaker pace asynchronously, ignoring any sensed events, thus interrupting the antegrade limb of the reentrant circuit. Figure 28-12 shows initiation of PMT by loss of atrial capture with termination of the tachycardia by a spontaneous ventricular beat.

Figure 28–12. Initiation and termination of pacemaker-mediated tachycardia. *Top,* Two atrial pacing stimuli fail to capture, followed by ventriculoatrial conduction of a ventricular paced beat. The resulting atrial beat *(AS)* is sensed and triggers another ventricular beat, and the process repeats. Had the retrograde atrial beat occurred during the postventricular atrial refractory period, it would not have triggered a ventricular paced beat. *Bottom,* Spontaneous ventricular beat inhibits the ventricular pacing, terminating the process. Atrial electrogram tracings are shown at the bottom of each panel. *AP,* Atrial pace; *AR,* atrial refractory; *BV,* biventricular pace; *VS*, ventricular sense.

Permanent Pacing

The two most common indications for permanent pacing are high-grade AV block and sinus nodal dysfunction. AV block may be congenital or acquired, with surgical damage to the conduction system the most common cause of acquired AV block. In patients with surgical AV block, there may be recovery of normal conduction with resolution of edema. In general, permanent pacing is not recommended unless there has been no recovery for 7 to 14 days.[23] Occasionally, if the surgeon is confident that the conduction system has been permanently damaged or if temporary pacing is not reliable, permanent pacemakers may be implanted before 7 days after the initial injury. Elective pacing for congenital AV block in the first decade of life usually is prompted by symptoms, low ventricular rates, or ventricular ectopy. Elective pacing is commonly recommended in the second decade of life even for asymptomatic patients with congenital heart block, based on studies showing that the first symptom in teenagers and adults may be catastrophic.[24] Pacing for sinus nodal dysfunction is most commonly performed in patients with structural heart disease, usually following extensive atrial surgery such as Fontan operation or atrial repair of transposition of the great arteries.

In older children and adults, transvenous pacing is the preferred route for pacing because of better pacing thresholds, easier lead placement, and lower susceptibility to lead fractures than with epicardial leads. In younger children, however, concern about venous occlusion in a patient who will require many decades of pacing often favors placement of epicardial pacemaker leads. The development of epicardial leads that elute a small amount of dexamethasone appears to improve epicardial lead performance,[25] although epicardial lead fractures remain a problem that is cause for concern. In patients requiring a lifetime of pacing, various approaches to allow atrial and ventricular pacing are commonly needed (Figure 28-13).

Newer Indications for Pacing

Data on adults have suggested that biventricular pacing, with independent stimulation of the right and left ventricles, improves ventricular function in some patients with heart failure. Limited data are available in the pediatric population on this approach to heart failure treatment (often referred to as cardiac resynchronization therapy). Certainly, if pacing is otherwise required in a patient with impaired ventricular function, a biventricular pacing system should be considered. However, identifying patients most likely to benefit from this modality and the best technique for optimizing the timing of activation between the ventricles remains unresolved. Ventricular pacing also has been suggested to be helpful in patients with hypertrophic cardiomyopathy.

Tachycardia Therapies

Vagal Maneuvers

"Vagal maneuvers" once were the most commonly used intervention for terminating SVTs. They occasionally terminate ventricular tachycardias as well. Mechanical maneuvers such as the Valsalva maneuver or carotid sinus massage usually produce effective vagal stimulation beyond infancy. In infants, a similar reflex vagal response sometimes can be elicited by applying firm, steady abdominal pressure or by applying an ice pack to the face. These maneuvers should be attempted

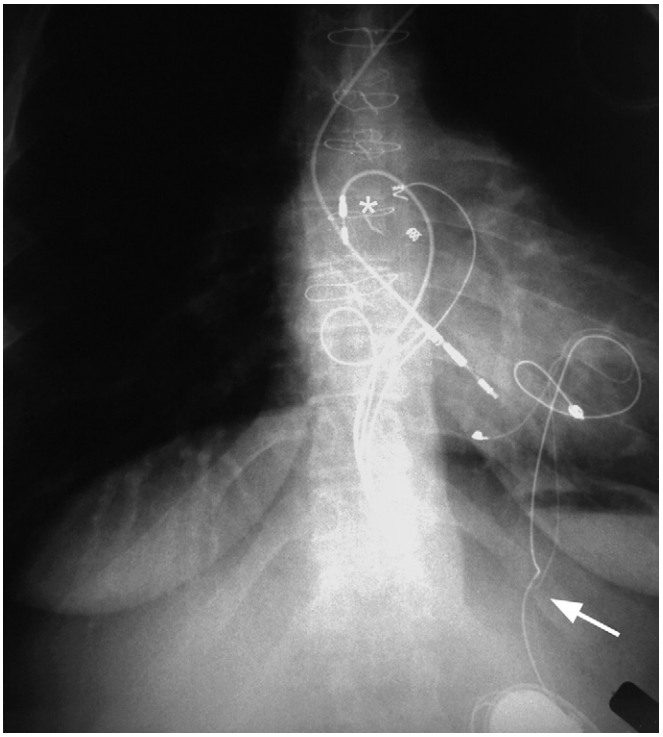

Figure 28–13. Chest x-ray film of a patient with many abandoned pacing leads. There is a bipolar transvenous lead with the tip in the right ventricle. Another bipolar transvenous lead has been used as an epicardial atrial lead *(asterisk).* There are two screw-in epicardial leads, one atrial and one ventricular. The atrial lead has a fractured electrode. There are two other types of epicardial leads more toward the apex, one of which is fractured *(arrow),* and the other of which is kinked. Only the kinked lead is functional. *(From Sliz NB Jr, Johns JA: Cardiac pacing in infants and children,* Cardiol Rev *8:223-239, 2000.)*

for 15 to 30 seconds. Endotracheal suctioning may terminate tachycardias by this mechanism. Although it rarely has been used since adenosine became available, pharmacologic vagal stimulation can be achieved directly with the acetylcholinesterase inhibitor edrophonium (Tensilon, 0.1 to 0.2 mg/kg). Phenylephrine (0.01 to 0.1 mg/kg boluses or continuous infusion of 10 to 100 μg/kg/min) sufficient to raise the systolic blood pressure by at least 50% to a maximum of 180 mm Hg also induces a potent reflex vagal response.

Acute Pharmacologic Therapies

Adenosine. An endogenous nucleoside with profound effects on SA node and AV node conduction, adenosine has become a mainstay in the acute treatment of SVT with normal QRS duration.[16] Administered as a rapid bolus, it produces transient but profound depression of AV nodal conduction and should reliably terminate reciprocating tachycardias (AV nodal reentry, AV reentry). Although less commonly recognized, adenosine also may interrupt AV reentry by directly blocking accessory pathway conduction.

Given the prevalence of AV reentry and AV nodal reentry among otherwise healthy young patients, adenosine often is advocated for wide QRS tachycardias as a therapeutic and/or diagnostic maneuver. Its effects are mediated through specific membrane receptors coupled to inhibitory G proteins modulating K channel function. These receptors are found not only in the AV and SA nodes but also on atrial myocytes. It usually causes transient AV block without terminating most primary atrial tachycardias but instead may transiently suppress atrial automatic tachycardias (ectopic atrial or junctional) and occasionally may terminate intraatrial reentrant tachycardias. Certain ventricular tachycardias may be adenosine sensitive, particularly those originating because of abnormal triggering in the right ventricular outflow tract.

Adenosine must be administered rapidly (50 to 250 μg/kg) because of rapid metabolism by erythrocytes. If tachycardia is not terminated, determination must be made regarding whether a larger dose is warranted, the dose was given too slowly, or VA or AV conduction was altered without terminating tachycardia (see discussion on diagnosis). Therefore it is important to record an ECG strip during adenosine administration so that important diagnostic or therapeutic clues are not missed. Because of its brief effect (a half-life of 8 to 10 seconds), tachycardias sometimes immediately reinitiate following successful termination. If they reinitiate, readministration of the same dose should be attempted rather than increasing the dose further.

In addition to effects on the AV node, adenosine can produce sinus arrest, which may be prolonged in the setting of intrinsic SA nodal dysfunction in the presence of drugs that interfere with its metabolism, such as dipyridamole and diazepam, or with drugs that may exaggerate its effects, such as class I, II, or III antiarrhythmic drugs. High doses should not be used indiscriminately in these situations. The use of adenosine in patients with reactive airway disease may be problematic because adenosine occasionally triggers severe bronchospasm. Conversely, its effects may be antagonized by aminophylline and other methylxanthines the patient may be receiving.

Adenosine produces dramatic but transient chest pain, along with systemic vasodilatation, both of which tend to increase sympathetic tone. As a result, adenosine may paradoxically accelerate tachycardias if termination is unsuccessful or, in the case of primary atrial tachycardias (atrial flutter or fibrillation), may produce more rapid conduction over the AV node (after initially slowing the ventricular rate). Various secondary arrhythmias may occur following administration of adenosine, particularly ventricular ectopy, atrial fibrillation, or, rarely, ventricular fibrillation. Although these effects usually are transient, emergency external cardioversion should always be available whenever adenosine is administered. The appropriateness of adenosine has been questioned in patients with known ventricular preexcitation syndromes (WPW syndrome) or suspected ventricular tachycardias. Nevertheless, its thoughtful and careful use remains invaluable for both diagnosis and treatment of many tachycardias.

Antiarrhythmic Agents. The addition of pharmacologic agents following adenosine administration should be guided by the clinical situation, known or suspected tachycardia mechanism, and response to adenosine administration. In some cases (such as in patients with wide QRS tachycardia or in hemodynamically compromised patients), it may be most appropriate to proceed directly to pacing termination or cardioversion if adenosine is unsuccessful in restoring sinus rhythm. In other instances, acute antiarrhythmic drug therapy may be warranted.[26]

Antitachycardia drugs usually are classified according to their surface ECG effects, which often correlate closely with their cellular electrophysiologic effects. The Vaughan Williams

classification divides drugs into those that block cardiac sodium channels (class I), block β-adrenoreceptors (class II), prolong repolarization (class III), and block calcium channels (class IV). Digoxin and adenosine, which are not included in this classification scheme, exert their primary antiarrhythmic effects on the AV node. Magnesium also has depressant effects on the AV node and suppresses early and late afterdepolarizations (triggered activity). Many of the available drugs manifest properties of more than one class, which contribute collectively to their antiarrhythmic action.[27]

In general, class I drugs (particularly IA and IC) slow conduction in atrial, ventricular, or accessory pathway tissue and class III drugs increase refractoriness in these same tissues. Class IA drugs usually accomplish both effects. β-Adrenergic antagonists, calcium channel antagonists, digoxin, and adenosine act primarily by slowing AV nodal conduction or inhibiting abnormal automaticity. Thus the latter group of drugs is primarily used for reciprocating tachycardias using the AV node (ART, ORT, AVNRT) or to induce second-degree AV block during a primary atrial tachycardia. In contrast, class IA, IC, and III drugs may be more effective in terminating or directly suppressing primary atrial tachycardias and may be effective for reciprocating tachycardias.[5,26]

Despite the various antiarrhythmic agents available for chronic therapy, relatively few are suitable for acute administration to the critically ill patient either because the drugs are not available in intravenous formulation or they have significant negative inotropic effects when administered intravenously (Table 28-3). This discussion is limited to agents suitable for acute and short-term parenteral administration.

All antiarrhythmic agents have the potential for producing bradycardia, particularly when administered acutely, and most have negative inotropic and/or hypotensive effects. Careful observation is required during initial administration and subsequent infusion of all intravenous antiarrhythmic agents. Although many are contraindicated in cases of heart failure or hypotension, therapy may be necessary if the arrhythmia is contributing significantly to the patient's hemodynamic compromise.

Procainamide. Procainamide is useful for various SVTs and ventricular tachycardias in the intensive care setting. Its broad electrophysiologic effects include both conduction slowing and increased refractoriness in atrial tissue, ventricular tissue, and accessory AV connections. Unlike quinidine, procainamide can be administered intravenously. Effective plasma concentrations (6 to 10 μg/dL) can be readily achieved with a total loading dose of 15 mg/kg over 15 minutes (or in small bolus increments at a similar rate). Careful and repeated blood pressure monitoring is required as loading ensues because of potential negative inotropic and direct vasodilator effects. We prefer to administer intravenous procainamide by hand in 1 mg/kg aliquots at 1- to 2-minute intervals, rather than using a continuous infusion on a pump. In a patient not set up for continuous direct arterial blood pressure monitoring, we set the noninvasive blood pressure monitor to measure blood pressure at 1- or 2-minute intervals. An acceptable noninvasive blood pressure measurement is then the cue to give the next aliquot of procainamide. If hypotension results, the administration should be momentarily interrupted until blood pressure returns toward normal. In primary atrial tachycardias, a vagolytic effect may increase the ventricular response over the AV node. Occasionally, atrial tachycardia that is conducting 2:1 to the ventricle slows sufficiently to allow 1:1 conduction, converting a hemodynamically stable rhythm to an unstable rhythm. Thus one should always be prepared to use cardioversion if necessary.

Procainamide, like other class IA and class III drugs, is contraindicated in patients with the congenital or acquired long QT syndromes. Regular monitoring of plasma concentration every 6 to 12 hours is necessary during intravenous administration to maintain levels between 5 and 10 μg/dL. The active metabolite N-acetylprocainamide contributes to the antiarrhythmic action; higher levels of the parent drug may be necessary in patients lacking the enzyme to produce this metabolite.

Lidocaine. Intravenously administered lidocaine is useful for suppressing and sometimes terminating ventricular tachycardias in children. Although somewhat less likely to acutely terminate ventricular tachycardias than procainamide, bretylium, or amiodarone, lidocaine's lack of significant negative inotropic effect often makes it more attractive for this indication. The usual loading dose is 1 to 2 mg/kg acutely or 3 mg/kg over 20 to 30 minutes, followed by a 20 to 50 μg/kg/min infusion. Lidocaine levels should be monitored to prevent central nervous system (CNS) toxicity. With chronic use (4 to 7 days), accumulation of the metabolite glycine xylide may impair drug efficacy by interfering with the parent drug effect at the sodium channel. Despite traditional recommendations for its use in ventricular fibrillation, lidocaine actually increases defibrillation energy requirements. It probably is superior to phenytoin for ventricular arrhythmias related to digitalis toxicity, but more specific therapies are available (see magnesium, pharmacologic, and toxic arrhythmias).

β-Blocking Agents. A limited number of β-blocking agents are useful for intravenous treatment of tachycardias. Acutely, their role is generally limited to incessant tachycardias, which seem to be dependent on sympathetic tone, and ventricular tachycardias related to myocarditis, ischemia/reperfusion injury, or congenital long QT syndromes. In hemodynamically unstable patients, β-blocking agents should be used cautiously because of hypotension and potential sinus bradycardia once tachycardia terminates. All may produce bronchospasm, hypotension, or bradycardia or may depress ventricular function.

Esmolol, a short-acting, nonselective β-blocker with a half-life of 2 to 5 minutes, can be administered as a continuous infusion. A loading dose of 500 μg/kg is followed by an infusion of 50 to 100 μg/kg/min. The infusion can be titrated upward by doubling every 3 to 5 minutes up to 500 μg/kg/min. Repeat loading doses may be useful as the infusion is increased. Its very short half-life is excellent for short-term use, but extended efficacy is limited by tachyphylaxis. For longer-term intravenous administration, propranolol (0.02 to 0.1 mg/kg) and metoprolol (0.05 to 0.10 mg/kg) are administered by slow intravenous infusion every 4 to 6 hours, carefully observing for hypotension (or bradycardia). Metoprolol, a selective β_1-blocker, may be preferable for ventricular arrhythmias and in patients with reactive airway disease.

Amiodarone. Amiodarone is arguably the single-most potent antiarrhythmic drug available, both in the acute, intravenous setting and when administered chronically. At sufficient doses, it is often effective in controlling various tachycardias

Table 28–3 Treatment of Bradycardias, Supraventricular Tachycardias, and Ventricular Tachycardias

	Primary Therapies	Secondary Therapies	Long-Term Therapies
BRADYCARDIAS			
Sinus bradycardia	Atropine 0.01 mg/kg	Temporary pacemaker	Permanent pacemaker (AAIR, DDDR)
	Epinephrine 0.1 mg/kg	Isoproterenol infusion	
	Transcutaneous pacemaker		
AV block (high-grade)	Transcutaneous pacemaker	Temporary pacemaker	Permanent pacemaker (DDDR)
SUPRAVENTRICULAR TACHYCARDIAS			
Sinus tachycardia	Identify cause(s)	Sedation, pain control	β-Blockers, if chronic
		Adjust catecholamines	Consider nonsinus mechanism
		Respiratory support	
Paroxysmal supraventricular tachycardia, AV nodal reentrant tachycardia	Vagal maneuvers	Esmolol	β-Blockers, class I, class III
	Adenosine	Verapamil	Amiodarone
	Transesophageal termination	Procainamide (IV)	Radiofrequency ablation
		Amiodarone (IV)	Radiofrequency ablation
	Procainamide	Class I, class III	
AET and other incessant supraventricular tachycardia	Amiodarone	β-blockers	
	Esmolol	Amiodarone	
	Avoid cardioversion		
Atrial flutter <24 hours	Rate-control (diltiazem IV)	Pace termination	Radiofrequency ablation
	Procainamide	(transesophageal, intracardiac)	Antitachycardia pacemaker
	Pace termination with pacemaker		
	DC cardioversion		
	Ibutilide (transesophageal echocardiography if duration unknown of >24 hours to rule out thrombus)		
Atrial fibrillation <24 hours	Same as above, except pace termination not feasible)		
Chaotic atrial tachycardia	Procainamide, amiodarone	β-Blocker (rate control)	Propafenone, amiodarone
VENTRICULAR TACHYCARDIAS			
Monomorphic (conscious, stable)	Procainamide/lidocaine	Procainamide/lidocaine	Defined by substrate
	DC cardioversion	Amiodarone	
	Pace termination if PM, ICD		
Known heart disease	Same	Amiodarone	ICD, Radiofrequency ablation
			Amiodarone
Known idiopathic	Consider IV verapamil	β-Blocker	Ca-channel blocker
	Avoid cardioversion		β-Blocker
			Radiofrequency ablation
Pulseless (monomorphic, polymorphic)	DC cardioversion	Amiodarone (unless long QT)	ICD
	β-Blocker	β-blocker	
	Amiodarone	Magnesium	
Ventricular fibrillation	Defibrillation	Epinephrine	ICD
		Vasopressin	

AET, Atrial ectopic tachycardia; *AV,* atrioventricular; *ICD,* implantable cardioverter-defibrillator; *IV,* intravenous; *PM,* pacemaker.

refractory to other antiarrhythmic agents.[28] Although typically regarded as a class III agent, its effects are considerably more diverse. It not only prolongs repolarization (by blocking potassium channels), but to varying degrees it blocks some sodium channel (class I effect), calcium channel (class IV effect), and β receptors (class II effect).

Amiodarone is administered as a total loading dose of 5 mg/kg divided into 1 mg/kg aliquots given at 5- to 10-minute intervals. The loading can be truncated if arrhythmia control is achieved. If hypotension ensues, volume expansion or calcium chloride (10 to 30 mg/kg) should be administered. If arrhythmia control is not achieved, a second loading dose can be administered 30 to 60 minutes later. A continuous infusion of 10 mg/kg over 24 hours can be administered if ongoing therapy is desired.

Because of amiodarone's slow elimination and its potential for significant vasodilatation, its usage usually should be limited to arrhythmias truly refractory to other agents or certain arrhythmias recognized as poorly responsive to conventional therapy. Furthermore, because of its slow elimination, the absence of spontaneous arrhythmias following acute administration may obscure the determination of whether ongoing therapy is warranted for several days or weeks. Similarly, amiodarone may obscure subsequent diagnostic efforts and inhibit induction of arrhythmias at electrophysiologic study for days or weeks after ceasing administration. Cessation of intravenous therapy at the earliest possible opportunity is advisable. When necessary, oral therapy should be deferred until necessary diagnostic issues (sometimes including formal electrophysiologic study) have been addressed. Because of the potential for chronic toxicity, dronedarone, a noniodinated analogue to amiodarone, has recently been approved for use in adults as an alternative for treatment of atrial fibrillation. Its use in other arrhythmias and its use in pediatric patients remain to be evaluated.

Calcium Channel–Blocking Agents. Verapamil and, more recently, diltiazem have proved useful for terminating SVT involving the AV node (AV reentry, AV nodal reentry). However, their acute efficacy is no greater than that of adenosine, and both may cause hypotension or cardiovascular collapse in young infants or patients with poor ventricular function.[29] Either drug can be useful as an alternative to adenosine when tachycardias have repeatedly reinitiated following termination with adenosine.

Both agents may help slow the ventricular response over the AV node during atrial flutter or fibrillation. Verapamil is administered as a bolus of 0.15 mg/kg. Diltiazem can be administered as a bolus of 0.15 to 0.35 mg/kg and can be infused continuously at 0.05 to 0.2 mg/kg/hr if ongoing effect is necessary. In addition to vasodilatation and negative inotropic effects, both can accelerate antegrade conduction over accessory pathways in patients with WPW syndrome. Therefore they are contraindicated for patients with WPW syndrome with atrial fibrillation over the accessory pathway, and generally they should not be administered during uncharacterized wide QRS tachycardias. Likewise, oral calcium channel blockers generally should not be used as maintenance therapy for patients with WPW syndrome. If hemodynamic compromise develops, intravenous calcium gluconate should be administered immediately.

Magnesium Sulfate. Magnesium (administered as 25 to 50 mg/kg magnesium sulfate) has proved useful in the treatment of certain ventricular and supraventricular arrhythmias. Its actions appear to be mediated through depression of early and late afterdepolarizations; depressant effects on AV nodal conduction; and, at high doses, indirect inhibition of sodium-potassium adenosine triphosphatase. It has proved most effective in the acute treatment of torsades de pointes and as a temporizing measure in the treatment of arrhythmias associated with digoxin toxicity.[30] Therapeutic efficacy is not restricted to situations where hypomagnesemia is present (although hypomagnesemia may predispose to afterdepolarization-dependent arrhythmias).

Although magnesium has efficacy comparable with that of adenosine in the acute termination of SVT resulting from AV reentry and AV nodal reentry, it has more severe and lasting adverse effects. It has little demonstrable effect in the acute treatment of monomorphic ventricular tachycardias or polymorphic ventricular tachycardias not associated with QT prolongation. Although administration of magnesium for various ventricular arrhythmias has become popular, its usage generally should be restricted to the situations described or for cases of documented severe hypomagnesemia.

Digoxin. Digoxin historically has been used for various supraventricular arrhythmias, including AV reentry, AV nodal reentry, and primary atrial tachycardias. Its therapeutic role has been questioned in numerous situations. Digoxin terminates ORT slowly, is associated with a high recurrence rate in infants, and may increase the risk of rapid antegrade conduction during atrial fibrillation in older patients and possibly infants with preexcitation. Its usage is further confounded by potentially dangerous interactions with other medications likely to be administered concurrently including quinidine, verapamil, amiodarone, flecainide, phenytoin, and warfarin. Even with intravenous loading, the therapeutic effect on the AV node may be unpredictable in onset and often inadequate. Like calcium channel–blocking agents, it should be avoided altogether in the treatment of patients with ventricular preexcitation (WPW syndrome). At toxic dosages, its direct cellular effects may predispose to dangerous tachycardias and bradycardias. Thus given the availability of an increasing number of preferable alternatives, its appropriate usage as an acute antiarrhythmic agent is limited.

Cardioversion and Defibrillation

Cardiovascular collapse or failure of mechanical and pharmacologic interventions for tachycardias may warrant cardioversion. For tachycardias with discrete QRS complexes, synchronization with the QRS should be confirmed (the default mode for most defibrillators is nonsynchronized, and most revert to nonsynchronized shocks after each shock is delivered). Proper synchronization may require changing the ECG lead configuration to achieve an upright QRS complex.

Several factors may determine the success of cardioversion and defibrillation. Energy requirements may vary from 0.25 to 1 J/kg for SVTs to greater than 2 J/kg for ventricular tachycardias. Newer defibrillators with a "biphasic" rather than "monophasic" waveform have reduced defibrillation energy requirements. Electrode (paddle) location is an important variable. If conversion is not achieved with low or moderate energy levels, consideration should be given to changing electrode position before using higher energy levels. Automatic tachycardias are characteristically refractory to cardioversion and may account for treatment failure. Finally, some antiarrhythmic drugs, particularly sodium channel–blocking drugs

(see later discussion), increase defibrillation energy requirements and pacing thresholds, whereas other drugs (QT-prolonging drugs) appear to have a favorable effect.[31]

The availability of automatic external defibrillators injects an additional complexity into the use of external cardioversion and defibrillation. Each ICU should carefully consider how to best configure devices for automatic versus manual defibrillation operation and which electrode system (ECG leads, paddles, and patches) best suits the particular patient population and care team.[32]

Approach to Therapy

Extrasystoles

In general, isolated extrasystoles do not require treatment unless they are sufficiently frequent to impair hemodynamics (e.g., incessant bigeminy or trigeminy with pulse deficit) or they serve as frequent initiating events for tachycardias. In otherwise healthy children and adolescents, extrasystoles may be a benign finding. In other settings, "complex" ventricular extrasystoles may identify patients at increased risk for cardiac arrest. Even in such situations, prophylaxis may not decrease and may actually increase the risk. Effort should instead be directed at identifying possible causes and correcting any predisposing factors, which include ischemia, electrolyte disorders, acidosis, pericarditis, or direct trauma from recent cardiac surgery, blunt or penetrating chest trauma, and intracardiac catheter-induced irritation. Numerous drugs, including digoxin, catecholamines, or drugs associated with the acquired long QT syndrome, may produce extrasystoles. Frequent extrasystoles occasionally are the sole manifestation of myocarditis.

Sustained Tachycardias

Most sustained tachycardias observed in the intensive care setting warrant immediate attention and intervention. Sinus tachycardia may indicate the need for additional sedation and analgesia or may reflect hemodynamic compromise as a consequence of anemia, hypovolemia, or impaired myocardial function. Sinus tachycardia as a consequence of hyperthermia may be poorly tolerated in children already critically ill, especially following cardiac surgery. Sinus tachycardia may reflect an underlying neuroendocrine process such as hyperthyroidism or pheochromocytoma requiring acute medical intervention (β-blocker) while instituting therapy for the underlying disorder.

Nonsinus tachycardias in patients with primary rhythm disturbances (rather than as a complication of another problem) may warrant therapy to prevent life-threatening events, prevent the development of myocardial dysfunction as a consequence of chronic (incessant) tachycardia, or simply alleviate acute tachycardia-related symptoms such as chest pain, lightheadedness, and palpitations. The acuity of the situation dictates the approach to therapy. Tachycardias occurring secondary to other abnormalities (structural heart disease, metabolic derangements, drug toxicity) should always be regarded as high risk for serious hemodynamic deterioration.

Unstable Patients

The approach to patients with tachycardia is determined largely by the degree of hemodynamic compromise (see Table 28-3). Patients who are hemodynamically unstable or in cardiovascular collapse resulting from sustained tachycardia almost always warrant prompt cardioversion or defibrillation. In these patients, measures that otherwise would be appropriate, such as vagal maneuvers, adenosine administration, or attempts to differentiate SVT from ventricular tachycardia, should be deferred. Delaying prompt termination of tachycardia in the unstable patient may further compromise the hemodynamic status and increase the risk of other end-organ damage. Only when tachycardia is known to be incessant or unresponsive to cardioversion (e.g., JET, atrial ectopic tachycardia, chaotic tachycardia, and PJRT) should antiarrhythmic medications (and other supportive measures) replace cardioversion in the unstable patient.

Cardiopulmonary resuscitation should always be instituted in the absence of a pulse or blood pressure, as is typically the case for polymorphic ventricular tachycardia and ventricular fibrillation. Although hemodynamic and ventilatory support should be initiated immediately and maintained following tachycardia termination as necessary, cardioversion (with bag and mask ventilation initially) should take precedence over other interventions.[33] Although congestive heart failure may accompany tachycardias (as in an infant with SVT of several hours' duration), aggressive diuresis should be avoided; patients may benefit initially from fluid resuscitation. Even mild intravascular volume contraction in the face of subsequent tachycardia recurrences further compromises ventricular filling and results in more severe hypotension. Underlying factors contributing to the tachycardia should be sought, including hypoxia, infection (cardiac or systemic), drug toxicities (see later), and electrolyte derangements.

Once tachycardia is terminated, acute therapies may focus on either suppressing recurrences or terminating them when they recur. In critically ill patients, the latter may be preferable, at least initially. Although antiarrhythmic medications eventually may be necessary to suppress recurrences, most have negative inotropic or vasodilating effects, particularly when administered intravenously. Often it is preferable to delay specific therapy after initial termination until ventricular function improves. Most recurrences of SVTs can be safely treated with temporary pacing or adenosine rather than with repeated cardioversions. In the event of frequent recurrences, a transesophageal catheter may be left in place for this purpose, or a transvenous atrial pacing catheter may be warranted in selected patients. Similarly, temporary ventricular pacing may be useful in some circumstances for recurrent ventricular tachycardia. Although adenosine can be administered repeatedly because of its short half-life, the resulting vasodilatation may be poorly tolerated in patients with tachycardia mechanisms unresponsive to adenosine.

Treatment Failure

When seemingly appropriate electrical and pharmacologic interventions fail to terminate tachycardias, three possibilities should be considered: erroneous diagnosis, unrecognized tachycardia reinitiation, or a technical error in the termination technique.

Errors in Diagnosis

As noted previously, automatic atrial tachycardias, JET, and occasionally chaotic atrial tachycardia might be mistaken for tachycardias with reentrant mechanism (ORT, AVNRT, and

primary atrial reentry). Each of these conditions usually is refractory to electrical termination (either pace termination or cardioversion), yet the diagnosis may be subtle if atrial activity is obscured.

Confusion between ventricular tachycardias and SVTs with prolonged QRS probably remains the most frequent diagnostic error. Occasionally the presumption of ventricular tachycardia may lead to ineffective treatments. For example, following cardiac surgery, incessant, monomorphic wide QRS tachycardia that is refractory to cardioversion may actually be JET with postsurgical bundle branch block. Brief atrial pacing at a faster rate may be necessary to confirm the diagnosis.

Certain tachycardias such as torsades de pointes related to long QT syndromes (congenital or drug-induced) or bidirectional ventricular tachycardia resulting from digoxin toxicity must be recognized to provide more appropriate and specific therapies to prevent recurrences following cardioversion.

Unrecognized Reinitiation

Unrecognized reinitiation may occur following medical termination, pace termination, or cardioversion. In some tachycardias (as in PJRT or other incessant forms of SVT), reinitiation is expected, but it also may occur inadvertently as the result of continued pacing beyond the point of termination or may be facilitated by sinus pauses, junctional beats, or ectopic beats following adenosine or cardioversion. Again, measures to decrease the factors favoring reinitiation (e.g., shorter pacing bursts, antibradycardia pacing, and coadministration of an antiarrhythmic drug) should be used rather than further increases in energy or dose of the terminating therapy. With frequent terminations and reinitiations of tachycardia, multiple repeated cardioversions are likely ineffective and may cause myocardial injury.

Improper Technique

Appropriate administration of adenosine is accomplished through an intravenous catheter (peripheral or central) by rapid push followed immediately with ample flush. Because of rapid metabolism by erythrocytes, arterial administration may be ineffective in terminating tachycardia (yet still produce vasodilatation). Errors in cardioversion or pacing technique are generally attributable to insufficient energy or improper electrode (or paddle) placement.[32] For pace termination, the stimulator must be capable of sufficient output for the pacing modality being used (see section on temporary pacing). Intensive care personnel should be familiar with the defibrillation devices available in the ICU, including adjustment of ECG gain and lead selection to allow synchronous cardioversion when appropriate. However, in ventricular fibrillation or polymorphic tachycardia, asynchronous countershock is necessary. Use of excessive energy may damage the myocardium and, when repeated, may lead to preterminal bradycardias, which are refractory to all pacing modalities and progress to complete electromechanical dissociation if hypoxia and acidosis are not corrected.

Specific Arrhythmias

Primary Arrhythmias

Some arrhythmias require unique therapeutic approaches or are seen with sufficient frequency to warrant a brief review (Box 28-1).

Orthodromic Reciprocating Tachycardia in Infancy

Infants with ORT can present with tachycardia in utero, at birth, or within the first weeks to months of life. Intrauterine tachycardia can result in abnormal hemodynamics resulting from limited ventricular filling times accentuated by atrial systole against closed AV valves. Retrograde systemic venous flow during tachycardias may contribute to low cardiac output, congestive heart failure, and nonimmune hydrops fetalis prenatally.[34] Postnatally, tachycardia sustained beyond a few hours may result in congestive heart failure that may progress to shock, acidosis, and complete cardiovascular collapse.[35] In the latter situation, ORT may be terminated during resuscitation efforts such that its causative role remains unrecognized. Thus SVT should be considered in the differential diagnosis of neonatal shock, along with other conditions such as sepsis, aortic coarctation, and congenital adrenal hyperplasia in which sinus tachycardia associated with cardiovascular collapse would be expected.

The transesophageal electrophysiologic (TEP) study is useful in determining tachycardia mechanism[36] and especially for assessing drug efficacy. The negative predictive value of TEP (noninducible with no clinical recurrence) is 89% and

Box 28–1 Rhythm Disturbances

Primary Rhythm Disturbance

Paroxysmal supraventricular tachycardias (AV reentrant tachycardia, AVNRT)
- Congenital AV block
- Congenital long QT syndrome, Brugada syndrome
- Other genetic arrhythmias
- Ventricular tachycardias resulting from Purkinje hamartoma
- Verapamil-sensitive ventricular tachycardias
- Accelerated ventricular rhythm

Secondary Rhythm Disturbances

Early Postoperative Arrhythmias

JET
- Postsurgical AV block
- Early primary atrial tachycardia

Late Postoperative Arrhythmias

Ventricular arrhythmias (postoperative tetralogy of Fallot)
- Sick sinus syndrome

Metabolic Derangements

Electrolyte disturbances
- Endocrine derangements (thyroid)
- CNS injury
- Hypothermia, hyperthermia
- Acute hypoxia (newborns)
- Acute myocardial infarction

Drug Toxicity, Proarrhythmia

Digoxin
- Cocaine
- Tricyclic antidepressants
- Antiarrhythmic drugs
- Quinidine/sotalol
- Flecainide/encainide
- Organophosphates

Infectious

Lyme disease
- Myocarditis, endocarditis

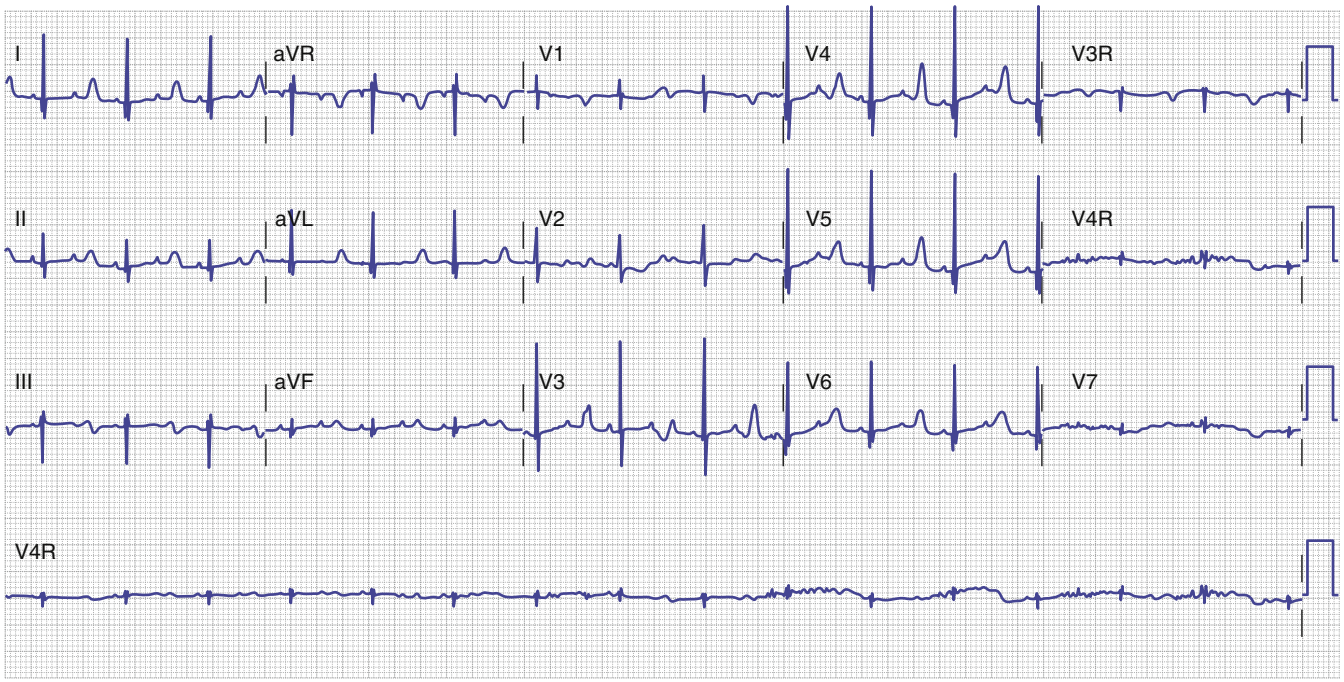

Figure 28–14. Congenital long QT syndrome presenting with 2:1 atrioventricular block. The corrected QT interval is >560 ms, resulting in "functional" block of every other sinus beat in the His-Purkinje system.

increases to 96% when stimulation is also performed after administration of isoproterenol.[37] Long-term drug therapy is not always necessary, because approximately half of infants have no inducible tachycardia at TEP by age 1 year.[38]

Tachycardia-Induced Cardiac Dysfunction

Although most SVTs are paroxysmal or episodic, chronic SVTs pose a unique problem. Many are minimally symptomatic and are recognized only by the inappropriately fast rate. However, with time, varying degrees of congestive heart failure become evident, and ventricular dysfunction may be severe. Even then, the diagnosis may not be immediately evident. As a consequence, chronic tachycardia must be considered in any patient presenting with gradually progressive congestive heart failure. In one series, chronic atrial tachycardia was present in 37% of patients initially diagnosed with "idiopathic" cardiomyopathy and listed for heart transplant.[39]

In patients with structurally normal hearts, the most common incessant SVTs are PJRT and ectopic atrial tachycardia. These conditions may occur throughout infancy, childhood, and adolescence. The rates (often less than 200 beats/min) and normal PR interval during tachycardia may lead to an erroneous diagnosis of sinus tachycardia secondary to the hemodynamic compromise (see Approach to Diagnosis section). An abnormal P-wave axis on 12-lead ECG, determination of the "intrinsic heart rate" following complete autonomic blockade, and Holter monitoring to look for interruptions in the tachycardia with changes in P-wave morphology are helpful.

Electrophysiologic study still may be necessary to establish the diagnosis. In infants, incessant ventricular tachycardias and the rare congenital form of JET also are seen.

In each of these entities, it is important first to recognize the primary role of the tachycardia in producing secondary congestive symptoms and to recognize the futility of acute therapies such as adenosine, pace termination, and cardioversion. Most are catecholamine dependent so that inotropic agents may aggravate the situation and compromise the efficacy of antiarrhythmic regimens, whereas β-blocking agents may be useful despite the presence of heart failure. Once the diagnosis is established, chronic antiarrhythmic therapy is instituted to control or limit the tachycardia. Uncontrolled, severe cardiac symptoms may result, but ventricular dysfunction improves once tachycardia is suppressed medically or treated by catheter ablation.[40] Despite the severity of heart failure, antiarrhythmic medications that depress ventricular function usually are well tolerated.

Congenital Atrioventricular Block

Congenital heart block is usually the result of either maternal connective tissue disease (45%) or structural congenital heart disease (53%), particularly L-transposition of the great arteries or left atrial isomerism. Mothers with connective tissue disease are frequently asymptomatic but may have detectable anti-Ro/SSA antibodies. In a prospective study of mothers with anti-Ro/SSA antibodies, the risk of congenital AV block was 2%.[41] The L-type calcium channel is the likely target of these autoantibodies.[42] Rarely, congenital AV block is the initial manifestation of congenital long QT syndrome (Figure 28-14).[43] Temporary pacing in congenital AV block may be required to treat symptoms or secondary ventricular arrhythmias. In a subset of patients, ventricular dysfunction may develop despite pacing therapy.[44] Guidelines and indications for permanent pacing have been established.[23]

Chaotic Atrial Tachycardia

Chaotic atrial tachycardia is a primary atrial tachycardia characterized by three or more different P-wave morphologies and irregular, rapid atrial rates (Figure 28-15). Although atrial flutter may be associated with it, episodes usually are self-limited, and cardioversion is neither indicated nor effective. Asymptomatic patients with slow or intermittent tachycardia may

Figure 28–15. Chaotic atrial tachycardia. Note two discrete P-wave morphologies before conversion to sinus rhythm.

require no treatment. Occasionally digoxin is used to limit AV conduction when atrial rates are excessive or to enhance contractility in the setting of tachycardia-induced cardiomyopathy.[45] An association with respiratory syncytial virus has been described in some patients.[11] Various agents have been used in symptomatic cases; amiodarone and propafenone are the most effective.[45,46]

Long QT Syndromes

The long QT syndromes are a diverse group of disorders, both congenital and acquired, in which individuals are at risk for torsades de pointes and sudden death because of abnormalities in ventricular repolarization. In both congenital and acquired forms, the rate-corrected QT intervals usually exceed 0.46 second, and more typically are greater than 0.48 to 0.50 second. Associated anomalies of T-wave morphology, including T-wave alternans, "bifid" T waves, and prominent U waves, are common. It may be difficult to establish the diagnosis of congenital long QT syndrome because QT prolongation may not be severe. In fact, affected individuals sometimes have a normal QTc.[47] Congenital long QT syndrome should be considered in all patients with QT prolongation and a history of syncope, cardiac arrest, or seizures or a family history of unexplained sudden death. The diagnosis should be strongly considered in any child presenting with syncope or sudden death in whom polymorphic ventricular tachycardia or multiform ventricular premature beats are documented. Incidental QT prolongation in an asymptomatic child (with a negative family history) may warrant further scrutiny and possibly serial Holter monitoring. However, unless the QTc is markedly prolonged (longer than 0.48 to 0.50 second), the diagnosis should be withheld until or unless further suggestive features are noted. Finally, all infants presenting with second-degree or third-degree AV block should be evaluated for the possibility of long QT syndrome.[43]

Patients with symptoms or arrhythmias associated with QT prolongation require careful evaluation for secondary causes, which include CNS injury, hypocalcemia, hypokalemia, and drugs that prolong the QT interval. The list of drugs that prolong the QT interval is extensive and includes antiarrhythmic and noncardiac drugs, most of which block I_{Kr}, the rapid component of the delayed rectifier potassium current.[48] Updated lists of these drugs are available at www.qtdrugs.org.

Torsades de pointes is the specific arrhythmia associated with long QT syndromes and is responsible for the symptoms (Figure 28-16). This characteristic arrhythmia is recognized

Figure 28–16. Torsades des pointes in a teenage patient with long QT syndrome. This arrhythmia is associated with no pulse and results in syncope. It often terminates spontaneously but otherwise rapidly degenerates to ventricular fibrillation.

by progressive undulation in the QRS axis, resulting in a "twisting" appearance, and usually is associated with a specific initiation with a VPB following a pause (often following a previous VPB). Many episodes are not sustained, and even prolonged episodes may terminate spontaneously. Torsades de pointes that degenerates to ventricular fibrillation requires defibrillation.

Because the stress caused by defibrillation may trigger recurrent arrhythmias, defibrillation should be performed in an unconscious or sedated patient. Treatment of immediate recurrence of torsades de pointes is challenging and includes magnesium sulfate, increasing the heart rate with temporary pacing or isoproterenol, and sedation.[49] For most acquired long QT syndromes (and some congenital forms), increasing the heart rate using isoproterenol or by pacing shortens the QT interval, but isoproterenol may exacerbate some forms of the congenital long QT syndrome.[50] Therefore isoproterenol should be used only when there is underlying bradycardia and cardiac pacing cannot be started immediately. Correcting hypokalemia, hypomagnesemia, or hypocalcemia and removing potentially causative agents may be important in the ICU setting.

The molecular/genetic basis of the congenital long QT syndrome was discovered in the 1990s. To date, mutations have been discovered in twelve genes.[51] Most of these genes encode channels or proteins that regulate potassium and sodium currents, and rarely calcium channel currents. The type and location of

the genetic mutation may determine to some extent the expression of the clinical syndrome. However, as mentioned earlier, this disorder has variable expression of severity (i.e., variable penetrance). This variability in expression in related individuals with the same mutation suggests the influence of environmental factors and/or the presence of other modifier genes.

Genetic Arrhythmias

Other genetic causes of arrhythmias deserve brief mention. Brugada syndrome, the syndrome of ST-segment elevation in the right precordial leads and a high incidence of sudden cardiac death in the absence of cardiac structural abnormalities, was first recognized in 1992.[52] Since then, there has been tremendous advancement in the understanding of the clinical, genetic, cellular, and molecular aspects of this disease.[53] Although relatively rare (incidence 5 per 10,000), it accounts for 4% to 12% of all sudden deaths (20% in patients with structurally normal hearts). Implantation of a defibrillator is the only established effective treatment and is indicated for symptomatic patients.[54]

Catecholaminergic polymorphic ventricular tachycardia is an uncommon arrhythmia occurring in children and adolescents with structurally normal hearts. The characteristic arrhythmia of ventricular tachycardia with beat-to-beat alternation of the QRS axis occurs with physical or emotional stress and can be asymptomatic. Mutations in the cardiac ryanodine receptor gene (*RyR2*) or cardiac calsequestrin (*CASQ2*) underlie catecholaminergic bidirectional ventricular tachycardia, and patients with the disease are at risk for sudden cardiac death and ventricular fibrillation.[55,56] β-blockers can suppress bidirectional ventricular tachycardia, but data suggest they provide incomplete protection from arrhythmias.[57] Flecainide may target the underlying mechanism and provide even greater protection from exercise-induced arrhythmias.[58]

Genetic cardiomyopathies that are associated with sudden death include arrhythmogenic right ventricular dysplasia and hypertrophic cardiomyopathy. Arrhythmogenic right ventricular dysplasia is a disease of autosomal dominant inheritance characterized by fatty replacement of right ventricular myocardium and risk for ventricular tachycardia and sudden death.[59] Linkage analysis has yielded genetic heterogeneity, and currently approximately 50% of symptomatic individuals harbor a mutation in one of the five major components of the cardiac desmosome.[60] Hypertrophic cardiomyopathy is an inherited cardiac muscle disorder disease that affects sarcomeric proteins, resulting in small vessel disease, myocyte and myofibrillar disorganization, and fibrosis with or without myocardial hypertrophy.[61] These features may result in significant cardiac symptoms and are a potential substrate for arrhythmias. Risk stratification for sudden death is an important component in the management of these patients.

Ventricular Tachycardia in Ostensibly Healthy Patients

Accelerated ventricular rhythm is observed occasionally in neonates in the first few days of life at rates only slightly faster than the appropriate sinus rates. The rhythm competes with the sinus mechanism, and alternation between sinus and ventricular rhythm with fusion beats is common. The rhythm is self-limited, does not usually result in hemodynamic compromise, and carries a good prognosis. No specific therapy is necessary unless rates are excessive.[62] A similar rhythm is seen in older children and usually has a similarly benign course.[63] Two other characteristic ventricular tachycardias may be seen in otherwise healthy children and adolescents. One arises from the right ventricular outflow tract, resulting in a left bundle branch block pattern with inferior QRS axis. This pattern may be incessant, in which case the term "repetitive monomorphic ventricular tachycardia" has been used. The other arises from the posterior fascicle of the left-sided conduction system, producing a right bundle branch block pattern with leftward QRS axis (Figure 28-17). This tachycardia has been called fascicular, Belhassen, or verapamil-sensitive ventricular tachycardia. Interestingly, the response to verapamil may result in misclassification as "SVT with aberrant conduction."

Although ventricular tachycardia can be seen without any apparent underlying heart disease, a rigorous search for occult heart disease often is fruitful. Cardiac tumors (rhabdomyomas, fibromas, hamartomas) and myocarditis can be associated with ventricular arrhythmias.[64]

Secondary Rhythm Disturbances

Certain arrhythmias characteristically follow operative treatment of CHD. Among those observed in the early postoperative period are complete heart block, JET, and primary atrial tachycardias. Late postoperative arrhythmias include ventricular arrhythmias following tetralogy of Fallot repair and atrial arrhythmias following the Mustard/Senning and Fontan procedures.

Postoperative Arrhythmias

Postsurgical Atrioventricular Block. Inadvertent damage to the AV conduction system may occur with cardiac surgery, especially after closure of ventricular septal defects (particularly associated with l-loop ventricles), during resection of septal tissue, or after insertion of prosthetic valves in the tricuspid, aortic, or mitral position. Bradycardia from AV block can be initially managed using isoproterenol to accelerate the ventricular rate. When anticipated or recognized in the operating room, temporary pacing wires usually are left in place. Although temporary pacing frequently is necessary for rate support, permanent pacemaker implantation usually should be delayed 7 to 14 days to allow for potential recovery of AV conduction. Most patients who recover AV conduction do so within 9 days of surgery.[65]

Junctional Ectopic Tachycardia. JET immediately following cardiac surgery may be mistaken for third-degree AV block, but on rewarming ventricular rates approach or exceed 200 bpm. Atrial wires or esophageal electrography confirms the key diagnostic features: AV dissociation with normal QRS and the regular ventricular rate faster than the atrial rate. Appropriately timed atrial systoles conducted to the ventricle result in "advancement" of the tachycardia cycle (without a change in QRS morphology or subsequent pause). If the QRS is normal but the RR interval does not shorten with appropriately timed atrial systoles, JET with retrograde (VA) conduction or third-degree AV block with JET as the escape rhythm should be suspected.

Infants with JET usually are severely ill, and β-adrenergic agonists, fever, and endogenous catecholamines accelerate the tachycardia. Initial treatment of postoperative JET includes sedation and analgesia, withdrawal of adrenergic stimulants (to the extent possible), and cooling blankets or cool soaks

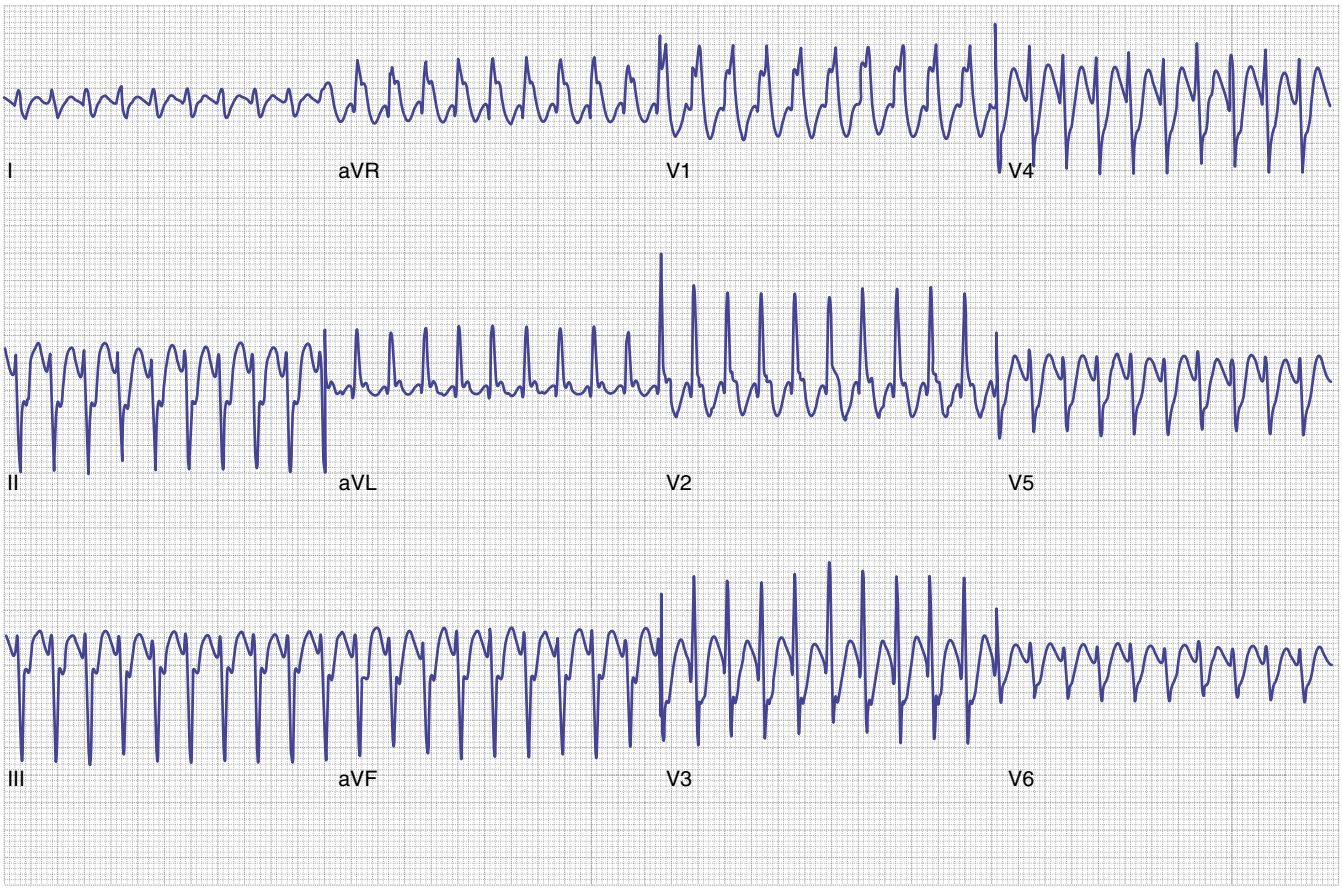

Figure 28–17. Idiopathic ventricular tachycardia in an otherwise healthy 12-year-old. Note right bundle branch block pattern with superior axis, typical of origin within the left posterior fascicle region of the left ventricular septum (sometimes called *Belhassen tachycardia).*

using an electric fan to foster evaporative cooling. The tachycardia may be suppressed by temporary overdrive (atrial) pacing, by pacing at a rate sufficient to produce 2:1 AV block, or by AVT mode pacing to provide AV synchrony.[66] Intravenous amiodarone has been used with perhaps the greatest efficacy.[67] Although emergency radiofrequency ablation has been performed in rare instances, aggressive temporizing measures, including extracorporeal membrane oxygenation, appear warranted given the transient nature of this arrhythmia.

Late Postoperative Arrhythmias

Atrial tachycardia and bradycardia are common late sequelae following the Senning and Mustard operations for D-transposition of the great arteries, atrial septal defect closure, and the Fontan procedure for tricuspid atresia and single ventricle.[68] Patients with these arrhythmias appear to be at increased risk for sudden death, although whether death is the result of atrial tachycardia itself, associated bradycardia, degeneration to ventricular tachycardia, or even nondysrhythmic events remains unclear.

Likewise, in patients with repaired or palliated CHD, ventricular arrhythmias may develop that are associated with risk for sudden death. There seems to be little justification for empirical drug therapy to suppress asymptomatic ventricular arrhythmias in these patients. Earlier repair is believed to decrease the incidence of serious problems. Still, the relative contributions of postoperative hemodynamic abnormalities, the natural history of the unrepaired lesions, and surgical technique to the development of late arrhythmias remain uncertain. Similarly, the roles of pacemaker/defibrillator therapy, prospective electrophysiologic study, and antiarrhythmic drug testing are not well established. Because both bradycardias and tachycardias develop in many patients, the correlation of symptoms with electrophysiologic abnormality is important in guiding therapy.

Metabolic Derangements

Electrolyte Disturbances. Hyperkalemia causes characteristically tall ("peaked" or "tented") t waves with a narrow base with progressive changes at higher concentrations, including decreased P-wave amplitude, QRS prolongation, SA nodal and AV nodal block, and ultimately ventricular fibrillation. Mild to moderate hypokalemia may cause prominent U waves, diminished T-wave amplitude, T-wave inversion, and fusion of the T wave and U wave, along with increased spontaneous ventricular ectopy and inducible ventricular arrhythmias. Arrhythmias caused by hypokalemia are potentiated by catecholamines, and hypokalemia itself potentiates the toxic effects of digoxin and the proarrhythmic effects of drugs associated with drug-induced long QT syndrome.[69] Severe hypokalemia is associated with ventricular fibrillation.

Hypercalcemia produces T-wave inversion and shortens the QT interval. Hypocalcemia prolongs the time to the peak of the T wave (Q-aT) but not the QT interval itself. Isolated calcium abnormalities are uncommon, and arrhythmias caused

by such abnormalities are rare, although hypercalcemia may aggravate digitalis toxicity.[2]

Endocrine Disorders (Thyroid). Hyperthyroidism exerts both sympathetic-like and direct cardiovascular actions that produce sinus tachycardia and atrial fibrillation, but ventricular arrhythmias are uncommon. These arrhythmias respond to β-blockers and resolve when the euthyroid state is restored. Combination treatment with digoxin potentiates AV nodal block while minimizing negative inotropic effects. Hypothyroidism causes sinus bradycardia and AV conduction disturbances; QT interval prolongation is common but rarely associated with torsades de pointes.[70]

Central Nervous System Injury. The most common ECG change associated with CNS trauma and increased intracranial pressure is sinus bradycardia, usually with associated hypertension. These bradycardias appear to be vagally mediated and usually respond to atropine. However, potentially serious arrhythmias may occur within 24 hours following blunt trauma to the head, subdural hematoma, and subarachnoid hemorrhage. QT-interval prolongation is common and, in combination with bradycardia and hypokalemia, may provoke torsades de pointes.

Hypothermia and Hyperthermia. Mild hypothermia can cause a range of reversible ECG changes, including sinus bradycardia; prolongation of the PR, QRS, and QT intervals; and a characteristic secondary deflection on the terminal portion of the QRS (Osborn wave).[71] Severe hypothermia may cause more significant bradycardias, including AV block and asystole or ventricular tachycardias and ventricular fibrillation. Therapeutic hypothermia is associated with QT prolongation, and torsades de pointes has been reported.[72] In contrast, hyperthermia causes sinus tachycardia and may enhance other tachycardias such as PSVT, ectopic atrial arrhythmias, and especially JET in susceptible patients.

Acute Myocardial Infarction. Acute myocardial infarction is uncommon in young patients but may occur in cases of anomalous origin of the left coronary artery, when there is perinatal stress, following Kawasaki disease, with blunt chest wall trauma, and following cardiac transplantation and the arterial switch procedure. It can occur after air embolism in cyanotic CHD or after open heart operations. The diagnosis may be overlooked in infants and children because of the inconsistency of symptoms and relatively poor (60%) clinical recognition by electrocardiography.[73] Nevertheless, acute infarction may result in various rhythm disturbances, including sinus bradycardia (as a result of the Bezold-Jarisch reflex), AV conduction disturbances, intraventricular block, and asystole.

Arrhythmias Resulting from Drug Toxicity

Digoxin. Digoxin toxicity may cause various arrhythmias and should be suspected in any patient in whom a new arrhythmia develops during digoxin therapy. Likewise, digoxin ingestion should be considered in patients with acute arrhythmias, particularly those associated with CNS and gastrointestinal symptoms (although noncardiac adverse effects may be absent with acute ingestion). Accelerated junctional rhythm may be the first arrhythmia seen. Progressive AV block is common. Sinus bradycardia resulting from either SA node exit block or sinus arrest may occur, as can atrial fibrillation (but usually not atrial flutter). Ectopic atrial arrhythmias may occur. Nearly any ventricular arrhythmia may occur, including multiform ventricular extrasystoles, bigeminy, ventricular tachycardia (particularly "bidirectional" VT, otherwise only seen in rare genetic arrhythmia syndromes; Figure 28-18), and ventricular fibrillation.[74]

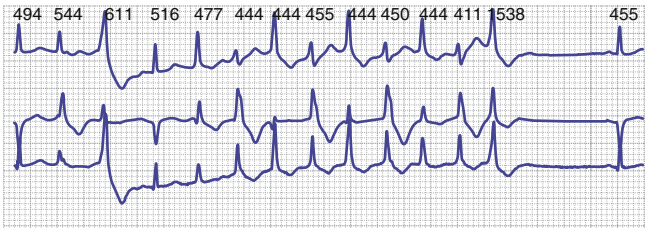

Figure 28–18. Bidirectional ventricular tachycardia. This unusual arrhythmia is only seen in patients with digoxin toxicity and two rare genetic arrhythmia syndromes: Andersen-Tawil syndrome (periodic paralysis and ventricular arrhythmias) and catecholaminergic polymorphic ventricular tachycardia. The patient is asymptomatic during this arrhythmia, but patients appear to be at risk for ventricular fibrillation.

In general, digoxin concentrations less than 2 ng/mL are considered nontoxic. Neonates usually tolerate levels as high as 3.5 ng/mL. Nevertheless, neonates and other intensive care patients may be more susceptible to digoxin toxicity because of renal dysfunction, electrolyte imbalances, and hypoxia. Hypokalemia, excessive calcium infusions, and rapid sinus rates exacerbate digitalis-related arrhythmias.

Purified digoxin-specific Fab antibody fragment, which binds the drug and is eliminated in the urine, is used to treat digoxin toxicity. Prophylactic treatment with this preparation should be gauged according to the quantity ingested, the time since ingestion, and the serum digoxin level. Magnesium sulfate is a useful temporizing treatment while specific antibody treatment is being implemented. Cardioversion should be reserved for life-threatening tachycardias or those unresponsive to these therapies.

Cocaine. Life-threatening ventricular arrhythmias, cardiac arrest, and myocardial infarction can occur in healthy individuals with normal coronary arteries following cocaine ingestion and in prenatally exposed neonates.[75,76] Cocaine produces myocardial ischemia and infarction by inducing severe local coronary vasoconstriction, increasing myocardial-metabolic demand through its potent chronotropic effects, and increasing afterload. In infarct models, cocaine directly potentiates arrhythmias induced by catecholamines.[77] These factors favor the use of β-adrenergic antagonists as first-line treatment for cocaine-related arrhythmias. Additionally, cocaine blocks fast inward sodium channels, similar to class I antiarrhythmic agents.[78] QT prolongation and torsades de pointes have been observed.

Tricyclic Antidepressants and Phenothiazine. Phenothiazines and tricyclic antidepressants produce electrophysiologic (and potentially antiarrhythmic) effects similar to quinidine and procainamide. They slow conduction velocity in atrial and ventricular tissue, prolong repolarization, and exert anticholinergic effects accounting for the observed

ECG changes of conduction disturbances, prolonged QT intervals and QRS duration, and various tachycardias and bradycardias.[79] Sinus tachycardia, atrial and ventricular tachycardias, and AV conduction disturbances distal to the AV node occur occasionally during normal therapeutic administration and may reflect individual susceptibility to QT-prolonging agents. "Unmasking" of the Brugada syndrome has been reported after administration of tricyclic antidepressants.[80]

Arrhythmias commonly follow intentional overdose, resulting in hypotension (due to α-blocking effects), severe anticholinergic effects (neuromuscular and mucosal), seizures, and coma. Quinidine and procainamide are contraindicated for tachycardias because of these agents. In patients manifesting early cardiotoxicity, arrhythmias may develop 3 to 7 days following ingestion, apparently because of release of tissue stores. Therefore ECG monitoring should be continued for at least 24 to 48 hours after apparent ECG and rhythm normalization and longer if severe arrhythmias are observed.

Infections

Myocarditis may cause atrial and ventricular tachycardias or acquired heart block. Lyme disease may produce high-grade acute AV block. Although AV conduction usually normalizes with appropriate antibiotic therapy, temporary pacing may be required.[81] Antibiotic treatment should be instituted based on the history and ECG findings alone while awaiting confirmatory serology. Bacterial endocarditis can cause AV conduction disturbances, particularly when the aortic valve is involved. Unstable or persisting conduction abnormalities (longer than 7 days) carry a high risk of mortality (43% to 80%) and are indications for early valve replacement.[82]

Myocarditis may be responsible for some cases of ventricular tachycardia in otherwise healthy individuals and may range from chronic ventricular ectopy or tachycardia to fulminant and refractory arrhythmias leading to electromechanical dissociation. Chaotic atrial tachycardia may occur in the setting of infection with respiratory syncytial virus, although the cause of this association is unclear. Finally, paroxysmal tachycardias of any etiology may be exacerbated by acute infections that cause fever, dehydration, and increased sympathetic tone. Short-term modifications of chronic therapy may be necessary, particularly when oral administration becomes impractical.

Chapter 29

Shock States

Lincoln S. Smith and Lynn J. Hernan

PEARLS

- Shock is recognized by the features of tachycardia, tachypnea, and abnormalities of perfusion, as evidenced by skin perfusion, quality of pulses, mental status, and dysfunction of other organ systems.
- Pediatric patients with shock most often present with myocardial dysfunction ("cold" shock), although older children and adolescents may present with the adult picture of vascular dysfunction ("warm" shock).
- Neonates in shock must be treated for both septic shock and cardiogenic shock resulting from ductal-dependent congenital heart disease until an echocardiogram can confirm the cardiac anatomy. These conditions cannot be ruled out by physical examination. Therefore, all neonates with shock should be given prostaglandin infusion as part of their resuscitation. Pulmonary hypertension, hypocalcemia, and hypoglycemia frequently complicate shock in neonates.
- Pediatric patients in shock generally have absolute or relative hypovolemia, and the first line of resuscitation should be a fluid bolus of 20 mL/kg. Administration of more fluid should be based on rapid assessment of hemodynamic status.
- Early endotracheal intubations allow advantageous redistribution of the compromised cardiac output, and afterload reduces the left ventricle.
- Timely recognition and early aggressive goal-directed therapy reduces mortality in septic shock.

The clinical syndrome of shock is one of the most dramatic, dynamic, life-threatening problems faced by the physician in the critical care setting. Although untreated shock is universally lethal, mortality may be considerably reduced with proper recognition, diagnosis, monitoring, and treatment.

Definition and Physiology

Shock is an acute, complex state of circulatory dysfunction that results in failure to deliver sufficient amounts of oxygen and other nutrients to meet tissue metabolic demands. If prolonged, it leads to multiple organ failure and death. Therefore shock states can be viewed as a state of acute cellular oxygen deficiency. Shock can be caused by any serious disease or injury, but whatever the causative factors, it is always a problem of inadequate cellular sustenance. It is the final common pathway to death.

Delivery of oxygen is a direct function of cardiac output (CO) and arterial oxygen content (CaO_2):

Delivery of oxygen:

$$DO_2 = CO \times CaO_2$$

$$CO = \text{Heart rate (HR)} \times \text{Stroke volume (SV)}$$

$$CaO_2 = (Hgb \times 1.34 \times SaO_2) + (0.003 \times PaO_2)$$

Stroke volume is a function of preload, afterload, contractility, and diastolic relaxation. Therefore optimizing heart rate, contractility and diastolic relaxation, and preload and afterload improves cardiac output. Oxygen-carrying capacity can be increased by raising hemoglobin and optimizing its saturation with oxygen. Oxygen delivery can be improved by manipulation of all these factors.

Calculation of oxygen delivery provides a measure of global oxygen delivery and may not reflect regional hypoperfusion and localized ischemia. Inadequate oxygen delivery can result from either limitation or maldistribution of blood flow. Reduced oxygen content (anemia, poor arterial oxygen saturation) necessitates higher cardiac output to maintain oxygen delivery. In certain situations (fever, sepsis, trauma), metabolic demands may exceed normal oxygen delivery. Impairment of the extraction or utilization of oxygen by cells and mitochondria creates a functional arteriovenous shunt and may be the harbinger of multiorgan dysfunction syndrome.[1-3]

When oxygen delivery fails to meet cellular oxygen demands, various compensatory mechanisms are activated. Therefore shock is a dynamic process. The exact cardiorespiratory pattern detected clinically depends on the complex interaction of patient, illness, time elapsed, and treatment provided.

Because of its progressive nature, shock can be divided into phases: compensated, uncompensated, and irreversible. In compensated shock, vital organ function is maintained primarily by intrinsic regulatory mechanisms. Previously healthy children can compensate and maintain normal blood pressure during hypoperfusion states. Therefore identification of the early compensated stage of shock is crucial. Diagnosing a patient as having early compensated shock, rather than mere dehydration, may be the difference between a patient who is appropriately resuscitated and one for whom resuscitative efforts are delayed. As shock progresses, the cardiovascular system's ability to compensate is exceeded, and microvascular

perfusion becomes marginal. Cellular function deteriorates, affecting all organ systems. Terminal or irreversible shock implies damage to key organs of such magnitude that death occurs even if therapy restores cardiovascular function to adequate levels.

The ability to respond to shock states varies with age and depends on developmental aspects of the autonomic nervous, circulatory, respiratory, renal, and immunologic systems, as well as the presence of other medical conditions.

Recognition and Assessment of the Shock State

The early diagnosis of shock requires a high index of suspicion and knowledge of conditions that predispose children to shock. Interviews of the parents, physicians, nurses, and emergency medical services personnel caring for the child provide valuable information. A rapid and focused physical examination of a patient in shock is essential (Box 29-1).

Early signs of compensated shock may be subtle and should not be missed. They include tachycardia, tachypnea, mildly prolonged capillary refill, orthostatic hypotension, and mild alteration of mental status (e.g., lethargy, irritability). In patients with sepsis, other signs of early compensated shock may be plethora, warm extremities, bounding pulses, and a widened pulse pressure.

The contribution of laboratory tests to the initial evaluation of patients in shock is limited. Blood gases and serum lactate levels may quantify the degree of acidosis and are widely used as markers for the effectiveness of treatment. However, an increased understanding of microcirculatory aberrations and cellular hypoxia has raised awareness of the limitations of tests on pooled venous samples. This has stimulated a search for a minimally invasive means of sampling regional circulations.[4] Gastric tonometry,[5,6] near-infrared spectroscopy,[7,8] rectal tonometry,[9] and sublingual capnography[10,11] are methods currently being investigated to evaluate regional circulation. Their clinical utility is unproven at this time.

Repeated evaluation and monitoring of the patient in shock by a competent observer, with appropriate intervention, remains the most effective and sensitive physiologic monitor available.

Treatment of Shock

General Principles

Shock is a clinical syndrome of inadequate tissue oxygenation. In addition to treatment of the primary underlying process, therapeutic efforts involve optimizing and balancing oxygen delivery and oxygen consumption. Efforts to reduce oxygen requirements at a time when oxygen delivery is compromised are important. Intubation, mechanical ventilation, sedation, paralysis, and control of fever are ways to reduce oxygen consumption. Even routine nursing procedures can increase oxygen consumption by up to 20% to 30% in healthy adults.[12]

Intubation and Mechanical Ventilation

Viires et al.[13] studied spontaneously breathing dogs during cardiogenic shock. During a low cardiac output state, blood flow to the diaphragm was substantially increased, while blood flow to the liver, brain, and quadriceps was significantly decreased. Intubation, mechanical ventilation, and paralysis resulted in redistribution of blood flow from the diaphragm to the liver, brain, and quadriceps. A similar study of endotoxic shock in dogs demonstrated that respiratory muscle blood flow rose significantly in spontaneously breathing dogs.[14] During shock states, there is often increased work of breathing and respiratory distress related to capillary leak and acidosis.

Intubation and mechanical ventilation can allow redistribution of cardiac output from the muscles of respiration to vital organs during shock (when cardiac output and oxygen delivery are compromised). Positive pressure ventilation also has the effect of reducing afterload to the left ventricle (potentially improving stroke volume) (see Chapter 26).

Fluid Resuscitation

Regardless of the underlying insult, all patients in shock have an absolute or relative hypovolemia. A primary goal of initial therapy must be restoration of effective circulating volume. Early fluid resuscitation is the cornerstone of immediate therapy.[15,16] In a study of pediatric septic shock patients, Carcillo et al.[15] correlated the volume of fluid given in the first hour of presentation and reversal of hypovolemia to outcome. Patients who received the largest volume of fluid in the first hour of resuscitation had the lowest mortality. Persistent hypovolemia was associated with increased mortality. Fluid resuscitation must be guided by repeated evaluation of the patient's hemodynamic status.

Vasoactive Infusions

Vasoactive infusions are commonly used when patients have been adequately fluid-resuscitated but hemodynamics remain deranged. Infusions of catecholamines (dopamine, dobutamine, epinephrine, norepinephrine), phosphodiesterase inhibitors (inamrinone, milrinone), and vasopressin are most commonly used. The choice of vasoactive infusion is dependent on the physiologic derangement requiring treatment (Table 29-1). Catecholamines work through stimulation of α_1, α_2, β_1, β_2, and dopaminergic receptors to increase intracellular cyclic guanosine monophosphate (cGMP) and cause the appropriate response (Table 29-2). Phosphodiesterase inhibitors increase cGMP by preventing its degradation

Box 29–1 Physical Assessment in Shock

1. State of consciousness: restless, anxious, agitated, comatose
2. Skin: temperature, perfusion, moistness, color, turgor, rash
3. Mucous membranes: color, moistness
4. Nail beds: color, capillary refill
5. Central capillary refill
6. Peripheral veins: collapsed or distended
7. Pulse: rate, rhythm, quality
8. Blood pressure: orthostatic changes, pulse pressure
9. Respiration: rate, depth, effort, crackles, adequacy of aeration
10. Urine: concentration, hourly output

within the cell (see Chapter 25). Vasopressin causes vasoconstriction by direct stimulation of vascular smooth muscle cell V1 receptors.[17-22] Vasopressin also potentiates systemic adrenergic effects.[12,24-26] Vasopressin[20-22] and terlipressin[27-31] (a synthetic analog of vasopressin with a similar pharmacodynamic profile, but with a significantly longer half-life) have also shown some utility in the treatment of catecholamine-resistant shock.

Other Therapies

The finding of hypocalcemia in infants who present in shock should raise the suspicion of left ventricular dysfunction. Hypocalcemia causes left ventricular dysfunction in neonates and is reversible with calcium therapy.[32] Of note, 30% of neonates with DiGeorge syndrome are hypocalcemic.

Neonates, who have low glycogen stores and increased metabolic requirements during shock, may quickly develop hypoglycemia.[32] Shock in neonates is frequently complicated by pulmonary hypertension.

Table 29–1 Therapies for Hemodynamic Patterns in Shock States

	Blood Pressure or Systemic Vascular Resistance		
Hemodynamic Pattern	**Normal**	**Decreased**	**Elevated**
Septic shock			
Stroke index ↑↔	None	α_1, V_1	None
Stroke index ↓	β_1	α_1 and β_1	$\beta_1 + \beta_2$, or PDE
Cardiogenic shock	β_1	α_1 and β_1	$\beta_1 + \beta_2$, or PDE
Myocardial dysfunction (complicating critical illness)*	β_1 and/or β_2	α_1 and β_1	$\beta_1 + \beta_2$, or PDE
Congestive heart failure	β_1 and/or β_2	β_1	$\beta_1 + \beta_2$, or PDE
Bradycardia	None	β_1	None

*For example, acute respiratory distress syndrome or anthracycline therapy.
PDE, Phosphodiesterase inhibitor.

Adrenal insufficiency should be suspected in patients with refractory shock resulting from trauma (head or abdominal), history of steroid use within past 6 months, sepsis, or treatment with etomidate. Direct damage to the hypothalamus, anterior pituitary, or adrenals may result in cortisol deficiency. In septic shock, adrenal hemorrhage has been the paradigm of adrenal insufficiency, but increasing evidence indicates transient relative or functional adrenal insufficiency in septic shock (see section on septic shock).

Extracorporeal membrane oxygenation (ECMO) has been used to support patients of all ages with shock. The Extracorporeal Life Support Organization (ELSO) maintains a database of patients treated with ECMO from member institutions around the world. The registry was searched for data on patients treated with ECMO (from 1985 through January 2010) with any mention of the diagnosis of shock (Lynn Hernan, personal communication, 2010). The registry revealed 1512 pediatric patients (age ≤21 years old) who were treated with ECMO for any diagnosis which included the descriptor shock. The overall mortality was 60%. Sixty-five percent of patients were 1 year of age or younger. Forty-four percent of pediatric patients treated with ECMO for shock were neonates. In patients aged 21 years or younger treated with ECMO, the etiology of shock was cardiogenic in 46%, septic in 22%, hypovolemic in 11%, traumatic or surgical in 1%, and other or unspecified in 20%. The mortality across the groups ranged from 56% to 64%.

Multisystem Effects of Shock

Management of the multisystem deterioration that occurs in shock states is as important as treating the underlying condition. Respiratory, gastrointestinal, central nervous system, renal, and hematologic abnormalities in shock must be identified and treated. Multiple organ dysfunction syndrome (MODS) is the derangement of two or more organs after an insult. The severity of MODS has been associated with increased mortality in PICU patients.[33-35]

Respiratory

Respiratory failure frequently accompanies shock states. It may result from failure of the ventilator pump (i.e., respiratory muscle fatigue) and/or deterioration of lung function (i.e., acute respiratory distress syndrome). For these reasons and

Table 27–2 Vasoactive Medications

	α_1	β_1	β_2	D_1	V_1
Dopamine*	Vasoconstriction	Inotropy, chronotropy	Vasodilation	Renal vasodilation	
Norepinephrine	Vasoconstriction	Inotropy			
Epinephrine†	Vasoconstriction	Inotropy, chronotropy	Vasodilation		
Dobutamine		Inotropy	Vasodilation		
Vasopressin	Potentiates	Potentiates			Vasoconstriction
Inamrinone, milrinone		Non–receptor-mediated inotropy, lusitropy, and vasodilation			

*Dose related: at low infusion rates, D_1 receptor effects predominate; at intermediate rates, β_1 and β_2 receptor effects predominate; at high rates, α_1 effects predominate on peripheral vasculature.
†Dose related: at low infusion rates, β receptor effects predominate; at high rates, α effects predominate on peripheral vasculature.

for maximizing oxygen delivery, increased inspired oxygen is essential in all children with shock. Early tracheal intubation protects the airway, provides relief from respiratory muscle fatigue, facilitates provision of positive airway pressure, redistributes blood flow from the muscles of respiration to core organs, afterload-reduces the left ventricle, and reduces oxygen demands of respiratory muscles. Patients should be ventilated with a lung protective strategy (see Chapter 51).

Renal

Renal failure may develop in association with any of the shock syndromes. Shock-related renal failure is a continuum of acute prerenal azotemia through classic acute tubular necrosis to cortical necrosis. Renal support is essential to prevent prolonged renal shutdown in shock states. Volume augmentation to correct absolute or relative hypovolemia is essential. Although low-dose dopamine (3 to 5 μg/kg/min) improves renal blood flow,[36,37] it also impairs renal oxygen kinetics, inhibits protective feedback loops with the kidney, and may worsen tubular injury.[38,39] It has failed to show benefit in preventing or altering the course of acute renal failure in adults.[38,39] Dopamine may also inhibit secretion of prolactin, growth hormone, and thyrotropin in critically ill children.[40]

Acute anuric renal failure may require treatment with peritoneal dialysis, ultrafiltration, continuous hemofiltration or hemodiafiltration, or hemodialysis (see Chapter 72). High-output renal failure may occur in shock states without previous oliguria. The polyuria associated with this condition may falsely suggest adequate renal perfusion and adequate vascular volume at a time when the patient's intravascular volume is, in fact, depleted. Restoration of renal perfusion pressure remains the standard of care.

Populations for whom early renal replacement therapies result in decreased mortality have not been consistently identified.[41,42] There is evidence that fluid overload is related to mortality in critically ill children with renal dysfunction.[43] If renal dysfunction exists, all medications and therapies should be adjusted for creatinine clearance.

Coagulation

Coagulation abnormalities (e.g., disseminated intravascular coagulation) probably occur to some extent in all forms of shock. Monitoring of prothrombin time, partial thromboplastin time, and platelet count and observation for abnormal bleeding are essential. Replacement therapies specifically designed to replace absent clotting factors seem to be the most advantageous treatments. Use of vitamin K, fresh-frozen plasma, cryoprecipitate, and platelet transfusions should correct most coagulopathies. If general replacement therapy is ineffective, and the patient is at risk for complications, specific factor therapy may be indicated.

Coagulopathy is ubiquitous in all patients with severe sepsis.[44] Recombinant activated protein C has been shown to decrease mortality in adults with severe sepsis (see section on septic shock).

Use of plasmapheresis, plasma exchange, and plasma filtration as therapy for treating sepsis-induced multiple organ system failure and improving outcome remains experimental.[42,45-49]

Hepatic

The degree of hepatic dysfunction may determine a patient's ultimate outcome in severe shock states. Maintaining adequate circulation helps maintain liver function and prevents further hepatocellular damage. Liver function tests should be performed early and followed frequently. If dysfunction exists, drugs requiring hepatic metabolism must be carefully titrated.

Gastrointestinal

Gastrointestinal disturbances after hypoperfusion and stress include bleeding, ileus, and bacterial translocation. Ileus may result from electrolyte abnormalities, administration of narcotic medications, or from shock itself. Abdominal distension from ileus or ascites may cause respiratory compromise, especially in infants. Use of prophylactic medications (H_2 blockers, protein pump inhibitors, sucralfate) to prevent gastrointestinal hemorrhage is unproven.[50] Use of histamine antagonists has been associated with an increased incidence of nosocomial pneumonias.[50,51]

Acute nonocclusive mesenteric ischemia is a devastating condition characterized by intense, prolonged splanchnic vasoconstriction, intestinal mucosal hypoxia, and acidosis. Mesenteric ischemia eventually leads to transmural necrosis of the bowel, bacterial translocation, sepsis, and multisystem organ dysfunction.[52-54] Morbidity and mortality for this condition are high because the signs/symptoms are nonspecific, delaying diagnosis. Prevention of gut ischemia through adequate oxygen delivery may prevent bacterial translocation. Some clinicians advocate the use of selective gut decontamination and early enteral nutrition.[55-56] Most children with shock will tolerate postpyloric enteral feeding, although GI feeding complications are more common than in critically ill patients without shock.[57,58]

Endocrine

Multiple endocrine problems involving fluid, electrolytes, and mineral balance may arise and complicate the management of children in shock. Severe abnormalities of calcium homeostasis can occur during the course of acute hemodynamic deterioration.

Hypoadrenalism may exacerbate the shock state. Patients who have been administered corticosteroids within 6 months preceding the onset of shock should be considered for stress doses of glucocorticoids. Patients in shock because of head or abdominal trauma may have disruption of the hypothalamic-anterior pituitary-adrenal axis. Adrenal hemorrhage has been demonstrated as a manifestation of severe sepsis, but more commonly patients may develop a relative or functional adrenal insufficiency (see section on septic shock).

Functional Classification and Common Underlying Etiologies

Shock states can be classified into six functional categories (Box 29-2). Such tidy classifications imply a degree of precision that will be misleading when approaching an individual patient. Vicious cycles play a prominent role in most shock syndromes. Any given patient, over time, may display features of any functional category or features of multiple categories.

Hemodynamic profiles of these categories are summarized in Table 29-1.

Hypovolemic Shock

Etiology and Pathophysiology

Hypovolemia is the most common cause of shock in infants and children. Hypovolemic shock is best defined as a decrease in the intravascular blood volume to such an extent that effective tissue perfusion cannot be maintained. Etiologies include hemorrhage (see Chapter 112), fluid and electrolyte loss (see Chapter 67), endocrine disease (see Chapter 77), and plasma loss (Box 29-3).

Hypovolemia causes a decrease in preload leading to a decrement of stroke volume and reduction in cardiac output. Activation of peripheral and central baroreceptors produces an outpouring of catecholamines, and the resulting tachycardia and peripheral vasoconstriction are initially adequate to support the blood pressure with little or no evidence of hypotension. Acute losses of 10% to 15% of the circulatory blood volume may be well tolerated in healthy children who have intact compensatory mechanisms. An acute loss of 25% or more of the circulating blood volume, however, frequently results in a clinically apparent hypovolemic state that requires immediate, aggressive management.

The most reliable indicators of early, compensated hypovolemic shock in children are persistent tachycardia, cutaneous vasoconstriction, and diminution of the pulse pressure. The best clinical evidence of decreased tissue perfusion is skin mottling, prolonged capillary refill, cool extremities, and decreased urine output. Systemic arterial blood pressure is frequently normal, the result of increased systemic vascular resistance, making blood pressure measurement of limited value in managing the patient with compensated hypovolemic shock. Neurologic status is normal or only minimally impaired.

With continued loss of blood volume or with delayed or inadequate blood volume replacement, the intravascular fluid losses surpass the body's compensatory abilities, causing circulatory and organ dysfunction. Stroke volume and cardiac output are decreased. The pronounced systemic vasoconstriction and hypovolemia produce ischemia and hypoxia in the visceral and cutaneous circulations. Altered cellular metabolism and function occur in these areas, resulting in damage to blood vessels, kidneys, liver, pancreas, and bowel. Patients become hypotensive, acidotic, lethargic or comatose, and oliguric or anuric. It is important to emphasize that arterial blood pressure falls only after compensations are exhausted, which may occur long after the precipitating event and only after a severe reduction in cardiac output. Terminal phases of hypovolemic shock are characterized by myocardial dysfunction and widespread cell death.

Therapy

Initial treatment of the child in hypovolemic shock is similar regardless of etiology. Therapy begins with the establishment or assurance of adequate oxygenation and ventilation. Oxygen should always be the first drug administered. Once the airway is assured or established (may require intubation) and ventilation is adequate, measures to restore an effective circulating blood volume should begin immediately. Placement of an adequate intravenous or intraosseous catheter and rapid volume replacement are the most important therapeutic maneuvers to reestablish the circulation (see Chapter 15). Central venous catheterization is infrequently necessary during initial resuscitation.

The choice of fluid depends on the nature of the loss. Early correction of hypovolemia is the major factor preventing the later complications of shock. Isotonic crystalloid solutions, which are readily available, safe, and the least expensive, should be used in initial volume resuscitation. The first fluid bolus (20 mL/kg) should be administered as rapidly as possible. Heart rate, pulse pressure, blood pressure, peripheral perfusion, quality of mentation, and volume of urine output should be monitored. Improvement in these measurements should be expected if the blood volume loss is approximately 20%. Under these conditions, a rapid response to resuscitation can be anticipated. Maintenance fluid administration then can be initiated and vital signs monitored. The appropriate maintenance fluid depends on the measurements of serum electrolytes, total protein, and hematocrit.

The end point of fluid resuscitation should be normalization of arterial blood pressure, pulse pressure, peripheral perfusion, and heart rate; establishment of adequate urine output; and a decrease in the metabolic acidosis. If shock persists, continued aggressive fluid resuscitation in aliquots of 20 mL/kg should be initiated with rapid assessment of response to therapy. If the patient does not show improvement after several isotonic fluid boluses, more aggressive monitoring and reevaluation of the diagnosis may be required. Causes of ongoing vascular depletion should be sought. Patients in profound hypovolemic shock will require frequent or continuous monitoring of heart rate, arterial blood pressure, arterial blood gases, central venous pressure (CVP), and urinary output.

Uncomplicated, promptly treated hypovolemic shock usually does not lead to a significant capillary injury and leak. However, severe, prolonged hypovolemic shock, traumatic shock with extensive soft-tissue injury, burn shock, or sepsis complicating hypovolemic shock may seriously impair capillary integrity. Therefore, once adequate circulation and urine output have been restored, fluid administration may be reduced unless there are demonstrable ongoing fluid losses. Continued assessment of hemodynamic status and vascular volume is essential to guide further therapy.

The amount of fluid necessary to restore effective circulating blood volume depends on the amount lost (deficit) and the rate of ongoing loss. The total amount of fluid given often exceeds the total volume lost because of expanded capacitance of the vascular space and dysfunction of cellular membranes. Ongoing fluid losses from chest tube drains, biliary drains, bowel, edema formation, or other losses of bodily fluids may dictate the use of solutions other than crystalloid. Enough fluid must be given to provide adequate cardiac filling pressure. Adequate filling pressure only ensures that one determinant of cardiac performance—preload—has improved. It does not ensure adequate contractility, ejection of blood, and perfusion of tissue beds. A child with nonhemorrhagic hypovolemic shock should respond to 40 mL/kg of crystalloid solution. If a child is unresponsive to this amount of fluid resuscitation, the child must be evaluated for complicating factors. Causes of refractory shock include unrecognized pneumothorax or pericardial effusion, intestinal ischemia (volvulus, intussusception, necrotizing enterocolitis), sepsis, myocardial dysfunction, adrenocortical insufficiency, and pulmonary hypertension.

The first approach to further diagnosis of patients in persistent hypovolemic shock is the establishment of a central venous catheter for measurement of CVP. In the hypotensive patient, a CVP of less than 10 mm Hg, in the absence of pulmonary edema, should be carefully augmented by fluid infusion until that level of preload is reached. If there is no improvement in blood pressure, peripheral perfusion, or urine output, cardiogenic causes of circulatory failure must be considered. Arterial blood gases, hematocrit, serum electrolytes, glucose, and calcium should be reevaluated. Correction of acidosis, hypoxemia, or metabolic derangements is essential. Blood and other appropriate sites must be cultured and broad-spectrum parenteral antibiotic coverage begun if sepsis is suspected. Shock persisting in the face of a CVP exceeding 10 mm Hg may be an indication for placement of a flow-directed thermodilution pulmonary artery catheter and/or an echocardiogram.

Because many factors affect preload measurements, the absolute value of the CVP and pulmonary capillary pressure measurement may be less important than the change in measurement in response to therapeutic interventions. Used this way, these measurements allow detection of limitation in cardiac competence and therefore provide an important guide for volume replacement. Fluid administration should be discontinued when ventricular filling pressure rises without evidence of improvement in cardiovascular performance. At such a time, an inotropic agent may be necessary.

In the case of hemorrhagic hypovolemia, blood must be obtained and transfused if hypotension persists despite early crystalloid infusions. The patient with severe anemia in shock may need emergency transfusion of uncrossmatched blood as part of the initial resuscitation. The hematocrit may be a poor indicator of the severity of hemorrhage because it may not immediately decline in the setting of acute hemorrhagic shock. The possibility of occult intrathoracic or intraabdominal bleeding must be considered. Concomitant with fluid resuscitation of hemorrhagic shock, early surgical intervention may be indicated to control the source of bleeding. In the setting of hemorrhagic shock caused by penetrating trauma in adults, surgical control of the bleeding site may be more important than initial fluid resuscitation in improving patient outcome.[14]

Cardiogenic Shock or Congestive Heart Failure

Etiology and Pathophysiology

Cardiac shock is the pathophysiologic state in which an abnormality of cardiac function is responsible for the failure of the cardiovascular system to meet the metabolic needs of tissues. The common denominator is depressed cardiac output, which in most instances is the result of decreased myocardial contractility. Cardiogenic shock or congestive heart failure (CHF) during infancy and childhood is a diagnostic and therapeutic challenge because of its myriad etiologies (Box 29-4).

Cardiac function can be depressed in patients with shock of noncardiac origin. Myocardial dysfunction is frequently a late manifestation of shock of any etiology. Although the cause of myocardial dysfunction in such patients is not completely understood, the following mechanisms have been proposed: (1) specific toxic substances released during the course of shock that have a direct cardiac depressant effect, (2) myocardial edema, (3) adrenergic receptor dysfunction, (4) impaired sarcolemmic calcium flux, and (5) reduced coronary blood flow resulting in impaired myocardial systolic and diastolic function.[20]

Another form of cardiogenic shock is caused by diastolic dysfunction. Impaired myocardial relaxation changes the pressure-to-volume ratio during diastole and increases ventricular pressure at any volume. This lack of myocardial relaxation is hemodynamically unfavorable because increased left ventricular diastolic pressure is transmitted to the lung and results in pulmonary edema and dyspnea. Elevated left ventricular diastolic pressure also decreases myocardial perfusion pressure and can lead to subendocardial ischemia. Such patients present with "heart failure" but may have normal left ventricular systolic function. Diastolic properties of the ventricle appear to be the first to become abnormal in patients with ischemic heart disease or disorders associated with ventricular hypertrophy.[61,62] Therefore when approaching a patient with

cardiogenic shock, it is important to characterize both systolic and diastolic function. Therapy designed to improve systolic function may impair myocardial diastolic function (see Chapter 19).[62]

Clinical Assessment

The appropriate management of CHF in infancy is critically dependent upon the specific etiology; accurate and rapid diagnosis is of prime importance. Recognition begins with a careful history and physical examination (Box 29-5) and is supplemented by chest radiography, electrocardiography, and echocardiography.

Two-dimensional and Doppler echocardiographic studies provide important information about the size, thickness, and performance of the heart and delineation of cardiac malformations. Doppler investigation of the diastolic mitral inflow pattern is useful in assessing the presence of diastolic dysfunction.[62]

As opposed to hypovolemic shock, compensatory responses can have deleterious effects in patients with cardiogenic shock. Compensatory responses are nonspecific and imprecise and may contribute to the progression of shock by further depressing cardiac function. As contractility deteriorates and cardiac output decreases, systemic vascular resistance increases, in response to neurohumoral mediators, in order to maintain circulatory stability.[63] However, this increase in afterload adds to the heart's workload and further decreases pump function. Therefore, in cardiogenic shock, a vicious cycle is established. Because of the self-perpetuating cycle, compensated phases of cardiogenic shock may not be observed. Patients are tachycardic, hypotensive, diaphoretic, oliguric, acidotic, and poorly perfused. Extremities are cool and mental status is altered. Hepatomegaly, jugular venous distension, rales, and peripheral edema may be observed. Cardiac output is depressed, and elevations in CVP, pulmonary capillary wedge pressure, and systemic vascular resistance are observed.

Therapy

Box 29-6 lists the general supportive and pharmacologic measures used in the treatment of severe CHF or cardiogenic shock. These measures are designed to increase tissue oxygen supply, decrease tissue oxygen requirements, and correct metabolic abnormalities. The initial therapy for cardiogenic shock is to support the heart with supplemental oxygen and mechanical ventilation. Preload should be optimized to allow the patient to take advantage of Starling mechanisms.

Although volume expansion and correction of metabolic derangements (e.g., pH, glucose, calcium, magnesium) may enhance cardiac function, pharmacologic interventions are usually necessary to improve cardiac function. This approach to treatment relies on the use of drugs having the ability to restore or augment myocardial contractility, improve cardiac output, and bring about restoration and maintenance of blood flow. The proper choice of drug(s) requires knowledge of the exact hemodynamic disturbance and of the pharmacology of the drugs (see Tables 29-1 and 29-2) (see Chapter 25).

In neonates presenting in shock within the first 2 weeks of life, a lesion with ductal-dependent systemic output should be suspected, and prostaglandin E_1 (PGE_1) (0.05 to 0.1 μg/kg/min) should be infused emergently until a cardiac echocardiogram can be obtained. This is a lifesaving intervention; opening and maintaining ductal patency is the only medical intervention that can restore adequate systemic cardiac output.

Proper use of the various vasoactive drugs often requires the presence of indwelling arterial and central venous catheters. A pulmonary artery catheter may be helpful if the patient is not responding to therapy and shock is not resolving as expected. The presence of these monitoring devices allows the generation of data that will characterize the hemodynamic state, direct appropriate therapy, and allow for evaluation of the response to therapy. There is no usual drug or dose in shock; instead, therapy must be continually tailored to the patient's response.

Box 29–6 General Principles in Management of Cardiogenic Shock or Severe Congestive Heart Failure

I. Minimize myocardial oxygenation demands
   1. Intubation and mechanical ventilation
   2. Maintain normal core temperature
   3. Provide sedation
   4. Correct anemia
II. Maximize myocardial performance
   1. Correct dysrhythmias
   2. Optimize preload: fluid boluses; if congested, appropriate salt and water restriction and appropriate use of venodilators and/or diuretics
   3. Improve contractility: provide oxygen, guarantee ventilation, correct acidosis and other metabolic abnormalities, inotropic and lusitropic drugs
   4. Reduce afterload: provide sedation and pain relief, correct hypothermia, appropriate use of vasodilator
III. Rule out congenital heart or traumatic heart disease
IV. Explore surgical options

Myocardial Contractility: Inotropic Agents

The catecholamines are the most potent positive inotropic agents available; however, effects are not limited to inotropy. The catecholamines also possess chronotropic properties and have complex effects on vascular beds of the various organs of the body. Consequently, the choice of an agent may depend as much on the state of the circulation as it does on the myocardium.

The most commonly used catecholamines are norepinephrine, epinephrine, dopamine, and dobutamine.[64] Fenoldopam has been used to augment diuresis and improve hemodynamics after cardiac surgery and in septic shock.[65,66]

The digitalis glycosides may augment myocardial contractility, but because of a narrow therapeutic-to-toxic ratio, long half-life, and dependence of clearance on renal (digoxin) or hepatic function, their use in patients with cardiogenic shock should be avoided. These compounds have the advantage of improving contractility without further increasing the heart rate. They can be used once the shock is resolved.

Inamrinone, milrinone, and enoximone 133 belong to a class of nonglycoside, nonsympathomimetic inotropic agents that act via potent and selective inhibition of phosphodiesterase. Intravenous administration of inamrinone or milrinone increases cardiac output and reduces cardiac filling pressures and systemic vascular resistance with minimal effect on the heart rate and systemic blood pressure of adult patients. These drugs are particularly useful in the treatment of cardiogenic shock because they improve diastolic function (lusitropy), increase contractility, and reduce afterload by peripheral vasodilation without a consistent increase in myocardial oxygen consumption. These agents require careful bolus dosing prior to initiating an infusion; a rapid infusion of the bolus dose may cause hypotension. Both of these drugs have relatively long half-lives, and they should be used cautiously in the presence of significant hypotension. Milrinone may be preferred over inamrinone because of inamrinone's tendency to cause thrombocytopenia.

Afterload Reduction: Vasoactive Drugs

Neurohumoral compensatory mechanisms that initially compensate for a fall in output of the failing heart in time become a major part of the problem.[63] The kidney's response to a decrease in cardiac output leads to expansion of extracellular fluid volume which may lead to circulatory congestion and edema. Systemic vasoconstriction raises aortic impedance, which maintains perfusion pressure in the face of declining cardiac output but may impair ventricular function. After resuscitation, therapy is directed to counteract these physiologic responses: for example, use of vasodilators to oppose systemic vasoconstriction, angiotensin-converting enzyme inhibitors to block the renin-angiotensin system, and diuretics to prevent or reverse abnormal fluid retention. They should not be used as first-line therapy to reverse shock.

Numerous vasodilators, representing several different pharmacologic classes, improve cardiac performance and lessen clinical symptoms via arterial and venous smooth muscle relaxation. Arterial relaxation should increase ejection fraction, increase stroke volume, and decrease end-systolic left ventricular volume. Some evidence suggests some vasodilator drugs increase left ventricular compliance, which should improve diastolic function.[62] Venous relaxation should shift

blood into the periphery and reduce right and left ventricular diastolic volume, with attendant beneficial effects on pulmonary and systemic capillary pressure. This ought to be reflected in decreased edema, reduced myocardial wall stress, and improved diastolic perfusion of the myocardium.

For treatment of cardiogenic shock, intravenous vasodilators with rapid onsets of action and short half-lives are preferred. Selection of a vasodilator agent should depend on its principal hemodynamic effects and the specific hemodynamic abnormalities in individual patients. Factors that increase systemic resistance, such as hypothermia, acidosis, hypoxia, pain, and anxiety, should be treated before vasodilator drugs are considered.

Use of vasodilators in shock is generally limited to situations in which cardiac dysfunction is associated with elevated ventricular filling pressures, elevated systemic vascular resistance, and normal or near-normal systemic arterial blood pressure. Occasionally, the combination of vasodilator and inotropic therapy results in hemodynamic improvement not attainable with either approach alone.

There is a growing awareness that right ventricular dysfunction plays a pivotal role in some of the most frequently encountered and important cardiopulmonary disorders in children, including congenital heart disease, acute respiratory distress syndrome, bronchopulmonary dysplasia, and other chronic pulmonary disorders. The ability of the right ventricle to respond to the increased pulmonary vascular resistance seen in these situations often determines outcome. Therefore, measures to decrease pulmonary vascular resistance have become more common in the treatment of many seriously ill pediatric patients. Such measures include supplemental oxygen, hyperventilation, metabolic and respiratory alkalosis, inhaled nitric oxide, prostaglandin E_1, prostacyclin, analgesia, and sedation.[67-69]

Surgical Intervention

A number of congenital cardiac defects may present in severe CHF and cardiogenic shock. Diagnosis of these defects is critical because surgery is the definitive therapy. Prostaglandin E_1 infusion may allow for resuscitation and stabilization until surgery can be accomplished in ductus-dependent obstruction to systemic blood flow (e.g., hypoplastic left heart syndrome, interruption of the aortic arch, coarctation of the aorta).

Cardiac function can sometimes be supported temporarily by mechanical means, including intraaortic balloon counterpulsation, left ventricular assist device, and ECMO. Cardiac transplantation has become an important tool for treating patients with severe myocardial dysfunction who otherwise would die of their heart disease.

Specific Etiologies

Cardiomyopathy

Patients may present in shock with dilated cardiomyopathy. The etiologies of acute dilated cardiomyopathies are listed in Box 29-4. Myocarditis is one of the more common causes of dilated cardiomyopathy in previously healthy children. The clinical presentation of myocarditis in pediatric patients is varied. Carditis may cause myocardial dysfunction or dysrhythmia, or it may be "clinically silent." Tachycardia (in the absence of fever) and tachypnea are usual presenting symptoms. In acute myocarditis, the history of illness is very short (hours to days). Life-threatening dysrhythmias in patients with acute myocarditis include ventricular tachycardia and supraventricular tachycardia. Initial resuscitation of the patient with myocarditis is the same as for other forms of cardiogenic shock; however, patients with myocarditis and other dilated cardiomyopathies may not respond as well to traditional inotropic therapy.[70,71] In addition, catecholamine infusions may promote the development of dysrhythmias.

Once the diagnosis of myocarditis is made, treatment with steroids or intravenous immunoglobulin (IVIg) (1 g/kg/day for 2 days) is recommended to modulate the inflammatory response.[72,73] Use of ECMO has been lifesaving in patients with acute myocarditis whose shock does not reverse with conventional therapy or in whom arrhythmias are unremitting. We queried the ELSO registry for cases of myocarditis treated with ECMO from 1987 through 2009. There were 485 pediatric cases (age 21 years or younger), with a median run time of 6.8 days (range, 0 to 51.9 days). The survival was 62% (Lynn Hernan, personal communication, 2010).

Hypoxic-Ischemic Injury

Shock following a generalized hypoxic-ischemic episode (e.g., near-drowning, sudden infant death syndrome) is frequently encountered in infants and children with no preexisting cardiovascular or pulmonary disease. Data have shown that shock following hypoxic-ischemic events is cardiogenic. This shock is characterized by a low cardiac index, elevated right and left heart filling pressures, elevated systemic and pulmonary vascular resistances, decreased oxygen consumption, and elevated oxygen extraction index. In many patients, the mean systemic arterial blood pressure is elevated, which suggests the increase in systemic vascular resistance is exaggerated. Studies have documented progressive systolic and diastolic myocardial dysfunction immediately after successful cardiac resuscitation.[74] All of these observations have important therapeutic implications because the increased vascular resistance and decreased cardiac output may prevent adequate tissue perfusion following anoxic injury.

Cardiac Injury in Trauma

Blunt cardiac injury can cause myocardial contusion, myocardial concussion, aneurysm, septal defects, chamber rupture, valvular rupture, and bleeding into or damage to the pericardium. Each of these entities has separate presentations, although the lesions often are concurrent. Every pediatric trauma patient deserves a careful cardiac evaluation. Of note, both left and right ventricular function may be impaired significantly in children with isolated head injury. The myocardial injury seen in children with head injury appears to be related to high levels of catecholamines with resultant myocardial ischemia.[75]

Obstructive Shock

Etiology and Pathophysiology

Obstructive shock is caused by the inability to produce adequate cardiac output despite normal intravascular volume and myocardial function. Causative factors may be located within the pulmonary or systemic circulation or associated with the heart itself. Examples of obstructive shock include acute pericardial tamponade, tension pneumothorax, pulmonary or

systemic hypertension, and congenital or acquired outflow obstructions. Recognition of the characteristic features of these syndromes is essential, because most of the causes can be treated provided the diagnosis is made early.

Specific Etiologies

Cardiac Tamponade

Cardiac tamponade is defined as hemodynamically significant cardiac compression resulting from accumulating pericardial contents that evoke and defeat compensatory mechanisms. The pericardium may contain effusion fluid, purulent fluid, blood, or gas.

Clinical manifestations of tamponade may be insidious, especially when it occurs in conditions such as malignancy, connective tissue disorders, renal failure, or pericarditis. In early phases, the symptoms are nonspecific. As cardiac output becomes restricted, the overall picture resembles CHF; however, the lungs usually are clear. Findings on physical examination that suggest cardiac tamponade include pulsus paradoxus, narrowed pulse pressure, pericardial rub, and jugular venous distension. Echocardiography is of particular value in detecting the presence of pericardial effusion and can provide clues about the presence of tamponade. In rapid tamponade caused by hemorrhage, as in trauma, shock dominates the picture. Left untreated, it leads to electromechanical dissociation.

The definitive treatment of cardiac tamponade is removal of pericardial fluid or air by surgical drainage or pericardiocentesis. Removal of even a small volume of fluid can rapidly improve blood pressure and cardiac output. Surgical drainage by either thoracotomy or a subxiphoid limited surgical approach should be considered for traumatic tamponade.

Pericardiocentesis should be performed as soon as possible if the patient is considered to be in a life-threatening condition. Pericardiocentesis is a blind procedure; introduction of the needle should be monitored by echocardiography whenever possible. The subxiphoid approach is generally preferable (see Chapter 15).

Medical management is not a substitute for drainage but may avert a catastrophe until pericardiocentesis or surgical drainage can be safely performed. The principles of medical management include blood volume expansion to maintain venoatrial gradients and inotropic agents. In addition, any anticoagulant or thrombolytic therapy should be withheld or discontinued if pericardiocentesis is anticipated. Diuretics, which reduce blood volume, and digoxin or other agents, which slow the heart, are contraindicated in tamponade.

Coarctation/Interrupted Arch

Infants with aortic arch interruption or juxtaductal coarctation of the aorta may depend on patency of the ductus arteriosus to provide adequate lower body perfusion. In many such infants, the ductus arteriosus constricts after birth, resulting in severe heart failure, poor systemic perfusion, and acidemia. Many of the signs and symptoms of coarctation with shock are indistinguishable from shock of other etiologies.[76] A high index of suspicion must be maintained for infants who present in shock in the first month of life. In severely ill infants in whom the diagnosis of coarctation or interruption of the aorta is clinically suspected, it is appropriate and often lifesaving to start a continuous prostaglandin E_1 infusion before diagnostic evaluation is performed.

Distributive Shock

Etiology and Pathophysiology

Distributive shock results from maldistribution of blood flow to the tissue. Abnormalities in distribution of blood flow may result in profound inadequacies in tissue oxygenation, even in the face of a normal or high cardiac output. Such maldistribution of flow generally results from widespread abnormalities in vasomotor tone. Distributive shock may be seen with anaphylaxis, spinal or epidural anesthesia, disruption of the spinal cord, or inappropriate administration of vasodilatory medication.

Treatment generally includes reversal of the underlying etiology and vigorous fluid administration. In severe cases of distributive shock unresponsive to fluids, vasopressor infusions may be necessary.

Septic Shock

The incidence of pediatric septic shock in the United States is approximately 0.56 cases per 1000 population.[77] The incidence is highest in infants (5.16 cases per 1000 population) and falls rapidly after the first year. There are an estimated 42,000 cases per year with a case fatality rate of 10.3% (or approximately 4400 deaths per year). The average cost per case of pediatric sepsis in the U.S. is estimated to be greater than $40,000. The estimated national total annual cost is $1.97 billion.[77] Sepsis and septic shock are significant causes of mortality in children and consume a significant amount of U.S. health care dollars.

Etiology and Pathophysiology

Septic shock is the most complex and controversial type of shock and merits independent classification. Septic shock is often a combination of multiple problems, including infection, relative or absolute hypovolemia, maldistribution of blood flow, myocardial depression, and multiple metabolic, endocrine, and hematologic problems. Thus shock in sepsis contains many elements of the other types of shock discussed previously (hypovolemic, cardiogenic, and distributive shock) (see Chapters 91 and 103).

Septic shock encompasses a cascade of metabolic, hemodynamic, and clinical changes resulting from invasive infection and the release of microbial toxins in the bloodstream. Correlation of clinical findings with the type of invading microorganism has been attempted. However, the systemic inflammatory response is independent of the type of invading organism (bacterial, virus, fungus, *Rickettsia*) and is a host-dependent response.[78]

The pathophysiology of septic shock is incompletely understood. A combination of the direct effects of microbial agents, microbiologic toxins, the patient's inflammatory response to infection, and activation of endogenous mediators results in the cardiovascular instability and multisystem organ failure.[79] Septic shock is a constellation of signs and symptoms that reflect multiple organ system derangement at the subcellular level. Mediator release seems to be the final common pathway

to the development of this shock state regardless of etiology.[78] Some mediators are cytokines, tumor necrosis factor, interleukin-1, interleukin-6, kinins, eicosanoids, platelet activating factor, and nitric oxide.

The clinical pattern and presentation of septic shock vary greatly and are dependent on the dynamic interplay of the invading organism, time to treatment, and the host response to the infection and treatment. All patients present with an absolute or functional hypovolemia. Several factors may contribute to hypovolemia. Increased microvascular permeability, arteriolar and venular dilation with peripheral pooling of intravascular volume, inappropriate polyuria, and poor oral intake all combine to result in reduced effective blood volume. Volume loss secondary to fever, diarrhea, vomiting, or sequestered third space fluid also contributes to hypovolemia.

Abnormal hemodynamic responses constitute a primary hallmark of septic shock.[80] The most common presentation (80%) in children is low cardiac index with or without abnormalities of vascular tone.[25] These children present with tachycardia, mental status changes, diminished peripheral pulses, mottled cold extremities, and prolonged capillary refill (more than 2 seconds). Adults and some children (20%) present in a hyperdynamic state characterized by an elevated (or normal) cardiac output and decreased systemic vascular resistance. On physical examination, patients appear plethoric with warm extremities. They have tachycardia, bounding (or collapsing) pulses, and a widened pulse pressure. High fever, mental confusion, and hyperventilation may be present. At this stage the inexperienced observer may fail to recognize shock. Paradoxically, hypotension may occur in the presence of a normal or elevated cardiac output. In either case, hypotension is not necessary to make the diagnosis of shock.

Progression of sepsis is characterized by a loss of cardiac compensation for diminishing systemic vascular resistance, possibly as a result of inflammatory-mediated capillary leak, vasodilation, and/or toxin-mediated cardiac depression. Some patients die of refractory hypotension as a result of a low systemic vascular resistance.[82]

The progression from high to low cardiac output may occur rapidly. As cardiac output decreases, the physical symptoms change to those of a hypoperfused state. The patient has tachypnea, tachycardia, hypotension, weak thready pulses, mottled cold extremities, and delayed capillary refill. As tissue perfusion worsens, anaerobic metabolism ensues and lactic acid accumulates.

Progressive deterioration in oxygen consumption and oxygen extraction portends a poor prognosis. In pediatric patients with septic shock, oxygen consumption is dependent on oxygen delivery.[83] This is similar to the physiologic relationship seen in pediatric patients with cardiogenic shock, suggesting that these two groups could be resuscitated with the same physiologic principles. In addition to oxygen, impaired use of other metabolic substrates has been demonstrated in septic shock. Prior to the onset of cellular hypoxia,[1-3] dysregulation of glucose, fat, and amino acids occurs. Changes in glycolysis and gluconeogenesis are possibly the earliest metabolic manifestation of sepsis.[84] Insulin responsiveness,[85] intracellular calcium,[86] glucose distribution,[87] and adrenergic effects[88] have all been implicated.

Although most adults present with hyperdynamic septic shock, most children and especially infants, who have limited cardiac reserve, present with a low cardiac output state clinically indistinguishable from cardiogenic shock.[81] Even during the hyperdynamic state seen in adults, myocardial contractility is depressed because of myocardial depressant factor, diffuse myocardial edema, adrenergic receptor dysfunction, and impaired sarcolemmic calcium flux.[89] Survival of children in septic shock is related to the speed and adequacy of resuscitation. When resuscitation is delayed or inadequate, cellular hypoxia and multiple system organ failure ensue and are the final common pathway to death.

In recognition that pediatric septic shock differs from adult septic shock, and that the clinical presentation is similar to shock from other etiologies, standardized definitions for SIRS, sepsis, septic shock (Box 29-7), and organ dysfunction (Box 29-8) were developed in an attempt to allow comparison within and across clinical trials.[90] While complete and detailed, the clinical utility of these definitions is questioned.[91]

Therapy

Primary therapeutic goals for the initial treatment of septic shock are identification of the shock state, rapid reversal of cardiovascular dysfunction, and control of the infection.

Removal or control of microorganisms by surgical debridement, drainage, and antibiotic therapy is a crucial component of treatment of septic shock. Antibiotic treatment is appropriate in patients with circulatory shock whenever an infectious etiology cannot be ruled out. Choice of antibiotic therapy is determined by the clinical scenario, likely organisms, and local antibiotic sensitivities. Whenever possible, blood, urine, and samples from other potential infected sites should be sent

Box 29–7 Definitions for Sepsis and Septic Shock

Bacteremia	**Presence of Viable Bacteria in Blood**
Infection	Proven infection (culture, stain, PCR) or clinical syndrome with high probability of infection (e.g., lobar pneumonia with negative culture, purpura fulminans in meningococcemia)
Systemic inflammatory response syndrome	At least 2 of 4 of the following criteria (one must be abnormality of temperature or WBC count) 1. Core temperature >38.5° C or <36° C 2. Tachycardia (HR >2 SD for age) or bradycardia (HR <10th percentile for age) if <1 year old 3. Tachypnea (RR >2 SD for age) 4. WBC count elevated or depressed, or >10% band forms
Sepsis	SIRS + infection
Severe sepsis	Sepsis + ≥1 of the following organ dysfunctions: 1. Cardiovascular dysfunction or 2. Respiratory dysfunction or 3. Two other organ dysfunctions
Septic shock	Sepsis + cardiovascular dysfunction

PCR, Polymerase chain reaction; *WBC,* white blood cell; *HR,* heart rate; *SD,* standard deviation; *RR,* respiratory rate.
Modified from Goldstein B, Giroir B, Randolph A, et al: International pediatric sepsis consensus conference: definitions for sepsis and organ dysfunction in pediatrics, *Pediatr Crit Care Med* 6:2-8, 2005.

Box 29–8 Organ Dysfunction Criteria

Cardiovascular	After isotonic fluid bolus ≥40 mL/kg in 1 hour: Hypotension: BP <5th percentile for age *or* systolic BP <2 SD below normal age *or* Need for vasoactive drug to keep BP in normal range *or* ≥2 of the following: 1. Unexplained metabolic acidosis: base deficit >5.0 mEq/L 2. Lactic acidosis more than twice the upper limit of normal 3. Oliguria: urine output <0.5 mL/kg/hr 4. Prolonged capillary refill: >5 sec 5. Core to peripheral temperature gap >3° C
Respiratory	PaO_2/FiO_2 <300 in absence of cyanotic congenital heart disease or preexisting lung disease *or* $PaCO_2$ >65 torr or 20 torr over baseline *or* FiO_2 = 0.50 to keep saturations ≥92% *or* Need for invasive or noninvasive mechanical ventilation
Neurologic	GCS score ≤11 *or* Acute mental status change: decrease in GCS ≥3 points from abnormal baseline
Hematologic	Platelet count <80,000/mm^3 or 50% decline in platelet count (for hematology/oncology patients) *or* INR > 2
Renal	Serum creatinine ≥twice the upper limit of normal for age or twofold increase in baseline creatinine
Hepatic	Total bilirubin ≥4 mg/dL (outside neonatal period) *or* ALT twice upper limit of normal

BP, Blood pressure; *SD,* standard deviation; *GCS,* Glasgow Coma Scale; *INR,* international normalized ratio; *ALT,* alanine aminotransferase.

for culture and susceptibility testing before broad-spectrum antibiotic therapy is initiated. It may be necessary to give antibiotics before obtaining cultures.

Cardiovascular Support

The primary goal in the initial management of septic shock is to restore hemodynamic stability. Increasing oxygen delivery by maximizing cardiac output and arterial oxygen content and minimizing oxygen requirements are fundamentals of management.[15,116]

Restoration of preload by volume resuscitation is the first therapeutic measure.[16] Early and effective expansion of the circulating blood volume may enhance oxygen delivery and prevent progression of the septic shock state. Patients in septic shock have an enormous fluid requirement caused primarily by peripheral vasodilation and capillary leak. Initial fluid requirements of septic patients frequently exceed 60 mL/kg,[16] and patients may require as much as 200 mL/kg. Fluids must be given incrementally, with attention to clinical signs of volume overload, and the administration of pressors may mask hypovolemia.[92] Placement of a thermodilution pulmonary artery catheter may be indicated in children who demonstrate a sluggish response to fluid infusion, show clinical or echocardiographic evidence of myocardial dysfunction, or fail to respond to appropriate cardiovascular support.

There continues to be debate regarding the use of crystalloid or colloid solutions for volume expansion in sepsis.[93] Packed red blood cells may be used if the hematocrit is less than 30% because red blood cell transfusion increases oxygen delivery to the tissues. However, expansion of oxygen-carrying capacity may not improve oxygen consumption.[94] Transfusion of pRBCs as part of a strategy to increase mixed venous oxygen saturation (SVO_2) to greater than 70% resulted in improved outcome in pediatric septic shock.[95]

Some patients respond to fluid resuscitation alone, but many patients require therapy with vasoactive infusions (inotropes, pressors, or dilators). Inotropy with catecholamines or phosphodiesterase inhibitors may be effective in reversing myocardial depression and improving contractility. An evidence-based guideline for the management of resuscitation and support of children and neonates with septic shock was issued in 2009.[16] Updated evidence-based algorithms for resuscitation for children (Fig. 29-1) and neonates (Fig. 29-2) are easy to use and have been shown to improve outcomes across diverse patient populations.[16] The emphasis remains on the first hour of fluid resuscitation and use of vasoactive infusions directed to goals of threshold HR, normal BP, and capillary refill time 2 seconds or less. Severity of shock states has been categorized according to hemodynamic reponses (Table 29-3).[16]

Aggressive use of goal-directed therapies, which emphasize rapid recognition of shock and aggressive resuscitation in the first hours of shock, have been shown to improve mortality in both the pediatric[16,96] and adult patient populations.[97]

A significant advance in the treatment of severe sepsis has emerged from the finding that the immune/inflammatory cascade and the coagulation pathways are closely intertwined.[44,98] Cytokines activate coagulation and inhibit fibrinolysis, and the procoagulant thrombin can activate inflammation. Patients with severe sepsis may be coagulopathic, and several studies have demonstrated acquired protein C deficiency in up to 90% of adult septic patients.[44] This deficiency is associated with poor outcome.[99] Phase III trials of recombinant human activated protein C (rhAPC) demonstrate significant reductions in morbidity[101] and mortality rates in adults.[101]

Doubt about the effectiveness of activated rhAPC in both pediatric and adult patients has been expressed.[102,103] An increased incidence of significant bleeding was seen in adult and pediatric trials of rhAPC.[101,103] The RESOLVE study of the use of rhAPC in pediatric septic shock was stopped for lack of efficacy.[103]

Nutrition

Septic patients develop protein/caloric malnutrition as a principal manifestation of their metabolic response to sepsis.[104] In patients who were previously malnourished or remained hypermetabolic, this rapidly developing malnutrition is believed to contribute to morbidity and mortality. However, the abnormalities in intermediary metabolism (see the

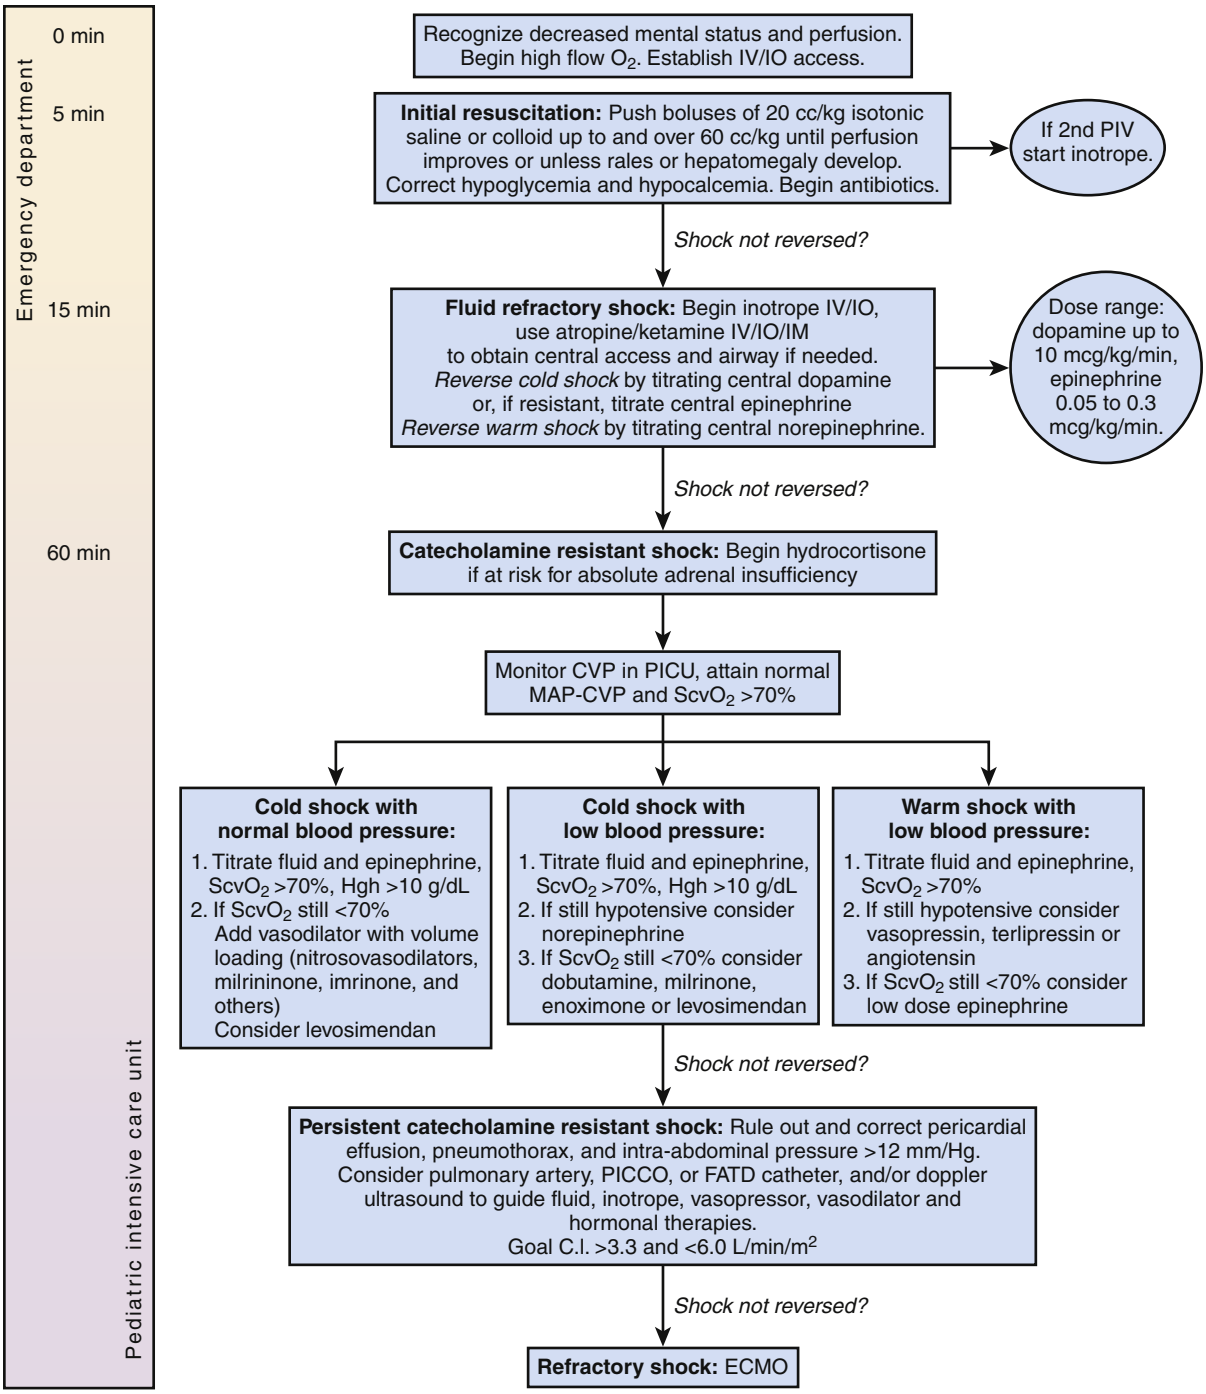

Figure 29–1. Algorithm for time-sensitive, goal-directed stepwise management of hemodynamic support in infants and children. Proceed to next step if shock persists. (1) First hour goals: restore and maintain heart rate thresholds, capillary refill ≤2 sec, and normal blood pressure in the first hour/emergency department. Support oxygenation and ventilation as appropriate. (2) Subsequent intensive care unit goals: if shock is not reversed, intervene to restore and maintain normal perfusion pressure (mean arterial pressure [MAP], central venous pressure [CVP]) for age, central venous O_2 saturation >70%, and CI >3.3, <6.0 L/min/m^2 in pediatric intensive care unit (PICU). *Hgb,* Hemoglobin; *PICCO,* pulse contour cardiac output; *FATD,* femoral arterial thermodilution; *ECMO,* extracorporeal membrane oxygenation; *CI,* cardiac index; *CRRT,* continuous renal replacement therapy; *IV,* intravenous; *IO,* intraosseus; *IM* intramuscular. *(Modified from Brierley J, Carcillo JA, Choong K, et al:* International pediatric sepsis consensus conference: definitions for sepsis and organ dysfunction in pediatrics, Crit Care Med *37:666-688, 2009.*

Multisystem Effects of Shock section) make the provision of an adequate level of metabolic support challenging. Parenteral or enteral nutrition should begin as soon as cardiovascular stability is achieved. Many clinicians advocate the early use of enteral feedings to prevent gut mucosal atrophy and bacterial translocation.[57,58,105]

Experimental/Unproved Therapies

ECMO has been used to support myocardial and/or pulmonary function during sepsis. We queried the ELSO registry (1976 through January 2010) for ECMO use in all (neonatal, pediatric, and adult) patients with sepsis or septic shock. A total of 2960 patients were identified: 2409 neonates (81%)

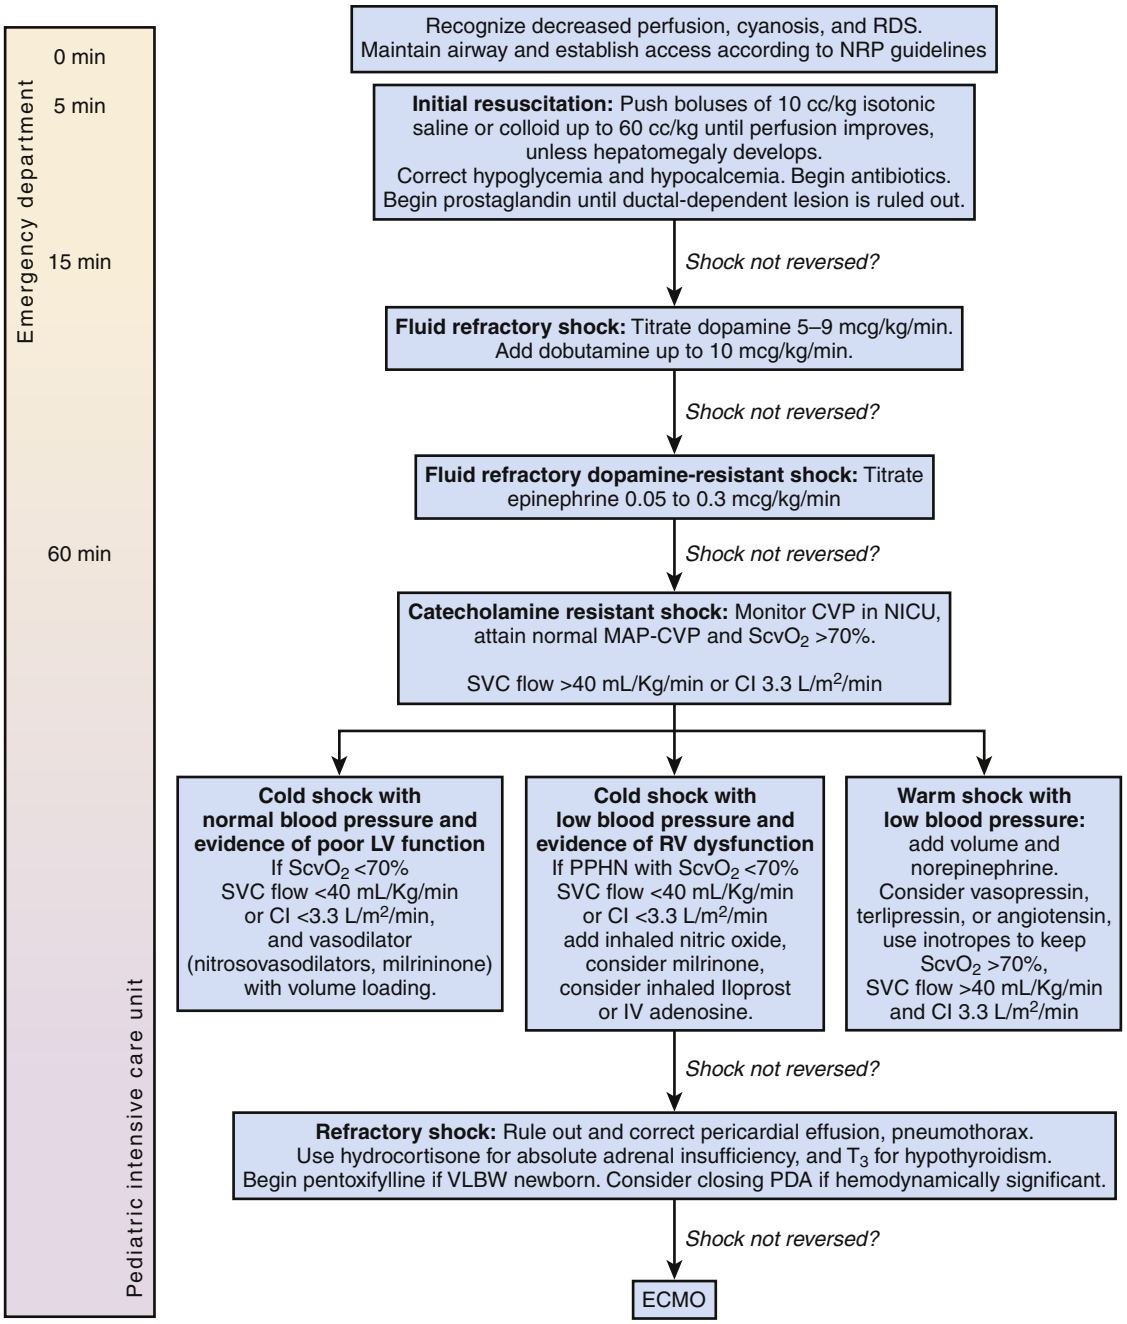

Figure 29–2. Algorithm for time-sensitive, goal-directed stepwise management of hemodynamic support in newborns. Proceed to next step if shock persists. (1) First hour goals: restore and maintain heart rate thresholds, capillary refill ≤2 sec, and normal blood pressure in the first hour. (2) Subsequent intensive care goals: restore normal perfusion pressure (mean arterial pressure [MAP], central venous pressure [CVP]), preductal and postductal O_2 saturation difference <5%, and either central venous O_2 saturation ($ScvO_2$) >70%, superior vena cava (SVC) flow >40 mL/kg/min, or cardiac index (CI) >3.3 L/min/m^2 in the neonatal intensive care unit (NICU). *RDS,* Respiratory distress syndrome; *NRP,* Neonatal Resuscitation Program; *PDA,* patent ductus arteriosus; *ECMO,* extracorporeal membrane oxygenation. *(Modified from Brierley J, Carcillo JA, Choong K, et al:* International pediatric sepsis consensus conference: definitions for sepsis and organ dysfunction in pediatrics, Crit Care Med *37:666-688, 2009.)*

and 551 patients older than 1 month (19%). Overall survival was 67%, but there was a significant difference in the survival of neonates versus other patients. Survival in the neonatal group was 74% versus 40% in all other patients.

The presence of adrenal insufficiency in septic shock has been widely studied. Meta-analyses of early studies using a short course of high-dose ("shock") glucocorticoids found no benefit and possibly increased mortality rate.[106,107] Subsequent observations of adrenal hemorrhage and cytokine-mediated adrenal insufficiency identified a select group of patients who benefit from glucocorticoid replacement (50 mg intravenously every 6 hours) over a prolonged period (7 days).[108,109] Increased knowledge of the close intertwining of the hypothalamic-pituitary-adrenal axis with inflammatory mediators led to the concepts of "functional adrenal insufficiency" or "relative adrenal insufficiency."[109] In many cases, the insufficiency is temporary.[108,109] A random cortisol level of 25 μg/dL or less in hypotensive septic adult patients is more sensitive and

Table 29–3 ACCM Hemodynamic Definitions of Shock

Cold or warm shock	Hypoperfusion manifested by: ↓ Mental status or capillary refill >2 sec (cold shock) or flash capillary refill (warm shock) *or* ↓ (cold shock) or ↑ (warm shock) peripheral pulses *or* mottled cool extremities (cold shock) or ↓ urine output <1 mL/kg/h
Fluid-refractory dopamine-resistant shock	Persistent shock after: ≥60 mL/kg fluid resuscitation (when appropriate) and dopamine to 10 μg/kg/min
Catecholamine-resistant shock	Persistent shock after use of direct-acting catecholamines: epinephrine and norepinephrine
Refractory shock	Persistent shock despite goal-directed use of inotropes, vasopressors, vasodilators, and maintenance of metabolic (glucose, calcium) and hormonal (thyroid, hydrocortisone, insulin) homeostasis

specific than low-dose or high-dose corticotropin stimulation tests at identifying a group of septic patients as steroid-responsive. Responsiveness was defined as cessation of the need for pressor support within 24 hours of initiation of steroids (100 mg every 8 hours). Sixty-one percent of adult patients had relative adrenal insufficiency as defined by the random cortisol level or response to steroid therapy.[110]

A randomized, double-blind, crossover study of a continuous infusion of low-dose (100 mg loading dose over 30 minutes followed by 10 mg/h) hydrocortisone in septic adults showed improved hemodynamics and an antiinflammatory benefit without evidence of immunosuppression.[111]

The incidence of adrenal dysfunction in pediatric sepsis may be as high as 52% and is associated with increased vasopressor requirement and longer duration of shock.[112]

The use of stress-dose steroids for general adjunctive therapy for pediatric septic shock remains controversial. Steroids should be given to patients with known adrenal insufficiency or who are at risk for adrenal insufficiency (chronic or recent steroid use; purpura fulminans; etomidate or ketoconazole administration; and hypothalamic, pituitary, or adrenal disease).[16,130] The safety and efficacy of stress-dose steroids administered to pediatric patients with relative adrenal insufficiency is unproven, and poses potential risks to patients.[130]

Many pharmacologic agents and therapies have been evaluated as adjunctive treatments in sepsis and septic shock. They include inhibitors of arachidonic acid metabolism and inhibitors of thromboxane and leukotriene formation; exchange transfusion and plasmapheresis[45,46,113,114,131]; white blood cell transfusions; passive immunotherapy; toxic oxygen scavengers; inhibitors of myocardial depressant factors; and fibronectin administration.[80,115] Although these therapies have significant potential therapeutic usefulness, further study is required before they can be recommended.

The recognition of sepsis as the systemic inflammatory response to an invading microorganism led to therapies targeted at modulating inflammation, such as the administration of antagonists or antibodies to various cytokines (e.g., tumor necrosis factor).[115,116] In preliminary studies, monoclonal antibodies and therapies directed toward lipid A of endotoxin appeared to favorably affect the outcome of patients with gram-negative sepsis. Further trials demonstrated no improvement in survival in patients given these antibodies.[117] Anticytokine therapies directed at tumor necrosis factor and interleukin-1 similarly demonstrated no benefit or worsened survival in patients with septic shock.[116,118] However, reevaluations of studies using anti–tumor necrosis factor-α may have revealed subpopulations for whom there is a survival benefit.[119]

Therapies designed to modulate the immune response,[120,121] inhibit neutrophil function, or inhibit synthesis of nitric oxide (endothelial-derived relaxing factor) have demonstrated no clinical benefit in septic shock.[118] Other areas being explored with regard to the pathophysiology and treatment of septic shock include factors that promote apoptosis,[116,121,122] use of insulin to maintain tight glucose control and normoglycemia,[123-125,132] and use of vasopressin[20-22,126-129] or terlipressin[27-31] in sepsis. These therapies have shown some promise but remain unproven.

Summary

Shock is a life-threatening condition that has a myriad of causes. In order to survive shock, recognition of the shock state and resuscitative efforts must be achieved early, the etiology elucidated, and ongoing monitoring and therapy instituted. The astute clinician who recognizes shock, institutes therapy, and continuously assesses response to therapy offers the child the best chance for a quality survival.

Cardiac Bypass for Repair of Congenital Heart Disease in Infants and Children

J. William Gaynor and Darryl H. Berkowitz

PEARLS

- Pediatric patients are not small adults with respect to their physiology, responses to cardiopulmonary bypass (CPB) and the conditions under which repairs are performed. Many pediatric heart operations are performed under conditions of deep hypothermia (with or without circulatory arrest). Dilutional effects of CPB may enlarge circulating blood volume by 200% to 300%. Blood gas management usually makes use of pH-stat methodology during cooling.
- Neurologic abnormalities or injuries may occur prior to operation and CPB. Preoperative risk factors include episodes of decreased cerebral blood flow, ductal-dependent blood flow with low diastolic pressures, history of balloon atrial septostomy, ongoing systemic inflammation, genetic polymorphisms, a congenital syndrome, low birth weight or a history of preoperative extracorporeal membrane oxygenation (ECMO) or ventricular assist device (VAD).
- CPB will affect the brain, myocardium, lungs, kidneys, endocrine, and gastrointestinal systems through its generation of nonpulsatile flow. It causes hypoperfusion secondary to hypothermia and lower than normal perfusion pressures. CPB triggers the inflammatory cascade and increases extracellular fluid. Unfortunately, there is lack of agreement surrounding preventive therapies and thus research continues.
- Efforts to limit inflammation include design of smaller circuits to reduce requirements for blood in the prime; the use of biocompatible circuits, the addition of steroids to the prime; and the use of modified ultrafiltration (MUF) at the termination of bypass. These maneuvers are intended to limit blood-circuit interactions, decrease the production of mediators, and filter inflammatory mediators out of the circulation.
- Termination from bypass in the pediatric patient is complicated by the effects of deep hypothermia on organ function and coagulation. The repair can cause heart block. Malignant supraventricular tachycardia can occur. There may be residual intracardiac shunts and outflow tract obstructions. Abnormal pulmonary vascular reactivity may result in hypoxia, acidosis, and acute right ventricular failure.
- In the adult, postbypass acute ventricular failure may be treated with an intraaortic balloon pump or VAD. In the pediatric patient, acute ventricular failure, malignant rhythm, or pulmonary failure is often treated with ECMO.

The history of surgery for congenital heart disease is relatively brief. The first successful intracardiac operation took place less than 60 years ago. The groundwork for the performance of cardiac surgery began in two very different arenas. Clinically, surgeons had gained valuable experience in the battle theaters of World War II with removal of foreign bodies from inside the heart.[1] Experimentally, DeBakey devised a hand-driven pump in 1934. Later, rudimentary bubble or film oxygenators were added to this device. Another important line of experimentation was pursued by Bigelow and colleagues, who described the application of hypothermia to cardiac surgery in 1950. Although two groups successfully performed surgery to repair atrial septal defects, these were performed without the assistance of cardiopulmonary bypass. F. John Lewis successfully closed an atrial septal defect under deep hypothermic arrest in 1951[2] and a group led by Gross and Wilkins described the atrial well technique in 1953, whereby they opened the right atrium and sewed to it a silo, which then filled with blood, enabling them to operate on the beating heart by feel.[3] Between 1951 and 1954, other groups described various forms of cardiopulmonary bypass. Collectively, there were 18 described operations with only one survivor (operated on May 18, 1953, by J.H. Gibbon). Interestingly enough, the survivor was the first in his series after which he recorded five consecutive deaths, resulting in his abandonment of the technique.[4] Failures were attributable to incorrect preoperative diagnoses, ventricular dysfunction at termination of bypass, hypovolemia, surgical errors, and ventricular failure within the convalescence period. During this same period, C. Walton Lillehei and colleagues described a technique known

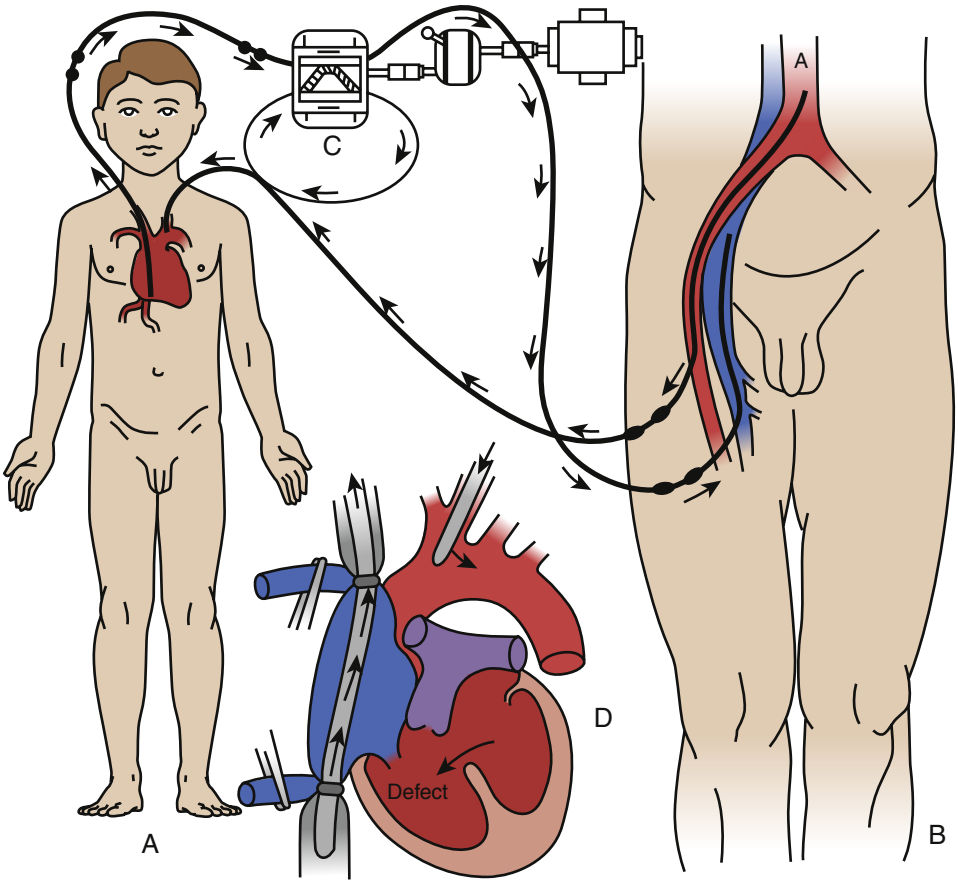

Figure 30–1. Controlled cross circulation. *(Modified from Lillehei CW: Controlled cross circulation for direct-vision intracardiac surgery: correction of ventricular septal defects, atrioventricularis communis, and tetralogy of Fallot,* Post Grad Med [Minneapolis] *17:288-396, 1955.)*

as controlled cross-circulation whereby a "donor," usually one of the patient's parents, functioned as a pump/oxygenator (Figure 30-1). The first case was described in 1954. After this, they described 45 patients, with 18 patient and no donor deaths. Although clearly an extremely high mortality, this represented a great improvement.[5] Interestingly enough, after this data was published, some commentators suggested abandonment of further research into the bypass machine. In May 1955, a team lead by Kirklin of the Mayo Clinic published an initial series of 8 patients who were operated on by a machine similar to that of Gibbon. Despite a mortality rate of 50%, this was clearly an improvement over the early bypass patients. In conclusion, Kirklin declared that "Use of this system established excellent conditions for precise, unhurried intracardiac surgery."[6] Thus began the modern age of cardiac surgery. What followed over the next few decades was experimentation with different types of oxygenators, culminating in the formulation of microporous hollow-fiber membranes. These oxygenators were made of hollow fibers within a hard plastic shell. They had a large surface area/volume ratio, thus making them extremely efficient for gas exchange. Other advantages included being easy to produce in large numbers, in different sizes, and with noncompliant blood/gas compartments. These collective advantages made them ideal for pediatric cardiac surgery.

Over the last three decades, surgeons have been able to offer improved palliations for diseases that were uniformly fatal up until that point. Teams routinely used deep hypothermic circulatory arrest to perform complex repairs. This chapter outlines present understanding of cardiopulmonary bypass: attempts that are made to protect vital organs and our present day options for myocardial support postbypass. Looking forward into the next decade, the issues of functional survival into midlife; neurologic outcomes; and such technical questions as blood conservation, further decreasing the inflammatory response to bypass, and circuit miniaturization will come to the forefront of research.

Cardiopulmonary Bypass in Infants Versus Adults

The management of CPB in the pediatric patient is very different from that of the adult (Table 30-1). The most important of these are the routine use of hypothermia with or without circulatory arrest, the use of low perfusion pressures, and, of great clinical importance, marked hemodilution. Thus pediatric patients are exposed to the extremes of physiologic tolerance. These factors, coupled with immature organ systems, place pediatric patients at great risk during the period of cardiopulmonary bypass. In addition to these differences, which are directly attributable to the differences between the two age groups, there are additional factors unique to the pediatric patient that further complicate the management strategy. Box 30-1 lists some of these factors. From the surgical perspective, several technical challenges exist. Venous and arterial cannulae have potential effect on hemodynamics. Collateral vessels may

Table 30–1 Differences Between Adult and Pediatric Cardiopulmonary Bypass

Parameter	Adult	Pediatric
Hypothermic temperature	Rarely <25-32° C	Commonly 15-20° C
Circulatory arrest	Uncommon	Common
Pump prime		
Dilutional effect on blood volume	25%-33%	200%-300%
Additional additives	Blood, albumin	
Perfusion pressure	50-80 mm Hg	20-50 mm Hg
Influence of pH management	Minimal at moderate hypothermia	Marked at deep hypothermia
Measured $PaCO_2$ differences	30-45 mm Hg	20-80 mm Hg
Glucose regulation		
Hypoglycemia	Rare; requires liver injury	Common ↓ glycogen stores
Hyperglycemia	Frequent; insulin bolus/infusion	Less common; rebound ↓↓ glucose

Altered thermoregulation
Poor tolerance for micoroemboli

allow blood return to the heart during bypass (making visibility a challenge). Collaterals may also steal blood away from vital organs making organ preservation difficult.[7] Coronary anomalies that accompany many congenital cardiac lesions complicate repair, and the multiple suture lines required for repair may bleed after surgery in patients with coagulopathy.

Physiology of Cardiopulmonary Bypass

The safe conduct of CPB in the neonate and infant requires a comprehensive understanding of the physiologic effects that occur. Variables include circuit design, hemodilution, choice of cannulae, degree of hypothermia, acid-base strategies, and flow rates, and include the decision to use deep hypothermic circulatory arrest.

Hypothermia

The reason for the use of hypothermia during CPB is protection of the myocardium and other vital organs. To this end, three distinct methods are used: moderate hypothermia (25° to 32° C), deep hypothermia (18° to 20° C), and deep hypothermic circulatory arrest (DHCA) where circulation is shut down completely at 16° to 18° C.

Normothermia and moderate hypothermia are used in cases where the surgeon is able to safely cannulate both vena cavae in order to operate within the heart. This, of cours,e can be done even on the smallest of patients, bearing in mind that the cannulae may cause vena caval obstruction and impaired drainage that can adversely affect both cerebral and abdominal perfusion, independent of perfusion pressure. Deep hypothermia with reduced pump flow to as low as 25 to 50 mL/kg/min will allow the surgeon to perform corrective surgeries with only minimal return of blood to the surgical field while at the same time maintaining vital organ perfusion. DHCA is used for the repair of complex intracardiac lesions as well as reconstruction of the aorta. Once circulation has ceased, the surgeon is able to remove all cannulae and work in a completely bloodless and unobstructed field. An alternative for aortic surgeries is DHCA with low-flow antegrade cerebral perfusion with an arterial cannula in the innominate artery and drainage via a suction catheter or venous cannula in the right atrium/superior vena cava. Flow rates of between 20 and 50 mL/kg/min to a perfusion pressure of 30 to 50 mm Hg are used.[8]

The principal clinical effect of hypothermia is to reduce metabolic rate and molecular movement. As temperature is lowered, both basal and functional cellular metabolism are reduced, and the rate of adenosine triphosphate consumption is decreased. Whole body oxygen consumption decreases directly with body temperature. The cerebral metabolic rate ($CMRO_2$) has been found to exponentially decrease as temperature decreases throughout the clinically relevant temperature range of 37° to 18° C.[9,10] The reduction in $CMRO_2$ has been calculated to be between 82% and 87% of baseline in both the canine model and the pediatric population.[9] The relationship between temperature and metabolic rate is quantified experimentally by calculating a temperature coefficient known as the Q10. It is defined as the ratio of metabolic rates at two different temperatures separated by 10° C. In the adult population, this has been found to be 2.4 to 2.8, while in the pediatric population it is 3.65. This shows that in the pediatric population there is a greater decrease in metabolic rate as the core body temperature drops. Clinically, this translates to potentially greater brain and organ protection with hypothermic temperatures.

In contrast to the role that hypothermia plays in cerebral protection, it has less importance in protection of the myocardium; indeed, it has been suggested that electrical quiescence accounts for approximately 90% of myocardial protection at normothermia.[11] It has been found that a decrease in perfusion temperature has a possible deleterious effect on the myocardium, as it leads to abnormal calcium and sodium handling. As Na^+/K^+ ATPase inhibition occurs with a falling temperature, it gives rise to an increase in intracellular sodium. This may then result in an increased activity of the Na^+/Ca^{2+} exchanger, with an increase in intracellular calcium.[12] This may play an important part in the development of an entity described as rapid cooling contracture, which is thought to play a role in postbypass myocardial dysfunction. This effect of cooling on myocardial performance may be felt more in neonates and infants, as their lower total body and cardiac masses make them susceptible to more rapid temperature changes.[13]

The adverse effects of rapid cooling have been demonstrated experimentally in the kidneys, liver, and lungs as well. In clinical practice, however, many variables are involved and there does not seem to be readily apparent injury to the patient from rapid cooling.[14,15] It does appear that the neonate is able to tolerate the stress of profound hypothermia without difficulty. The reason for this may be the fact that neonates possess differential ionic channel density or have different membrane function when compared to older subjects. These theories remain speculative.

The use of hypothermia in pediatric cardiac surgery is commonplace. It aids in organ function during ischemia, it allows the surgeon to operate in a bloodless surgical field in the case of DHCA, and CPB is safer.

Pulsatile Versus Nonpulsatile Flow

The question whether pulsatile flow could improve outcome compared to nonpulsatile flow remains unanswered. The basis for this concern stems from the suggestion that nonpulsatile perfusion may be associated with microcirculatory dysfunction and thus may be important in the genesis of post-CPB myocardial, cerebral, and renal dysfunction.[16] The desirability of pulsatile perfusion has been contemplated and studied since the introduction of extracorporeal circulation in the 1950s.

The difference between these two modes of perfusion is not simply the generation of a pulse pressure. Pulsatile flow also depends upon creation of an energy gradient and thus pump flow as well as arterial pressure must be included.[17] This relationship was described by Shepard in 1966[18] and is known as the Energy Equivalent Pressure Formula:

$$\text{EEP} = (\int fp\,\text{dt}) / (\int f\,\text{dt})$$

Thus it is the ratio of the area under the hemodynamic power curve ($\int \text{fp}dt$) and the area under the pump flow curve ($\int \text{f}dt$), where f is the pump flow rate, p is the arterial pressure (in mm Hg), and dt indicates that the integration is performed over time (t). EEP is measured in mm Hg, and therefore a comparison can be made between it and mean arterial pressure (MAP). The difference between these two measurements is the energy generated by the bypass machine, be it a pulsatile or nonpulsatile device.[17] This difference must then be applied to the surplus hemodynamic energy (SHE) formula:

$$\text{SHE} = 1332(\text{EEP} - \text{MAP})$$

The unit of measure of this formula is the erg, which measures energy. Pulsatile flow is best represented by an energy gradient rather than a pressure gradient. Pulsatile perfusion produces greater SHE units than nonpulsatile perfusion.[19] This improved generation of energy units may translate into improved regional and global blood flow to vital organs.[20] The converse is also true, that when there is no difference in energy level generated between pulsatile and nonpulsatile flow then there is no difference in vital organ blood flow (see Figure 30-2).[21]

Pulsatile flow appears to improve organ flow during CPB and function in the post-CPB period. In a pilot study of 50 patients, Alkan et al.[22] described improved myocardial function in the pulsatile group based upon the observation that this group of patients required less inotropic support. The same investigators found equivalent findings in a follow-up study of 215 patients.[20] This was similar to experimental findings of improved myocardial blood flow and function even after up to 60 minutes of DHCA.[23]

Cerebral blood flow patterns have also been studied and experimental animal models have been used to find differences in flow techniques. It is noted that both methods of perfusion show decreased flow when compared to pre-CPB. The findings showed that cerebral hemispheric, basal ganglia, brainstem, and cerebellar flows were better maintained in the pulsatile group. This was found at normothermic CPB, pre-DHCA, post-DHCA and even post-CPB. An important factor related to these findings is that cerebral vascular resistance is found to be lower under pulsatile perfusion during and after normothermic CPB.[19] Interestingly, authors involved in the aforementioned work have performed other studies that do not agree with these findings but, despite this, they make a point of concluding that in their opinion pulsatile flow remains a better choice based upon its ability to generate more hemodynamic energy, which in turn may maintain the microcirculation to a greater degree.[21,24]

Postoperative ventilation and the effects of CPB on pulmonary function are important clinical markers in patients undergoing cardiac surgery. In their large clinical study, Alkan et al.[20] found that time to extubation and length of ICU stay were significantly shorter in the pulsatile perfusion group, from which it can be concluded that pulmonary function was improved in this group. Renal function was also a marker analyzed in this study, and it was found that urine output was significantly improved in the pulsatile group, although the serum creatinine was similar in both groups. Indeed, it has been shown that pulsatile perfusion increased renal, and specifically renal cortical, flow. Pulsatile perfusion also played a role in decreasing edema and ischemic changes found in renal tubules, as compared to nonpulsatile flow.[25]

One of the biggest problems faced by clinicians when patients are placed on CPB is the inflammatory cascade that is initiated secondary to the exposure of patient's blood to the foreign surface of the bypass circuit, surgical trauma, ischemia/reperfusion, hemodilution, hypothermia, and possibly changes related to the artificial nature of perfusion. The end result is organ dysfunction that affects the myocardial, pulmonary, hepatic, and renal systems. The release of cytokines from damaged endothelium is increased. The use of pulsatile cardiopulmonary bypass has been associated with a lower concentration of interleukin-8 (IL-8), leading authors to speculate that this may improve outcomes with regard to function and microcirculation of vital organs.[22,26]

Despite encouraging experimental and clinical results with the use of pulsatile flow, broad use of this technique has not yet occurred. Multicenter trials have been called for but as yet, these have not occurred. The result is that nonpulsatile flow remains the perfusion technique most widely used in pediatric cardiac surgery.

Strategies for Blood Gas Management: Alpha-Stat and pH Stat

Another topic of considerable debate in pediatric CPB is the question of interpretation and management of pH, most specifically at deep hypothermia. In adult patients undergoing CPB, the commonest cause of brain injury is related to the

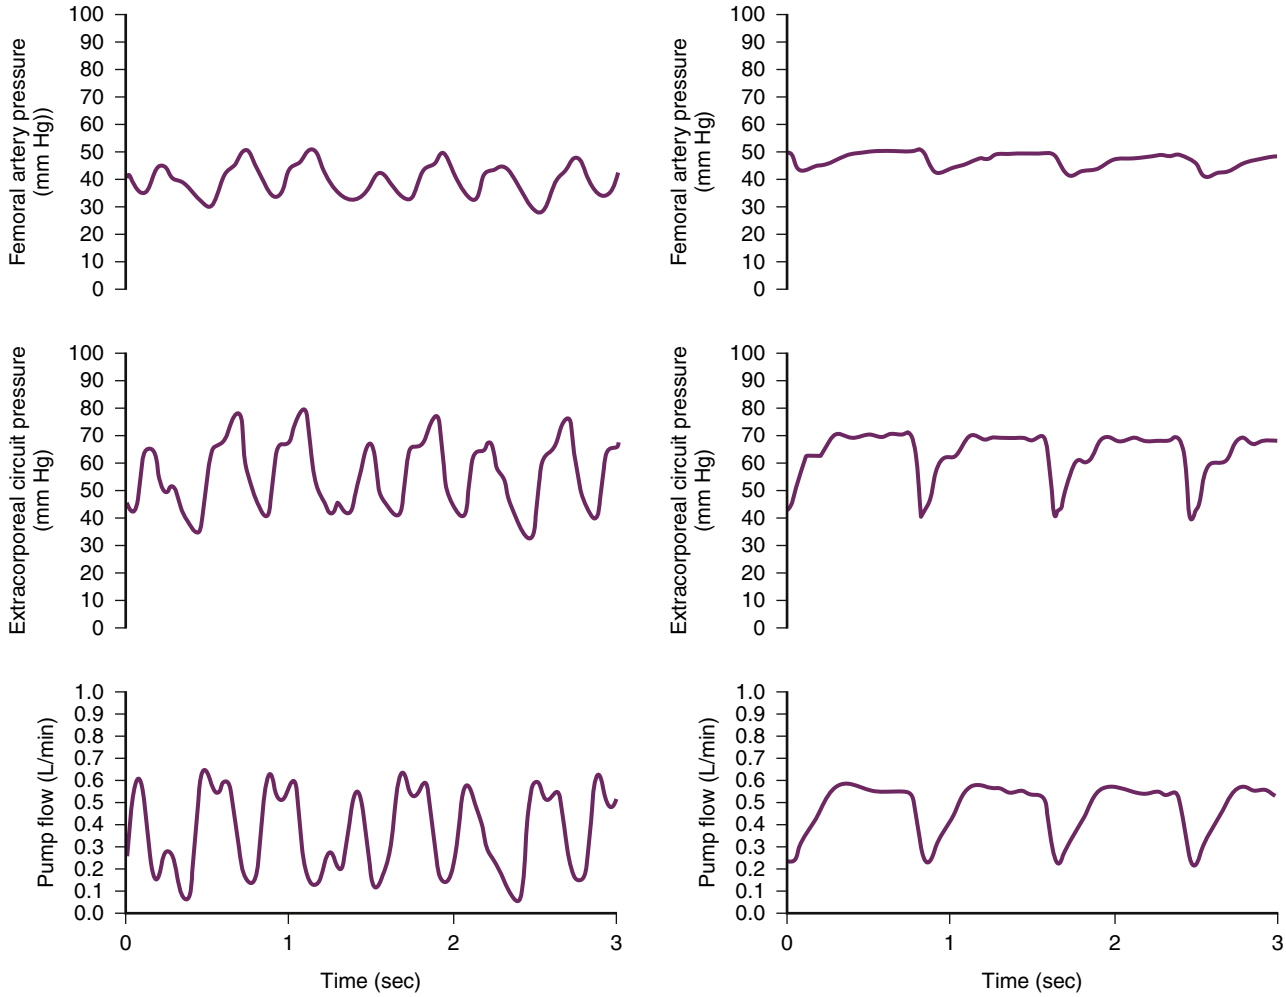

Figure 30–2. Pressure wave differences between pulsatile and nonpulsatile flow. *(Modified from Undar A, Masai T, et al: Effects of perfusion mode on regional and global organ blood flow in a neonatal piglet model,* Ann Thorac Surg *68:1336-1343, 1999.)*

delivery of embolic material to the cerebral vasculature. The etiology of brain injury in children is thought to result from hypoperfusion with cerebral hypoxia/ischemia during periods of low flow or DHCA.[26] As has been mentioned in prior discussion, many pediatric cardiac operations are performed under conditions of decreased flow rates with moderate to deep hypothermia, with the aim of protecting against vital organ injury. It would thus follow that strategies that result in the lowest cerebral rate of oxygen consumption ($CMRO_2$) would offer the best protection.

The temperature at which the pH is reported is of fundamental importance. Within the body, maintenance of electrochemical neutrality is necessary to ensure that cellular protein and enzymes function optimally. This neutrality occurs when there are equal concentrations of positively and negatively charged ions within aqueous solutions. As the temperature begins to drop, the dissociation constant of aqueous systems will increase, and thus the concentration of H^+ begins to decrease. As pH is the inverse log of H^+ and electrochemical neutrality must be maintained, the pH of the solution will increase. Electrochemical neutrality is also maintained within cells, and thus we can hypothesize that the pH within cells is a pH of neutrality. Hence we would then assume that the intracellular pH would change with a change in temperature to maintain neutrality. Analysis on ectothermic animals shows that intracellular pH remains at or near this pH of neutrality even as body temperature drops. For this to occur, there are two additional processes that occur. The first is a buffer system with a pK value close to that of the intracellular pH and whose pK changes as temperature changes. The buffering capacity of the imidazole of the amino acid histidine has these characteristics. Histidine is found commonly within intracellular proteins as well as enzymes. The term alpha refers to the degree of dissociation of the imidazole, i.e., the ratio of unprotonated to total imidazole; under normal conditions within the intracellular compartment, this has a value of 0.55. This dissociation (and hence the alpha value) will remain constant over a range of temperatures, as there is a proportional change of the neutral pH of water, the pKa of imidazole, and the tissue pH. The second necessary process is that the CO_2 content of the blood must remain constant as body temperature drops. This is the alpha-stat condition. If, however, during hypothermia the pH remains constant, then the alpha number of the imidazole will change and thus there may be a change in protein structure or enzyme function. This is known as the pH-stat condition. In this management technique, in order for the pH to remain constant through the range of hypothermic temperatures, CO_2 is added (Figure 30-3).

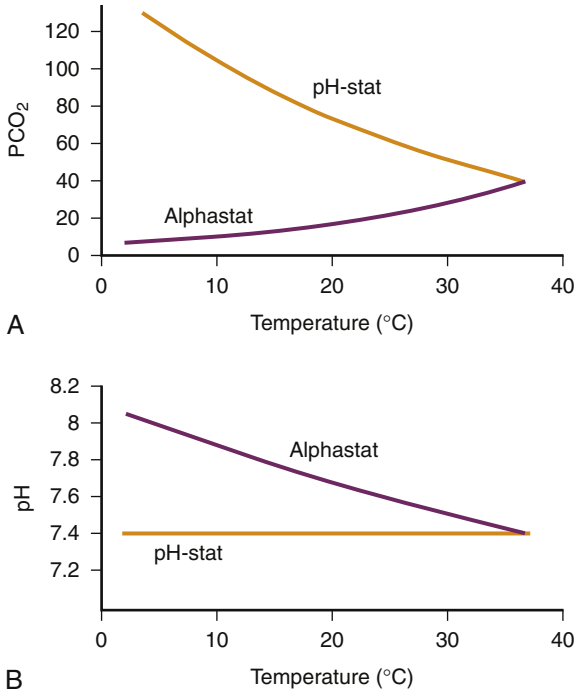

Figure 30–3. The effect of temperature on blood plasma pCO_2 and pH. *(Modified from Tallman RD: Acid-base regulation, alpha-stat, and the emperor's new clothes,* J Cardiothorac Vasc Anesth *11:282-288, 1997.)*

Into the 1990s, based upon adult studies and strategies, the alpha-stat technique was thought to have a better neuroprotective outcome. Despite the lack of prospective data, it gained widespread use amongst institutions performing cardiac surgery on children.[26] In a neurodevelopmental follow up of 16 patients who had undergone Senning operations, Jonas and colleagues reviewed perfusion techniques and pH strategy. They found that the use of alpha-stat strategy prior to DHCA was associated with poorer developmental scores. The authors postulated that the lower cerebral blood flow associated with alpha-stat might result in inadequate cooling. This study, despite having the groups at different ages at the time of assessment and being underpowered with respect to numbers, hinted at a possible need to change strategies in the pediatric population.[27] Another more devastating neurologic complication of pediatric cardiac surgery is the development of choreoathetosis. In two studies, including one from the above group, patients underwent DHCA and later went on to develop choreoathetosis. After analysis, apart from having the use of DHCA in common, it was found that all of the affected patients were managed using alpha-stat.[28,29] Laboratory studies have demonstrated that the use of pH-stat appears to offer better cerebral protection. Neonatal piglets were used in these studies, with DHCA times varying from 60 to 90 minutes. In the studies referenced, the markers used to compare the two management strategies included microvascular diameter during cooling and rewarming, cerebral tissue oxygenation, brain cooling, and metabolic markers of ischemia, such as extrastriatal dopamine production.[31,32] The effects on brain cooling include a faster rate of cooling which is uniform across all regions of the brain, especially the cortical white matter.[33] The results of these showed pH-stat to be superior in all of the aforementioned categories in the cooling phases of DHCA as well as in the recovery phase. In the first prospective trial on the use of pH-stat management in the cooling phases of DHCA, du Plessis and colleagues found that there was a greater degree of cerebral cooling, as measured by tympanic membrane temperature, in the pH-stat group. This they attributed to increased cerebral blood flow, which appeared to be equally distributed throughout the brain. In keeping with these data, this group also had more rapid recovery of electroencephalographic (EEG) activity compared to those in whom alpha-stat management had been used. EEG-confirmed seizures were also increased twofold in the alpha-stat group.[26] Although a section in this chapter will be dedicated to the discussion of monitoring with near-infrared spectroscopy (NIRS), studies suggest that the use of alpha-stat is associated with lower signals during cooling, indicating that this method results in insufficient cerebral blood flow and oxygenation.[34,35] The next question to be answered will be whether this improved brain perfusion and cooling seen with pH-stat will translate into improved neurologic outcomes. Patients enrolled in this trial underwent neurodevelopmental testing at 1 year of age, using standardized tests. There was no difference in scores based on treatment group assignment. The authors concluded that the "use of alpha-stat versus pH-stat acid-base management strategy during reparative infant cardiac operations with deep hypothermic cardiopulmonary bypass was not consistently related to either improved or impaired early neurodevelopmental outcomes."

The effects of pH/CO_2 on other organ systems have also been studied. Myocardial protection is also obviously of great concern to the entire care team. In a study performed by Nagy et al. in which troponin I was used as the marker of myocardial injury, it was found across a spectrum of patients, including some with pulmonary hypertension and cyanotic congenital heart disease, that those in whom pH-stat was used had better myocardial performance after CPB.[36] They postulated that pH-stat might induce a more even myocardial temperature during cooling due to hypercapnia-induced vasodilation. Oxygen delivery may also be improved as the oxygen-hemoglobin dissociation curve shifts rightward with the increase in CO_3. Lastly, they suggested that the hypercapnia-induced inhibition of pyruvate dehydrogenase, which leads to a decrease in lactate production, may also be of great benefit. As a secondary outcome, their study also suggested that postoperative ventilation and length of ICU stay may be shorter in the pH-stat group. Improved myocardial performance had also been found in the du Plessis study, where there appeared to be a higher cardiac index within the first 18 hours after CPB with lower inotropic use, less hypotension, and less metabolic acidosis compared to the alpha-stat group. These patients also had significantly less mechanical ventilation and shorter ICU stays.[26]

Despite these advantages, there is concern that the use of pH-stat may result in a change in the internal pH (pHi) of cells that would lead to a prolonged depletion of high energy phosphates during rewarming, which in turn would lead to cellular damage. Experimental evidence, however, seems to suggest that the pHi of cells is regulated independently of the extracellular environment. Hiramatsu et al. showed that the pHi was alkalotic irrespective of the use of alpha-stat or pH-stat strategies during the cooling phase, but that it tended towards acidosis with the onset of DHCA.[30] The data then suggested that there was a quicker recovery of both pHi and ATP using the pH-stat technique. As mentioned before, this was on the basis of a greater oxygen reserve secondary to increased

blood flow and oxygen delivery in the cooling phase. In conclusion, it would seem that the evidence presented here would undoubtedly indicate that a prudent approach would be for the use of pH-stat management during the cooling phase of deep hypothermic CPB; indeed, there is also some evidence from these studies that this strategy should be employed in the rewarming phases as well. Many centers, including our own, use alpha-stat during rewarming with good clinical outcome

Neurologic Injury and Protection

The last 30 years have seen the advent of surgical techniques and management strategies that have changed a diagnosis from universally fatal to one that can be palliated well into adulthood. The challenge we now face is the long-term effects that these very techniques and strategies have on neurodevelopmental outcomes. In contrast to the adult population where neurologic injury commonly involves thromboembolic stroke, in the pediatric population the injury results in more subtle effects such as attention-deficit problems and difficulties with fine and gross motor control, visual motor integration, and executive functioning. The end result of these problems is school failure and low self-esteem. This "developmental signature" is similar to that seen in very low birth weight premature infants.[37]

It is quite alarming to note that long-term follow-up has found that neurodevelopmental impairment occurs in more than 50% of children who have cardiac surgery as newborns or young infants.[38] Many studies of neurodevelopmental outcome after cardiac surgery in infancy have focused on injury during the intraoperative period as the likely cause of adverse outcomes. However, there is increasing evidence that brain development is abnormal in children with congenital heart disease (CHD), and injury can often be identified prior to surgery. Patient-specific factors such as genetic abnormalities, socioeconomic status, and maternal education are more important determinants of neurodevelopmental outcomes than are intraoperative management strategies.[39] Box 30-2 highlights a number of factors that influence neurologic outcome.

From Hsai T-J, Gruber PJ: Factors influencing neurologic outcome after neonatal cardiopulmonary bypass: what we cannot control, *Ann Thorac Surg* 81: S2381-8, 2006.

Preoperative Factors

Neonates with CHD have a higher incidence of cerebral dysgenesis than those in the general population.[40] The era of staged reconstruction of hypoplastic left heart syndrome began in the late 1970s. The diagnosis was fatal prior to that time. In a series of postmortem examinations from the early- to mid-1980s, 29% of the patients had either minor or major central nervous system (CNS) abnormalities. The absence of dysmorphic features did not preclude CNS abnormalities.[41]

Periventricular leukomalacia (PVL) is one of the most frequent and severe neuronal injuries specific to the neonatal brain. It is caused by necrosis of deep white matter adjacent to the lateral ventricles. The mechanism is thought to be related to hypoxic/ischemic injury to immature oligodendrocytes, the very cells responsible for myelination throughout the central nervous system. In early life, the brain undergoes an intensive period of neuronal development and axonal growth; thus the white matter of the brain is particularly susceptible to injury.[40] It is during this period that the brain is susceptible to ischemia-reperfusion injury due to its fragile vascularity, high metabolic activity, and immature autoregulation. PVL occurs not only in the period surrounding CPB but also in premature infants and after such insults as hypoxia, hypoglycemia, and meningitis. The incidence in infants with CHD prior to cardiopulmonary bypass has been estimated to be between 16% and 25%,[42,43] with this rate increasing to between 54% and 73%[43,44] post-CPB, based upon magnetic resonance imaging (MRI) studies. Studies have been performed using both MRI and fetal ultrasound and have demonstrated altered cerebral blood flow in fetuses with congenital heart disease; this may therefore be a basis of abnormal brain development. MRI studies have also found alarmingly low cerebral blood flow in infants with CHD prior to surgery, in some cases less than 10 mL/100 g/min.[45] Other associated factors include the presence of ductal-dependent blood flow with resultant diastolic hypotension that lowers cerebral perfusion, balloon atrial septostomy with possible embolic phenomena,[46] and ongoing systemic inflammation due to endotoxemia from mesenteric hypoperfusion.[38]

An interesting genetic association has also been found. Apolipoprotein E (APOE) is an important lipoprotein that aids in cholesterol metabolism as well as being an important cofactor in neuronal repair. There are three common forms of APOE (E2, E3, and E4), which are encoded by three alleles (ε2, ε3, and ε4). Research has shown that the APOE genotype has a strong association as a determinant of neurologic recovery following CNS injury. The presence of the APOE ε2 allele is associated with lower Psychomotor Developmental Index (PDI) and Mental Developmental Index (MDI) scores when compared to age-matched normals. Other associated risk factors include a confirmed genetic syndrome, lower birth weight, small head circumference at 1 year, preoperative intubation, and history of ECMO or ventricular assist device.[47,48]

The intraoperative period is a time of great risk to the child. In two contrary sets of data, two apparently different neurologic outcomes were found. In a study performed in patients undergoing atrial septal defect closure either surgically or via

catheter, there was a significant decrease in intelligence quotient in those undergoing surgery.[49] However, preliminary data from another cohort failed to show a decrease in neurocognitive function in 41 patients with age ranges from 5 to 18 years exposed to CPB for closure of simple atrial or ventricular defects, or for simple valve surgery.

Factors that likely result in poorer neurodevelopmental outcomes include anesthetic-related issues encompassing a decrease in cardiac output with decreased oxygen delivery at the time of transition from negative to positive pressure ventilation, and also the negative inotropic effects of anesthetic agents. Hypoxia may worsen prior to establishment of CPB, particularly in those with ductal-dependent flow, as the surgeon dissects around the ductus causing vasospasm. Once on CPB, numerous factors may occur that may have an adverse effect. These include malposition of both the arterial and venous cannulae with resultant poor flow characteristics and venous drainage leading to cerebral hypoperfusion; embolic phenomena including air and thrombus (may occur despite meticulous circuit check, adequate anticoagulation, and deairing of the heart once repair is undertaken); the inflammatory response induced by CPB; the effects of DHCA with ischemia-reperfusion injury and uneven cerebral cooling; hemodilution; pH management; and the effect of collateral steal of blood away from vital organs.[38,40] Once weaning from CPB has taken place, it is the effect of continued myocardial dysfunction with decreased oxygen delivery and hypoxia that may lead to ongoing brain injury. The need for ECMO for postcardiotomy support (2% to 5% of patients)[50] carries significant morbidity and mortality, with up to 50% of survivors showing neurodevelopmental problems.[51]

Postoperative Factors

In the postoperative period, ongoing low cardiac output and hypoxia may result in continued neurologic damage. Other factors that may play an important part in the genesis of injury during this period include hyperthermia, endocrine abnormalities, acid-base disturbance, and disruption of cerebral vasoregulation. Cerebral vascular autoregulation is disrupted after CPB, and thus it is important to maintain adequate cerebral perfusion pressure. Longer postoperative length of stay has consistently been shown to be associated with worse neurodevelopmental outcomes, suggesting that events in the postoperative period modify the risk of an adverse outcome.

Neuromonitoring and Neuroprotection

A multitude of factors can result in neurologic injury, either independently or in combination. Neuroprotection should begin from birth. In the preoperative period, clinicians should be aware that severe hypoxia, low perfusion pressure in the form of low diastolic pressure, low cardiac output states, respiratory alkalosis, and hyperthermia may be variables in neurologic injury. In the transition to the operating room and controlled ventilation, clinicians should be attentive to changes that result in the aforementioned factors. How then can we protect the brain?

In recent years, interest has been focused on neurologic monitoring with near-infrared spectroscopy (NIRS), transcranial Doppler, EEG, and jugular venous saturation alone or in combination, as opposed to using surrogate markers of perfusion pressure, mixed venous saturation, and acid-base status.[52]

NIRS provides a real-time, noninvasive assessment of regional cerebral oxygenation and has been validated with jugular venous saturation.[52] In this method, a venous-weighted approximation of tissue oxygen saturation is measured with a venous:arterial blood ratio of 85:15. This technology uses modifications of Beer's equation. Infrared light passes through the skin, penetrates through tissue, and then returns, whereupon allowing assessment of the oxyhemoglobin saturation of tissues at a depth of 2 cm. Subtraction of the shallow light path from the deep light path allows assessment of brain oxygenation.[52] The INVOS 5100 (Somanetics, Inc, Troy, Mich.), which is approved by the FDA for use in adults and children, calculates a regional cerebral saturation index (rSO_2i) by computing the ratio of oxyhemoglobin to total hemoglobin. It has a range of 15% to 95%. These monitors are best used as trend monitors, with a fall of 20% from baseline being significant.[53] Factors that affect cerebral oxyhemoglobin saturation include cerebral perfusion pressure, cerebral blood flow, arterial oxyhemoglobin saturation, $PaCO_2$, and cerebral metabolic rate. The baseline values have been quantified, with 70% being normal in adults. Studies of single-ventricle patients, and laboratory studies, have suggested that a saturation below 30% suggests dependence on anaerobic metabolism.[54,55]

NIRS has thus been used to guide a safe duration of DHCA, proper placement of CPB cannulae, and also to guide optimal flow during low-flow cerebral perfusion during deep hypothermia.[56-58] Some authors have even suggested that the placement of a NIRS probe over the anterior abdominal wall or renal bed will give an idea of somatic flow that in conjunction with cerebral NIRS will give invaluable data with respect to adequacy of perfusion.[59,60] EEG monitoring is theoretically attractive for the detection of hypoperfusion or ischemia on the basis of altered signals. It is, however, not routinely feasible, as the technology is bulky and the signals may be affected by electrical interference from electrocautery, patient temperature, anesthetic agents used, and CPB itself. EEG is, however, useful for quantification of anesthetic depth, occurrence of electrical silence with DHCA, and of course the presence of epileptiform activity in the postoperative period that may indicate neuronal damage.[53]

Transcranial Doppler (TCD) provides a real-time monitor of cerebral blood flow velocity and the occurrence of embolic phenomena during CPB. The instrument uses pulsed-wave ultrasound, usually at 2 MHz frequency. The units display the frequency of the Doppler signals; peak systolic and mean flow velocities (in centimeters per second); and the pulsatility index, which is the peak velocity minus the end-diastolic velocity divided by the mean velocity.[61] The added advantage of the device is the identification of microemboli via high intensity transient signals displayed as an audible click for each event. The most consistent and reproducible technique is to monitor the middle cerebral artery through the temporal window, which is located superior to the zygoma and anterior to the tragus. Clinically, either an inflow arterial obstruction, which will be seen by a drop in the peak Doppler signal, or an outflow obstruction, which is diagnosed by a decrease in the diastolic flow signal, can be appreciated. The etiologies include malposition of the arterial cannula, arterial line obstruction, changes to perfusion pressure, and changes in the flow rates,

or alternatively obstruction to venous drainage from the head by superior vena caval cannula malposition, kinking of the venous line, or after the creation of a superior cavopulmonary anastomosis.[52]

Jugular venous bulb saturation (SjO_2), as its name implies, measures the saturation of the venous blood by the placement of a retrograde catheter into the jugular venous bulb located, approximately, just cephalad of the C1-C2 disc. The jugular veins drain almost all blood from the brain, but up to 6.6% of this blood comes from extracranial sources including the emissary and frontal veins and the facial vein, which contributes the most extracranial blood.[62] Another potential anatomic problem with this monitoring technology is that blood does not drain equally into the two jugular venous bulbs. In the pediatric population, the use of SjO_2 has been studied in the context of optimal cooling time in those undergoing DHCA. As the temperature drops, the brain will extract less oxygen as its metabolic demands fall. Under optimal conditions, as the temperature falls, the SjO_2 rises, until the difference between the arterial saturation and the jugular venous saturation becomes minimal.[63] At this point, it can be concluded that the metabolic rate of the brain has reached a nadir at which maximal protection is occurring. This technique is clearly invasive and thus studies have been performed comparing this technique to NIRS. These studies demonstrate that although there is a good correlation, certain limitations occur.[64-67] These involve the accuracy of NIRS at low SjO_2; NIRS may have difficulty reading values greater than 90% when cerebral metabolism is slowing, and has questionable accuracy at low flow rates. The best correlations between the modalities occur in patients who weigh less than 10 kg, because of their lesser scalp and skull thickness.[65,66]

Some centers use triple monitoring; that is, NIRS, EEG, and TCD. The advantage of this is that the monitoring is noninvasive and relatively easy to apply. Once an abnormality is detected, adjustments in patient positioning, cannula position, blood pressure, hemoglobin, $PaCO_2$, and depth of anesthesia may be needed in the prevention of potential neurologic injury.[38,52,53,61] In a study of triple monitoring on 250 patients, at first the investigators did not treat any changes that were observed, as this phase was an attempt to validate this triple monitoring. Twelve (26%) of 46 of these patients developed early postoperative neurologic problems inclusive of seizures, coma, hemiparesis, movement, vision or speech disorder. In the group in which an intervention was performed when a problem was found, the complication rate decreased to 7 out of 130 patients (6%). Of note in the study was that in the remaining 74 patients in whom no changes were detected, 5 patients had adverse outcomes. Of the monitoring modalities, EEG found 5% of the abnormalities, while NIRS and TCD found 58% and 37%, respectively.[68] A recent meta-analysis of NIRS monitoring alone found it to be a useful adjunct, but that greater clinical relevance can be achieved by combining modalities. However, despite measuring regional cerebral saturation, there is a paucity of data suggesting improved neurologic outcome based upon these numbers alone.[69]

Box 30-3 illustrates a suggested strategy for neuroprotection and monitoring during CPB. A recent study failed to demonstrate an association between a low rSO_2 during CPB and neurologic outcome.[70] It did, however, show that there appeared to be an association between preoperative MRI findings of brain immaturity and outcome. This led the authors to suggest that the preoperative MRI finding of immaturity, which results in vulnerability to injury, may be a useful marker for long-term outcome.[70]

Box 30–3 Comprehensive Strategy for Brain Protection

CPB Factors

Adequate perfusion pressure
Adequate DO_2 as measured by SvO_2/ABG
Limit inflammatory response: steroids/leukocyte–depleting filters/heparin-coated circuitry
Use of filters to avoid air/particulate emboli
Ensure adequate anticoagulation
pH-stat management for any temperature ≤ normothermia
Hematocrit ≤30 (≤1 year of age) or ≥25 (≥1 year of age)
Hyperglycemia
Hypothermia

DHCA

Adequate cooling times of at least 20 minutes
Hyperoxygenation prior to arrest
Limit time to ≤40 minutes
Alternative perfusion strategies:
  Intermittent cerebral perfusion
  Low-flow CPB
  Antegrade cerebral perfusion

Monitoring

Near-infrared spectroscopy
Electroencephalography
Transcranial Doppler

Neuroprotection must be continued well into the postoperative phase. We know that cerebral autoregulation is not normal in the immediate postoperative period and thus adequate perfusion is reliant on MAP. Important management strategies include avoiding alkalosis and hypocarbia as these may further decrease cerebral blood flow, and early treatment of hypoxia, hyperthermia, acid-base disturbance, and electrolyte abnormalities. It has been suggested that continued NIRS monitoring in the postoperative phase may be useful at guiding therapy to protect the brain, but its impact on neurodevelopmental outcomes remains unclear.[38]

Myocardial Protection

Experimental evidence suggests that neonatal and infantile myocardium will have an earlier accumulation of lactate that in turn inhibits glycolysis and the generation of ATP. The decreased ATP will prevent the uptake of calcium by the sarcoplasmic reticulum. As such, the immature myocardium that relies on glucose as its major energy substrate and extracellular calcium for excitation coupling is at a major disadvantage.[71-73] The end result is earlier ischemic damage compared to the adult. Unfortunately, most patients operated on in infancy have associated cyanosis, myocardial hypertrophy, hypoxia, volume and pressure overload, and acidosis. Thus it is obvious that these factors, coupled with immature myocardial physiology, place these patients at an enormous disadvantage. The presence of large amounts of collateral flow associated with a number of congenital abnormalities will result in increased flow to the left heart that can result in the washing away of cardioplegia and constant myocardial warming. Either of these

factors can result in inadequate myocardial protection.[74] It has been found that up to 90% of patients who do not survive the perioperative period show some form of myocardial necrosis that exists in the absence of coronary artery obstruction. This necrosis may affect the entire subendocardium and lead to endocardial fibrosis with late myocardial dysfunction.[75]

The major factors that will aid in myocardial protection are electrical quiescence achieved by the infusion of cardioplegia into the aortic root after aortic crossclamping or directly into the coronary arteries, hypothermia, and the prevention of myocardial distension. Cardioplegia solution is infused, under the direction of the surgeon, by the perfusionist. The principles that guide the composition of the solution include (1) ability to produce rapid cardiac arrest, (2) hypothermia, (3) metabolic substrates, (4) appropriate pH, and (5) membrane stabilization (i.e., low Ca^{2+}, Mg^{2+}, steroids, O_2 radical scavengers).[76] Historically, crystalloid cardioplegia has been used. Apart from the high concentration of potassium that is responsible for the electrical quiescence, the concentrations of both calcium and magnesium have been found to be important. Ideally the solution should be hypocalcemic and hypermagnesemic. Experimental studies have shown that under hypoxic conditions (cyanotic heart disease), hypocalcemic cardioplegia allows for improved recovery from hypoxic damage. It has been found that high levels of intracellular Ca^{2+} during ischemia and reperfusion lead to increased cellular injury.[76] The importance of high levels of magnesium is twofold: the prevention of calcium entry into hypoxic myocardial cells and the prevention of arrhythmia in the immediate post-bypass period.[76] The two most widely used crystalloid cardioplegia solutions are the del Nido and St. Thomas solutions. The del Nido solution contains Na^+ of 153 mmol/L, K^+ of 24 mmol/L, Cl^- of 132 mmol/L, Ca^{2+} of 0.4 mmol/L, Mg^{2+} of 6.2 mmol/L, lidocaine of 140 mg/L, and mannitol of 2.6 g/L. St. Thomas' solution contains Na^+ of 129 mmol/L, K^+ of 16 mmol/L, Cl^- of 140 mmol/L, Ca^{2+} of 1.2 mmol/L, Mg^{2+} of 16 mmol/L, and no mannitol or lidocaine. Each solution has its proponents and opponents.

Three phases of cardioplegia have been described: induction, maintenance, and reperfusion. Induction of cardioplegia covers the initial dose that results in electrical silence soon after initiation of CPB. All hearts receive noncoronary collateral blood flow via pericardial connections and, in some patients with aortopulmonary collaterals, this may be more significant. The presence, size, and number of these vessels may be variable, and thus the flow may be of sufficient volume to wash out the cardioplegia. This will result in an increase in myocardial temperature, as the collateral flow will bring blood to the heart that is at the temperature of the systemic perfusate and also, importantly, a possible return of electrical activity. This is the rationale to give intermittent doses of cardioplegia every 10 to 30 minutes.[75-77] The periodic cardioplegia will result in 1) maintenance of arrest, 2) restoring myocardial hypothermia, 3) buffering acidosis and washing away acidic metabolites, 4) replenishing high-energy phosphates, and (5) counteracting edema with hyperosmolarity[75,76] This is the maintenance phase of cardioplegia. The reperfusion phase is a critical time, as the mode of reperfusion appears to be more important than the duration of ischemia. In a study performed on 103 patients with both cyanotic and acyanotic congenital heart disease, one group received intermittent boluses of cold cardioplegia, while the second group received the same cardioplegia strategy, to which was added 300 mL/m^2 of the same cardioplegia solution at 35° C, just prior to aortic crossclamp removal. This is known as terminal warm blood cardioplegia (TWBCP) and is often used in adult cardiac surgery. The use of TWBCP was associated with higher numbers of patients resuming spontaneous sinus rhythm, decreased inotropic use to wean from CPB (although nearly all patients in the study required inotropic support postoperatively in the ICU), improved lactate extraction, decreased troponin T, and decreased heart-type fatty acid binding protein. The latter two markers are indicative of cellular damage and necrosis. It would thus appear that the use of TWBCP may provide additional protection by improving myocardial aerobic energy metabolism and decreasing cellular damage.[77]

Three additional factors are of importance in optimal cardioplegia: adequate coronary distribution, the delivery pressure of cardioplegia solution, and whether one uses crystalloid versus blood cardioplegia. Although the pediatric patient generally does not suffer from coronary artery disease, the presence of aortic insufficiency, severe septal and ventricular hypertrophy, and the need to move the coronaries (arterial switch operation) are important considerations. Despite the requirement that the cardioplegia be delivered at a certain pressure to ensure adequate distribution, care must be taken not to perfuse the myocardium at too high a pressure as this may itself lead to myocardial and vascular endothelial cell damage, increased edema, and decreased ATP levels. A pressure of between 30 and 50 mm Hg has been shown to be adequate.[75] The use of blood cardioplegia results in myocardial arrest in an oxygenated state, with no loss of ATP in the period of electrical activity prior to arrest. This is contrasted to the use of crystalloid where there is a high loss of ATP during this same period. Several authors and commentators have concluded that there appears to be a distinct advantage in the use of blood cardioplegia over crystalloid, be it at cold or warm temperatures.[75-77,79-82] Some of these advantages included lower coronary sinus lactate, improved cardiac index, better echocardiographic evidence of left ventricular function, increased heat-shock protein (produced in myocardial cells in response to stress), and decreased troponin I release, which may correlate with less myocardial injury.

In addition to these factors, meticulous surgical technique that prevents myocardial tissue injury secondary to tissue trauma, heart block, coronary kinking, and coronary air is of great importance. Anesthesia factors that may aid myocardial protection include a thorough understanding of the underlying physiology both prior to and after surgical intervention, ventilator settings that will aid and not impede myocardial function (e.g., attempts to keep pulmonary artery pressures low so as to off-load the right ventricle), and precise use of inotropic, vasodilator, or antiarrhythmic therapies.

Pulmonary Effects of Cardiopulmonary Bypass

The institution of CPB may have deleterious effects on the lungs. It is, however, important to note that there is a group of patients who present to the operating room with preexisting abnormal pulmonary physiology. This is often caused by their preexisting cardiac condition. Some patients exhibit the ill effects of increased pulmonary blood flow due to unrestricted left-to-right shunt. The presentation at surgery is thus

a spectrum of patients who have been successfully medically palliated with antifailure therapy, those who have failed medical therapy, and, worst case scenario, those with established pulmonary hypertension. This latter possibility is commonly found in those with trisomy 21 who are operated upon at or after 6 months of age. The pulmonary hypertension occurs due to unrestricted pulmonary blood flow that results in hypertrophic changes to the media of the pulmonary arteries. This places these patients at a clear disadvantage at the weaning phase of CPB. In some, this may be severe enough that the patient may suffer acute right ventricular failure, resulting in a failure to wean from CPB and thus necessitating the use of acute extracorporeal support. Other patients in whom vascular reactivity and pulmonary hypertension may be an issue during weaning and separation from cardiopulmonary bypass include neonates, by virtue of their pulmonary vasoreactivity, a carryover from the fetal circulation, and those patients in whom there is an obstruction to pulmonary venous drainage, be it at the level of the pulmonary veins or due to restrictive atrial septae associated with left-sided obstructive lesions. The lungs may be a source as well as a target of the inflammatory response associated with CPB.[83] The result of this is capillary leak and extravasation of fluid into the alveolar spaces with resultant poor oxygen exchange and a detrimental effect on pulmonary mechanics. Etiologic factors associated with capillary leak include hemodilution with resultant decrease in oncotic pressure, ischemia-reperfusion injury, and the sequestration of activated neutrophils, cytokines, complement, and leukotrienes within the pulmonary vascular bed during the period of CPB. At the onset of CPB, perfusion will cease through the pulmonary bed, and that in turn leads to a decrease in alveolar stability.[84] Clinical studies have also shown that there are changes to functional residual capacity (FRC) during CPB. Initially there is an increase in FRC as the chest cavity is opened. This will, however, change to a decrease with the cessation of pulmonary flow and alveolar collapse. There is a further decease in FRC with chest closure, continued inflammatory effects, and the presence of extravasated fluid.[84] It can thus be appreciated that all these factors lead to the inevitable decrease in PaO_2 encountered in the immediate postbypass period.

Although the use of steroids has been shown to improve postoperative pulmonary function by decreasing the inflammatory effects on the lung, it is the use of modified ultrafiltration (MUF) that has greatly improved pulmonary function and oxygenation/ventilation in the immediate post-CPB phase. The use of MUF has two apparent effects:

1. The reduction of total body water and, with this, an associated decrease in lung water that leads to improved lung compliance and decreased airway pressure[85]
2. A decrease in inflammatory markers, which leads to a decrease in capillary leak.[86]

The clinical result is decreased mechanical ventilation, faster time to extubation, and decreased ICU time.[85,87] The use of MUF has allowed the practice of early extubation at many institutions. The patient population in which early extubation is key to further management is the single-ventricle population after the cavopulmonary anastomosis and Fontan completion. In those patients, the flow through the pulmonary bed is entirely passive and can be adversely affected by positive-pressure ventilation, leading to a decrease in cardiac output that is clearly detrimental. Early extubation, for the purposes of this discussion, is defined as extubation upon arrival to the ICU immediately postoperatively. This strategy is also commonly applied to patients undergoing such diverse procedures as coarctation surgery, shunt procedures, ASD, VSD, and conduit revision, to name a few.

Renal Function and Protection on Cardiopulmonary Bypass

The development of acute kidney injury (AKI) is multifactorial and can be subdivided into preoperative, intraoperative, and postoperative causes. The etiologies of the preoperative injury are mainly associated with neonates and infants as their renal physiology is immature. Glomerular filtration rate (GFR) is lower in this age group due to lower mean arterial pressure and high renovascular resistance with GFR maintained by postglomerular efferent arteriolar vasoconstriction that is dependent on high levels of angiotensin II activity. It is for this reason that the angiotensin-converting enzyme inhibitors are used in these patients with extreme caution.[88]

Preventive and treatment strategies aim to maintain systemic oxygen delivery, maintain perfusion pressure to vital organs, and prevent any further deterioration in function. Thus, in the preoperative phase, careful attention must be paid to balancing pulmonary and systemic perfusion (Qp/Qs). Soon after birth the pulmonary resistance begins to fall, and thus in patients with ductal-dependent systemic flow, pulmonary blood flow may increase. The increase in pulmonary blood flow results in a concomitant decrease in systemic flow. This may decrease perfusion of vital organs. Management at this time will therefore include prostaglandin infusion to maintain ductal-dependent systemic flow, low inspired FiO_2 to increase PVR, support of cardiac function, and early corrective or palliative surgery. Intraoperative aims include many of the factors that are discussed elsewhere in this chapter including dampening the inflammatory response, decreasing DHCA time, the effects of nonpulsatile versus pulsatile CPB, decreasing circuit size, and limiting the exposure to blood products. After the completion of CPB, the aims of preventative management include decreasing total body water and inflammatory mediators by means of modified ultrafiltration; ensuring that there are no residual lesions that may impact Qp/Qs or directly affect cardiac function; and ensuring appropriate and ongoing cardiac support in the form of inotropic drugs, vasopressors, vasodilators, and diuretics.

The incidence of AKI varies depending on surgical procedure, ranging from 0.7% for short, uncomplicated operations such as atrial septal defect closure, to 59% for longer, more complicated operations such as the arterial switch. Across the entire spectrum of procedures the incidence varies from 6% to 17%. Renal replacement therapy is required in 2.3% to 11.5%.[89-91] Mortality rates in this subgroup of patients may be as high as 79%.[90] Box 30-4 describes the risk factors associated with the development of acute kidney injury (AKI) in the immediate post-CPB period. Although this has been collated from data collected over the last 10 to15 years, it seems that the incidence of acute post-CPB renal failure is decreasing.[90] It is unknown whether this can be ascribed to improved perfusion techniques, improved surgical technique, improved drug therapies, or improved understanding and management in the ICU. The development of AKI is a risk factor for mortality as well as for prolonged hospital stay and an associated

Box 30–4 Risk Factors for the Development of Acute Renal Failure

Age ≤1 year
Elevated Aristotle/RACHS-1 (categories 4-6) surgical complexity scores
Long bypass time
Long crossclamp time
Deep hypothermic circulatory arrest
Increased use of blood products
Low post-CPB cardiac output
Inotropic support (especially epinephrine and isoproterenol)
Low trough blood pressure on postoperative day 1

increase in hospital costs. Despite these alarming numbers, the diagnosis may prove difficult, as consensus as to the definition is not clear. The important factor to remember is that by the time the laboratory values begin to change significantly, damage may already have occurred. A number of attempts have been made to find a reliable marker. Candidates include the use of p-RIFLE (pediatric risk, injury, failure, loss, and end-stage renal disease) which estimates the decrease in creatinine clearance[92]; renal neutrophil gelatinase-associated lipocalin (NGAL), which is expressed during ischemic injury, sepsis, and posttransplant[93]; and interleukin 18 (IL-18).[94] The advantage of early detection is the early institution of therapy. Two forms of therapy have been used in this setting: peritoneal dialysis (PD) and continuous renal replacement therapy (CRRT). Advantages of CRRT include rapid removal of excess body fluid, treatment of life-threatening hyperkalemia, and the ease in which the circuit can be placed in parallel with an ECMO circuit. In this setting, CRRT is usually achieved by a venovenous circuit with the utilization of the internal jugular, subclavian, or femoral veins. In one study using this approach, up to 90% of patients were discharged with normal renal function.[89]

Endocrine Response to Cardiopulmonary Bypass

The use of CPB, with and without the use of DHCA, is associated with considerable endocrine stress.[95] In a study of 22 infants ranging in age from 2 days to 18 months with a mix of both cyanotic and acyanotic conditions who all underwent repair utilizing DHCA, the authors found that there was an increase in both endogenous epinephrine and norepinephrine. This increase persisted from the cooling phase through the warming phase and up to the end of the study, which unfortunately ended with chest closure. These findings led the authors to conclude that there is considerable sympathoadrenal stress associated with CPB and DHCA, despite what appeared to be adequate anesthesia and analgesia. The nonlinear relationship between duration of arrest and the postarrest values possibly indicated that the tissues were beginning to become hypoxic; thus trending these values could suggest a safe time for DHCA.[96] Clinically, however, these elevations in catecholamines are of unknown significance.

The end point of the hypothalamic-pituitary-adrenal axis, that is, the secretion of glucocorticoids, is important in the setting of cardiac surgery, as studies suggest that the effect of these glucocorticoids include: 1) enhanced vascular sensitivity to catecholamines, 2) increased myocardial β-adrenergic receptors, 3) increased renin substrate and calcium availability, 4) inhibition of vasodilation and catecholamine degradation. The end result of these factors may be that glucocorticoids enhance myocardial and vascular responsiveness to catecholamines. In studies performed on critically ill neonates, infants, and children with hypotension refractory to volume resuscitation as well as inotropic support, adrenal insufficiency was found, with clinical improvement upon administration of corticosteroids.[97] Despite these findings, there is still considerable disagreement in the literature as to the optimal dosing and timing, or whether corticosteroids should even be administered.[98-101]

Thyroid hormone levels have been found to become suppressed after critical illness and surgical procedures. This has the potential to cause a number of problems in the post-CPB period including prolonged ventilation, increased inotropic requirements, and increased need for diuretic therapy.[102] Endogenous mediators including glucocorticoids, tumor necrosis factor, and IL-6 are released in response to CPB and lead to low postoperative triiodothyronine (T_3). Interestingly, there is an initial surge of free hormone after the institution of CPB, followed by low total and free T_3/T_4 levels. The nadir of this effect occurs between 12 and 48 hours after bypass and lasts up to 5 days.[102,103] At a cellular level, the effect of thyroid hormone is to influence the entry and extrusion of calcium from the cardiac myocyte via the sarcoplasmic reticulum and cell membrane. Thus low T_3 has a profound effect on myocardial function and may be manifest by both systolic and diastolic dysfunction and by increased vascular resistance, which collectively are seen clinically as a low cardiac output state.[103] Treatment with T_3 either as repeated bolus therapy or infusion in the immediate postoperative period has been shown to improve systolic and mean arterial blood pressure and cardiac output, which in turn leads to improved renal perfusion and negative fluid balance.[104,105]

Hyperglycemia in the critically ill adult patients is known to be associated with higher morbidity and mortality.[106-108] Hyperglycemia is a normal response to stress. Surgery, with its associated stress response, results in an increase in counterregulatory hormones (epinephrine, glucagon, growth hormone, and cortisol). The result is increased hepatic glucose mobilization, impaired peripheral glucose utilization, relative insulin deficiency, and thus hyperglycemia.[108] This is further complicated by the insulin resistance found in cardiac surgery patients. It has been found that during hypothermia, glucose levels increase and insulin decreases. On rewarming, glucose levels continue to rise, with an associated rise in insulin. In addition to these etiologic factors, the administration of corticosteroids and inotropes also plays a role. Three retrospective studies in the pediatric population showed similar findings to the adult studies, namely that hyperglycemia was associated with increased morbidity and mortality.[109-111] The differences, however, were that in contrast to the adult experience (where initial glucose level was associated with mortality), in the pediatric group, the peak level as well as continued elevation were associated with complications. The morbidities described in these studies included prolonged ventilation, prolonged ICU stay, and increased rates of infection. In a study performed on neonates who underwent arterial switch operations, it was found that in a group of patients whose blood sugar averaged over 200 mg/dL, there was no increased risk of adverse event.[112] Another concern for clinicians is the effect of posttherapy hypoglycemia and the possibility of associated

neurologic damage. A clinical study performed by Ballweg et al. demonstrated that there was no associated worsening of neurodevelopmental outcome at 1 year in those patients who demonstrated early postoperative hyperglycemia.[113] There is currently insufficient evidence to support a beneficial effect of tight glycemic control during cardiac surgery in infants. There is, however, strong evidence of the adverse effects of persistent hyperglycemia in this patient population.

Systemic Inflammation

The perioperative period is a potentially deleterious time, as the combination of anesthesia, the stress of surgery, and the immune-stimulating effects of the CPB circuit combine to result in a systemic inflammatory response. Indeed, it has been found that certain patients, including those with single-ventricle physiology, may have an activated inflammatory response prior even to the commencement of CPB.[114] Possible etiological factors include: 1) cellular activation with contact of blood products with the surface of the bypass circuit; 2) mechanical shear stress as the blood passes through suction systems and filters; 3) tissue ischemia and reperfusion; 4) hypotension and hemodilution; 5) administration of blood products; and 6) hypothermia (mild, moderate, and deep hypothermia).[83] These factors will result in the activation of both humoral and cellular immune responses that generate the activation of the complement, coagulation, and fibrinolytic pathways. Collectively, these pathways result in endothelial damage, capillary leak, and organ dysfunction. In the literature, up to 50% of children have pulmonary and cardiovascular dysfunction attributable to this proinflammatory response in the post-CPB period.[115] The pediatric population may be at increased risk compared with the adult population, as the body surface area to circuit size is greater.

Figure 30-4 demonstrates the effects of surgical trauma and CPB. Complement activation occurs by both the alternative (contact with foreign surfaces, that is, bypass circuitry) and classical pathways (protamine-related). These two pathways result in the elevation of C3a and C5a, and C4a with additional C3a respectively. Elevations of C3a and C5a lead to activation and degranulation of neutrophils, release of histamine from mast cells and basophils, and platelet aggregation. These elevations have been associated with poor outcomes, with severe organ dysfunction, prolonged mechanical ventilation, and poor outcome.[83,116] Contact activation of clotting factor XII results in the eventual activation of kallikrein and bradykinin. The effect of increased kallikrein is the positive feedback on the activation of more factor XII, while the increased bradykinin results in the stimulation of B_1 and B_2 receptors. The effect of their stimulation is the production of nitric oxide, free radicals,

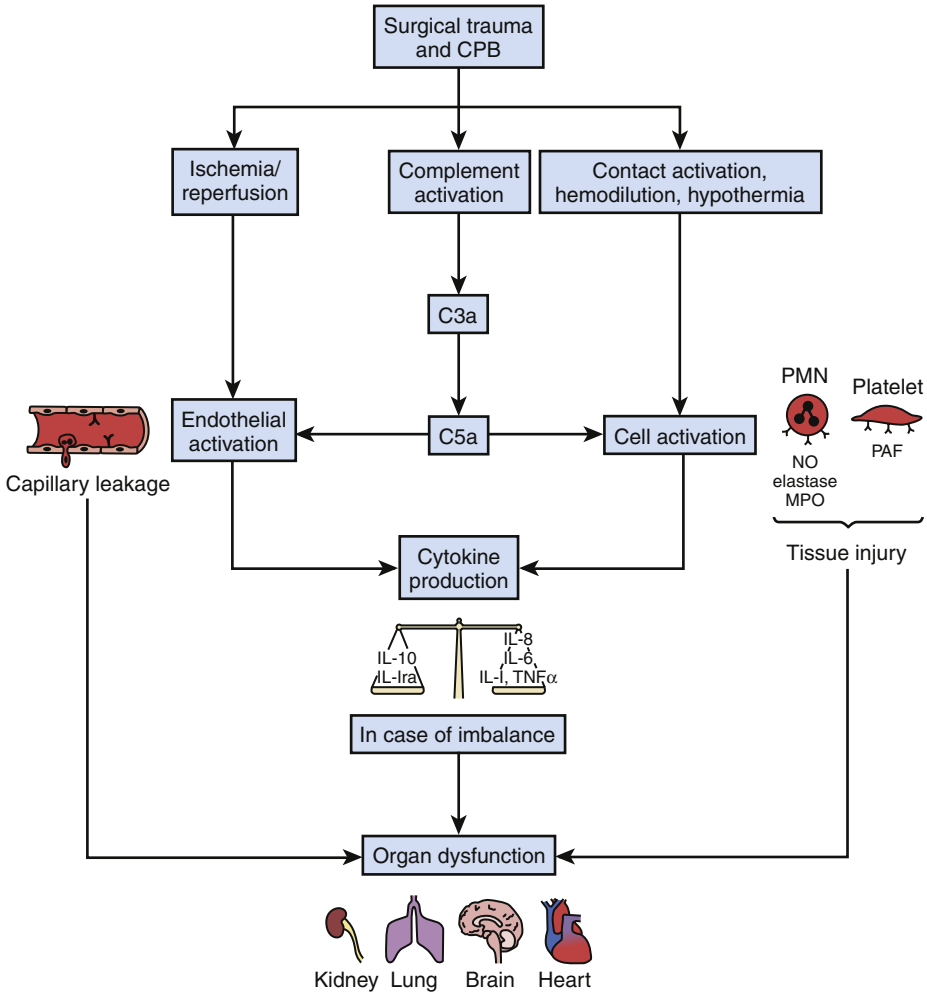

Figure 30–4. Illustration of the effects of surgical trauma and CPB. *(Modified from Brix-Christensen V: The systemic inflammatory response after cardiopulmonary bypass in children,* Acta Anaesthesiol Scand *45:671-679, 2001.)*

eicosanoids, and cytokines. This will result in vasodilation and increased capillary permeability, which in turn may lead to organ dysfunction.[114,117] B_2 receptors have also been found in the brain and this may play a role in the genesis of ischemia-reperfusion injury.[94] Cytokines are produced by a wide range of cells including monocytes, macrophages, lymphocytes, and endothelial cells. These factors are either proinflammatory in the form of interleukins (IL) 6 and 8 and tumor necrosis factor α (TNF-α), or antiinflammatory in interleukin 10 and interleukin-1 receptor antagonist. An increase in TNF-α has been demonstrated to be associated with increased capillary leak[117]; however, other studies have failed to show any significant increase.[115,118] Elevations in IL-6 and IL-8 have been shown to correlate with compromised postbypass cardiopulmonary function with increased inotropic requirements, severe capillary leak syndrome, and an increase in mortality.[83,114,115,118] The balance therefore between the proinflammatory and antiinflammatory responses may thus be altered in those who demonstrate an aggressive systemic inflammatory response. In uncomplicated cases, the systemic inflammatory response is self-limited and is only of a few days duration.[115]

The more important question is what can be done to prevent initiation of this inflammatory process. Several therapeutic maneuvers have been proposed including the addition of steroids to the pump prime; the use of indomethacin or aprotinin; heparin-coated CPB circuitry; and the use of ultrafiltration.[101] The administration of steroids into the pump prime seems a logical therapeutic measure. However, data supporting this were derived from adult patients undergoing coronary artery bypass grafting.[119] Studies in the pediatric population have demonstrated variable results, and indeed there does not appear to be agreement on timing or dosing of steroids.99 In one study, there were measurable differences in the degree of inflammatory markers found between the 15 test subjects and the 14 controls. In this study, although the age at the time of surgery, the CPB times, and aortic crossclamp times were similar, they did not reach statistical significance. The authors found that in the steroid group there was a decrease in the concentrations of IL-6 and TNF-α. They noted, however, that these decreases were after the initiation of bypass and prior to MUF in the TNF-α group, and after the removal of the crossclamp in the IL-6 group. The concentration of C3a, however, was not different between groups. In terms of clinical effect, the steroid-treated group had lower alveolar arterial oxygen differences, lower temperatures (due to lower cytokine levels), required less supplemental fluid in the first 24 hours, had better renal function, and had less ICU time.[120] A further study looking into the effects of administration of steroids (methylprednisolone 30 mg/kg) 4 hours before surgery as well as intraoperatively, compared to a cohort that received only intraoperative steroids, found that the group who received two doses had reduced levels of IL-6 and IL-10, and a clinical advantage as outlined in the first study.[121] Results of other studies have, however, not shown positive results. In a study that included patients 3 months of age or older, but weighing no more than 7 kg, 24 patients were given steroids while 26 were not. An obvious weakness of the study was that the dose and timing of the steroids were not mentioned. Investigators found no differences in the inflammatory or clinical markers between the groups.[119] As has been indicated elsewhere in this discussion, a large, randomized, prospective study is essential in order to properly elucidate this question.

Aprotinin, a serine protease inhibitor, was reported to help preserve platelet function, to decrease bleeding diatheses associated not only with CPB but also other procedures including spinal surgery, and also to have antiinflammatory effects. Studies concluded that its use had beneficial effects on post-CPB organ function and improved hemodynamic stability. However, after published data in the adult literature suggested that there was a thrombosis and renal failure risk with its use, the drug was voluntarily removed from the market in November of 2007.[122,123] In the pediatric literature, safety studies looking at these effects failed to concur with the adult studies[124,125] As with many clinical questions in the literature, some studies even questioned the drug's efficacy.[125,126]

Exposure of blood to the bypass circuit itself is probably the main factor in initiation of the inflammatory cascade. Two strategies have been used to attenuate this response: miniaturization of bypass circuits, and coating the circuit in an attempt to make it more biocompatible. Other strategies that have been used by clinicians in an attempt to minimize the inflammatory effects include ultrafiltration and the use of biocompatible circuits. It appears that a multimodal strategy is essential to decrease the deleterious effects of the multisystem inflammatory cascade that is incited by CPB.

Management of Cardiopulmonary Bypass

The trend in modern pediatric bypass equipment is to reduce the size of the extracorporeal circuit in order to reduce the prime volume. The priming volume may actually exceed the blood volume of the neonate by as much as 200% to 300%. This is in contrast to the adult CPB patient where the priming volume accounts for only between 25% and 33% of the patient's blood volume. The effects of CPB have led surgeons to perform operations without the use of CPB and interventional cardiologists to close atrial and ventricular septal defects in the catheterization laboratory.[127-132] Indeed, some undertake a hybrid approach for closure of ventricular septal defects and other procedures such as stenting of the pulmonary arteries, in which the surgeon obtains direct access to the heart and the procedure is performed using transcatheter techniques by an interventional cardiologist.[133]

Hemodilution

Research into the effects of CPB on the inflammatory cascade and organ dysfunction that occur in the postbypass period have also found that the use of blood products plays a significant role in the inflammatory response. These effects include an elevation in complement and inflammatory cytokines.[134] The use of blood in the pump prime, especially in neonates, infants, and patients who will undergo DHCA and hypothermic low-flow bypass, is based upon earlier published data that suggested that a hematocrit between 20% and 25% was associated with acute and long-term sequelae.[135] Acutely, there appeared to be a lower minimum cardiac index in the post-CPB phase, higher serum lactate levels at 60 minutes post-CPB, and a greater increase in total body water in the first postoperative day. At 1 year of age, this same group tested lower on the Psychomotor Development Index both in absolute number and also in a greater number of subjects who tested 2 standard deviations from the population mean.

Although these authors suggested that a hematocrit below 25% was associated with worse outcomes, both acutely and at 1 year follow-up, they could not identify a target hematocrit that was optimal. A later study comparing a hematocrit of 25% to one of 35% was also undertaken. Apart from a greater intraoperative fluid accumulation with the lower hematocrit there were no reported differences between groups both in the early postoperative period and at 1-year neurodevelopmental follow-up.[136] Thus it appears that a hematocrit of 25% or more may be adequate. At our institution we keep the hematocrit at least at 30% in patients younger than 1 year and at least 25% in those older than 1 year, irrespective of congenital abnormality. Based on these targets, blood is added into the prime volume as needed.

Circuit Miniaturization

The desire to maintain hematocrit at the aforementioned levels and the discrepancy between patient size and circuit volume has led researchers to attempt to miniaturize circuits. This has the advantage of not only decreasing the total surface area the patient will contact but also raises the possibility of a bloodless prime. Methods that may be used to achieve this include using biocompatible coated circuitry and oxygenators, the use of vacuum-assisted venous drainage, the ability to decrease circuit length by bringing the pump as close to the patient as possible, and finally, the exclusion of certain circuit components, for example, arterial line filters and in-line cardioplegia.[137]

Biocompatible Circuits

The initiation of CPB results in the activation of the five proteolytic plasma systems (coagulation, fibrinolysis, complement activation, kallikrein-kinin, and contact systems) as well as leukocytes, platelets, and endothelial cells. One option is to modify the surface of the circuit and dampen the response.

Box 30-5 describes the ideal biocompatible circuit.[137] Surface modification can be achieved by four techniques: coating, chemical modification, attachment of macromolecules, and blending of polymers.[138] Studies using these modified circuits have found modification of the inflammatory response by some (e.g., polymethoxyethylacrylate or PMEA, a polymer blend; and heparin-coated circuits)[139-142] and improvement in platelet count (phosphorylcholine, a circuit coating) in others.[143] Some studies have also suggested that these modified circuits may even improve urine output postoperatively and decrease the time that ventilation is required.[141,142] It would seem that these latter effects are on the basis of a decrease in the inflammatory response and capillary leak, but evidence of a significant clinical benefit is still lacking.

Box 30–5 Properties of the Ideal Circuit

Inability to initiate thrombogenesis
Inability to initiate hemolysis
No complement activation
No toxicity of products extracted from the circuit by the blood
Chemical inertness so that no toxic metabolites are generated

From Janvier G, Baquey C, et al: Extracorporeal circulation, hemocompatibility, and biomaterials, *Ann Thorac Surg* 62:1926-1934, 1996.

Circuit Design

The use of smaller circuit size, and thus prime volume, is aimed at decreasing hemodilution, which might decrease transfusion requirements, and decreasing the severity of the inflammatory response, thus reducing hospital costs because of improved outcomes.[144] Techniques that investigators have used in order to create these smaller circuits have included: low prime volume oxygenators, reservoirs, and arterial filters; shorter extracorporeal circuitry; remote pump heads; use of venous vacuum (which can, in turn, result in the use of smaller venous tubing), and, in certain configurations, removal of parts of the classic circuit, most frequently the arterial line filter.[134,144-149] Such devices have been shown to be safe, even in the neonatal population, with priming volumes as low as 110 mL. Other descriptions have included configurations where the bypass circuit is placed as close to the operating table as possible with either the surgeon or assistant straddling the circuitry.

A wide range of operations have been described using these adjustments. They range from ASD and VSD surgery to such complex procedures as the arterial switch operation and even the stage 1 palliation of hypoplastic left heart syndrome. With changes to the circuitry comes a permissible degree of hemodilution, requiring that patients be continuously monitored by means of hemoglobin concentration, mixed venous oxygen saturation, regional cerebral oxygenation, and pump plasma lactate. Values of less than 7 g/dL, less than 70%, less than 50% and greater than 4 mmol/L, respectively, have been used as transfusion triggers.[146,148]

Animal experimentation using circuit miniaturization with deep hypothermia and asanguineous prime has found a decrease in the inflammatory cascade. Tumor necrosis factor was decreased and primed neutrophils from donor blood were obviously absent. These donor-originated neutrophils are key factors in the genesis of the CPB-induced inflammatory cascade and capillary leak leading to organ dysfunction. Further analysis found improved right ventricular cardiac index, improved pulmonary vascular resistance index, and improved dynamic pulmonary compliance in animals exposed to asanguineous prime. The authors concluded that these could be attributed to a decrease in total lung water associated in turn with decreased inflammation.[150] A separate study found that there was improved postbypass cerebral blood flow. The authors postulated that this might lead to improved long-term neurologic outcome.

Oxygenators

In the pediatric population, oxygenators must provide efficient gas exchange over a wide range of temperatures (10° C to 40° C), pump flow rates (0 to 200 mL/kg/min) , line pressures, gas flow rates, and hematocrits as low as 15%. Both bubble and membrane oxygenators can achieve effective gas exchange under these diverse conditions. Historically three different types of oxygenators have been used, namely the film-type, bubble-type, and membrane-type. In the film-type, a thin blood film is created, with gas exchange taking place on the surface of the film. In this method, there is no mechanical introduction of gas into the blood and thus trauma to red blood cells is minimal. However, a large surface area is necessary, with a large priming volume. The bubble oxygenator

uses bubbles that are introduced directly into the blood. It has advantages in that the effective surface area for gas exchange is large due to the surface area of the bubbles. The obvious disadvantage, however, is that the introduction of the bubbles causes red cell trauma. In addition to this, the bubbles must clearly be removed from the circuit and this requires a settling chamber, which may in turn require added volume in the circuit.

The third oxygenator is the membrane type, the one that is most widely used today. In this technique, the blood is exposed to oxygen through a gas-permeable membrane and thus, because there is no direct contact between gas and blood, trauma is minimal.[151] Refinements in early membrane oxygenator design occurred in the 1980s, with the introduction of microporous hollow fibers with blood flowing over the outside of the fiber and gas flowing down the fiber lumen. This increased the efficiency of gas exchange and, at the same time, decreased manufacturing costs to be in line with the cheaper bubble oxygenators.[152]

Common to all CPB circuits is the presence of gaseous microemboli. These may be caused by pulsatile bypass, low venous reservoir levels, vacuum-assisted venous drainage, venous line air, field suckers, drug administration, and blood sampling. Perfusionists may utilize a number of methods to decrease this, ranging from filtration at the time of circuit setup, ensuring adequate volumes within the venous reservoir, and the placement of arterial line filters.

Unfortunately, the arterial line filter may add as much as 20% to 40% to the prime volume.[153] Arterial line filters are used in 96% of North American centers, whereas in Europe, they have not been commonplace for a number of years.[153]

The first oxygenator specifically designed for pediatrics was the Dideco Kids D100 neonatal oxygenator (Sorin Group, Mirandola, Italy). It was first evaluated at Duke on a series of 6 neonates: two underwent Norwood procedures, two truncus arteriosus repairs, and two, arterial switch operations. The investigators noted that the total priming volume for the oxygenator was only 31 mL and this enabled the priming volume of the circuit to be decreased by 12.5%. The change to this oxygenator did not compromise oxygenation, and apart from the 1 unit of packed red blood cells and fresh frozen plasma originally added as the prime, no further blood products were used to maintain a hematocrit greater than 35%.[154] The Terumo Medical Corporation, Tokyo, Japan has manufactured a miniature oxygenator with an incorporated arterial line filter. The total prime volume is only 43 mL. In clinical evaluations, it was found to be easy to use, decreased the number of gaseous emboli, and was easily incorporated into their miniature circuit setup.[153] It can thus be appreciated that newer generation neonatal oxygenators have an advantage in that they are specifically designed for this patient population, are easy to use, and have the benefit of small prime volumes, which enable teams to attempt to achieve the goal of asanguineous prime.

Initiation of Cardiopulmonary Bypass

Prior to the initiation of cardiopulmonary bypass, the entire team must plan a strategy for the safe undertaking of the planned procedure. The surgical team ensures that the proper instrumentation is available, that the lines that will be used for the bypass are appropriately sized, and that they are cut to appropriate length under the direction of the surgeon. In addition to this, the surgical team assembles the appropriate mechanical or tissue valves and thaws homograft tissue patches that may be required by the surgeon for specific repairs (e.g., pulmonary artery patches or aortic augmentation). A major concern for the anesthesia team is the smooth transition from spontaneous to controlled ventilation. This transition may lead to changes in intrathoracic pressure, heart rate, and pulmonary:systemic blood flow that may be poorly tolerated. The question of whether the patient is to be intubated orally or nasally is practitioner and institution dependent. In addition, the anesthesia team will place peripheral intravenous lines, and invasive monitoring in the form of an arterial line, with or without a central venous line. Central venous catheters are also institution-dependent, with some groups avoiding them in favor of direct intracardiac lines placed by the surgeon prior to the termination of CPB. The reasoning is to avoid stenosis or thrombosis of the central veins, particularly in single-ventricle patients whose venous drainage from the head and neck is integral to survival. Other preparations include the placement of Foley catheters, the adjustment of the temperature of under-body cooling blankets, institution of topical cooling in the form of ice bags to the head (in those undergoing DHCA), and the placement of further monitoring (e.g., EEG, cerebral oximeters, or transcranial Doppler).

Specific surgical factors that need to be considered include the potential for the use of DHCA, accessing defects through the right side of the heart, whether or not an aortic cross clamp will be necessary, and whether the size of the child being operated on will influence cannulation strategy. Options available to the surgeon include dual caval cannulation for patients having repairs of ASD, VSD, atrioventricular canal defects, tetralogy of Fallot, and transposition of the great vessels with VSD; and single venous cannulation, mainly for those cases in which DHCA will be used, including augmentation of the aortic arch, Norwood stage 1 palliation, cavopulmonary anastomosis, and Fontan completion, to name a few. In these cases, CPB is used to decrease patient temperature. Cooling is usually performed over a 20-minute period down to a target temperature of 18° C. Once the target temperature has been achieved, circulation is shut down and the cannulae are removed so that the repair may take place in a bloodless field. Meticulous de-airing of the circuit is critical to this population to avoid cerebral air embolus, remembering that air may cross any of the intracardiac shunts.

It is essential to check that the cannulae are appropriately positioned prior to going on to CPB. This will include the correlation of the pressure in the aorta with the invasive arterial line and making sure that the venous cannulae are in the correct direction and that they are not potentially abutting the wall of either the vena cava or right atrium. Once the patient is placed on to CPB, ventilation will cease and it is thus important to observe the oxygenation difference between the venous and the arterial cannulae, as well as the SvO_2 that is measured from the bypass circuit. Box 30-6 lists both direct and indirect measures of adequate perfusion. Based upon this list of measures, there are a number of management strategies that may be employed should there be indications of decreased perfusion. The perfusionist will ensure that the cardiac index is adequate based on the patient's weight or increase mean arterial pressure with the use of vasopressor agents. In the event that the cerebral saturations or jugular venous bulb saturation

decreases, it is imperative that the surgeon check for correct placement of both arterial and venous cannulae. The arterial cannula may be directing blood away from the head vessels, and the venous cannula may be positioned so that it is causing obstruction to venous drainage from the head and thus decreasing cerebral perfusion pressure. Cerebral perfusion pressure (CPP) is calculated from the following calculation: CPP = MAP − ICP (or jugular venous pressure) and thus we see that alterations of either the arterial inflow or obstruction to outflow may result in the aforementioned decrease in perfusion pressure. Other important factors that must be assessed are adequacy of hemoglobin/hematocrit and oxygenation.

Anticoagulation

At birth, concentrations of the vitamin K-dependent clotting factors (II, VII, IX, X), contact factors (XI and XII) and the anticoagulant and inhibitory factors (antithrombin III, protein C, protein S, CI esterase inhibitor, and plasminogen) are all reduced. The mechanisms may include decreased hepatic synthesis or increased clearance secondary to increased metabolic rate.[155,156] Despite these apparent abnormalities, normal neonates have preserved coagulation function. The same, however, cannot be said for patients with cyanotic heart disease. This group is known to have impaired coagulation prior to surgery on the basis of polycythemia, abnormal platelet count and function, decreased factor concentration (V, VII, and VIII), and increased fibrinolysis.[156,157] Box 30-7 lists factors that are associated with coagulopathy in neonates and infants presenting for surgery with cardiopulmonary bypass.

The institution of CPB will result in activation of the clotting cascade, and thus therapeutic anticoagulation is vital to prevent the formation of clot within the circuit and the disastrous effects of possible thromboembolism into the arterial tree. The anticoagulant universally used in both adult and pediatric CPB is heparin. At the Children's Hospital of Philadelphia, the patient is given 200 U/kg, either by the surgeon as a direct injection into the right atrium, or by the anesthesiologist into a peripheral intravenous site. Some institutions use between 300 and 400 U/kg. The goal is for activated clotting time (ACT) to be no less than 480 seconds. This is based upon early work by Bull and colleagues who formulated a heparin-protamine dose-response curve in the attempt to avert the use of either excess heparin or protamine.[158] The mechanism by which heparin works is by binding to antithrombin III (ATIII), resulting in a conformational change in the enzyme and enhancing its activity. Under normal conditions, there is a continuous balance between coagulation and anticoagulation within the body. ATIII functions to inactivate thrombin and other proteases, most notably factor Xa, thus preventing ongoing propagation of the clotting cascade. The effect of heparin on ATIII is to increase its efficacy by a factor of a thousand. As mentioned earlier, the level of ATIII is decreased in neonates and will only reach adult levels by 3 to 6 months. Despite this, it has been found that there are two other thrombin inhibitors, namely heparin cofactor II and α_2-macroglobulin. In neonates and infants, the concentration of α_2-macroglobulin is twice as high as that of ATIII. In a study by Guzzetta et al., it was found that, despite these concerns, there was a statistically significant prolongation in ACT and that a heparin dose-response relationship occurred in the neonatal group. The authors postulated that this could be on the basis that either neonates generate less thrombin or that ACT is a poor indicator of anticoagulation in this age group.[159] The problem in the neonatal and early infant population is what to make of the ACT and whether or not there is sufficient anticoagulation despite ACT prolongation. Based upon these misgivings, some authors have suggested that using a heparin concentration protocol may be more effective.[160,161] Using this technique, despite decreased thrombin and preserved factor VIII levels which indicate improved anticoagulation, there was increased bleeding and increased blood requirement.[160]

A concern in patients presenting for repeat cardiac surgery is the possibility of these patients developing heparin-induced thrombocytopenia (HIT). The syndrome itself is an immune-mediated phenomenon of platelet activation resulting in thrombocytopenia and diffuse venous and even arterial thrombosis. Thrombocytopenia will occur some days after the exposure to unfractionated heparin .with platelet counts dropping to between 20 and 100×10^9/L. It is important, however, to be mindful of any drop in the platelet count. A drop in the count by 50%, even if still in the normal range, is considered to of significance. There are two forms of HIT. HIT 1 is a transient early onset of a nonimmune-mediated decrease in platelet count that does not require the discontinuation of heparin. HIT 2 is immune-mediated with a decrease in platelet count by at least 50%.[162] In the adult literature, the

incidence is reported to be 1% to 3% post-CPB, with a thrombotic morbidity of between 38% and 81% and a mortality of 28%.[163] The antibodies are formed against platelet factor 4 (PF4), which is found on the surface of activated platelets as well as on endothelial cell surfaces secondary to heparin exposure. The presence of these antibodies occurs in up to 50% of adult cardiac surgery patients, but only the quoted 1% to 3% will go on to develop the syndrome.[163] This suggests that, although the platelet antibody is itself common after CPB, in and of itself it does not confer increased risk. A pediatric series including neonates, infants, and young children revealed an incidence of 1.3%.[164] As in the adult population, a study of older children looking at positive antibody screen found the same incidence as in the adult population of 50%.[165]

The question then is what to do with patients who have a history of HIT or HIT-associated thrombosis. There are three alternatives: 1) the use of an alternative anticoagulant with the complete avoidance of all heparin both intraoperatively and postoperatively; 2) standard heparin anticoagulation with a platelet antagonist; and 3) waiting until the disappearance of HIT antibodies and proceeding with heparin anticoagulation.[162] Box 30-8 lists the alternatives to heparin. Of this list of drugs, only the thrombin inhibitors lepirudin and argatroban have been used to any degree. Argatroban has the advantage that it is metabolized in the liver, can be monitored by ACT, and has a half-life of less than 60 minutes. The problem, however, is that there are no standardized dosing protocols. Initial bolus dosing was inconsistent across the literature with a range of 35 to 750 μg/kg and infusion rates between 2 and 65 μg/kg/min. Further bolus doses for inappropriate ACT were on the order of 20 μg/kg.[167-169] Problems included no reversal drug and the use of nonstandardized protocols that resulted in increased bleeding and blood use. Lepirudin is more difficult to use based upon its longer $T^{1/2}$ at 40 to 80 minutes, the need for ecarin clotting time (ECT), and renal excretion. It is also possible to monitor lepirudin with the aPTT but this test would take too long in the setting of CPB. Just as with argatroban, there is no reversal agent. Dosing of this agent follows the adult dosing of a bolus of 0.25 mg/kg and 0.2 mg/kg into the CPB circuit, although a single group suggested increasing these doses due to a greater volume of distribution.[170-172]

At the termination of CPB, as the cannulae are being removed, protamine will be administered to reverse the anticoagulation due to heparin. As with many areas in practice, there is a range of dosing used in the clinical arena. As mentioned, at the Children's Hospital of Philadelphia the heparin dosing is 200 IU/kg, and for reversal the protamine dosing is 4 mg/kg, with a maximum of 100 mg. This works out to be a ratio of protamine to heparin of 2:1 based on 1 mg of protamine to 100 IU (sometimes referred to as 1 mg) of heparin. In a survey of units within Great Britain and Ireland, there was a reported ratio of 0.3:1 to 2:1 after a uniform heparin dose of 300 IU/kg. In adult cardiac surgery, adverse reactions to the administration of protamine are common and include anaphylactic and anaphylactoid reactions as well as pulmonary hypertensive events. These reactions range from minor hypotensive events to fatal cardiovascular collapse. Although catastrophic events are rare, adverse events occur in up to 2.6% of adult patients.[173] Risk factors for adults include the use of protamine-containing insulin, previous drug reaction or exposure, vasectomy, rate of infusion, and allergy to protamine or fish. A study looking at the incidence in the pediatric population under16 years of age found that in a series of 1249 anesthesias, the incidence of hypotension that persisted for greater than 5 minutes was 1.76%. The authors noted that this might have included causes other than protamine reaction, due to the proximity to termination of CPB. Of interest in this study were the associated risk factors for hypotension, namely female sex, large dose of protamine, and small heparin doses.[174] Vigilance for pulmonary hypertension, hypoxemia, and cardiovascular collapse cannot be overemphasized at the time of protamine reversal.

Termination of Cardiopulmonary Bypass

To terminate CPB, a number of important criteria must be met. These must be identified and treated concomitantly at a time when the patients' clinical condition may be tenuous.

General Principles

Prior to the termination of CPB, an adequate cardiac rhythm must be established, and, if the native rhythm is inadequate either by rate or rhythm itself, the heart will need external stimuli in the form of atrial and/or ventricular epicardial pacing. The use of inotropic support will obviously depend on the case, the presence of preexisting myocardial dysfunction, and the duration of CPB. In the pediatric setting, this may take the form of dopamine, epinephrine, and milrinone, but under certain circumstances vasopressin may be necessary. Concomitant with this will be the reexpansion of the lungs and resumption of ventilation. It is important that the lungs are fully reexpanded, as atelectasis will lead not only to hypoxemia but also to direct compression of the pulmonary vascular bed. The combination of these two factors will lead to an increase in pulmonary vascular resistance and pulmonary artery pressure. In the neonate who already has an extremely reactive pulmonary bed, this may precipitate a spiral of increasing hypoxia, worsening pulmonary artery pressure, and subsequent right ventricular failure, which may necessitate placing the patient back onto CPB or even ECMO. The principles of preventing this phenomenon include adequate ventilation, ensuring adequate oxygenation, avoiding hypothermia, avoiding acidosis, the use of the phosphodiesterase inhibitor milrinone, and using inhaled nitric oxide as a direct pulmonary artery vasodilator.

Anatomical Considerations and the Use of Transesophageal Echocardiography

Essential to the termination of CPB is an anatomically sound repair. This is true from a simple repair such as a secundum atrial septal defect to the complexities of a stage I Norwood reconstruction for the single ventricle. The effects of CPB on the myocardium are well known. The longer the bypass time, the worse its effects of failure to establish electrical quiescence, unequal myocardial cooling, and ongoing inflammation may become. A myocardium recovering from these insults will not function well should there be residual outflow tract obstruction, abnormal coronary flow, or abnormal flow through intracardiac baffles. The role of the intraoperative transesophageal echocardiography (TEE) is vital in diagnosing these problems in patients who are difficult to wean from CPB or who are possibly more cyanotic than expected. In the early days of TEE, probe size limited use in small patients and neonates—precisely the group of patients undergoing the most complex of procedures. Fortunately, in recent years, probes have been developed that can be used in patients down to approximately 2.5 kg.[175] The incidence of post-CPB residual defects diagnosed by TEE that will go on to require a second CPB run is approximately 7% to 9.6%.[176-178] This is clearly a significant number of patients who might otherwise have required later reoperation or even postoperative emergent ECMO cannulation due to acute cardiac failure. Complications associated with passage of the TEE probe include failure to pass the probe, esophageal trauma that includes laceration or even perforation, airway compression, and hemodynamic compromise. The hemodynamic issues are related to compression of structures, including the ascending and descending aorta, left atrium, pulmonary artery and veins, and superior vena cava.[178] Fortunately, these more serious complications are rare. In a study of 22 patients between 2 and 5 kg who underwent TEE examination before and after CPB, no differences in lung function or arterial blood gas were found. In two patients, the probe was removed because of concerns about ventilation that were unrelated to the TEE probe. The aforementioned parameters did not change before or after the removal of the probe.[179]

Another study performed by the same authors, looking at hemodynamic parameters, found that there was an incidence of compromise in 1.7% of patients.[178] Despite the theoretical concerns in the smallest of patients, TEE examinations can be performed safely.

Hypothermia

If the procedure was performed at anything but normothermia, the patient needs to be rewarmed back to normal temperature. Hypothermia may result in a wide range of abnormalities. Experimental evidence suggests that hypothermia will result in a negative inotropic effect at the atrial level, an effect that may be detrimental at the termination of CPB, as normal atrial function is an important contributor of ventricular preload.[180] Hypothermic effects on ventricular function include bradycardia, heart block, reduction of fibrillation threshold, and increase in pacing threshold. These effects may occur even at moderate hypothermia.[174] Termination of CPB necessitates an adequate heart rate, which may require external pacing, and thus normothermia is vital. Another important problem related to hypothermia in the cardiac surgery patient is the effect that it has on bleeding. It appears that hypothermia will affect both platelet function and the coagulation cascade. The defect in platelet function is related an impaired release of thromboxane A_2 which is necessary for the formation of the platelet plug. Coagulation is affected by a temperature-dependent decrease in enzyme function. These effects may occur at even 1° to 2° C below normal.[181,182] Even if patients are normothermic on termination of CPB, for obvious reasons it is imperative to keep patients warm thereafter, as temperature may drift downwards soon after resumption of spontaneous circulation, placing them at risk once again.

Bleeding

The origins of the ongoing coagulopathy upon termination of bypass are multifactorial and include complement cascade activation due to CPB, therapeutic hypothermia as part of CPB, dilution, consumption of circulating clotting factors, and ongoing bleeding from the surgical site. Obviously, strategies to prevent blood loss must start at the beginning of CPB. These attempts focus on limiting hemodilution, the use of antifibrinolytic agents, and use of fresh whole blood in the prime volume.

The antifibrinolytics that have been used are the serine protease inhibitor aprotinin and the lysine analogs ε-aminocaproic acid and tranexamic acid. Aprotinin inhibits kallikrein and plasmin with resultant decrease in hemostatic activation, inhibition of fibrinolysis, inhibition of the inflammatory cascade, and preservation of platelet function. It is eliminated via the kidneys, reabsorbed in the proximal tubule, and then enzymatically broken down in phagolysosomes. Attempts have been made to establish the overall effects of the drug; this has been difficult, however, as published studies have included small groups of patients, nonheterogeneous groups, and inconsistent dosing. It does appear that there were trends toward less bleeding, improved transpulmonary pressure gradients suggesting decreased inflammation and capillary leak, improved myocardial function, and decreased postoperative ventilation.[183] As mentioned previously, problems were identified in adult cardiac patietns with respect to postoperative renal failure and thrombosis risk following aprotinin. This drug is no longer used, even in pediatric cardiac surgery, despite pediatric data which may suggest that there is no statistically significant renal failure, need for dialysis, worsened neurologic outcome, or mortality (early or late) in the pediatric group.[184-188] At this time, there is no plan to reintroduce the drug to market. The role of the lysine analogues has also long been studied. The mechanism of action is to interfere with the binding of plasminogen to fibrin that is necessary for the activation of plasminogen to plasmin. Both drugs are eliminated via the kidneys with terminal T½ of 2 hours. The apparent advantages in comparison to aprotinin include the lack of an immunological response, low cost, suggestion of platelet protection, and similar efficacy to aprotinin with respect to bleeding. A meta-analysis containing over 1000 patients found decreased bleeding in both cyanotic and acyanotic patients, decreased transfusion requirements, decreased sternal closure time, and improved reexploration rates with the use of the lysine analogues. In two of the reviewed articles there was no improvement in postoperative ventilation time, suggesting that these drugs have no

antiinflammatory effect.[183] In another meta-analysis including all three of the aforementioned drugs, the effect on bleeding was found to be similar comparing aprotinin to tranexamic acid with insufficient data to draw conclusions about the use of ε-aminocaproic acid.[189] In a further randomized study, the two lysine analogues were compared in a cohort of patients ranging in age from 2 months to 14 years, all with cyanotic heart disease. Both drugs had similar efficacy in decreasing postoperative blood loss as well as the use of blood products.[190]

Introduced into the adult world in the late 1980s with investigations in pediatrics in the early 1990s, the use of fresh whole blood in the priming volume (between 24 hours and 48 hours old) carried a theoretical advantage over stored blood or reconstituted blood (made of packed red cells, FFP, and platelets) in that the coagulation factors and platelets had little time to degrade due to cold storage, thus improving postbypass hemostasis. Other advantages cited by proponents are the decrease in systemic inflammation, manifested as decreased edema and improved organ function.[191] A study involving patients under 21 years of age with either cyanotic or acyanotic conditions had one group receive very fresh whole blood (less than 6 hours old), another group receive fresh whole blood, and a third group receive reconstituted blood. All subjects who required blood in the prime solution received whole blood. Once the heparin was reversed, any further bleeding and/or volume requirements were met with the assigned blood. It was found that patients who received the reconstituted blood had significantly more bleeding in comparison to the other two groups and that the most significant decrease in bleeding was in patients who were transfused fresh whole blood and were less than 2 years of age undergoing complex repairs. Another interesting finding from this was that despite theoretical advantages of the very fresh whole blood, there was no significant difference in bleeding between the two whole blood groups.[192] Further investigation into the question of fresh whole blood has looked at comparing reconstituted fresh whole blood versus banked blood and also into reconstituted blood versus fresh whole blood.[191,193] A head-to-head comparison of fresh whole blood versus reconstituted blood (packed red cells and FFP) in circuit prime had outcomes in favor of the reconstituted blood. Although there was no difference in chest tube output and requirements for transfusions between the two groups, the fresh whole blood was associated with increased perioperative fluid overload, increased ventilation, and prolonged ICU stay. The authors concluded that although the reconstituted blood group required more donor exposure (four donors as compared with three and a half in the fresh whole blood group), in their opinion the clinical hazards of fresh whole blood outweighed the risk of increased exposure. Despite these findings, there is ongoing debate and, as further research is performed into circuit size, this debate may be resolved by the use of asanguineous prime.[193] Proponents of fresh whole blood would also suggest that there is a decrease in bleeding observed when it is administered after CPB, on the basis of preservation of clotting factors and platelets in the fresh blood.

Ongoing bleeding despite the above strategies occurs after a wide variety of operations especially in patients with cyanotic heart disease, patients having long bypass times, after DHCA, and with operations that involve multiple suture lines. In these patients, it is useful to perform coagulation studies, platelet counts, and fibrinogen levels to better guide therapy. The problem, however, comes in that there are not many institutions that can perform these tests quickly enough so that the results are still clinically relevant. Ongoing bleeding is treated with packed red cells or fresh whole blood, with component therapy transfused as needed in the form of cryoprecipitate, platelets, or even FFP. Desmopressin (DDAVP) has been used because it decreases platelet dysfunction after CPB. Desmopressin will increase the release of von Willebrand factor (vWF) multimers and factor VIII from endothelial storage sites. Factor VIII levels increase immediately and levels of vWF peak in 30 to 60 minutes. The net effect in adults is to augment platelet adhesion and aggregation.[194] Comparable results have not been seen in pediatric patients, with studies finding no improvement in coagulation in patients who have been given the medication as a prophylactic measure.[194,195]

In patients who continue to bleed despite attempts to correct coagulopathy with blood products, recombinant factor VII may be administered. Unfortunately, as with many drugs, pediatric dosing is extrapolated from adults. The dose thus is between 90 and 120 μg/kg, given every 2-3 hours. Studies have demonstrated that the half-life of factor VII in pediatrics may be half of that in the adult and that clearance is faster, suggesting the need for higher doses.[196] It has also been suggested that transfusion of coagulation factors, fibrinogen, and platelets prior to the administration of factor VII may also affect the dosing regimen.[196] Pediatric experience has suggested it to be extremely efficacious but with some limitations and potential complications. The cost is extremely high, with a 1- to 2-mg vial costing around $1000, and with some patients obviously requiring more than just the one vial. The other concerns surround clot formation and thrombosis. Case reports have described mediastinal clot formation that in some cases has required emergency evacuation.[197] Recombinant factor VII has also been used successfully in patients with intractable bleeding on ECMO. In this subgroup of patients, there is obviously concern for circuit thrombosis that would have catastrophic consequences and it has been suggested that the dosing be reduced to 30 to 50 μg/kg.[196] Yet another study has demonstrated no complications using the standard dose of 90 to 120 μg/kg in a group of ECMO patients.[198] Despite its very important place in the management of the post-CPB patient, there is still much investigation around the use of this drug with respect to remain questions about optimal dosing and administration interval.

Modified Ultrafiltration

The net effect of the proinflammatory state caused by CPB is a capillary leak, increase in total body water, and edema formation. This phenomenon, although affecting the entire body, will be especially problematic for the lungs, myocardium, and brain. Pulmonary compliance will decrease, and the end result of myocardial edema is both systolic and diastolic dysfunction.[199,200] First described in 1991 by Naik and colleagues, modified ultrafiltration (MUF) was formulated to improve the removal of this excess body fluid after the termination of CPB. These authors described that their new technique was better able to remove body water and elevate hematocrit when compared to conventional ultrafiltration that is employed while the patient is still on bypass.[201] The perfusionist employs a number of forms of filtration, during and after CPB, all of which are aimed at limiting the inevitable increase in total

body water, as well as removal of electrolytes and inflammatory mediators. Prime ultrafiltration (PUF) is used when packed red cells are added to the prime volume. The aim of this filtration technique is to prevent unfavorable electrolyte elevations associated with stored blood, increase the pH toward the physiologic range, and decrease the inflammatory response.[202] Conventional ultrafiltration (CUF) is employed throughout CPB, with a common use being the removal of extra volume and electrolytes added to the circuit after the use of cardioplegia. In zero-balance ultrafiltration (ZBUF), crystalloid is added to the circuit at the time of ultrafiltration. A complication of ultrafiltration during CPB is depletion of the venous reservoir volume, and thus ZBUF is an attempt to counter this hypovolemia. Dilutional ultrafiltration is the last method of ultrafiltration used with the patient on CPB. The aim of this method is the dilution of a given electrolyte whose concentration is elevated. Dilution is achieved by the addition of hypotonic fluid (e.g., half-normal saline) into the circuit at the time of the ultrafiltration. The common goal of these methods is removal of excess free water and inflammatory mediators and maintaining the hematocrit at a safe level during CPB.

Since the description of the technique of MUF, studies have shown that it improves both cardiac and pulmonary function, increases hematocrit, and removes inflammatory mediators, and that these effects are more potent than with other ultrafiltration techniques. The technique of MUF includes the following modifications to the CPB circuit upon weaning from bypass. A clamp is applied which functionally disconnects the venous line from the venous reservoir. A line is then brought up to connect the ultrafilter directly onto the venous line (as shown in Figure 30-5). A roller pump is then interposed between the blood source and the filter to ensure blood moves toward the patient at a rate of approximately 200 mL/min. Suction is also applied to the filter at about −125 mm Hg to achieve a filter rate of approximately 100 to 150 mL/min.[203,204] Saline is used to chase the blood still in the venous reservoir through the circuit (allowing reinstitution of CPB, if necessary) and also to maintain right atrial filling pressure at the desired level. The end points are time (usually 15 to 20 minutes), the desired hematocrit of at least 40%, replacement of the venous reservoir with crystalloid, or the patient's inability to tolerate the procedure.

Box 30-9 shows the positive effects of MUF. The advantages of MUF with respect to cardiac function have been studied across the spectrum of patients.[203,206] The improvement in myocardial performance appears to result from a reduction of myocardial edema. It has been shown that after MUF there is an increase in systolic function coupled with an increase in end-diastolic length and a decrease in end diastolic pressure. These improvements in diastolic function indicate improvement in left ventricular compliance.[203] This is in agreement with earlier clinical observations made by Naik and his team in their original description. They observed that there was a universal rise in blood pressure and an apparent decrease in the myocardial dimension.[202] Overall, MUF leads to improved left and right heart function. MUF has been shown to also improve pulmonary vascular resistance, even in those patients who had elevated pulmonary pressure in the preoperative phase, an effect that lasts into the postoperative phase.[204,205] The patient with single-ventricle physiology is potentially at risk during the process of MUF because blood is drawn away from the aorta and coronaries as well as from pulmonary flow (in those patients with a modified Blalock-Taussig shunt). In a study by Gaynor and colleagues, however, this was shown to be a safe procedure after the Norwood procedure, with similar improvements in myocardial function as noted earlier.[206]

Improving pulmonary function is important not only for myocardial function but for ventilation and oxygenation,

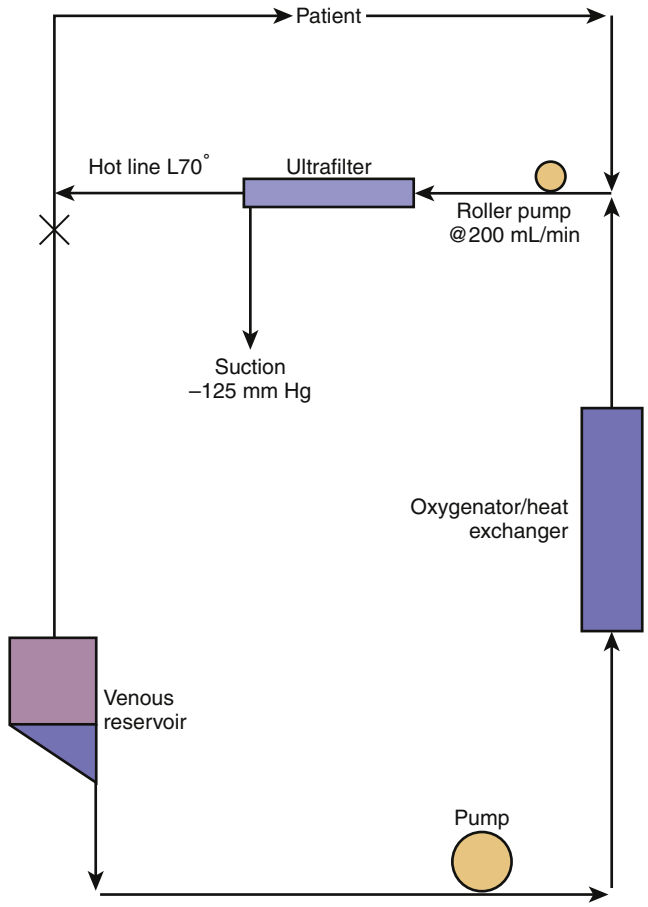

Figure 30–5. Setup for modified ultrafiltration. *(Modified from Davies MJ, Nguyen K, Gaynor JW, et al: Modified ultrafiltration improves left ventricular systolic function in infants after cardiopulmonary bypass,* J Thorac Cardiovasc Surg *115:316-370, 1998.)*

Box 30–9 Effects of Modified Ultrafiltration

General effects
- ↓ Total body water
- ↓ Inflammatory markers

Cardiac effects
- LV: improved systolic and diastolic function
- RV: improved function due to ↓ pulmonary arterial pressure

Pulmonary effects
- ↓ Interstitial water
- ↑ Compliance
- ↑ Ventilation/oxygenation
- ↓ Pulmonary artery pressure

Hematological effects
- ↑ Clotting factors/fibrinogen
- ↑ Plasma protein
- ↓ Transfusion requirements

translating into a decreased need for postoperative mechanical ventilation. Pulmonary dysfunction after CPB is manifest as lowered compliance, increased pulmonary vascular resistance, and a decrease in gas exchange. This pulmonary dysfunction is caused by hemodilution that decreases plasma oncotic pressure, resulting in an increase in interstitial fluid. This is coupled with the atelectasis that occurs secondary to absence of ventilation during CPB. Furthermore, the lung is obviously ischemic during bypass, which leads to the production of oxygen free radicals once the lung is reperfused. Lastly, other factors such as hypothermia and foreign body contact of blood with the CPB circuit result in the release of inflammatory mediators that may further worsen pulmonary damage.[204] The effects of MUF are thus secondary to a decrease in interstitial fluid, which in turn leads to increased pulmonary compliance, improved oxygenation, and a decrease in pulmonary artery pressure. All these positive factors will also lead to improvement of right ventricular function.[204,205] MUF has also been shown to improve the coagulopathy associated with CPB and to decrease transfusion requirements. CPB will lead to a hemodilutional state that affects hematocrit and coagulation factors, as well a separate effect on platelet number and function. The effect of MUF will lead to an increase in hematocrit (which in patients with single ventricle physiology will improve oxygen saturation and oxygen-carrying capacity) and improvements in the level of coagulation factors by clearing the dilutional volume. This will in turn lead to improved coagulation, decreased bleeding, and a decrease in blood requirements. These effects have been shown in neonates and in those with prolonged CPB, two groups associated with increased bleeding. Despite these obvious advantages, MUF has no effect on platelets.[204-208]

Creation of a superior cavopulmonary anastomosis and Fontan completion will increase venous pressure. This is the primary etiological association found in a subgroup of these patients who develop postoperative pulmonary or pericardial effusions. In an early study looking in to the effect of MUF on associated morbidities, it was found that there was a significant reduction in effusions. The difference was found to be most significant in the Fontan group where the incidence was 48.5% in the control group versus 10.5% in the MUF group. In those patients undergoing cavopulmonary anastomosis, 11.5% of those in the control group had effusions versus 4.9% in the MUF group.[208] The morbidity and mortality associated with ongoing effusions include chronic hypoxia and ongoing protein loss resulting in anasarca and immune suppression. These findings have been supported by other studies.[205,209] Clearly, the use of MUF plays an important role in decreasing this morbidity and mortality. Recent advances have also included the creation of a fenestration in the Fontan baffle that serves as a pressure release from the now high-pressure venous system into the atrial chamber.

The systemic inflammatory response that is generated by CPB can prove deleterious to organ function. Huang et al. showed that the use of continuous ultrafiltration and MUF will lead to a decrease in the concentration of IL-6 but had no effect on endothelin-1 (ET-1).[210] Contrary to this study, Bando and colleagues showed that a combination of dilutional ultrafiltration with MUF will result in a decrease in ET-1, thus decreasing the pulmonary/systemic pressure ratio and also reducing ventilatory requirements.[211] In a third study, the addition of a polysulfone ultrafilter to the MUF circuit for both conventional ultrafiltration and MUF improved the removal of IL-6 and tumor necrosis factor.[212]

Despite all these positive effects of MUF, there are important safety concerns. These include inadvertent cooling during the procedure; hypotension if too much blood is drawn off via the arterial line; and varying technical difficulties with the circuit, such as air cavitating out of solution in the arterial line, clotted MUF circuit, and exsanguination due to unclamping of the oxygenator circuit.

The effect of hypoperfusion/reperfusion has the potential to cause a breakdown in the normal gastrointestinal mucosal barrier. The translocation of endotoxins into the bloodstream may result in hypotension, fever, hypermetabolism, tissue damage, and coagulopathy, all factors that can cause problems as patients are being weaned from CPB. In a study by Yngaard et al.,[213] it was found that the endotoxin load significantly increased during cardiopulmonary bypass, peaking at the end of CPB. The use of MUF significantly decreased the load from 24.2 ng at the peak to 9 ng after MUF, with the majority of the load found in the ultrafiltrate. In a separate study quoted by these authors, it was found that an endotoxin load greater than 4 ng/kg may depress myocardial function. The conclusion of the study was that despite not fully removing the endotoxin load, MUF may aid in the modification of the inflammatory response seen.[213]

The use of MUF has become standard in congenital cardiac surgery. In most centers, patients undergo continuous ultrafiltration in one form or another during CPB, and MUF is performed on weaning from bypass.

Delayed Sternal Closure

In some patients, there is an apparent period of hemodynamic and ventilatory stability that is followed by instability of varying degrees upon sternal closure. This may necessitate that the sternum remain open for a period ranging from a few hours up to a few days. This is achieved by placing a tube strut between the two sternal edges (a rigid tube, e.g., a size 4 to 5 mm ETT may suffice) and then closing the skin with a Gore-Tex patch. Concerns for this technique are obviously the risk of infection, tamponade due to inadequate drainage, and the inability to perform standard CPR in the face of cardiopulmonary arrest. Sternal closure can subsequently be achieved either in the ICU or in the operating room. At the Children's Hospital of Philadelphia, this is routinely performed in the ICU with good results.

Conclusions

The management of the cardiac surgery patient has improved greatly over the past 6 decades, with patients who as little as 30 years ago would have had no management options now living and sometimes thriving into adulthood. The treatment and successful outcomes of these potentially complex patients is dependent on a team approach. The management often begins in the ICU or cardiologist's office and runs the full spectrum of anesthesia, perioperative nursing, perfusionists, surgeons, and intensivists. Looking forward over the next decade, the questions of circuit miniaturization, neurocognitive outcome, and intrauterine interventions will be in the forefront of research.

Critical Care After Surgery for Congenital Cardiac Disease

Alexandre T. Rotta, Peter C. Laussen, and David L. Wessel

PEARLS

- Echocardiography is the preferred imaging modality for assessment and delineation of intracardiac anatomic features before surgery in children. Accurate anatomic diagnosis is now routine, so most children can have surgery without preoperative cardiac catheterization.
- A typical and predictable decrease in cardiac index typically occurs 6 to 12 hours after separation from cardiopulmonary bypass.
- Milrinone administered during the early postoperative period plays a significant role in decreasing the likelihood of low cardiac output syndrome.
- Patients with restrictive physiology from hypertrophy and diastolic dysfunction of the right ventricle, such as those after tetralogy of Fallot repair, require high right-sided filling pressures to achieve adequate cardiac output. Consequently, these patients are more prone to hepatic congestion, anasarca, pleural effusions, and ascites.
- Inhaled nitric oxide plays an important role in the management of postoperative pulmonary hypertension in the cardiac intensive care unit. It is particularly effective in the postoperative course of patients with venous hypertensive disorders, such as total anomalous pulmonary venous connection and congenital mitral stenosis.
- Hyperglycemia is a frequent occurrence in the cardiac intensive care unit and has been associated with increased morbidity and mortality during the postoperative period. Careful glycemic control with insulin administration might improve outcomes, but one must be aware of the risk of iatrogenic hypoglycemia.
- Hypoxemia after bidirectional cavopulmonary anastomosis generally is a sign of decreased cardiac output, is poorly responsive to nitric oxide, and tends to improve with maneuvers that increase venous return through the superior vena cava, such as head elevation and controlled hypoventilation/mild hypercapnia.
- Liberation from positive pressure mechanical ventilation should be accomplished as soon as feasible in patients after a Fontan operation, because spontaneous breathing improves pulmonary blood flow, arterial oxygen saturation, and ventricular preload.
- Ventricular ectopy and elevated atrial pressures after the arterial switch operation should raise suspicion of myocardial ischemia from insufficient coronary blood flow.
- Postoperative care of the patient with hypoplastic left heart syndrome after stage I palliation (Norwood procedure) requires adequate balancing of the pulmonary and systemic blood flows. A high arterial oxygen saturation denotes excessive pulmonary blood flow and is generally accompanied by decreased systemic blood flow, acidosis, and end-organ dysfunction.

Congenital anomalies account for the largest diagnostic category among causes of infant mortality in the United States.[1] Structural heart disease leads the list of congenital malformations. Of the more than 4 million children born each year in the United States, nearly 40,000 have some form of congenital heart disease (CHD). Approximately half of these children appear for therapeutic intervention within the first year of life, and the vast majority of them require critical care expertise. Patients with congenital or acquired heart disease compose a major diagnostic category for admissions in large pediatric intensive care units (ICUs) across the country, representing 30% to 40% or more of ICU admissions in many centers.

Newborn Considerations

Care of the critically ill neonate requires an appreciation of the special structural and functional features of immature organs, the interactions of the "transitional" neonatal circulation, and the secondary effects of the congenital heart lesion on other organ systems.[2-4] The neonate appears to respond more quickly and profoundly to physiologically stressful circumstances, which may be expressed in terms of rapid changes in pH, lactic acid, blood glucose, and temperature. Neonates have diminished fat and carbohydrate reserves compared with older children. The higher metabolic rate and oxygen consumption of the neonate play a significant role in

the rapid onset of hypoxemia when these patients become apneic. Immaturity of the liver and kidney may be associated with reduced protein synthesis and glomerular filtration such that drug metabolism is altered and hepatic synthetic function is reduced. These issues may be compounded by the normal increased total body water of the neonate compared with the older patient, along with the propensity of the capillary system of the neonate to leak fluid from the intravascular space. This is especially prominent in the lung of the neonate in whom the pulmonary vascular bed is nearly fully recruited at rest, and lymphatic recruitment required to handle increased mean capillary pressures associated with increases in pulmonary blood flow may be unavailable.[4] The neonatal myocardium is less compliant than that of the older child, is less tolerant of increases in afterload, and is less responsive to increases in preload. Younger age also predisposes the myocardium to the adverse effects of cardiopulmonary bypass (CPB) and hypothermic ischemia implicit in support techniques used during cardiac surgery. These factors do not preclude intervention in the neonate but simply dictate that extraordinary vigilance be applied to the care of these children and that intensive care management plans take into account their immature physiology.

The observed benefits of neonatal reparative operations in patients with two ventricles are numerous (Box 31-1). They continue to dictate that care of the newborn with complex CHD after CPB be a central feature of cardiac intensive care. Elimination of cyanosis and congestive heart failure (CHF) early in life optimize, conditions for normal growth and development. Palliative procedures such as pulmonary artery bands and systemic-to-pulmonary artery shunts may not fully address cyanosis or CHF and may introduce their own set of physiologic and anatomic complications. Some examples of improved outcomes with a single reparative operation rather than staged palliation as a newborn are well known, are supported by published literature, and evoke little controversy. Approaches that have been abandoned include banding the pulmonary arteries in truncus arteriosus,[5] staging repair of type B interrupted aortic arch (IAA),[6] and staging rather than repairing in a single session transposition of the great arteries with IAA.[7] In other conditions (e.g., severely cyanotic newborn with tetralogy of Fallot [TOF]), the risks and benefits of neonatal repair versus a palliative shunt are debatable.[8]

Whereas the neonate may be more labile than the older child, there is ample evidence that this age group is more resilient in its response to metabolic or ischemic injury. In fact, the neonate may be particularly capable of coping with some forms of stress. Tolerance of hypoxemia in the neonate is characteristic of many species,[9] and the plasticity of the neurologic system in the neonate is well known. Neonates with obstructive left heart lesions often present with profound metabolic acidosis but can be effectively resuscitated without persistent organ system impairment or sequelae as the rule rather than the exception. The pliability and mobility of vascular structures in the neonate improve the technical aspects of surgery. Reparative operations in neonates take advantage of normal postnatal changes, allowing more normal growth and development in crucial areas such as myocardial muscle, pulmonary parenchyma, and coronary and pulmonary angiogenesis. Postoperative pulmonary hypertensive events are more common in the infant who has been exposed to weeks or months of high pulmonary pressure and flow.[5,10] This seems especially true for such lesions as truncus arteriosus, complete atrioventricular (AV) canal defects, and transposition of the great arteries with ventricular septal defects (VSDs). Finally, cognitive and psychomotor abnormalities associated with months of hypoxemia or abnormal hemodynamics may be diminished or eliminated by early repair. However, if early reparative surgery results in more exposures to CPB (e.g., repeated conduit changes) and any associated cognitive or subtle adverse effects on motor function, then the risk-to-benefit assessment needs to be modified accordingly.

Box 31–1 Advantage of Neonatal Repair

Early elimination of cyanosis
Early elimination of congestive heart failure
Optimal circulation for growth and development
Reduced anatomic distortion from palliative procedures
Reduced hospital admissions while awaiting repair
Reduced parental anxiety while awaiting repair

Preoperative Care

Optimal preoperative care involves (1) initial stabilization, airway management, and establishment of adequate vascular access; (2) complete and thorough noninvasive delineation of the anatomic defect(s); (3) evaluation and treatment of secondary organ dysfunction, particularly the brain, kidneys, and liver; (4) cardiac catheterization if necessary, typically for (A) physiologic assessment, (B) interventional procedures such as balloon atrial septostomy or valvotomy, or (C) anatomic definition not visible by echocardiography (e.g., coronary artery distribution in pulmonary atresia with intact ventricular septum or delineation of aortopulmonary collaterals in TOF with pulmonary atresia); and (5) surgical management when cardiac, pulmonary, renal, and central nervous systems (CNS) are optimized.

Physical Examination and Laboratory Data

A complete history and physical examination are required, with special attention directed to the extent of cardiopulmonary impairment, airway abnormalities, and associated extracardiac congenital anomalies.[11] Intrathoracic and extrathoracic airway problems in patients with Down syndrome, disorders of calcium homeostasis and immunologic deficiencies in patients with aortic arch abnormalities, and renal abnormalities in patients with esophageal atresia and CHD are a few of the associated congenital abnormalities with which the anesthesiologist should be familiar. Intercurrent pulmonary infection is a common and significant finding in chronically overcirculated lungs. The presence, degree, and duration of hypoxemia are important details that, in the absence of iron deficiency, are reflected in the hematocrit. The nadir of physiologic anemia during infancy may contribute to left-to-right shunting by decreasing the relative pulmonary vascular resistance (PVR).[12]

Chest radiography can be used to asses heart size, pulmonary vascular congestion, airway compression, and areas of consolidation or atelectasis. The electrocardiogram (ECG) may reveal rhythm disturbances and demonstrate ventricular

strain patterns (ST and T-wave changes) characteristic of unphysiologic pressure or volume burdens on the ventricles. Electrolyte abnormalities caused by CHF and forced diuresis also must be evaluated preoperatively. Severe hypochloremic metabolic alkalosis may occur in some patients. It is important to discontinue digoxin preoperatively and to avoid hyperventilation and administration of calcium to these patients during induction of anesthesia, because the alkalotic hypokalemic, hypercalcemic, hypotensive, dilated, digoxin-bound myocardium fibrillates with ease.

Echocardiographic and Doppler Assessment

Advances in echocardiographic imaging have had an enormous impact on the diagnosis of CHD.[13] Accurate anatomic diagnosis now is routine in children without the need for cardiac catheterization. Echocardiography is the preferred imaging modality for assessment of intracardiac anatomic features in young children. However, one should be aware of the current limitations of echocardiographic and Doppler techniques so that alternative diagnoses can be considered when intraoperative or postoperative findings are inconsistent with the working echocardiographic diagnosis.

Skilled echocardiographers accurately interpret the alignment of cardiac chambers and great vessels but cannot always visualize an atrial septal defect (ASD) or VSD, although color flow mapping techniques have vastly improved diagnostic capabilities. An ASD can be indirectly inferred from right ventricular (RV) volume overload and interventricular septal shift. Distal pulmonary artery architecture and conduits between a ventricle and a great artery are poorly imaged by echocardiography, and pressure gradients in these areas are not always measurable with Doppler techniques. Quantification of AV valve regurgitation may be subjective and nonquantitative. Accuracy of echocardiographic diagnosis is limited by an inadequate window for imaging in obese patients, older children, and some postoperative patients. Techniques for three-dimensional echocardiography that may improve diagnostic capabilities, such as defining the mechanism of valve regurgitation or visualization of complex anatomic features, are now available and are gradually gaining popularity among selected services.

Doppler measurements add greatly to noninvasive diagnostic capabilities. Measurements of pressure gradients across semilunar valves and other obstructions frequently are accurate but may not always correlate with peak systolic ejection gradients measured at catheterization. As good as echocardiographic diagnosis of anatomic defects and Doppler measurements of pressure gradients and valve function have become, the standard for assessment of physiology when other clinical information is ambiguous or contradictory remains cardiac catheterization.

Cardiac Catheterization

When echocardiographic analysis with Doppler measurements and color flow mapping is complete and unambiguous, preoperative assessment may no longer require cardiac catheterization. Catheterization typically is not performed before infant or neonatal operations for VSDs, complete AV canal defects, TOF, IAA, hypoplastic left heart syndrome (HLHS), or coarctation of the aorta. However, in older patients with complex anatomy, such as a single ventricle, physiologic data from catheterization may be essential. This technique allows description of the direction, magnitude, and approximate location of intracardiac shunts. Intracardiac and intravascular pressures are measured to determine the presence of obstructions and whether shunt orifices are restrictive or nonrestrictive. Pressure gradients across sites of obstruction must be considered in light of simultaneous blood flow; a small pressure gradient measured at a time of low cardiac output is misleading.

Normal intracardiac pressure and saturation values in children are described in Chapter 24. Normally, there is no significant change in oxygen saturation from vena cava to pulmonary artery. In the child with CHD, the superior vena cava (SVC) gives the best indication of true mixed venous oxygen saturation; a 5% or greater step-up in saturation downstream suggests the presence of a left to right shunt.[14] It would occur at the level of the right atrium with an ASD, in the right ventricle with a VSD, and in the pulmonary artery with a patent ductus arteriosus (PDA). The magnitude of the left-to-right shunt can be calculated from the Fick equation. The oxygen consumption of the patient usually is measured, as are the saturation values, but subsequent flow and resistance calculations can be in error. The frequently used term Q_p/Q_s (pulmonary-to-systemic blood flow ratio) can be derived simply from the measured oxygen saturation values.

The patient whose aortic blood is fully saturated can be safely assumed to have no significant right-to-left shunting. However, when a right-to-left shunt is present, aortic blood is hypoxemic. Blood samples should also be obtained from the pulmonary veins, left atrium, and left ventricle for oxygen saturation determination and ascertainment of the source of desaturated blood. Pulmonary venous desaturation implies a pulmonary source of venous admixture (e.g., pneumonia, atelectasis, other pulmonary disease). Intrapulmonary shunting may substantially alter the anesthetic plan and the postoperative ventilatory requirements of the patient.

In the presence of a left-to-right shunt and elevated PVR, pressure and saturation measurements often are repeated, with the patient breathing 100% oxygen to assess both the reactivity of the pulmonary vascular bed and any contribution of ventilation-perfusion abnormalities to hypoxemia. If breathing 100% oxygen increases pulmonary blood flow and dramatically increases Q_p/Q_s (with a fall in PVR), potentially reversible processes such as hypoxic pulmonary vasoconstriction probably are contributing to the elevated PVR. The patient with a high, unresponsive PVR and a small left-to-right shunt despite a large shunt orifice may have extensive pulmonary vascular damage from irreversible obstructive pulmonary vascular disease. If so, surgical repair usually is contraindicated if the child is older than 1 year.[15]

During cardiac catheterization, anatomic abnormalities are identified angiographically. Special angled views provide specific information about the location and extent of congenital defects.[16] Ventricular function is assessed angiographically and physiologically (e.g., by pressure measurements). The calculated size of a cardiac chamber may have an important bearing on its ability to support the circulation of a child with hypoplastic ventricles.

Magnetic Resonance Imaging and Angiography

Magnetic resonance imaging (MRI) and magnetic resonance angiography (MRA) have emerged as important diagnostic modalities in the evaluation of the cardiovascular system after the development of ECG-gated MRI. Image acquisition is triggered to the patient's ECG to counter motion artifacts and to acquire cine sequences that allow imaging of cardiac structures and visualization of blood flow throughout the cardiac cycle. In addition to providing excellent anatomical and three-dimensional images, particularly of the pulmonary veins and thoracic aorta, it also is possible with MRA to qualitatively assess valve and ventricular function and to quantify flow, ventricular volume, mass, and ejection fraction.[17,18] Whereas ferromagnetic implants near the region of interest might produce artifact, sternal wires and vascular clips produce relatively minor disturbances; therefore MRI can be performed in patients who have undergone previous cardiac surgery. Contraindications include patients with pacemakers, recently implanted endovascular or intracardiac implants, and aneurysm clips on vessels that will be exposed directly to the magnetic field.

Assessment of Patient Status and Predominant Pathophysiology

Frequently, congenital heart defects are complex and can be difficult to categorize or conceptualize. Rather than trying to determine the management for each individual anatomic defect, a physiologic approach can be taken. The following questions should be asked:

1. How does the systemic venous return reach the systemic arterial circulation to maintain cardiac output? What intracardiac mixing, shunting, or outflow obstruction exists?
2. Is the circulation in series or parallel? Are the defects amenable to a two-ventricle or single-ventricle repair?
3. Is pulmonary blood flow increased or decreased?
4. Is there a volume load or pressure load on the ventricles?

Appropriate organization of preoperative patient data, preparation of the patient, and decisions about monitoring, anesthetic agents, and postoperative care are best accomplished by focusing on a few major pathophysiologic problems, beginning with whether the patient is cyanotic, in CHF, or both. Most pathophysiologic mechanisms in the patient's disease that are pertinent to the perioperative plan and to optimal preparation of the patient focus on one of the following major problems: severe hypoxemia, excessive pulmonary blood flow, CHF, obstruction of blood flow from the left heart, and poor ventricular function. Although some patients with CHD present with only one problem, many have multiple interrelated problems.

Severe Hypoxemia

Many of the cyanotic forms of CHD present in the ICU with severe hypoxemia (Pao_2 <50 mm Hg) during the first few days of life, but without respiratory distress. Infusion of prostaglandin E_1 (PGE_1) in patients with decreased pulmonary blood flow maintains or reestablishes pulmonary flow through the ductus arteriosus. This may also improve mixing of venous and arterial blood at the atrial level in patients with transposition of the great arteries.[19] Consequently, neonates rarely require surgery while they are severely hypoxemic. During preoperative preparation with PGE_1, neurologic examination and blood chemistry analysis of renal, hepatic, and hematologic function are necessary to assess the effects of severe hypoxemia during or after birth on end-organ dysfunction.

Cyanotic patients who present for surgery after infancy require adequate preoperative and postoperative hydration to prevent the thrombotic problems caused by polycythemia. Adequate quantities of blood products for treatment of the coagulopathies also are needed, as outlined earlier. Premedication must be given cautiously so as not to cause hypoventilation in these patients.

PGE_1 dilates the ductus arteriosus of the neonate with life-threatening ductus-dependent cardiac lesions and improves the patient's condition before surgery. PGE_1 can reopen a functionally closed ductus arteriosus for several days after birth, or it can maintain patency of the ductus arteriosus for several months postnatally.[19,20] The common side effects of PGE_1 infusion—apnea, hypotension, fever, CNS excitation—are easily managed in the neonate when normal therapeutic doses of the drug (0.02–0.05 μg/kg/min) are used.[21] However, PGE_1 is a potent vasodilator, so intravascular volume frequently requires augmentation. Patients with intermittent apnea resulting from administration of PGE_1 may require mechanical ventilation preoperatively.

PGE_1 usually improves the arterial oxygenation of hypoxemic neonates who have poor pulmonary perfusion as a result of obstructed pulmonary flow (critical pulmonic stenosis or pulmonary atresia). By providing pulmonary blood flow from the aorta via the ductus arteriosus, an infusion of PGE_1 improves oxygenation and stabilizes the condition of neonates with these lesions. The improved oxygenation reverses the lactic acidosis that may have developed during episodes of severe hypoxia. PGE_1 administration for 24 hours usually markedly improves the condition of a severely hypoxemic neonate with restricted pulmonary blood flow.[22]

Excessive Pulmonary Blood Flow

Excessive pulmonary blood flow is frequently the primary problem of patients with CHD. The intensivist must carefully evaluate the hemodynamic and respiratory impact of left-to-right shunts and the extent to which it contributes to the perioperative course in the ICU. Children with left-to-right shunts may have chronic low-grade pulmonary infection and congestion that cannot be eliminated despite optimal preoperative preparation. If so, surgery should not be postponed further. Respiratory syncytial viral infections are particularly prevalent in this population, but improvements in intensive care have markedly improved outcome with this and other viral pneumonias.[23]

Aside from the respiratory impairment caused by increased pulmonary blood flow, the left heart must dilate to accept pulmonary venous return that might be several times normal. If the body requires more systemic blood flow, the heart responds inefficiently. Most of the increment in cardiac output is recirculated to the lungs. Eventually, symptoms of CHF appear.

Children with failing hearts increase endogenous catecholamine production and redistribute cardiac output to favored organs by their increased heart rate and decreased extremity perfusion. In the most severe cases, the evaluation reveals a child whose body weight is below the third percentile for

age and who is tachypneic, tachycardic, and dusky in room air. The child may have intercostal and substernal retractions and skin that is cool to the touch. Capillary refill may be prolonged. Expiratory wheezes usually are audible. Medical management with digoxin and diuretics may improve the patient's condition, but the diuretics may induce profound hypochloremic alkalosis and potassium depletion that often persist after surgery.

Obstruction of Left Heart Outflow

Patients who require surgery to relieve obstruction to outflow from the left heart are among the most critically ill children for whom the intensivist must care. These lesions include interruption of the aortic arch, coarctation of the aorta, aortic stenosis (AS), and mitral stenosis or atresia as part of the HLHS. These neonates present with inadequate systemic perfusion and profound metabolic acidosis. The initial pH may be below 7 despite a low $Paco_2$. Systemic blood flow is largely or completely dependent on blood flow into the aorta from the ductus arteriosus.

Ductal closure in the neonate with these problems causes dramatic worsening of the patient's condition. The patient becomes critically ill or even moribund and requires PGE_1 infusion (see previous section) for survival. PGE_1 allows blood flow into the aorta from the pulmonary artery because it maintains the patency of the ductus arteriosus.[22,24] PGE_1 infusion improves perfusion and metabolism in neonates with acidosis, metabolic derangements, and renal failure because of inadequate systemic perfusion, so surgery generally can be deferred until the patient's condition improves. Ventilatory and inotropic support and correction of metabolic acidosis, along with calcium, glucose, and electrolyte abnormalities are often indicated preoperatively. The stabilization period also allows assessment of the magnitude of end-organ dysfunction caused by the preceding period of inadequate systemic perfusion. Adequacy of resuscitation, rather than severity of illness at presentation, appears to influence postoperative outcome.[25]

Ventricular Dysfunction

Ideally, the intensivists should participate in the care of all preoperative patients who have a planned admission to the ICU. Understanding the extent of ventricular dysfunction preoperatively provides considerable insight into intraoperative and postoperative events. Although patients with large shunts may have complete mixing of systemic and venous blood and only mild-to-moderate hypoxemia as a result of their excessive pulmonary blood flow, the price paid for near-normal arterial oxygen saturation is chronic ventricular dilation and dysfunction and pulmonary vascular obstructive disease. Consequently, narrowing the shunt or a staged approach to single-ventricle repair may be indicated before any other elective surgery can be undertaken. Older patients with CHD and poor ventricular function as a result of chronic ventricular volume overload (aortic or mitral valve regurgitation or long-standing pulmonary-to-systemic arterial shunts) present a different problem, amenable to some extent by afterload reduction. However, in all of these circumstances, when the heart is dilated and volume overloaded, there is a propensity for ventricular fibrillation during sedation, anesthesia, and/or intubation of the airway.

Assessment should include an estimation of the patient's functional limitation as an indicator of myocardial performance and reserve, quantification of the degree of hypoxia and the amount of pulmonary blood flow, and evaluation of PVR. For patients with increased Q_p/Q_s, systemic blood flow should be optimized without further augmenting pulmonary flow during induction of anesthesia in the ICU or in the operating room. However, during maintenance and emergence from anesthesia, retraction of the lung, positional changes, and abdominal distension may increase the hypoxemia and compromise the function of a dilated, poorly contractile ventricle. If this sequence occurs during surgery, patient management must be altered to improve pulmonary blood flow.

In addition, systolic function of the ventricle may be impaired by intrinsic myopathic abnormalities related to drug toxicity (e.g., doxorubicin [Adriamycin]), inborn enzyme deficiencies, or acquired inflammatory or infectious disease. Patients with such dilated cardiomyopathies require optimization of ventricular performance with emphasis on inotropic support and afterload reduction. In many centers, these patients are admitted to the ICU for inotropic support and optimization of hemodynamic state before a planned surgical intervention.

Postoperative Care

Assessment

When the clinical course of patients after cardiac surgery deviates from the usual expectation of uncomplicated recovery, our first responsibility is to verify the accuracy of the preoperative diagnosis and the adequacy of surgical repair. For example, a young infant who is acidotic, hypotensive, and cyanotic after surgical repair of TOF may tempt us to ascribe these findings to the vagaries of ischemia/reperfusion injury of CPB or transient, postoperative stiffness of the right ventricle. However, the real culprit may be an additional VSD undetected preoperatively and therefore not closed, a residual VSD around the surgical patch, or residual RV outflow obstruction. Any of these anatomic issues and more can produce serious adverse outcomes. Getting the right postoperative assessment is imperative and treatment follows accordingly. Evaluation of the postoperative patient relies on examination, monitoring, interpretation of vital signs, or other bedside data and imaging (Box 31-2). When the accuracy of the diagnosis and adequacy of the repair are established, then a low cardiac output

Box 31–2 Ten Intensive Care Strategies to Diagnose and Support Low Cardiac Output States

1. Know in detail the cardiac anatomy and its physiologic consequences
2. Understand the specialized considerations of the newborn and implications of reparative rather than palliative surgery
3. Diversify personnel to include experts in neonatal and adult congenital heart disease
4. Monitor, measure, and image the heart to rule out residual disease as a cause of postoperative hemodynamic instability or low cardiac output
5. Maintain aortic perfusion and improve the contractile state
6. Optimize preload (including atrial shunting)
7. Reduce afterload
8. Control heart rate, rhythm, and synchrony
9. Optimize heart lung interactions
10. Provide mechanical support when needed

state can be presumed and treatment optimized. Treating low cardiac output states and preventing cardiovascular collapse often are the central features of pediatric cardiac intensive care and are the focus of this chapter.

Optimizing preload involves more than just giving volume to a hypotensive patient. There are numerous considerations to fluid balance involving types of isotonic fluid, ultrafiltration in the operating room, optimal hematocrit, and use of furosemide, thiazides, and possibly newer drugs such as fenoldapam or nesiritide. Fluid itself can be detrimental if excess extravascular water results in interstitial edema and end-organ dysfunction of vital organs such as the heart, lungs, and brain. Perhaps permitting a right-to-left shunt at the atrial level would optimize preload to the left ventricle in some conditions (see the following section). Maintaining aortic perfusion after CPB and improving the contractile state of the heart with higher doses of catecholamines are reasonable goals, but may have particularly deleterious consequences in the newborn myocardium after hypothermic CPB. The benefits of afterload reduction are well known, but in excess it results in hypotension and cardiovascular collapse or renal or cerebral insufficiency. Pacing the heart can stabilize the rhythm and hemodynamics, but it also may contribute to dyssynchronous, inefficient contraction of the heart or induce other arrhythmias. Mechanical support of the failing myocardium, in the form of extracorporeal membrane oxygenation (ECMO) or ventricular assist devices, although lifesaving in many instances, has its own set of time limitations and morbid complications. Almost every treatment approach has its own set of adverse effects that may be damaging. Supporting cardiac output in the postoperative patient is a balance between the promise and poison of therapy.

The initial assessment after cardiac surgery begins with review of the operative findings. This includes details of the operative repair and CPB, particularly total CPB or myocardial ischemia (aortic cross-clamp) times; concerns about myocardial protection; recovery of myocardial contractility; typical postoperative systemic arterial and central venous pressures; findings from intraoperative transesophageal echocardiography, if performed; and vasoactive medication requirements. This information guides subsequent examination, which should focus on the quality of the repair or palliation plus clinical assessment of cardiac output (Box 31-3). In addition to a complete cardiovascular examination, a routine set of laboratory tests should be obtained, including a chest radiograph, 12- or 15-lead ECG, blood gas analysis, serum electrolytes and glucose, ionized calcium and lactate measurements, complete blood count, and coagulation profile.

Monitoring

Monitoring central venous pressure is routine for many patients after cardiac surgery, except those who undergo the least complex procedures. For example, we do not routinely place a central venous catheter in patients undergoing thoracic procedures, such as coarctation of the aorta, vascular ring, or PDA ligation, or in patients undergoing cardiotomy with a short period of mildly hypothermic CPB, such as an ASD repair. Intracardiac or transthoracic left atrial (LA) catheters are often used to monitor patients after complex reparative procedures. Pulmonary arterial (PA) catheters now are seldom used but may be particularly useful if the postoperative management anticipates a problem such as (1) a residual lesion producing an intracardiac left-to-right shunt (e.g., multiple VSDs); (2) residual RV outflow tract obstruction, as a catheter "pullback" can be performed to measure the RV-to-PA pressure gradient; and (3) pulmonary hypertension, thereby allowing rapid detection of pressure changes and assessment of the response to interventions.

LA catheters are especially helpful in the management of patients with ventricular dysfunction, coronary artery perfusion abnormalities, and mitral valve disease. The mean LA pressure typically is 1 to 2 mm Hg greater than mean right atrial (RA) pressure, which generally varies between 1 and 6 mm Hg in nonpostoperative pediatric patients undergoing cardiac catheterization. In postoperative patients, mean LA and RA pressures both are often greater than 6 to 8 mm Hg. However, they generally should be less than 15 mm Hg. The compliance of the right atrium is greater than that of the left atrium except in the newborn, so pressure elevations in the right atrium of older patients with two ventricles typically are less pronounced.

Possible causes of abnormally elevated LA pressure are listed in Box 31-4. In addition to pressure data, intracardiac catheters in the RA (or a percutaneously placed central venous catheter), LA, and PA can be used to monitor the oxygen saturation of systemic venous or pulmonary venous blood.

Table 31-1 lists the causes of abnormally high or low RA, LA, and PA oxygen saturations, which can be measured at the bedside in the ICU. After reparative surgery, patients with no intracardiac shunts and adequate cardiac output may have a mild reduction in RA oxygen saturation to approximately 60%. Lower RA oxygen saturation does not necessarily indicate low cardiac output, if a patient has arterial desaturation (common mixing lessons, lung diseases, etc.) and the arteriovenous oxygen difference is normal at 25%, there may be appropriate oxygen delivery and extraction. Elevated RA oxygen saturation often is the result of left-to-right shunting at the atrial level (e.g., from the left atrium, anomalous pulmonary vein, or left ventricular [LV]-to-RA shunt). Blood in the left atrium normally is fully saturated with oxygen (i.e., approximately 100%). The two chief causes of reduced LA oxygen saturation are an atrial level right-to-left shunt and pulmonary venous desaturation from abnormal gas exchange.

Box 31–3 Signs of Heart Failure or Low Cardiac Output States

Signs

Cool extremities/poor perfusion
Oliguria and other end-organ failure
Tachycardia
Hypotension
Acidosis
Cardiomegaly
Pleural effusions

Monitor and Measure

Heart rate, blood pressure, intracardiac pressure
Extremity temperature, central temperature
Urine output
Mixed venous oxygen saturation
Arterial blood gas pH and lactate
Laboratory measures of end-organ function
Echocardiography

In the absence of left-to-right shunts, PA oxygen saturation is the best representation of the "true" mixed venous oxygen saturation because all sources of systemic venous blood should be thoroughly combined as they are ejected from the right ventricle. When elevated, this saturation is useful in identifying residual left-to-right shunts after repair of VSD(s). The absolute value of the PA oxygen saturation is a predictor of significant postoperative residual shunt. In patients after TOF or VSD repair, PA oxygen saturation greater than 80% within 48 hours of surgery with supplemental O_2 at a fractional inspired oxygen concentration (Fio_2) less than 0.5 is a sensitive indicator of significant left-to-right shunt (Qp/Qs >1.5) 1 year after surgery.[26] Determination of PA oxygen saturation also can be useful in patients with systemic-to-pulmonary artery collaterals because flow from these vessels into the pulmonary arteries can increase oxygen saturation.

Box 31–4 Common Causes of Elevated Left Atrial Pressure After Cardiopulmonary Bypass

1. Decreased ventricular systolic or diastolic function
   Myocardial Ischemia
   Dilated cardiomyopathy
   Systemic ventricular hypertrophy
2. Left atrioventricular valve disease
3. Large left-to-right intracardiac shunt
4. Chamber hypoplasia
5. Intravascular or ventricular volume overload
6. Cardiac tamponade
7. Arrhythmia
   Tachyarrhythmia, junctional rhythm
   Complete heart block

Table 31–1 Causes of Abnormal Right Atrial, Left Atrial, or Pulmonary Artery Oxygen Saturation

Location	Elevated	Reduced
RA	Atrial level left-to-right shunt	↑Vo_2 (e.g., low CO, fever)
	Anomalous pulmonary venous return	↓Sao_2 saturation with a normal A-V O_2 difference
	Left ventricular-to-right atrial shunt	Anemia
	↑Dissolved O_2 content	Catheter tip position (e.g., near CS)
	↓O_2 extraction	
	Catheter tip position (e.g., near renal veins)	
LA	Does not occur	Atrial level right-to-left shunt
		↓Pvo_2 (e.g., parenchymal lung disease)
PA	Significant left-to-right shunt	↑O_2 extraction (e.g., low CO, fever)
	Small left-to-right shunt with incomplete mixing of blood	Sao_2 saturation with a normal A-V O_2 difference
	Catheter tip position (e.g., PA "wedge")	Anemia

A-V, Arteriovenous; *CO,* cardiac output; *CS,* coronary sinus; *LA,* left atrium; *PA,* pulmonary artery; *Pvo_2,* pulmonary vein oxygen tension; *RA,* right atrium; *Sao_2,* arterial oxygen saturation; *Vo_2,* oxygen consumption.

Low Cardiac Output Syndrome

Although some causes of low cardiac output after CPB are attributable to residual or undiagnosed structural lesions, progressive low cardiac output states do occur. Several factors have been implicated in the development of myocardial dysfunction after CPB including (1) the inflammatory response associated with CPB, (2) the effects of myocardial ischemia from aortic cross-clamping, (3) hypothermia, (4) reperfusion injury, (5) inadequate myocardial protection, and (6) ventriculotomy (when performed). The expression and prevention of reperfusion injury after aortic cross-clamping on CPB is the subject of intense investigation. The typical decrease in cardiac index in newborns after an arterial switch operation (ASO) has been well characterized (Figure 31-1).[27] In a group of 122 newborns, the median maximal decrease in cardiac index that typically occurred 6 to 12 hours after separation from CPB was 32%. One fourth of these newborns reached a nadir of cardiac index that was less than 2 L/min/m^2 on the first postoperative night. Low cardiac output syndrome (LCOS) does occur in the postoperative patient, but appropriate anticipation and intervention can do much to avert morbidity or the need for mechanical support. Signs of low cardiac output are listed in Box 31-3. Mixed venous oxygen saturation, whole blood pH, and lactate are laboratory measures commonly used to evaluate the adequacy of tissue perfusion and hence cardiac output.

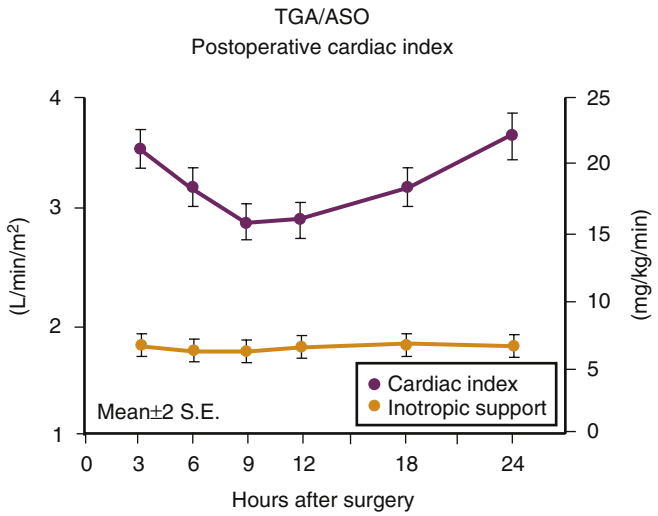

Figure 31–1. Cardiac index (*left axis*) measured in infants after the arterial switch operation declines during the first 12 hours and was not the result of any reduction in inotropic support (*right axis*). One fourth of the patients reach a value less than 2 L/min/m^2. The median reduction in cardiac index the first night is 33%. *(From Wernovsky G, Wypij D, Jonas RA, et al: Postoperative course and hemodynamic profile after the arterial switch operation in neonates and infants. A comparison of low-flow cardiopulmonary bypass and circulatory arrest,* Circulation *92:2226-2235, 1995.)*

Volume Adjustments

After CPB, the factors that influence cardiac output, such as preload, afterload, myocardial contractility, heart rate, and rhythm, must be assessed and manipulated. Volume therapy (increased preload) is commonly necessary, followed by appropriate use of inotropic and afterload-reducing agents. Atrial pressure and the ventricular response to changes in atrial pressure must be evaluated. Ventricular response is judged by observing systemic arterial pressure and waveform, heart rate, skin color, peripheral extremity temperature, peripheral pulse magnitude, urine flow, core body temperature, and acid-base balance.

Preserving and Creating Right-to-Left Shunts

Selected children with low cardiac output may benefit from strategies that allow right-to-left shunting at the atrial level in the face of postoperative RV dysfunction. A typical example is early repair of TOF, when the moderately hypertrophied, noncompliant right ventricle has undergone a ventriculotomy and may be further compromised by an increased volume load from pulmonary regurgitation secondary to a transannular patch on the RV outflow tract. In these children it is very useful to leave the foramen ovale patent to permit right-to-left shunting of blood, thus preserving cardiac output and oxygen delivery despite the attendant transient cyanosis. If the foramen is not patent or is surgically closed, RV dysfunction can lead to reduced LV filling, low cardiac output, and ultimately LV dysfunction. In infants and neonates with repaired truncus arteriosus, the same concerns apply and may even be exaggerated if RV afterload is elevated because of pulmonary artery hypertension.

Right Ventriculotomy and Restrictive Physiology

RV "restrictive" physiology in infants and children who have undergone congenital cardiac surgery has been demonstrated by echocardiography as persistent antegrade diastolic blood flow into the pulmonary circulation after reconstruction of the RV outflow. This occurs in the setting of elevated RV end-diastolic pressure and RV hypertrophy, and the right ventricle demonstrates diastolic dysfunction with an inability to relax and fill during diastole. The right ventricle usually is not dilated in this circumstance, and pulmonary regurgitation is limited because of the higher diastolic pressure in the right ventricle.[29]

The term *restrictive RV physiology* is also commonly used in the immediate postoperative period in patients who have a stiff, poorly compliant, and sometimes hypertrophied right ventricle. The elevated ventricular end-diastolic pressure restricts filling during diastole, and therefore stroke volume and preload to the left ventricle, causes an increase in RA filling pressure and therefore causes systemic venous hypertension. Because of the phenomenon of ventricular interdependence, changes in RV diastolic function and septal position in turn affect LV compliance and function. Factors contributing to diastolic dysfunction include lung and myocardial edema after CPB, inadequate myocardial protection of the hypertrophied ventricle during aortic cross-clamp, coronary artery injury, residual outflow tract obstruction, volume load on the ventricle from a residual VSD or pulmonary regurgitation, and dysrhythmias.

A low cardiac output state with increased right-sided filling pressure (usually >10 mm Hg) is the common feature of neonatal restrictive RV physiology. As a result of the low cardiac output state, patients often have cool extremities, are oliguric, and may have a metabolic acidosis. As a result of the elevated RA pressure, hepatic congestion, ascites, increased chest tube losses, and pleural effusions may be evident.

These patients may be tachycardic and hypotensive with a narrow pulse pressure. Preload must be maintained despite elevation of RA pressure. Significant inotropic support often is required (typically dopamine 5-10 μg/kg/min and/or low-dose epinephrine 0.05-0.1 μg/kg/min). A phosphodiesterase inhibitor, such as milrinone, is beneficial because of its lusitropic properties. Sedation and paralysis often are necessary for the first 24 to 48 hours to minimize the stress response and associated myocardial work.

Patients may be desaturated initially after surgery (typical range, 75% to 85%) because of this shunting. As RV compliance and function improve (usually within 2 to 3 postoperative days), the amount of shunt decreases and both antegrade pulmonary blood flow and arterial oxygen saturation (Sao_2) increase.

Mechanical ventilation may have a significant impact on RV afterload and the amount of pulmonary regurgitation. In addition, an increase in PVR because of hypothermia, acidosis, and either hypoinflation or hyperinflation of the lung also increases afterload on the right ventricle and pulmonary regurgitation. Synchronized intermittent positive pressure ventilation with the lowest possible mean airway pressure should be the aim, as discussed previously.

This concept has been extended to older patients with single-ventricle physiology who are at high risk for Fontan operations.[30] The Fontan circulation relies on passive flow of blood through the pulmonary circulation without benefit of a pulmonary ventricle. If an atrial septal communication or fenestration is left at the time of the Fontan procedure, the resulting right-to-left shunt helps to preserve cardiac output. These children have fewer postoperative complications.[31] It is better to shunt blood right to left and accept some decrement in oxygen saturation but maintain ventricular filling and cardiac output rather than have high oxygen saturation but low blood pressure and cardiac output.

Pharmacologic Support

Catecholamines

Preload adjustments often do not provide adequate cardiac output. Use of pharmacologic agents to support cardiac output is common.[32,33] Table 31-2 lists common vasoactive drugs used in the ICU and their actions. Many prefer to use dopamine first in doses of 3 to 10 μg/kg/min. Dosages greater than 15 μg/kg/min are rarely used because of the known vasoconstrictor and chronotropic properties of dopamine at very high doses. However, extreme biologic variability in pharmacokinetics and pharmacodynamics defies placing narrow limits on recommended dosages. Dobutamine's chronotropic and vasodilatory advantages recognized in adults with coronary artery disease have not always proved equally efficacious in clinical studies in children. The significant chronotropic effect

Table 31–2 Summary of Selected Vasoactive Agents

Agent	Doses (IV)	Peripheral Vascular Effect	Cardiac Effect	Conduction System Effect
Noncatecholamines				
Digoxin (total digitalizing dose)	20 μg/kg premature	Increase peripheral vascular resistance 1 to 2+; acts directly on vascular smooth muscle	Inotropic effect 3 to 4+; acts directly on myocardium	Slows sinus node slightly; decreases AV conduction more
	30 μg/kg neonate (0–1 mo)			
	40 μg/kg infant (<2 yr)			
	30 μg/kg child (2-5 yr)			
	20 μg/kg child (>5 yr)			
Calcium chloride	10–20 mg/kg/dose (slowly)	Variable; age dependent; vasoconstrictor	Inotropic effect 3+; depends on ionized Ca^{2+}	Slows sinus node; decreases AV conduction
Gluconate	50–100 mg/kg/dose (slowly)			Reflex tachycardia
Nitroprusside	0.5–5 μg/kg/min	Donates nitric oxide group to relax smooth muscle and dilate pulmonary and systemic vessels	Indirectly increases cardiac output by decreasing afterload	
Nitroglycerin	0.5–10 μg/kg/min	Primarily venodilator; as a nitric oxide donor, may cause pulmonary vasodilation and enhance coronary vasoreactivity after aortic cross-clamping	Decreases preload; may decrease afterload; reduces myocardial work related to change in wall stress	Minimal
Milrinone	50–75 μg/kg loading dose	Systemic and pulmonary vasodilator	Diastolic relaxation (lusitropy); measurable inotropic effect	Minimal tachycardia
	0.25–1.0 μg/kg/min maintenance			
Vasopressin	0.003–0.002 μg/kg/min	Potent vasoconstriction	No direct effect	None known
Thyroid hormone	0.05–0.10 μg/kg/min	Vasodilation	Positive inotropy	Tachycardia
Triiodothyronine (T3)				
Natriuretic peptide (nesiritide)	0.01–0.03 μg/kg/min	Natriuresis; little experience in children; diuretic effects controversial	Positive inotropy; diastolic relaxation	

	Peripheral Vascular Effect						*Cardiac Effect*
Agent	**Dose Range**	α	β_2	Δ	β_1	β_2	**Comment**
Catecholamines							
Phenylephrine	0.1–0.5 μg/kg/min	4+	0	0	0	0	Increases systemic resistance, no inotropy; may cause renal ischemia; useful for treatment of TOF spells
Isoproterenol	0.05–0.5 μg/kg/min	0	4+	0	4+	4+	Strong inotropic and chronotropic agent; peripheral vasodilator; reduces preload; pulmonary vasodilator; limited by tachycardia and oxygen consumption
Norepinephrine	0.1–0.5 μg/kg/min	4+	0	0	2+	0	Increases systemic resistance; moderately inotropic; may cause renal ischemia
Epinephrine	0.03–0.1 μg/kg/min 0.2–0.5 μg/kg/min	2+ 4+	1–2+ 0	0 0	2–3+ 4+	2+ 3+	β_2 effect with lower doses; best for blood pressure in anaphylaxis and drug toxicity
Dopamine	2–4 μg/kg/min 4–8 μg/kg/min > 10 μg/kg/min	0 0 2–4+	0 2+ 0	2+ 2+ 0	0 1–2+ 1+	0 1+ 2+	Splanchnic and renal vasodilator; may be used with isoproterenol; increasing doses produce increasing α effect
Dobutamine	2–10 μg/kg/min	1+	2+	0	3–4+	1–2+	Less chronotropy and arrhythmias at lower doses; effects vary with dose similar to dopamine; chronotropic advantage compared with dopamine may be be apparent in neonates
Fenoldapam	0.05–1 μg/kg/min (see text; little experience in children)						Powerful D_1 agonist; little chronotropic or inotropic effect but may redistribute flow to renal bed and improve urine output

and increased oxygen consumption induced by isoproterenol have also increasingly limited its use in neonates and infants. Epinephrine is occasionally useful for short-term therapy when high systemic pressures are sought, provided the temporary increase in peripheral vascular resistance can be tolerated. High doses of epinephrine occasionally are necessary to increase pulmonary blood flow across significantly narrowed systemic-to-pulmonary artery shunts when oxygen saturations are low and falling. Arginine vasopressin has been advocated for states of refractory vasodilation associated with low circulating vasopressin levels as may rarely occur after CPB in children.[34] Vasopressin has been used to treat low systemic blood pressure in postoperative pediatric cardiac patients with pulmonary hypertension where it may ameliorate hypoxic pulmonary vasoconstriction and not exacerbate pulmonary hypertension.[35]

In the past, the side effects of inotropic support of the heart with catecholamines seemed a lesser concern in children than in adults with an ischemic, noncompliant heart. Tachycardia, an increased end-diastolic pressure and afterload, and increased myocardial oxygen consumption, despite their undesirable side effects, were tolerated by most children in need of inotropic support after CPB. However, with increasing perioperative experience in neonates and young infants, the adverse effects of vasoactive drugs have become more evident. The less compliant neonatal myocardium, such as the ischemic adult heart, may raise its end-diastolic pressure during higher doses of dopamine infusion or may develop even more extreme noncompliance. Actual myocardial necrosis caused by high doses of epinephrine infusions has been identified in neonatal animal models after CPB.[36,37] Although these agents do increase the cardiac output, the concomitant increase in ventricular filling pressure is less well tolerated by the immature myocardium than it is in older children. Many of the complex corrective procedures performed in neonates and small infants are accompanied by transient postoperative arrhythmias that are either induced or exacerbated by catecholamines, which can have a profound adverse effect on the patient's recovery after surgery. Diastolic function is crucial in older patients with single ventricles and can be adversely affected by catecholamines. Nevertheless, the predictable and often significant decrease in cardiac output documented by many investigators after CPB in infants and older children continues to justify the practice of judiciously using catecholamines to support the heart and circulation while weaning them from CPB and during the immediate postoperative period.

Type III Phosphodiesterase Inhibitors

Milrinone has emerged as an important inotropic agent for use in children after open heart surgery.[38-40] It is a nonglycosidic, noncatecholamine inotropic agent with additional vasodilatory and lusitropic properties used extensively in adults for treatment of heart failure and now also abundantly used in pediatric practice. This class of drugs exerts its principal effects by inhibiting phosphodiesterase III, the enzyme that metabolizes cyclic adenosine monophosphate (cAMP). By increasing intracellular cAMP, calcium transport into the cell is favored, and the increased intracellular calcium stores enhance the contractile state of the myocyte. In addition, reuptake of calcium is a cAMP-dependent process, and these agents may enhance diastolic relaxation of the myocardium (lusitropy) by increasing the rate of calcium reuptake after systole. The drug also appears to work synergistically with low doses of β-agonists and has fewer side effects than other catecholamine vasodilators, such as isoproterenol. In critically ill postoperative newborns, milrinone increases cardiac output, lowers filling pressures, and reduces pulmonary artery pressures.[39]

The Prophylactic Intravenous Use of Milrinone after Cardiac Operation in Pediatrics (PRIMACORP) trial investigated the efficacy and safety of prophylactic milrinone use to prevent LCOS after cardiac surgery in high-risk pediatric patients.[40] The study was a multicenter, randomized, double-blind, placebo-controlled trial using three parallel treatment groups (low-dose: 25 μg/kg bolus over 60 minutes followed by a 0.25 μg/kg/min infusion for 35 hours; high-dose: 75 μg/kg bolus followed by 0.75 μg/kg/min; or placebo). The composite endpoint of death or the development of LCOS was evaluated at 36 hours and at the follow-up visit. Among 238 treated patients, the prophylactic use of high-dose milrinone significantly reduced the risk of death or the development of LCOS relative to placebo with a relative risk reduction of 55% ($P = .023$) in the treated patients (Figure 31-2). Patients who developed LCOS had a significantly longer cumulative duration of mechanical ventilation and hospital stay in comparison with those who did not develop LCOS. The authors concluded that the prophylactic use of high-dose milrinone after pediatric congenital heart surgery reduces the risk of LCOS. Dopamine and milrinone have emerged as our most commonly used inotropic agents, often used in combination to achieve increased cardiac output, maintain arterial perfusion pressure, and improve diastolic relaxation.

Thyroid Hormone

LCOS typically overlaps with the time that free and total triiodothyronine (T_3) levels are significantly suppressed after surgical reconstruction, namely, during the first 24 to 48 hours postoperatively. This is a significant observation, as T_3 is the predominant form of biologically active thyroid hormone and is known to improve cardiac output by improving the inotropic state of animal and human hearts while decreasing systemic vascular resistance. Limited studies of T_3 supplementation after cardiac surgery have been performed in children. Mainwaring et al.[41] gave two bolus doses of T_3 after the Fontan

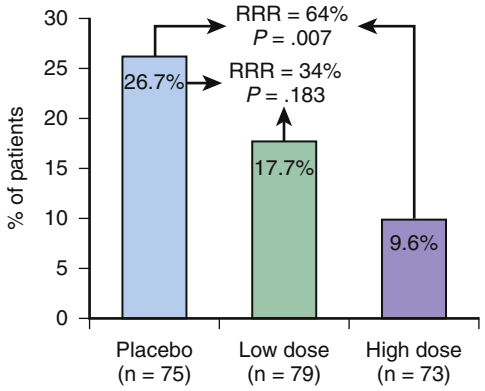

Figure 31–2. Primary end point: development of low cardiac output syndrome (LCOS) or death in the first 36 hours. *(From Hoffman TM, Wernovsky G, Atz AM, et al: Efficacy and safety of milrinone in preventing low cardiac output syndrome in infants and children after corrective surgery for congenital heart disease,* Circulation *107:996-1002, 2003.)*

procedure to 10 children ages 19 to 42 months. Compared with a historical control group, the T_3 patients had a significantly shorter period of mechanical ventilation. Bettendorf et al.[42] randomized 40 children undergoing a wide variety of cardiac procedures to receive bolus dosing of T_3 or placebo. Cardiac output reportedly was higher in the treatment group but was estimated by echocardiography. Chowdhury et al.[43] randomized 28 children aged 0 to 18 years to a 5-day continuous infusion of T_3 (0.05-0.15 μg/kg/hour) or placebo. Among neonates, the T_3 group had lower severity of illness scores and lower inotrope requirements. The T_3 group also had a trend toward higher mixed venous oxygen saturations, fewer days of mechanical ventilation, and a shorter postoperative length of stay. No adverse effects of T_3 administration were recorded in any of these small series.

Thus the current literature demonstrates that infants undergoing cardiac surgery experience significant depression of T_3 levels and that supplementation of T_3 may have an impact on physiologic variables if not other measures of improved outcomes. Larger trials with more rigorous trial designs are under way and may address whether certain subgroups at particular risk for LCOS may benefit from T_3 administration. At this time, the routine use of T_3 is not supported by the existing literature.[44]

Other Afterload-Reducing Agents

When systemic blood pressure is elevated and cardiac output appears low or normal, a primary vasodilator is indicated to normalize blood pressure and to decrease the afterload on the left ventricle. This is especially true for the newborn myocardium, which is particularly sensitive to changes in afterload and tolerates elevated systemic resistances poorly. Although nitroprusside has no known direct inotropic effects, this potent vasodilator has the advantage of being readily titratable and possessing a short biologic half-life. Use of nitroglycerin avoids the toxic metabolites cyanide and thiocyanate associated with nitroprusside use (especially in hepatic and renal insufficiency), but its potency as a vasodilator is less than that of nitroprusside. Inhibitors of angiotensin-converting enzyme have proved to be important adjuvants to chronic anticongestive therapy in pediatric patients. Intravenous (IV) forms are available and may be useful in treatment of systemic hypertension immediately after coarctation repair or when afterload reduction with these inhibitors would benefit patients unable to receive oral medications. Sudden hypotension with the IV forms may limit use among infants.

The natriuretic hormone system is an important regulator of neurohumoral activation, vascular tone, diastolic function, and fluid balance. Preliminary data suggest that the endogenous biologic activity of the natriuretic hormone system is decreased after pediatric CPB. In theory, infusions of brain natriuretic peptide could oppose the neurohumoral mechanism associated with vasoconstriction and fluid retention after pediatric CPB. In randomized adult studies after CPB, natriuretic hormone infusions suppress the renin-angiotensin-aldosterone axis and improve cardiac loading conditions, cardiac index, and urine output.[45,46] Several services in North America have now accrued experience with nesiritide infusions in children.

Fenoldapam is a new dopaminergic agent useful in the treatment of systemic hypertension. It may have salutary effects on renal blood flow. It has no known chronotropic or inotropic effects on the heart but reduces afterload and may augment urine output in critically ill newborns after cardiac surgery.

Levosimendan is a calcium sensitizer that enhances the contractile state of the ventricle by increasing myocyte sensitivity to calcium and induces vasodilation. Levosimendan increases cardiac output by increasing stroke volume. It is independent of cAMP pathways that characterize the mechanism of action of both the catecholamines and the type III phosphodiesterase inhibitors. With its positive inotropic effects, levosimendan may be of value as adjunctive therapy to other inotropic drugs in patients who are refractory or tachyphylactic to other forms of inotropic support. Its hemodynamic effect in children is uncertain, but its pharmacokinetic profile seems similar to adults.[47]

Other Strategies

Newer strategies to support low cardiac output associated with cardiac surgery in children include use of atrioventricular pacing for patients with complete heart block or prolonged interventricular conduction delays and asynchronous contraction.[48] Appreciation of the hemodynamic effects of positive and negative pressure ventilation may assist cardiac output. Avoidance of hyperthermia and even induced hypothermia may provide end-organ protection during periods of low cardiac output. Antiinflammatory agents including monoclonal antibodies, competitive receptor blockers, inhibitors of compliment activation, and preoperative preparation with steroids are being actively investigated in an effort to prevent and protect major organs from ischemic injury imposed by CPB and the reperfusion injury associated with the recovery period.

Diastolic Dysfunction

Occasionally there is an alteration of ventricular relaxation, an active energy-dependent process, which reduces ventricular compliance. This is particularly problematic in patients with a hypertrophied ventricle undergoing surgical repair, such as TOF or Fontan surgery, and after CPB in some neonates when myocardial edema may significantly restrict diastolic function (i.e., "restrictive physiology").[28,29] The ventricular cavity size is small, and the stroke volume is decreased. β-Adrenergic antagonists and calcium channel blockers add little to the treatment of this condition. In fact, hypotension or myocardial depression produced by these agents often outweigh any gain from slowing the heart rate. Calcium channel blockers are relatively contraindicated in neonates and small infants because of their dependence on transsarcolemmal flux of calcium to both initiate and sustain contraction.

A gradual increase in intravascular volume to augment ventricular capacity, in addition to the use of low doses of inotropic agents, has proved to be of modest benefit in patients with diastolic dysfunction. Tachycardia must be avoided to optimize diastolic filling time and decrease myocardial oxygen demands. If low cardiac output continues despite treatment, therapy with vasodilators can be carefully attempted to alter systolic wall tension (afterload) and thus decrease the impediment to ventricular ejection. Because the capacity of the vascular bed increases after vasodilation, simultaneous volume replacement is often indicated. Milrinone or enoximone is

useful under these circumstances because these agents are noncatecholamine so-called inodilators with vasodilating and lusitropic (improved diastolic state) properties, in contrast with other inotropic agents. Nesiritide also may play a particularly important role in lowering LV filling pressures in patients with heart failure.

Managing Acute Pulmonary Hypertension in the Intensive Care Unit

Children with many forms of CHD are prone to develop perioperative elevations in PVR.[49] This situation may complicate the postoperative course, when transient myocardial dysfunction requires optimal control of RV afterload.[50]

Although postoperative patients with pulmonary hypertension often are presumed to have active and reversible pulmonary vasoconstriction as the source of their pathophysiology, the critical care physician is obligated to explore anatomic causes of mechanical obstruction that impose a barrier to pulmonary blood flow. Elevated LA pressure, pulmonary venous obstruction, branch pulmonary artery stenosis, or surgically induced loss of the vascular tree all raise RV pressure and impose an unnecessary burden on the right heart. Similarly, a residual or undiagnosed left-to-right shunt raises pulmonary artery pressure postoperatively and must be addressed surgically. Extended use of pulmonary vasodilator strategies only augments residual or undiagnosed shunts and increases the volume load on the heart.

Several factors peculiar to CPB may raise PVR: Pulmonary vascular endothelial dysfunction, microemboli, pulmonary leukostasis, excess thromboxane production, atelectasis, hypoxic pulmonary vasoconstriction, and adrenergic events all have been suggested to play a role in postoperative pulmonary hypertension. Postoperative pulmonary vascular reactivity has been related not only to the presence of preoperative pulmonary hypertension and left-to-right shunts but also to the duration of total CPB. Treatment of postoperative pulmonary hypertensive crises has been partially addressed by surgery at earlier ages, pharmacologic intervention, and other postoperative management strategies (Table 31-3).

Table 31–3 Critical Care Strategies for Postoperative Treatment of Pulmonary Hypertension

Encourage	Avoid
Anatomic investigation	Residual anatomic disease
Opportunities for right-to-left shunt as "pop-off"	Intact atrial septum in right heart failure
Sedation/anesthesia	Agitation/pain
Moderate hyperventilation	Respiratory acidosis
Moderate alkalosis	Metabolic acidosis
Adequate inspired oxygen	Alveolar hypoxia
Normal lung volumes	Atelectasis or overdistention
Optimal hematocrit	Excessive hematocrit
Inotropic support	Low output and coronary perfusion
Vasodilators	Vasoconstrictors/increased afterload

Pulmonary Vasodilators

Many IV vasodilators have been used with variable success in patients with pulmonary hypertensive disorders requiring critical care. Older style vasodilators such as tolazoline, phenoxybenzamine, nitroprusside, or isoproterenol had little biologic basis for selectivity or enhanced activity in the pulmonary vascular bed.[51] However, if myocardial function is depressed and the afterload reducing effect on the left ventricle is beneficial to myocardial function and cardiac output, then these drugs may be of some value. However, in addition to drug-specific side effects, they all have the limitation of potentially profound systemic hypotension, critically lowering right (and left) coronary perfusion pressure and simultaneously increasing intrapulmonary shunt. Even with selective infusions of rapidly metabolized, intravenously administered vasoactive drugs into the pulmonary circulation, systemic drug concentrations and systemic hemodynamic effects can be appreciable.

Prostacyclin appears to have somewhat more selectivity for the pulmonary circulation but at high doses can precipitate a hypotensive crisis in unstable postoperative patients with refractory pulmonary hypertension. It is best suited for chronic outpatient therapy in severe forms of primary pulmonary hypertension.[52-54] Agents that improve ventricular function in addition to reducing afterload (e.g., type III phosphodiesterase inhibitors) are more appealing when cardiac output is low.

As an alternative approach to nonspecific vasodilators, it seems logical to target vasoconstrictors known to be associated with pathologic states or critical events. In this regard, endothelin, a potent vasoconstrictor, is elevated in persistent pulmonary hypertension of the newborn, in children with CHD, and in patients after CPB, and seems a likely candidate for investigation of specific receptor blockers. Petrossian et al.[55] showed promising amelioration of postoperative pulmonary hypertension associated with CPB in animal models of increased pulmonary blood flow (from intracardiac shunts) when pretreated with endothelin-A receptor blockers. Undoubtedly, because the causes of pulmonary hypertension in the intensive care setting frequently are multifactorial, our "best" therapy will be multiply targeted. Adding phosphodiesterase inhibitors to prostacyclin infusions, endothelin blockers, thromboxane inhibitors, and inhaled nitric oxide (NO) all may have individual and combined merit with synergism enhancing efficacy.

NO is a selective pulmonary vasodilator that can be breathed as a gas and distributed across the alveoli to the pulmonary vascular smooth muscle.[56] It is formed by the endothelium from L-arginine and molecular oxygen in a reaction catalyzed by NO synthase. It then diffuses to the adjacent vascular smooth muscle cells where it induces vasodilation through a cyclic guanosine monophosphate-dependent pathway.[57] Because NO exists as a gas, it can be delivered by inhalation to the alveoli and then to the blood vessels, which lie in close proximity to ventilated lung. Because of its rapid inactivation by hemoglobin, inhaled NO may achieve selective pulmonary vasodilation when pulmonary vasoconstriction exists. It has advantages over intravenously administered vasodilators that cause systemic hypotension and increase intrapulmonary shunting. Inhaled NO lowers pulmonary artery pressure in a number of diseases without the unwanted effect of systemic

hypotension. This effect is especially dramatic in children with cardiovascular disorders and postoperative patients with pulmonary hypertensive crises.[50,58,59]

Therapeutic uses of inhaled NO in children with CHD abound in the ICU. For example, newborns with total anomalous pulmonary venous connection (TAPVC) frequently have obstruction of the pulmonary venous pathway as it connects anomalously to the systemic venous circulation. When pulmonary venous return is obstructed preoperatively, pulmonary hypertension is severe and demands urgent surgical relief. Increased neonatal pulmonary vasoreactivity, endothelial injury induced by CPB, and intrauterine anatomic changes in the pulmonary vascular bed in this disease contribute to postoperative pulmonary hypertension. Inhaled NO dramatically reduces pulmonary hypertension without change in heart rate, systemic blood pressure, or vascular resistance.

Patients with TAPVC, congenital mitral stenosis, and other pulmonary venous hypertensive disorders associated with low cardiac output appear to be among the most responsive to NO. These infants are born with significantly increased amounts of smooth muscle in their pulmonary arterioles and veins. Histologic evidence of muscularized pulmonary veins and pulmonary arteries suggests the presence of vascular tone and capacity for change in resistance at both the arterial and venous sites. The increased responsiveness to NO seen in younger patients with pulmonary venous hypertension may result from pulmonary vasorelaxation at a combination of precapillary and postcapillary vessels.

Several groups have reported successful use of inhaled NO in a variety of other congenital heart defects after cardiac surgery. It may be especially helpful when administered during a pulmonary hypertensive crisis.[59] NO use after Fontan procedures,[60] after VSD repair, and with a variety of other anatomic lesions has been described. Prophylactic use of inhaled NO in patients at risk for developing postoperative pulmonary hypertensive crises is thought by some to reduce the duration of mechanical ventilation.[61] Oxygen saturation in response to inhaled NO generally does not improve in very young infants who are excessively cyanotic after a bidirectional Glenn anastomosis. Increasing cardiac output and cerebral blood flow may have much greater impact on arterial oxygenation. Elevated pulmonary vascular tone is seldom the limiting factor in the hypoxemic patient after the bidirectional Glenn operation.[62]

Inhaled NO can be used diagnostically in neonates with RV hypertension after cardiac surgery to discern those with reversible vasoconstriction. Failure of the postoperative newborn with pulmonary hypertension to respond to NO successfully discriminated anatomic obstruction to pulmonary blood flow from pulmonary vasoconstriction. Failure of the postoperative newborn to respond to NO should be regarded as strong evidence of anatomic and possibly surgically remediable obstruction.[63]

If withdrawal of NO is necessary before resolution of the pathologic process, hemodynamic instability can be expected. The withdrawal response to inhaled NO can be attenuated by pretreatment with the type V phosphodiesterase inhibitor sildenafil.[64] Sildenafil inhibits the inactivation of cyclic guanosine monophosphate within the vascular smooth muscle cell and has the potential to augment the effects of endogenous or exogenously administered NO to effect vascular smooth muscle relaxation. Sildenafil can be administered in an oral or IV form and has a somewhat selective pulmonary vasodilating capacity while lowering LA pressure and providing a modest degree of afterload reduction in some postoperative children. Chronic oral administration of sildenafil to adults with primary pulmonary hypertension improves exercise capacity, which suggests an important therapeutic application of the IV preparation in postoperative congenital heart surgery.

Cardiac Tamponade

Chest closure is a time of particular instability after operations for CHD. The small infant's mediastinum makes compression of the heart and cardiac tamponade ever-present possibilities after chest closure, despite patent drainage tubes and surgical resection of the anterior pericardium. The warning signs of tamponade frequently are subtle in small children, even minutes before cardiovascular collapse from tamponade. Any significant deterioration in hemodynamics after chest closure first should be attributed to tamponade if ventilation and cardiac rhythm are adequate. The signs of tamponade include tachycardia, hypotension, narrow pulse pressure, and high filling pressures on both the left and right sides of the heart.

Acute myocardial perforation with tamponade occasionally occurs during interventional cardiac catheterization procedures. Prompt support of the circulation with volume infusions and pressor support, along with immediate catheter drainage of the pericardial space, are essential in the event of this complication. Hemopericardium after ventricular puncture usually is self-limited, as the muscular ventricle seals the perforation after the responsible wire or catheter is removed. However, laceration of the more thin-walled atrium may require suture repair under direct vision in the operating room.

Other causes of cardiac tamponade are seen in patients with CHD, and treatment frequently requires the assistance of an intensivist for either pericardiocentesis or sedation and monitoring for that definitive procedure. Postoperative tamponade from bleeding immediately after operation, as discussed earlier, is best handled by facilitation of chest tube drainage or reopening the sternotomy. These patients usually are still anesthetized and mechanically ventilated so that new anesthetic considerations and choices are limited. However, some children develop pericardial effusions during other phases of their illness because of hydrostatic influences (e.g., patients with modified Fontan operations) or postpericardiotomy syndrome. Fluid in the pericardial space may accumulate under considerable pressure, and filling of the heart is impaired. If this problem is left unattended, the transmural pressure in the atria diminishes as intraatrial pressures rise, and diastolic collapse of the atria can be observed echocardiographically. Patients become symptomatic with a narrow pulse pressure, pulsus paradoxus, tachycardia, respiratory distress, abdominal pain progressing to decreased urine output, hyperkalemia, metabolic acidosis, and hypotension with tremendous endogenous catecholamine response.

In summary, aggressive identification and treatment of low cardiac output conditions after cardiac surgery is central to the critical care of children with CHD. Successful application of these strategies and thoughtful use of pharmacologic intervention undoubtedly has contributed to the remarkable decline in mortality associated with congenital heart surgery in the past two decades. However, despite these interventions, additional (mechanical) support is sometimes necessary as a bridge to recovery.

Mechanical Support of the Circulation

Despite the expanding options for pharmacologic support, the circulation cannot be adequately supported in some patients in both preoperative and postoperative situations. Mechanical assist devices have an important role in providing short-term circulatory support to enable myocardial recovery and the potential for longer term support while the patient is awaiting cardiac transplantation. Although a variety of assist devices are available for adult-size patients, ECMO is the predominant mode of support for children.

More than 300 children per year who receive ECMO for cardiac support are reported to the Extracorporeal Life Support Registry, with the majority of patients placed on ECMO after cardiotomy.[65] Although more than 60% of these patients are decannulated from ECMO, the overall survival to discharge has been only 42% of reported cases.

At Riley Hospital for Children, Indiana University, ECMO has been used to support the circulation in more than 130 patients. Neonates comprise 52% of all our cardiac ECMO patients, with a survival rate to discharge of 50% in the last 5 years. The pediatric group (infant through 16 years) comprises 48% of our total experience with a survival rate to discharge of 48% in the same period.

Substantial institutional variability in patient selection for ECMO makes comparison of published experience difficult. Centers with an efficient and well-established ECMO service are more likely to use this form of support in patients with low cardiac output. Furthermore, surgical technique and bypass management are additional confounding factors that make comparisons of the use and indications for ECMO between institutions difficult to interpret. Nevertheless, this form of mechanical support can be demonstrated to be lifesaving, and it can be argued that it should be available when needed for selected patients after congenital heart surgery General indications and contraindications for ECMO support of the circulation in patients with CHD are summarized in Box 31-5 and Box 31-6.

Preoperative Stabilization

Extracorporeal membrane oxygenation may be useful for critically ill neonates before cardiac surgery, thereby enabling preoperative stabilization and limiting end-organ dysfunction before repair. Indications include severe low output state (e.g., critical AS), pulmonary hypertension (e.g., obstructed totally anomalous pulmonary venous return), and severe hypoxemia (e.g., transposition with pulmonary hypertension). These have been relatively rare indications for ECMO at Riley Hospital for Children, Indiana University, and other major centers.

Failure to Wean from Cardiopulmonary Bypass

Patients who fail to wean from CPB may be connected directly to an ECMO circuit in the operating room and brought to the ICU in the hope of recovering myocardial function. These children typically had poorer survival rates for many reasons, including severity and complexity of disease and increased bleeding. A critical decision for using ECMO in this circumstance is whether the patient is a suitable candidate for cardiac transplantation if there is no significant recovery of function. Clearly, patient selection can have an enormous influence on outcomes in this category. As practitioners gained experience with and acceptance of mechanical support, its successful use in the transition from CPB increased.[66]

Box 31–5 Typical Indications for ECMO

I. Inadequate oxygen delivery
   A. Low cardiac output
      1. Chronic (cardiomyopathy)
      2. Acute (myocarditis)
      3. Weaning from cardiopulmonary bypass
      4. Preoperative stabilization
      5. Progressive postoperative failure
      6. Pulmonary hypertension
      7. Refractory arrhythmias
      8. Cardiac arrest
   B. Profound cyanosis
      1. Intracardiac shunting and cardiovascular collapse
      2. Acute shunt thrombosis
      3. Acute respiratory failure exaggerated by underlying heart disease
      4. Congestive heart disease complicated by other newborn indications for ECMO, such as meconium aspiration syndrome, PPHN, pneumonia, sepsis, respiratory distress syndrome
II. Support for intervention during cardiac catheterization

Box 31–6 Relative Contraindications for ECMO

End-stage, irreversible, or inoperable disease
Family, patient directives to limit resuscitation
Significant neurologic or end-organ impairment
Uncontrolled bleeding within major organs
Extremes of size and weight
Inaccessible vessels during resuscitation

Postcardiotomy

In general, ECMO appears to be most effective as a therapeutic option for patients who have a period of relative stability after reparative cardiac surgery but then develop progressive myocardial or respiratory failure or have a sudden cardiac arrest. This typically occurs during the first 24 hours after surgery, and subsequent survival may be better in this group of patients after a period of myocardial rest and decompression.

Bridge to Transplantation

Although ECMO can be used to resuscitate the circulation and prevent end-organ dysfunction while the patient is awaiting potential myocardial recovery, it also can be used as a bridge to transplantation.[67] However, with limitations related to donor availability and the potential complications while the patient is on ECMO, in particular bleeding, end-organ dysfunction, and sepsis, the decision to proceed with listing for transplantation should be made early during the ECMO run. If there is no discernible recovery of myocardial function after 48 to 72 hours on ECMO support, transplant evaluation should be completed for appropriate patients.[68] Selected prospective transplant recipients experiencing waiting times longer than 2 or 3 weeks should be considered for longer term devices such as the Berlin Heart.

Resuscitation

The rapid deployment of ECMO during active CPR (E-CPR) in a pulseless circulation remains a contentious issue. The underlying premise is that survival after a sudden cardiac

arrest and standard resuscitation in children is poor irrespective of the resuscitation setting.[69-73] Therefore a number of pediatric institutions have developed a rapid response system to provide early deployment and cannulation for ECMO. A recent review of the Extracorporeal Life Support Organization database[65] showed that E-CPR accounted for only 2.6% of all reported ECMO runs (696 of 26,242 runs). Survival to hospital discharge was 38%. In a multivariable model, pre-ECMO factors such as cardiac disease and neonatal respiratory disease, white race, and pre-ECMO arterial blood pH >7.17 were associated with decreased odds of mortality. During ECMO, renal dysfunction, pulmonary hemorrhage, neurologic dysfunction, CPR during ECMO, and arterial blood pH <7.2 were associated with increased odds of mortality. Nevertheless, E-CPR rescued one third of patients in whom death was otherwise certain.[74]

The ability to efficiently and rapidly support the circulation or respiration in patients after cardiac surgery (and in children with cardiac disease in general) has improved our ability to salvage a group of children who previously most likely would have died. This type of support is believed to account for a substantial part of the decline in surgical mortality during the end of the 1990s.

The rapid deployment system for E-CPR during cardiopulmonary arrest and resuscitation can be used in a variety of locations throughout the hospital, including the ICU, cardiac catheterization laboratory, emergency department, and noncardiac operating rooms. Typically, one should wait only moments (i.e., after two or three rounds of resuscitation medications) before determining that return of cardiovascular stability during CPR is unlikely and that ECMO should be deployed. Many centers have an ECMO circuit ready and saline primed at all times in the ICU. A neonatal membrane is generally used in this setup (size 0.8-1.5 m^2; appropriate for patients 2-15 kg). For older children and adults, a fresh circuit with a hollow-fiber membrane can be used that takes little time to deair and can be established within 15 minutes. After the patient is stable on ECMO, the hollow fiber can be changed out for a conventional membrane if longer term support is necessary. Blood products are added when they are available (typically after cannulation), and crystalloid is removed by direct withdrawal from the circuit into a syringe or by a volume-matched amount of ultrafiltration. Surgeons trained in cannulation techniques for open chest, groin, or neck routes, ECMO specialists, and cardiac ICU physicians should be immediately available in-house 24 hours per day.

Extracorporeal Membrane Oxygenation Cannulation, Stabilization, and Evaluation

Depending on the circumstances of hemodynamic decompensation (impending or actual cardiac arrest; nonoperated or postoperative cardiac patient) and surgeon preference, vascular access is obtained either by transthoracic approach with direct cannulation of the right atrium and aorta or peripherally through the neck or femoral vessels. Medical support and resuscitation (i.e., airway stabilization with hand ventilation, intravascular volume replacement, catecholamine infusions, correction of electrolyte imbalance, sodium bicarbonate administration, arrhythmia suppression, cardiac pacing, core temperature cooling, and cardiac massage) are continued throughout the cannulation procedure and commencement of venoarterial extracorporeal support until a stable circulation is achieved.

The ECMO circuit is a "closed" circuit, which is an important distinction to a CPB circuit in which cardiotomy suction is used during cardiac surgery. There is very limited ability to handle any air in the venous limb of the ECMO circuit, and careful deairing of both the arterial and venous cannulas is essential when connecting to the ECMO circuit. In our institution, blood flow is driven by a roller pump using a servoregulatory mechanism. This system permits high flow rates with minimal hemolysis and protects against air entrainment. Priming volumes are determined by the surface area of the oxygenator membrane. The circuit is initially vacuumed with carbon dioxide to eliminate nitrogen, which leads to bubble formation after introduction of the saline priming solution. Normosol solution (Abbott Laboratories, Abbott Park, Ill.) is used to displace the CO_2, and after the system has been debubbled, 5% albumin is added to decrease adsorption of fibrinogen to the circuit components during the subsequent blood priming.

After cannulation, the patient is connected to the ECMO circuit and the roller pump is adjusted to gradually achieve the desired flow rates of approximately 100 to 150 mL/kg, depending on the underlying cardiopulmonary physiology. Intracardiac and arterial blood pressures, including waveform characteristics, are noted. Usually, vasopressor infusions are used to maintain mean arterial blood pressure greater than 45 mm Hg in neonates and greater than 60 to 70 mm Hg in children and adults. A chest radiograph is obtained to check cannulas, line position, endotracheal tube, and lung parenchymal status.

Elevated premembrane pressures (i.e., >350 mm Hg) at normal flows without change in postmembrane pressure and evidence of blood-to-gas leak constitute membrane oxygenator dysfunction and may dictate oxygenator replacement. Extensive thrombus or consumptive coagulopathy with hypofibrinogenemia and thrombocytopenia are other indications for circuit replacement. When ECMO flow appears inadequate to meet the needs of the patient and limited venous drainage restricts additional flow, interpretation of arterial and atrial pressures may aid the formulation of a differential diagnosis (Table 31-4). Low flow states and/or significant hypotension require immediate analysis and intervention.

Assessing the adequacy of flow soon after initiation of ECMO is of paramount importance. Answering a checklist of questions assists this assessment.

1. **Is the systemic ventricle adequately decompressed?** Venting the left atrium may be necessary to lower the LA pressure and decrease LV wall stress, thereby minimizing ongoing myocardial injury. Adequate decompression and signs of pulmonary edema can be assessed early by echocardiography. If not decompressed, strategies include (1) placing a vent in the left atrium by direct placement via the atrial appendage or pulmonary veins through an open chest or by a transcatheter approach in the catheterization laboratory[75] and (2) augmenting ventricular ejection by judicious use of inotropic agents.
2. **Are the perfusion pressure and flow adequate?** This determination can be made by assessment of perfusion pressure, patient color and appearance, presence of acidosis, adequate clearance of lactate, and appropriately sized and positioned cannulas. Hypotension with mean arterial blood pressure less than 30 mm Hg in neonates or less than 50 mm Hg in larger children and adults requires prompt evaluation and treatment.

Table 31–4 Assessment of Low Flow States During ECMO

Problem	Observations	Treatment Options
Inadequate oxygen delivery and organ perfusion	Tachycardia, mottled skin, cool extremities, poor capillary refill, hypotension, oliguria, metabolic acidosis, hyperlactatemia, rising serum creatinine, and liver function test results	Check cannula position Increase ECMO flow Increase native cardial output
Inadequate ECMO flow; circuit chatters, bladder collapse, inadequate venous return, or high postmembrane pressure	Atrial pressures normal: Venous cannula malposition Venous cannula too small Venous thrombus formation Excessive runoff through aortopulmonary shunt	Reposition venous cannula Replace or add second venous cannula Surgically remove thrombus or thrombolysis Narrow shunt, embolize collaterals
	Atrial pressures low: Bleeding	Surgically explore, administer coagulation factors and blood, administer antifibrinolytics, reduce heparin
	Systemic vasodilation	Treat sepsis, administer vasoconstrictors
	Atrial pressures high: Tamponade Left ventricular overdistension	Surgically explore, evacuate blood and clot
		Place vent in left atrium, support ejection with catecholamine
	Aortic regurgitation	Reposition aortic cannula, assess need for aortic valve replacement
	Membrane pressures high: Arterial cannula malposition Arterial cannula too small	Reposition cannula Replace or add second arterial cannula (bifemoral arterial cannulation)

Is hemostasis achieved? This is not an uncommon problem in the immediate postoperative period. Prompt control of bleeding has a direct influence on subsequent outcome. Tamponade physiology affects venous return, circuit line pressure, and ECMO flows; mediastinal reexploration may be necessary to evacuate clot and control bleeding. In addition to surgical exploration, replacement of coagulation factors and use of antifibrinolytics must be considered (e.g., aminocaproic acid bolus 100 mg/kg followed by 30 mg/kg/hour infusion). Initial guidelines include transfusion of packed red blood cells to maintain the hematocrit at greater than 35%, cryoprecipitate to keep the serum fibrinogen level greater than 150 mg/dL, and concentrated platelet transfusions to maintain the platelet count greater than 100,000/mm^3. A heparin bolus (50 U/kg) usually is given at the time of cannulation, followed by infusion (20-30 U/kg/hour) adjusted to maintain an activated clotting time of 180 to 200 seconds.

3. **Are there specific considerations based on underlying pathology?** Management of an aortopulmonary shunt is critical in patients with single-ventricle physiology. Systemic and pulmonary flow should be balanced by either partially clipping the shunt or by using high ECMO flows. On ECMO, circuit flows up to 200 mL/kg/min or more usually are necessary to maintain adequate systemic perfusion while accounting for runoff into the pulmonary circulation through the shunt. Although partial temporary narrowing of the shunt may be advisable in some circumstances, it is unwise to completely occlude the only source of pulmonary blood flow to the pulmonary endothelium. It is possible to bypass the membrane oxygenator in patients after the Norwood procedure with a Blalock-Taussig shunt without lung disease if higher flows are maintained and the shunt is patent.[76] This maneuver simplifies the circuit and may permit less use of heparin. Thus ECMO effectively becomes a ventricular assist device.

   Problems related to cannula placement and adequacy of venous drainage must be considered in patients with single-ventricle physiology and complex venous anatomy, such as heterotaxy syndrome or possible vessel occlusion from prior catheterizations, and in patients with a cavopulmonary connection. The site of cannulation is affected by vessel patency, and the underlying physiology might influence the number of venous cannulae used. For example, patients with a superior cavopulmonary anastomosis (bidirectional Glenn shunt [BDG]) as the primary source of pulmonary blood flow often require separate venous drainage of the SVC and inferior vena cava (IVC), unless there is congenital interruption of the infrahepatic IVC with drainage of lower body blood to the azygos vein. In the latter case, a single venous cannula in the SVC might be sufficient. On the other hand, placement of a cannula in the SVC may be detrimental in patients with BDG physiology because of the potential for reduced cerebral venous drainage and therefore decreased cerebral perfusion. This also is a concern for patients with Fontan physiology. Although it may be possible to achieve adequate drainage with a venous cannula placed in the Fontan baffle, an additional SVC catheter often is necessary to achieve the desired or necessary flows on ECMO.[77]

4. **Is there adequate end-organ perfusion?** After stable flows and perfusion have been achieved, the ventricles have been decompressed, and hemostasis has been secured, potential end-organ injury should be evaluated. For patients who have long-standing cyanotic heart disease, it may be preferable to start ECMO using a lower oxygen concentration (closer to room air) to attenuate the potential ischemia/reperfusion injury and potential for injury from reactive

oxygen species. Neurologic protection must be considered. For patients placed on ECMO during active resuscitation, mild hypothermia (34° C) should be maintained for the first 12 to 24 hours on ECMO to prevent secondary neurologic injury. Assessment with head ultrasound, electroencephalography, or computed tomographic (CT) scan should be considered early. Muscle relaxants should not be given and sedation minimized to allow an appropriate daily clinical assessment. In addition, renal function, liver function, risk for sepsis, and possible gut ischemia should be frequently evaluated.

5. **Residual cardiac defects.** If a patient fails to wean from ECMO or if there is a delay in anticipated recovery of myocardial function, the possibility of a residual surgical problem must always be considered. This usually is difficult to diagnose by echocardiography alone, and cardiac catheterization (i.e., diagnostic or interventional) should be considered.

Daily Management

The daily management of a patient on ECMO or other forms of extracorporeal life support requires meticulous assessment of cardiorespiratory function, end-organ perfusion and injury, evolving complications such as bleeding or sepsis, and the mechanics of the ECMO circuit. After ECMO cannulation and initial resuscitation, high flow rates (100-200 mL/kg/min depending on the underlying pathophysiology) are used to "rest" the heart and decompress the ventricle(s). However, in contrast to the concept of "resting the lungs" for patients who are placed on ECMO for respiratory failure and lung injury, it is important that the heart regain contractile function and conduction as soon as possible to maintain a workload and avoid involution of the myocardial mass. For this reason, inotropic support may be reintroduced earlier in cardiac patients compared with those on ECMO purely for respiratory support. Atrioventricular synchrony should be established as soon as possible. This can be achieved with external pacing if necessary. It is very important that dysrhythmias occurring on ECMO be treated promptly. Although it may be possible to maintain adequate systemic perfusion and ECMO flows, the heart may overdistend in the presence of certain dysrhythmias, particularly ventricular fibrillation, resulting in irreversible myocardial injury.

Transient endothelial dysfunction is common after ECMO is established, identical to the injury resulting from CPB, and causes an elevated PVR and ventilation/perfusion abnormalities.[78] Permitting or promoting the heart to eject some blood into the pulmonary circulation while on ECMO may help endothelial recovery and prevent pulmonary hypertension when weaning from ECMO. It is important to remember that the pulmonary venous blood entering the left ventricle and ejected into the coronary circulation may be significantly desaturated, which could cause myocardial ischemia or delay myocardial recovery. For this reason, mechanical ventilation is continued on cardiac ECMO to ensure pulmonary venous blood is well saturated. Ventilator settings are adjusted primarily according to lung compliance, which may reflect the degree of preexisting cardiac-related or parenchymal lung disease. Tidal volumes of 7 to 9 mL/kg with peak inspiratory pressures not exceeding 25 to 28 cmH_2O, positive end-expiratory pressure (PEEP) of 5 to 10 cmH_2O and FIo_2 of 0.3 to 0.4 usually are maintained in patients with normal lung compliance. Changes in ventilator settings are guided by physical examination, assessment of compliance based on hand ventilation and lung volumes, and appearance of the lung fields on daily chest radiographs. Fluid retention and body wall edema are very common in cardiac patients on ECMO because of (1) endothelial dysfunction and capillary leak associated with reperfusion injury and inflammatory response,[79] (2) changes in oncotic pressure depending on the priming solution, and (3) decreased urine output secondary to alterations in perfusion and the influence of antidiuretic hormone, renin-angiotensin, and atrial natriuretic factor production.[80] Diuretic therapy is started early to achieve a negative fluid balance and treat anasarca as soon as possible; fluid overload is one of the most important factors that will determine eventual successful weaning from cardiac ECMO and longer-term survival. Furosemide bolus (1 mg/kg) followed by continuous infusion (0.2-0.3 mg/kg/hour) usually is the first choice to induce diuresis, provided adequate renal perfusion has been achieved with ECMO flow and no significant or irreversible renal injury occurred before starting ECMO. Chlorothiazide (10 mg/kg per dose every 12 hours) is added if the response to furosemide is suboptimal. Ultrafiltration is used in the setting of excessive fluid retention despite maximal diuretic therapy and circulatory support. Suspension of ultrafiltration is advisable in the setting of low atrial pressures with hypotension and frequent circuit shutdown because of low volume or pressure sensing within the bladder, at least until hemodynamics stabilize.

Neurologic assessment, although difficult in patients on ECMO, must be performed regularly. Abrupt changes in heart rate, blood pressure, skin perfusion, and pupillary size could indicate seizure activity in paralyzed patients. Findings of concern should be promptly evaluated by cranial ultrasound, head CT scan, or electroencephalography because changes or abnormalities will impact the decision to continue ECMO support. Sedation and analgesia also must be continually reassessed. Muscle relaxation is advisable in unstable patients but can be used intermittently as needed once the patient and ECMO flows are stable enough to allow neurologic evaluation. Parenteral nutritional support should be initiated within 1 to 2 days after establishing ECMO, although it can be deferred if the ECMO course likely will be relatively short (i.e., <4 days), and introduction of enteral nutrition soon after discontinuing ECMO is anticipated. Patients receiving mechanical support are at high risk for nosocomial infection, especially from skin flora with a direct portal of entry through catheters, chest sites, and open or closed sternotomy wounds. Patients with unexplained hemodynamic instability, coagulopathy, and elevated white blood cell count or fever should be pan-cultured and broad-spectrum antibiotic cover initiated.

Weaning from Extracorporeal Membrane Oxygenation

The strategies for weaning from cardiac ECMO often are quite different from those used for weaning patients who are on ECMO for respiratory support. A thorough understanding of the underlying cardiac physiology and cardiorespiratory interactions and an appreciation for the expected range of oxygen saturations is important. Because of the high risk of complications and substantial mortality in cardiac patients associated with duration of mechanical circulatory support beyond 1 week, consideration as to when and how to wean

cardiac patients from ECMO should begin soon after cannulation once circulatory stability has been established. The disease process and circumstances resulting in hemodynamic failure or cardiac arrest may influence the expected duration of mechanical support. For example, patients who fail to separate from CPB after cardiac surgery because of severe pulmonary hypertension usually respond to a 24- to 48-hour period on ECMO with inhaled NO therapy and inotropic support of the right heart. Similarly, patients who have a low cardiac output state or suffer cardiac arrest after cardiac surgery may have residual defects that allow rapid weaning and decannulation soon after reoperation. The likelihood of recovery of ventricular function should be decided within the first 48 to 72 hours so that cardiac transplantation status can be ascertained. ECMO instituted for catheter intervention or arrhythmia ablation procedures may be discontinued within hours of patient cannulation.[81] In contrast, patients with severe cardiomyopathies or those awaiting heart transplantation may require mechanical assistance for a much longer period. Patients with severe bronchiolitis as a result of respiratory syncytial virus complicating repair of CHD on CPB typically require 2 to 3 weeks of ECMO support for respiratory failure.

Patients requiring cardiovascular support with ECMO are partially weaned within the first 48 hours to assess myocardial function by echocardiography and hemodynamic evaluation. An acceptable Pao_2 obtained while the ECMO circuit is clamped, varies substantially according to the underlying anatomy and pathophysiology. If transthoracic cannulation was used and bleeding problems occurred during the ECMO run, the mediastinum may require exploration before or during the weaning process. If only a short period of reconditioning of the myocardium is anticipated, the patient frequently is sedated and paralyzed, dopamine infusion is increased to 5 to 10 μg/kg/min, intravascular volume status is optimized, and ventilator settings are adjusted according to lung compliance and expected arterial O_2 saturation. ECMO flow is decreased by 25% to 50% over a period of several hours until the circuit is clamped. Volume is infused to achieve appropriate preload. Echocardiographic assessment of ventricular systolic function, valvar function, systemic and pulmonary outflow obstruction, and location and direction of intracardiac shunts is useful before weaning and when a change in hemodynamics occurs after the circuit has been clamped. Arterial blood gases, serum lactate levels, and systemic (mixed) venous saturation are important guides to the stability of the circulation, ventilation, and adequacy of perfusion after the circuit has been clamped. Decannulation from ECMO is undertaken once the patient has maintained a stable circulation and acceptable gas exchange for up to 4 hours.

Cardiovascular Interactions with Other Organs

Respiratory Function and Heart-Lung Interaction

Altered respiratory mechanics and positive pressure ventilation may have significant influence on hemodynamics after congenital heart surgery. Therefore the approach to mechanical ventilation should not only be directed at achieving a desired gas exchange but also should be influenced by the potential cardiorespiratory interactions of mechanical ventilation. Ventilation strategy must be matched to the hemodynamic status of each patient to achieve adequate cardiac output and gas exchange. Frequent adjustments may be necessary during the postoperative period, with attention to changes in lung volume and airway pressure. Changes in lung volume have a major effect on PVR, which is lowest at the lung's functional residual capacity (FRC), whereas both hypoinflation or hyperinflation may result in a significant increase in PVR because of altered traction on alveolar septa and extraalveolar vessels.

Positive pressure ventilation influences preload and afterload on the heart (Table 31-5).[82-84] Increased lung volume and intrathoracic pressure decrease preload to both the right and left atria. The afterload on the pulmonary ventricle is increased during a positive pressure breath secondary to the changes in lung volume and increase in mean intrathoracic pressure. If this is significant or there is limited functional cardiac reserve, RV stroke volume may be reduced and end-diastolic pressure increased. This in turn may contribute to a low cardiac output state and signs of RV dysfunction, including tricuspid regurgitation, hepatomegaly, ascites, and pleural effusions. In contrast to the right ventricle, the afterload on the systemic ventricle is decreased during a positive pressure breath secondary to a fall in the ventricle transmural pressure. The systemic arteries are under higher pressure and are not exposed to radial traction effects during inflation or deflation of the lungs. Therefore changes in lung volume will affect LV preload, but the effect on afterload is dependent on changes in intrathoracic pressure alone rather than changes in lung volume. Therefore positive pressure ventilation and PEEP may have a significant beneficial effect in patients with LV failure.

Patients with LV dysfunction and increased end-diastolic volume and pressure can have impaired pulmonary mechanics secondary to increased lung water, decreased lung compliance, and increased airway resistance. The work of breathing is increased, and neonates can fatigue early because of limited respiratory reserve. A significant proportion of total body oxygen consumption is directed at the increased work of breathing

Table 31–5 Cardiorespiratory Interactions of a Positive Pressure Mechanical Breath

	Afterload	Preload
Pulmonary ventricle	Elevated	Reduced
	Effect: ↑ RVEDp	Effect: ↓ RVEDV
	↑ RVp	↓ RAp
	↓ Antegrade PBF	
	↑ PR and/or TR	
Systemic ventricle	Reduced	Reduced
	Effect: ↓ LVEDp	Effect: ↓ LVEDV
	↓ LAp	↓ LAp
	↓ Pulmonary edema	
	↑ Cardiac output	

LAp, Left atrial pressure; *LVEDp,* left ventricular end-diastolic pressure; *LVEDV,* left ventricular end-diastolic volume; *PBF,* pulmonary blood flow; *PR,* pulmonary regurgitation; *RAp,* right atrial pressure; *RVEDp,* right ventricular end-diastolic pressure; *RVEDV,* right ventricular end-diastolic volume; *RVp,* right ventricular pressure; *TR,* tricuspid regurgitation.

in neonates and infants with LV dysfunction, contributing to poor feeding and failure to thrive. Therefore positive pressure ventilation has an additional benefit in patients with significant volume overload and systemic ventricular dysfunction by reducing the work of breathing and oxygen demand.

The use of PEEP in patients with CHD has been controversial. It initially was perceived not to have a significant positive impact on gas exchange, and there was concern that the increased airway pressure could have a detrimental effect on hemodynamics and contribute to lung injury and air leak. Nevertheless, PEEP increases FRC, enabling lung recruitment, and redistributes lung water from alveolar septal regions to the more compliant perihilar regions. Both of these actions improve gas exchange and reduce PVR. Therefore PEEP should be used in mechanically ventilated patients after congenital heart surgery. However, excessive levels of PEEP can be detrimental by increasing afterload on the right side of the circulation. This may be especially true in the Fontan circulation. Usually 3 to 5 cmH_2O of PEEP helps maintain FRC and redistribute lung water without causing hemodynamic compromise. Of course the optimal condition for the Fontan circulation occurs when the patient can breathe spontaneously, generating negative pleural and intrathoracic pressures that assist systemic venous return. If lung volume can be maintained and work of breathing minimized without any positive pressure ventilation, then the Fontan circulation is best served. Early transition to a pressure-support mode of breathing and aim to extubation during the first few postoperative hours is our goal.

Special Respiratory Problems for the Cardiac Patient

Diaphragmatic paresis (reduced motion) or paralysis (paradoxical movement) may precipitate and promote respiratory failure, particularly in the neonate or young infant who relies on diaphragmatic function for breathing more than older infants and children (who can recruit accessory and intercostal muscles if diaphragmatic function proves inadequate). Injury to the phrenic nerve, usually the left, may occur during operations that require dissection of the branch pulmonary arteries well out to the hilum (e.g., TOF, ASO), arch reconstruction from the midline (e.g., Norwood operation), manipulation of the SVC (Glenn shunts), takedown of previous systemic-to-pulmonary shunts, or after percutaneous central venous access. Phrenic injury may occur more frequently at reoperation, when adhesions and scarring may obscure landmarks. Topical cooling with ice during deep hypothermia may also cause transient phrenic palsy. Increased work of breathing on low ventilator settings, increased P_{CO_2}, and a chest radiograph revealing an elevated hemidiaphragm are suggestive of diaphragmatic dysfunction. The chest x-ray film may be misleading, however, if it is taken during at the end of inspiration when lung volume is at its highest. Ultrasonography or fluoroscopy is useful for identifying diaphragmatic motion or paradoxical excursion. Recovery of diaphragmatic contraction usually occurs; however, if a patient fails to tolerate repeated extubations despite optimizing cardiovascular and nutritional status and diaphragmatic dysfunction persists with volume loss in the affected lung, then the diaphragm may require surgical plication. Although only a temporary effect is gained, the prevention of collapse and volume loss in the affected lung may provide the critical advantage needed for liberation from positive pressure ventilation.

Pulmonary edema, pneumonia, and atelectasis are the most common causes of lower airway and alveolar abnormalities that interfere with gas exchange. If a bacterial pathogen is identified, therapy includes antibiotics and pulmonary toilet. If the cause is pulmonary edema, therapy is aimed at lowering the LA pressure through diuresis and pharmacologic means to reduce afterload and improve the lusitropic state of the heart. For infants, fluid restriction frequently is incompatible with adequate nutrition; therefore an aggressive diuretic regimen is preferable to restriction of caloric intake. Adjustment of end-expiratory pressure and mechanical ventilation serve as supportive therapies until the alveoli and pulmonary interstitium are cleared of the fluid that interferes with gas exchange.

Pleural effusions and ascites may occur in patients after a Fontan operation or reparative procedures requiring a right ventriculotomy (e.g., TOF, truncus arteriosus) with transient RV dysfunction. Especially in young patients, pleural effusions and increased interstitial lung water may be a manifestation of right heart failure. This seems logically related to raised systemic venous pressure impeding lymphatic return to the venous circulation. The lymphatic circuit often is functioning at full capacity in these children. Fluid in the pleural space or peritoneum and intestinal distension compete with intrapulmonary gas for thoracic space. Evacuation of the pleural space or drainage of ascites and decompression of the intestinal lumen allow the intrapulmonary gas volume to increase.

Weaning from Mechanical Ventilation

Early tracheal extubation of children after congenital heart surgery is not a new concept but has received renewed attention with the evolution of "fast track" management for cardiac surgical patients. Early extubation generally refers to tracheal extubation within a few hours (i.e., 4-8 hours) after surgery, although in practice it means the avoidance of routine overnight mechanical ventilation. Factors to consider when planning early extubation are given in Table 31-6. For any patient, a thorough review of the preoperative clinical status and surgical procedure is necessary immediately upon admission to the ICU, followed by a detailed examination and assessment of monitoring and laboratory data. Although procedures vary from patient to patient, carefully constructed postoperative order sheets are useful for directing initial management and planning.

A number of published reports have described successful tracheal extubation in neonates and older children after congenital heart surgery, either in the operating room or soon after in the cardiac ICU.[85] This has been possible without significant compromise of patient care, and a low incidence of reintubation or hemodynamic instability has been reported. This fast track strategy has been extended to routine early (within 24 hours of surgery) discharge from hospital. Although overzealous attempts to achieve this goal can have a negative impact on patients and families (e.g., discharge at 24 hours to hotel with chest tube still in place), the practice has streamlined the care of these children and highlights the advances in perioperative care that now permit hospital discharge of infants and older children within 24 hours of repair of congenital heart defects on CPB.[86]

Table 31–6 Considerations for Planned Early Extubation After Congenital Heart Surgery

Patient factors	Limited cardiorespiratory reserve of the neonate and infant
	Pathophysiology of specific congenital heart defects
	Timing of surgery and preoperative management
Anesthetic factors	Premedication
	Hemodynamic stability and reserve
	Drug distribution and maintenance of anesthesia on bypass
	Postoperative analgesia
Surgical factors	Extent and complexity of surgery
	Residual defects
	Risks for bleeding and protection of suture lines
Conduct of bypass	Degree of hypothermia
	Level of hemodilution
	Myocardial protection
	Modulation of the inflammatory response and reperfusion injury
Postoperative management	Myocardial function
	Cardiorespiratory interactions
	Neurologic recovery
	Analgesia management

Central Nervous System

The dramatic reduction in surgical mortality in recent decades has been accompanied by a growing recognition of adverse neurologic sequelae in some survivors. Central nervous system abnormalities may be a function of coexisting brain abnormalities or acquired events unrelated to surgical management (e.g., paradoxical embolus, brain infection, effects of chronic cyanosis), but central nervous system insults appear to occur most frequently during or immediately after surgery. In particular, support techniques used during neonatal and infant cardiac surgery (e.g., CPB, profound hypothermia, circulatory arrest) have been implicated as important causes of brain injury.[87]

During hypothermic CPB, multiple perfusion variables may influence the risk of brain injury. These variables include (but probably are not limited to) (1) the total duration of CPB and the duration and rate of core cooling, (2) pH management during core cooling, (3) duration of circulatory arrest, (4) type of oxygenator, (5) presence of arterial filtration, and (6) depth of hypothermia. Undoubtedly, there is interaction between these various elements, and central nervous system injury after CPB most likely is multifactorial. Early postoperative studies (in the ICU) revealed a higher incidence of neurologic issues in patients undergoing circulatory arrest, including a higher incidence of clinical and electroencephalographic (EEG) seizures, a longer recovery time to the first reappearance of EEG activity, and greater release of the brain isoenzyme of creatine kinase.

Seizures are the most commonly observed neurologic consequence of cardiac surgery with an incidence in older studies of 4% to 25%. Although the incidence of seizures in the ICU has dramatically declined in recent years, when seizures occur they should be treated aggressively with benzodiazepines, phenobarbital, or phenytoin. Importantly, one should limit practices that may have been associated with brain injury after CPB: rapid cooling on CPB and use of prolonged hypothermic circulatory arrest, extreme alpha-stat strategy of intraoperative pH management, extreme hemodilution to hematocrits less than 20, applying heat lamps to infants on arrival in ICU, hypocapnic hyperventilation, and prolonged muscle relaxation (masking seizure observations). We are especially loath to permit hyperthermia to any degree in the early postoperative period.

Intraventricular hemorrhage may occur as a consequence of perinatal events or circulatory collapse in the first few days of life. It is commonly associated with prematurity. Our approach has been to screen all premature infants or asphyxiated babies with a head ultrasound before CPB, which involves extensive anticoagulation, hemodynamic perturbation, and risk for bleeding extension. Surgical intervention is delayed for several days if intraventricular bleeding is documented. The strategy of deferring operations in very premature newborns for several days after birth is associated with a low incidence of intraventricular hemorrhage in these high-risk patients despite use of CPB.[88]

Renal Function and Postoperative Fluid Management

Risk factors for postoperative renal failure include preoperative renal dysfunction, prolonged bypass time, low cardiac output, and cardiac arrest. In addition to relative ischemia and nonpulsatile flow on CPB, angiotensin II–mediated renal vasoconstriction and delayed healing of renal tubular epithelium have been proposed as one mechanism for renal failure. Postoperative sepsis and nephrotoxic drugs may further damage the kidneys.

Because of the inflammatory response to bypass and significant increase in total body water, fluid management in the immediate postoperative period is critical. Capillary leak and interstitial fluid accumulation may continue for the first 24 to 48 hours after surgery, necessitating ongoing volume replacement with colloid or blood products. A fall in cardiac output and increased antidiuretic hormone secretion contribute to delayed water clearance and potential prerenal dysfunction, which could progress to acute tubular necrosis and renal failure if a low cardiac output state persists.

During CPB, optimizing the circuit prime, hematocrit, and oncotic pressure; attenuating the inflammatory response with steroids; and use of modified ultrafiltration techniques have been recommended to limit interstitial fluid accumulation.[89] During the first 24 hours after surgery, maintenance fluids should be restricted to 50% of full maintenance and volume replacement titrated to appropriate filling pressures and hemodynamic response.

Oliguria in the first 24 hours after complex surgery and CPB is common in neonates and infants until cardiac output recovers and neurohumoral mechanisms abate. Although diuretics are commonly prescribed in the immediate postoperative period, the neurohumoral influence on urine output is

powerful. Time after CPB and enhancement of cardiac output through volume and pharmacologic adjustments are the most important factors that will promote diuresis.

Peritoneal dialysis, hemodialysis, and continuous venovenous hemofiltration provide alternate renal support in patients with severe oliguria and renal failure. Besides enabling water and solute clearance, maintenance fluids can be increased to ensure adequate nutrition. The indications for renal support vary but include blood urea nitrogen greater than 100 mg/dL, life-threatening electrolyte imbalance such as severe hyperkalemia, ongoing metabolic acidosis, fluid restrictions limiting nutrition, and increased mechanical ventilation requirements secondary to persistent pulmonary edema or ascites.

A peritoneal dialysis catheter can be placed into the peritoneal cavity at the completion of surgery or as a bedside procedure later in the ICU. Indications include the need for renal support or for reducing intraabdominal pressure from ascites that may compromise mechanical ventilation. Drainage may be significant in the immediate postoperative period as third space fluid losses continue, and replacement with albumin and/or fresh-frozen plasma may be necessary to treat hypovolemia and hypoproteinemia.

Gastrointestinal Issues

After cardiac surgery in neonates and children, adequate nutrition is exceedingly important. These critically ill children often have decreased caloric intake and increased energy demand after surgery; the neonate, in particular, has limited metabolic and fat reserves. Total parenteral nutrition can provide adequate nutrition in the hypercatabolic phase of the early postoperative period.

Upper gastrointestinal bleeding and ulcer formation may occur after the stress of cardiac surgery in children and adults. There are limited reports of the efficacy of histamine H_2 antireceptors, sucralfate, or oral antacids in pediatric cardiac patients, although their use is common in many ICUs. Hepatic failure may occur after cardiac surgery (particularly after the Fontan operation and typically is characterized by elevated liver enzymes and coagulopathy).

Necrotizing enterocolitis, although typically a disease of premature infants, is seen with considerable frequency in neonates with CHD. Risk factors include (1) left-sided obstructive lesions, (2) umbilical or femoral arterial catheterization/angiography, (3) hypoxemia, and (4) lesions with wide pulse pressures (e.g., systemic-to-pulmonary shunts, PDA, especially in transposition of the great arteries and severe aortic regurgitation) producing retrograde flow in the mesenteric vessels during diastole. Frequently, multiple risk factors exist in the same patient, making a specific etiology difficult to establish. Treatment includes continuous nasogastric suction, parenteral nutrition, and broad-spectrum antibiotics. Bowel exploration or resection may be necessary in severe cases.

Infection

Low-grade (<38.5° C) fever during the immediate postoperative period is common and may be present for up to 3 to 4 days, even without a demonstrable infectious etiology. However, there are several reports of increased susceptibility to infection after CPB. CPB may activate complement and other mediators of inflammation but also can lead to derangements of the immune system and increase the likelihood of infection. A centrally mediated etiology of fever after CPB has been postulated.

Sepsis and nosocomial infection after cardiac surgery contribute substantially to overall morbidity. Despite the recent increased use of broad-coverage, third-generation cephalosporins, these agents do not seem to be more effective in decreasing postoperative infections. Meticulous catheter insertion and daily care routines, along with early removal of indwelling catheters in the postoperative patient, may reduce the incidence of sepsis.[90]

Mediastinitis occurs in up to 2% of patients undergoing cardiac surgery. Risk factors include delayed sternal closure, early reexploration for bleeding, or reoperation. Mediastinitis is characterized by persistent fever, purulent drainage from the sternotomy wound, instability of the sternum, and leukocytosis. *Staphylococcus* is the most common offending organism. Treatment usually involves debridement and irrigation with parenteral antibiotic therapy. Duration of therapy seldom exceeds 2 weeks.

Hyperglycemia

Hyperglycemia is a frequent occurrence in the pediatric cardiac intensive care unit.[91,92] As many as 97% and 78% of patients exhibit at least one blood glucose measurement above 125 mg/dL and 200 mg/dL, respectively, after surgical repair of congenital cardiac defects.[91,92] The duration of postoperative hyperglycemia in these patients has been strongly and independently associated with increased morbidity and mortality rates. [91,92]

Strict glycemic control with insulin administration has been shown to reduce morbidity and mortality rates significantly for adult patients admitted to a surgical ICU.[93] A recent report of the first glycemic control outcome trial conducted in children with a sample largely comprised of postoperative cardiac patients showed decreased mortality, shorter ICU length of stay, and decreased markers of inflammation in patients treated with insulin to maintain fasting blood glucose levels.[94] Of significant concern in that trial, however, was the finding that 24.9% of children undergoing strict glycemic control had at least one episode of severe hypoglycemia (blood glucose <40 mg/dL).[94] The use of a more permissive glycemic range (90-140 mg/dL) has been postulated as an optimal target that would be associated with a lower incidence of hypoglycemia compared with an euglycemic range, without incurring the negative effects of hyperglycemia (Figure 31-3).[95] A randomized controlled trial of glycemic control using this more permissive target is yet to be performed.

Critical Care Management of Specific Lesions

Single-Ventricle Anatomy and Physiology

For a variety of anatomic lesions, the systemic and pulmonary circulations are parallel, with a single ventricle effectively supplying both systemic and pulmonary blood flow (Table 31-7). The relative proportion of ventricular output to either the pulmonary or systemic vascular bed is determined by the relative resistance to flow in the two circuits. The pulmonary arterial and aortic oxygen saturations are equal, with mixing of the systemic and pulmonary venous

Euglycemia (60-125 mg/dL), mild hyperglycemia (126-139 mg/dL), moderate hyperglycemia (140-179 mg/dL), severe hyperglycemia (>180 mg/dL), or permissive glycemic target (90-140 mg/dL). *a, P* <.0125 by chi-square test with Bonferroni correction. *(Data from Ulate KP, Lima Falcao GC, Bielefeld MR,* et al: *Strict glycemic targets need not be so strict: a more permissive glycemic range for critically ill children.* Pediatrics *122[4]:e898-e904, 2008.)*

Table 31–7 Factors Contributing to a Lower than Anticipated Oxygen Saturation in Patients with Common Mixing Lesions

Etiology	Considerations
Low F_{IO_2}	Low delivered oxygen concentration
	Failure of oxygen delivery device
Pulmonary vein desaturation	**1. Ventilation perfusion defects**
	Alveolar process (e.g., edema/infection/atelectasis)
	Restrictive process (e.g., effusion/bronchospasm)
	2. Intrapulmonary shunt
	Severe RDS
	Pulmonary AVM
	PA-to-PV collateral vessel(s)
↓ Pulmonary blood flow	Anatomic RV outflow obstruction
	Anatomic pulmonary artery stenosis
	Increased PVR
	Atrial level right-to-left shunt
	Ventricular level right-to-left shunt
↓ Oxygen content	**1. Low mixed venous oxygen level**
	Increased O_2 extraction: Hypermetabolic state
	Decreased O_2 delivery: Low cardiac output state
	2. Anemia

AVM, Arteriovenous malforamtion; *F_{IO_2},* fractional inspired concentration of oxygen; *PA,* pulmonary artery; *PV,* pulmonary vein; *PVR,* pulmonary vascular resistence; *RDS,* respiratory distress syndrome; *RV,* right ventricle.

return within a "common" atrium. Assuming equal mixing, normal cardiac output, and full pulmonary venous saturation, Sao_2 of 80% to 85%, with mixed venous oxygen saturation of 60% to 65%, indicates Q_p/Q_s is approximately 1 and hence a balance between systemic and pulmonary flow. Although "balanced," the single ventricle still must receive and eject twice the normal amount of blood: one part to the pulmonary circulation and one part to the systemic circulation. A Q_p/Q_s greater than 1 implies an intolerable volume burden on the heart. Although there may be specific management issues for certain defects with single-ventricle physiology, nevertheless there are common management considerations to balance flow and augment systemic perfusion.

Preoperative Management

Changes in PVR have a significant impact on systemic perfusion and circulatory stability, especially preoperatively when the ductus arteriosus is widely patent. In preparation for surgery, it is important that systemic and pulmonary blood flow be as well balanced as possible to prevent excessive volume overload and ventricular dysfunction that reduces systemic and end-organ perfusion. For example, a newborn with HLHS who has an arterial oxygen saturation greater than 90%, a wide pulse width, oliguria, cool extremities, hepatomegaly, and metabolic acidosis has severely limited systemic blood flow. Even though ventricular output is increased, the blood flow that is inefficiently partitioned back to the lungs is unavailable to the other vital organs. Immediate interventions are necessary to prevent imminent circulatory collapse and end-organ injury. In this "overcirculated" state, PVR is falling as it should in the normal postnatal state, and the ductus arteriosus is maintained widely patent with prostaglandin infusion to permit unrestricted blood flow from the single right ventricle across the ductus to the systemic bed. Blood flow manipulation of mechanical ventilation and inotropic support may temporarily stabilize the patient (see the following section), but surgery should not be delayed. Similarly, in a patient with pulmonary atresia and an intact ventricular septum, LV-dependent pulmonary circulation occurs. Ductal patency is necessary for pulmonary blood flow. As PVR falls, pulmonary blood flow will be excessive and eventually will steal from the systemic circulation. Preoperative management should focus on an assessment of the balance between pulmonary (Q_p) and systemic flow (Q_s). This is best achieved by thorough and continuous reevaluation of the clinical examination for cardiac output state and perfusion, an evaluation of chest radiograph for cardiac size and pulmonary congestion, a review of laboratory data for alterations in gas exchange, acid-base status,

and end-organ function, and echocardiographic imaging to assess ventricular function and AV valve competence. A central venous line positioned in the proximal SVC may be useful to monitor volume status and sample for mixed venous oxygen saturation as a surrogate of cardiac output and oxygen delivery. Central venous lines are not necessary in all circumstances; they may have significant complications in small newborns and do not substitute for clinical examination.

Initial resuscitation involves maintaining patency of the ductus arteriosus with a PGE_1 infusion at a rate of 0.02 to 0.05 μg/kg/min. Intubation and mechanical ventilation are not necessary in all patients. Patients usually are tachypneic, but provided the work of breathing is not excessive and systemic perfusion is maintained without a metabolic acidosis, spontaneous ventilation often is preferable to achieve an adequate systemic perfusion and balance of Q_p and Q_s. A mild metabolic acidosis and low bicarbonate level may be present but may not indicate poor perfusion and a lactic acidosis specifically. If the presentation involved circulatory collapse and end-organ dysfunction, then a period of days may be required to establish stability and allow return of vital organ function before surgery.

Patients require intubation and mechanical ventilation because of apnea secondary to PGE_1, presence of a low cardiac output state, or for manipulation of gas exchange to assist balancing pulmonary and systemic flow. Sao_2 greater than 90% indicates pulmonary overcirculation, that is, Q_p/Q_s greater than 1. PVR can be increased with controlled mechanical hypoventilation to induce a respiratory acidosis, often necessitating sedation and neuromuscular blockade, and with a low FIo_2 to induce alveolar hypoxia. Ventilation in room air may suffice, but occasionally a hypoxic gas mixture is necessary. This is achieved by adding nitrogen to the inspired gas mixture, reducing the FIo_2 from 0.17 to 0.19. Although these maneuvers often are successful in increasing PVR and reducing pulmonary blood flow, remember that these patients have a limited oxygen reserve and may desaturate suddenly and precipitously. Controlled hypoventilation in effect reduces FRC and therefore the oxygen reserve, which is further reduced by use of an hypoxic inspired gas mixture. An alternate strategy is to add carbon dioxide to the inspiratory limb of the breathing circuit, which also increases PVR, but because a hypoxic gas mixture is not used, systemic oxygen delivery is maintained.[96,97] Patients who have continued pulmonary overcirculation with high Sao_2 and reduced systemic perfusion despite these maneuvers require early surgical intervention to control pulmonary blood flow. At the time of surgery, a snare can be placed around either branch of the pulmonary artery to effectively limit pulmonary blood flow.

Decreased pulmonary blood flow in preoperative patients with a parallel circulation is reflected by hypoxemia with Sao_2 less than 75%. Preoperatively this may result from restricted flow across a small ductus arteriosus, increased PVR secondary to parenchymal lung disease, or increased pulmonary venous pressure secondary to obstructed pulmonary venous drainage or a restrictive ASD. Sedation, paralysis, and manipulation of mechanical ventilation to maintain an alkalosis may be effective if PVR is elevated. NO as a specific pulmonary vasodilator also may be useful in this situation. Systemic oxygen delivery is maintained by improving cardiac output and maintaining hematocrit greater than 40%. Among some newborns with HLHS, pulmonary blood flow may be insufficient because mitral valve hypoplasia in combination with the occasional finding of a restrictive or nearly intact atrial septum severely restricts pulmonary venous return to the heart. The newborn is intensely cyanotic and has a pulmonary venous congestion pattern on chest radiograph. Urgent interventional cardiac catheterization with balloon septostomy or dilation (or stent placement) of a restrictive ASD may be necessary.[98,99] Immediate surgical intervention and palliation is preferred in some centers.

Systemic perfusion is maintained with the use of volume and vasopressor agents. Inotropic support often is necessary because of ventricular dysfunction secondary to the increased volume load. Systemic afterload reduction with agents such as phosphodiesterase inhibitors may improve systemic perfusion, although they also may decrease PVR and thus not correct the imbalance of pulmonary and systemic flow. Oliguria and a rising serum creatinine level may reflect renal insufficiency from a low cardiac output. Necrotizing enterocolitis is a risk secondary to splanchnic hypoperfusion, and we prefer not to enterally feed newborns with a wide pulse width and low diastolic pressure (usually <30 mm Hg) before surgery. It is important to evaluate end-organ perfusion and function.

Bidirectional Cavopulmonary Anastomosis

In this procedure, also known as a *bidirectional Glenn shunt,* the SVC is transected and connected end-to-side to the right pulmonary artery, but the pulmonary arteries are left in continuity. Therefore flow from the SVC is bidirectional into both left and right pulmonary arteries. The SVC becomes the only source of pulmonary blood flow, and IVC blood returns to the common atrium. Performed between age 3 to 6 months, the BDG has proved to be an important early staging procedure for patients with single-ventricle physiology because the volume and pressure load is relieved from the systemic ventricle yet effective pulmonary blood flow is maintained. Q_p/Q_s is always less than 1, and the volume load to the single right ventricle is relieved compared with a systemic-to-pulmonary artery shunt. However, it is impractical in the newborn whose pulmonary cross sectional area is inadequate to accommodate sufficient passive pulmonary blood flow for tolerable oxygenation.

The BDG usually is performed on CPB using mild hypothermia with a beating heart. Therefore the complications related to CPB and aortic cross-clamping are minimal, and patients can be weaned and extubated in the early postoperative period.[100] Systemic hypertension is common after a BDG. The etiology remains to be determined, but possible factors include improved contractility and stroke volume after the volume load on the ventricle is removed and brainstem-mediated mechanisms secondary to the increased systemic and cerebral venous pressure. Treatment with vasodilators may be necessary during the immediate postoperative period and during the weaning process.

After the BDG anastomosis, arterial oxygen saturation should be in the 80% to 85% range. Persistent hypoxemia often is secondary to a low cardiac output state and low Svo_2. Treatment is directed at improving contractility, reducing afterload, and ensuring the patient has a normal rhythm and hematocrit. Hyperventilation is not an effective strategy to increase pulmonary blood flow and oxygen saturation in patients after a BDG anastomosis, as hypocapnia causes

cerebral vasoconstriction and effectively decreases the venous return from the SVC (the source of pulmonary blood flow). Instead, arterial oxygen saturation in these patients often benefits from normocapnia or a mild to moderate degree of hypercapnia. Increased PVR is an uncommon cause, and inhaled NO is rarely beneficial in these patients. This finding is not surprising because PA pressure and resistance and vascular tone are not high enough after this surgery to see a demonstrable benefit from NO.[76] Persistent profound hypoxemia should be investigated in the catheterization laboratory to evaluate hemodynamics, look for residual anatomic defects limiting pulmonary flow, such as PA stenosis or a restrictive ASD, and coil any significant venous decompressing collaterals, if present.

Fontan Procedure

Since the original description in 1971,[101] the Fontan procedure and subsequent modifications have been successfully used to treat a wide range of simple and complex single-ventricle congenital heart defects.[102] The repair is "physiologic" in that the systemic and pulmonary circulations are in series and cyanosis is corrected. However, given the current long-term outcome data, perhaps the repair should be viewed as palliative rather than curative.[103,104] The mortality and morbidity associated with this surgery have declined substantially over the years, and many patients with stable single-ventricle physiology can lead normal lives.[105] Considerations in managing a cavopulmonary connection are given in Table 31-8. Systemic venous pressure of 10 to 15 mm Hg and LA pressure of 5 to 10 mm Hg, that is, a transpulmonary gradient of 5 to 10 mm Hg, is ideal.

Intravascular volume must be maintained and hypovolemia must be treated promptly. Venous capacitance is increased, and as patients rewarm and vasodilate after surgery, a significant volume requirement of approximately 30 to 40 mL/kg on the first postoperative night is not unusual. Changes in mean intrathoracic pressure and PVR have a significant effect on pulmonary blood flow. Pulmonary blood flow has been shown to be biphasic after the Fontan procedure, and earlier resumption of spontaneous ventilation is recommended to offset the detrimental effects of positive pressure ventilation.[106,107] Using Doppler analysis, it has been demonstrated that pulmonary blood flow predominantly occurs during inspiration in a spontaneously breathing patient, that is, when the mean intrathoracic pressure is subatmospheric. Therefore the method of mechanical ventilation after a Fontan procedure requires close observation. A tidal volume of 8 to 10 mL/kg with the lowest possible mean airway pressure is appropriate. Although it is preferable to wean from positive pressure ventilation in the early postoperative period, hemodynamic responses must be closely monitored.

If appropriate selection criteria are followed, patients undergoing a modified Fontan procedure will have a low PVR without labile pulmonary hypertension. Therefore vigorous hyperventilation and induction of a respiratory and/or metabolic alkalosis often are of little benefit in this group of patients, and the related increase in mechanical ventilation requirements may be detrimental. A normal pH and $Paco_2$ of 40 mm Hg should be the goal and, depending on the amount of right-to-left shunt across the fenestration, the arterial oxygen saturation usually is in the 80% to 90% range.

Table 31–8 Management Considerations Following a Modified Fontan Procedure

	Aim	Management
Baffle (right side)		→ or ↑ Preload
Pressure 10–15 mm Hg	Unobstructed venous return	Low intrathoracic pressure
	PVR <2 Wood units • m^2	Avoid increases in PVR, such as from acidosis, hypoinflation and hyperinflation of the lung, hypothermia, and excess sympathetic stimulation
Pulmonary circulation	Mean Pap <15 mm Hg	Early resumption of spontaneous respiration
	Unobstructed pulmonary vessels	
Left atrial	Sinus rhythm	Maintain sinus rhythm
Pressure 5–10 mm Hg	Competent AV valve	→ or ↑ Rate to increase CO
	Ventricle	→ or ↓ Afterload
	Normal diastolic function	→ or ↑ Contractility
	Normal systolic function	PDE inhibitors useful because of vasodilatory, inotropic, and lusitropic properties
	No outflow obstruction	

AV, Atrioventricular; *CO,* cardiac output; *Pap,* pulmonary arterial pressure; *PDE,* phosphodiesterase; *PVR,* pulmonary vascular resistance.

However, PVR may increase after surgery, particularly secondary to an acidosis, hypothermia, atelectasis and hypoventilation, vasoactive drug infusions, and stress response. Any acidosis must be treated promptly. If the cause is respiratory, ventilation must be adjusted. A metabolic acidosis reflects poor cardiac output and treatment directed at the potential causes, including reduced preload to the systemic ventricle, poor contractility, increased afterload, and loss of sinus rhythm.

The use of PEEP continues to be debated. The beneficial effects of an increase in FRC, maintenance of lung volume, and redistribution of lung water need to be balanced against the possible detrimental effect of an increase in mean intrathoracic pressure. A PEEP of 3 to 5 cmH_2O, however, rarely has either hemodynamic consequence or substantial effect on effective pulmonary blood flow.

Alternative methods of mechanical ventilation have been used in these patients. High-frequency ventilation has been used successfully, although the hemodynamic consequences of the raised mean intrathoracic pressure must be continually evaluated.[108] Negative-pressure ventilation can be beneficial by augmenting pulmonary blood flow.[109] The development of new negative-pressure ventilators and cuirasses and jackets has increased the interest in this mode of ventilation for this group of patients, but the experience is relatively small and indications are not defined. Application is cumbersome.

Nonspecific pulmonary vasodilators, such as sodium nitroprusside, glycerol trinitrate, PGE_1, and prostacyclin have been used to dilate the pulmonary vasculature in an effort to improve pulmonary blood flow after a Fontan procedure, but the results are variable. Although PVR may fall, pulmonary blood flow also could increase as a result of reduced ventricular end-diastolic pressure after improved ventricular function secondary to the fall in systemic afterload. The response to inhaled NO also is variable, and the improvement may be related to changes in ventilation/perfusion matching rather than a direct fall in PVR.

Afterload stress is poorly tolerated after a modified Fontan procedure because of the increase in myocardial wall tension and end-diastolic pressure. The phosphodiesterase inhibitors milrinone and amrinone are particularly beneficial. Besides being weak inotropes with pulmonary and systemic vasodilating properties, their lusitropic action assists by improving diastolic relaxation and lowering ventricular end-diastolic pressure, thereby improving effective pulmonary blood flow and cardiac output.

Specific Complications After the Fontan Procedure

Pleuropericardial Effusions. The incidence of recurrent pleural effusions and ascites has decreased since the introduction of the fenestrated baffle technique. Nevertheless, for some patients they remain a major problem with associated respiratory compromise, hypovolemia, and possible hypoproteinemia. They usually occur secondary to persistent elevation of systemic venous pressure, and reevaluation with cardiac catheterization may be indicated.

Rhythm Disturbances. Atrial flutter and/or fibrillation; heart block; and, less commonly, ventricular dysrhythmia may have a significant impact on immediate recovery and on long-term outcome.[110] Sudden loss of sinus rhythm initially causes an increase in LA and ventricular end-diastolic pressure and a fall in cardiac output. The SVC or PA pressure must be increased, usually with volume replacement, to maintain the transpulmonary gradient. Prompt treatment with antiarrhythmic drugs, pacing, or cardioversion is necessary.

Premature Closure of the Fenestration. Not all patients require a fenestration for a successful, uncomplicated Fontan operation. Those with ideal preoperative hemodynamics often maintain adequate pulmonary blood flow and cardiac output without requiring a right-to-left shunt across the baffle. Similarly, not all Fontan patients who received a fenestration use it for a right-to-left shunt in the immediate postoperative period. These patients are fully saturated after surgery and may have an elevated right-sided filling pressure but nevertheless maintain an adequate cardiac output. The problem is predicting which patients are at risk for low cardiac output after a Fontan procedure, and who will benefit from placement of a fenestration. Even patients with ideal preoperative hemodynamics may manifest a significant low output state after surgery. Because of this possibility, the vast majority of patients having a Fontan procedure at Riley Hospital for Children, Indiana University, are fenestrated.

Premature closure of the fenestration may occur in the immediate postoperative period, leading to a low cardiac output state with progressive metabolic acidosis and large chest drain losses from high right-sided venous pressures. Patients may respond to volume replacement, inotrope support, and vasodilation; however, if hypotension and acidosis persist, cardiac catheterization and removal of thrombus or dilation of the fenestration may be urgently needed.

Persistent Hypoxemia. Arterial O_2 saturation levels may vary substantially after a modified Fontan procedure. Common causes of persistent arterial O_2 desaturation less than 75% include a poor cardiac output with a low Svo_2, a large right-to-left shunt across the fenestration, or additional "leak" in the baffle pathway producing more shunting. An intrapulmonary shunt and venous admixture from decompressing vessels draining either from the pulmonary artery to the systemic venous circulation or from the systemic vein to the pulmonary venous system are additional causes. Reevaluation with echocardiography and cardiac catheterization may be necessary.

Low Cardiac Output State. An elevated LA pressure after a modified Fontan procedure may reflect poor ventricular function from decreased contractility or increased afterload stress, atrioventricular valve regurgitation, and loss of sinus rhythm (Table 31-9). The right-sided filling pressure must be increased to maintain the transpulmonary gradient and treatment with inotropes and vasodilators initiated. If a severe low output state with acidosis persists, takedown of the Fontan operation and conversion to a BDG anastomosis or other palliative procedure might be lifesaving.

Tetralogy of Fallot

Pathophysiology

The four anatomic features of TOF are VSD, RV outflow tract obstruction, overriding of the aorta, and RV hypertrophy. In addition, there may be VSDs of the muscular region of the septum and right-sided obstruction of the pulmonary valve and the main and branch pulmonary arteries.

Resistance to RV outflow forces systemic venous return from right to left across the VSD (complex shunt) and into the aorta, producing arterial desaturation. Pulmonary blood flow is less than systemic flow. The amount of blood that shunts right to left through the VSD varies with the magnitude of the RV outflow tract obstruction and with SVR. Distal PVR is low and has minimal influence on shunting. Systemic vasodilation, in conjunction with increasing dynamic infundibular stenosis, intensifies right-to-left shunting and therefore hypoxemia, producing hypercyanotic "spells." Such spells can occur at any time before surgical correction of the anomalies and can be life-threatening. Their treatment is outlined in the after section. Because the morbidity associated with recurrent hypercyanotic spells is significant, many physicians consider recurrent episodes of hypercyanosis an indication for corrective surgery at any age.

Critical Care Management for the Early Postoperative Course

The surgical approach to TOF may involve either an early or delayed repair. Delayed repair requires early palliation with a systemic-to-pulmonary artery shunt to prevent

Table 31–9 Etiology and Treatment Strategies for Patients with Low Cardiac Output Immediately Following the Fontan Procedure

Low Cardiac Output	Etiology	Treatment
INCREASED TPG		
Baffle >20 mm Hg LAp <10 mm Hg ↑ TPG >> 10 mm Hg	Inadequate pulmonary blood flow and preload to left atrium Increased PVR Pulmonary artery stenosis	Volume replacement Reduce PVR Correct acidosis Inotropic support
Clinical state High Sao_2/low Svo_2 Hypotension/ tachycardia Core temperature high Poor peripheral perfusion SVC syndrome with pleural effusions and increased chest tube drainage Ascites/hepato-megaly Metabolic acidosis	Pulmonary vein stenosis Premature fenestration closure	Systemic vasodilation Catheter or surgical intervention
NORMAL TPG		
Baffle >20 mm Hg LAp >15 mm Hg TPG normal 5–10 mm Hg	Ventricular failure Systolic dysfunction Diastolic dysfunction AVV regurgitation and/or stenosis	Maintain preload Inotrope support Systemic vasodilation Establish sinus rhythm or atrioventricular synchrony
Clinical state Low Sao_2/low Svo_2 Hypotension/ tachycardia Poor peripheral perfusion Metabolic acidosis	Loss of sinus rhythm ↑ Afterload stress	Correct acidosis Mechanical support Surgical intervention, including takedown to BDG and transplantation

AVV, Atrioventricular valve; *BDG,* bidirectional Glenn anastomosis; *LAp,* left atrial pressure; *PVR,* pulmonary vascular resistance; Sao_2, systemic arterial oxygen saturation; *SVC,* superior vena cava; Svo_2, SVC oxygen saturation; *TPG,* transpulmonary gradient.

hypercyanotic episodes, followed by a transatrial and transpulmonary artery repair between ages 12 and 18 months. Excellent outcome has been achieved with this approach, and the need for a transpulmonary valve annulus outflow patch (transannular patch) at the time of surgery is reduced.[111] The risks of cyanosis and complications related to a systemic-to-pulmonary artery shunt argue for early complete repair of TOF. This can be performed in the neonate or young infant depending on the degree of obstruction and arterial oxygen saturation level.[112] Complete repair in neonates and young infants may more often require a transventricular approach to close the VSD, with pericardial augmentation of the RV outflow tract. A ventriculotomy is performed in the RV outflow tract and frequently is extended distally through the pulmonary valve annulus and beyond any associated pulmonary artery stenosis. The outflow tract is enlarged with pericardium or synthetic material, and obstructing muscle bundles are resected to relieve the outflow tract obstruction.[113] Being smaller and younger, these patients may be at increased risk for complications associated with CPB. Pulmonary regurgitation results after a transannular incision that may compromise ventricular function in the postoperative period. At Riley Hospital for Children, Indiana University, the routne use of a PTFE monocusp valve for reconstruction of the right ventricular outflow tract results in significantly less pulmonary regurgitation compared to traditional nonvalved transannular patch repairs.[114] In approximately 8% of patients, abnormalities in the origin and distribution of the coronary arteries preclude placement of the RV outflow patch,[115] making it necessary to bypass the stenosis by placing an external conduit from the body of the right ventricle to the pulmonary artery.[116]

Preoperative management of these patients should maintain systemic vascular resistance, minimize PVR, and avoid myocardial depression. Hypercyanotic spells in nonanesthetized children are traditionally treated initially with 100% oxygen by face mask, a knee-chest position (to increase SVR), and morphine sulfate. This regimen usually causes the dynamic infundibular stenosis to relax while maintaining systemic resistance. Deeply cyanotic and lethargic patients are given rapid IV crystalloid infusions to augment circulating blood volume. Continued severe hypoxemia is treated with a vasopressor (e.g., phenylephrine 1-2 μg/kg) to increase SVR and sometimes with judicious use of IV propranolol or esmolol to slow the heart rate. The latter allows more filling time and relaxes the infundibulum.[117] If a hypercyanotic spell persists despite treatment, immediate surgical correction of the anomaly is indicated. The child can be anesthetized with IV narcotics, and an inhalation agent such as halothane may be beneficial to reduce hyperdynamic outflow tract obstruction. Anesthetic agents that predominantly decrease SVR, such as isoflurane, should be used with caution. The pattern of mechanical ventilation is critical, as excessive inspiratory pressure or short expiratory times increases the mean intrathoracic pressure and further reduces antegrade flow across the RV outflow.

When weaning patients from CPB after tetralogy repair, the aim of therapy is to support RV function and minimize afterload on the right ventricle. This is particularly important after repair in neonates or small infants. Although systolic dysfunction of the right ventricle may occur after neonatal ventriculotomy, more commonly the clinical picture is one of a "restrictive physiology" reflecting reduced RV compliance or diastolic function.[28,29] Factors contributing to diastolic dysfunction include ventriculotomy, lung and myocardial edema after CPB, inadequate myocardial protection of the hypertrophied ventricle during aortic cross-clamp, coronary artery injury, residual outflow tract obstruction, volume load on the ventricle from a residual VSD or pulmonary regurgitation, and arrhythmias.

Patients usually separate from CPB with a satisfactory blood pressure and atrial filling pressures less than 10 mm Hg on inotropic support, such as dopamine 5 to 10 μg/kg/min.

However, in neonates during the first 6 to 12 hours after surgery, a low cardiac output state with increased right-sided filling pressures from diastolic dysfunction is common after a right ventriculotomy, and continued sedation and paralysis usually are necessary for the first 24 to 48 hours to minimize the stress response and associated myocardial work. Preload must be maintained, despite elevation of RA pressure.

In addition to high right-sided filling pressures, pleural effusions and/or ascites may develop. Significant inotropic support is often required, and a phosphodiesterase inhibitor, such as milrinone, is beneficial because of the lusitropic properties. Because of the restrictive physiology, even a relatively small volume load from a residual VSD or pulmonary regurgitation is often poorly tolerated in the early postoperative period, and 2 to 3 days may be required before RV compliance improves after surgery and cardiac output increases. Although the patent foramen ovale or any ASD usually is closed at the time of surgery in older patients, it is beneficial to leave a small atrial communication after neonatal repair. In the face of diastolic dysfunction and increased RV end-diastolic pressure, a right-to-left atrial shunt maintains preload to the left ventricle and therefore cardiac output. Patients may be desaturated initially after surgery because of this shunting. As RV compliance and function improve, the amount of shunt decreases and both antegrade pulmonary blood flow and arterial oxygen saturation increase.

Arrhythmias after repair include heart block, ventricular ectopy, and junctional ectopic tachycardia. It is important to maintain sinus rhythm to prevent additional diastolic dysfunction and an increase in end-diastolic pressure. Atrioventricular pacing may be necessary for heart block. Complete right bundle branch block is typical on the postoperative ECG.

Most patients recover systolic ventricular function postoperatively. However, there is a small group of patients, especially those repaired at older ages, in whom significant ventricular dysfunction remains.[118,119] Pulmonary valve insufficiency may contribute to residual ventricular systolic dysfunction.[120] The most common cause of systolic dysfunction immediately after repair of CHD is a residual or unrecognized additional VSD,[121] which causes a volume load on the left ventricle and pressure load on an already stressed right ventricle, leading to RV failure and poor cardiac output. A residual VSD combined with a residual RV outflow obstruction is particularly deleterious.

In some patients, the distal pulmonary arteries may be so hypoplastic and stenotic that they cannot be satisfactorily corrected. Suprasystemic pressure develops in the right ventricle, which in some cases can be ameliorated by partially opening the VSD to allow an intracardiac right-to-left ventricular shunt. This shunt unloads the compromised right ventricle at the expense of decreased arterial oxygen saturation.

Critical Care Management for Late Postoperative Care

Reconstruction of the RV outflow tract may lead to significant problems that affect RV function and risk for arrhythmias over time. Although most of the long-term outcome data pertain to patients after TOF repair, similar complications and risks are likely for those who have undergone an extensive RV outflow reconstruction, such as placement of a conduit from the right ventricle to the pulmonary artery for correction of pulmonary atresia, truncus arteriosus, and the Rastelli procedure for transposition of the great arteries with pulmonary stenosis.

Complete surgical repair of TOF has been successfully performed for more than 40 years, with studies reporting a 30- to 35-year actuarial survival of approximately 85%.[122] Many patients report leading relatively normal lives, but RV dysfunction may progress after repair and may be evident only on exercise stress testing or echocardiography. A spectrum of problems may develop, ranging from a dilated right ventricle with systolic dysfunction to diastolic dysfunction from a poorly compliant right ventricle, and these problems must be thoroughly evaluated preoperatively. In addition, continued evaluation is necessary because of the increased risk for ventricular arrhythmias and late sudden death. Factors that may adversely affect long-term survival include older age at initial repair, initial palliative procedures, and residual chronic pressure and/or volume load as occurs from pulmonary insufficiency or stenosis.

Systolic dysfunction secondary to a residual volume load from pulmonary regurgitation after tetralogy repair is a predictor of late morbidity. It is reflected as cardiomegaly on chest x-ray film, an increase in RV end-diastolic volume by echocardiography,[120] and a reduction in anaerobic threshold, maximal exercise performance, and endurance on exercise testing.[123] Patients who have significant pulmonary regurgitation and reduced RV function are at potential risk for a fall in cardiac output during anesthesia, particularly as positive pressure ventilation may increase the amount of regurgitation. Once again, it is difficult to predict those patients who are more likely to have instability during anesthesia for noncardiac surgery, nor is it possible to formulate a "recipe" for anesthesia that will be suited to all patients. Nevertheless, preoperative exercise testing may provide some insight into hemodynamic reserve.

An important group to distinguish consists of those who have continued restrictive physiology or diastolic dysfunction secondary to reduced ventricular compliance. They usually do not have cardiomegaly, they demonstrate better exercise tolerance, and the risk for ventricular dysrhythmias is possibly decreased. Although the right ventricle is hypertrophied, function is generally well preserved on echocardiography, with minimal pulmonary regurgitation.

The incidence of significant RV outflow obstruction developing over time is low. Residual obstruction contributes to early mortality within the first year after surgery but is well tolerated in the long term. A gradient more than 40 mm Hg across the RV outflow is uncommon, and the pressure ratio between the right ventricle and left ventricle usually is less than 0.5. The gradient may become more significant with time, but as the progression usually is slow, RV dysfunction occurs late.

A wide variation in the incidence of ventricular ectopy has been reported in numerous follow-up studies, including up to 15% of patients on routine ECG and up to 75% of patients on Holter monitor. Multiple risk factors, including an older age at repair, residual hemodynamic abnormalities, and duration of follow-up, have all been considered important.[124] In common with these factors are probable myocardial injury and fibrosis from chronic pressure and volume overload, as well as cyanosis. Although ventricular ectopy is common in asymptomatic patients during ambulatory ECG Holter monitoring and exercise stress testing, it often is low grade and has

not identified those patients at risk for sudden death. Electrophysiologic induction of sustained ventricular tachycardia (VT), especially when monomorphic, is suggestive of the presence of a reentrant arrhythmic pathway. Although dependent on the stimulation protocol used to induce VT, the presence of monomorphic VT in a symptomatic patient with syncope and palpitations is significant and indicates treatment with radiofrequency ablation, surgical cryoablation, antiarrhythmic drugs, or placement of an implantable cardioverter-defibrillator.[125] The risk for ventricular dysrhythmias during anesthesia and ICU care for subsequent hospitalizations is unknown. Although preoperative prophylaxis with antiarrhythmic drugs is not recommended, a means for external defibrillation and pacing must be readily available.

Pulmonary Atresia

Pathophysiology

Atresia of the pulmonary valve or main pulmonary artery forms a spectrum of cardiac defects, the management of which depends on the extent of atresia, size of the right ventricle and tricuspid valve (TV), presence of a VSD and collateral vessels, surface area of the pulmonary vascular bed, and coronary artery anatomy. At birth, pulmonary blood flow is derived from either a PDA or other aortopulmonary collateral blood vessels. These collaterals, which arise from the descending aorta and supply both lungs, may be extensive. The right ventricle usually is hypertrophied, and a restrictive physiology is common during initial postoperative recovery.[126]

At one end of the spectrum, critical pulmonary stenosis may exist with a variable degree of hypoplasia of the right ventricle, TV, and pulmonary artery. There is no VSD. With critical pulmonic stenosis, only a pinhole orifice is present in the pulmonic valve, but the right ventricle is generally less hypoplastic than with pulmonary atresia. A fixed obligatory shunt of all systemic venous return occurs from the right to the left atrium, where blood mixes completely with pulmonary venous blood. Some blood may flow into the right ventricle, but because there is no outlet, blood regurgitates back across the TV and eventually reaches the left atrium and left ventricle. Pulmonary blood flow is derived exclusively or predominantly from a PDA. These patients usually do not have extensive aortopulmonary collateral blood flow; consequently, they often become cyanotic when the PDA closes after birth. Critical pulmonary valve stenosis can be effectively treated by balloon dilation in the catheterization laboratory. Antegrade flow across the RV outflow may not improve immediately but may gradually increase over days as RV compliance improves.

Pulmonary valve atresia or short-segment main pulmonary artery atresia, with a VSD and normal size TV, right ventricle, and branch pulmonary arteries, is completely repaired in the neonate. The procedure usually involves placement of a pericardial patch to reconstruct the outflow tract. If there is long-segment pulmonary artery atresia, a homograft "conduit" is necessary to reconstruct the RV outflow. Conduits may be extrinsically compressed or kinked at the time of sternal closure, causing partial RV outflow obstruction or direct compression of a coronary artery leading to ischemia.

The intracardiac anatomy of TOF with pulmonary atresia is similar to that of simple TOF, but the RV outflow tract is atretic. Because of the atretic RV outflow tract, all systemic venous return courses right to left through the VSD. Therefore complete mixing of pulmonary and systemic venous return occurs in the left ventricle and aorta, producing arterial hypoxemia. Infants with TOF and associated pulmonary atresia regularly exhibit significant systemic-to-pulmonary collateral flow. If antegrade flow is established from the right ventricle into the main pulmonary artery by a reparative procedure, the left-to-right shunt via collateral flow will impose a diastolic load on the left ventricle. Preoperative occlusion of these collateral vessels can be accomplished by interventional techniques in the cardiac catheterization laboratory but may leave the child precariously cyanotic in the hours before operation. The most effective temporizing therapy is to reduce oxygen consumption (e.g., anesthesia, mechanical ventilation) and to increase the systemic perfusion pressure across other systemic-to-pulmonary communications.

Patients with pulmonary atresia, a VSD, but small right ventricle and TV may not tolerate a complete initial repair. The right ventricle may be unable to cope with the entire cardiac output, resulting in a low output state and RV failure (see the following section). Alternative management strategies therefore include initial palliation with a shunt and/or RV outflow patch to improve pulmonary blood flow, or a repair of the outflow tract with fenestration of the VSD patch to enable a right-to-left shunt at that level. Two-ventricle repair ultimately may be limited by growth of the TV.[126] If the right ventricle subsequently grows, the shunt and the patent foramen ovale ASD and VSD can be closed surgically.

Patients with pulmonary atresia and an intact ventricular septum usually have a small right ventricle and TV, a condition that often makes them unsuitable for a two-ventricle repair in the long term. Initial palliation with an aortopulmonary shunt is necessary. Reconstruction of the RV outflow with a pericardial patch or interventional catheter techniques also may be considered if the right ventricle is a sufficient size such that a two ventricle could be considered. Before intervention, the coronary anatomy should be determined, usually by cardiac catheterization. A large conal branch or aberrant left coronary artery across the RV outflow tract may restrict the size of a ventriculotomy and placement of a patch or conduit. Patients with pulmonary atresia, a hypoplastic right ventricle, and intact ventricular septum may have numerous fistulous connections (sinusoids) between the small hypertensive RV cavity and the coronary circulation.[127] Therefore a significant proportion of the myocardium may depend on coronary perfusion directly from the right ventricle. If, in addition, proximal coronary artery stenoses are restricting coronary perfusion from the aortic root, then decompression of the right ventricle after reconstruction of the RV outflow tract can lead to myocardial infarction.

At the worst end of the spectrum, severe pulmonary atresia may be associated with a hypoplastic right ventricle and diminutive pulmonary arteries that are not suitable for primary repair. A palliative procedure with a Blalock-Taussig or central shunt is usually necessary at first to improve pulmonary blood flow, followed by staged single-ventricle repair (see section on managing Fontan physiology).

Multiple aortopulmonary collateral arteries may be present, supplying some or all segments of the lung. They can be associated with a large left-to-right shunt, contributing to volume overload and pulmonary hypertension. Larger collateral vessels supplying significant portions of the lung can

be anastomosed or "unifocalized" to the native pulmonary arteries, with the ultimate aim being to establish full antegrade pulmonary blood flow. Smaller vessels to some segments of lung can be coiled in the cardiac catheterization laboratory, provided there is antegrade flow from the native pulmonary arteries to those lung segments.

When the pulmonary arteries are very diminutive, it is important to establish early antegrade flow from the right ventricle to the pulmonary artery, in an effort to promote growth and establish a pathway to the pulmonary arteries for subsequent balloon dilation. A Blalock-Taussig shunt may be necessary to provide sufficient pulmonary blood flow if the pulmonary arteries and right ventricle are small. Initially, the VSD can be left open, and postoperative management of cyanosis or CHF will be determined by the size of and the resistance offered by the pulmonary circuit. The course in these patients can be dynamic and demanding for even the most experienced practitioners. When collaterals are occluded in the operating room and right ventricle to diminutive pulmonary artery continuity is established, cyanosis may ensue and therapy is aimed at lowering PVR and/or (re)establishing adequate pulmonary blood flow. On the other hand, if the child is fully saturated in the aorta with elevated pulmonary artery oxygen saturation and LA pressure, then a left-to-right shunt through the VSD may be developing, which will produce a volume load on the left ventricle and an unstable postoperative course, dictating VSD closure. When the patient is not fully saturated in the aorta but is suffering from a volume-loaded left ventricle with low cardiac output and high LA pressure postoperatively, excessive systemic-to-pulmonary collaterals may be the culprits, requiring catheterization laboratory investigation and occlusion or immediate reoperation.

Critical Care Management

Critical care management of patients with pulmonary atresia is similar to that for TOF, except that hypercyanotic spells do not occur in the same fashion. Maintaining the patency of the ductus for the perioperative treatment of neonates with pulmonary atresia and critical pulmonary stenosis is essential. If the right ventricle is sufficiently well developed and the main pulmonary artery is present, it may be possible to perform a pulmonary valvotomy and provide adequate pulmonary blood flow without a supplemental systemic-to-pulmonary artery shunt. The goal of therapy is to improve oxygenation and decrease RV afterload. Because the underdeveloped noncompliant right ventricle requires high filling pressures, consequently there may be substantial right-to-left shunting through the foramen ovale, making these infants hypoxemic during the immediate postoperative period. With growth and improved compliance of the right ventricle, the right-to-left shunting diminishes and the infant's oxygenation improves substantially. If hypoxemia persists, a PGE_1 infusion should be started to increase pulmonary blood flow through the ductus arteriosus while arrangements are made to surgically create a pulmonary artery to systemic artery shunt.

In patients with long-segment pulmonary atresia, the need for a conduit to bridge the gap between the right ventricle and the pulmonary artery complicates the repair. Again, RV failure may occur postoperatively, especially when there is a residual VSD or an outflow obstruction. The conduit may obstruct acutely during chest closure, further elevating pressure in the right ventricle.

After the VSD is closed and blood flow is from the right ventricle to the pulmonary arteries, there may be excessive pulmonary blood flow ($Q_p/Q_s > 1$) as a result of the combined flow into the pulmonary arteries from the right ventricle and from aortopulmonary collaterals just described. If this occurs, the patient develops CHF and requires intraoperative inotropic support of the heart and an extended period of postoperative mechanical ventilation. With large collateral flows, the pulse pressure is large and diastolic pressure low. The patient may require surgery to ligate the collateral vessels or may require embolization.

Critical Care Management for Late Postoperative Care

Patients with TOF and pulmonary atresia are subject to the same late problems and complications as patients with TOF alone. In addition, they may develop progressive conduit obstruction after surgery. Conduit obstruction is accelerated by the presence of a porcine valve in the conduit.[128,129] Consequently, unless the patient has severe pulmonary hypertension, valveless conduits or homografts now are preferred by many.[116] At Riley Hospital for Children, Indiana University, the preferred repair involves the implantation of a heterologous bovine jugular vein bioprosthesis (Medtronics Contegra) with a trileaflet venous valve.[130] This has been the valved conduit of choice in patients younger than 18 years of age, whenever pulmonary regurgitant volume load to the RV is undesirable.[130] Recent data from our institution suggest that small caliber bovine jugular vein conduits may have significantly improved freedom from dysfunction at 5 and 10 years' follow-up compared to pulmonary homografts in patients operated during the first 2 years of life.[131]

Tricuspid Atresia

Pathophysiology

In this condition, an imperforate TV and hypoplasia of the right ventricle are present, often accompanied by a VSD of variable size and by pulmonic stenosis. A fixed obligatory shunt of all systemic venous return occurs from the right atrium through the patent foramen ovale or ASD into the left atrium, where complete mixing takes place. The degree of hypoxemia depends on the amount of pulmonary blood flow, which is regulated by the severity of the pulmonic stenosis. The common presentation is characterized by significant hypoxemia caused by the decreased pulmonary blood flow induced by either a restrictive VSD or a severe pulmonic stenosis.

Critical Care Management

The reparative operation of choice for tricuspid atresia is a modified Fontan procedure, but a palliative procedure may initially be required to improve pulmonary blood flow. A pulmonary artery band may be needed if the pulmonary blood flow is increased, or a shunt may have to be created for the severely hypoxemic child with decreased pulmonary blood flow upon ductal closure. The critical care management and complications are those discussed in the sections

on shunts, banding, and modified Fontan procedures. Complications of chronic hypoxemia and cyanosis are also present.

Transposition of the Great Arteries

Pathophysiology

With transposition of the great arteries, the right ventricle gives rise to the aorta. Almost 50% of patients with this anomaly have a VSD, and some of them have a variable degree of subpulmonic stenosis. Oxygenated pulmonary venous blood returns to the left atrium and is recirculated to the pulmonary artery without reaching the systemic circulation. Similarly, systemic venous blood returns to the right atrium and ventricle and is ejected into the aorta again. Obviously, this arrangement is compatible with life only for a few circulation times unless there is some mixing of pulmonary and systemic venous blood via a PDA or an opening in the atrial or ventricular septum at birth. The physiologic disturbance in these patients is one of inadequate mixing of pulmonary and systemic blood rather than one of inadequate pulmonary blood flow.

Mixing of blood at the atrial level can be improved by balloon atrial septostomy. If dangerous levels of hypoxemia persist after the septostomy and metabolic acidosis ensues, an infusion of PGE_1 can maintain the patency of ductus arteriosus, increase pulmonary blood flow (by increasing left-to-right shunting across the PDA), and thereby increase the volume of oxygenated blood entering the left atrium. The volume-overloaded left atrium is likely to shunt part of its contents into the right atrium and thereby improve the oxygen saturation of aortic blood. Unlike the kinetics with other lesions, increased shunting of blood during anesthesia improves arterial oxygen saturation before correction of the transposition.

Critical Care Management

Depending on the particular anatomy and the presence of a VSD or pulmonary stenosis, one of three corrective procedures is used. The intraoperative and postoperative problems encountered differ with each type of procedure.

Atrial Baffle Procedure (Mustard and Senning). An atrial level partition is created with baffling to redirect pulmonary venous blood across the TV to the right ventricle and thus to the aorta.[132,133] Systemic venous return is directed across the atrial septum to the mitral valve, into the left ventricle, and out the pulmonary artery. Although the pulmonary and systemic circuits are then connected serially instead of in parallel, this arrangement leaves the patient with a morphologic right ventricle and TV in continuity with the aorta. Therefore this ventricle must work against systemic arterial pressure and resistance.

One problem with atrial baffles is that they can obstruct systemic and pulmonary venous return.[134] When this occurs, the patient manifests signs and symptoms of systemic venous obstruction, as evidenced by SVC syndrome or other signs of systemic venous hypertension. When the pulmonary venous pathway is obstructed, pulmonary venous hypertension may be manifested by respiratory failure, poor gas exchange, and pulmonary edema. Severe pulmonary venous obstruction is manifested in the operating room by the presence of copious amounts of bloody fluid in the endotracheal tube, low cardiac output, and frequently poor oxygenation. Residual interatrial shunts also may cause intraoperative or postoperative hypoxemia. Long-term rhythm disturbances and the limitations of ventricular and AV valve function have made this operation nearly obsolete.

Arterial Switch Operation (Jatene Procedure). Because of the complications associated with atrial baffle procedures, Jatene and others explored whether anatomic correction of this lesion, by dividing both great arteries and reattaching them to the opposite anatomically correct ventricle, would improve survival.[135,136] This procedure requires excision and reimplantation of the coronary arteries to the neoaorta (formerly the proximal main pulmonary artery). The success of the arterial switch procedure depends on adequate preparation of the left ventricle and technical proficiency with the coronary transfer. Anatomic correction of transposition of the great vessels is done during the neonatal period when PVR (LV afterload) and LV pressure are high. Left ventricular mass decreases progressively after birth in this lesion, and if the ability of the left ventricle to tolerate the work required is misjudged, the child may develop severe LV failure postoperatively and require inotropic support and afterload reduction to provide normal cardiac output. Infants with transposition of the great arteries who are older than a few weeks of age and have an intact ventricular septum may have decreased LV pressure and mass. In such cases, the left ventricle may not tolerate the work required to perfuse the systemic vessels. However, if the neonate has a nonrestrictive VSD, the left ventricle is accustomed to high pressure and may tolerate the increased workload at any age. In older patients with an intact ventricular septum, banding the pulmonary artery can prepare the left ventricle to function as a systemic ventricle by increasing its afterload and muscle mass. If the left ventricle is "prepared" by banding the pulmonary artery and augmenting pulmonary blood flow with a modified Blalock-Taussig shunt, then an arterial switch procedure usually can be accomplished 1 week later, after hypertrophy and hyperplasia have occurred.[137] However, during this interval these patients are cyanotic, with a volume-loaded right ventricle and a pressure-loaded left ventricle, and they may require considerable pharmacologic support.[138]

In experienced centers, the incidence of mortality after neonatal repair of transposition of the great arteries now is less than 3% and may be less than 2% for most anatomic arrangements of coronary arteries if the aortic arch is normal.[139] Midterm follow-up of these patients shows excellent outcome. Alternative operations are reserved almost exclusively for patients with particularly difficult coronary anatomy [140,141] or pulmonic (neo-aortic) stenosis.

Myocardial ischemia or infarction may occur after mobilization and reimplantation of the coronary arteries, especially if they are stretched or twisted. Inotropic support, maintenance of coronary perfusion pressures, control of heart rate, and treatment with vasodilators may be particularly useful, as in adult patients with myocardial ischemia. Postoperative bleeding and tamponade occur more commonly with this operation because of the presence of multiple arterial anastomoses.

Ventricular Switch (Rastelli Procedure). In patients with a large VSD and severe subpulmonic stenosis, the VSD can be closed obliquely to direct LV flow to the aorta. The pulmonary valve is oversewn and the right ventricle is connected to the pulmonary artery with a conduit.[142]

Complications of the Rastelli procedure include obstruction of LV outflow as a result of narrowing of the subaortic region by the VSD patch. The conduit also may obstruct during or after the immediate postoperative period. A small but significant incidence of heart block in these patients can be a difficult postoperative problem.

Late Postoperative Care

Patients who have both a pulmonary ventricle and a morphologic right ventricle remaining as the systemic ventricle can be regarded as having a physiologic or functional two-ventricle repair. Actuarial survival rates at 15 years have been quoted up to 85%; however, significant long-term functional deterioration is likely with increasing risk for right heart failure, sudden death, and dysrhythmias.[143,144] This situation is evidenced by systemic (right) ventricular dysfunction and TV regurgitation long after the repair.[145] These patients also are prone to develop significant atrial dysrhythmias, including supraventricular tachyarrhythmias and sick sinus syndrome later in life.[146] The arrhythmias may be preceded by RV dysfunction but also may be an isolated finding and is potentially the major cause of sudden death in these patients. A number of large follow-up series have reported the probability of a patient remaining in sinus rhythm after an atrial level repair is 50% at 10 years and 40% at 20 years. Function of the sinus node may be seriously impaired by the atrial manipulations during surgery, and sick sinus syndrome (requiring pacemaker insertion) may occur late in the postoperative period. The atrial baffle provides a functional repair, although despite this, many patients continue to maintain relatively active lives with few subjective symptoms. Objective exercise testing on intermediate and late follow-up may demonstrate limited RV reserve in as many as 50% of patients. Exercise duration, peak heart rate response, and peak minute oxygen consumption have all been reported to be reduced compared with age-matched controls.[147]

One of the major advances in congenital heart surgery over the past 10 to 15 years has been the development of the ASO to correct transposition of the great arteries. In experienced centers, the early hospital mortality is less than 3%, and actuarial analyses indicate a 98% survival rate at 5 to 10 years.[139] Long-term survival data are not available given that the oldest survivors are only in their 20s, but based on intermediate-term follow-up data the risk for reoperation and complications after ASO remains small.

Virtually all coronary artery patterns are amenable to ASO. No particular pattern has been associated with late death. A report of coronary artery angiography in 366 patients after ASO (median age at follow-up, 7.9 years) revealed coronary artery stenosis or occlusion in 3% of patients.[148] The long-term significance of these coronary artery abnormalities has not been determined. Despite the angiographic findings, evaluation with serial ECG, exercise testing, and wall-motion abnormalities on echocardiography rarely demonstrate evidence of ischemia.[149]

After repair, the "native" pulmonary valve becomes the "neo-aortic" valve. A 30% incidence of trivial-to-mild aortic regurgitation has been reported on intermediate-term follow-up, without significant hemodynamic changes.[150] Severe regurgitation is unusual.

There appears to be a very low incidence of significant rhythm disturbances after ASO.[151] Supravalvar pulmonary artery stenosis was an early complication but now is less common with surgical techniques that extensively mobilize, augment, and reconstruct the pulmonary arteries. Supravalvar AS may develop but is rare.

Assessment of myocardial performance using echocardiography, cardiac catheterization, and exercise testing after ASO have demonstrated function identical to that in age-matched controls.[152] Based on the currently available clinical, functional, and hemodynamic data, a patient who has undergone ASO with no evidence of subsequent problems should be treated as any patient with a structurally normal heart when presenting for noncardiac surgery.

Late complications of the Rastelli procedure include progressive conduit obstruction and RV hypertension, residual VSDs, and occasionally subaortic obstruction from diversion of LV outflow across the VSD to the aorta.

Total Anomalous Pulmonary Venous Connection

Pathophysiology

Patients with TAPVC are cyanotic because their pulmonary veins connect to a systemic vein and they have various degrees of pulmonary venous obstruction. The venous connection may be above the level of the heart (e.g., to the SVC, innominate, or azygos vein), directly to the right atrium, or below the level of the heart and the diaphragm (e.g., to the hepatic veins). Patients with this anomaly must have a patent foramen ovale or an ASD that allows blood flow to the left side of the heart.

This anatomic arrangement provides complete mixing of all systemic and pulmonary venous blood in the right atrium. Unless there is significant stenosis of the pulmonary venous connection, most of this right atrial blood passes through the right ventricle into the pulmonary artery, which increases pulmonary blood flow. If pulmonary venous return is significantly diminished from obstruction, there is increased pulmonary venous congestion and decreased pulmonary blood flow.

Critical Care Management

These patients may be very ill, with hypoxemia, severe pulmonary edema, and pulmonary artery hypertension. Resuscitation, including mechanical ventilation, PEEP, and inotropic support of the myocardium, is followed by early surgical intervention to relieve the pulmonary venous obstruction. Although patients are hypoxemic, their primary pathology is caused by obstructed venous return from the lungs. Therapy that increases pulmonary blood flow (e.g., PGE_1) must be avoided. Surgical repair of TAPVC requires attachment or redirection of the pulmonary venous confluence to the left atrium.

Intraoperative and postoperative problems often are related to residual or recurrent stenosis of the pulmonary veins. In patients who had severe stenosis and pulmonary venous hypertension preoperatively, the pulmonary vascular bed is highly reactive. This reactivity may produce high pulmonary artery pressures and poor RV function after bypass and during

the early postoperative period. Critical care management of these patients after completion of the repair should emphasize inotropic support of the right ventricle, avoidance of myocardial depressant drugs, and minimization of PVR. Early extubation of the trachea usually is not feasible. Mechanical ventilation with gentle hyperventilation and other postoperative therapy to decrease PVR are required. Inhaled NO has been particularly useful in this population.[153]

Critical Care Management for Late Postoperative Care

Other than the potential for late development of recurrent pulmonary venous obstruction, these patients generally do well and have good cardiovascular reserve once recovery from the surgery is complete.[154] The size of the pulmonary veins at birth may be a predictor of late complications with recurrent pulmonary vein stenosis.[155]

Atrial Septal Defect

Pathophysiology

There are three anatomic varieties of ASD. The most common, ASD secundum, is a deficit in the septum primum, which ordinarily covers the region of the foramen ovale. ASD primum is a deficit of the inferior portion of the atrial septum (endocardial cushion) usually accompanied by a cleft in the anterior leaflet of the mitral valve. Sinus venous defects are located near the junction of the right atrium and the SVC or IVC. They frequently are associated with a partial anomalous pulmonary venous connection.

Left-to-right shunting (simple) occurs at the atrial level, causing a low-pressure volume load to the right ventricle. Pulmonary blood flow is increased, but generally not enough to make these patients symptomatic during early childhood. However, later in life, as the left ventricle becomes less compliant and the LA pressures increase, the left-to-right shunt and volume load increase and symptoms of CHF may occur. In rare patients the long-standing increase in pulmonary blood flow causes pulmonary vascular obstructive disease.[156]

Critical Care Management

The defect can be closed directly with sutures or, if it is sufficiently large, with a synthetic patch. Sinus venosus defects associated with partial anomalous pulmonary venous connection require a more extensive patch that also directs the partial anomalous pulmonary venous return into the left atrium.

These patients are among the healthiest encountered in the cardiac intensive care unit. Early tracheal extubation is usual. Atrial arrhythmias, including atrial flutter and atrial fibrillation, are rarely seen during the postoperative period. Mitral regurgitation may occur in patients who have undergone repair of an ASD primum. Although transient LV failure has been reported, these patients rarely require inotropic support. Residual ASDs are uncommon, but occasionally failure to recognize partial anomalous pulmonary venous return results in a residual left-to-right shunt. Most patients can be extubated during the immediate postoperative period or in the operating room. With the exceptions mentioned, these patients usually have nearly normal cardiovascular function and reserve after repair.

Ventricular Septal Defect

Pathophysiology

Defects in the ventricular septum occur at several locations in the muscular partition dividing the ventricles. Simple shunting occurs across the ventricular septum. The magnitude of pulmonary blood flow is determined by the size of the VSD and the PVR.[157] With a nonrestrictive defect, high LV flows and pressures are transmitted to the pulmonary artery. Therefore surgical repair is indicated within the first 2 years of life to prevent the progression of pulmonary vascular obstructive disease.[49] In patients with established pulmonary vascular disease, the pulmonary arteriolar changes may not recede when the defect is closed. In such cases, there may be progressive PVR elevation.[158,159] The growth and development of the pulmonary vascular bed are significant factors in the patient's ability to normalize pulmonary vascular hemodynamics after surgery.[160] When PVR approaches or exceeds systemic vascular resistance, right-to-left shunting occurs through the VSD and the patients develop progressive hypoxemia (Eisenmenger syndrome). Closing the VSD in this circumstance adds the risk for acute right heart failure to that of progressive increases in PVR.

Critical Care Management

The defects are closed during CPB. The most common septal defect, the membranous defect, is often repaired through a right atriotomy and the TV. However, lesions in the inferior apical muscular septum or those high in the ventricular outflow tract may require a left or right ventriculotomy. If so, postoperative ventricular function may be impaired.

Before repair, measures that decrease PVR may appreciably increase left-to-right shunting in patients with a nonrestrictive defect and may increase the degree of CHF. Postoperative RV or LV failure may be a manifestation of the preoperative status of the myocardium, a result of the ventriculotomy and CPB, or both. Small infants who fail to thrive, who are malnourished, and who have significant CHF preoperatively may have excessive lung water and may require prolonged mechanical ventilation postoperatively.[161] Such infants may have limited intraoperative tolerance for anesthetics that depress the myocardium or for maneuvers that increase pulmonary blood flow.

Persistent CHF and an audible murmur postoperatively, evidence of low cardiac output, or the need for extensive inotropic support intraoperatively suggests that a residual or previously unrecognized additional VSD is continuing to place a volume and pressure load on the ventricles. When PVR is increased preoperatively, the increase in RV afterload caused by closure of the VSD may be poorly tolerated, leading to the need for inotropic support of the heart and measures to decrease PVR. Occasionally ventricular outflow tract obstruction is caused by placement of the septal patch. Transesophageal echocardiography performed in the operating room is an important tool in diagnosing this problem so it can be addressed before complete separation from CPB. Aortic regurgitation caused by prolapse of one of the aortic valve cusps can develop in subaortic or subpulmonic VSDs. In addition, heart block may occur after closure of VSDs with a patch. A pacemaker may be needed to maintain an adequate heart rate and cardiac output.

Critical Care Management for Late Postoperative Care

In the absence of residual VSDs, outflow obstruction, and heart block, most of these patients regain relatively normal myocardial function, especially if the VSD is repaired early.[162] However, a small percentage of patients, especially those in whom a large defect was repaired late in childhood, continue to have some degree of ventricular dysfunction and some pulmonary hypertension.[163]

Atrioventricular Canal Defects

Pathophysiology

The endocardial cushion defect, or complete common AV canal, consists of defects in the atrial and ventricular septa and the AV valvular tissue. All four chambers communicate and share a single common AV valve. The atrial and ventricular shunts communicate volume and systemic pressures to the right ventricle and pulmonary artery. The ventricular shunt orifice usually is nonrestrictive (simple shunt); therefore PVR governs the degree of excess pulmonary blood flow. Mitral regurgitation and direct left-ventricular-to-right-atrial shunting may further contribute to atrial hypertension and total left-to-right shunting.

Critical Care Management

Surgical repair of this lesion consists of division of the common AV valve and closure of the ASD and VSD with a single patch. In addition, the mitral valve (and sometimes the TV) requires suture approximation and resuspension of the separated portions.

Before surgical repair, these patients have large left-to-right shunts. As a result of their high pulmonary blood flows, they have CHF and pulmonary hypertension. Myocardial depressants and therapies that decrease PVR while increasing shunt flow may be poorly tolerated before repair. Some patients, especially older children, may have obstructive pulmonary vascular disease. All of the potential complications of ASD and VSD closures are seen in these patients. In addition, the mitral valve may be severely regurgitant.[164] Inotropic support for the failing heart, afterload reduction for mitral regurgitation, and measures to decrease PVR may be required intraoperatively and postoperatively after repair.

Patients with Down syndrome frequently have an associated complete AV canal. Measures to decrease PVR and the use of prolonged ventilatory support are often necessary because their airways and pulmonary vascular beds tend to be hyperreactive. The large tongues, hypotonia, upper airway obstruction, and difficult vascular access of these patients pose additional problems. The most frequent postoperative problems in patients with Down syndrome are residual VSDs, mitral insufficiency,[165] and pulmonary hypertension.[10]

Patent Ductus Arteriosus

Pathophysiology

The ductus arteriosus is a fetal vascular communication between the main pulmonary artery at its bifurcation and the descending aorta below the origin of the left subclavian artery. When patent, it provides a simple shunt between the systemic and pulmonary arteries. The magnitude and direction of flow between the systemic and pulmonary vessels are determined by the relative resistances to flow in the two vascular beds and the diameter (resistance) of the ductus itself. With a large, nonrestrictive ductus and low PVR, the pulmonary blood flow is excessive and the volume load of the left heart is large. Systolic and diastolic flow away from the aorta may steal blood from vital organs (e.g., pulmonary steal) and compromise end-organ function at many sites.[166] In addition, overcirculated lungs and elevated LA pressure increase the work of breathing.[167,168]

Critical Care Management

Although the PDA of premature infants can often be closed medically with indomethacin, contraindications to use of this agent (e.g., intracranial hemorrhage, renal dysfunction, and hyperbilirubinemia) may require surgical closure of the defect.[169] Whereas thoracotomy and surgical ligation of the ductus arteriosus are standard in older infants and children, some centers now occlude the ductus with a percutaneously inserted vascular umbrella[170] or by using video-assisted thoracoscopic surgery.[171] Advantages of video-assisted thoracoscopic surgery compared with open thoracotomy include decreased postoperative pain, shorter hospital stay, and decreased incidence of chest wall deformity.[172]

Healthy asymptomatic patients undergoing surgery can be extubated in the operating room, allowing many options for anesthetic management. However, the fragile premature infant with severe lung disease may require mechanical ventilation for protracted periods after ligation of the ductus arteriosus. Fentanyl, pancuronium, oxygen, and air constitute a common anesthetic regimen for this procedure.[173] Management of the premature infant in the operating room requires special considerations of gas exchange, hemodynamic performance, temperature regulation, metabolism, and drug and oxygen toxicity. Thoracotomy and lung retraction usually decrease lung compliance and increase oxygen and ventilatory requirements. A transient rise in systemic blood pressure with ligation of the ductus arteriosus may increase LV afterload or elevate cerebral perfusion pressure to the detriment of a premature patient. Inadvertent ligation of the left pulmonary artery or descending aorta has occurred because the ductus arteriosus is often the same size as the descending aorta.

The ductus is located near the recurrent laryngeal nerve (RLN), which may be damaged during the procedure. In addition to the close relationship of the RLN to the PDA and descending aorta, the RLN has a variable course that may be difficult to identify during dissection. Prior reports of PDA ligation performed by open thoracotomy indicate that the incidence of RLN injury is 1.2% to 8.8%.[174,175] RLN paralysis causes hoarseness and is not detected until the endotracheal tube is removed. The incidence may be reduced by location of the RLN within the thorax before ligation or clip placement using direct intraoperative stimulation of the RLN and evoked electromyogram monitoring.[176]

Ligation of an isolated ductus arteriosus generally results in normal cardiovascular function and reserve several months postoperatively.[177]

Truncus Arteriosus

Pathophysiology

With truncus arteriosus the embryonic truncus fails to separate normally into the two great arteries. A single great artery leaves the heart and gives rise to the coronary, pulmonary, and systemic circulations. The truncus straddles a large VSD and receives blood from both ventricles.

Complete mixing of systemic and pulmonary venous blood in the single great artery causes mild hypoxemia. One or two pulmonary arteries may originate from the ascending truncus; the pulmonary artery orifice is seldom restrictive. The resulting shunt (simple) produces excessive pulmonary blood flow early in life as the PVR decreases. This "pulmonary steal" may elevate the arterial oxygen saturation and decrease the systemic blood flow. In such a case, net systemic oxygen transport decreases and lactic acidosis develops. Children with truncus arteriosus are at risk for developing early pulmonary vascular obstructive disease.[178] Regurgitation of blood through the truncal valve may place an additional volume load on the ventricles.

Critical Care Management

Complete repair of this lesion should be performed early, even in the neonate, before the development of irreversible pulmonary vascular changes.[5,179] The VSD is closed with a synthetic patch, and the pulmonary arteries are detached from the truncus. Continuity is established between the right ventricle and the pulmonary arteries with a valved conduit.[180] The truncal valve may require valvuloplasty if a significant amount of blood regurgitates through it.

Critical care management preoperatively centers around control of pulmonary blood flow and ventricular support. Pulmonary blood flow may increase further with anesthetic agents, hyperventilation, alkalosis, and oxygen administration, resulting in hypotension and acute ventricular failure. If measures for *increasing* PVR do not decrease pulmonary flow, temporary occlusion of one branch of the pulmonary artery with a tourniquet limits pulmonary flow and restores systemic perfusion pressure until CPB can be instituted. Because these patients are often in high-output CHF, myocardial depressants should be used with caution.

Immediately after repair, the combination of persistent pulmonary artery hypertension and RV failure can be fatal. Hence, aggressive measures should be taken to provide adequate myocardial function and lower PVR. A residual VSD adds volume and pressure load on the ventricles and may have a devastating impact on the patient's hemodynamics and oxygenation. A VSD should be suspected in patients who are not doing well postoperatively. Any residual VSD should be repaired if feasible. Truncal valve regurgitation or stenosis may induce LV failure early during the postoperative period.

Critical Care Management for Late Postoperative Care

Obstruction of the pulmonary conduit and the accompanying RV hypertension may occur early or late during the postoperative course. Usually the conduit is unable to support flow in the growing child after several postoperative years. Late development of truncal (aortic) valve regurgitation is possible. For patients who underwent repair later in childhood, residual persistent pulmonary hypertension may be a problem.

Left-Sided Obstructive Lesions

Pathophysiology

This category includes valvar, subvalvar, and supravalvar mitral and aortic stenosis (AS), aortic coarctation, and IAA. Although these lesions can occur as isolated defects, they often are accompanied by other congenital cardiac defects. Identification of additional structural defects is necessary for optimal preoperative, surgical, and postoperative treatment.

Patients with LV outflow tract obstruction tend to present as either neonates or young infants with significant LV dysfunction and CHF or later in childhood with LV hypertrophy but few symptoms. The dramatic presentation of a neonate with circulatory collapse typically occurs with lesions that obstruct systemic blood flow so severely that right-to-left shunting at the ductus arteriosus is required to perfuse the body. As the ductus significantly narrows or closes, the left ventricle becomes acutely pressure overloaded and begins to fail, leading to pulmonary edema and respiratory distress. When systemic perfusion becomes inadequate, the patient develops hypotension, weak pulses, metabolic acidosis, and oliguria. Classic examples include severe (or "critical") valvar AS, coarctation of the aorta, and HLHS (see earlier single ventricle discussion).

If the obstruction is less severe, the child can make the transition through ductal closure without notable LV dysfunction and maintain an adequate cardiac output. Over time, however, the pressure overload on the LV stimulates generalized hypertrophy. If untreated and significant, long-term pressure overload can cause LV diastolic dysfunction (compliance falls and end-diastolic pressure rises, causing pulmonary venous hypertension), LV systolic dysfunction, and episodic myocardial ischemia. Clinical manifestations of these changes can include reduced exercise tolerance, exertional chest pain, ventricular dysrhythmias, syncope, and sudden death. Significant LV dilation and/or clinical signs of CHF are ominous findings associated with a poor prognosis and an increased surgical mortality rate.

Aortic Stenosis

Of the three anatomic subtypes of AS, valvar AS occurs more frequently than subvalvar or supravalvar AS. The newborn with critical valvar AS who develops hypotension and acidosis as the ductus arteriosus closes requires resuscitation with PGE_1 to restore aortic flow plus mechanical ventilation and inotropic support to achieve stabilization before an intervention is performed. Currently, balloon dilation of the stenotic aortic valve during cardiac catheterization is the preferred intervention at many centers.[181] A surgical valvotomy under direct vision using CPB is the surgical alternative. Despite successful relief of obstruction, significant LV dysfunction and low cardiac output often persist for days after the procedure and require continued treatment with mechanical ventilation and vasoactive drugs. Until LV function recovers and can support the entire cardiac output, continuation of prostaglandin infusion may be necessary to maintain patency of the ductus arteriosus. Patients should be carefully evaluated after balloon aortic valvuloplasty for residual AS and aortic regurgitation, the chief potential complication of valve dilation, especially if cardiac output does not improve over several days.

Older infants, children, and adolescents with moderate (pressure gradient 50-70 mm Hg at catheterization) or severe

(pressure gradient >70 mm Hg at catheterization) valvar AS also are generally good candidates for balloon aortic valvuloplasty. If more than mild aortic regurgitation coexists with AS, however, a surgical intervention is preferred to balloon valvuloplasty.

The pathophysiology produced by all types of aortic outflow obstruction is similar, that is, the pressure-overloaded LV becomes progressively hypertrophied and develops reduced compliance and an abnormally elevated end-diastolic pressure.

Initial assessment of obstruction relief can occur when the patient is still in the catheterization laboratory or operating room by either direct pressure measurements or echocardiography. Nevertheless, reevaluation for residual obstruction by physical examination and/or echocardiography in the ICU as patients recover from anesthesia and baseline physiology returns is important because outflow gradients can change. A significant residual obstruction should be suspected in any patient with persistent low cardiac output after the intervention. Poor recovery of LV function after surgery can occur secondary to inadequate myocardial protection with cardioplegia in hearts with significant ventricular hypertrophy. Patients with marked hypertrophy are also at greater risk for developing VT and ventricular fibrillation early after surgery.

In patients with preserved LV systolic function who undergo an uncomplicated procedure, such as aortic valvuloplasty or subvalvar membrane resection, myocardial recovery after CPB is typically rapid and inotropic support is usually not required. Systemic hypertension is more common after relief of LV outflow obstruction, especially during emergence from anesthesia and sedation. Antihypertensive therapy in the initial 24 to 48 hours may be necessary to prevent aortic suture line and reconstructed valve leaflet disruption from excessive stress and to allow adequate hemostasis. Both beta-blockers (e.g., labetalol, propranolol, and esmolol) and vasodilators (e.g., nitroprusside), alone or usually in combination, are effective for lowering blood pressure in these patients.

In addition to assessing aortic valve and LV function, an evaluation for complications specific to each procedure is required. For example, if a myectomy is required as part of the resection of fibromuscular subvalvar AS, the possibility of a new VSD, mitral valve injury, and left bundle branch block should all be assessed. After the Ross procedure, it is important to assess patients for RV outflow tract and LV outflow tract obstruction, because the RV outflow tract is also reconstructed with a valved conduit.

Coarctation of the Aorta

Coarctation of the aorta is a constriction in the descending aorta located at the level of insertion of the ductus arteriosus. Narrowing of the aortic lumen is asymmetric, with the majority of the obstruction occurring because of posterior tissue infolding, leading to the common description of a posterior aortic "shelf." Depending on the severity of constriction, patients can present as neonates with severe obstruction (a "critical" coarctation of the aorta) upon ductal closure, as infants with CHF, or as children/adolescents with no symptoms except for upper body hypertension (especially with exercise).

Neonates presenting with critical coarctation of the aorta can often be distinguished clinically from patients with critical AS by their clearly discrepant upper versus lower body pulses, perfusion, and blood pressures. Other features at presentation, including evidence of CHF and inadequate blood flow to tissues, are similar. Because ductal narrowing or closure is common after hospital discharge, these patients often become critically ill and suffer end-organ damage before the ductus arteriosus can be reopened and resuscitation accomplished. Intestinal and renal ischemia leading to necrotizing enterocolitis and renal failure, respectively, are well-known complications of critical coarctation of the aorta. Echocardiography often reveals additional left-sided defects such as bicuspid aortic valve, valvar AS, aortic arch hypoplasia, and VSD. Preoperative management includes treatment with PGE_1 plus mechanical ventilation, inotropic agents, and diuretic agents, as needed, and adequate time for end-organ recovery before performing an intervention.

Coarctation of the aorta also occurs in association with complex defects such as D-transposition of the great arteries, single ventricle, and complete AV canal defect. If the ductus arteriosus is patent during echocardiographic evaluation of a neonate with suspected CHD, it often is not possible to predict the severity of coarctation of the aorta with confidence. A patient can have an abnormally narrowed aorta just proximal to the site of ductal insertion (i.e., the aortic isthmus) and a posterior shelf but still not develop a severe coarctation of the aorta after ductal closure. Therefore evaluation of the potential severity of coarctation of the aorta in the ICU often involves a strategy of close monitoring for aortic obstruction without PGE_1 to allow the PDA to close, followed by clinical and echocardiographic reassessment. An intervention to reduce aortic obstruction is indicated in any neonate with clinical or echocardiographic evidence of reduced ventricular function or impaired cardiac output. These indications are more important than the systolic blood pressure difference between upper and lower body per se, although differences greater than 30 mm Hg often are accompanied by diminished ventricular function.

The postoperative management of patients after surgical repair of coarctation of the aorta can vary depending on age at intervention. However, the key issues for assessment in all patients are adequate relief of obstruction and preservation of spinal cord function. Upper and lower body blood pressures and pulses should be compared serially and the lower extremities monitored closely for the return of sensation and voluntary movement in the early postoperative period. Equal pulses and a reproducible systolic blood pressure difference less than 10 to 12 mm Hg between upper and lower extremities indicate an excellent repair. Neonates and young infants typically require 1 to 2 days of mechanical ventilation after repair, and they are more likely to receive inotropic agents, especially if ventricular function was diminished before surgery. Older children and adolescents can frequently be extubated in the operating room and rarely require inotropic support. In fact, these patients are increasingly likely with older age at repair to have significant hypertension,[182] which should be treated aggressively early after surgery to reduce the risk of aortic suture disruption and bleeding. Beta-blockers and vasodilators, along with adequate analgesia and sedation, are effective. Patients with long-standing coarctation of the aorta frequently have persistent systemic hypertension despite an adequate repair; continued treatment with angiotensin-converting enzyme inhibitors is advocated to achieve normal blood pressures.

Four uncommon complications are associated with surgical repair of coarctation of the aorta. Postcoarctectomy syndrome

manifests as abdominal pain and/or distension in older patients and is presumed to be caused by mesenteric ischemia from reflex vasoconstriction after restoration of pulsatile aortic flow. Recurrent laryngeal nerve and phrenic nerve trauma can cause vocal cord paralysis and hemidiaphragm paresis or paralysis, respectively, with neonates and infants at highest risk. Disruption of lymphatic vessels or thoracic duct trauma can produce a chylous effusion that may require treatment by drainage and/or dietary modification.

Catheter-directed balloon angioplasty is used to treat both native and residual coarctation of the aorta.[183] The results of native coarctation of the aorta dilation after early follow-up appear similar to published surgical results, but aortic aneurysm formation has been reported.[184] Balloon angioplasty of recurrent coarctation of the aorta after surgery is effective and is generally preferred to reoperation.

Interrupted Aortic Arch

Patients with IAA typically present as neonates with either a loud systolic murmur or circulatory compromise as the ductus arteriosus closes. Therefore patient presentation can be similar to other severe left-sided obstructive lesions such as critical AS, critical coarctation of the aorta, and HLHS. Unlike either critical AS or coarctation of the aorta, however, severe pressure overload on the LV does not occur in the presence of an unrestrictive VSD, which functions as a "pop off" for LV outflow. The approach to resuscitation is similar to that described for the other ductal-dependent left-sided obstructive lesions, with attention to the possibility of pulmonary overcirculation as for HLHS.

Postoperative management issues specific to patients with IAA include assessment of possible residual left-sided obstruction, both in the aortic arch and in the subaortic region, shunting across a residual VSD, hypocalcemia (related to DiGeorge syndrome), dysrhythmias, and LV dysfunction with low cardiac output secondary to global effects of CPB and DHCA. Left-lung hyperinflation on postoperative chest radiographs suggests compression of the left mainstem bronchus. This complication tends to occur after difficult arch reconstructions when tension on the aorta causes it to press on the anterior surface of the bronchus, thus producing distal air trapping.

Hypoplastic Left Heart Syndrome

Pathophysiology. Among the congenital heart lesions, perhaps the most controversial has been management of HLHS. HLHS is a uniformly fatal disease if left untreated, and debates continue over a staged palliation, versus neonatal transplantation, versus comfort care alone. The results of surgical management vary among institutions and are clearly dependent upon expertise and experience,[184] the clinical condition of the neonate at presentation,[185] prematurity, multiple congenital anomalies, presence of an intact atrial septum, later age of presentation,[186] and degree of hypoplasia of left heart structures.[187,188]

This common example of single-ventricle physiology also represents the most severe form of obstructive left heart lesion. An anatomic spectrum of disease is implied for the lesion, but in its most severe and common presentation there is atresia or marked hypoplasia of the aortic and mitral valves with critical underdevelopment of the left atrium, left ventricle, and ascending aorta. A 1- or 2-mm ascending aorta gives rise to the coronary circulation and the head vessels before converging with the ductus arteriosus, where the aorta becomes larger and supplies the circulation to the lower body. Pulmonary venous return arrives in the diminutive LA and cannot cross the atretic mitral valve; therefore it is directed to the RA and RV, where common mixing occurs with the systemic venous return and all blood is ejected into the pulmonary artery. Systemic blood flow is then supplied from the pulmonary artery, right-to-left, across the PDA. As the PDA constricts in the neonatal period, systemic blood flow decreases and all ventricular output is directed to the lungs. The Q_p/Q_s ratio approaches infinity as Q_s nears zero. Therefore the paradoxical presentation of high Po_2 (70-150 mm Hg) in the face of shock and profound metabolic acidosis is seen. When the ductus arteriosus is reopened with PGE_1, systemic perfusion is reestablished, the acidosis resolves, and the Po_2 returns to the range of 40 to 60 mm Hg, representative of a Q_p/Q_s ratio between 1 and 2.

Critical Care Management. Adequate preoperative resuscitation with PGE_1 and correction of metabolic acidosis and end-organ dysfunction are crucial to the preparation and management of patients with this lesion. Further facilitation of resuscitation can be enhanced by judicious use of inotropic agents, which can optimize cardiac output and blood flow to organs such as the kidneys. However, excessive delay in the timing of surgical intervention results in gradual reduction in PVR over days, with excessive pulmonary blood flow and inadequate systemic perfusion. The surgical reconstructive approach to this lesion now commonly entails three operations that ultimately aim to provide a 2- to 5-year-old child with a reconstructed aortic arch and a Fontan-type circulation for single-ventricle physiology.[188,189] In the first stage of the reconstruction (Norwood operation),[190] the pulmonary artery is transected at the bifurcation and an anastomosis is performed to the ascending aorta, which has been surgically incised so that the aortic and pulmonary arterial confluence arises together from the single right ventricle as the neoaorta, which is extended into the remaining native aorta using homograft material. Pulmonary blood flow is established with a modified Blalock-Taussig shunt, usually 3.5 mm in diameter. The atrial septum is excised to ensure free flow of pulmonary venous return over to the TV. In addition to HLHS, the Norwood operation is used to repair other complex single-ventricle defects with systemic outflow obstruction or hypoplasia.[191]

The critical care considerations are the same as those outlined for patients with single-ventricle physiology. Perioperative management requires careful manipulation of PVR and SVR and support of ventricular function to provide adequate, but not excessive, pulmonary blood flow and systemic oxygen delivery while maintaining sufficient systemic and coronary artery perfusion.

Postoperative Management

Evolution of treatment strategies. Common teaching has held that postoperative mortality and hemodynamic lability are attributable to myocardial dysfunction and the physiologic burden imposed by a shunt-dependent pulmonary circulation in parallel with systemic blood flow. Treatment strategies have emphasized factors that may affect the balance between pulmonary and systemic blood flow. Immediately after a Norwood operation, PVR may be transiently elevated but

soon decreases. Once PVR falls, treatment is aimed at raising resistance to blood flow through the lungs and redirecting cardiac output to the systemic circulation. High inspired concentration of oxygen, hyperventilation, alkalosis, systemic vasoconstriction, and anemia will cause further increase in pulmonary blood flow and should be avoided. Therapies designed to raise PVR and thereby direct aortic blood flow to the systemic circulation have focused on lowering the FIo_2 or allowing the $Paco_2$ to rise with the pH falling toward 7.3. Further measures, such as ventilation with hypoxic gas mixtures or added carbon dioxide, have been advocated by some centers and have been intermittently embraced and abandoned by others. Validation of the effectiveness of these techniques to balance the pulmonary and systemic circulations has been difficult.

The clinical focus on caring for the newborn who has undergone Norwood palliation for HLHS has evolved in stages over the past 20 years. The early emphasis was on manipulating the PVR by optimizing mechanical ventilation (i.e., mean airway pressure, tidal volume, rate and inspiratory time, FIo_2, and Pco_2). It soon became apparent that the majority of this effort was aimed in the postoperative period to raise PVR and lower pulmonary blood flow while increasing systemic blood flow. Like any therapeutic strategy, manipulating gas exchange and inspired gases had its own set of adverse effects. High FIo_2 has well-defined pulmonary toxicity that may appear in a matter of days or even hours after exposure. Use of low FIo_2 (below room air concentrations) to raise PVR transiently and stabilize patients is both counterintuitive and a relatively uncommon therapy in clinical medicine. Whether iatrogenically induced or as part of a pathologic process, alveolar hypoxia can be life threatening when aggravated by unexpected hypoventilation. A mechanically ventilated and sedated patient on an FIo_2 less than 0.21 has little safety margin for dangerous hypoxemia even in the most intensively monitored environments. Excellent animal models of chronic pulmonary hypertension are produced by relatively brief exposure to hypoxic gas. A newborn breathing hypoxic gas mixtures in the preoperative period of stabilization may have a favorable response by raising PVR and diminishing pulmonary blood flow. However, if this treatment is prolonged during preparation for reconstructive or transplantation surgery, the caretakers may be frustrated by subsequent elevation in PVR that persists during and after weaning from CPB.

In centers where neonates are allowed to awaken and breathe spontaneously during the immediate postoperative period, pulmonary blood flow may become excessive and further stimulate hyperventilation and respiratory alkalosis. Adding carbon dioxide to the inspired gas may reverse this trend toward respiratory alkalosis and stabilize the relative balance of the pulmonary and systemic circulations if the forces that drive minute ventilation are suppressed with agents for sedation or analgesia. However, the metabolic cost of carbon dioxide breathing in an awakening child given little analgesia may discourage widespread application of this technique until the physiologic advantage over conventional means of controlling alveolar ventilation and $Paco_2$ has been demonstrated. This is especially true in unsedated, preoperative patients where factors controlling respiration during carbon dioxide breathing may permit minimal change of $Paco_2$ but substantially increase the respiratory rate and work of breathing.

The introduction of a 3.5-mm systemic-to-pulmonary shunt (rather than a 4-mm shunt) and the appreciation of the surgical complexity of an appropriately placed shunt did as much to reduce excessive pulmonary blood flow in the infants as did manipulation of the ventilator. Although the smaller shunts were associated with a rare but real incidence of shunt thrombosis, those involved in postoperative care found patient management with a small shunt substantially easier than struggling with a 4-mm shunt off of an innominate artery. By the late 1980s, it was apparent that this palliated circulation was required for only 10 to 12 weeks to reach an adequate patient size for the newly applied second stage of the procedure (bidirectional Glenn) to be performed. Therefore a relative increase in cyanosis (from a smaller shunt) was believed to be a justifiable price for more stable early postoperative hemodynamics. However, mortality rates did not plummet with the recognition of the advantage of smaller shunts and manipulating PVR, although by then many more centers were undertaking a staged reconstructive approach to HLHS. In the early 1990s, attention was redirected to the observation, that arterial oxygen saturation was only one variable in the assessment of Q_p/Q_s and that a perfectly "acceptable" arterial oxygen saturation of 80% in this disease may represent severe pulmonary overcirculation if the mixed venous oxygen saturation was only 20%. Hence a renewed interest in measuring and monitoring arterial and mixed venous oxygen saturations emerged. Thus in overcirculated patients with a small (3.5 mm) fixed-diameter shunt off of the subclavian artery, there was less emphasis on micromanagement of PVR and more interest in pharmacologically supporting cardiac output while reducing the *systemic* afterload to diminish the driving pressure across the shunt. Use of the alpha-blocker phenoxybenzamine has been advocated by some for blunting systemic vascular reactivity and dilating the peripheral circulation,[192] but its potent, long-lasting effects and associated hypotension that is not ameliorated by the usual alpha-agonist vasoactive agents can be challenging. The phosphodiesterase inhibitors then enjoyed a new and extensive application in pediatric critical care: lowering SVR, increasing cardiac output, and lowering filling pressures. The new strategy was to monitor (arteriovenous) Do_2, support cardiac output, and reduce SVR.

Later in the decade, the observation of limited coronary reserve, low mixed venous oxygen saturation, rising lactate, and hemodynamic collapse in the first 48 hours helped emphasize the fundamental limitation of myocardial function and cardiac output in the early postoperative period. The morphologic right ventricle and TV seem ill suited to support adequate systemic plus pulmonary blood flow. Several centers then embraced mechanical support of the circulation temporarily for the failing Norwood patient in the early postoperative period.

Specific considerations for the Norwood operation. Management of patients after a Norwood-type operation is complex. Intensive monitoring is essential because the patient's clinical status can change abruptly with rapid deterioration. Persistent or progressive metabolic acidosis is a bad prognostic sign and must be aggressively managed. Considerations in the assessment of the circulation after the Norwood operation are given in Table 31-10.

Ideally the pH should be 7.40, $Paco_2$ 40 mm Hg, and Pao_2 40 mm Hg in room air, with a mixed venous O_2 saturation

Table 31–10 Management Considerations for Patients Following a Norwood Procedure

Scenario	Etiology	Management
Sao_2 ~80%		No intervention
Svo_2 ~60%	Balanced flow	
Normotensive	$Q_p = Q_s$	
Sao_2 >90%		Raise PVR
Hypotension	OVERCIRCULATED $Q_p = Q_s$ Low PVR Large BT shunt Residual arch obstruction	Controlled hypoventilation Low Fio_2 (0.17–0.19) Add CO_2 (3%–5%) Increase systemic perfusion Afterload reduction, vasodilation Inotropic support Surgical shunt revision
Sao_2 <75%		Lower PVR
Hypertension	UNDERCIRCULATED $Q_p < Q_s$ High PVR Small, kinked, thrombosed BT shunt	Controlled hyperventilation Alkalosis Sedation/paralysis Increase cardiac output Inotropic support Hematocrit >40% Surgical interventon
Sao_2 <75% Hypotension Low Svo_2	Low cardiac output Ventricular failure Myocardial ischemia Residual arch obstruction Atrioventricular valve regurgitation	Minimize stress response Inotropic support Surgical revision Consider mechanical support Consider transplantation

BT, Blalock-Taussing; *Fio_2,* inspired oxygen concentration; *PVR,* pulmonary vascular resistance; *Q_p,* pulmonary blood flow; *Q_s,* systemic blood flow; *Sao_2,* arterial oxygen saturation; *Svo_2,* mixed venous oxygen saturation.

of 60% reflecting a well-balanced circulation. Higher saturations can be achieved if the systemic circulation is well dilated without compromising perfusion pressure. Frequent changes in mechanical ventilation settings and FIo_2 may be necessary in the first few hours after surgery. However, manipulations of FIo_2 in the face of a restrictive 3.5-mm shunt may have less impact on pulmonary blood flow than would systemic vasodilation.[193] Leaving the sternum open after surgery may facilitate lower filling pressures, a balanced circulation, and stable ventilation pattern.

Deep sedation or even muscle paralysis and anesthesia often are continued after surgery to minimize the stress response until the patient has a stable circulation and gas exchange. Inotropic support with dopamine and occasionally low doses of epinephrine usually are required, titrated to systemic pressure and perfusion. Afterload reduction with milrinone as second-line agents is beneficial to reduce myocardial work and improve systemic perfusion. Monitoring SVC O_2 saturations, as a measure of mixed venous O_2 saturation (Svo_2) and cardiac output, is useful in this assessment.[194] Volume replacement to maintain preload is essential, aiming for a common atrial pressure approximating 10 mm Hg.

The type, diameter, length, and position of the shunt affects the balance of pulmonary and systemic flow. Generally, a 3.5-mm modified Blalock-Taussig shunt from the distal innominate artery provides adequate pulmonary blood flow without excessive steal from the systemic circulation for most full-term neonates. Nevertheless, a shunt resulting in a low diastolic pressure (<30 mm Hg) in turn affects perfusion to other vascular beds, particularly the coronary, cerebral, renal, and splanchnic perfusion. This may contribute to a prolonged and difficult postoperative course.

Overcirculation in the immediate postoperative period with an Sao_2 greater than 90% may reflect a low PVR or increased flow across the shunt if the shunt size is too large or the perfusion pressure increased from residual aortic arch obstruction distal to the shunt insertion site. The increased volume load on the systemic ventricle results in congestive cardiac failure and progressive systemic hypoperfusion with cool extremities, oliguria, and possibly metabolic acidosis. Although manipulation of mechanical ventilation and inspired oxygen concentration may help limit pulmonary blood flow, surgical revision to reduce the shunt size may be necessary.

If there is significant diastolic runoff through a large shunt, coronary perfusion may be reduced and lead to ischemia, low output, arrhythmias, and cardiac arrest. Rhythm disturbances are uncommon in the immediate postoperative period after a Norwood operation, and a sudden loss of sinus rhythm, and particularly heart block or ventricular fibrillation, should increase the suspicion of myocardial ischemia.

In the immediate postoperative period, mild hypoxemia with a Sao_2 of 70% to 75% and Pao_2 of 30 to 35mm Hg is preferable to an overcirculated state with high systemic oxygen saturations and falling mixed venous oxygen saturation. Pulmonary blood flow often increases on the first postoperative day as ventricular function improves and PVR falls during recovery from CPB. Pulmonary venous desaturation from parenchymal lung disease such as atelectasis, pleural effusions, and pneumothorax requires aggressive management.

Persistent desaturation and hypotension reflects a low cardiac output from poor ventricular function, thereby decreasing the perfusion pressure across the shunt. Svo_2 is low (often <40%), and treatment directed first at augmenting contractility with inotropic agents and subsequently reducing afterload with a vasodilator. This is a serious clinical problem with a high mortality after a Norwood operation. The related myocardial ischemia and acidosis further impair myocardial function and systemic perfusion, leading to circulatory collapse.

Atrioventricular valve regurgitation and residual aortic arch obstruction are important causes of persistent low cardiac output and inability to wean from mechanical ventilation. Echocardiography is useful for assessing valve and ventricular function but is less accurate for assessing the degree of residual arch obstruction. Cardiac catheterization is sometimes necessary and will enable fine-tuning of hemodynamic support or balloon dilation of a hypoplastic segment of narrowed aorta. Occasionally, surgical revision of the aortic arch or atrioventricular valve is necessary, although this is seen more commonly in the interval before the bidirectional cavopulmonary shunt.

A more recent modification of the Norwood procedure involves placement of conduit from the right ventricle to the

PA confluence (RVPA shunt).[195-197] The primary advantage of this procedure in the immediate postoperative period is improved diastolic perfusion without runoff across an aortopulmonary shunt. Ventricular function is less likely to be compromised after surgery because the volume load to the ventricle is reduced from a lower Q_p/Q_s, along with a reduced risk for myocardial ischemia because of improved coronary perfusion. Perfusion to cerebral, renal, and splanchnic circulations also is likely to be improved with the lack of diastolic runoff to the pulmonary circulation, which may enhance postoperative recovery. Because pulmonary blood flow occurs only during ventricular systole across the right ventricle to pulmonary artery conduit, there may be a critical reduction in pulmonary blood flow and excessive hypoxemia, especially during periods of low cardiac output or if there is dynamic obstruction to flow at the ventricular insertion site. Efforts to overcome this limitation by creating a larger RV incision run the longer-term risk of ventricular dysfunction, arrhythmias or aneurysm formation.

A recent multicentric, randomized, controlled trial involving 549 neonates with HLHS demonstrated a significantly improved transplantation free survival for patients randomized to receive a RVPA shunt compared to those palliated with a modified Blalock-Taussig shunt (74% vs. 64%, $P = .01$).[198] Moreover, major concerns about the potential for harmful effects of the right ventriculotomy proved to be unwarranted, at least at early follow up, although additional, unplanned interventions were more frequent in the RVPA shunt group to maintain shunt patency. The major benefit of the RVPA shunt seems to be an increased survival rate in the early period after the procedure, but longerterm follow-up will be required to assess effects beyond the 12-month period assessed in this trial.[198] The short-term survival advantage of the Sano modification of the Norwood operation for centers where mortality rate after the Norwood operation already was below 15% will be hard to demonstrate.

Orthotopic heart transplantation has gained acceptance as an alternative treatment for HLHS.[199] Neonatal transplants appear to be well tolerated, and some centers have avoided maintenance steroid therapy while achieving excellent midterm results using transplantation as the sole therapeutic option for this disease.[199,200] Others have successfully advocated a combined approach using either transplantation or staged reconstruction, depending on the pathophysiologic state of the child and the availability of a donor heart.[201] However, the critical shortage of donor organs places a marked limitation on correction of this common congenital heart lesion.

It is apparent that many children have derived benefit from a completed, staged reconstruction or heart transplantation for this previously fatal illness. They are often able to lead active, productive lives and to develop normally.[202,203] Both survival and developmental outcomes for this disease are improving worldwide. However, the long-term prognosis for this evolving therapy will not be known for several years.

Recently, an innovative alternative to the stage I Norwood palliation that eliminates the insult associated with CPB in the fragile neonate with HLHS has been developed. This approach combines interventional cardiac catheterization techniques with less involved surgery: the *hybrid procedure*.[204] The goal is to replicate the physiologic state of the Norwood procedure by the combination of three interventions: 1) placement of bilateral pulmonary artery bands to limit blood flow to the lungs, 2) placement of an endovascular stent to maintain the long term patency of the ductus arteriosus, and 3) balloon atrial septostomy with or without stenting of the atrial communication to ensure adequate mixing and unrestricted left to right atrial flow.[204,205] The procedure is accomplished through a standard medial sternotomy and does not require CPB.

The procedure requires superb coordination between the surgical and cardiac catheterization teams. It is generally performed in a hybrid suite consisting of a large modern cardiac catheterization laboratory with enough room to accommodate the surgeons and supporting operating room staff, in addition to the interventional cardiology team and anesthesiologists. Preliminary results have been encouraging with early mortality comparable with that of standard protocols (about 15%-20%).[206,207] Direct comparison of the two methods is complicated, as the hybrid procedure generally has been reserved for patients regarded as high risk for bypass surgery (low birth weight, unstable haemodynamics, and poor ventricular function).[205] Interstage mortality rates are high (15%-20%),[208] and case-matched studies have shown no benefit over conventional surgery.[207] One barrier to the widespread impementation of the hybrid procedure is that results of conventional surgery in the low-risk groups are now so good that many centers of excellence have been reluctant to undertake a new procedure with its attendant learning curve.

The hybrid procedure poses some unique technical challenges. The ductal stent position is crucial and, if patients have a diminutive ascending and transverse aorta, then the procedure does not address this impediment to coronary flow. If the transverse aorta is small, the stent itself might distort or interfere with retrograde flow into the arch, and for this reason most centres do not recommend the hybrid approach in the setting of a small transverse arch.[205] Nevertheless, the procedure has a role in the management of patients with HLHS and, with continued encouraging results,[209] it will most likely find a niche among high-risk patients or as a bridge to transplantation.[210]

Up to 50% of patients that survive the stage I hybrid procedure require catheter re-intervention due to stent migration or restrictive flow across the atrial communication.[208] The stage II procedure becomes much more extensive than the conventional stage II because the aortic arch needs to be reconstructed (excising the ductal stent), the bands removed, and the pulmonary arteries repaired with a patch in addition to creating the the cavopulmonary connection.[205] Consequently, the stage II after the hybrid procedure carries substantial operative mortality (10%-15%) and this needs to be taken into account when comparing it with conventional techniques.[208,209] No consensus exists on the future of the hybrid procedure. This innovative approach offers potential benefits that still need to be proven by careful study and long-term follow-up.

Summary

The cardiac ICU has become the epicenter of activity in large cardiovascular programs. Nowhere are collaborative practices and multidisciplinary skills more valued or necessary. A curriculum in cardiac intensive care is now formally incorporated into cardiology training. Pediatric intensive care training programs have a mandate to include curricula and experience

in management of postoperative cardiac patients. Additional cardiac intensive care training is offered in selected centers to pediatric intensive care specialists wishing to pursue a career in the cardiac ICU. Specialists in this field must have in-depth training in pediatric intensive care and cardiology as the scope of practice goes well beyond the cardiovascular system and requires expertise in complex respiratory physiology, diagnosis and management of multiorgan system dysfunction, and the various supportive techniques vital to the discipline of intensive care, to name a few. Increased complexity of disease, advances in technology and applied research, shortened lengths of stay, and improved survival all describe the fast-paced specialized environment that has accompanied the development of this new specialty of pediatric cardiac intensive care. Although the dramatic reduction in mortality has been gratifying in cardiac intensive care and is attributable to many factors, achieving 100% survival with minimal morbidity remains our elusive goal. It will challenge the next generation of practitioners.

Cardiac Transplantation

F. Jay Fricker

PEARLS

- Indications for transplantation are cardiomyopathy and complex palliated congenital heart disease with severe myopathic ventricular dysfunction.
- Pediatric patients on inotropic support or circulatory support and who have life-threatening arrhythmia receive priority for available pediatric donors.
- Selection of the agent to initiate inotropic support has evolved from sympathomimetic agents (dobutamine/dopamine) to the phosphodiesterase inhibitor milrinone.
- Virtual crossmatch is now utilized in sensitized patients to improve organ allocation.
- It is imperative that immune suppression be initiated immediately after heart transplantation.
- The high-risk period for acute allograft rejection is in the first month after transplantation.
- Complications of immune supression are infection, acute renal failure, malignancy, and hyperglycemia.

It has now been a quarter of a century since the first successful pediatric heart transplant was performed at Stanford University.[1] The introduction of cyclosporine as the primary immune suppressant agent used in solid organ transplantation was a key discovery because it was the first selective immunosuppressive agent used in solid organ transplant recipients. It has spared corticosteroid use and has made heart transplantation a cost-effective procedure.[2] In the past 25 years, perioperative mortality has become negligible even in patients with the most complex congenital heart defects. Advances have occurred in our understanding of the immune system, and improvement in critical care management of both donor and recipient patients has resulted in an increased survival benefit. This chapter reviews critical care management of the pediatric patient with cardiopulmonary failure who is evaluated for orthotopic heart transplantation. Donor management, physiology of the transplanted heart, and preoperative and perioperative critical care all play important roles in the successful outcome of critically ill children with no option other than heart replacement surgery.

Indications for transplantation are cardiomyopathy and complex palliated congenital heart disease with severe myopathic ventricular dysfunction.[3] The Pediatric Heart Transplant Study Group reviewed the causes of death after heart transplantation from a prospective database initiated in 1993. Patients were entered into the database on an intention-to-treat basis.[4-6] Using parametric data analysis with competing outcomes, death while waiting for transplant has been analyzed for all age groups, pretransplant diagnosis, blood type, and urgency status. Early death after heart transplant has been categorized as primary heart allograft failure. This includes inadequate preservation from long ischemic time and primary right ventricular failure from high pulmonary vascular resistance (PVR). Acute allograft rejection is an exceedingly rare event immediately after implantation. Late death after transplant is the result of posttransplant coronary vasculopathy, malignancy, or nonadherence to immune suppression regimens.[7,8]

The technical complexities of heart transplantation in children with palliated congenital heart disease contributed to the early perioperative mortality, which exceeded 30%. In addition, difficulties in estimating PVR, variable pulmonary artery anatomy, and complications from multiple repeat thoracotomy and sternotomy all contributed to early morbidity and mortality.[9] Solid organ preservation, surgical experience, and recipient selection have all improved with experience, resulting in reduced perioperative mortality that is equivalent to transplantation of the primary cardiomyopathic patient who has not had a previous sternotomy.[9,10] Primary transplantation in the neonate with hypoplastic left heart syndrome (HLHS) has caused controversy, because an acceptable surgical alternative is available and infant donor heart resources are limited.[11] In reviews from the Pediatric Heart Transplant Study Group Database, the mortality of infants waiting for donor heart availability exceeds 25%.[4] In recent years, deaths while waiting for transplantation have decreased, but this decrease reflects the smaller number of infants listed and those who have opted for the Norwood procedure and single-ventricle palliation. The Norwood procedure does not preclude the possibility of future transplantation.

Late death after heart transplantation is related to either accelerated allograft coronary artery disease or primary malignancy.[12,13] The major cause of death in the adolescent heart transplant recipient is now noncompliance with the medical regimen.[7] With the decrease in perioperative mortality, we now expect 5-year survival after heart transplantation to exceed 80%. From the newest survival data (International Society for Heart and Lung Transplantation 2009 Report), the transplant half-life (the time at which 50% of the recipients remain alive) is 11.3 years for teens and 15.8 years for infants.[14] Rehospitalization after the first year is rare, and quality of life has been excellent.[15]

Critical Care of the Pediatric Patient Waiting for Heart Transplantation

An inadequate number of good donor hearts is available to satisfy the number of potential adult recipients. Statistics from the United Network for Organ Sharing (UNOS) demonstrate this discrepancy between the number of potential recipients for heart and lung transplants and the availability of potential donors.[16] Donor availability for the pediatric patient is not as critical. Pediatric patients usually receive an appropriate donor offer unless they are infants or are adolescents of a size such that they are competing with critically ill adult patients. Guidelines from UNOS regarding organ distribution have changed to ensure that pediatric adolescent donors are available first to potential adolescent and young adult pediatric recipients for both heart and lungs.

For potential heart transplant recipients, urgency criteria have been established for the most critically ill patients. Pediatric patients on inotropic support or circulatory support or who have life-threatening arrhythmia receive priority for available donors (Box 32-1).

Management of the Potential Heart Transplant Recipient

The pretransplant management of the critically ill patient with end-stage myocardial dysfunction can determine the outcome of that patient after thoracic transplant. The principles of inotropic support, preservation of end-organ function, and attention to issues of nutrition and infection are the same for all critically ill patients in the pediatric intensive care unit.

Evaluation of the potential heart transplant recipient requires a careful pretransplant hemodynamic assessment. This information can guide the fluid and inotropic therapy by optimizing preload and afterload while waiting for organ availability. The critical hemodynamic information influencing the function of the donor heart is an assessment of pulmonary artery pressure and PVR in the recipient before implantation. High PVR is associated with an increased perioperative transplant mortality rate and adverse long-term outcome.[17,18] A transpulmonary gradient greater than 15 mm Hg (mean pulmonary arterial pressure minus mean left atrial pressure) is associated with a higher incidence of heart graft dysfunction.[18] Preoperative hemodynamic assessment should include measurement of both left and right heart pressures with interventions to manipulate the PVR if elevated. Remeasuring hemodynamics with Fio_2 of 1, nitric oxide, prostacyclin, and aggressive vasodilator therapy to decrease systemic vascular resistance (SVR) can help determine whether the patient is a heart transplant candidate or if he or she should be considered for lung or heart and lung transplantation.[19,20]

Box 32–1 Heart Transplantation Justification: Pediatric Cardiology Status IA

- Requires assistance with a ventilator
- Requires assistance with a mechanical assist device (e.g., extracorporeal membrane oxygenation, left ventricular assist device)
- Requires assistance with an intra-aortic balloon pump
- Patient younger than 6 months with congenital or acquired heart disease exhibiting reactive pulmonary hypertension >50% of systemic blood pressure levels
- Requires infusion of a single high-dose inotrope (e.g., dobutamine ≥7.5 μg/kg/min or milrinone ≥0.5 μg/kg/min)
- Patient does not meet any of the criteria specified above but has a life expectancy without a heart transplant of less than 14 days (i.e., refractory arrhythmia)

Inotropic Support

Critically ill children with myopathic ventricular dysfunction severe enough for them to be in the intensive care unit are on inotropic support. These agents increase contractility through a common pathway of increasing intracellular levels of cyclic adenylate monophosphate (cAMP). Increased cytoplasmic levels of cAMP cause increased release of calcium from the sarcoplasmic reticulum and increase contractile force generation. Increases in cAMP occur either by β-adrenergic–mediated stimulation (increase in production) or phosphodiesterase III (PDE III) inhibition (decreased degradation). Milrinone has proven to be a well-tolerated agent. Intravenous administration of milrinone increases cardiac output and reduces cardiac filling pressures, PVR, and SVR, with minimal effect on heart rate. Milrinone has been well studied in the pediatric population, and the benefit is primarily related to effect on SVR and PVR rather than inotropy.[21,22] Milrinone is initiated at doses of 0.25 μg/kg/min and increased to 1 μg/kg/min without adverse effects. Although atrial and ventricular ectopy are less common with milrinone than dobutamine, ventricular ectopy/ventricular tachycardia can occur with the initiation of milrinone therapy. Tachyphylaxis is unusual with this agent. Milrinone has a long half-life and should be used cautiously in patients with hypotension. This drug is primarily excreted in the urine, so concentrations can increase in the presence of renal failure. We have observed severe hypotension and renal dysfunction precipitated by use of an angiotensin-converting enzyme inhibitor in a patient already on milrinone infusion. The addition of low-dose dobutamine (5-10 μg/kg/min) or epinephrine (dose 0.01-0.05 μg/kg/min) can help stabilize the critically ill child who is not responding adequately to milrinone therapy alone.

Nesiritide, a recombinant B-type natriuretic peptide, is now approved for treatment of acutely decompensated heart failure. Endogenous B-type natriuretic peptide is a cardiac hormone produced by the failing heart, and nesiritide is identical to the naturally occurring peptide. Nesiritide reduces preload and afterload, leading to increases in cardiac output/index without reflex tachycardia or direct inotropic effect. In addition, this drug promotes natriuresis and diuresis, and suppresses the renin-angiotensin axis and endogenous catecholamines. Although this drug has not been studied extensively in the pediatric age group, in our and others' experiences, it has been found to be a safe and effective adjunctive therapy.[23,24]

Mechanical Support

Most patients waiting for transplantation who are on inotropic support do not remain hemodynamically stable indefinitely. Progressive end-organ dysfunction ensues, requiring escalation of support that includes multiple inotropic agents, in addition to respiratory and circulatory support. Mechanical

circulatory support has become an important addition to the treatment armamentarium for the infant or child with decompensated heart failure and low cardiac output unresponsive to pharmacologic maneuvers.[25] Options include extracorporeal membrane oxygenation (ECMO), intra-aortic balloon, and left and right ventricular assist devices. Experience with ECMO as a bridge to heart transplantation has been reported by several pediatric transplant centers.[26,27] ECMO support can be used for 2 to 3 weeks without major complications from bleeding or infection, extending the window for donor organ availability. Isolated ventricular support devices, such as the Thoratec, Berlin Heart,[28] and DeBakey centrifugal pump, are now available for children.[29,30] The Berlin Heart EXCOR has become the primary extrcorporeal circulatory device in infants and children. The current data from Berlin Heart show there have been a total of 698 patients supported for more than 47,000 days with this pneumatic-driven device (personal communication, Berlin Heart). The longest time of support in an individual patient was 902 days, with an average of 68 days of support before transplantation, explant, or death. The pediatric demography is that this device is used for all pediatric age ranges, but the mean age of 5 years and the median age of 2 years reflect the benefit in small children because of the availability of a pump size that can deliver 10-mL stroke volume. Actuarial survival of patients at 1 year who have been bridged to heart transplant or explanted now exceeds 80% (personal communication, Berlin Heart). In the past, use of these devices had always been considered extraordinary and usually proposed in patients with severe end-organ dysfunction. Placement of a device in a patient with multisystem organ failure usually results in a poor outcome. We propose that these devices be placed early, before end-organ dysfunction; doing so will enable rehabilitation of the patient, who then becomes a more optimal candidate for organ transplantation.

Anticoagulation

All patients with severe myocardial dysfunction are at risk for complications of systemic and pulmonary embolus. In our experience, nearly all explanted hearts have mural thrombi in both the left and right ventricles. Pulmonary emboli lead to increased PVR and the potential for lung abscess. The most devastating result of systemic embolus is stroke. All patients waiting for transplantation should be managed with systemic anticoagulation. Heparin is preferred, but warfarin is acceptable in a stable patient on inotropic support. We add a word of caution regarding the use of low-molecular-weight heparin for prophylaxis. Enoxaparin cannot be easily reversed in a patient who must go to the operating room emergently because a donor heart has been identified. Cardiovascular surgeons prefer using heparin for prophylactic anticoagulation.

Management of the Potential Heart Donor

Many potential heart donors are lost because of suboptimal management after brain death has occurred. Associated with brain death is a catecholamine surge causing unnatural circulatory physiology that rapidly evolves, making management of the donor difficult. This intense sympathomimetic outflow initially causes vasoconstriction resulting in tachycardia, hypertension, and increased myocardial oxygen demand. The result can be a direct injury to the myocardium in the potentially transplantable heart. Myocardial structural damage is seen and includes myocytolysis, contraction band necrosis, subendocardial hemorrhage, edema formation, and interstitial mononuclear infiltration.[31] This initial sympathetic outflow is followed by a loss of sympathetic tone resulting in marked vasodilatation and hypotension. The hypotension and cardiovascular collapse are related to decreased SVR rather than primary myocardial dysfunction. Large fluid volumes and high-dose inotropic agents at α-adrenergic dosing range are administered, causing volume overload and vasoconstriction that can injure all donor organs. Hearts that are supported on high-dose inotropic agents will likely exhibit myocardial injury. A risk factor that predicts donor heart failure is a history of use of high-dose dopamine, dobutamine greater than 20 μg/kg/min, and epinephrine greater than 0.1 μg/kg/min.

Hormonal changes occur with brainstem injury and death. Early depletion of antidiuretic hormone causes inappropriate diuresis. Depletion of free triiodothyronine (T_3) has been implicated in myocardial dysfunction. Falling insulin levels lead to decreased intracellular glucose levels. A significant decrease in cortisol levels contributes to cardiovascular instability.[32,33]

Our present understanding of the physiology of brain death has resulted in "protocol" development for management of the potential donor. The principles of support include the following:

- Invasive cardiovascular monitoring maintaining a mean arterial blood pressure greater than 60 mm Hg and central venous pressure of 6 to 10 mm Hg.
- Vasopressin is now the first-line blood pressure support medication because it treats diabetes insipidus in addition to supporting blood pressure. Infusion of less than 2.5 U/hour usually is sufficient to increase mean arterial blood pressure and not cause end-organ injury.
- Respiratory support to maximize oxygen delivery to transplantable organs. Recommended ventilatory strategies are aimed at optimizing oxygenation and preventing lung injury.
- Hormonal support including high-dose corticosteroids in the form of Solu-Medrol, insulin, and, possibly, infusions of the thyroid hormone T_3 or T_4. The benefits of thyroid hormone replacement in the brain-dead donor are debated, but there are studies supporting their use.[32] Resuscitation of the "marginal donor heart" is worth the effort, given the shortage of available donor organs. Administration of T_3 has been advocated for reversal of myocardial dysfunction induced by the catecholamine surge of brain death.[32]

Pediatric heart transplantation after declaration of cardiocirculatory death has received significant interest in the transplant community because of the shortage of donor organs. Protocols are controversial because donor care is provided under the direction of the pediatric intensivists. The donor is moved to the operating room and femoral arterial and venous lines are inserted for access to perform organ resuscitation. The donor is given comfort care, extubation is accomplished, and the donor is monitored for circulatory death by auscultation of the heart and palpation of pulses. When circulatory death has occurred, the donor is observed for a period of 1.25 to 3 minutes before death is declared. If cardiocirculatory death occurs within 30 minutes after extubation, the donor is declared a candidate for organ donation. Cold cardioplegia

is infused into the catheter that was positioned in the ascending aorta, sternotomy is performed and topical cooling of the heart is initiated, and the inferior vena cava is opened to prevent distension of the heart. The routine technique for cardiectomy is then performed.[34] Organ donation after circulatory death for kidney and liver transplantation is becoming more common but since the heart is more vulnerable to ischemia, this practice has not become common. The practice of transplantation after cardiocirculatory death for any organ remains an ethically controversial practice for many pediatric critical care intensivists.[35]

Critical Care Management of the Orthotopic Heart Transplant Recipient

Intraoperative Considerations

Heart replacement can be accomplished in virtually any congenital heart anomaly, because the aorta, pulmonary arteries, and left atrium are in a relatively constant position near the midline. Regardless of malposition or positional relationships of the great arteries, the aorta of the recipient can be mobilized to make anastomosis with the donor aorta possible. The left atrium is a midline structure, and even when anomalies of the pulmonary venous return exist, pulmonary veins usually approach the midline and can be incorporated into the repair.[36]

Techniques of implantation have not changed significantly since the original description.[1,37] The newest innovation is the bicaval anastomosis.[38,39] This technique has the advantage of preserving sinus node function.[40] Implantation techniques require that the pulmonary veins come to the midline. The pulmonary artery and aorta can be malpositioned but this adds little to the technical difficulty of the procedure. Aortic root size mismatch can, however, cause technical difficulty. Implantation of recipients with complex congenital heart disease usually can be accomplished by harvesting additional donor pulmonary artery, aorta, and caval tissue to replace deficient recipient tissue or to correct malposition of the vena cava or great arteries.[36,41]

Donor heart function is related to proper management of the donor and the total ischemic time of the donor heart. The amount of time the aorta is cross-clamped on the donor until the aortic anastomosis is completed on the recipient (total ischemic time) is a major factor determining early postoperative donor heart function. Nevertheless, donor hearts have been exposed to more than 8 hours of ischemia and recovered function after transplantation.

Early Perioperative Management

The early perioperative management of the recipient is not significantly different from the management of any postcardiac surgical patient. The physiologic responses of the newly transplanted heart are altered because of denervation. The major changes related to autonomic denervation include diastolic dysfunction and exaggerated response to exogenously administered catecholamines. The transplanted heart also must adapt to a new environment related to recipient lung function and elevated PVR.

Autonomic system denervation results in a relatively fixed heart rate without respiratory variation. Heart rates are between 90 and 110 bpm, but can be faster because of exogenous catecholamine administration. (The sinus node is transplanted with the donor heart.) Heart rates can be slower if the recipient has been exposed to amiodarone pretransplant or if there was injury to the blood supply of the donor sinus node at the time of donor heart removal.

Early blood pressure instability is common because of loss of baroreceptor regulation and dependence of the transplanted heart on endogenous or exogenous catecholamines. Hypertension occurs because of a fixed stroke volume into a systemic vascular bed that is abnormal because of longstanding increase is systemic vascular resistance from compensatory heart failure. Size mismatch between donor and recipient can also contribute to the hypertension because of a large stroke volume from the transplanted heart. The other concern about donor heart/recipient mismatch is "big heart," or hyperperfusion syndrome. A well-functioning large allograft generates a large stroke volume causing systemic hypertension and high cardiac output in a patient who previously had a low cardiac output state. This increase in cerebral blood flow has the potential to cause cerebral vasoconstriction and symptomatic seizures, headache, or changes in mental status.[42] These symptoms are limited to the first few days after transplantation. There is a gradual adaptation in allograft stroke volume to the needs of the recipient. This adaptation of oversized cardiac allografts in children is part of the "shrink and grow" phenomenon previously described.[42] The oversized donor heart eventually undergoes remodeling with regression of hypertrophy. Although this is a rare problem in children, symptomatic hypertension must be treated aggressively early in the perioperative period.

Early myocardial function of the transplanted heart is dependent on catecholamine support. Small infusions of β-adrenergic agents such as isoproterenol for several days are often necessary to maintain optimal heart allograft function.[43]

The hemodynamics of the transplanted heart reflect a significant shift to the left of the pressure/volume curve. Diastolic dysfunction can be demonstrated from the early transplant period. Why this hemodynamic abnormality is present early because of preservation injury is understandable, but diastolic dysfunction persists well into the recovery phase and beyond. Fluid administration of 10 mL/kg to a heart transplant recipient months remote from transplant will uncover an occult restrictive hemodynamic pattern. Pulmonary artery wedge pressure will increase by twofold, and right atrial pressure will increase more than expected.[44] In the normal heart, right atrial pressure will not change and left atrial pressure will increase by 1 to 2 mm Hg in response to a fluid challenge.

Diastolic dysfunction is a significant impairment to early allograft function, limiting cardiac output. Diastolic dysfunction emphasizes the importance of heart rate and early sinus node function. The capability for temporary pacing in the early perioperative period is mandatory.

Management of Early Heart Allograft Dysfunction

Early heart allograft dysfunction is related to primary failure of the heart allograft because of unsuspected injury to the heart prior to procurement or because of preservation injury. The other major cause of primary allograft failure is elevated PVR in the recipient. Allograft failure is rarely caused by acute

antibody-mediated injury. Risk factors associated with donor heart dysfunction, if present, should be factored into the decision of accepting that particular heart for your patient. Obviously the condition of the recipient and the expected length of survival would mandate, at least, consideration for acceptance of a "marginal heart."

Risk factors for donor heart dysfunction include "down time of the donor" (length of initial resuscitation), evidence of myocardial injury with elevation of troponin I, and a history of high-dose inotropic support (dopamine/dobutamine >20 μg/kg/min or epinephrine/norepinephrine >0.1 μg/kg/min) in the donor. Objective assessment of donor heart function can be made by obtaining an echocardiogram and electrocardiogram. The echocardiogram assesses donor heart systolic function (shortening fraction or left ventricular ejection fraction), and will detect the presence of mitral valve regurgitation or wall-motion abnormalities. The presence of any of these abnormalities makes the donor heart "marginal" for transplantation. In assessing the donor heart function, serial echocardiograms are imperative before determining that the heart is not usable for transplantation. Abnormal heart function seen in the midst of the catecholamine storm of brain death can recover. Repeating the echocardiogram remote from the initial resuscitation period or after the reduction or discontinuation of inotropic support can increase one's confidence in accepting the donor heart.

The other major reason for primary donor heart dysfunction is right heart failure from high pulmonary vascular resistance (PVR). We have known since the early days of heart transplantation that the donor right ventricle will not function when exposed to an abnormal pulmonary circulation. High PVR in the recipient increases perioperative morbidity and mortality and can affect late survival. All potential heart recipients undergo cardiac catheterization prior to heart transplantation to document the anatomy of systemic and pulmonary venous connections, determine pulmonary artery size and distribution, and calculate PVR. The upper limit of PVR associated with successful orthotopic heart transplantation is not known. Criteria developed from the adult heart transplant experience indicate that a PVR greater than 6 Wood units or a transpulmonary gradient (pulmonary artery mean pressure minus left atrial mean pressure) greater than 15 mm Hg is associated with increased perioperative mortality. The transpulmonary gradient is the most useful number for estimating PVR, because measurement of cardiac output in the catheterization laboratory can be flawed. In children, PVR index (PVRI), determined by dividing transpulmonary gradient by cardiac index, is more useful, because children come in all sizes. PVRI less than 6 index units is associated with low perioperative mortality. Orthotopic heart transplants have been successful with PVRI greater than 6 and as high as 10 index units, but with increased morbidity and mortality rates. The diagnosis of high PVR is evident as the patient is weaned from cardiopulmonary bypass. Intraoperative transesophageal echocardiography demonstrates dilatation of the right ventricle and a small, underfilled left heart. Acute management of high PVR and right heart dysfunction includes high Fio_2 and administration of nitric oxide at 20 to 40 ppm. The need for continuous pulmonary vasodilator medications in the immediate perioperative period is unusual, but prostacyclin and sildenafil have both proved effective in this situation.[45]

The sinus node artery from the donor heart is at risk at the time of procurement, and the incidence of sinus node dysfunction causing junctional rhythm or atrial flutter/fibrillation is 10% to 20%. Nearly 5% of children require pacemaker therapy after transplantation because of sinus node dysfunction.[46] All transplant recipients have temporary pacing wires, so bradyarrhythmias are not an issue. If the patient is in atrial flutter/fibrillation, then cardioversion should be performed. Persistent sinus node dysfunction with bradycardia can be problematic because of early diastolic dysfunction of the heart allograft. In the usual scenario, the patient returns from the operating room in an atrial paced rhythm. When the pacemaker is turned off, the underlying rhythm is a junctional rate between 100 and 120 beats/min. As inotropic support is discontinued, the junctional rate slows to an unacceptable rate in the 50 to 80 beats/min range. Usually an occasional atrial contraction is conducted, but the sinus node has been injured. Initiating theophylline at a dose of 10 mg/kg/day is helpful. Permanent pacing is recommended if sinus or atrial conducted rhythm has not returned within 2 weeks.

Heart Allograft Rejection and Immune Suppression

It is imperative that immune suppression be initiated early after heart transplantation. Solid organ transplants transfer antigen-presenting cells (APCs) that are recognized by the recipient's human leukocyte antigen (HLA) immune system as foreign, which sets up a cascade of lymphocyte stimulation and proliferation. These lymphocytes then migrate to the heart allograft, where they can adhere to myocytes and endothelial receptors and cause tissue destruction. T-cell activation is the prime mover of allograft rejection. The initial signal is T-cell receptor binding of antigen on the surface of an APC. The APC is derived from the donor in the form of a monocyte, or a tissue macrophage. Interaction of the APC and T-cell receptor causes release of interleukin (IL)-1 from the APC, which causes activation of the T cell. Activated T cells secrete IL-2 and other lymphokines that induce proliferation of activated T cells, which migrate to the allograft causing tissue damage.

Initial immune suppression protocols include high-dose corticosteroids, induction with IL-2 receptor blockade, or antithymocyte globulin, followed by introduction of the calcineurin inhibitors cyclosporine or tacrolimus (Table 32-1).

Induction protocols with lympholytic agents OKT3 or antithymocyte globulin are effective in delaying the time until the first allograft rejection episode but do not have a long-term survival benefit.[47] The benefit of induction with IL-2 receptor blockade in preventing early heart allograft rejection is supported by recent studies.[48]

Corticosteroids have been part of standard protocols since the early days of solid organ transplantation. High-dose methylprednisolone (5 to 10 mg/kg) is administered at the time of aortic cross-clamp removal and continued in tapering doses over the first several days after surgery. Corticosteroids have immunosuppressive properties and benefit the allograft because of membrane-stabilizing and antioxidant effects on the graft.

More controversial is the timing of the introduction of calcineurin inhibitors cyclosporine and tacrolimus. A major complication in the early perioperative course after heart transplantation is renal dysfunction. In the past, calcineurin

Table 32–1 Immune Suppression in the Intensive Care Unit

Agent	Mechanism of Action	Dose	Monitoring	Major Side Effect(s)
INDUCTION IMMUNE SUPPRESSION				
Corticosteroids	Redistribution of peripheral lymphocytes, inhibition of lymphokine IL-2 production, impairment of macrophage response to lymphocyte signals	2 mg/kg days 1-3 1 mg/kg days 4-7	Glucose	Infection, cushingoid appearance, hypertension, hyperlipidemia, glucose intolerance
Basiliximab	Monoclonal antibody binds to IL-2 receptor	20 mg >35 kg 10 mg <35 kg, administer days 1 and 4	CBC	Anaphylaxis
Antithymocyte globulin	Nonspecific T-cell lysis	1.5 mg/kg/day for 5–7 days	T-lymphocyte subsets	Thrombocytopenia, anaphylaxis, infection, PTLD, localized pain with RATG administration, serum sickness
Cyclosporine	Calcineurin inhibitor, inhibition of T-cell receptor lymphokine production and T-cell proliferation	2.5 mg/kg/24 hours IV	Monoclonal whole blood assay 100–400 ng/mL, depending on time since transplantation	Nephrotoxicity, central nervous system seizures, decreased magnesium, hypertension, hirsutism, gingival hyperplasia
Tacrolimus	Calcineurin inhibitor, inhibition of T-cell receptor lymphokine production and T-cell proliferation	IV: 0.03–0.05 mg/kg/24 hr Oral: 1.0 mg bid; increase dose based on daily level	5–15 ng/mL, whole blood	Nephrotoxicity, anemia/neutropenia, headache, tremors, insomnia, glucose intolerance
MAINTENANCE IMMUNE SUPPRESSION				
Cyclosporine		5–20 mg/kg bid or tid		
Tacrolimus		0.3 mg/kg/day divided bid		
Sirolimus	Inhibition of T-cell activation and proliferation by preventing translation of mRNA	Loading dose of 3 mg/m^2 PO, then 1 mg/m^2/day given 4 hours after cyclosporine or tacrolimus	Triglycerides, platelets 5–10 mg/mL	Nephrotoxicity, hyperlipidemia, thrombocytopenia, leukopenia, gastrointestinal intolerance
Azathioprine	Antimetabolite inhibits purine and DNA synthesis	1–2 mg/kg/day	WBC <4000 ANC >1500	Bone marrow suppression
Mycophenolate mofetil		30–60 mg/kg/day in divided doses	WBC <4000 ANC >1500	Bone marrow suppression, gastrointestinal intolerance
Prednisone		1–3 mg/kg/day		
ACUTE CELLULAR REJECTION				
Methylprednisolone		10–25 mg/day for 3–4 days		
Antithymocyte globulin		1.5 mg/kg/day for 7–14 days		Peripheral lymphocyte count, platelet count

ANC, Absolute neutrophil count <1000; *PTLD,* posttransplant lymphoproliferative disease; *RATG,* rabbit antithymocyte globulin.

inhibitors cyclosporine and tacrolimus were major contributors. The APC and lymphocyte receptor interaction occurs within hours of the transplant; therefore, early introduction of calcineurin inhibitors is important. Because bioavailability of these drugs is so variable, early, continuous IV administration of these drugs have been a standard protocol.[49] We continue to experience a group of recipients who develop acute renal failure with intravenous administration of these drugs and therefore avoid IV use of cyclosporine and tacrolimus. Current protocols are based on oral/nasogastric administration of a standard dose of tacrolimus beginning on the day of transplant. Target levels of this drug are reached 3 to 5 days after transplant if subsequent doses are based on the trough level obtained each morning (see Table 32-1).[50]

The high-risk period for acute cellular rejection (ACR) is the first month after transplantation. ACR is a phenomenon that rarely occurs in the first week after transplant. Hyperacute rejection is uncommon, but can occur when a heart transplant recipient has preformed HLA antibody that reacts with a donor who has those specific HLA antigens. A positive crossmatch will be reported, which means the recipient's serum causes lysis of donor T cells obtained from lymph nodes from the donor at the time of organ procurement. Heart transplant recipients at risk for hyperacute rejection are identified by

measuring the presence of HLA antibody in their serum. Specificity and quantification of these HLA antibodies can be measured by Luminex beads, which enable a virtual crossmatch to be done between potential donors and recipients. Children with palliated congenital heart disease are at particular risk for HLA sensitization because of exposure to blood products at the time of their previous surgical procedures. Rapid institution of plasmapheresis immediately after implantation and continuing through the first several days after the operation is the optimal way to clear the offending antibody causing heart allograft dysfunction.

The diagnosis of ACR is made by endomyocardial biopsy. Histopathology in cardiac tissue obtained by endomyocardial biopsy remains the gold standard for diagnosis of acute cardiac allograft rejection. The numbers of infiltrating lymphocytes and the presence of myocyte injury are used to grade rejection and to guide allograft rejection therapy. Surveillance endomyocardial biopsies are performed within the first 2 weeks after transplant and then at strategic times depending on the size of the child, available access, and the technical difficulty of obtaining tissue.

Clinical recognition of acute allograft rejection can be subtle, but is obviously important because tissue diagnosis is not always possible, and surveillance techniques using peripheral blood, electrocardiography, and echocardiography have limitations. Acute cellular rejection can be present in the allograft without any symptoms or clinical findings. When ACR has progressed to hemodynamically significant allograft dysfunction, then symptoms of abdominal pain and vomiting are prevalent, and findings of systemic venous congestion, liver enlargement, and low cardiac output dominate. Symptoms of pulmonary venous congestion/pulmonary edema are rare findings. When ACR is suspected, histologic confirmation is always desirable if it can be safely performed. The principles of management are to acutely augment immune suppression with methylprednisolone or a lympholytic agent depending on the histologic and clinical severity of the heart allograft dysfunction. Following acute treatment, increases in maintenance of immune suppression agents are prescribed and follow-up endomyocardial biopsy is scheduled.

Complications of Immune Suppression in Heart Transplant Recipients Occurring in the Pediatric Intensive Care Unit

Infection

Infections are a major cause of mortality and morbidity in the early period after heart transplantation.[51,52] Factors that predispose to infection can be divided into preexisting factors related to the donor and recipient, and factors secondary to events in the intraoperative and postoperative periods. For example, the site of the organ transplanted provides a clue to the site of infection. Renal transplant recipients acquire urinary tract infections, whereas heart transplant recipients are exposed to chest cavity infections. The type and severity of the underlying illness leading to organ failure can increase the risk for rejection. Children with cardiomyopathy can be severely malnourished, require prolonged mechanical respiratory or circulatory support, and have chronic indwelling venous catheters, all of which predispose to infection. The presence of a pretransplant pulmonary infarction is associated with lung abscess in the posttransplant recovery period.[53] Neonates may experience severe sepsis from coagulase-positive staphylococci more often than older children.

The herpes virus family plays a significant role in infections occurring after transplantation. The clinical expression of cytomegalovirus and Epstein-Barr virus infection in the young patient is more severe because it is often a primary exposure.[54] Clinical infections related to these viruses rarely present before 1 month following organ transplantation and are most common in the first 6 months after heart transplantation.

Antibiotic management of the heart transplant recipient in the intensive care unit can be focused primarily on clinical suspicion, time of infection after transplant, and predisposing factors. Immune suppression is selective and targets T cells. Neutrophil function is normal except for the effect of high-dose corticosteroids. Neutropenia can occasionally be a problem because of bone marrow suppression caused by antimetabolites and tacrolimus. Prophylactic antibiotics, in the form of third-generation cephalosporins, are used for patients after sternotomy and continued until chest tubes and central lines are removed. The strategy against infection includes initial isolation, routine surveillance cultures, and regular replacement of indwelling catheters. In the early setting after transplantation, temperature elevation should indicate active infection and serious complication. If an infection is suspected, early and aggressive investigation is necessary and broad-spectrum antibiotics/antifungal agents should be initiated until the source of the fever is identified.

Renal Function

Acute renal failure is a major complication following orthotopic heart transplantation. Renal failure is multifactorial in etiology, and the premorbid risk factors of heart transplant recipients cannot necessarily be controlled. We can monitor and control use of calcineurin-inhibitor immune suppression agents. Therapeutic strategies include delayed initiation of cyclosporine and tacrolimus by using antithymocyte globulin or IL-2 receptor blockade for induction of immune suppression. The other option is to use a modified oral/nasogastric protocol for tacrolimus administration.[55] This protocol targets tacrolimus levels to below 6 ng/mL in the first 3 days after transplantation and then aggressively increases dosing and target level over the next 4 days. It is important to avoid early IV administration of these agents, because they invariably lead to renal afferent arteriolar vasoconstriction and oliguria. If renal dysfunction is complicating the posttransplant course, it is still difficult to withdraw calcineurin inhibitors completely, but lowering the target level to less than 6 ng/L and substituting higher doses of mycophenolate mofetil and adding sirolimus are reasonable options.[56] The other means for reversing renal toxicity is to target mechanisms of calcineurin inhibitor toxicity. Renal arteriolar vasoconstriction is an imbalance between vasodilator prostaglandins and vasoconstrictor thromboxane A_2. Thus prostaglandin E1 (PGE1) has been used for promoting renal vasodilatation, with some success. Oral PGE1 analogues have received mixed reviews. Calcium channel antagonists have also been used to prevent renal toxicity. Felodipine has been shown to cause a naturesis and to prevent the decline in renal hemodynamics produced

by angiotensin II. We have not had enough experience using this potentially useful drug in reversing cyclosporine/tacrolimus nephrotoxicity.[57]

Diabetes Mellitus

Hyperglycemia is common after heart transplantation with tacrolimus-based immune suppression. The combination of decreased insulin production from islet cells caused by tacrolimus and decreased peripheral utilization related to high-dose corticosteroids results in nonketotic hyperglycemia. Insulin is initially mandatory in management but often can be discontinued if the tacrolimus dose is reduced and the corticosteroid portion of maintenance immune suppression is discontinued.[58]

Future Management Strategies for Critical Care of Infants and Children with Cardiopulmonary Failure

Heart transplantation in children has gained wide acceptance as an important adjunct to treatment of children with end-stage cardiomyopathic function from cardiomyopathy and palliated congenital heart disease. Successful transplantation has produced longer and better-quality lives for many infants and children. Ten-year survival free of malignancy and coronary vasculopathy is the expected outcome.[59]

The future is moving toward fewer transplant procedures in children. Palliation techniques for complex congenital heart disease (i.e., single-ventricle Fontan procedure) are improving, and most of these patients will survive well into adulthood before requiring transplantation. Complications of adolescents with transposition of the great arteries who have undergone a Senning procedure and now present with systemic or right ventricular dysfunction will begin to disappear because of success with the arterial switch.

The natural history of cardiomyopathy is changing because of our understanding of the cellular mechanisms of myocardial function. New treatment strategies using angiotensin receptor and β-adrenergic blockade therapy are delaying or replacing the need for heart transplantation.

Circulatory support is being miniaturized by the development of the Berlin Heart and the DeBakey centrifugal pump. These devices can cause reversed ventricular modeling, allowing discontinuation of support without heart replacement therapy. The other major benefit of circulatory support is that, if initiated early, it can rehabilitate the child, recover end-organ function, and reduce the risks of heart transplantation surgery.

Physiologic Foundations of Cardiopulmonary Resuscitation

Adnan M. Bakar, Kenneth E. Remy, and Charles L. Schleien

PEARLS

- Both the cardiac and thoracic pump mechanisms play a role in infants and children during cardiopulmonary resuscitation, so attention to excellent chest compression technique with an emphasis on "push hard, push fast" is critical to attaining sufficient cardiac output to maintain coronary and cerebral blood flow.
- Use of any vasoconstrictor (including vasopressin) should be sufficient to raise aortic diastolic pressure during cardiopulmonary resuscitation above the critical level for resuscitation success (>15 to 20 mm Hg).
- Amiodarone may be the most effective pharmacologic treatment for shock-resistant ventricular tachycardia or fibrillation.
- Use of the biphasic defibrillator is an important advance in the treatment of tachyarrhythmias and has advantages in its safety profile compared with monophasic defibrillators.
- Post–cardiac arrest resuscitative care is critical to survival and includes appropriate uses of inodilators and neuroprotective strategies, including mild to moderate hypothermia.

With the development of basic cardiopulmonary resuscitation (CPR) in the early 1960s, skilled resuscitation teams both in and out of the hospital were formed. The development of CPR saved lives; previously every victim of cardiac arrest had died. Soon thereafter, successful resuscitation of patients by basic life support measures, defibrillation, and medications became common even as long as 5 hours after commencement of CPR. Data show that the success of CPR depends on many factors. Rapid institution of basic life support measures (i.e., bystander CPR for sudden out-of-hospital cardiac arrest and immediate electrical countershock for ventricular fibrillation (VF) improve the chances of survival for patients experiencing sudden out-of-hospital cardiac arrest.[1] These measures led to the growing deployment of automatic external defibrillators (AEDs) in public places. Although immediate defibrillation currently is the standard of care, accumulating evidence indicates that basic life support and other measures directed at restoring energy substrates to the myocardium before countershock in patients with prolonged VF may further improve outcome.[2-4]

Other preexisting factors that play a role in successful resuscitation include the patient's age, prior medical condition, presenting cardiac rhythm, and the etiology of cardiac arrest. In 2008, a multiinstitutional prospective study was published that examined these preexisting factors and further described in two additional studies the clinical characteristics, hospital course, and outcomes of a cohort of children after in-hospital or out-of-hospital arrest. Besides demonstrating differences in clinical characteristics, these studies offered future considerations for the care of children who had experienced cardiac arrest and postresuscitative care, including hypothermia.[5,6] The low resuscitation rate in children, even when the patient does not have preexisting disease, probably results from the high incidence of asystole as the presenting rhythm. Asystole is the most common presenting rhythm in both in-hospital and out-of-hospital arrests, and is noted in 55% to 70% of victims.[7-11] Bradycardia and pulseless electrical activity (PEA) are other common rhythms. The high incidence of asystole in children who experience cardiac arrest can be explained by systemic disturbances such as hypoxia, acidosis, sepsis, and hypovolemia that commonly precede the arrest. Although ventricular arrhythmias usually are reported to be infrequent (range, 1.3% to 3.8%),[12] out-of-hospital series report VF in 10% to 19% of victims younger than 20 years.[13] These series, along with the observation that the frequency of witnessed arrest is much lower than in adults,[14] suggests that ventricular rhythms may be more common than usually estimated and that delay in resuscitation results in progression of nonperfusing rhythms to asystole. Increasing availability of AEDs may be contributing to the increased recognition of ventricular arrhythmias in out-of-hospital pediatric cardiac arrest. In specialized cardiac intensive care units (ICUs), ventricular arrhythmias account for as many as 30% of the arrests.[15]

In their original work on CPR, Kouwenhoven et al.[16] proposed that blood flow during closed-chest compressions resulted from squeezing of the heart between the sternum and vertebral column, now termed the cardiac blood flow mechanism. In fact, the precise mechanism by which forward circulatory flow is generated during closed-chest cardiac massage has major implications for current approaches to CPR. Other methods, such as vest CPR, simultaneous compression ventilation CPR (SCV-CPR), active compression-decompression CPR (ACD-CPR) both without and with an impedance

threshold valve (ITV), and interposed abdominal compressions with CPR (IAC-CPR), take into account advances in our understanding of the mechanism of blood flow during resuscitation.

The pharmacology of resuscitation remains controversial, and these controversies have led to major changes in the guidelines for CPR. Use of sodium bicarbonate, calcium chloride, and glucose remains unresolved at this time. The role of epinephrine and especially high-dose epinephrine has been readdressed because of concerns over postresuscitation deleterious effects on myocardial performance and poor outcomes. Evidence favoring a role for vasopressin, with a relatively pure vasoconstrictor effect, is accumulating. The role of lidocaine as the antiarrhythmic of choice for ventricular ectopy has been questioned as new data on the efficacy of amiodarone in persons in cardiac arrest have been generated. Research is ongoing into alternative vasoconstrictors[17] and the use of "pharmacologic cocktails" that may include β-blockers, antiarrhythmic agents, antioxidants, nitroglycerin,[1,18,19] and a vasoconstrictor in attempts to improve the resuscitation outcome and postresuscitation cardiac function.

Developments in the use of direct current countershock have occurred. Biphasic defibrillators are now widely in use and appear to improve the success of defibrillation at lower delivered energies and, it is hoped, decrease myocardial injury. As noted, the role of "shock first" is being reassessed because the success of electrical countershock in restoring spontaneous circulation declines rapidly after 3 to 4 minutes have elapsed.

Postresuscitation cerebral preservation has become an important area of focus, and mild therapeutic hypothermia has been found to improve neurologic outcome after adult cardiac arrest.

This chapter discusses the physiologic foundations of CPR. In the first section, the possible mechanisms of blood flow by the thoracic and cardiac pump mechanisms are discussed, including how the specific chest geometry of children and infants helps decide which of these mechanisms applies. Then newer CPR techniques, which take into account the physiologic mechanisms discussed in the first section, are discussed. Controversies and advances in pharmacologic management during CPR and current guidelines for use of drugs for resuscitation are addressed. New developments in the use of countershock, including the timing of shocks, the energy used, and the type of current delivery system used (biphasic or monophasic), are discussed. Finally, the role of therapeutic hypothermia is reviewed.

Mechanisms of Blood Flow

Cardiac Versus Thoracic Pump Mechanism

The cardiac pump hypothesis holds that blood flow is generated during closed-chest compressions when the heart is squeezed between the sternum and the vertebral column. This mechanism of flow implies that ventricular compression causes closure of the atrioventricular valves and that ejection of blood reduces ventricular volume. During chest relaxation, ventricular pressure falls below atrial pressure, allowing the atrioventricular valves to open and the ventricles to fill. This sequence of events resembles the normal cardiac cycle and occurs during cardiac compression when open-chest CPR is used.

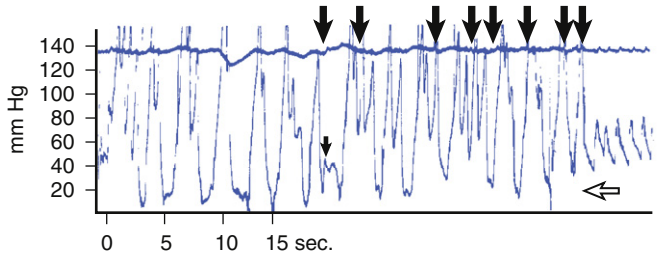

Figure 33–1. Cough-cardiopulmonary resuscitation during prolonged ventricular asystole after coronary arteriographic injection. An 18-second period of asystole after right coronary arteriographic injection is depicted. During this period, the patient coughed every 2 seconds, generating peak aortic pressures >140 mm Hg. *Large arrows* mark the intrinsic QRS complexes after the 18-second period of asystole. *Small arrow* marks the resultant aortic pressure from the first intrinsic beat. The patient continued to cough until the cardiac rhythm stabilized 40 seconds later. *(From Criley JM, Blaufuss AH, Kissel GL: Cough-induced cardiac compression. Self-administered form of cardiopulmonary resuscitation,* JAMA *263:1246, 1976.)*

Numerous clinical observations have conflicted with the cardiac pump hypothesis of blood flow. In 1964, Mackenzie et al.[20] found that closed-chest CPR produced similar elevations in arterial and venous intravascular pressures, the result of a generalized increase in intrathoracic pressure. In 1976, Criley et al.[21] made the dramatic observation that several patients in whom VF developed during cardiac catheterization produced enough blood flow to maintain consciousness by repetitive coughing (Figure 33-1). The production of blood flow by increasing thoracic pressure without direct cardiac compression describes the thoracic pump mechanism of blood flow during CPR.

During normal cardiac function, the lowest pressure in the vascular circuit occurs on the atrial side of the atrioventricular valves. This low pressure compartment is the downstream pressure for the systemic circulation, which allows venous return to the heart. Angiographic studies show that blood passes from the venae cavae through the right heart into the pulmonary artery and from the pulmonary veins through the left heart into the aorta during a single chest compression.

Echocardiographic studies show that, unlike normal cardiac activity or during open-chest CPR, during closed-chest CPR in both dogs[22] and humans,[23] the atrioventricular valves are open during blood ejection and aortic diameter decreases rather than increases during blood ejection. These findings during closed-chest CPR support the thoracic pump theory and argue that the heart is a passive conduit for blood flow (Figure 33-2).[24]

Initial measurements of hemodynamic data during chest compression for CPR found the generation of almost equal pressures in the left ventricle, aorta, right atrium, pulmonary artery, and esophagus (Figure 33-3).[25] The finding that all intrathoracic vascular pressures are equal implies that suprathoracic arterial pressures must be higher than suprathoracic venous pressures. The unequal transmission of intrathoracic pressure to the suprathoracic vasculature establishes the gradient necessary for blood flow. The transmission of intrathoracic pressure to the suprathoracic veins may be modulated by venous valves. The presence of these jugular venous valves has been demonstrated in animals[26] and humans[27,28] undergoing CPR. An ultrasonography study of healthy children confirmed the presence of these valves in 84% of 239 jugular

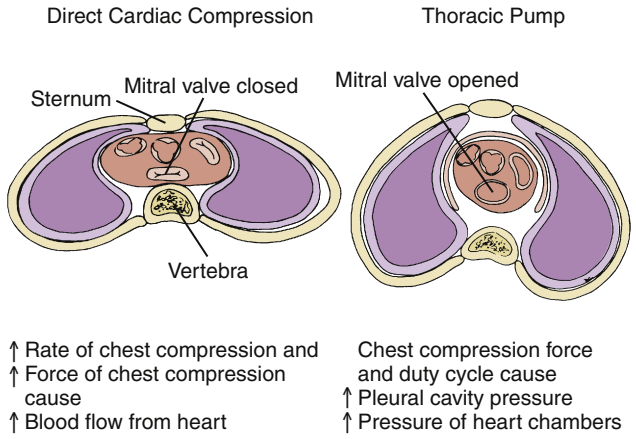

Figure 33–2. Possible mechanisms for blood flow during cardiopulmonary resuscitation include direct cardiac compression *(left)* and the thoracic pump *(right)*. With direct cardiac compression, an increase in chest compression rate causes an increase in blood flow by squeezing the heart between the vertebral column and sternum. With the thoracic pump mechanism, factors that increase pleural pressure cause an increase in pressure within the heart chambers and ultimately an increase in blood flow. *(From Schleien CL et al: Controversial issues in cardiopulmonary resuscitation,* Anesthesiology *71:135, 1989.)*

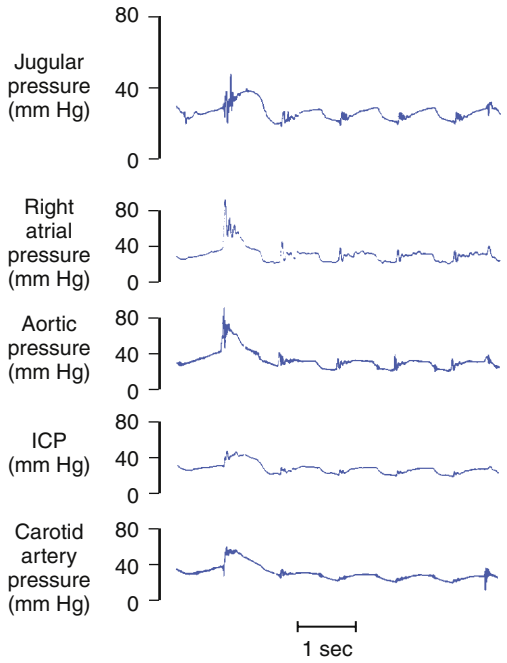

Figure 33–3. Original record during conventional cardiopulmonary resuscitation. The first compression for conventional cardiopulmonary resuscitation follows the lung inflation that occurred during the previous release phase. Note increase in pressure on this compression. *ICP,* Intracranial pressure. *(From Koehler RC, Chandra N, Guerci AD, et al: Augmentation of cerebral perfusion by simultaneous chest compression and lung inflation with abdominal binding after cardiac arrest in dogs,* Circulation *67:266, 1983.)*

veins studied. The valves were bilateral in 74% of children.[29] Transmission of intrathoracic pressure to the intracranial vault during CPR indicates that any such valve function is partial. Pathologic studies have also identified valves in the subclavian vein in the large majority of cadavers studied (87%). The absence of these valves in some patients is postulated to lead to failure of closed-chest CPR.[30]

Subsequent hemodynamic and echocardiographic studies found different results. Deshmukh et al.[31] demonstrated in a porcine model that mitral valve function persisted throughout resuscitation in 17 of 22 animals and that in successfully resuscitated animals, maximal aortic pressure exceeded that in the right atrium throughout the resuscitation. In another porcine model of resuscitation, Hackl et al.[32] manipulated the compressive force and depth of resuscitation by using a mechanical resuscitator. The frequency of mitral valve closure during compressive systole was directly proportional to the force and depth of chest compression. When the depth of compression reached 25% of the anteroposterior diameter, valve closure occurred in 95% of cycles. They concluded that the mechanism of blood flow was dependent on the force and depth of compression. In a study of CPR using transesophageal Doppler echocardiography in adults, Porter et al.[33] demonstrated mitral valve closure in compressive systole in the majority of patients (12 of 17) but not all patients. Peak mitral flow occurred in diastole and was significantly higher in the group with mitral valve closure. Peak mitral flow occurred during compressive systole in those without valve closure. Left ventricular fractional shortening correlated with change in anteroposterior chest wall diameter and not mitral valve flow. These authors concluded that nonuniform increased intrathoracic pressure plays a role in determining whether valve closure occurs during chest compressions. As noted, a decrease in aortic dimension during CPR has been demonstrated by echocardiography and taken as evidence for the thoracic pump mechanism of blood flow. Hwang et al.[34] readdressed this issue using transesophageal echocardiography. They studied the aortic dimension of the proximal and distal thoracic aorta and noted a decrease in the aortic dimension in the distal aorta directly inferior to the zone of direct compression and an increase in the dimension of the proximal aorta. They also noted mitral valve closure in all subjects and a decrease in left ventricular (LV) volume of almost 50% at end compression. These findings were believed to be most consistent with the cardiac pump mechanism of blood flow.[35] Kim et al.[36] also used transesophageal echocardiography to explore the role of the LV during nontraumatic arrests. They noted that during the compression phase of CPR, there was anterograde flow from the ventricle to the aorta, as well as retrograde flow toward the mitral valve. The mitral valve remained closed during compression and open during relaxation, while the aortic valve remained open during compression and closed during relaxation, which they concluded to be consistent with the cardiac pump mechanism.

The cardiac pump mechanism appears to predominate during closed-chest CPR in specific clinical situations. As noted, increasing the applied force during chest compressions increases the likelihood of direct cardiac compression.[32,36] A smaller chest size may allow for more direct cardiac compression. Adult dogs with small chests have better hemodynamics during closed-chest CPR than do dogs with large chests. Because the infant chest is smaller and more compliant than the adult chest, direct compression of the heart during CPR is more likely to occur. Blood flow during closed-chest CPR in a piglet model of cardiac arrest is higher than that achieved in adult models.[37] In contrast to adult animals, increasing intrathoracic pressure by SCV-CPR does not augment vascular pressure or regional organ blood flow during CPR in piglets.[38] The failure of SCV-CPR to increase blood

flow in the infant implies that direct compression occurs with conventional CPR and that additional intrathoracic pressure is of no benefit.

Rate and Duty Cycle

In 2010 the American Heart Association (AHA) recommended a rate of chest compressions of at least 100 per minute.[39] At faster rates, blood flow is enhanced whether the thoracic pump mechanism or the cardiac pump mechanism is invoked. Duty cycle is defined as the ratio of the duration of the compression phase to the entire compression-relaxation cycle expressed as a percent. For example, at a rate of 30 compressions/min, a 1.2-second compression time produces a 60% duty cycle. If blood flow is generated by direct cardiac compression, then the stroke volume is determined primarily by the force of compression. Prolonging the compression (increasing the duty cycle) beyond the time necessary for full ventricular ejection should have no additional effect on stroke volume. Increasing the rate of compressions should increase cardiac output because a fixed, relatively small volume of blood is ejected with each cardiac compression. In contrast, if blood flow is produced by the thoracic pump mechanism, the volume of blood to be ejected comes from a large reservoir of blood contained within the capacitance vessels in the chest. With the thoracic pump mechanism, flow is enhanced by increasing either the force of compression or the duty cycle but is not affected by changes in compression rate over a wide range of rates.[27] Additionally, the "push hard, push fast" recommendation is based on the maintenance of a higher compression rate with a higher force of compression. Allowing total recoil of the chest allows for full blood return during the relaxation phase of the cycle.[40]

Mathematical models of the cardiovascular system confirm that blood flow is determined by both the applied force and the compression duration with the thoracic pump mechanism.[41] A mathematical model equating CPR to a circuit, constructed by Babbs,[42] determined that while hemodynamics did not vary with compression rate, total flow and coronary flow were greatest when compression time equaled 30% of cycle time.

It appears from experimental animal data that both the thoracic pump and cardiac pump mechanisms can effectively generate blood flow during closed-chest CPR. Differences between various studies may be attributed to differences in animal models or compression techniques. Important differences in animal models include chest wall geometry, compliance and elastic recoil, compliance of the diaphragm, and intraabdominal pressure. Differences in technique include the magnitude of sternal displacement, compression force, momentum of chest compression, compression rate, and duty cycle. Experimental and clinical data support both mechanisms of blood flow during CPR in human infants.

Results of several studies in dogs demonstrated a benefit of a compression rate of 120 per minute compared with slower rates during conventional CPR.[43,44] In studies of piglets,[45] puppies,[46] and humans,[27,47] no differences were found comparing different rates of compression during conventional CPR. In a study of piglet CPR, duty cycle was the major determinant of cerebral perfusion pressure. The duty cycle at which venous return became limited varied with age. A longer duty cycle was more effective in younger piglets.[45]

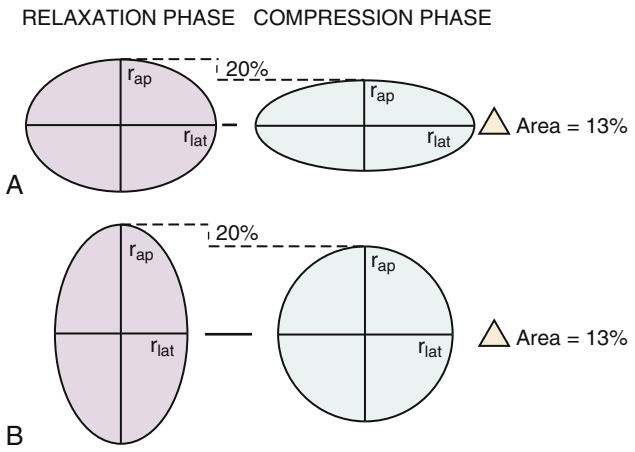

Figure 33–4. Changes in area of ellipses with constant circumference. Each ellipse is labeled with the anteroposterior *(ap)* and lateral *(lat)* radii, and a 20% anteroposterior compression is applied. Indicated change in area equals relaxed area – compressed area. **A,** Initial anteroposterior/lateral ratio = 0.7, and compression leads to positive ejection because relaxed area – compressed area is negative. **B,** Initial anteroposterior/lateral ratio = 1.4, and compression toward a circular shape results in an increase in area. *(From Dean JM, Koehler RC, Schleien CL, et al: Age-related changes in chest geometry during cardiopulmonary resuscitation,* J Appl Physiol *62:2212, 1987.)*

The discrepant importance of rate and duty cycle in various models (by different investigators) is confusing. However, increasing the rate of compressions during conventional CPR to 100 per minute satisfies both those who prefer the faster rates and those who support a longer duty cycle. This is true clinically because producing a longer duty cycle is easier when compressions are administered at a faster rate.

Chest Geometry

Chest geometry plays an important role in the ability of extrathoracic compressions to generate intrathoracic pressure. Shape, compliance, and deformability, which change greatly with age, are the chest characteristics that have the greatest impact during CPR.

The change in cross-sectional area of the chest during anterior to posterior delivered compressions is related to its shape (Figure 33-4).[48] The ratio of the chest anteroposterior diameter to the lateral diameter is referred to as the thoracic index. A keel-shaped chest, as seen in an adult dog, has a greater anteroposterior diameter and thus a thoracic index greater than 1. A flat chest, as in a thin human, has a greater lateral diameter and thus a thoracic index less than 1. A circular chest has a thoracic index equal to 1. A circle has a larger cross-sectional area than either of these elliptical chests. As an anteroposterior compression flattens a circle, the cross-sectional area decreases and compresses its contents. In contrast, as an anteroposterior compression is applied to the keel-shaped chest, the cross-sectional area increases as a circular shape is approached. The cross-sectional area of the keel-shaped chest does not decrease until the chest compression continues past the circular shape to flatten the chest. This implies a threshold past which the compression must proceed before intrathoracic contents are decreased and squeezed.[48] Thus the rounder, flatter chests of small dogs and pigs may require less chest displacement than the keel-shaped chests of adult dogs

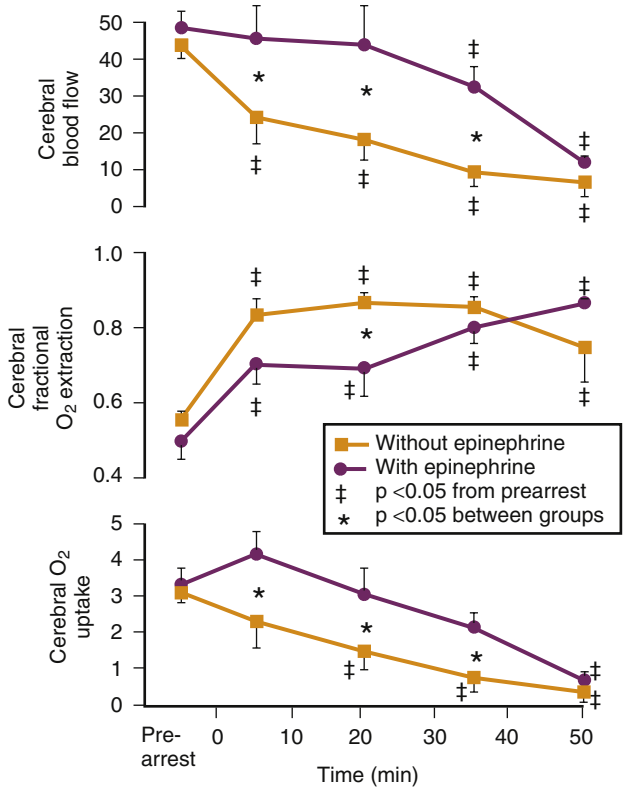

Figure 33–5. Total cerebral blood flow, cerebral fractional O_2 extraction, and cerebral O_2 uptake before cardiac arrest and during 50 minutes of cardiopulmonary resuscitation in the groups with and without epinephrine.

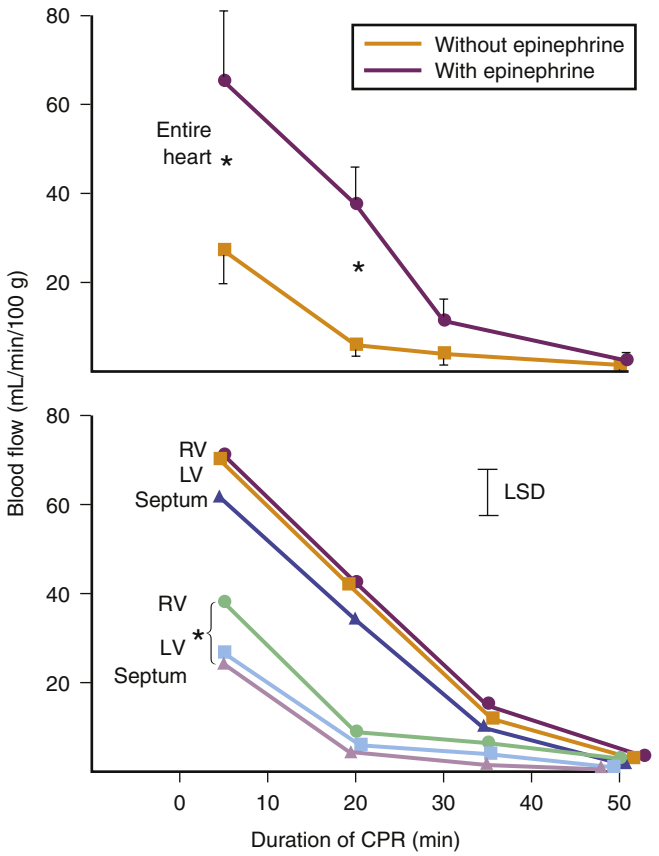

Figure 33–6. Top, Total myocardial blood flow during cardiopulmonary resuscitation (CPR) in piglets with and without epinephrine. *Asterisk* indicates significant difference between groups at 5 and 20 minutes. Bottom, Blood flow to right ventricular free wall *(RV, circle),* left ventricular free wall *(LV, squares),* and interventricular septum *(triangles)* in the groups with and without epinephrine. Standard error bars are omitted for clarity, but the least significant difference bar *(LSD,* derived from Duncan multiple-range test) is shown for comparisons among heart regions within an animal group. (Means must differ by height of bar for $P < .05$.) LSD for comparing means between groups is twice that shown for within-group LSD. *Asterisk* indicates that RV blood flow was greater than LV and septal blood flows at 5 minutes in the group without epinephrine. Flows in all three regions in the group with epinephrine were greater than those in the respective regions in the group without epinephrine at 5 and 20 minutes. *(From Schleien CL, Dean MJ, Koehler RC, et al: Effect of epinephrine on cerebral and myocardial perfusion in an infant animal preparation of cardiopulmonary resuscitation,* Circulation *73:809, 1986.)*

to generate thoracic ejection of blood. This dynamic has been demonstrated in small dogs having round chests compared with adult dogs having keel-shaped chests.[49]

As humans age, the cartilage of the rib cage calcifies and chest wall compliance decreases. Older patients may require greater compression force to generate the same sternal displacement. A 3-month-old piglet requires a much greater compression force for anteroposterior displacement than its 1-month-old counterpart.[48] Direct cardiac compression is more likely to occur in the more compliant chest of younger animals. Cerebral and myocardial blood flow during closed-chest CPR was much higher in infant piglets than in adults[50] (Figures 33-5 and 33-6). This finding supports the cardiac pump mechanism of blood flow in infants because the level of organ blood flow achieved during closed-chest CPR in piglets approaches the level achieved during open-chest cardiac massage in adults.

Marked deformation of the chest can occur during prolonged CPR and may alter the effectiveness of CPR (Figure 33-7).[50] Over time, the chest assumes a flatter shape, producing a larger percent decrease in cross-sectional area at the same absolute chest displacement. Progressive deformation may be beneficial if it leads to more direct cardiac compression. Unfortunately, too much deformation may decrease the recoil of the chest wall during the relaxation phase, leading to decreased cardiac filling. A progressive decrease in the effectiveness of chest compressions to produce blood flow is seen in piglets receiving conventional CPR.[50] Permanent deformation of the chest in this model approaches 30% of the original anteroposterior diameter. Attempting to limit deformation by increasing intrathoracic pressure from within during CPR with SCV-CPR was ineffective.[51] Using a thoracic vest to limit deformation when performing CPR greatly decreased the permanent chest deformation (3% vs. 30%) but did not attenuate the deterioration of vital organ blood flow with time.[52]

The characteristics of chest geometry of animals may relate to that in humans. Body weight, surface area, chest circumference, and diameter did not correlate with the magnitude of aortic pressure produced during CPR in a study of nine adults already declared dead.[52] A direct comparison of adult and pediatric human CPR has not been performed. The higher intravascular pressures and organ blood flow during CPR in infants compared with adults may result from more effective transmission of the force of chest compression because of the higher compliance and greater deformability of the infant chest.

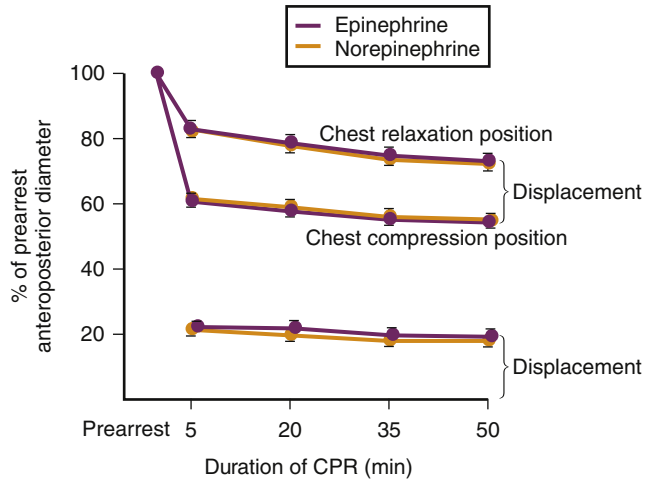

Figure 33–7. Piston position during chest compression and relaxation phases of the cycle, and net piston displacement expressed as a percent of prearrest anteroposterior chest diameter (12.0 ± 0.3 cm) in piglets. Note that displacement was essentially unchanged over the 50-minute duration, but marked deformation occurred during the relaxation phase by 5 minutes and continued to further deform over the 50-minute period in the groups with or without epinephrine. *CPR,* Cardiopulmonary resuscitation. *(From Schleien CL, Dean MJ, Koehler RC, et al: Effect of epinephrine on cerebral and myocardial perfusion in an infant animal preparation of cardiopulmonary resuscitation,* Circulation *73:809, 1986.)*

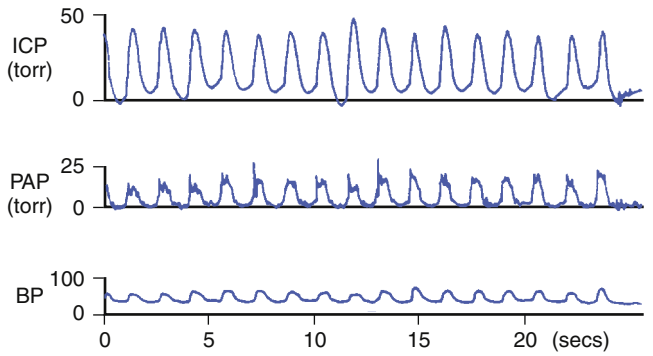

Figure 33–8. Relationship of intracranial pressure (ICP), pulmonary artery pressure (PAP), and arterial blood pressure (BP) during closed-chest cardiac massage. Note that each chest compression is accompanied not only by a rise in arterial and pulmonary artery pressure but also by a sharp rise in intracranial pressure. *(From Rogers MC, Nugent SK, Stidham GL: Effects of closed-chest cardiac massage on intracranial pressure,* Crit Care Med *7:454, 1979.)*

Effects of Cardiopulmonary Resuscitation on Intracranial Pressure

When chest compressions are applied, the increase in intrathoracic pressure is transmitted through the venous system of the head and neck to the intracranial vault, resulting in an increased intracranial pressure (ICP). Pressure is transmitted via the paravertebral veins and the cerebrospinal fluid during CPR in dogs.[53] Large swings in ICP corresponding to chest compressions occur in children undergoing CPR (Figure 33-8).[54] This transmission of intrathoracic pressure to the intracranial contents accounts for the low cerebral perfusion pressure by increasing the downstream pressure and cerebral blood flow during closed-chest CPR.

The relationship of ICP to intrathoracic pressure during CPR is linear. In dogs receiving conventional CPR, ICP increased by one third of the rise of intrathoracic pressure in a range from 10 to 90 mm Hg.[53] However, some modes of CPR change the intrathoracic to ICP relationship. In dogs, abdominal binding increases the transmission of pressure to the intracranial space to one half of the rise of intrathoracic pressure.[55] SCV-CPR, a mode of CPR designed to generate higher intrathoracic pressure, is similar to conventional CPR in its transmission of pressure to the cranium. Open-chest CPR decreases the transmission of pressure and improves cerebral perfusion pressure compared with conventional CPR. Thus increasing intrathoracic pressure may decrease cerebral blood flow because of the increase in downstream pressure, the ICP.

In this regard, ACD-CPR and ACD-ITV-CPR may have an advantage over conventional CPR. These techniques are designed to reduce intrathoracic pressure. Lindner et al.[56] showed in a porcine model that cerebral perfusion is increased with ACD-ITV-CPR compared with standard CPR. Using an adult porcine model of hypothermic VF arrest, the same group demonstrated by microdialysis techniques improved lactate/pyruvate ratios and reduced glucose accumulation in the ACD-ITV group compared with standard CPR.[57] In a pediatric porcine model of resuscitation, Voelckel et al.[58] found that ACD-CPR with ITV provided superior cerebral blood flow compared with standard CPR.

Newer Cardiopulmonary Resuscitation Techniques

Simultaneous Compression Ventilation Cardiopulmonary Resuscitation

SCV-CPR is a technique designed to increase blood flow during conventional CPR by increasing the thoracic pump mechanism contribution to blood flow. Delivering a breath simultaneously with every compression, instead of after every fifth compression, increases intrathoracic pressure and augments blood flow produced by closed-chest CPR.

Experimental studies have shown that SCV-CPR increases carotid blood flow compared with conventional CPR alone.[59] Subsequent studies confirmed physiologic advantages of SCV-CPR in canine models.[25] However, in infant piglets[51] and small dogs,[49] SCV-CPR offered no advantage over conventional CPR. In these small animals, the compliance and geometry of the chest may allow more direct cardiac compression. Thus higher intrathoracic pressure may be achieved with conventional CPR alone.[45,50] Coronary perfusion pressure (CPP) was either only minimally increased or even decreased in humans during SCV-CPR compared with conventional CPR. Survival was significantly worse in both animals[60] and humans[61] who received SCV-CPR compared with conventional CPR. No study has shown an increased survival rate with this technique of CPR.

Interposed Abdominal Compression Cardiopulmonary Resuscitation

IAC-CPR is the delivery of an abdominal compression during the relaxation phase of chest compression. An extensive review by Babbs[62] has been published. IAC-CPR may augment conventional CPR in several ways. First, IAC-CPR may return venous blood to the chest during chest relaxation.[63,64] Second, IAC-CPR increases intrathoracic pressure and augments the

Figure 33–9. Device for performing active compression-decompression CPR. The upper part is a handle and the lower part is a suction cup. *(Courtesy AMBU Corporation. From Halperin H: New devices for generating blood flow during cardiopulmonary resuscitation,* Curr Opin Crit Care *10:188-192, 2004.)*

duty cycle of chest compression.[63,65] Third, IAC-CPR may compress the aorta and return blood retrograde to the carotid or coronary arteries.[64] IAC-CPR is an attractive alternative to some of the newer techniques of CPR because it requires no additional equipment for implementation; however, it does require training and manpower.

In animal experiments, cardiac output and cerebral and coronary blood flow were improved when comparing IAC-CPR with conventional CPR,[66] but not in an infant model.[67] Initial human studies also demonstrated an increase in aortic pressure and CPP during IAC-CPR compared with conventional CPR.[68] Four randomized controlled trials have compared IAC-CPR with standard CPR. The first trial reported in 1985 by Mateer et al.[69] was the largest and included 291 patients. IAC-CPR was applied in the field by paramedics until ambulance transport. No differences in mortality were found. The later trials involved a total of 279 hospitalized patients.[70,71,269] The results from these trials are more positive, and a meta-analysis of these studies found an increased likelihood of return of spontaneous circulation (ROSC) and intact survival to discharge with IAC-CPR versus standard CPR.[72] Although no intraabdominal trauma was detected in any of the 426 patients in these trials, one pediatric case report demonstrated direct pancreatic injury. Alternative techniques for abdominal hand position were studied in adult swine.[73,74] A stacked hand position similar to the usual position for chest compression over the abdominal aorta was compared with a diffuse hand position in which the hands were placed on the abdomen separately. This study demonstrated a significant increase in aortic diastolic pressure compared with standard CPR. However, CPP was not augmented because the right atrial diastolic pressure was also elevated. Stacked hand position was found to produce a CPP equivalent to standard CPR. Diffuse hand position, however, was associated with decreased CPP, so if the technique is applied, this hand position should be avoided. Application of IAC-CPR is limited by the need for training and for the additional manpower. Although it has not been studied in a pediatric group, with skilled personnel available, IAC-CPR should be considered for use with inpatient arrests.

Active Compression-Decompression Cardiopulmonary Resuscitation and Impedance Threshold Valve Interposition

ACD-CPR uses a negative pressure "pull" on the thorax during the release phase of chest compression using a hand-held suction device (Figure 33-9).[75] This technique improves vascular pressures and minute ventilation during CPR in animals[77,78] and humans.[75,79] The mechanism of benefit of this technique is attributed to enhancement of venous return by the negative intrathoracic pressure generated during the decompression phase; in addition, it reverses the chest wall deformation that accompanies standard CPR.[80] Preliminary results in adults were promising,[77,81,82] and a large multiinstitutional study of ACD-CPR completed in Europe found that ACD-CPR was superior to standard CPR. In this study, a total of 750 patients were randomly assigned to receive standard CPR or ACD-CPR. In the experimental group, 5% survived to 1 year (12 patients with intact neurologic status), versus 2% (three patients with intact neurologic status) in the standard group.[83] However, a number of other trials have not shown a difference between standard CPR and ACD-CPR. A Cochrane Database Systematic Review concluded there was no consistent benefit from use of this technique.[84] The effectiveness of

ACD-CPR appears to be relatively site specific. Explanations for this variability have focused on the effectiveness of training for providers and intersite variation of on-scene advanced life support techniques.[80] Use of ACD-CPR requires significantly more physical effort than conventional CPR, and this requirement may have influenced outcome.[85] No device is currently cleared for clinical use in the United States at this time.

Use of an inspiratory threshold valve has been evaluated in attempts to improve the outcome with ACD-CPR.[83,86] This technique involves the use of a valve placed between the ventilating bag and the airway, which is designed to close when the tracheal pressure falls below atmospheric pressure, enhancing the development of negative intrathoracic pressure during ACD-CPR (Figures 33-10 and 33-11). Animal studies,[87,88] including a young porcine model,[58] showed improved organ perfusion, and brain microdialysis studies demonstrated decreased lactate accumulation and improved glucose utilization.[57] In a small series of patients, diastolic pressure was raised along with CPP and end-tidal CO_2 ($EtCO_2$) release.[89] These studies led to an inclusion of the technique as an acceptable alternative to standard CPR in the 2000 AHA guidelines and subsequent revised guidelines.[90] Plaisance et al.[83] reported on a series of 400 patients randomly assigned to ACD-CPR with ITV or sham ITV. Survival at 24 hours was significantly improved. There was a nonsignificant trend toward improved neurologic survival, with 6 of 10 discharged patients having intact survival compared with 1 of 8 discharged survivors in the sham ITV group. In two randomized control studies by Wolcke et al. and Plaisance et al. of 610 adults in cardiac arrest in the out of hospital setting, use of ACD-CPR plus the ITD was associated with improved ROSC and 24-hour survival rates when compared with CPR alone.[91] The addition of the ITD was associated with improved hemodynamics during standard CPR in one clinical study.[90] The ultimate role of this technique, which requires specialized equipment and significant resuscitator training, remains to be determined.[83,92]

Vest Cardiopulmonary Resuscitation

Vest CPR uses an inflatable bladder resembling a blood pressure cuff that is wrapped circumferentially around the chest and inflated phasically to increase intrathoracic pressure. Because chest dimensions are changed minimally, direct cardiac compression is unlikely. In addition, the even distribution of the force of compression over the entire chest wall decreases the likelihood of trauma to the skeletal chest wall and its thoracic contents.

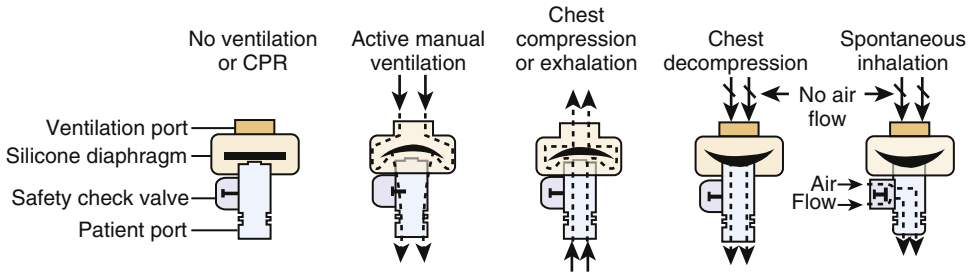

Figure 33–10. Schematic diagram of impedance threshold valve. During a positive pressure ventilation the valve is open and gas flows. During chest compression or exhalation air moves freely through the valve. During chest decompression airflow is impeded by the valve decreasing intrathoracic pressure. During spontaneous ventilation the check valve opens allowing gas flow. *CPR,* Cardiopulmonary resuscitation. *(From Lurie KG, Barnes TA, Zielinski TM, et al: Evaluation of a prototypic inspiratory impedance valve designed to enhance the efficiency of cardiopulmonary resuscitation,* Resp Care *48[1]:52-57, 2003.)*

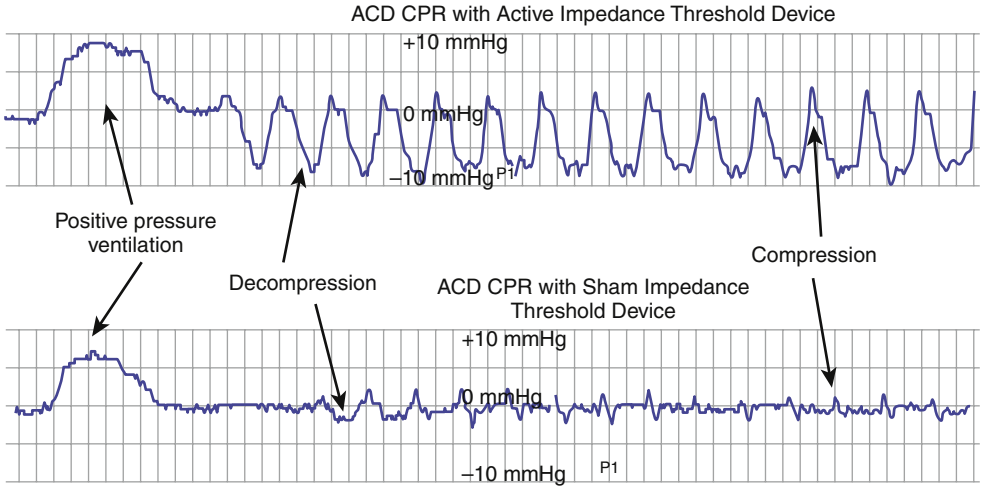

Figure 33–11. Example of intratracheal pressures, a surrogate for intrathoracic pressures, in a patient undergoing cardiopulmonary resuscitation (CPR) with an automated compression device (ACD) with and without an impedance threshold device attached to a face mask. CPR was delivered at 100 compression/decompression cycles/min with a synchronized compression/ventilation ratio of 15:2. Note the absence of significant decreases in intratracheal pressures with a sham device. With the active impedance threshold device, wide fluctuations in intratracheal pressure are seen with each compression and decompression. *(Courtesy M. Lurie, MD, and Advanced Circulatory Systems, Inc.)*

Improvement of cerebral and myocardial blood flows[93,94] and survival[95,96] with vest CPR compared with conventional CPR was seen in dogs. In piglets, a 3% permanent chest deformation was seen after 50 minutes of vest CPR,[52] compared with an almost 30% deformation produced during an equivalent period of conventional CPR.[50] In a human study, vest CPR increased aortic systolic pressure but had little effect on aortic diastolic pressure compared with conventional CPR.[97] Despite its late application, vest CPR improved the hemodynamics and the rate of ROSC in adult patients in another study.[98] Evidence from a case control study of 162 adults documented improvement in survival to the emergency department when vest CPR was administered by adequately trained personnel to patients in cardiac arrest in the out-of-hospital setting.[99] The lack of metallic parts has allowed vest CPR to be used experimentally during nuclear magnetic resonance spectroscopy to study brain intracellular pH.[100] The vest also has been used as an external cardiac assist device in nonarrested dogs with heart failure.[101] Clinically, the use of vest CPR depends on sophisticated equipment and remains experimental at this time.

Abdominal Binding

Abdominal binders and military antishock trousers have been used to augment closed-chest CPR. Both methods apply continuous compression circumferentially below the diaphragm. Three mechanisms have been proposed for augmentation of CPR by these binders. First, binding the abdomen decreases the compliance of the diaphragm and raises intrathoracic pressure. Second, blood may be moved out of the intrathoracic structures to increase circulating blood volume. Third, applying pressure to the subdiaphragmatic vasculature and increasing its resistance may increase suprathoracic blood flow. These effects increase aortic pressure and carotid blood flow in both animals[25] and humans.[102] Unfortunately, as aortic pressure increases, the downstream component of CPP, namely, right atrial pressure, increases to an even greater extent, resulting in decreased CPP and myocardial blood flow.[22] These techniques also lower the cerebral perfusion pressure by enhanced transmission of intrathoracic pressure to the intracranial vault, which raises ICP (the downstream component of cerebral perfusion pressure). Clinical studies have failed to show an increased survival when an abdominal binder or military antishock trouser suit was used to augment CPR.

Open-Chest Cardiopulmonary Resuscitation

Use of open-chest cardiac massage has generally been replaced by closed-chest CPR. Compared with closed-chest CPR, open-chest CPR generates higher cardiac output and vital organ blood flow. During open-chest CPR there is less elevation of intrathoracic, right atrial, and intracranial pressure, resulting in higher coronary and cerebral perfusion pressure and higher myocardial and cerebral blood flow.[103]

Open-chest CPR is not a technique that can be applied by most health care personnel. It can be used in the operating room, ICU, or emergency department equipped with the necessary surgical and technical equipment and personnel. It is easily used in the operating room or ICU after cardiac surgery when the open chest can be easily accessed. Open-chest CPR is indicated for cardiac arrest resulting from cardiac tamponade, hypothermia, critical aortic stenosis, and ruptured aortic aneurysm. Other indications include cardiac arrest resulting from penetrating or crushed chest wall abnormalities that make closed-chest CPR impossible or ineffective.[40] Open-chest CPR is indicated for select patients when closed-chest CPR has failed, although exactly which patients should receive this method of resuscitation under this condition is controversial. When initiated early after failure of closed-chest CPR, open-chest CPR may improve outcome.[104] When performed after 15 minutes of closed-chest CPR, open-chest CPR significantly improves CPP and the rate of successful resuscitation.[105]

Cardiopulmonary Bypass

Because of the low rate of survival after prolonged CPR, more aggressive methods have been suggested to improve its success: cardiopulmonary bypass (CPB) and extracorporeal membrane oxygenation CPR.[39]

CPB is one of the most effective ways to restore circulation after cardiac arrest. Animal studies show that CPB increases survival at 72 hours, increases recovery of consciousness, and preserves the myocardium better than does conventional CPR.[106] In dogs, CPB resulted in better neurologic outcome than conventional CPR after a 4-minute ischemic period; however, neurologic outcome was dismal in both groups when the ischemic period lasted 12 minutes.[106] Some 90% of dogs survived 24 hours after 15 to 20 minutes of cardiac arrest, but only 10% survived when the arrest time was prolonged to 30 minutes when CPB was used for stabilization during defibrillation.[108] CPB decreased myocardial infarct size in a model involving coronary artery occlusion compared with conventional CPR.[109] In all animal models, CPB improves the success of resuscitation compared with conventional CPR.

Human experience with CPB for cardiac arrest outside the operating room is growing. Morris et al.[110] reviewed these data. Accumulated experience now includes seven pediatric series reporting on 127 cases and 10 adult series reporting on 331 cases. Overall survival is excellent compared with conventional CPR despite long arrest times. In both groups, survival to decannulation is approximately 60% despite average precannulation CPR times, where reported, ranging from 16 to 60 minutes for children and from 20 to 80 minutes for adults. Long-term survival is remarkable, with 47% of children and 31% of adults achieving long-term survival. In the largest series of children reported by Morris et al.,[110] between 1995 and 2002, 64 children underwent 66 extracorporeal membrane oxygenation (ECMO) runs initiated during active resuscitation with chest compressions or internal cardiac massage. Of these patients, 33 (50%) were decannulated and survived for more than 24 hours, 21 (33%) survived to hospital discharge, and 16 (26%) reportedly had no major changes in neurologic outcome. The average duration of CPR before cannulation in the survivors was 50 minutes. Of the six surviving children who required more than 60 minutes of CPR before ECMO, three had no apparent change in neurologic status. During the same period, 73 children underwent standard CPR; 10 received CPR for more than 30 minutes, with no survivors. Duncan et al.[111] reported a series of 18 pediatric cardiac surgical patients at the Boston Children's Hospital who received ECMO during active chest compressions. Of the first seven patients, only 29% survived. This led to the development of a rapid ECMO deployment strategy in which an ECMO pump is

kept saline-primed in the ICU at all times, allowing initiation of extracorporeal support within 15 minutes. Precannulation support times dropped from an average of 90 minutes but still remained high at an average of 50 minutes. Of the remaining 11 patients, 10 were decannulated successfully, with 6 long-term survivors, 5 of whom were in New York Heart Association class I. This rapid deployment strategy likely will become more commonplace in large pediatric centers.

Under current 2010 AHA guidelines, centers should consider extracorporeal membrane oxygenation CPR for in-hospital cardiac arrest refractory to standard resuscitation attempts if the condition leading to cardiac arrest is reversible or amenable to heart transplantation, if excellent conventional CPR has been performed after no more than several minutes of no-flow cardiac arrest, and if the institution is able to rapidly perform ECMO. Long-term survival has been reported even after more than 150 minutes of CPR in selected patients.[112]

Data are emerging involving the role of ECMO in persons with refractory ventricular fibrillation.[113] These data have solely been in the form of case reports but may represent a future direction for the care of patients with VF. In 2006, Samson et al.[114] reported successful treatment of in-hospital VF in children with ECMO after cardiac arrest who had an initial rhythm of VF and immediate initiation of CPR.

CPB and ECMO require a great deal of technical support and sophistication. In units with preprimed circuits on standby, CPB can be implemented quickly and with moderate success in a population of children who would otherwise almost certainly die. The success with some patients undergoing very long CPR times followed by ECMO use is encouraging and suggests the possibility of reversible myocardial injury as a cause of resuscitation failure in a subset of patients. Overall, ECMO is unlikely to have a major impact on pediatric outcome because of its limited availability.

Transcutaneous Cardiac Pacing

Transcutaneous cardiac pacing (TCP) is used as a method for noninvasive pacing of the ventricles for a relatively short period. Emergency cardiac pacing is successful in resuscitation only if it is initiated soon after the onset of arrest. In the absence of in situ pacing wires or an indwelling transvenous or esophageal pacing catheter, TCP is the preferred method for temporary electrical cardiac pacing. Since 1992, the AHA advanced cardiovascular life support (ACLS) guidelines have recommended the early use of an external pacemaker in patients with symptomatic bradycardia or asystole.[115]

Since Zoll[116] established TCP in 1952 as a clinically useful method of pacing adult patients during ventricular standstill (Stokes-Adams attacks) and bradycardia-associated hypotension, numerous anecdotal reports have supported its use for bradycardic or asystolic arrests. Zoll et al.[117] reported successful in-hospital resuscitation of 12 of 16 patients with hypotensive bradycardia or asystole if TCP was initiated within 5 minutes of the arrest. In contrast, if TCP was started between 5 and 30 minutes after the arrest, only 8 of 44 patients with either of these rhythms could be resuscitated.[117] In two controlled clinical trials of prehospital TCP, no differences in the survival rate or success of resuscitation were observed in paced and nonpaced patients who had asystole or PEA.[118,119] In patients with symptomatic bradycardia, TCP improved resuscitation and the survival rate.[120]

To date the efficacy of TCP in resuscitation of children has not been studied. Beland et al.[121] showed that effective TCP could be achieved in hemodynamically stable children during induction of anesthesia for heart surgery. They were successful in 53 of 56 pacing trials, and the patients experienced no complications.[121]

TCP is indicated for patients whose primary problem is impulse formation or conduction and who have preserved myocardial function. TCP is most effective in patients with sinus bradycardia or high-grade atrioventricular block with slow ventricular response who also have a stroke volume sufficient to generate a pulse. TCP is not indicated for patients in prolonged arrest because in this situation TCP usually results in electrical but not mechanical cardiac capture, and its use may delay or interfere with other resuscitative efforts.

To set up pacing, one electrode is placed anteriorly at the left sternal border and the other posteriorly just below the left scapula. Smaller electrodes are available for infants and children; adult-sized electrodes can be used in children weighing more than 15 kg.[121] Electrocardiographic leads should be connected to the pacemaker, the demand or asynchronous mode selected, and an age-appropriate heart rate used. The stimulus output should be set at zero when the pacemaker is turned on and then increased gradually until electrical capture is seen on the monitor. The output required for a hemodynamically unstable rhythm is higher than that for a stable rhythm in children in whom the mean stimulus required for capture was between 52 and 65 mA. After electrical capture is achieved, one must ascertain whether an effective arterial pulse is generated. If pulses are not adequate, other resuscitative efforts should be used.

The most serious complication of TCP is induction of a ventricular arrhythmia.[122] Fortunately, this complication is rare and may be prevented by pacing only in the demand mode. Mild transient erythema beneath the electrodes is common. Skeletal muscle contraction can be minimized by using large electrodes, a 40-ms pulse duration, and the smallest stimulus required for capture. Sedatives or analgesics may be necessary in the patient who is awake. If defibrillation or cardioversion is necessary, one must allow a distance of 2 to 3 cm between the electrode and paddles to prevent arcing of the current.

Pharmacology

Adrenergic Agonists

In 1963, only 3 years after the original description of closed-chest CPR, Pearson and Redding[123] described the use of adrenergic agonists for resuscitation. They subsequently showed that early administration of epinephrine in a canine model of cardiac arrest improved the success rate of CPR. They also demonstrated that the increase in aortic diastolic pressure by administration of α-adrenergic agonists was responsible for the improved success of resuscitation. They theorized that vasopressors such as epinephrine were of value because the drug increased peripheral vascular tone, not because of a direct effect on the heart.[124]

Yakaitis et al.[125] investigated the relative importance of α- and β-adrenergic agonist actions during resuscitation. Only 27% dogs that received a pure β-adrenergic receptor agonist along with an α-adrenergic antagonist were resuscitated successfully, compared with all of the dogs that received a pure α-adrenergic agonist and a β-adrenergic antagonist

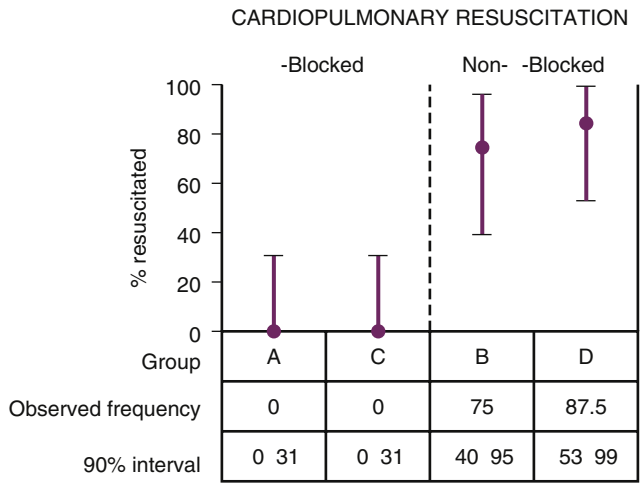

Figure 33–12. Beneficial effect of α-adrenergic activity on resuscitation. Animals in group A received phenoxybenzamine; group B received propranolol; group C received phenoxybenzamine and propranolol; and group D received no drug. The 90% confidence intervals are reported for the sample size and observed resuscitation success. The lack of overlap between the α- and non–α-blocked groups indicates a significant benefit ($P \leq .01$) during resuscitation when α-adrenergic activity is intact. *(From Yakaitis RW, Otto CW, Blitt CD: Relative importance of alpha and beta adrenergic receptors during resuscitation,* Crit Care Med *7:293, 1979.)*

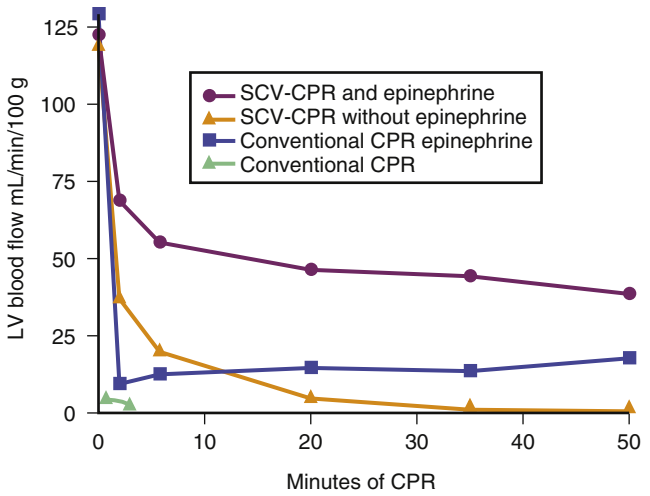

Figure 33–13. Left ventricular (LV) blood flow before arrest and during four types of cardiopulmonary resuscitation (CPR). Note the rapid falloff of LV blood flow when epinephrine is not used. *SCV-CPR,* Simultaneous compression ventilation CPR. *(From Michael JR, Guerci AD, Koehler RC, et al: Mechanisms by which epinephrine augments cerebral and myocardial perfusion during cardiopulmonary resuscitation in dogs,* Circulation *69:822, 1984.)*

(Figure 33-12). Later studies reconfirmed this finding. Michael et al.[37] demonstrated that the α-adrenergic effects of epinephrine result in intense vasoconstriction of the resistance vessels of all organs of the body, except those supplying the heart and brain. Because of the widespread vasoconstriction in nonvital organs, adequate perfusion pressure and thus blood flow to the heart and brain can be achieved despite the fact that cardiac output is very low during CPR (Figure 33-13).[50]

The increase in aortic diastolic pressure associated with epinephrine administration during CPR is critical for maintaining coronary blood flow and enhancing the success of resuscitation. Even though the contractile state of the myocardium is increased by use of β-adrenergic agonists in the spontaneously beating heart, during CPR, β-adrenergic agonists actually may decrease myocardial blood flow by increasing intramyocardial wall pressure and vascular resistance. This decrease in mycoardial blood flow could redistribute intramyocardial blood flow away from the subendocardium, increasing the likelihood of ischemic injury to this region.[126] Moreover, evidence indicates that left ventricular end-diastolic pressure (LVEDP) rises with epinephrine use, reducing the overall impact of the vasoconstrictor effects of epinephrine on CPP. Tang et al.[127] showed elevated LVEDP and decreased measures of diastolic performance in epinephrine-resuscitated rats after induced VF compared with phenylephrine-resuscitated animals or epinephrine-resuscitated animals who also received a β-blocker. Similar data were found by McNamara, who used a rat pup model of asphyxial arrest. LVEDP was increased and diastolic function indices decreased with epinephrine compared with either saline solution alone or epinephrine combined with verapamil. These data imply that excessive β-adrenergic effects prevent the intracellular calcium reuptake during diastole that is required for myocardial relaxation. By its inotropic and chronotropic effects, β-adrenergic stimulation increases myocardial oxygen demand, which, when superimposed on low coronary blood flow, increases the risk of ischemic injury. This combination of increased oxygen demand by β-adrenergic agonists[128] and decreased oxygen supply may damage an already ischemic heart, raising the question of whether a pure α-adrenergic agonist would be better than epinephrine, which has significant β-adrenergic effects (Box 33-1). The effects on energy utilization and oxygen supply not only have implications for the success of the initial resuscitation but also for the postresuscitation function of the myocardium.

A number of studies have attempted to settle this controversy and actually have shown that pure α-adrenergic agonists can be used in place of epinephrine during CPR. Phenylephrine[50,124,125] and methoxamine are two pure α-adrenergic agonists that have been used in animal models of CPR with success equal to that of epinephrine. More recently, vasopressin has been studied as a noncatecholamine vasoconstrictor in the management of patients who experience cardiac arrest.[12] This agent is discussed in the section on vasopressin. These agents cause peripheral vasoconstriction and increase aortic diastolic pressure, resulting in improved myocardial

Box 33–1 α-Adrenergic vs. β-Adrenergic Agonist Effects

α-Adrenergic Effects

- Vasoconstrict peripheral vessels
- Maintain aortic diastolic pressure
- Improve coronary blood flow
- *No* metabolic stimulatory effect

β-Adrenergic Effects

- Vasodilate peripheral vessels
- Decrease aortic diastolic pressure
- Increase cellular metabolic rate
- Positive inotrope
- Increase intensity of ventricular fibrillation
- Increase heart rate and/or dysrhythmias following resuscitation

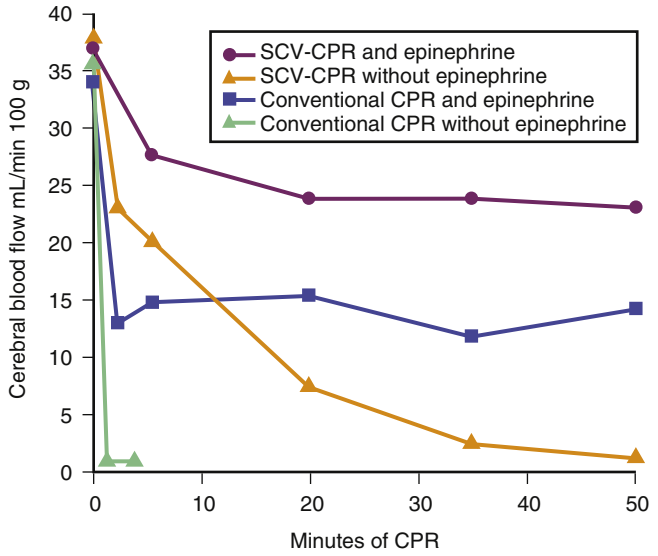

Figure 33–14. Cerebral blood flow before arrest and during four types of 50 minutes of cardiopulmonary resuscitation (CPR). *SCV-CPR,* Simultaneous compression ventilation CPR. *(From Michael JR, Guerci AD, Koehler RC, et al: Mechanisms by which epinephrine augments cerebral and myocardial perfusion during cardiopulmonary resuscitation in dogs,* Circulation *69:822, 1984.)*

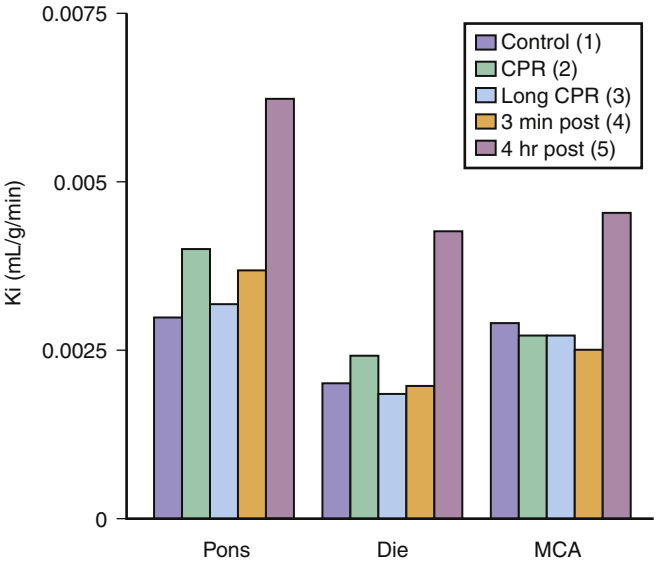

Figure 33–15. Transfer coefficient (K_i) of α-aminoisobutyric acid for pons, diencephalon (DIE), and middle cerebral (MCA) artery regions. Control group; 8 minutes ischemia and 10 minutes cardiopulmonary resuscitation (CPR); 8 minutes ischemia and 40 minutes cardiopulmonary resuscitation; 3 minutes after resuscitation; 4 hours after resuscitation. Group 5 in each region $*P < .05$, different from group 1 by one-way analysis of variance and Dunnett test for all three regions. *(From Schleien CL, Koehler RC, Schaffner DH, et al: Blood-brain barrier disruption after cardiopulmonary resuscitation in immature swine,* Stroke *22:477, 1991.)*

and cerebral blood flow. This effect results in a higher oxygen supply/demand ratio in the ischemic heart and, at least, a theoretical advantage over the combined α- and β-adrenergic agonist effects of epinephrine. These agonists,[124,130] as well as vasopressors such as vasopressin,[12] have been used successfully for resuscitation. These drugs maintain blood flow to the heart during CPR as well as epinephrine does. In an animal model of VF cardiac arrest, a resuscitation rate of 75% was reported for both epinephrine- and phenylephrine-treated groups. In this study, the ratio of endocardial to epicardial blood flow was lower in the group treated with epinephrine, suggesting the presence of subendocardial ischemia.[50] However, studies of this kind are difficult to interpret because of the inability to measure the degree of α-receptor activation by the different vasopressors. The higher subendocardial blood flow in the phenylephrine group may have been the result of less α-receptor activation.[131-133] Moreover, some investigators have questioned the merits of using a pure α-adrenergic agonist during CPR. Although the inotropic and chronotropic effects of β-adrenergic agonists may have deleterious hemodynamic effects during CPR administered for VF, increases in both heart rate and contractility increase cardiac output when spontaneous coordinated ventricular contractions are achieved.

Cerebral blood flow during CPR, like coronary blood flow, depends on peripheral vasoconstriction and is enhanced by use of α-adrenergic agonists. This action produces selective vasoconstriction of noncerebral peripheral vessels to areas of the head and scalp without causing cerebral vasoconstriction.[50] As with myocardial blood flow, pure α-agonist agents are as effective as epinephrine in generating and sustaining cerebral blood flow during CPR in adult animal models[130] and in infant models (Figure 33-14).[50] No difference in neurologic deficits 24 hours after cardiac arrest was found between animals receiving either epinephrine or phenylephrine during CPR.[134]

Analogous to the heart, β-adrenergic agonists could increase cerebral oxygen uptake if a sufficient amount of drug crosses the blood-brain barrier during or after resuscitation. In addition, adrenergic agonists may vasoconstrict or dilate cerebral vessels, depending on the balance between α- and β-adrenergic receptors. Epinephrine and phenylephrine had similar effects on cerebral blood flow and metabolism, maintaining normal cerebral oxygen uptake for 20 minutes of CPR in dogs. This finding implies that cerebral blood flow was high enough to maintain adequate cerebral metabolism and that β-receptor stimulation did not increase cerebral oxygen uptake, despite the fact that the combined effects of brain ischemia and CPR can increase the permeability of the blood-brain barrier to drugs used during CPR or when enzymatic barriers to vasopressors (e.g., by monoamine oxidase) are overwhelmed during tissue hypoxia. Mechanical disruption of the barrier could occur during chest compressions by large fluctuations in cerebral venous and arterial pressures or as a result of hyperemia, the large increase in cerebral blood flow that occurs during the early reperfusion period when the cerebral vascular bed is maximally dilated following resuscitation, particularly if systemic hypertension occurs.[135] No blood-brain barrier permeability changes during CPR immediately after resuscitation or 4 hours after resuscitation were found in adult dogs.[135] However, after 8 minutes of cardiac arrest and 6 minutes of CPR in piglets, the blood-brain barrier was permeable to the small neutral amino acid α-aminoisobutyric acid 4 hours after cardiac arrest (Figure 33-15).[136] The increase in permeability could be prevented by prearrest administration of conjugated superoxide dismutase and catalase,[137] indicating a role of oxygen free radicals in the pathogenesis of this injury to the blood-brain barrier (Figure 33-16). These endothelial membrane changes frequently were associated with the

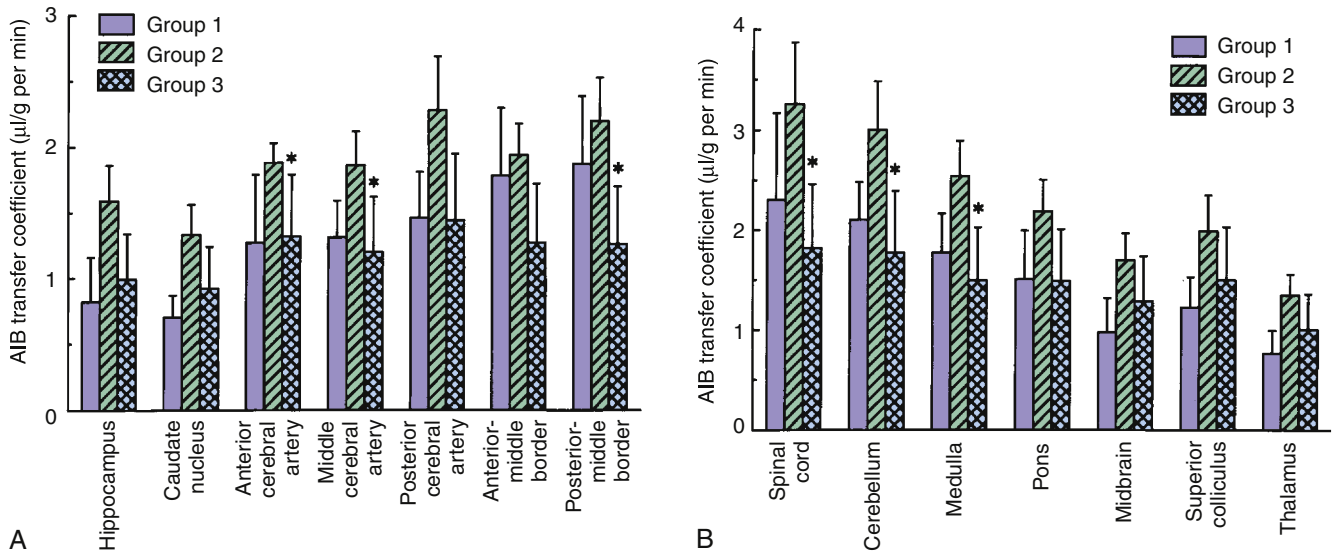

Figure 33–16. **A,** Bar graph showing transfer coefficient of α-aminoisobutyric acid (AIB) from plasma to brain in hippocampus, caudate nucleus, and primary supply and border regions of cerebral arteries in nonischemic time controls (group 1; n = 5), ischemia group treated with polyethylene glycol (PEG) (group 2; n = 8), and ischemia group treated with PEG-superoxide dismutase and PEG-catalase (group 3; n = 8). Error bars represent standard error of the mean (SEM). *$P < .05$ between groups 2 and 3 by Mann-Whitney U test. **B,** Transfer coefficient of AIB from plasma to brain in caudal brain regions in nonischemic time controls (group 1; n = 5), ischemia group treated with PEG (group 2; n = 8), and ischemia group treated with PEG-superoxide dismutase and PEG-catalase (group 3; n = 8). Error bars represent SEM. *$P < .05$ between groups 2 and 3 by Mann-Whitney U test. *(From Schleien CL, Eberle B, Schaffner DH, et al: Reduced blood-brain barrier permeability after cardiac arrest by conjugated superoxide dismutase and catalase in piglets,* Stroke *25:1830, 1994.)*

presence of intravascular polymorphonuclear and monocytic leukocytes.[138] Whether leukocytes disrupt the blood-brain barrier by release of toxic substances, such as oxygen free radicals or proteases, or appear in the postischemic microvessels as an epiphenomenon of a more important derangement is unknown (Figure 33-17).

Figure 33–17. Transmission electron micrograph of an infant piglet brain 4 hours after 8 minutes of cardiac arrest and 6 minutes of cardiopulmonary resuscitation (magnification ×5000). An intravascular leukocyte, which has the morphologic features of a monocyte, is adherent to the endothelial surface of a venule and appears to be occluding the lumen. The luminal surface of the endothelial cell contains membrane blebs and discontinuities. *(From Caceres MJ, Schleien CL, Kuluz JW, et al: Early endothelial damage and leukocyte accumulation in piglet brains following cardiac arrest,* Acta Neuropathol *90:582, 1995.)*

Vasopressin

The role of vasopressin as a noncatecholamine vasoconstrictor in the management of patients who experience cardiac arrest has received a great deal of interest. Work by Lindner in Europe and Landry in the United States during the past 2 decades has established sufficient evidence of efficacy for its use to be included in the 2010 AHA Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care.[39,112] Vasopressin can be used as an alternative to the first or second dose of epinephrine for refractory VF in adults, and according to the 2010 AHA Guideline, its evidence class is indeterminate[39]; it is also an option of indeterminate merit for children.[112] Increasing evidence indicates that vasopressin is a useful agent in the management of shock of multiple etiologies and therefore may have a role in postresuscitation management of the arrest victim.

Arginine vasopressin is a short peptide hormone secreted by the posterior pituitary gland in response to changes in tonicity and changes in effective intravascular volume, signaled primarily via baroreceptor unloading in the aorta. Severe shock is the most potent stimulus to vasopressin secretion. Serum levels twentyfold to 200-fold higher than normal may be found immediately after cardiac arrest, as well as in other severe shock states. Despite these observations, lower than expected vasopressin levels have been found in some patients with profound shock,[139-141] and patients dying of cardiac arrest have been found to have significantly lower vasopressin levels than do survivors.[142] The cause of lower than expected vasopressin levels in some patients is unclear. Observations in dogs suggest depletion of vasopressin stores as a potential mechanism. Dogs subjected to profound hemorrhagic shock have an early massive elevation of vasopressin levels immediately after the event, followed by a depression of levels below that expected within 1 hour of the insult. Severe depletion of vasopressin

stores from the posterior hypophysis was noted in these animals.[141] These animals developed a catecholamine-refractory vasodilatory shock that responded dramatically to low doses of vasopressin.[143] These observations have led to an exploration of the use of vasopressin in both cardiac arrest and shock states.

Vasopressin is an extremely potent vasoconstrictor. Its effects on vascular tone are primarily mediated through interaction with a specific G protein–coupled receptor referred to as the $V1_a$ receptor, which is distributed widely throughout vascular beds.[139] Of note, the $V1_a$ receptor is linked to the same second messenger system as the α-adrenergic receptor that mediates vasoconstriction through an alteration of intracellular calcium levels. However, in the pulmonary circulation, vasopressin activation of V1 receptors mediates the release of nitric oxide and causes pulmonary vasodilation. Vasopressin also interacts with its V_2 receptor, which regulates aquaporin expression on the renal collecting duct epithelium. Stimulation of the V_2 receptor occurs at substantially lower levels than those required to activate the $V1_a$ receptor.

Vasopressin use during resuscitation has been studied in animals and humans. In an adult porcine model of VF, vasopressin at a dose of 0.8 μg/kg was found to be superior to the maximally effective dose of epinephrine 200 μg/kg in restoring left ventricular myocardial blood flow, increasing diastolic CPP and total cerebral blood flow, as well as rates of ROSC. Moreover, the duration of the effect was sustained for 4 minutes compared with 1.5 minutes for epinephrine.[56,129] Adverse effects noted in the postresuscitation phase included decreased renal and adrenal blood flow and reduced cardiac output.[144,145]

In a pediatric porcine model of cardiac arrest,[146] vasopressin at a dose of 0.8 μg/kg was not as effective as epinephrine, 200 μg/kg, in restoring LV myocardial blood flow or achieving ROSC. Only 1 of 6 animals achieved ROSC compared with 6 of 6 in the epinephrine group. A combination group that received both epinephrine, 45 μg/kg, and vasopressin, 0.8 μg/kg, fared better (ROSC in 4 of 6 animals). Possible explanations for the difference between adult and juvenile animals include different dose-response curves for the two drugs, failure of maturation of vasopressin receptors, a different distribution of vasopressin receptors than seen in adults, or the different experimental model.

In an initial small randomized clinical trial of vasopressin compared with epinephrine for refractory VF, the rate of achieving ROSC was higher in the vasopressin group.[147] These findings led to the inclusion of vasopressin in the adult guidelines. A large multicenter randomized trial of vasopressin for cardiac arrest in adults has been reported.[148] More than 1200 patients were randomly assigned in the field to receive two doses of either 40 International Units of vasopressin or 1 mg of epinephrine followed by additional treatment with epinephrine, if necessary. Vasopressin was equivalent to epinephrine in achieving survival to both hospital admission and discharge in patients with either PEA or VF. In patients with asystole, vasopressin was superior to epinephrine in achieving both survival to admission and discharge, although intact neurologic outcome was not improved. In patients in whom ROSC was not achieved after two doses of medication, a third dose of medication such as epinephrine could be added at the resuscitating physician's discretion. In the group receiving a third dose of medication such as epinephrine, survival was greater in the vasopressin group. Subsequently, a meta-analysis of five randomized trials showed no significant differences between vasopressin and epinephrine for ROSC, 24-hour survival, or survival to hospital discharge, while a subgroup analysis of the initial cardiac rhythm showed no significant difference in survival to hospital discharge.[149] In a study of 200 patients with in-hospital cardiac arrest, patients were randomly assigned to receive either 1 mg of epinephrine or 40 Units of vasopressin. Again, no statistical difference in survival to 1 hour or to hospital discharge was found between groups or subgroups.[150] The results of these studies led to the classification of evidence for vasopressin for use in adults as indeterminate in the 2010 AHA guidelines.[39]

The published experience with vasopressin in children who experience cardiac arrest is limited. The first case series of vasopressin use in CPR reported the outcome of four children with six prolonged refractory cardiac arrests that were unresponsive to standard resuscitation efforts.[151] Each child received one or more bolus doses of vasopressin (0.4 μg/kg) as rescue therapy. In all children, the initial rhythm was a form of PEA that deteriorated to asystole in four of six events. Three children had ROSC for more than 60 minutes, including one child with asystole. Two children survived for more than 24 hours and one survived to hospital discharge. A second retrospective case series of pediatric cardiac arrests unresponsive to epinephrine found that ROSC was achieved in 6 of 8 episodes that were treated with terlipressin, a long-acting synthetic analog of vasopressin, at a dose of 15 to 20 μg/kg. Four of those patients survived without neurologic sequelae.[152] A review of a national registry of in-hospital CPR showed that patients who received vasopressin had a lower incidence of ROSC greater than 20 minutes (22 [34%] of 64) than patients who did not receive the medication (675 [55%] of 1229).[153] The association of poor outcome with vasopressin persisted even with multivariate analysis with logistic regression to attempt to control for other factors that might effect ROSC. The current evidence only examines the use of vasopressin as a potential alternative when standard therapies, such as epinephrine, fail to cause ROSC. Unfortunately, variables such as dosing, timing of vasopressin infusion, or pediatric risk of mortality scores have not been controlled for in these studies. No double-blinded, randomized controlled studies have been performed, and thus no firm recommendations are available concerning the use of vasopressin for CPR in infants and children.

The current recommended dose of vasopressin for adults in cardiac arrest is 40 International Units. No data comparing this dose to other doses are available, and concern exists regarding postresuscitation complications related to this dose. We have selected 0.5 μg/kg as the standard for cardiac arrest. Further data are needed before more definitive dosing recommendations can be made.

Use of vasopressin in postresuscitation management may be considered. A relative vasopressin deficiency has been noted in a number of shock states, including hemorrhage, sepsis, and post-CPB, as well as in patients who have unsuccessful resuscitations. In these settings, shock may be refractory to catecholamines (norepinephrine doses of 2 to 4 μg/kg). These patients may respond to a vasopressin infusion, allowing the weaning of high-dose catecholamines. Although a role in the postresuscitation setting has not been demonstrated based on the data related to refractory shock, consideration of the use of vasopressin for refractory hypotension may be appropriate.

High-Dose Epinephrine

The physiologic responses of animals and humans to higher doses of epinephrine include higher cerebral blood flow,[154,155] increased myocardial and submyocardial blood flow, improved oxygen delivery relative to oxygen consumption,[132,156-158] and less depletion of myocardial adenosine triphosphate (ATP) stores with more rapid repletion of phosphocreatine.[159] Contrary results, with increased myocardial oxygen consumption and decreased myocardial blood flow, have been demonstrated during CPR following VF cardiac arrest.[35,38] In a piglet model, high-dose epinephrine (HDE) produced lower myocardial blood flow than achieved with standard-dose epinephrine (SDE).[154] In neonatal lambs following asphyxia-induced bradycardia, HDE resulted in higher heart rate but a lower stroke volume and cardiac output.[160]

Studies regarding survival of patients who were given HDE have been contradictory. In out-of-hospital patients who experienced cardiac arrest, HDE produced higher aortic diastolic pressure during CPR and increased the rate of ROSC compared with standard doses of epinephrine. Gonzalez et al.[161,162] demonstrated a dose-dependent increase in aortic blood pressure by epinephrine in patients who failed to respond to prolonged resuscitative efforts. Paradis et al.[163] showed that HDE increased aortic diastolic pressure and improved the rate of successful resuscitation in patients in whom ACLS protocols had failed. This group also reported on a series of 20 children treated with HDE and compared them with 20 historic control subjects consisting of children with cardiac arrest treated with SDE.[164] They reported that 14 of the children in the HDE group had ROSC, eight survived to hospital discharge, and three were neurologically intact. There were no survivors in the SDE comparison group. Other centers have claimed that higher-than-standard doses of epinephrine during CPR in children improve the hemodynamics and increase the success of CPR; however, no one has provided any valid data that suggest that HDE improves survival beyond the immediate postresuscitation period.[83,163,165,166] Based on these studies, the 1992 AHA guidelines for pediatric advance life support recommended HDE if an initial SDE failed to resuscitate the child.

Three large multicenter studies subsequently were published that dampened enthusiasm for the use of HDE. Stiell et al.[167] studied 650 adult patients after cardiac arrests who were randomly assigned to receive either an SDE or HDE (7 mg) epinephrine protocol. No differences were observed between the groups with regard to 1-hour survival (23% vs. 18%), rate of hospital discharge (5% vs. 3%), or neurologic outcome. Brown et al.[168] reported on 1280 adult patients who received either SDE (0.02 mg/kg) or HDE (0.2 mg/kg) after cardiac arrest. Again, no differences in ROSC, short-term survival, survival to hospital discharge, or neurologic outcome were observed between the two groups of patients. In a study of 816 adults, Callaham et al.[169] reported a higher ROSC in the HDE group. However, there were no differences in the rate of hospital discharge or ultimate survival of these patients. In addition to these studies, a specific pediatric animal study was published that failed to demonstrate a clear survival benefit for HDE, although the occurrence of ROSC appeared to be greater.[38] The 2000 AHA guidelines changed the recommendation for HDE to an option for second and subsequent doses of epinephrine.

Most recently, a prospective, randomized, double-blind clinical trial of HDE in 68 pediatric inpatients was reported by Perondi et al.[9] ROSC for more than 20 minutes was achieved in 15 of 34 patients who received HDE but in only 8 of 34 patients who received SDE ($P = .07$). However, survival to 24 hours occurred in only two of the HDE group versus seven of the SDE group ($P = .05$). In the group that experienced an asphyxial arrest, none of 12 treated with HDE was alive at 24 hours, whereas seven of 18 patients in the SDE group survived. Four survived to hospital discharge, and two patients were neurologically normal.[9] This trial reinforces concerns that HDE may account for some of the adverse effects that occur after resuscitation[136,172] and is the basis of the 2010 AHA guidelines' recommendation against the use of HDE during CPR.[39] As discussed previously, epinephrine can worsen myocardial ischemic injury secondary to increased oxygen demand and result in tachyarrhythmias, hypertension, pulmonary edema, hypoxemia, and cardiac arrest.[136,173] Use of a β-adrenergic antagonist during or after ROSC has been suggested to attenuate the adverse effects of epinephrine.[65,96,174] Epinephrine causes hypoxemia and an increase in alveolar dead space ventilation by redistributing pulmonary blood flow.[175,176] In one study, HDE (>15 mg) given to adults during CPR resulted in a lower cardiac index, systemic oxygen consumption, and oxygen delivery immediately after resuscitation.[160] Prolonged peripheral vasoconstriction by excessive doses of epinephrine may delay or impair reperfusion of systemic organs, particularly the kidneys and gastrointestinal tract.

Atropine

Atropine, a parasympatholytic agent, acts by blocking cholinergic stimulation of the muscarinic receptors of the heart, which usually results in an increase in the sinus rate and shortening of the atrioventricular node conduction time. Atropine may activate latent ectopic pacemakers. Atropine has little effect on systemic vascular resistance, myocardial perfusion pressure, or contractility.[177]

Atropine is indicated for treatment of asystole, PEA, bradycardia associated with hypotension, second- and third-degree heart block, and slow idioventricular rhythms. In children who present in cardiac arrest, sinus bradycardia and asystole are the most common initial rhythms, which makes atropine useful as a first-line drug. Atropine is particularly effective in clinical conditions associated with excessive parasympathetic tone.

The recommended dose of atropine is 0.02 mg/kg, with a minimum dose of 0.15 mg and a maximum dose of 2.0 mg. Smaller doses than 0.15 mg, even in small infants, may result paradoxically in bradycardia because of a central stimulatory effect on the medullary vagal nuclei by a dose that is too low to provide anticholinergic effects on the heart. Atropine may be given by any route, including intravenous, endotracheal, intraosseous, intramuscular, and subcutaneous. Its onset of action occurs within 30 seconds, and its peak effect occurs between 1 and 2 minutes after an intravenous dose. The recommended adult dose is 0.5 mg every 5 minutes until the desired heart rate is obtained up to a maximum of 2 mg. For asystole, 1 mg is given intravenously and repeated every 5 minutes if asystole persists. Full vagal blockade usually is obtained with a dose of 2 mg in adults.

Because of its parasympatholytic effects, atropine should not be used in patients in whom tachycardia is undesirable. In patients after myocardial infarction or ischemia with persistent bradycardia, atropine should be used in the lowest dose possible to increase heart rate. Using the lowest possible dose will limit tachycardia, a potent contributor to increased myocardial oxygen consumption, which could lead to VF. In addition, atropine should not be used in patients with pulmonary or systemic outflow tract obstruction or idiopathic hypertrophic subaortic stenosis because tachycardia decreases ventricular filling and lowers cardiac output in this setting.

Sodium Bicarbonate

The administration of sodium bicarbonate results in an acid-base reaction in which bicarbonate combines with hydrogen to form carbonic acid, which dissociates into water and carbon dioxide. Because of the generation of carbon dioxide, adequate alveolar ventilation must be present to achieve the normal buffering action of bicarbonate. Use of sodium bicarbonate during CPR remains controversial because of its potential adverse effects and the lack of evidence showing any benefit from its use during CPR.[178,179]

Sodium bicarbonate is indicated for correction of significant metabolic acidosis, especially when signs of cardiovascular compromise are present. Acidosis itself may have a number of negative effects on the circulation, including depression of myocardial function by prolonging diastolic depolarization, depressing spontaneous cardiac activity, decreasing the electrical threshold for VF, decreasing the inotropic state of the myocardium, and reducing the cardiac response to catecholamines. Acidosis also decreases systemic vascular resistance and attenuates the vasoconstrictive response of peripheral vessels to catecholamines. This effect is contrary to the desired effect during CPR. In addition, particularly in patients with a reactive pulmonary vascular bed, pulmonary vascular resistance is inversely related to pH. Rudolph and Yuan[180] observed a twofold increase in pulmonary vascular resistance in calves when pH was lowered from 7.4 to 7.2 under normoxic conditions. Therefore correction of even mild acidosis may be helpful in resuscitating patients who have the potential for increased right-to-left shunting through a cardiac septal defect, patent ductus arteriosus, or aortic-to-pulmonary shunt during periods of elevated pulmonary vascular resistance.

Multiple adverse effects of bicarbonate administration include metabolic alkalosis, hypercapnia, hypernatremia, and hyperosmolality. All of these adverse effects are associated with a high mortality rate. Alkalosis causes a leftward shift of the oxyhemoglobin dissociation curve, thus impairing release of oxygen from hemoglobin to tissues at a time when oxygen delivery already may be low. Alkalosis can result in hypokalemia, by enhancing potassium influx into cells, and ionic hypocalcemia, by increasing protein binding of ionized calcium. Hypernatremia and hyperosmolality may decrease tissue perfusion by increasing interstitial edema in microvascular beds. The marked hypercapnic acidosis that occurs during CPR on the venous side of the circulation, including the coronary sinus, may be worsened by administration of bicarbonate.[181,182] Myocardial acidosis during cardiac arrest is associated with decreased myocardial contractility. The mean venoarterial P_{CO_2} difference was 24 ± 15 mm Hg in five patients during CPR and actually increased from 16 to 69 mm Hg in one patient after administration of bicarbonate.[183] Another group showed a mean difference of 42 mm Hg between partial pressure of carbon dioxide in mixed venous blood (P_{vCO_2}) and P_{aCO_2} during CPR. Paradoxical intracellular acidosis after bicarbonate administration is possible because of rapid entry of carbon dioxide into cells with a slow egress of hydrogen ion out of cells. Paradoxical intracellular acidosis in the central nervous system after bicarbonate administration has been proposed but not definitively shown. In neonatal rabbits recovering from hypoxic acidosis, bicarbonate administration increased both arterial pH and intracellular brain pH as measured by nuclear magnetic resonance spectroscopy.[184] In another study, intracellular brain ATP concentration in rats did not change during severe intracellular acidosis in the brain produced by extreme hypercapnia.[185] The rats who maintained ATP concentration even in the face of severe brain acidosis had no functional or histologic differences from normal control subjects. Using nuclear magnetic resonance spectroscopy of the brain in dogs during cardiac arrest and CPR, intracellular brain pH decreased to 6.29 with total depletion of brain ATP after 6 minutes of cardiac arrest. However, following effective CPR, ATP levels rose to 86% of prearrest levels and to normal by 35 minutes of CPR despite ongoing peripheral arterial acidosis (Figure 33-18).[100] However, cerebral pH decreased in parallel with blood pH when CPR was started immediately after arrest. Bicarbonate administration ameliorated and did not worsen the cerebral acidosis, indicating that the blood-brain pH gradient is maintained during CPR.[186]

The 2010 AHA guidelines state that sodium bicarbonate has not been shown to improve outcome during CPR and

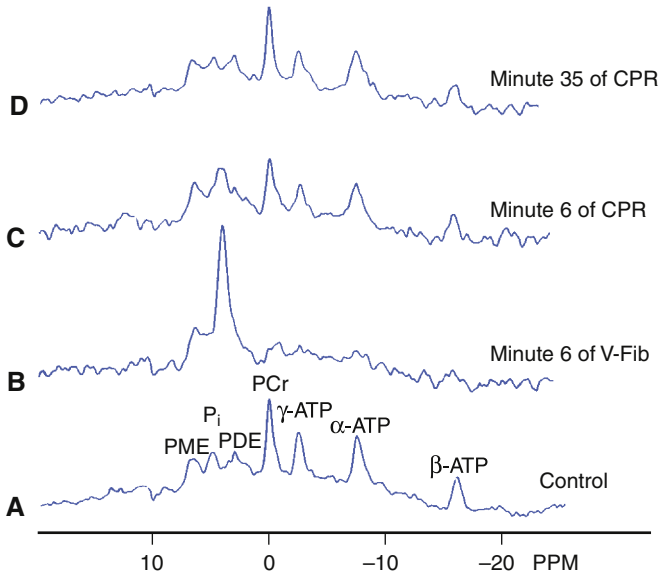

Figure 33–18. ^{31}P magnetic resonance spectroscopy spectra from in situ dog brain during vest cardiopulmonary resuscitation (CPR) after a 6-minute delay in the onset of CPR from time of arrest. Each spectrum was acquired in 1 minute. The frequency of the inorganic phosphate (P_i) peak is pH dependent. Note complete absence of adenosine triphosphate (ATP) and phosphocreatine (PCr), and pH_i = 6.28 in *trace B* after 6 minutes of ventricular fibrillation (v-fib) without CPR. After 6 minutes of CPR *(trace C),* ATP is more than 85% recovered, but pH is only 6.61. After 35 minutes of CPR *(trace D),* pH_i has returned to 7. *PDE,* phosphodiesters; *PME,* phosphomonoesters; *PPM,* parts per million. *(From Eleff SM, Schleien CL, Koehler RC et al: Brain bioenergetics during cardiopulmonary resuscitation in dogs,* Anesthesiology *76:77, 1992.)*

only recommends its use in special situations, such as intoxications.[39] A Cochrane study looking at the use of empirical sodium bicarbonate administration versus placebo in out-of-hospital cardiac arrests in 874 adults found no difference in survival to the hospital.[188] Levy[189] reviewed more than 30 animal studies evaluating the efficacy of sodium bicarbonate administration during CPR. Among studies with survival as the primary outcome, four showed benefit and seven did not. When assessing myocardial performance, 12 studies concluded that sodium bicarbonate worsened performance, two studies showed no difference, and no study showed benefit. When reviewing 19 retrospective human adult studies examining mortality rates, eight of these suggested a deleterious effect of sodium bicarbonate, 11 showed no difference in outcomes, and none showed benefit.[189] When $Paco_2$ and pH are known, the dose of bicarbonate to correct the pH to 7.4 is calculated using the following equation:

$$\text{Sodium bicarbonate (mEq)} = 0.3 \times \text{Weight} \times \text{Base deficit}$$

(Because of its possible adverse effects and the large venous to arterial carbon dioxide gradient that develops during CPR, we recommend giving half the dose that would be given based on a volume of distribution of 0.6.) If blood gases are not available, the initial dose is 1 mEq/kg, followed by 0.5 mEq/kg every 10 minutes of ongoing arrest. Alveolar ventilation must be maintained because of the generation of carbon dioxide and can be assessed only by serial measurements of arterial blood gases and pH. Because of the potential adverse effects of bicarbonate, the indications for its use at this time are limited to cardiac arrest associated with hyperkalemia, patients with preexisting metabolic acidosis, and after approximately 10 minutes of CPR.

$EtCO_2$ monitoring is useful during CPR because it provides important information regarding both pulmonary and cardiac function. $EtCO_2$ is measured instantaneously in the exhaled gas of every breath. In the absence of lung disease, $EtCO_2$ correlates closely with $Paco_2$, provided pulmonary blood flow is at least 20% to 25% of normal. As a respiratory monitor, $EtCO_2$ analyzers accurately distinguish a tracheal ($EtCO_2$ >10) from an esophageal ($EtCO_2$ <5) intubation in infants and children.[190-192] Because measurements are made with every breath, dislodgment of the endotracheal tube from the trachea can be identified immediately. When cardiac output is extremely low, as occurs during ineffective CPR, delivery of carbon dioxide to the lungs is so limited that the total amount exchanged across the alveolar-capillary membrane is markedly reduced. In this situation, the measured $EtCO_2$ is very low even when $Paco_2$ is elevated. As cardiac output increases, $EtCO_2$ increases and the difference between end-tidal and arterial CO_2 becomes smaller.[193] $EtCO_2$ has been correlated with CPP,[193] the critical parameter for resuscitation of the heart. However, a low $EtCO_2$ may occur in the presence of adequate cardiac output during CPR after the administration of epinephrine because of its ability to increase intrapulmonary shunting.[175,194,195] In this case, a low $EtCO_2$ underestimates cardiac output. Other causes of low $EtCO_2$ include airway obstruction, tension pneumothorax, pericardial tamponade, pulmonary embolism, hypothermia, severe hypocapnia (which occurs commonly with overaggressive hand ventilation), and esophageal intubation.

Levine et al.[196] monitored $EtCO_2$ in 150 adults with an out-of-hospital cardiac arrest who had electrical activity but no pulse. They found that after 20 minutes of ACLS, an $EtCO_2$ level of 10 mm Hg successfully predicted survival to hospital admission with a sensitivity, specificity, and positive- and negative-predictive value of 100%. Grmec and Klemen[197] prospectively studied the initial, average, maximal, minimal, and final $EtCO_2$ as a prognostic indicator for outcomes in adult resuscitation. They found that using an initial, average, and final $EtCO_2$ level of 10 mm Hg identified 100% of patients who were successfully resuscitated, with specificity of 74%, 90%, and 81%, respectively.[197] The 2010 AHA guidelines state that while use of $EtCO_2$ as an indicator of cardiac output may be useful in adults (evidence class IIb),[39] currently no studies have evaluated the use of $EtCO_2$ in pediatric arrests. However, given the noninvasive nature of $EtCO_2$ monitoring and also extrapolating from adult data, maintaining an $EtCO_2$ of >10 to 15 mm Hg through the use of $EtCO_2$ monitoring is recommended during pediatric arrests.[112]

Other Alkalinizing Agents

A number of other alkalinizing agents have been used experimentally in animals and humans. However, none has demonstrated any real advantages over sodium bicarbonate. Carbicarb, a solution of equimolar amounts of sodium bicarbonate and sodium carbonate, corrects metabolic acidosis without many of the adverse effects of sodium bicarbonate.[63] The buffering action of sodium carbonate occurs by consumption of carbon dioxide with generation of bicarbonate ion, as illustrated in the following equation:

$$Na_2CO_3 + CO_2 + H_2O = 2\ HCO_3^- + 2Na^+$$

During CPR, Carbicarb administration resulted in a greater increase in arterial pH and smaller increases in $Paco_2$, lactate, and serum osmolality in animals.[63,198,199] However, Carbicarb was not superior to sodium bicarbonate when used for hypovolemic shock in rats.[200]

Dichloroacetate (DCA) increases the activity of pyruvate dehydrogenase, which facilitates the conversion of lactate to pyruvate.[201] When administered to patients with lactic acidosis, DCA decreased lactate concentration by half and increased bicarbonate concentration and pH.[202] In other studies, DCA improved cardiac output, possibly by increasing myocardial metabolism of lactate and carbohydrate.[203,204] In a multicenter trial of patients with lactic acidosis, DCA did not improve outcome when compared with sodium bicarbonate.[205]

Tromethamine (THAM; tris-hydroxymethyl-aminomethane) is an organic amine that combines with hydrogen ion, causing CO_2 and H_2O to combine to form bicarbonate and hydrogen ion. A dose of 3 mL/kg should raise the bicarbonate concentration by 3 mEq/L. Adverse effects of THAM include hyperkalemia, hypoglycemia, and acute hypocarbia resulting in apnea. In addition, peripheral vasodilation may occur after administration of THAM during CPR, which is an undesirable effect. THAM is contraindicated in patients with renal failure.

Calcium

Recommendations for use of calcium in CPR are restricted to a few specific situations, namely, hypocalcemia, hyperkalemia, hypermagnesemia, and calcium channel blocker overdose. These restrictions are based on the possibility that exogenously administered calcium may worsen ischemia/reperfusion

injury. Intracellular calcium overload occurs during cerebral ischemia by the influx of calcium through voltage- and agonist-dependent (e.g., *N*-methyl-D-aspartate) calcium channels. Calcium plays an important role in the process of cell death in many organs, possibly by activating intracellular enzymes such as nitric oxide synthase, phospholipase A and C, and others.[206,207] Calcium channel blockers improve blood flow and function after ischemia to the heart,[208] kidney,[209] and brain.[210] Calcium channel blockers also raise the threshold of the ischemic heart to VF.[211] For these reasons, it appears that the recommended restrictions for use of calcium during CPR are well founded. On the other hand, no studies have shown that elevation of plasma calcium concentration, which occurs after calcium administration, worsens outcome of cardiac arrest. Because the normal ratio of extracellular to intracellular calcium is on the order of 1000:1 to 10,000:1, it seems unlikely that the rate of influx of calcium into cells would be influenced by a relatively small increase in its extracellular concentration.

The calcium ion is essential in myocardial excitation-contraction coupling, in increasing ventricular contractility, and in enhancing ventricular automaticity during asystole. Ionized hypocalcemia is associated with decreased ventricular performance and peripheral blunting of the hemodynamic response to catecholamines.[212,213] In addition, severe ionized hypocalcemia has been documented in adults experiencing out-of-hospital cardiac arrest (mean Ca 0.67 mmol/L),[212] during sepsis,[214] and in animals during prolonged CPR.[215] Thus patients at risk for ionized hypocalcemia should be identified and treated as expeditiously as possible. Both total and ionized hypocalcemia may occur in patients with chronic or acute disease. Total body calcium depletion leading to total serum hypocalcemia occurs in patients with hypoparathyroidism, DiGeorge syndrome, renal failure, pancreatitis, and long-term use of loop diuretics. Ionized hypocalcemia occurs after massive or rapid transfusion of blood products, a result of citrate and other preservatives in stored blood products that bind calcium. The magnitude of hypocalcemia in this setting depends on the rate of blood administration, the total dose, and the hepatic and renal function of the patient. Administration of 2 mL/kg/min of citrated whole blood causes a significant decrease in ionized calcium concentration in anesthetized patients.

The pediatric dose of calcium chloride for resuscitation is 20 mg/kg. The adult dose is 200 mg (2 mL of the 10% solution). Calcium gluconate is as effective as calcium chloride in raising ionized calcium concentration during CPR. Calcium gluconate is given at a dose of 30 to 100 mg/kg, with a maximum dose of 2 g in pediatric patients. Calcium should be given slowly through a large-bore, free-flowing intravenous line, preferably a central venous line. Severe tissue necrosis occurs when calcium infiltrates into subcutaneous tissue. When administered too rapidly, calcium may cause bradycardia, heart block, or ventricular standstill.

Srinivasan et al.[216] reviewed 1477 consecutive pediatric cardiopulmonary events submitted to the National Registry of Cardiopulmonary Resuscitation and reported on the prevalence of calcium administration. Of the children in the registry, 659 were documented as receiving calcium. Calcium was more likely to be used in pediatric facilities, ICUs, and in the settings of cardiac surgery, CPR performed for more than 15 minutes, asystole, and concurrently with other advanced life support medications. After controlling for confounding factors (demographics, immediate precipitating causes, arrest rhythm, concurrent ACLS medications, and duration of CPR), calcium administration during CPR was independently associated with poor survival to discharge and unfavorable neurologic outcomes. They found that 21% of patients survived to hospital discharge when calcium was used, compared with 44% who survived when calcium was not used. Only 15% of patients had a favorable neurologic outcome when calcium was used, compared with 35% with a favorable outcome when calcium was not administered.[216]

Glucose

Administration of glucose during CPR should be restricted to patients with documented hypoglycemia because of the possible detrimental effects of hyperglycemia on the brain during or following ischemia. Myers[217] found that infant monkeys that received glucose before cardiac arrest were more likely to develop seizures, prolonged coma, and brain death with cerebral necrosis than were those that received saline solution. Siemkowicz and Hansen[218] confirmed this finding when they demonstrated that after 10 minutes of global brain ischemia, the neurologic recovery of hyperglycemic rats was worse than that of normoglycemic control subjects. The mechanism by which hyperglycemia exacerbates ischemic neurologic injury may be increased production of lactic acid in the brain by anaerobic metabolism. During ischemia under normoglycemic conditions, brain lactate concentration reaches a plateau. In a hyperglycemic milieu, however, brain lactate concentration continues to rise for the duration of the ischemic period. The severity of intracellular acidosis during ischemia is directly proportional to the preischemic glucose concentration.[219] The negative effect of hyperglycemia during brain ischemia is predicated on the presence of at least a small amount of blood flow to brain tissue. In one study, collaterally perfused but not end-arterial brain tissue had greater neuronal damage during hyperglycemic focal ischemia (Figure 33-19).[220]

Clinical studies show a direct correlation between the initial postcardiac arrest serum glucose concentration and poor neurologic outcome.[209,221] However, a higher glucose concentration may just be an endogenous response to severe stress and thus a marker and not the cause of more severe brain injury.[64] In piglets, postischemic administration of glucose did not worsen neurologic outcome after global hypoxia-ischemia.[222] However, given the likelihood of additional ischemic and hypoxic events in the postresuscitation period, it seems prudent to maintain serum glucose in the normal range. Administration of insulin to hyperglycemic rats after global brain ischemia improved neurologic outcome.[223] The effect of insulin may be independent of its ability to lower blood glucose, because these investigators later showed that normoglycemic insulin-treated rats had a better outcome than normoglycemic placebo-treated control subjects.[224]

Using intensive insulin therapy, Van den Bergh et al.[225,226] strictly controlled the blood glucose levels of adults in a surgical ICU, maintaining levels between 80 and 110 mg/dL. This control of blood glucose levels appeared to reduce mortality and protect the central and peripheral nervous systems. However, a subsequent study in a medical ICU showed no difference in mortality between the intensive insulin therapy and control groups.[227] Another study showed that the use of

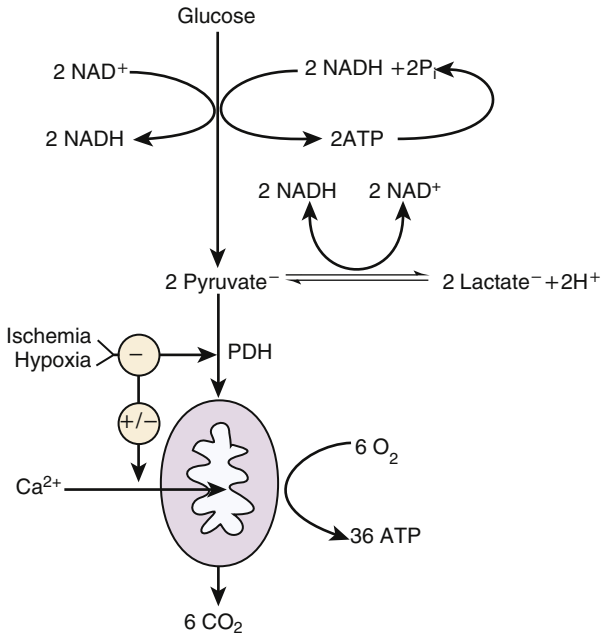

Figure 33–19. Schematic diagram illustrating the aerobic/anaerobic metabolism of glucose. Oxidation of pyruvate to CO_2 (and H_2O) by pyruvate dehydrogenase and citric acid cycle enzymes is retarded to blocked by oxygen deficiency, causing a reduction of pyruvate to lactate. If the adenosine triphosphate *(ATP)* formed during glycolysis is hydrolyzed (that is, if the ATP concentration stays constant), one molecule of H^+ is released for each molecule of lactate formed. If the mitochondria retain a membrane potential, they will sequester excess calcium entering the cell; however, if they deenergized (with collapse of their membrane potential), they will release their calcium content. *ADP,* Adenosine diphosphate; *NAD,* nicotinamide adenine dinucleotide; *NADH,* reduced nicotinamide adenine dinucleotide; P_i, intracellular phosphorus; *PDH,* pyruvate dehydrogenase.

intensive insulin therapy to maintain normoglycemia was associated with increased episodes of hypoglycemia.[228] Currently few pediatric data are available on the efficacy and safety of strict glucose control. Further study needs to be done to determine the blood glucose level at which to trigger intensive insulin therapy, as well as the optimal ranges at which to maintain blood glucose concentration.

Some groups of patients, including premature infants and debilitated patients with low endogenous glycogen stores, are more prone to the development of hypoglycemia during and after a physiologic stress (e.g., surgery).[229] Hypoglycemia poses a higher risk in the immature pediatric brain compared with the adult brain. Bedside monitoring of serum glucose is critical during and after a cardiac arrest and allows for intervention before the critical point of low substrate delivery is reached. The dose of glucose needed to correct hypoglycemia is 0.5 to 1.0 g/kg given as 10% dextrose in infants. The osmolarity of 50% dextrose is approximately 2700 Osm/L and is associated with intraventricular hemorrhage in neonates and infants.

Management of Ventricular Fibrillation

The management of lethal ventricular arrhythmias traditionally has not played a major role in resuscitation teaching or management for children because of the low incidence of these arrhythmias. Newer evidence gathered in the environment of rapid access defibrillation suggests that as many as 19% of the presenting rhythms in pediatric arrests are ventricular in origin, and represents as many as 5% to 15% of all pediatric victims of out-of-hospital cardiac arrest.[12,230] The incidence increases with age. Approximately 25% of children experiencing in-hospital cardiac arrest have ventricular tachycardia or fibrillation.[114] Moreover, the growing and aging population of children palliated for complex congenital heart disease in whom the occurrence of ventricular arrhythmias may be much higher than in the general pediatric population requires greater attention to ventricular arrhythmias than in the past. Other potential causes of ventricular arrhythmias include familial and acquired prolonged QT syndrome, other arrhythmogenic ventricular conditions,[231,232] cardiomyopathies, myocarditis, drug intoxications (such as illicit and accidental ingestion and therapeutic misadventures), electrolyte derangements (e.g., magnesium, calcium, potassium, or glucose), and hypothermia.

Advances have been made in the management of ventricular arrhythmias. Rapid access to defibrillation has been shown to reduce mortality in adults, and the development of public access defibrillation and AEDs has flowed from this knowledge. Initially AED devices had little utility for children, but the development of current-reducing electrodes and specific pediatric algorithms has made public access defibrillation a reality for children, and AEDs have been deployed in the many environments in which children would be the primary beneficiaries (e.g., schools and public swimming pools). When automated external defibrillators are used within 3 minutes of adult-witnessed ventricular fibrillation in children, long-term survival can occur in more than 70% of cases.[233,234] The technique of current delivery has undergone change with the development and deployment of biphasic defibrillators, which may offer increased efficacy with reduced risk of myocardial injury. Finally, amiodarone has started to replace lidocaine as the drug of choice for refractory ventricular arrhythmias and for atrial arrhythmias. The role of each of these factors in the resuscitation of pediatric arrest victims is discussed in the following section.

Defibrillation

VF is the chaotic electrical excitation of the ventricle, and the definitive treatment in accordance with the 2010 AHA guidelines is defibrillation.[39] The electrical mechanism is usually explained as a reentrant depolarization of the myocardium, initially in waves, that then take more circuitous routes and degenerate into smaller reentry circuits resulting in loss of the rhythmic contractile function of the ventricles.[235] This changing pattern of reentry circuits corresponds with the change from coarse to fine VF as the duration of fibrillation persists and may correlate with deterioration in energy stores associated with persistence of fibrillation.[236-238] Similarly, most cases of ventricular tachycardia are attributable to reentrant mechanisms, although increased automaticity is the likely mechanism in persons with drug-induced torsades de pointes and electrolyte disturbances such as hypokalemia and hypomagnesemia.[239] Nonpulsatile ventricular tachycardia with loss of effective contractile function of the heart rapidly deteriorates into VF. Loss of effective ventricular function with these arrhythmias requires emergent management.

The standard for management of VF and pulseless ventricular tachycardia is immediate defibrillation and high-quality CPR. Although the lowest energy dose for effective defibrillation and the upper limit for safe defibrillation in infants and children are not known, energy doses greater than 4 J/kg (up to 9 J/kg) have effectively defibrillated children.[112] The standard voltage dose for pediatric defibrillation is 2 J/kg. If unsuccessful, successive doses of defibrillation are repeated at 4 J/kg or more, not to exceed 10 J/kg or the maximum adult dose.[40] This dosage is based on data reported by Gutgesell et al.[240] in 1976. They reported 71 defibrillation attempts in 27 children. Efficacy was 91% with 2 J/kg and 100% with 4 J/kg. After initial defibrillation, CPR is performed for 2 minutes, followed by a rhythm check and then repeat shock if required. This sequence may then be repeated, with consideration given to initiate vasopressor therapy. Rhythms that fail to respond to three rounds are defined as "shock resistant." In this setting, the standard as defined in the AHA guidelines is amiodarone, 2 minutes, 5 mg/kg (or lidocaine, 2 minutes, if amiodarone is not available, or magnesium for torsades des pointes), followed by 2 minutes of CPR and continuation of the rhythm check-shock-CPR/vasopressor cycle (Figure 33-21). Reversible causes of VT/VF should also be investigated. Success in resuscitation is incumbent on immediate defibrillation with immediate CPR in between delivery of shocks.

It is important to continue to deliver appropriate CPR while gathering defibrillation equipment.[241,242] Additional important considerations when delivering shocks include paddle size, position, contact pressure, and use of electrode paste. Large paddles reduce thoracic impedance, and infants older than 1 year or weighing more than 10 kg should be treated with adult paddles.[243] Adhesive patch electrodes are an acceptable alternative to paddles[244-246] and can be used when available if their use does not cause a delay in therapy. Paddles should be positioned to achieve current flow through the heart, and an anterior-apex, or anterior-posterior placement is selected. Contact pressure has been demonstrated to reduce impedance. Firm pressure, which commonly is not properly applied, is required.[247] Proper electrode paste or gel is needed. Care is required to avoid smearing paste across the chest wall because doing so can lead to arcing of the circuit and a resultant short circuit. Bare paddles, ultrasound gel, pads soaked in saline solution, and alcohol pads are not acceptable alternatives to electrode cream or paste.[40]

The role of immediate defibrillation has come under question. The efficacy of defibrillation declines rapidly as fibrillation persists. When an arrest is witnessed and a defibrillator is immediately available, defibrillation likely will be successful. With any delay in resuscitation, the success of initial defibrillation declines at a rate estimated at between 7% and 10% per minute of continued fibrillation.[39] A number of studies have demonstrated in both animals and adults that if more than 3 to 5 minutes of fibrillation have occurred before institution of defibrillation, use of CPR for 90 to 180 seconds to restore myocardial energy stores will improve the likelihood of conversion to a perfusing rhythm with defibrillation.[2,4,248,249] Given the frequency of unwitnessed arrest in children and the relatively low frequency of ventricular arrhythmias, CPR first may be the appropriate response in children.

Use of biphasic defibrillators is another important advance in the management of tachyarrhythmias. Studies suggest that defibrillation with a biphasic waveform can be achieved with lower energy and less myocardial injury than with a standard monophasic defibrillator current.[250,251] The first commercially available devices were approved by the Food and Drug Administration in 1996. An evidence-based review was undertaken by the AHA and published in 1998.[252] The reviewers concluded that "low-energy, non-progressive biphasic waveform defibrillators may be used for both out-of-hospital and in-hospital VF arrest, including persistent or recurrent VF that does not respond to the initial low-energy shock." These conclusions were based on observational studies and case reports. Subsequently, Schneider et al.[253] reported a randomized controlled trial of biphasic versus monophasic defibrillation for out-of-hospital cardiac arrest. Of 338 arrests, 115 patients had VF and were shocked with an AED. Defibrillation in the initial shock series was successful in 98% of patients receiving biphasic shocks but in only 69% of those receiving monophasic shocks ($P < .0001$), providing further evidence that biphasic waveforms are more efficacious than monophasic waveforms (Figure 33-20).

Biphasic shocks appear to be at least as effective as monophasic shocks and less harmful. Published data on children are limited to case reports.[254] Animal data are supportive of the use of biphasic defibrillators in infants and children. Clark et al.[255] demonstrated in a piglet model that low-energy biphasic shocks were superior to monophasic shocks for converting catheter-induced VF. Both Tang et al.[256] and Berg et al.[236] studied the use of AEDs equipped with energy-reducing electrodes and found increased efficacy compared with monophasic waveforms. Berg et al. also demonstrated improved LV function 5 hours after resuscitation. Based primarily on adult data, these devices have come into widespread use in pediatric hospitals. According to the 2010 AHA recommendations, with a manual defibrillator, dosage recommendations for children remain 2 J/kg for the first attempt followed by 4 J/kg for subsequent attempts.[112,236,257]

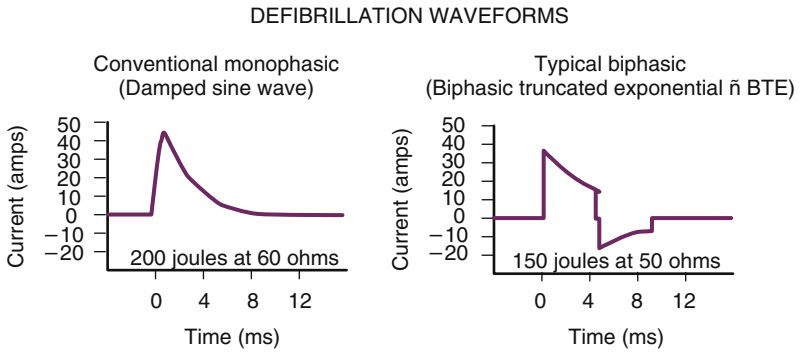

Figure 33–20. Schematic patterns of current flow for conventional monophasic and typical biphasic defibrillator waveforms.

In the early 1990s, as part of an AHA campaign to improve the abysmal rates of resuscitation from out-of-hospital cardiac arrest in adults, the development and deployment of AEDs was initiated. Both fixed and escalating dose devices were developed; however, the initial dose usually was at least 150 J in adults. Because of the high fixed energy doses, the devices were not recommended for use in children younger than 9 years. Moreover, use of these devices for young children was questioned because the arrhythmia detection algorithms used in these devices were developed for adults. Cecchin et al.[258] used the Agilent Herstream FR2 Patient Analysis System to analyze 696 five-second rhythms from 191 children younger than 12 years. Analysis revealed 100% accuracy for nonshockable rhythms and 96% accuracy for VF. This is similar to the accuracy reported for adults. In a more recent study, Atkinson et al.[239] tested the accuracy of the Lifepak 500 AED on 1561 fifteen-second rhythms from 203 children aged 1 day to 7 years. The device correctly identified 99% of coarse VF as shockable and 99.1% of nonshockable rhythms. A number of manufacturers (Zoll and Agilent) have developed energy-reducing electrodes that should allow use of these devices in young children.[239]

Since the 2000 AHA guidelines, data have shown that AEDs can be safely and effectively used in children of all ages. Current guidelines recommend use of an AED in children between the ages of 1 and 8 years who have no signs of circulation. The device should be adapted to deliver a pediatric dose with the use of a pediatric attenuator system that decreases the delivered energy to a dose suitable for children. When an attenuator system is not available, then the standard adult pads with corresponding dose should be delivered. In children younger than 1 year of age, a manual defibrillator is preferred; however, an AED with or without a pediatric attenuator may be used if necessary.[259]

Amiodarone

Amiodarone is an effective antiarrhythmic agent for both atrial and ventricular arrhythmias. The role of amiodarone in cardiac arrest was established after a series of studies demonstrated efficacy and superiority of amiodarone over lidocaine in the management of refractory VF and pulseless ventricular tachycardia in adults. Compared with lidocaine, amiodarone led to substantially higher rates of survival to hospital admission in patients with shock-resistant out-of-hospital VF.[260] These findings led to major changes in the AHA guidelines for management of ventricular arrhythmias (Table 33-1 and Figures 33-21 and 33-22).

Early reports on use of oral amiodarone in children were favorable.[261-263] Data on amiodarone use in children are limited to case reports and descriptive case series.[264-268] Nevertheless, it now is used widely for serious pediatric arrhythmias. It appears to be effective and have an acceptable short-term safety profile. In 2008, we examined the practice patterns of amiodarone use during in-hospital cardiac arrest. In this retrospective cohort study, it was noted that there has been a significant increase in amiodarone use for VF/ventricular tachycardia events during the past 5 years. It also was noted that the frequency of amiodarone use in adults correlated positively with the number of intensive care beds, suggesting that the emerging data and national guidelines affect resuscitation practice patterns.[269]

The growing pediatric experience among experts and inference from adult studies led to inclusion of amiodarone in the 2000 AHA pediatric advanced life support guidelines and continued in the 2010 AHA pediatric advanced life support guidelines as a drug of choice for pulseless ventricular tachycardia or VF, with class IIb level of evidence.[112] For hemodynamically stable ventricular tachycardia, it is also the drug of choice, with the level of evidence classified as IIb. Procainamide and lidocaine remain alternative drug choices. Amiodarone is commonly used for management of postoperative atrial and junctional ectopic tachycardia, especially in patients with ventricular pacing wires in place.

The wide range of effectiveness of amiodarone is demonstrated by the array of indications noted in the 2010 AHA guidelines for adults.[39] Its role in the management of atrial arrhythmias in adults includes the following: as an adjunct to electrical cardioversion of refractory paroxysmal

Table 33–1 Drug Therapy for Pulseless Arrest

Drug	Route of Administration	Dosage	How Applied
Epinephrine	IV, intraosseous, endotracheal	10 μg/kg	1:10,000 (0.1 mL/kg)
		100 μg/kg	1:1000 should be used for ETT
			(0.1 mL/kg)
Atropine	IV, intraosseous, endotracheal, subcutaneous	0.02 mg/kg (minimum dose = 0.15 mg)	
Sodium bicarbonate	IV, intraosseous	1 mEq/kg/dose	1 mEq/mL
		or	0.5 mEq/mL
		0.3 × weight (kg) × base deficit	
Calcium chloride	IV (intraosseous)	20 mg/kg	10% solution (100 mg/mL)
		0.2 mL/kg	
Lidocaine	IV (intraosseous), endotracheal	1 mg/kg	1%, 2%, 4% solution
Amiodarone	IV (intraosseous)	5 mg/kg	Dilute to 3 mg/mL
Magnesium	IV (intraosseous)	25–50 mg/kg for torsades des pointes or hypomagnesemia	50% solution

supraventricular tachycardia and atrial tachycardia, for rate control when digoxin has been ineffective, for pharmacologic conversion of atrial flutter, and for control of rapid ventricular response in preexcited atrial tachyarrhythmias. It is the drug of choice for junctional tachycardia with poor function. If function is preserved, amiodarone is an acceptable alternative to a β-blocker or calcium channel blocker. Its role in ventricular arrhythmias is outlined in Box 33-2.

The pharmacology of amiodarone is complex and may partially explain the wide range of efficacy. It is poorly absorbed orally and must be loaded intravenously in urgent situations. It is primarily classified as a Vaughn-Williams class III agent that blocks the ATP-sensitive outward potassium channels, causing prolongation of the action potential and refractory period. However, this effect requires intracellular accumulation. Upon intravenous loading, the antiarrhythmic effects primarily result from noncompetitive α- and β-adrenergic receptor blockade, calcium channel blockade, and effects on inward sodium current causing a decrease in anterograde conduction across the atrioventricular node and an increase in the effective atrioventricular refractory period. The full antiarrhythmic impact requires a loading period for up to 1 to 3 weeks to

achieve intracellular levels and full potassium channel blocking effects. Prolongation of the QT interval, an effect resulting from K-ATP channel blockade, is commonly described with amiodarone use; however, it does not manifest until several days into loading, underscoring its different effects during the acute period and after loading is accomplished. These effects are evident throughout all cardiac tissue, which may explain amiodarone's efficacy for so many arrhythmias, both atrial and ventricular. The α-adrenergic blockade leads to vasodilation, which may increase coronary blood flow.

Immediate hemodynamic effects of amiodarone are caused by the solubilizing agent Tween 80, which has both vasodilating and myocardial depressant effects.[270] Hypotension is commonly reported with intravenous administration and may limit the rate at which the drug can be given. The overall hemodynamic impact of intravenous administration depends on the balance of its effect on rate control, myocardial performance, and vasodilation. Cardiac output usually is unchanged or increases despite the decreased contractility because of both rate control and vasodilation. The effect on systemic vascular resistance and the limited impact on contractility make amiodarone the drug of choice for use in patients with impaired cardiac function.

The drug is highly lipid soluble, giving it a very large volume of distribution, which accounts for the need for loading over many days. Until all tissues are saturated, rapid redistribution out of the vascular compartment may lead to early recurrence of arrhythmias. Once tissue saturation has occurred, the half-life is estimated to be between 13 and 103 days.

Dosage recommendations for children are based on limited clinical studies and extrapolation of adult data. For life-threatening arrhythmias, the usual recommended dose is 5 mg/kg administered intravenously. This dose can be repeated if necessary to control the arrhythmia. Intravenous loading doses are followed by a continuous infusion of 10 to 20 mg/kg/day if there is a risk for arrhythmia recurrence. The ideal rate of bolus administration is unclear, but once diluted the drug is given by intravenous push in adults. The potential for profound vasodilation in children has led to concern by some pediatric intensivists and cardiologists, who recommend that amiodarone be given over 10 minutes as recommended in the package insert. This concern may not be valid in the pulseless arrest setting. Some delay always occurs with the current formulation of the intravenous drug because it must be diluted before it can be administered. Drug dilution should not delay

Box 33–2 Amiodarone (Intravenous)

- Intravenous amiodarone affects sodium, calcium channels, and α- and β-adrenergic blocking properties. The drug is useful for treatment of both atrial and ventricular arrhythmias.
- Amiodarone is also helpful for ventricular rate control of rapid atrial arrhythmias in patients with severely impaired LV function when digitalis has proved ineffective. Amiodarone is recommended after defibrillation and epinephrine in cardiac arrest with persistent VT or VF.
- Amiodarone is effective for control of hemodynamically stable VT, polymorphic VT, and wide-complex tachycardia of uncertain origin.
- Amiodarone is an adjunct to electrical cardioversion of refractory PSVTs, atrial tachycardia, and pharmacologic cardioversion of AF.
- Amiodarone can control rapid ventricular rate due to accessory pathway conduction in preexcited atrial arrhythmias.

administration of additional shocks. An average of five shocks are delivered to adults with refractory VF before amiodarone is administered. An alternative dosing regimen for children is administration of 1 mg/kg pushes every 5 minutes up to 5 mg/kg. This dose can be repeated up to 10 mg/kg if the arrhythmia is not controlled. Use of the small-aliquot bolus technique may be particularly appropriate for infants younger than 6 to 12 months.

Amiodarone administered intravenously leaches plasticizers, particularly DEHP, from polyvinyl chloride. This effect is enhanced at low infusion rates and at higher drug concentrations and may be minimized by frequent intermittent boluses. Whether these plasticizers have any significant toxicity at these doses is unknown, although evidence indicates testicular vacuolization in rodents. Additional caution is warranted in neonates because the solution contains benzyl alcohol, which is associated with metabolic acidosis and death in premature infants (gasping syndrome). Identification of the potential for these adverse events has led the manufacturer to issue a statement to health care professionals stating that use of intravenously administered amiodarone in pediatrics is not recommended. The AHA has responded with a reiteration of the recommendation for intravenous amiodarone use in the 2010 guidelines for emergency cardiac care. In the recommendation it concludes that practitioners should obtain expert consultation because complications may include bradycardia, heart block, and torsades de pointes ventricular tachycardia. Adverse reactions to amiodarone can be life-threatening. The drug prolongs the QT interval. In a series by Etheridge et al.,[265] 29 of 50 infants and children experienced mild-to-moderate prolongation of the QTc. In the series by Burri et al.,[264] "most" infants experienced prolongation. Although none of the pediatric case series described the development of drug-induced arrhythmias in patients, amiodarone-induced torsades de pointes has been described in case reports,[271] and, although less common than in adults, caution is warranted. Use of amiodarone should be avoided in combination with other drugs that prolong the QT interval. In addition, caution should be exercised in the setting of hypomagnesemia and other electrolyte abnormalities that predispose to torsades de pointes. Severe bradycardia and heart block have been described, especially in the postoperative period, and ventricular pacing wires are recommended in this setting.

The manufacturer of the intravenous preparation (Pfizer, New York) reports in the product literature a series of 61 children receiving amiodarone, of whom 36% had hypotension, 20% had bradycardia, and 15% had atrioventricular block. These complications were severe or life-threatening in some cases. In the published case series of children, the incidence of adverse effects appears to be much lower. In a series reported by Etheridge et al.,[265] two of six patients who received intravenously administered amiodarone experienced hypotension. In several other series, the incidence of hypotension ranged from zero of 15 to four of 40.[264,266,268] All patients who were believed to require treatment responded to a saline solution infusion or calcium. One patient with symptomatic bradycardia responded to temporary pacing. Two other patients required a reduction in the rate of drug infusion for mild bradycardia.

Noncardiac adverse effects are often seen, especially with chronic dosing.[272] The most serious adverse effect is the development of interstitial pneumonitis, seen most often in patients with preexisting lung disease.[273] The incidence in children is unknown. Rarely an acute respiratory distress syndrome–like illness has been reported in both infants and adults at the initiation of treatment.[274,275] The lung disease may remit with early discontinuation of the drug. Thyroid disorders may occur with chronic use. Desethylamidarone, the major metabolite of amiodarone, appears to have an antithyroid effect by noncompetitive binding to the nuclear receptors. Both hyperthyroidism with thyrotoxicosis and hypothyroidism have occurred. This may be of particular concern in the management of fetal tachycardias. Although amiodarone appears to be effective in controlling refractory life-threatening fetal tachycardias, evidence of fetal hypothyroidism was present in 19% of neonates based on cord blood thyroid-stimulating hormone.[276] Other forms of toxicity include hepatotoxicity that may progress to cirrhosis, photosensitivity and skin discoloration, and local inflammation and cellulitis at the infusion site. Injection site reactions occurred in five of 20 patients who received amiodarone through a peripheral intravenous line. Corneal opacities are a common finding with chronic therapy but apparently do not affect vision.

Postresuscitation Care

Hemodynamic instability is common after cardiac arrest. A persistently low cardiac index may lead to multiorgan failure and is associated with early death within the first 24 hours after arrest.[277,278] Therapies to address low cardiac output states have included the use of inodilators. Inodilators (inamrinone and milrinone) augment cardiac output with little effect on myocardial oxygen demand. An inodilator can be used to treat myocardial dysfunction with increased systemic or pulmonary vascular resistance.[279,280] Administration of fluids may be required because of the vasodilatory effects.

Inodilators have a long half-life with a long delay in reaching a new steady-state hemodynamic effect after changing the infusion rate (18 hours with inamrinone and 4.5 hours with milrinone). In case of toxicity, adverse effects may persist for several hours after the infusion is discontinued.

Amelioration of neurologic injury after cardiac arrest has been a goal of many investigators over the past decades (Box 33-3). With the completion of two multicenter trials on mild hypothermia after cardiac arrest, one from Europe and the other from Australia, this goal appears to have been partially realized. In both studies, adult patients presenting with out-of-hospital VF who were resuscitated underwent rapid cooling to a target temperature between 32.8° C and 34.8° C. This temperature was maintained for 12 to 24 hours. Both neurologic outcome and mortality were improved compared with the control groups. The odds ratio for improved neurologic outcome were 1.4 in the European study, which included 275 patients, and 5.25 in the Australian study, which included 77 randomized patients. The hypothermia groups had lower mean blood pressure, required more frequent use of epinephrine, and had higher systemic vascular resistance. Although these studies have a limited target population, data from animal studies[281] and other smaller case series[282] suggest that therapeutic hypothermia is a useful tool after cardiac arrest from all causes and its use appears warranted, especially because the incidence of serious attributable complications is low. Fink et al.[283] studied the feasibility of achieving mild hypothermia after pediatric arrest and found that they were reliably able to achieve a target temperature of 32°C to 34°C in less than 3 hours. A multi-institutional randomized controlled trial of systemic hypothermia for 48 hours after nontraumatic cardiac arrest (Therapeutic Hypothermia After Pediatric Cardiac Arrest [THAPCA-]) is now underway.

Future Directions

Despite the aforementioned therapeutic advances, continued efforts to clarify their applicability to infants and children is vital. Clinical trials have been hampered by the federal regulation know as the "final rule" for resuscitation research.[284] In 1996, as part of a broad-ranging effort to protect patients rights as human subjects, the standard of community consent for research that required immediate intervention was developed. Since that time, resuscitation research in both adults and children has been limited, with most trials conducted in Europe, Australia, and other countries, often with U.S. collaborators. The feasibility of defining a community standard to perform a hypothetical trial of hypothermia after postcardiac arrest in children was tested in 2004.[285] The relevant community was defined as hospital staff and the parents of ICU patients and parents of previously resuscitated children. They concluded that development of a study using an exemption from informed consent was feasible. However, in an accompanying editorial, Moler[284] reiterates that, despite feasibility, practicality is very different as evidenced by the complete lack of pediatric resuscitation trials since 1996. Whether revision of this rule will occur or techniques for acquiring community consent can be developed remains one of the major hurdles to future pediatric resuscitation research.

Chapter 34

Performance of Cardiopulmonary Resuscitation in Infants and Children

Robert M. Sutton, Robert A. Berg, and Vinay Nadkarni

PEARLS

- The four distinct phases of cardiac arrest and cardiopulmonary resuscitation (CPR) are:
  1. Prearrest
  2. No flow (untreated cardiac arrest)
  3. Low flow (CPR)
  4. Postresuscitation
- The most common precipitating event for cardiac arrests in children is respiratory insufficiency; adequate ventilation and oxygenation remain the first priority.
- High-quality CPR (i.e., push hard, push fast, allow full chest recoil, minimize interruptions, and don't overventilate) can improve cardiac arrest outcomes.
- Automated real-time corrective feedback devices improve CPR quality and short-term survival outcomes.
- Strategically focused therapies to specific phases of cardiac arrest and resuscitation can lead to more successful resuscitation in children.

Pediatric cardiac arrest is not a rare event. Approximately 16,000 American children (8-20/100,000 children/year) experience cardiopulmonary arrest each year.[1-5] Approximately half of these cardiac arrests occur in-hospital, and about half outside the hospital.[5,6] In times past, survival outcomes were not good and many children had severe neurological injury after their arrest event. With advances in resuscitation science and implementation techniques, survival from pediatric cardiac arrest has improved substantially over the past 25 years.[7] This chapter focuses on pediatric cardiac arrest, cardiopulmonary resuscitation (CPR), and other therapeutic interventions that have been specifically designed to improve outcomes from pediatric cardiac arrest.

Four Phases of Cardiac Arrest

The four distinct phases of cardiac arrest and CPR interventions are (1) prearrest, (2) no flow (untreated cardiac arrest), (3) low flow (CPR), and (4) postresuscitation. Interventions to improve the outcome of pediatric cardiac arrest should optimize therapies targeted to the time and phase of CPR, as suggested in Table 34-1.

Prearrest

The prearrest phase refers to relevant preexisting conditions of the child (e.g., neurologic, cardiac, respiratory, or metabolic problems) and precipitating events (e.g., respiratory failure or shock). It is known that pediatric patients who suffer an in-hospital cardiac arrest often have changes in their physiological status in the hours leading up to their arrest event.[8,9] Therefore, interventions during the prearrest phase focus on preventing the cardiac arrest, with special attention to early recognition and treatment of respiratory failure and shock. Rapid-response teams or medical emergency teams (METs) are in-hospital emergency teams designed specifically for this purpose. These teams respond to patients on general inpatient units who are at high risk of clinical decompensation and transfer these children to more acute care areas, with the goal to prevent progression to full cardiac arrest. Implementation of pediatric METs has been moderately successful; decreased cardiac arrest frequency and mortality have been demonstrated.[10-12] While METs cannot identify all children at risk for cardiac arrest, it seems reasonable to assume that transferring critically ill children to an intensive care unit (ICU) early in their disease process for better monitoring and more aggressive interventions can improve resuscitative care and clinical outcome.

No Flow/Low Flow

In order to improve outcomes from pediatric cardiac arrest, it is imperative to shorten the no-flow phase of untreated cardiac arrest. To that end, it is important to monitor high-risk patients to allow early recognition of the cardiac arrest and prompt initiation of basic and advanced life support. Effective CPR optimizes coronary perfusion pressure and cardiac output to critical organs to support vital organ viability during the low-flow phase. Important tenets of basic life support are push hard, push fast, allow full chest recoil between compressions,

Table 34–1 Phases of Cardiac Arrest and Targeted Interventions

Phase	Interventions
Prearrest phase: *Protect*	• Optimize community education regarding child safety • Optimize patient monitoring • Prioritize interventions to prevent progression to cardiac arrest • Early recognition and activation of medical emergency response teams
Arrest (no-flow): *Preserve*	• Minimize interval to BLS and ACLS phase • Organized 911/code blue response system • Preserve cardiac and cerebral substrate • Minimize interval to defibrillation, when indicated
Low-flow (CPR): *Resuscitate*	• Effective CPR to optimize myocardial blood flow and cardiac output • Avoid overventilation • Consider adjuncts to improve vital organ perfusion during CPR • Match oxygen delivery to oxygen demand • Consider extracorporeal CPR if standard CPR/ALS are not promptly successful
Postresuscitation: *Regenerate* Short-term	• Optimize cardiac output and cerebral perfusion • Treat arrhythmias, if indicated • Prevent hyper/hypoglycemia, hyperthermia • Consider mild resuscitative systemic hypothermia
Long-term	• Early intervention with occupational and physical therapy • Bioengineering and technology interface rehabilitation • Possible future role for stem cell transplantation

and minimize interruptions of chest compression. Achieving optimal coronary perfusion pressure, exhaled carbon dioxide concentration, and cardiac output during the low-flow phase of CPR is consistently associated with an improved chance for return of spontaneous circulation (ROSC) and improved short and long term outcome in both animal and human studies.[13-20] For ventricular fibrillation (VF) and pulseless ventricular tachycardia (VT), rapid detection and prompt defibrillation are vital for successful resuscitation. For cardiac arrests resulting from asphyxia and/or ischemia, provision of adequate myocardial perfusion and myocardial oxygen delivery are most important.

Postresuscitation

The postresuscitation phase includes management of the immediate postresuscitation stage, the next few hours to days, and long-term rehabilitation. The immediate postresuscitation stage is a high-risk period for ventricular arrhythmias and other reperfusion injuries. Interventions during the immediate postresuscitation stage and the next few days include adequate tissue oxygen delivery, treatment of postresuscitation myocardial dysfunction, and minimizing postresuscitation tissue injury (e.g., preventing postresuscitation hyperthermia, hyperglycemia/hypoglycemia and, perhaps, providing postresuscitation hypothermia). This postarrest phase may have the greatest potential for innovative advances in the understanding of cell injury and death, inflammation, apoptosis, and hibernation, ultimately leading to novel interventions. The rehabilitation stage concentrates on salvage of injured cells, recruitment of hibernating cells, and reengineering of reflex and voluntary communications of these cell and organ systems to improve functional outcome.

The specific phase of resuscitation dictates the focus of care. Interventions that improve outcome during one phase may be deleterious during another. For instance, intense vasoconstriction during the low-flow phase of cardiac arrest improves coronary perfusion pressure and the probability of ROSC. The same intense vasoconstriction during the postresuscitation phase increases left ventricular afterload and may worsen myocardial strain and dysfunction. Current understanding of the physiology of cardiac arrest and recovery allows us to only crudely manipulate blood pressure, oxygen delivery and consumption, body temperature, and other physiologic parameters in our attempts to optimize outcome. Future strategies likely will take advantage of increasing knowledge of cellular inflammation, thrombosis, reperfusion, mediator cascades, cellular markers of injury and recovery, and transplantation technology.

An overview of some of the pathophysiologic pathways perturbed by cardiac arrest and resuscitation, along with potential avenues for intervention, is shown in Figure 34-1.

Epidemiology of Pediatric Cardiac Arrest

Cardiovascular disease remains the most common cause of disease-related death in the United States, resulting in approximately 1 million deaths per year.[21] It is estimated that more than 400,000 Americans will have a cardiac arrest each year, nearly 90% in prehospital settings. While data regarding the incidence of childhood cardiopulmonary arrest are less robust, the best data suggest that about 16,000 American children suffer a cardiac arrest each year (annual incidence: 8 to 20 per 100,000 children per year).[1-5,22] For in-hospital arrests specifically, it is estimated that approximately 2% to 6% of all children admitted to pediatric intensive care units,[1,2,23] and 4% to 6% of children admitted to cardiac units will suffer a cardiac arrest.[24,25] In short, pediatric cardiac arrest is an important public health problem.

Outcomes from pediatric cardiac arrest have improved significantly over the past 20 years (Table 34-2). Nearly two thirds of children who have an in-hospital cardiac arrest are successfully resuscitated initially (i.e., attain sustained ROSC). Moreover, more than 25% of them will survive to hospital discharge, and many (nearly 75%) will have good neurologic function.[1-4,7,25-37] Factors that influence outcome from pediatric cardiac arrest include (1) the preexisting condition of the child, (2) the initial electrocardiographic (ECG) rhythm detected, (3) the duration of no-flow time (the time during an arrest without spontaneous circulation or provision of CPR), and (4) the quality of the life-supporting therapies provided during the resuscitation. With this knowledge, it is no surprise then that out-of-hospital pediatric arrests have worse outcomes compared to in-hospital arrests.[3,22,23,30,35,38-44] As many of these out-of-hospital events are not witnessed and bystander CPR is not common (less than 30% of children receive bystander CPR),[3] the duration of no-flow time can be

Many complex interconnections and feedback loops among these processes are omitted from the schematic in order to generate an overview of the processes and potential interventions. *a,* Excellent chest compressions with or without adjunctive devices; *b,* inotropes/vasoconstrictors; *c,* intra-/postresuscitative mild hypothermia; *d,* avoidance of superoxia; *e,* free radical scavengers; *f,* modulation of neurotransmitters; *g,* nitric oxide (NO) synthase inhibitors; *h,* strict avoidance of hyperthermia (fever); *i,* heparin/thombolytics; *j,* steroids; *k,* head at midline and 45 degrees elevated; *l,* consider extracorporeal membrane oxygenation; *m,* optimize oxygen-carrying capacity; *n,* decrease oxygen demand (sedation, neuromuscular blockade, mild hypothermia); *o,* mannitol.

prolonged. As a result, less than 10% of these children survive their initial event, and in those that do survive, neurological injury is common. These findings are especially troublesome given that bystander CPR more than doubles patient survival rates.[45]

Compared to adults, superior survival rates are documented after pediatric cardiac arrest, specifically after in-hospital events; 27% of children survive to hospital discharge compared with only 17% of adults.[7] These findings may be in part due to differences in the initial ECG rhythm detected. While pediatric arrests are less commonly caused by arrythmias, such as ventricular tachycardia or ventricular fibrillation—10% of pediatric arrests versus 25% of adult arrests—the superior pediatric survival rate reflects a substantially higher survival rate among children with asystole or pulseless electrical activity compared with adults (24% vs. 11%). Moreover, the higher survival rate seen in children is mostly attributable to a much better survival rate among infants and preschool age children compared with older children.[26] Although this is speculative, the higher survival rates in children may be due to improved coronary and cerebral blood flow during CPR because of increased chest compliance in these younger arrest victims.[46,47]

Interventions During the Low-Flow Phase: Cardiopulmonary Resuscitation

Airway and Breathing

During the low-flow state of CPR, cardiac output and pulmonary blood flow are approximately 25% of that during normal sinus rhythm; therefore, much less ventilation is necessary for adequate gas exchange from the blood traversing the pulmonary circulation. Moreover, animal and adult data indicate

that a rapid rate of assisted ventilation ("overventilation" from exuberant rescue breathing) during CPR is common and can substantially compromise venous return and cardiac output by increasing intrathoracic pressure.[48-50] Moreover, these detrimental hemodynamic effects are compounded when one considers the effect of interruptions in CPR to provide airway management and rescue breathing.[51-55] While overventilation is problematic, in light of the fact that most pediatric arrests are asphyxial in nature, provision of *adequate* ventilation is still important. The difference between arrythmogenic and asphyxial arrests lies in the physiology. In animal models of sudden VF cardiac arrest, acceptable PaO_2 and $PaCO_2$ persist for 4 to 8 minutes during chest compressions without rescue breathing.[56] This is in part because aortic oxygen and carbon dioxide concentrations at the onset of the arrest do not vary much from the prearrest state. As a result, the lungs act as a reservoir of oxygen during CPR, and adequate oxygenation and ventilation can continue without rescue breathing. However, during asphyxial arrest, blood continues to flow to tissues in the prearrest state, resulting in significant arterial and venous oxygen desaturation, elevated lactate levels, and depletion of the pulmonary oxygen reserve. Therefore, at the onset of resuscitation, there is substantial arterial hypoxemia and acidemia. In this circumstance, rescue breathing with controlled ventilation can be lifesaving. In contrast, the adverse hemodynamic effects from overventilation during CPR combined with the interruptions in chest compressions to open the airway and deliver rescue breathing are a lethal combination in certain circumstances such as VT/VF arrests. In short, the resuscitation technique should be titrated to the physiology of the patient to optimize patient outcome.

Circulation

Optimizing Blood Flow During Low-Flow Cardiopulmonary Resuscitation: Push Hard, Push Fast

When the heart arrests and no blood flows to the aorta, coronary blood flow ceases immediately.[57] At that point, provision of high-quality CPR (push hard, push fast) is necessary to reestablish flow. The goal during CPR is to maximize the myocardial perfusion pressure (MPP). Related by the following equation:

$$\text{MPP} = \text{Aortic diastolic blood pressure (AoDP)} - \text{Right atrial pressure (RAP)}$$

myocardial blood flow improves as the gradient between AoDP and RAP increases. During downward compression phase, aortic pressure rises at the same time as right atrial pressure with little change in the MPP. However, during the

decompression phase of chest compressions, the right atrial pressure falls faster and lower than the aortic pressure, which generates a pressure gradient perfusing the heart with oxygenated blood during this artificial period of "diastole." Several animal and human studies have demonstrated in both VT/VF and asphyxial models the importance of establishing MPP as a predictor for short term survival outcome (ROSC).[19,58-61]

Based on the equation above, MPP can be improved by strategies that increase the pressure gradient between the aorta and the right atrium. As an example, the inspiratory impedance threshold device (ITD) is a small, disposable valve that can be connected directly to the tracheal tube or face mask to augment negative intrathoracic pressure during the inspiratory phase of spontaneous breathing and the decompression phase of CPR by impeding airflow into the lungs. Application in animal and adult human trials of CPR has established the ability of the ITD to improve vital organ perfusion pressures and myocardial blood flow[51,62-65]; however, in the only randomized trial during adult CPR, mortality benefit was limited to the subgroup of patients with pulseless electrical activity.[66] Additional evidence that augmentation of negative intrathoracic pressure can improve perfusion pressures during CPR comes from the active compression-decompression device (ACD). The ACD is a handheld device that is fixed to the anterior chest of the victim by means of suction—think household plunger—that can be used to apply active decompression forces during the release phase, thereby creating a vacuum within the thorax. By actively pulling during the decompression phase, blood is drawn back into the heart by the negative pressure.[67] Animal and adult studies have demonstrated that the combination of ACD with ITD acts in concert to further improve perfusion pressures during CPR compared to ACD alone.[63] In the end, while novel interventions such as the ITD and ACD are promising to improve blood flow during CPR, the basic tenants of "push hard, push fast, minimize interruptions, and don't overventilate" are still the dominate factors to improve blood flow during CPR and chance of survival.

Chest Compression Depth

The pediatric chest compression depth recommendation of at least one-third anterior-posterior chest depth (approximately 4 cm in infants and 5 cm in children) is based largely upon expert clinical consensus, using data extrapolated from animal, adult, and limited pediatric data. Recently, Maher et al. published data from a case series of infants postcardiac surgery associating arterial blood pressure with qualitative chest compression depths. In this small study of 6 infants, chest compressions targeted to one-half anterior-posterior chest depth imparted improved systolic blood pressures compared to those at one-third anterior-posterior chest depth.[68] While a small series with qualitatively estimated chest compression depths, this is the first study to collect actual data from children supporting the existing chest compression depth guidelines. On the contrary, two recent studies using computer-automated tomography[69,70] suggest that depth recommendations based on a relative (%) anterior-posterior chest compression depth are deeper than those recommended for adults, and that a depth of one-half anterior-posterior chest depth is unattainable in most children. Future studies that collect data from actual children and that associate quantitatively measured chest compression depths with short- and long-term clinical outcomes (arterial blood pressure, end-tidal carbon dioxide, return of spontaneous circulation, survival) are needed.

Compression/Ventilation Ratios

The amount of ventilation provided during CPR should match, but not exceed, perfusion and should be titrated to the amount of circulation during the specific phase of resuscitation as well as the metabolic demand of the tissues. Therefore during the low-flow state of CPR when the amount of cardiac output is roughly 25% of normal, less ventilation is needed.[71] However, the best ratio of compressions to ventilations in pediatric patients is largely unknown and depends on many factors including the compression rate, the tidal volume, the blood flow generated by compressions, and the time that compressions are interrupted to perform ventilations. Recent evidence demonstrated that a compression/ventilation ratio of 15:2 delivers the same minute ventilation and increases the number of delivered chest compressions by 48% compared to CPR at a compression/ventilation ratio of 5:1 in a simulated pediatric arrest model.[72,73] This is important because when chest compressions cease, the aortic pressure rapidly decreases and coronary perfusion pressure falls rapidly.[57] Increasing the ratio of compressions to ventilations minimizes these interruptions, thus increasing coronary blood flow. These findings are in part the reason the American Heart Association (AHA) now recommends a pediatric compression/ventilation ratio of 15:2.

Duty Cycle

In a model of human adult cardiac arrest, cardiac output and coronary blood flow are optimized when chest compressions last for 30% of the total cycle time (approximately 1:2 ratio of time in compression to time in relaxation).[74] As the duration of CPR increases, the optimal duty cycle may increase to 50%. In a juvenile swine model, a relaxation period of 250 to 300 milliseconds (duty cycle of 40% to 50% at a compression rate of 120/min) correlates with improved cerebral perfusion pressures compared with shorter duty cycles of 30%.[75]

Circumferential Versus Focal Sternal Compressions

In adult and animal models of cardiac arrest, circumferential (vest) CPR has been demonstrated to improve CPR hemodynamics dramatically.[76] In smaller infants, it is often possible to encircle the chest with both hands and depress the sternum with the thumbs, while compressing the thorax circumferentially (thoracic squeeze). In an infant animal model of CPR, this "two-thumb" method of compression with thoracic squeeze resulted in higher systolic and diastolic blood pressures and a higher pulse pressure than traditional two-finger compression of the sternum.[77]

Open-Chest Cardiopulmonary Resuscitation

Excellent standard closed-chest CPR generates cerebral blood flow that is approximately 50% of normal. By contrast, open-chest CPR can generate cerebral blood flow that approaches normal. Whereas open-chest massage improves coronary perfusion pressure and increases the chance of successful defibrillation in animals and humans,[78-80] performing a thoracotomy to allow open-chest CPR is impractical in many situations. A retrospective review of 27 cases of CPR following pediatric blunt trauma (15 with open-chest CPR and 12 with closed-chest CPR) demonstrated that open-chest CPR increased hospital cost without altering rates of ROSC or survival to

discharge. However, survival in both groups was 0%, indicating that the population may have been too severely injured or too late in the process to benefit from this aggressive therapy.[81] Earlier institution of open-chest CPR may warrant reconsideration in selected special resuscitation circumstances.

Medications Used to Treat Cardiac Arrest

While animal studies have indicated that epinephrine can improve initial resuscitation success after both asphyxial and VF cardiac arrests, no single medication has been shown to improve survival outcome from pediatric cardiac arrest. A variety of medications are used during pediatric resuscitation attempts including vasopressors (epinephrine or vasopressin), antiarrhythmics (amiodarone or lidocaine), and other drugs such as calcium chloride and sodium bicarbonate. Each is discussed separately below.

Vasopressors

Epinephrine (adrenaline) is an endogenous catecholamine with potent α- and β-adrenergic stimulating properties. The α-adrenergic action (vasoconstriction) increases systemic and pulmonary vascular resistance. The resultant higher aortic diastolic blood pressure improves coronary perfusion pressure and myocardial blood flow even though it reduces global cardiac output during CPR. Adequacy of myocardial blood flow is a critical determinant of ROSC. Epinephrine also increases cerebral blood flow during CPR because peripheral vasoconstriction directs a greater proportion of flow to the cerebral circulation.[82-84] However, recent evidence suggests that epinephrine can decrease local cerebral microcirculatory blood flow at a time when global cerebral flow is increased.[85] The β-adrenergic effect increases myocardial contractility and heart rate and relaxes smooth muscle in the skeletal muscle vascular bed and bronchi; however, the β-adrenergic effects are not observed in the peripheral vascular beds secondary to the high dose used in cardiac arrest. Epinephrine also increases the vigor and intensity of VF, increasing the likelihood of successful defibrillation.

High-dose epinephrine (0.05 to 0.2 mg/kg) improves myocardial and cerebral blood flow during CPR more than standard-dose epinephrine (0.01 to 0.02 mg/kg) in animal models of cardiac arrest and may increase the incidence of initial ROSC.[86,87] Administration of high-dose epinephrine, however, can worsen a patient's postresuscitation hemodynamic condition. Retrospective studies indicate that use of high-dose epinephrine in adults or children may be associated with a worse neurologic outcome.[88,89] A randomized, controlled trial of rescue high-dose epinephrine versus standard-dose epinephrine following failed initial standard-dose epinephrine in pediatric in-hospital cardiac arrest demonstrated a worse 24-hour survival in the high-dose epinephrine group (1/27 vs. 6/23, $P < .05$).[90] Based on these clinical data, high-dose epinephrine cannot be recommended routinely for either initial or rescue therapy.

Vasopressin is a long-acting endogenous hormone that acts at specific receptors to mediate systemic vasoconstriction (V_1 receptor) and reabsorption of water in the renal tubule (V_2 receptor). The vasoconstriction is most intense in the skeletal muscle and skin vascular beds. Unlike epinephrine, vasopressin is not a pulmonary vasoconstrictor. In experimental models of cardiac arrest, vasopressin increases blood flow to the heart and brain and improves long term survival compared with epinephrine. However, vasopressin can decrease splanchnic blood flow during and following CPR and can increase afterload in the postresuscitation period.[91-95] Adult randomized controlled trials suggest that outcomes are similar after use of vasopressin or epinephrine during CPR.[96,97] During pediatric arrest, a case series of four children who received vasopressin during six prolonged cardiac arrest events suggested that the use of bolus vasopressin may result in ROSC when standard medications have failed.[98] However, a more recent retrospective study of 1293 consecutive pediatric arrests from the National Registry of CPR (NPCRP) found that vasopressin use, while infrequent (administered in only 5% of events), was associated with a lower likelihood of ROSC. Therefore, it is unlikely that vasopressin will replace epinephrine as a first-line agent in pediatric cardiac arrest. However, the available data suggest that its use in conjunction with epinephrine may deserve further investigation.

Calcium

Calcium is used frequently in cases of cardiac arrest, despite the lack of evidence for efficacy when it is administered routinely during resuscitation attempts. In the absence of a documented clinical indication (i.e., hypocalcemia, calcium channel blocker overdose, hypermagnesemia, or hyperkalemia), administration of calcium does not improve outcome from cardiac arrest.[37,99-107] To the contrary, three pediatric studies have suggested a potential for harm, as routine calcium administration was associated with decreased survival rates and/or worse neurological outcomes.[37,99,100]

Buffer Solutions

There are no randomized controlled studies in children examining the use of sodium bicarbonate for management of pediatric cardiac arrest. Two randomized controlled studies have examined the value of sodium bicarbonate in the management of adult cardiac arrest[108] and in neonates with respiratory arrest in the delivery room.[109] Neither was associated with improved survival. One multicenter retrospective in-hospital pediatric study found that sodium bicarbonate administered during cardiac arrest was associated with decreased survival, even after controlling for age, gender, and first documented cardiac rhythm.[99] Therefore, during pediatric cardiac arrest resuscitation, the routine use of sodium bicarbonate is NOT recommended.

Clinical trials involving critically ill adults with severe metabolic acidosis did not demonstrate a beneficial effect of sodium bicarbonate on hemodynamics despite correction of acidosis.[110,111] However, the presence of severe acidosis may depress the action of catecholamines, so the use of sodium bicarbonate may be considered in an acidemic child who is refractory to catecholamine administration.[112,113] Acidosis may increase the threshold for myocardial stimulation in a patient with an artificial cardiac pacemaker[114]; therefore administration of bicarbonate or another buffer is appropriate for management of severe documented acidosis in these children. Administration of sodium bicarbonate also is indicated in the patient with a tricyclic antidepressant overdose, hyperkalemia, hypermagnesemia, or sodium channel blocker poisoning. The buffering action of bicarbonate occurs when

a hydrogen cation and a bicarbonate anion combine to form carbon dioxide and water. If carbon dioxide is not effectively cleared through ventilation, its buildup counterbalances the buffering effect of bicarbonate. Because carbon dioxide readily penetrates cell membranes, intracellular acidosis may increase without adequate ventilation. Therefore, bicarbonate should not be used for management of respiratory acidosis.

Unlike sodium bicarbonate, tromethamine (THAM) buffers excess protons without generating carbon dioxide. Carbon dioxide is consumed following THAM administration. In a patient with limited ventilation, tromethamine may be preferable when buffering is necessary. Tromethamine undergoes renal elimination, and renal insufficiency may be a relative contraindication to its use. Carbicarb, an equimolar combination of sodium bicarbonate and sodium carbonate, is another buffering solution that generates less carbon dioxide than sodium bicarbonate. In a canine model of cardiac arrest comparing animals given normal saline, sodium bicarbonate, THAM, or Carbicarb, the animals given any buffer solution had a higher rate of ROSC than the animals given normal saline. In the animals given sodium bicarbonate or Carbicarb, the interval to ROSC was significantly shorter than in animals given normal saline. However, at the end of the 6-hour study period, all resuscitated animals were in a deep coma, so no inferences regarding meaningful survival can be drawn.[115] It is premature to recommend either THAM or Carbicarb during CPR at this time.

Postresuscitation Interventions

Temperature Management

Hyperthermia following cardiac arrest is common in children, and fever following cardiac arrest is associated with poor neurologic outcome.[116,117] Two seminal articles addressing adult out-of-hospital VF cardiac arrest have established that mild induced hypothermia (32° C to 34° C) is a clinically promising recent goal-directed postresuscitation therapy. In these randomized studies of comatose patients older than 18 years after VF cardiac arrest, outcomes were improved.[118,119] However, extrapolation of these findings to the pediatric arrest victim is difficult, as fever, trauma, stroke, and other ischemic conditions, common in pediatric cardiac arrest, are associated with poor neurologic outcome. Emerging neonatal trials of selective brain cooling and systemic cooling show promise in neonatal hypoxic-ischemic encephalopathy, suggesting that induced hypothermia may improve outcomes.[120,121] At a minimum, it is advisable to avoid hyperthermia in children following CPR. Using an approach of "therapeutic normothermia" with scheduled administration of antipyretic medications and the use of external cooling devices may be necessary to prevent hyperthermia in this population.

Glucose Control

Both hyperglycemia and hypoglycemia following cardiac arrest are associated with worse neurologic outcome.[122-125] While it seems intuitive that hypoglycemia would be associated with worse neurologic outcome, whether hyperglycemia per se is harmful or is simply a marker of the severity of the stress hormone response from prolonged ischemia is not clear. In critically ill adult patients, tight glucose control using an insulin infusion was associated with improved survival.[126,127] However, subsequent studies of nonsurgical adult populations and neonatal/pediatric trials have demonstrated no survival benefit and/or the potential for harm when rates of inadvertent hypoglycemia were high during treatment.[125,128-135] Using the available data, there is insufficient evidence to formulate a strong recommendation on the management of hyperglycemia in children with ROSC following cardiac arrest. If hyperglycemia is treated following ROSC in pediatric patients, blood glucose concentrations should be carefully monitored to avoid hypoglycemia.

Blood Pressure Management

Compared with healthy volunteers, adults resuscitated from cardiac arrest have impaired autoregulation of cerebral blood flow.[136] Hence they may not maintain adequate cerebral blood flow in the context of low systemic pressure and, likewise, may not be able to protect the brain from excessive blood flow and microvascular perfusion pressure in the context of systemic hypertension. However, in animal models, brief induced hypertension following resuscitation results in improved neurologic outcome compared with normotensive reperfusion.[137,138] Therefore, a practical approach to blood pressure management following cardiac arrest is to attempt to minimize blood pressure variability in this high-risk period following resuscitation.

Postresuscitation Myocardial Dysfunction

Postarrest myocardial stunning and arterial hypotension occur commonly after successful resuscitation in both animals and humans.[118,119,139-146] Animal studies demonstrate that postarrest myocardial stunning is a global phenomenon with biventricular systolic and diastolic dysfunction. This postarrest myocardial stunning is pathophysiologically and physiologically similar to sepsis-related myocardial dysfunction and post–cardiopulmonary bypass myocardial dysfunction, including increases in inflammatory mediators and nitric oxide production.[139,141,142,145] Because cardiac function is essential to reperfusion following cardiac arrest, management of postarrest myocardial dysfunction may be important to improving survival. The classes of agents used to maintain circulatory function (i.e., inotropes, vasopressors, and vasodilators) must be carefully titrated during the postresuscitation phase to the patient's cardiovascular physiology. Trials in animal models have shown that various vasoactive medications can effectively ameliorate postarrest myocardial dysfunction (e.g., dobutamine, milrinone, levosimendan).[147-151] Similarly, in human observational studies, fluid resuscitation and various vasoactive medications (i.e., epinephrine, dobutamine, and dopamine) have been provided for myocardial dysfunction syndrome.[118,119,140-144] In the end, optimal use of these agents involves close goal-directed titration, and the use of invasive hemodynamic monitoring may be appropriate.

Other Considerations

Quality of CPR

The quality of healthcare provider CPR during adult resuscitations typically does not comply with American Heart Association clinical practice guidelines. Long CPR-free intervals, shallow chest compressions, incorrect chest compression

rates, and overventilation are common.[152-155] Unfortunately, the quality of CPR performed during the resuscitation attempt is directly related to patient outcome.[52,152,156] Studies have shown in adults and in children that patients with a witnessed cardiac arrest[4] and those who receive bystander CPR[157] have an increased chance of survival. Those that suffer their in-hospital cardiac arrest at night or during weekends (presumably when the quality of resuscitation is not as good as in the daytime or on weekdays) have higher mortality.[158] Furthermore, pediatric outcomes are improved in hospitals staffed with highly trained pediatric specific providers.[22] Taken all together, these findings establish that the quality of resuscitative care, specifically early high-quality CPR, is an important determinate of patient survival.

In an effort to improve CPR quality, CPR-monitoring defibrillators with audiovisual feedback have been used during adult resuscitation, and improvements in CPR quality and clinical outcomes have been achieved.[156,159] In a recent pediatric article, the combination of focused bedside training and automated feedback defibrillators improved CPR guideline compliance of in-hospital providers.[154] However, there were still significant portions of the resuscitation that suffered from substandard resuscitative care. Future studies should continue to focus on novel ways to improve pediatric CPR during resuscitation attempts.

Extracorporeal Membrane Oxygenation Cardiopulmonary Resuscitation

Venoarterial extracorporeal membrane oxygenation (ECMO) has been increasingly used as a rescue therapy during CPR, especially for potentially reversible acute postoperative myocardial dysfunction or arrhythmias. Studies of extracorporeal CPR (E-CPR) have demonstrated favorable early survival outcomes in children with primary cardiac disease when E-CPR protocols were in place at the time of the arrest.[31,160-170] Interestingly, data has been mixed regarding the relationship between outcome and CPR duration before ECMO cannulation. CPR and ECMO are not curative treatments. They are simply cardiopulmonary supportive measures that restore tissue perfusion until recovery from the precipitating disease process is achieved. As such, they can be powerful tools. Thus E-CPR should be considered for children with cardiac arrest who have heart disease amenable to recovery or transplantation, if the arrest occurs in a highly supervised environment such as an intensive care unit with existing clinical protocols and available expertise and equipment to rapidly initiate extracorporeal life support (ECLS).

Ventricular Fibrillation and Ventricular Tachycardia in Children

Pediatric VF or VT has been an underappreciated pediatric problem. Recent studies indicate that VF and VT (i.e., shockable rhythms) occur in 27% of in-hospital cardiac arrests at some time during the resuscitation.[28] In a population of pediatric cardiac intensive care unit patients, as many as 41% of arrests were associated with VF or VT.[24] According to the National Registry of Cardiopulmonary Resuscitation (NRCPR) database, during in-hospital arrest, 10% of children had an initial rhythm of VF/VT. In all, 27% of the children had VF/VT at some time during the resuscitation.[28] The incidence of VF varies by setting and age.[171] In special circumstances, such as tricyclic antidepressant overdose, cardiomyopathy, status post–cardiac surgery, and prolonged QT syndromes, VF and pulseless VT are more likely.

The treatment of choice for short-duration VF is prompt defibrillation. In general, the mortality rate increases by 7% to 10% per minute of delay to defibrillation. Because VF must be considered before defibrillation can be provided, early determination of the rhythm by electrocardiography is critical. An attitude that VF is rare in children can be a self-fulfilling prophecy with a uniformly fatal outcome. The recommended defibrillation dose is 2 J/kg, but the data supporting this recommendation are not optimal and are based on old monophasic defibrillators. In the mid-1970s, authoritative sources recommended starting doses of 60 to 200 J for all children. Because of concerns for myocardial damage and animal data suggesting that shock doses ranging from 0.5 to 1 J/kg were adequate for defibrillation in a variety of species, Gutgesell et al. evaluated the efficacy of their strategy to defibrillate with 2 J/kg monophasic shocks. Seventy-one transthoracic defibrillations in 27 children were evaluated. Shocks within 10 J of 2 J/kg resulted in successful defibrillation in 91% of defibrillation attempts. The major determinant of successful defibrillation other than VF duration is countershock current. This current depends on the defibrillator energy and transthoracic impedance. Studies in children indicate that the transthoracic impedance of infants and children greatly overlap. Although there is a statistically significant correlation between size and transthoracic impedance, the correlation is weak. These studies provide only weak support for the present dogma that the defibrillator energy dose should vary directly with weight. Nevertheless, the present recommendation of 2 J/kg has stood the test of time.

Although the limited data regarding pediatric defibrillation used monophasic waveform shocks, most new defibrillators use biphasic waveform shocks. Defibrillation with these biphasic waveforms apparently is safer and more effective than monophasic waveform defibrillation. Therefore the use of 2 J/kg biphasic waveform shocks should be at least as effective as 2 J/kg monophasic shocks and possibly safer.

Antiarrhythmic Medications: Lidocaine and Amiodarone

Administration of antiarrhythmic medications should never delay administration of shocks to a patient with VF. However, after an unsuccessful attempt at electrical defibrillation, medications to increase the effectiveness of defibrillation should be considered. Epinephrine is the current first-line medication for both pediatric and adult patients in VF. If epinephrine and a subsequent repeat attempt to defibrillate are unsuccessful, lidocaine or amiodarone should be considered.

Lidocaine traditionally has been recommended for shock-resistant VF in adults and children. However, only amiodarone improved survival to hospital admission in the setting of shock-resistant VF compared with placebo.[172] In another study of shock-resistant out-of-hospital VF, patients receiving amiodarone had a higher rate of survival to hospital admission than patients receiving lidocaine.[173] Neither study included children. Because there is moderate experience with

amiodarone use as an antiarrhythmic agent in children and because of the adult studies, it is rational to use amiodarone similarly in children with shock-resistant VF/VT. The recommended dosage is 5 mg/kg by rapid intravenous bolus. There are no published comparisons of antiarrhythmic medications for pediatric refractory VF. Although extrapolation of adult data and electrophysiologic mechanistic information suggest that amiodarone may be preferable for pediatric shock-resistant VF, the optimal choice is not clear.

Pediatric Automated External Defibrillators

Automated external defibrillators (AEDs) have improved adult survival from VF.[174,175] AEDs are recommended for use in children 8 years or older with cardiac arrest.[176,177] The available data suggest that some AEDs can accurately diagnose VF in children of all ages, but many AEDs are limited because the defibrillation pads and energy dosage are geared for adults. Adapters having smaller defibrillation pads that dampen the amount of energy delivered have been developed as attachments to adult AEDs, allowing their use in children. However, it is important that the AED diagnostic algorithm is sensitive and specific for pediatric VF and VT. The diagnostic algorithms from several AED manufacturers have been tested for such sensitivity and specificity and therefore can be reasonably used in younger children.

Summary

Outcomes from pediatric cardiac arrest and CPR appear to be improving. Perhaps the evolving understanding of pathophysiologic events during and after pediatric cardiac arrest and the developing fields of pediatric critical care and pediatric emergency medicine have contributed to these apparent improvements. In addition, exciting breakthroughs in basic and applied science laboratories are on the immediate horizon for study in specific subpopulations of cardiac arrest victims. By strategically focusing therapies to specific phases of cardiac arrest, there is great promise that critical care interventions will lead the way to more successful cardiopulmonary and cerebral resuscitation in children.

Structure and Development of the Upper Respiratory System in Infants and Children

Linda Brodsky

PEARLS

- The upper airway and upper digestive tract are intimately related during embryogenesis and consequently have important anatomic relationships that must be considered in the context of one another. Failure to recognize and fully understand these relationships can lead to serious morbidity in the critically ill child.
- The structure of the upper airway undergoes enormous change from infancy through young adulthood. An understanding of the numerous variations, congenital anomalies, and resultant special vulnerabilities of the developing airway and how they relate to altered states of consciousness and underlying illness should result in better outcomes and a lower morbidity rate.
- The upper airway includes both the middle ear and connecting Eustachian tube and the paranasal sinuses, which drain into the nose. Iatrogenic manipulation of these connections, such as that which occurs with tube placement, may cause obstruction and secondary infection, complicating the clinical picture in a seriously ill child.

Respiration is vital to survival and is the first function that is protected in any critical medical situation. The respiratory tract can be divided into the upper or conducting airways and the lower or gaseous exchange airways. For the purposes of this chapter, the trachea down to the carina is included as part of the "upper" or conducting airways. The upper airway shares its development with that of the upper digestive tract, and the lower airway shares its development with the cardiovascular system.

The upper airway serves numerous functions, including air conduction, warming, purification, humidification, protection of the lower airways, and phonation, which is most often overlooked in the critical care setting.

In the fetus, the larynx allows fetal breathing (of amniotic fluid) until the moment of birth, when it assumes the role of protecting gas exchange between the environment and the newborn. Protection of the lower airway and phonation occur simultaneously. Thus the infant's first cry heralds its ability to sustain independent life. After breathing, eating becomes the infant's next priority, requiring some of the most complex neurologic coordination found in nature. When confronted with the challenges of maintaining a patent airway, deglutition, and vocalization, a well-functioning upper airway is of utmost importance.

Developmental Anatomy of the Upper Airway

The embryologic development of the nasal cavity, mouth, nasopharynx, oropharynx, and hypopharynx occurs in a separate developmental environment from that of the larynx, trachea, bronchi, and lung parenchyma. Early errors in development can affect both anatomic areas, but these errors are usually incompatible with life. Because the nose, mouth, pharynx, and part of the larynx develop from different embryonic structures than the rest of the larynx and lower respiratory tract, there are few coincident congenital anomalies between these two contiguous but developmentally distinct areas.

The branchial arches, which begin to appear during the fourth week of embryogenesis, give rise to most of the upper airway—nasal passages, pharynx, larynx, and striated muscles— involved in breathing and swallowing. The development of these structures is usually complete by week 14.

The respiratory system, including parts of the larynx, the trachea, and the lungs, also begins to appear during week 14, when the laryngotracheal groove develops into a diverticulum that subsequently separates from the pharynx. In the fourth and fifth weeks, the longitudinal tracheoesophageal folds fuse, forming the tracheoesophageal septum and dividing the foregut into ventral and dorsal portions. The ventral portion becomes the larynx, trachea, bronchi, and lungs, and the dorsal portion becomes the esophagus.

The embryogenesis of the larynx is complex. The cartilages and muscles are derived from the fourth and sixth branchial arches, and the epithelium is derived from the endoderm of

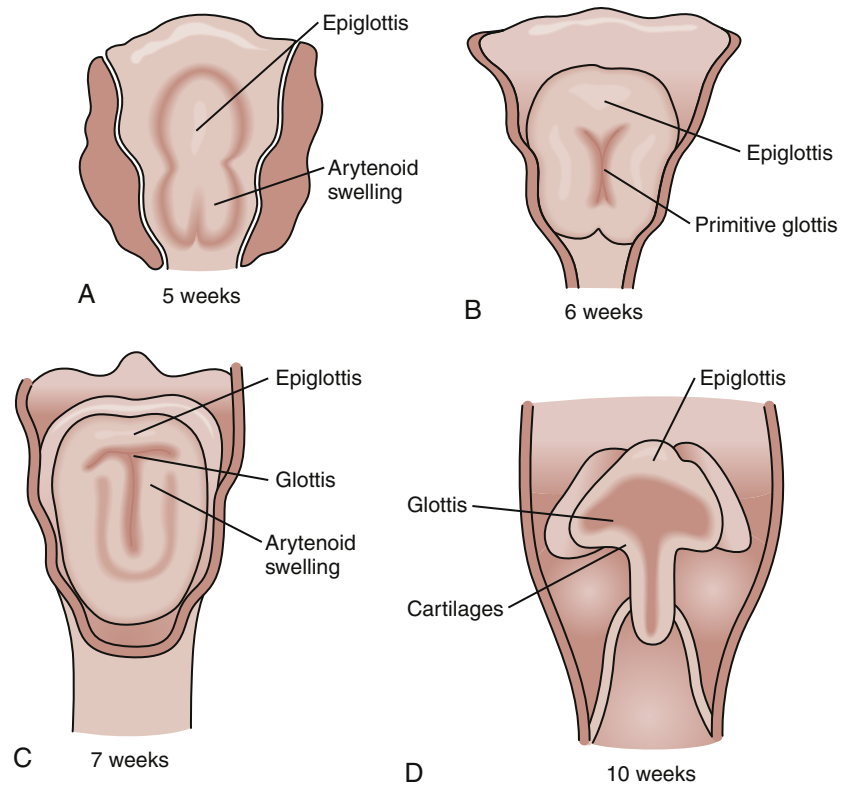

Figure 35–1. The embryologic development of the larynx. *(Modified from Arvedson J, Brodsky L:* Pediatric feeding and swallowing: management and assessment, *ed 2, Andover, United Kingdom, 2002, Thomson Learning.)*

the laryngotracheal tube. As this epithelium rapidly proliferates, the larynx is temporarily occluded until the 10th week, when recanalization occurs. Failure to recanalize can result in laryngeal webs, stenosis, or, rarely, atresia. The epiglottis forms by mesenchymal proliferation of the third and fourth branchial arches (Figure 35-1).

The tracheobronchial tree also has several embryonic origins. Its epithelium is derived from the laryngotracheal tube, and its connective tissue, cartilages, and muscles are derived from the surrounding splanchnic mesenchyme. All the cartilages of the trachea are C-shaped and thus are incomplete posteriorly, giving the airway flexibility to expand, except for the cricoid cartilage immediately below the true vocal folds. The cricoid cartilage is anatomically considered part of the larynx. It is the only cartilage in the airway to form a complete ring. Because of its inflexibility, edema from intubation and inflammation can result in serious, often avoidable injury.

Anatomy and Physiology of the Upper Airway

Nasal Passages

The upper airways begin at the tip of the nose and the vermilion border of the lips. Both the nasal and oral passages allow air stream from the environment through the larynx into the lungs where oxygen and carbon dioxide are exchanged through the alveoli into the cardiovascular system via capillaries. The mouth, oral cavity, and pharynx (oropharynx and hypopharynx) have the additional function of ingesting adequate amounts of food for growth and development.

The structure of the upper airways differs in the infant (Figure 35-2), young child, and young adult (Figure 35-3). Preferential nasal breathing is present in neonates and persists up until 6 months of age due to the high riding larynx in the neck with the soft palate and vallecula in close anatomic approximation.

The nasal tip and, in particular, the nasal valve area is the area of highest resistance in the upper airway. Infants who require enteral feeds are better served with an orogastric tube than a nasogastric tube and oxygen delivered by mask rather than by nasal prongs to avoid obstruction and injury to this area. The nasal cavity courses posteriorly until it meets the nasopharynx, a box-shaped structure where the oropharynx and nasopharynx meet.

The purpose of the nasopharynx is to serve as a conduit for air, a drainage area for the nose, paranasal sinuses, and middle ear via the Eustachian tube, and a resonator for speech. As growth occurs, the angle of the nasopharynx at the base of the skull becomes more acute, approximating 90 degrees in the adult. Elongation of the nasopharynx has implications not only for the placement of airway and feeding tubes but also for the production of a wide variety of sounds. The adenoid pad is located in the nasopharynx and sits against the muscles covering the cervical spine at the base of the skull. During the first years of life the adenoids may enlarge, but in most instances they begin to involute at about age 8 years extending through puberty unless ongoing inflammation from allergy, infection, or gastrointestinal reflux causes stimulation and growth.

The nasal passage is divided by the nasal septum, which is cartilaginous anteriorly and bony posteriorly. Injury to the anterior nasal septum is not uncommon with the use of nasal tubes, nasal prongs, or nonhumidified oxygen because of the thin epithelium overlying the cartilage anteriorly. Bacterial colonization frequently occurs when the nasal passages become dry and stasis of secretions occur. In the critically ill

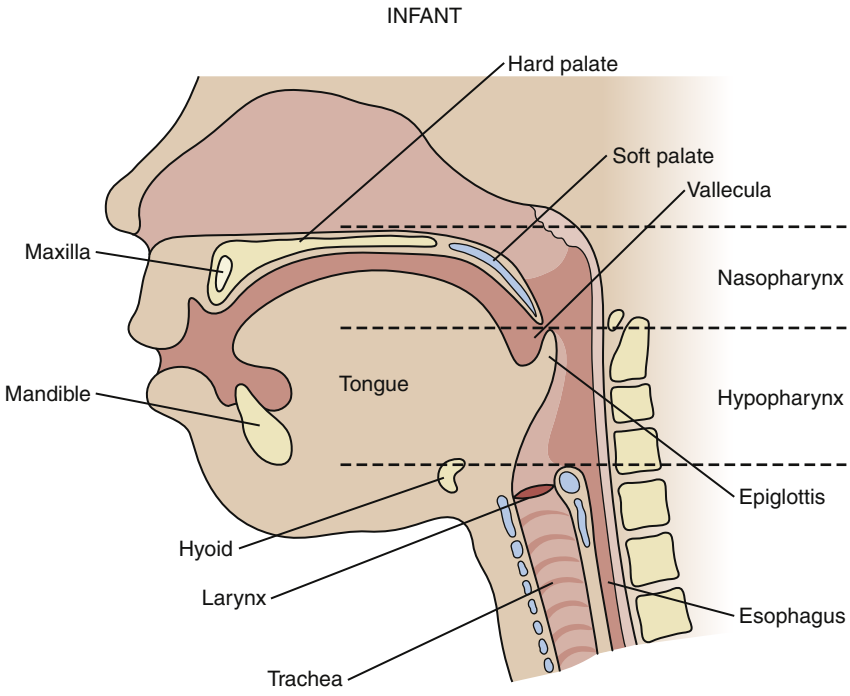

Figure 35–2. Lateral view of the infant's upper airway. The soft palate and vallecula form a tongue and groove relationship that effectively separates the oral cavity from the nasal cavity during the first 6 months of infancy when most children are primarily nasal breathers. This anatomic proximity effectively separates the oral route for ingestion from the nasal route for respiration. Anterior placement of the larynx has implications for intubation technique. *(Modified from Arvedson J, Brodsky L:* Pediatric feeding and swallowing: management and assessment, *ed 2, Andover, United Kingdom, 2002, Thomson Learning.)*

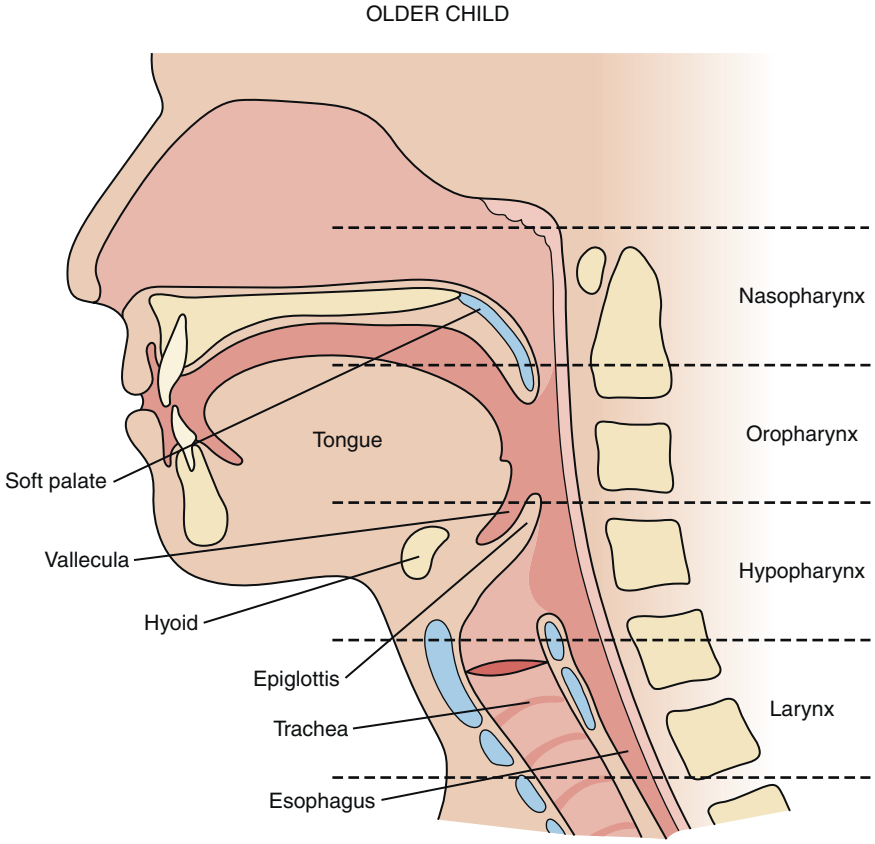

Figure 35–3. Lateral view of the older child's upper airway. Note the development of the oropharynx, a shared passage for eating and breathing. The tongue occupies less of the oral cavity. The larynx sits lower in the neck, which is unique to humans and has allowed for the development of human speech production. However, the shared passageway with the digestive system creates challenges in airway protection, particularly during intubation. *(Modified from Arvedson J, Brodsky L:* Pediatric feeding and swallowing: management and assessment, *ed 2, Andover, United Kingdom, 2002, Thomson Learning.)*

patient these conditions often are present, and further injury to this area increases the risk of epistaxis. Close attention to nasal hygiene may prevent these injuries.

Often overlooked are the ostia of the paranasal sinuses that drain into the nasal cavity and, like the Eustachian tube orifices (which drain into the nasopharynx), are considered part of the upper airways. However, their roles in air conduction are poorly understood. Iatrogenic nasal obstruction may lead to obstruction of ostia of the paranasal sinuses and Eustachian tube resulting in secondary infections in the middle ear and sinuses. Frequent assessments of the middle ear and nasal cavities are helpful.

The nose and paranasal sinuses are involved in respiration, humidification, and purification of inspired air. Except for the nasal vestibule and parts of the oral cavity, the pharynx, and the edges of the true vocal folds, ciliated, pseudo-stratified columnar epithelium lines the nasal passages, upper airway surfaces, and lower airway to the second order bronchi. The lateral nasal walls consist of bony prominences with specialized epithelium and submucosa called the nasal turbinates. The nasal turbinates are structured both to increase the surface area and to create turbulence to enhance the nasal functions of humidification, purification, and warming of the inspired nasal air. When these structures are bypassed, some of these functions are compromised, most notably humidification and purification. Close attention to humidity and "clean" air delivered by ventilators requires nursing vigilance and physician oversight.

Seromucinous glands are found throughout the entire upper airway from the sinonasal passages to the bronchi. Rich in immunoglobulins and other immune mediators, mucociliary clearance is always in the direction of the hypopharynx, where these secretions are swallowed. Therefore, movement of mucous is caudad in the nose and cephalad in the trachea and bronchi.

Mouth and Pharynx

The structures of the oral cavity include the lips, teeth, tongue, tonsils, and palate. The anterior structures are primarily involved in food bolus preparation and speech. However, the tongue may be absolutely or relatively enlarged for the space allotted. Children with Beckwith-Wideman syndrome have macroglossia; their tongue often sticks out of the mouth and may require reduction or airway bypass. Some craniofacial anomalies are characterized by micrognathia or retrognathia, when even a normal or smaller sized tongue may be posteriorly placed, causing laryngeal obstruction. Sometimes glossoptosis, by anatomic or physiologic mechanisms, can produce airway obstruction that prevents ventilation by natural or mechanical means unless an endotracheal tube bypasses the obstruction. Patients with Down syndrome can present with multilevel airway problems as a result of mid-face hypoplasia, a small nasopharynx, relatively large tongues, and a congenitally narrowed subglottic space.

The oropharynx begins posterior to the posterior tonsillar pillars with its superior border at the edge of the soft palate and its inferior border at the superior tip of the epiglottis. With growth and development the pharynx elongates so that an oropharynx develops between ages 2 and 3 years. The lateral walls of the pharynx consist of the three pairs of constrictor muscles that are innervated by cranial nerves V, IX, and X. Many of these nerves are also important in protection of the lower airways. The muscle tone of the constrictors is often compromised in neurologically impaired children and may cause airway collapse and obstruction, even in the absence of enlarged tonsils and adenoids or glossoptosis. The tonsils are found laterally, and when chronically or severely inflamed, they may enlarge and cause upper airway obstruction similar to that found in the adenoids at the nasopharyngeal level. Often, but not always, enlargement of the tonsils and the adenoids occur together.

The posterior structure, the oropharynx, is the crossroads for the nasopharynx from above and the hypopharynx from below. In infants, no oropharynx exists because the nasopharynx is blended directly into the hypopharynx as a result of the uvula being situated in the vallecula. At the base of the tongue, located in the vallecula (a wedge-shaped structure posterior to the epiglottis), are the lingual tonsils. When enlarged, they can cause airway obstruction and interfere with visualization of the glottis.

The hypopharynx is the most inferior of the shared passageways for respiration and deglutition. Superiorly it is defined by the tip of the epiglottis, which in the adult is at the level of the hyoid bone in the neck, a relationship that is variable in the infant and child. The inferior border of the hypopharynx is at the level of the cricopharyngeus muscle, which is the introitus of the esophagus and is located directly posteriorly to the cricoid cartilage (see Figures 35-2 and 35-3). Protection of the airway occurs in this area, particularly during deglutition. The anterior boundary of the hypopharynx is the larynx.

Larynx

The larynx is a complex organ that serves in respiration, protection of the lower airways, and phonation. There are no fewer than eight cartilages (excluding the cricoid cartilage), two ligaments, and almost a dozen paired and unpaired muscles that have various roles in the three primary functions of the larynx (Figure 35-4). The larynx begins at the level of the true vocal folds and extends to the inferior border of the cricoid cartilage.

Proper airflow requires that the larynx have functioning vocal folds so that during inspiration there is abduction of the true vocal folds, allowing the least restrictive inflow of air. During expiration, slight adduction occurs and the false vocal folds (also known as the ventricular folds) modulate the expiratory airflow.

Protection of the lower airways is key to survival. Prevention of aspiration of secretions or ingested food requires multilevel coordination of several sphincters. The most superior level is the epiglottis, which has a flattened lingual surface directing secretions laterally and posteriorly as it folds into the larynx during deglutition. The paired arytenoid cartilages sit at the posterior aspect of the larynx and provide the next level of protection. These cartilages, along with the coordination of the aryepiglottic folds (reinforced by the smaller cuneiform and corniculate cartilages) contract medially to close the glottis.

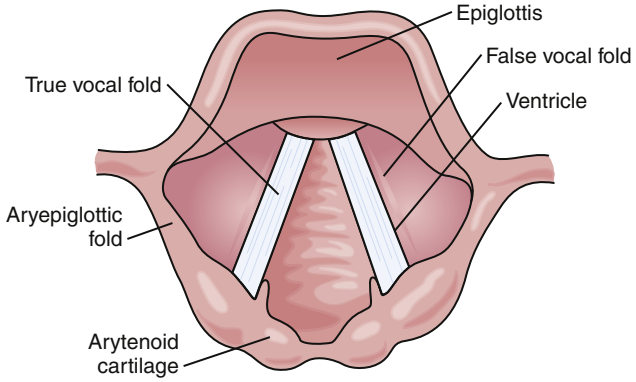

Figure 35–4. Superior (endoscopic) view of the endolarynx. *(Modified from Arvedson J, Brodsky L:* Pediatric feeding and swallowing: management and assessment, *ed 2, Andover, United Kingdom, 2002, Thomson Learning.)*

Table 35–1 Anatomic Airway Difference Between Infants and Children

Anatomic Location	Infant	Older Child
Oral cavity	Tongue fills mouth Edentulous Tongue rests between lips and sits against palate Relatively smaller mandible Uvula sits in vallecula separating oral from nasal cavity resulting in preferential nasal breathing	Mouth is larger, tongue rests on the floor of the mouth Dentulous Tongue rests behind teeth and not up against palate Mandibular-maxillary relationship relatively normal Uvula sits above epiglottis with respirations occurring through mouth and nose
Pharynx	No definite/distinct oropharynx Obtuse at skull base in nasopharynx	Elongation from nasopharynx through hypopharynx with distinct oropharynx 90-degree angle at skull base
Larynx/ tracheobronchial tree	One third adult size at laryngeal inlet Half of true vocal fold is cartilage Narrow, vertical epiglottis Subglottis size is 4-5 mm Tracheal rings more compliant	Less than one third of true vocal fold is cartilage Flat, wide epiglottis Subglottis enlarges with age

Modified from Arvedson J, Brodsky L: *Pediatric feeding and swallowing: management and assessment*, ed 2, Andover, United Kingdom, 2002, Thomson Learning.

Simultaneously, the larynx is elevated under the tongue and provides the airway with further protection during swallowing. Finally, the paired true and false vocal folds abduct and provide yet another level of protection. During quiet respiration, the highly innervated larynx repels unwanted secretions by the highly sensitive cough reflex, mediated primarily through cranial nerves IX and X. In the intubated, often sedated, or paralyzed child, these protective mechanisms are absent and the dangers of aspiration of secretions become of great concern. Frequent suctioning of oral cavity secretions may reduce this risk but is unlikely to eliminate aspiration completely.

Innervation of the larynx for its protective and respiratory functions is located centrally in the brainstem and is thus reflexive. The sensory and motor innervations to this area are key to proper function. Thus, following prolonged intubation, immediate return of function is unrealistic and a cautionary approach to the re-establishment oral feeds is prudent. Another issue to consider is that intubation may cause recurrent laryngeal nerve injury with vocal fold paralysis. The mechanism for this injury is believed to result from pressure on the cricoarytenoid joint close to where the nerve enters the larynx.

Interestingly, the most highly innervated areas of the larynx are the epiglottis and the posterior surfaces of the arytenoids. The chemical and thermal receptors are particularly sensitive to temperature and humidity in infants and young children. Cool mist can slow the rate of respiration and increase tidal volume, thereby having a positive effect on respiration. Other receptors in the larynx include joint, aortic, baroreceptors, and stretch receptors, the clinical significance of which has received little study in children.

Anatomic differences between the upper aerodigestive tracts of infants and children are listed in Table 35-1.

Trachea and Bronchi

Inferior to the larynx is the trachea, which conducts air to the bronchi, which then branch to ever smaller lumen tubes that eventually become alveoli, the anatomic location of gas exchange. The trachea is made of cartilaginous rings that are essentially the same diameter until they reach the carina, where the trachea splits into left and right main stem bronchi.

The right main stem bronchus is shorter, wider, and takes off at a less acute angle than does the left main stem bronchus and thus is the site of bronchial foreign body aspiration more often than is the left main stem bronchus. Bronchial intubation is more often encountered on the right. The right main stem bronchus leads to the right upper, middle, and lower lobes.

The left main stem bronchus is longer, narrower, and more acutely angled than the right main stem bronchus. Its bronchi lead to the lower and upper lobes and to the lingula. As mentioned previously, these airways are lined by pseudostratified, ciliated columnar epithelium. This epithelium is readily injured through suctioning. Prolonged intubation, particularly after tracheotomy, results in diffuse squamous metaplasia. Without functioning cilia, airway secretions remain in the airway and can be the source of irritation, inflammation, and atelectasis, all complicating factors in the management of the upper airway during a critical illness.

Chapter 36

Structure of the Respiratory System: Lower Respiratory Tract

Christopher A. D'Angelis, Jacqueline J. Coalson, and Rita M. Ryan

PEARLS

- Lungs increase in volume from about 250 mL at birth to 6000 mL in the adult.
- At birth, the pulmonary artery and aorta are comparable in medial thickness and configuration and are the same size; by age 2 years, elastic tissue decreases in the pulmonary artery and its thickness is only about 60% that of the aorta.
- Each bronchopulmonary segment is divided by connective tissue septa that define the smallest surgically resectable portions of the lung.
- The airway branching pattern in the lung undergoes multiple generations, yielding a total of 27 or 28 divisions when counting begins from the primary bronchus.
- The bronchial mucosa contains several epithelial cell types, with the ciliated cell comprising more than 90% of the epithelial cell population in the conducting airways, but the proportion and number of cilia per cell decrease from the proximal to distal airways.
- The acinus, which is approximately spherical in shape and has a diameter of about 7 mm and a length of 0.5 to 1 cm, is the gas exchange portion of the lung.
- Although there is disparity concerning the time alveolarization is completed, alveoli in a normal adult number from 300 to 500 million and have a diameter of 150 to 200 μm.
- The two epithelial cells of the alveolus are the gas-exchanging type I cell and the surfactant-producing type II cell that is responsible for epithelial repair.
- The alveolar-capillary unit is comprised of three major constituents: the epithelial lining of the alveolus, capillary endothelial cells, and a mixture of cellular and extracellular interstitial components.
- The large pulmonary arteries traverse with the cartilaginous airways and extend from the hilum to nearly halfway in the bronchial tree.
- Smaller pulmonary arteries measure between 100 and 1000 μm in diameter, branch with the bronchial tree, and lie close to bronchi and bronchioles.
- The pulmonary veins do not course with the bronchial tree and instead are seen within the interlobular septa.
- The diaphragm, the principal muscle of respiration, is essential during deep anesthesia because other muscles of respiration become inactive.

Lower Respiratory System

Lungs

Lung weights of children from birth to age 12 years have been published.[1-13] At birth, the lungs weigh about 40 g and double in weight by 6 months. Mature respiratory alveoli appear at approximately 36 weeks of gestation and continue to develop until about 2 years of age. By age 2 years, when most of the alveolarization process is completed, total lung weight is approximately 170 g. In the normal adult, the lungs weigh approximately 1000 g.[9] Lung volume increases from about 250 mL at birth to 6000 mL in the adult. The height of a normal adult lung is 27 cm at total lung capacity, but in the range of normal breathing it is approximately 24 cm in height. Externally, the lungs are paired structures that, with the mediastinum, fill the thoracic cavity. Normally the right lung is comprised of three lobes and the left lung consists of two lobes and the lingula, which arises from the left upper lobe. The lobes are separated by fissures and have hili that receive a primary lobar bronchus, pulmonary artery and veins, bronchial arteries and veins, lymphatics, and nerves (Figure 36-1).[14] The lobes are further subdivided into 19 bronchopulmonary segments that receive a primary segmental bronchi and a tertiary pulmonary artery branch and are drained by pulmonary veins. The pulmonary veins do not course with the airway and pulmonary artery dyad; instead, they course midway between the dyads and can be readily identified in the septa that run within the intersegmental septa. The connective tissue septa that demarcate each bronchopulmonary segment define the smallest surgically resectable portions of the lung.

Airways and Bronchus-Associated Lymphoid Tissue

The airway branching pattern in the lung undergoes multiple generations, yielding a total of 27 or 28 divisions when counting begins from the primary bronchus. The bronchi are the larger intrinsic cartilaginous airways and comprise nine to 12 generations starting with the primary bronchus and terminating in bronchi having a diameter of approximately 1 mm. Bronchioles, sometimes called membranous bronchioles or distal noncartilaginous airways, are the last of the conducting system. They comprise an additional 12 generations before ending as terminal bronchioles, the last purely conducting

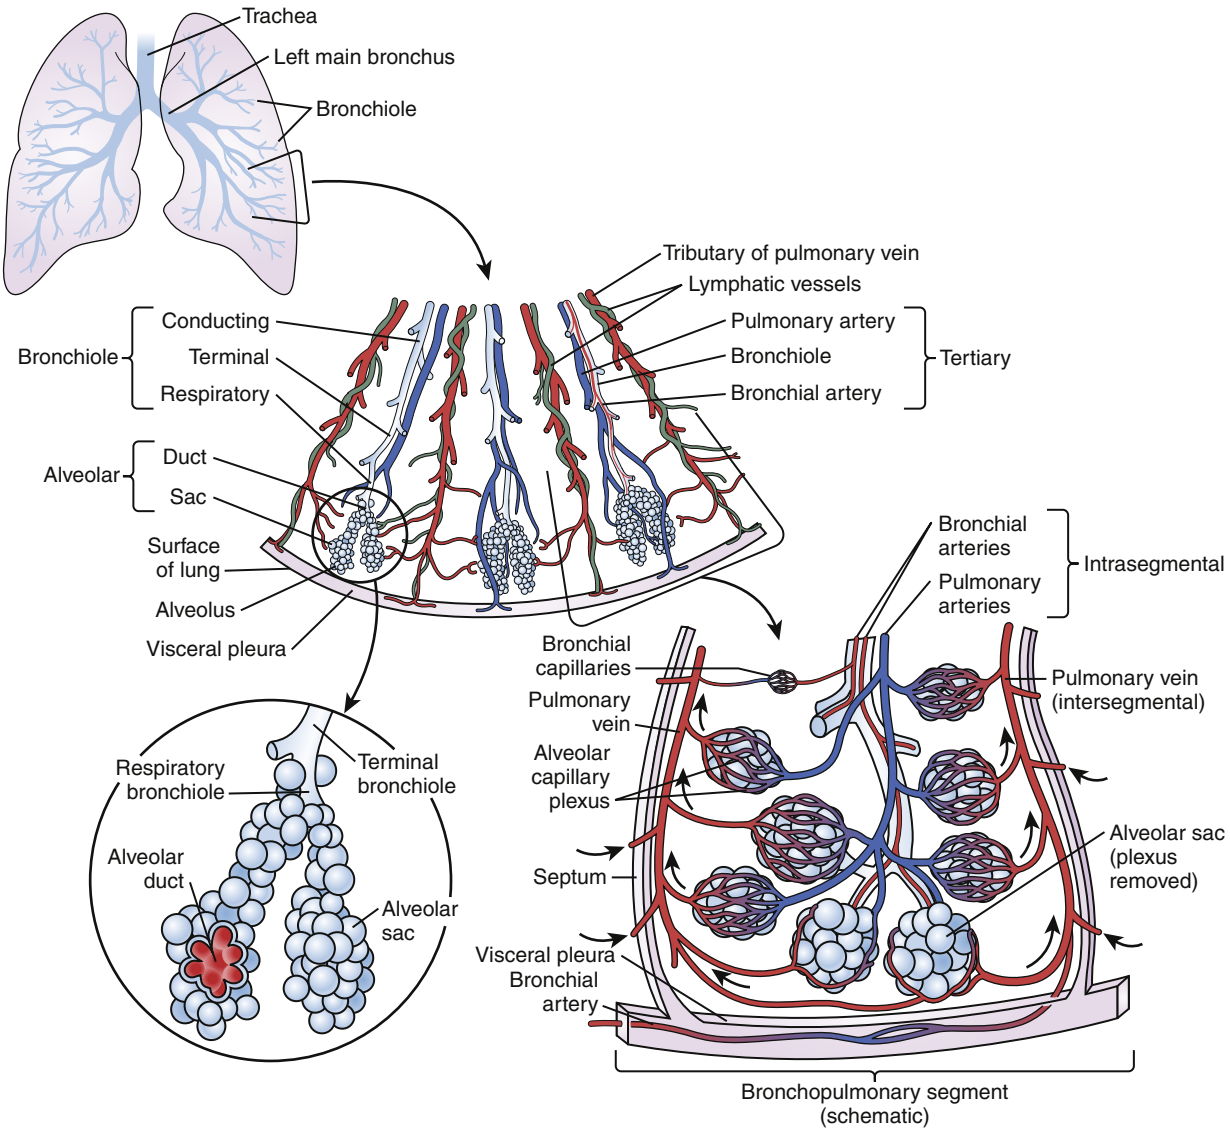

Figure 36–1. Internal structure and organization of lungs. Within the lungs, the bronchi and pulmonary arteries are paired and branch in unison. Segmental (tertiary) branches supply the bronchopulmonary segments. Each intrasegmental pulmonary artery ends in a capillary plexus in the walls of the alveolar sacs and alveoli. The pulmonary veins arise from the pulmonary capillaries and drain toward and then course within the septa between adjacent segments. Bronchial arteries are distributed along and supply the bronchial tree. Their distal-most branches supply capillary beds drained by the pulmonary veins, such as those of the visceral pleura (even though this small amount of blood is poorly oxygenated). *(Modified from Moore KL, Dalley, Arthur F:* Clinically oriented anatomy, *ed 5, 2006, Lippincott Williams & Wilkins.)*

structure in the lung. Horsfield[4] showed that the course from the trachea to the alveolar level may be as few as eight or as many as 24 airway branch points. This finding points out that a particular airway diameter may occur at various points along the distribution of the bronchial wall. Determination of the total cross section of airways is important in understanding the distribution of airway resistance. Weibel[12] showed that as the peripheral generations of the airways are approached, the total cross-sectional area of the lung is markedly increased, suggesting that peripheral airways account for only a small proportion of total airway resistance. In the adult, the asymmetrical dichotomous branching pattern results with each daughter branch decreasing an average of 0.75% of its parent branch, but an increase results from the combined cross-sectional area of the two daughter branches. It is well known, however, that peripheral airway resistance in children's lungs is disproportionately high. The size of the conducting airways is related to stature, so the airways' cross-sectional area in children increases at a slow rate with growth and aging. Because the peripheral airways make up a significant portion of the total respiratory resistance in children, disease in the bronchioles can be serious.

The bronchi maintain the histologic appearance of the trachea in that a mucosa, submucosa, muscularis, adventitia, and cartilaginous support are present. As the bronchi branch deeper into the lung parenchyma, the cartilage rings become plates and less regular, and the muscularis becomes continuous, being located between the submucosa and the cartilage plates. Also contained within the bronchial submucosa are mucus-secreting submucosal glands, nerves, ganglia, and bronchial arterial branches (Figure 36-2). As the bronchi decrease in diameter, the pseudostratified columnar epithelium becomes lower and the mucoserous glands become fewer in number. Although the glands wane in number in the

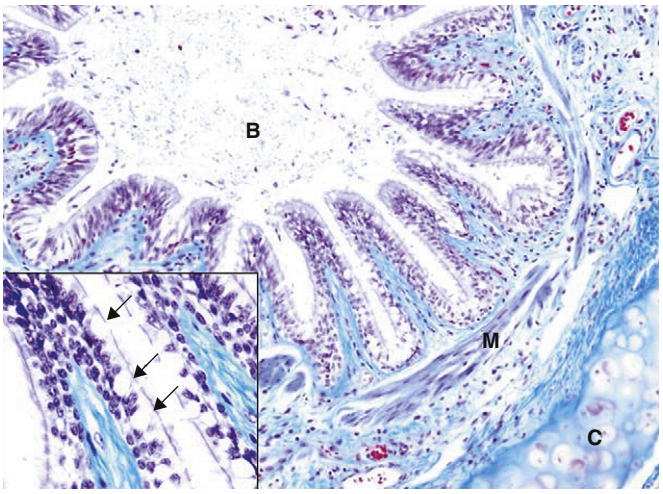

Figure 36–2. Bronchus (*B*) with surrounding smooth muscle (*M*) and cartilage (*C*). The airway mucosa (*insert*) is composed of ciliated epithelial cells and vacuolated goblet cells (*arrowheads*). (Gomori trichrome; ×40 and ×400.)

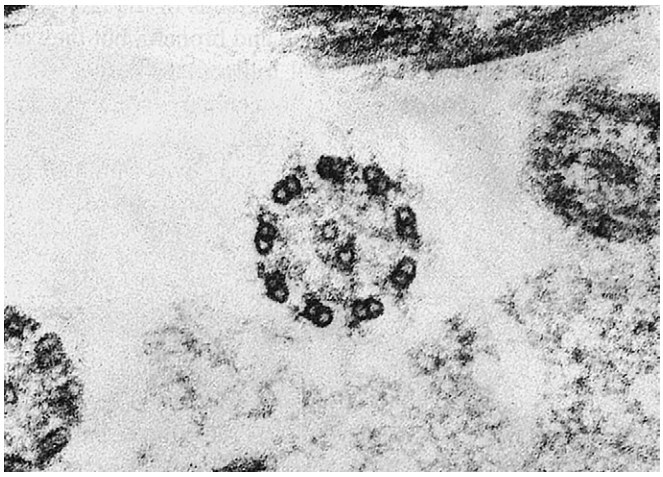

Figure 36–3. Internal structure of a cilium (no cell membrane evident) in which two axial tubules and nine peripheral duplex tubules are seen. Dynein arms are attached to several of the peripheral duplex tubules (×13,500).

more distal parts of the lung, mucous cells persist and can be found in very small bronchi and in some of the membranous bronchioles.

The bronchial mucosa contains several epithelial cell types: ciliated, mucus producing (goblet cells), basal, brush, and neuroendocrine. The ciliated cell constitutes more than 90% of the epithelial cell population in the conducting airways, but the proportion and number of cilia per cell decrease from the proximal to distal airways. The 9+2 microtubular structure within the cilia has been shown to be altered in the primary ciliary syndromes (Figure 36-3). In addition to its ciliary beating movement, the ciliated columnar cells regulate the depth of the composition of the periciliary fluid and transport ions across the epithelium. The basal cell has a progenitor cell role and also functions to maintain adherence of columnar cells to the basement membrane. The brush cell, thought to have a role in fluid absorption and/or chemoreceptor function, is found rarely in the tracheobronchial and alveolar epithelia.

The mucociliary apparatus is the primary defense mechanism in the respiratory system. Although mucous goblet cells secrete mucin, it is the submucosal glands that produce more than 90% of the mucus needed for mucociliary function. The glandular unit of the bronchial submucosa is comprised of mucous, serous, myoepithelial cells, collecting duct cells, and occasional neuroendocrine (Kulchitsky) cells. The physical characteristics of the mucous layer reveal that the superficial layer is more viscous than the deeper layer. This difference in consistency of the mucous layer allows the cilia to function properly, allowing a power and recovery stroke mechanism. The secretions include lysozyme, antileukoprotease, lactoferrin, and IgA. The secretory component of IgA is synthesized in bronchial gland cells and expressed on their basolateral cell surfaces to which IgA dimers synthesized by plasma cells bind. The complex is endocytosed by the glandular cell and then is secreted from its luminal surface.

Neuroendocrine cells can be solitary near the basal lamina between columnar cells or in collections called neuroepithelial bodies that occur near branch points of bronchi. A number of neural markers are expressed (e.g., 5-hydroxytryptamine, chromogranin A, neuron-specific enolase, synaptophysin) and a number of hormones are produced (e.g., endothelin, calcitonin, and bombesin [gastrin-releasing peptide]). They are more abundant in the fetus and likely have a role in lung growth or maturation.

Mast cells are an important population of cells found in great abundance in the submucosa and connective tissue in lungs. They contain cytoplasmic granules and produce two neutral proteases: chymase and tryptase. They release lysosomal enzymes (arylsulfatase, B-glucuronidase, myeloperoxidase) and various mediators (e.g., histamine, eosinophil chemotactic factor of anaphylaxis, and heparin), and they help mediate important physiologic events, such as IgE-dependent bronchial asthma.

Bronchus-associated lymphoid tissue (BALT) appears as isolated nodules in the connective tissue of the lamina propria of the bronchial tree and produces primarily IgG and secretory IgA. Collections of BALT cells tend to occur at airway bifurcations and are covered by a special epithelium that can undergo pinocytosis and transport solutes and particulate antigens. BALT is sparse at birth but starts accumulating thereafter. It is prominent in lungs of children and in diseased lungs of smokers and patients with bronchiectasis. Although more than 50% of the cells are B lymphocytes, T lymphocytes also are found (18%), along with follicular dendritic cells.[15] Sometimes these nodules bulge into the bronchial lumen. Additional lymphoid tissue in the lung is a rich supply of lymph nodes within the lung, at the carina, and along the trachea.

Although originally defined as having a lumen diameter less than 2 mm, the term "small airway" usually refers to a bronchiole. Histologically, the bronchiole is characterized by a transition from pseudostratified tall columnar epithelium to a more cuboidal ciliated form. In addition, the mucous goblet cell is replaced by the nonciliated Clara cell (Figures 36-4 and 36-5). In the bronchiolar epithelium, a ratio of about three ciliated cells to two nonciliated cells lines the lower airways. The Clara cell is identified as a dome- or tongue-shaped cell that protrudes into the bronchiolar lumen among the shorter ciliated cells. The Clara cell has varying features according to species but possesses an abundance of agranular reticulum and secretory granules. Clara cells synthesize and secrete Clara cell secretory protein (CC10, CC16), a unique 10-kDa protein similar to rabbit uteroglobin that has antiinflammatory and

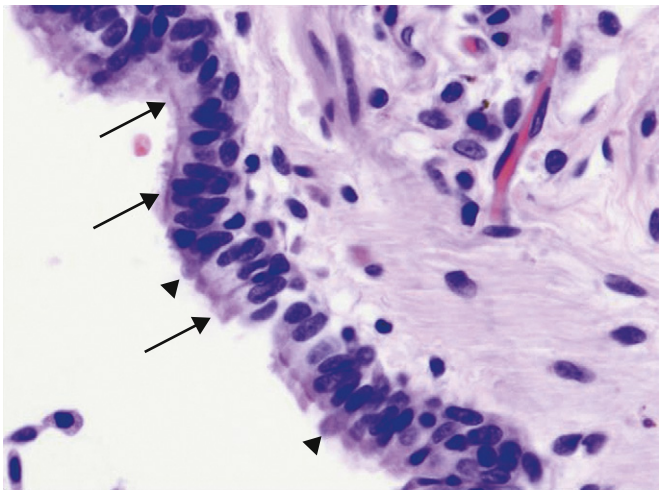

Figure 36–4. Distal conducting airway mucosa composed of some ciliated epithelial cells showing a terminal bar (*arrows*) and a noncilicated Clara cell (*arrowheads*). (Hematoxylin-eosin stain; ×400.)

immunoregulatory functions.[16] In addition, Clara cells secrete surfactant-associated proteins A, B, and D. Importantly, the Clara cell also functions as a progenitor cell that differentiates into ciliated cells following injury, and some investigators have shown that the Clara cell can differentiate into a type II epithelial cell.[17]

Within the wall of the bronchiole, the muscular layer becomes more prominent and submucosal glands and cartilage are absent. The bronchiole segment ends as a terminal bronchiole that marks the terminus of the conducting portion of the airway. The terminal bronchiole branches into two generations of respiratory bronchioles, which through further divisions give rise to additional respiratory bronchioles that have more alveoli in their walls, so-called second- and third-order respiratory bronchioles. By definition, respiratory bronchioles are alveolated, and they branch into two to three generations of alveolar ducts. The alveolar ducts are defined as those channels from which a series of alveoli open and are histologically characterized by having small clublike ends that contain muscle sphincters and elastic fibers. The ducts open

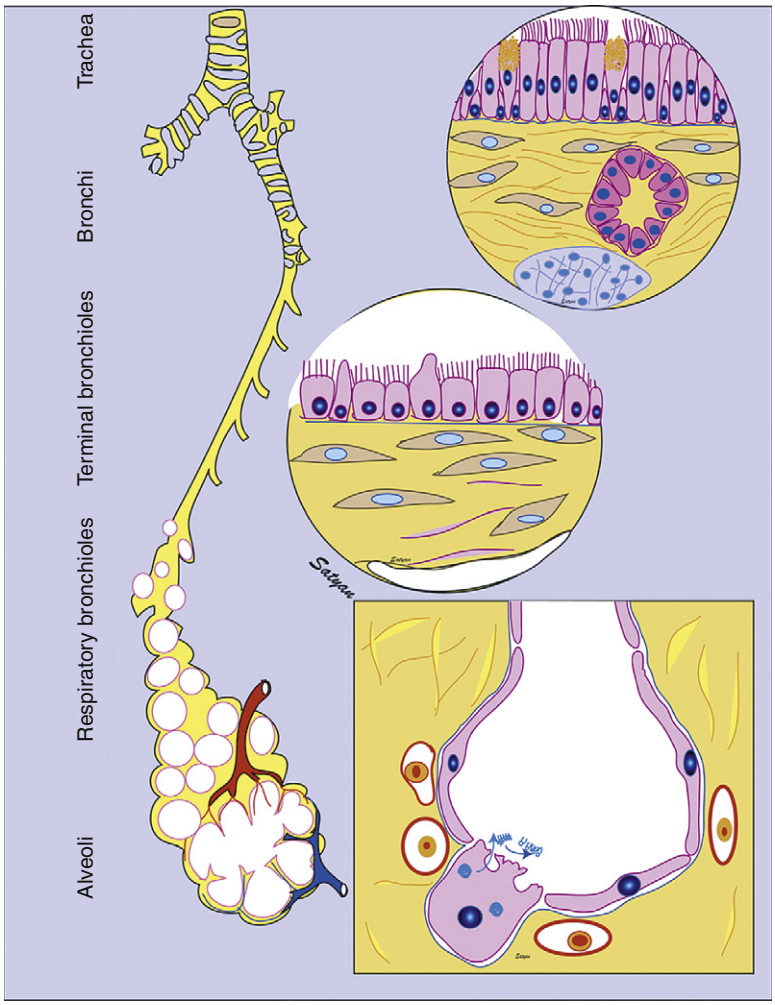

Figure 36–5. Respiratory tract epithelia. There is a progression from pseudostratified columnar epithelium with ciliated, goblet, and basal cells in the large conducting airways (*top circle*) to a more cuboidal ciliated epithelium in the small conducting airways with nonciliated Clara cells (*middle circle*). In the alveolar epithelium, flattened type I pneumocytes and cuboidal type II pneumocytes are present and are associated with an extensive capillary network (*box*). (Copyright Satyan Lakshminrusimha.)

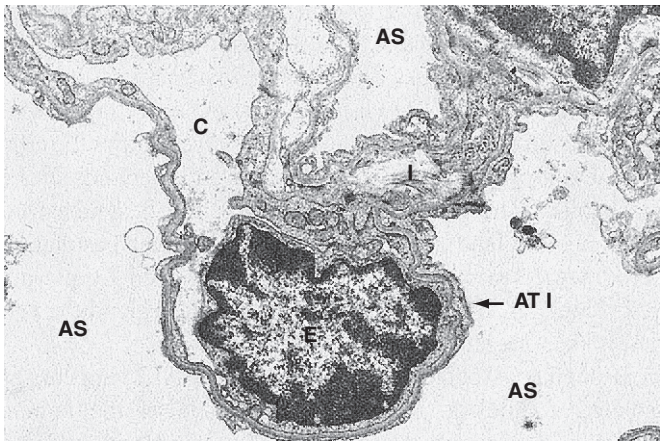

Figure 36–7. Both surfaces of the alveolar wall that separates the alveolar spaces (*AS*) are covered by thin extensions of alveolar type I epithelial cells (*ATI*). The capillary (*C*) is lined by endothelium (*E*). The epithelium and endothelium rest on a fused basement membrane on the thin portion of the alveolar wall and are separated by an interstitial space (*I*) in the thick portion of the alveolar wall (×5500).

into a final generation of alveolus-lined spaces, the multiloculated cup-shaped alveolar sacs (Figure 36-6).

Definitions of Special Lung Unit and Alveolar Formation

Each bronchopulmonary segment is further compartmentalized into smaller units termed *pulmonary lobules*. Each pulmonary lobule is supplied by a bronchiole that divides into a cluster of three to five terminal bronchioles and their associated respiratory tissue situated at the end of a bronchial pathway. The pulmonary lobule is roughly 1 to 2 cm in diameter, pyramidal in shape, and is bound by delicate connective tissue septa in which small proximal branches of pulmonary veins travel. The portion of the pulmonary lobule distal to the terminal bronchioles and consisting of several respiratory bronchioles, alveolar ducts, and ultimately alveoli is termed the pulmonary acinus. The acinus, which is approximately spherical in shape and has a diameter of about 7 mm and a length of 0.5 to 1 cm, is the gas exchange portion of the lung.

At the alveolar level, many changes occur in the postnatal period.[18-23] Although there is disparity concerning the time alveolarization is completed, evidence links the postnatal development of alveoli with elastic tissue fiber deposition.[20] At birth, primitive alveoli called saccules are evident, but approximately 50 million alveoli are already formed.[19] The number of alveoli in a normal adult can vary from 300 to 500 million, and they have a diameter of 150 to 200 μm. The early work by Dunnell[18] suggesting that new alveolar formation ceased at about age 8 years has been challenged by Thurlbeck,[22] who has shown that alveolarization appears to be nearly complete at about age 2 years. Lung volume correlates with body size, but alveolar surface area correlates with metabolic activity; thus alveoli become more complex in shape during maturation and as increasing levels of oxygen are required.

Alveolar-Capillary Unit

The alveolar-capillary unit is highly specialized to maximize diffusion between the blood and air gases (Figure 36-7).[24,25] The alveolar-capillary unit is comprised of three major constituents: the epithelial lining of the alveolus, capillary endothelial cells, and a mixture of cellular and extracellular intersitial components. This alveolar-capillary bed is the most extensive in the body and is contained within the epithelium-lined walls of adjacent alveoli, forming a gridlike network. The internal surface area of the adult lung is 70 to 80 m^2, of which 90% covers the pulmonary capillaries; thus the air-blood surface available for gas exchange is 60 to 70 m^2. The endothelial cells, which constitute about 30% of the total lung cells, contain few intracelluar organelles that are clustered together within the cytoplasm, allowing the cell to maximize its surface area. A number of adenine nucleotides, vasoactive amines, prostaglandins, vasoactive peptides, and lipoproteins can be metabolized and taken up within the numerous pinocytotic vesicles characteristic of pulmonary endothelial cells.

In addition to gas exchange, endothelial cells synthesize and secrete various locally acting substances such as nitric oxide, endothelins, prostacylin, tissue plasminogen activator, and thrombomodulin. Other functions include liquid and solid exchange and enzyme activity within the walls of the caveolae. At the ultrastructural level the blood-air barrier consists of a 0.1 to 0.2 μm thick septum comprised of a capillary endothelial cell and the type I pneumocyte with their intervening fused basal laminae. Within thicker portions of the alveolar wall, the alveolar epithelium and capillary endothelium are separated by the interstitial space.

The connective tissue space, or interstitium of the lung at the alveolar level, does not have lymphatics, but it can accumulate fluid that can be absorbed into the lymphatic system, which ends usually at the respiratory bronchiolar level. The interstitial cell population includes resident and migratory cell populations. Normally the interstitium contains macrophages, pericytes, myofibroblasts, mast cells, infrequent lymphocytes, and a few cells that are best termed undifferentiated, mesenchymal, or pluripotential because in disease they can differentiate into various cell types including fibroblasts, smooth muscle cells, and others. More than 25% of the interstitial cells cannot be identified definitively with the electron microscope, so it is understandable why most of the cells cannot be identified by light microscopy without special cell marker stains.

Figure 36–8. Electron micrograph showing the thin side of the air-blood barrier. The thin cytoplasmic extension of the type I epithelium contains only a few vesicles and shares a fused basement membrane with the endothelium that contains many caveolae (×18,000). *AS,* Alveolar space; *C,* capillary.

Figure 36–9. Cytoplasm of the alveolar type II cell has abundant lamellar inclusion bodies and surface membrane microvilli (×7500).

Two epithelial cell types line the alveoli. Type I cells have thin cytoplasmic extensions and have a very large surface area covering approximately 90% of the total alveolar surface (Figure 36-8). Numerically they form only about 40% of the epithelial cells, whereas the type II cell, which is cuboidal, constitutes 60% of the total number of epithelial cells but contributes less than 10% of the total alveolar surface area. Type I cells are exquisitely well adapted to allow for the rapid exchange of gases, and their micropinocytotic system probably plays a major role in the transport of solutes, such as albumin and immunoglobulin, in small quantities. They can be induced to ingest some particulates and can increase their number of pinocytotic vesicles, but they are not active in surfactant uptake.

The type II cell is the regenerative cell of the alveolar epithelium, serving as the stem cell following injury. It can repopulate the alveolar surface in about 5 days. It is cuboidal in shape and only numbers about one per alveolus. Ultrastructurally the type II cell has characteristic surface microvilli and cytoplasmic lamellar inclusions, which are the intracellular cytoplasmic storage forms of pulmonary surfactant (Figure 36-9). The inclusions evolve from multivesicular bodies or lysosomal granules, which progressively acquire the characteristic lamellae. In addition to its roles in the synthesis, secretion, and reuptake of surfactant, the type II cell synthesizes arachidonic acid metabolites, synthesizes and secretes connective tissue components of the basement membrane including fibronectin, synthesizes and secretes components of the complement system, expresses class II proteins of the major histocompatibility complex, among others, and has been found to be a critical source of many different growth factors during injury and repair.

Considerable data demonstrate clearly that several populations of macrophages exist: intraalveolar (pulmonary alveolar macrophage), septal (interstitial), pulmonary intravascular, and airway. Within the alveolar spaces, alveolar macrophages are abundant and form an important arm of the defense mechanism of the lung (Figures 36-10 and 36-11). They number approximately 23×10^9 in the lung (10% of the total cells of the alveolar compartment), and 50 to 100 are estimated per alveolus. They derive from three sources: bone marrow via blood monocyte, the interstitial macrophage pool, and proliferation of macrophages in the alveolar space. They are actively phagocytic and scavenge the surface of the alveoli for respired particulates (macrophages as so-called "dust cells"). Although seen free-floating in alveolar spaces in light microscopic preparations, the alveolar macrophage crawls along the surface of the epithelium, adhering with its filopodia. The macrophage has remarkable metabolic activities, has known immune functions, and is involved in lung injury and repair phenomena. Alveolar macrophages also play a role in surfactant uptake, removal, or catabolism. More than 100 macrophage-synthesized mediators have been identified, including many proinflammatory cytokines, and numerous ligands have been demonstrated. In normal bronchoalveolar lavage fluid, 90% of the cells are alveolar macrophages and 1% to 5% are lymphocytes (T-cell lymphocytes constituting 60% to 70% and B cells constituting 5% to 10%).

Lung Circulation

Pulmonary Vascular System

The pulmonary circulation is furnished by the pulmonary and the bronchial vascular systems.[26,27] During gestation, branches of the pulmonary arterial system are thick-walled and contain a medial layer of smooth muscle. At birth, the pulmonary artery and aorta are comparable in medial thickness and configuration. Elastic fibers tend to be long, uniform, unbranched, and parallel with one another. Following birth, the pulmonary vasculature undergoes extensive remodeling and by 2 years of age shows a media composed of short, branched, and loosely arranged elastic fibers. When fully matured, the pulmonary artery and its thickness is only about 60% that of the aorta. Only a few muscular arteries are seen accompanying terminal bronchioles at birth. Following birth, when pulmonary arterial pressures fall to normal levels, the muscle fibers diminish. Initially new vessels without muscle are formed, along with new respiratory units during lung growth. Smooth muscle extends peripherally into small arteries slowly, reaching arterioles at the respiratory bronchiolar level at 4 months, at the alveolar duct level at 3 years, and some alveoli at age 10 years.[28]

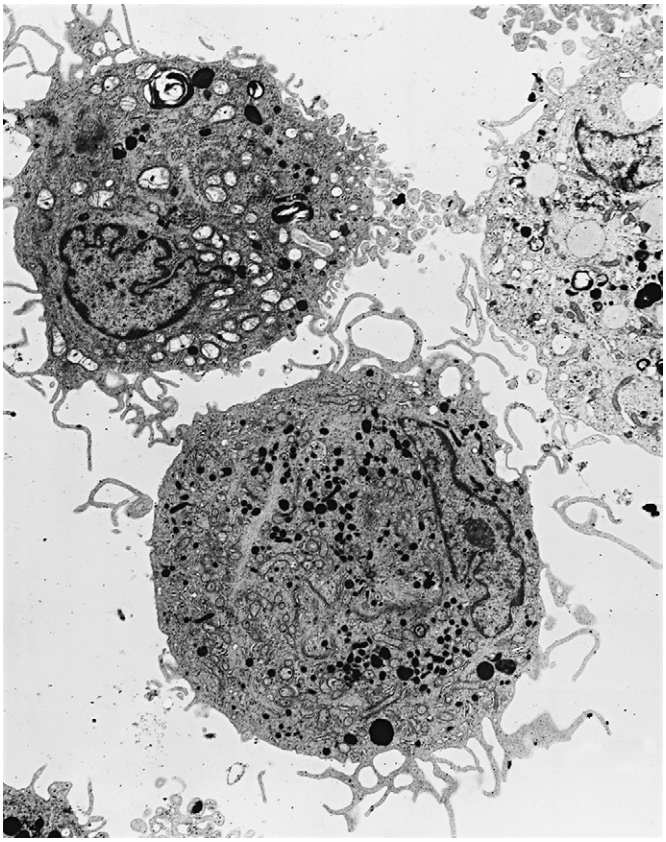

Figure 36–10. Alveolar macrophages recovered from bronchoalveolar lavage fluid contain abundant lysosomes and other cytoplasmic contents, including lipid droplets and surfactant remnants (×5300).

The criteria for recognizing various types of pulmonary vessels were put forth by Brenner[29] in 1935. The pulmonary arteries, which exceed 1000 μm in external diameter, are called elastic pulmonary arteries and traverse with the cartilaginous airways. They extend from the hilum to nearly halfway in the bronchial tree of the newborn, a pattern completed by week 16 of gestation and retained into adulthood. Pulmonary arteries measure between 100 and 1000 μm in diameter and have a distinct muscular media and internal and external limiting elastic membranes. The muscular arteries of the lung have thinner media than do their counterparts in the systemic circulation. Muscular pulmonary arteries branch with the bronchial tree and lie close to bronchi and bronchioles (Figure 36-12). Pulmonary arterioles are vessels that measure 100 μm in diameter and have only an endothelial lining and a single elastic lamina with little, if any, muscular media. These vessels usually are seen at the level of the alveolar ducts and in certain sites within the alveolar walls. Pulmonary capillaries are nonfenestrated, whereas bronchial capillaries are fenestrated. The appearance of pulmonary venules is identical to that of pulmonary arterioles, and serial sections are required to differentiate the two. In contrast with the pulmonary arteries, the larger branches of pulmonary veins do not course with the bronchial tree and instead are seen within the interlobular septa. The media of larger veins is composed of smooth muscle fibers, collagen,

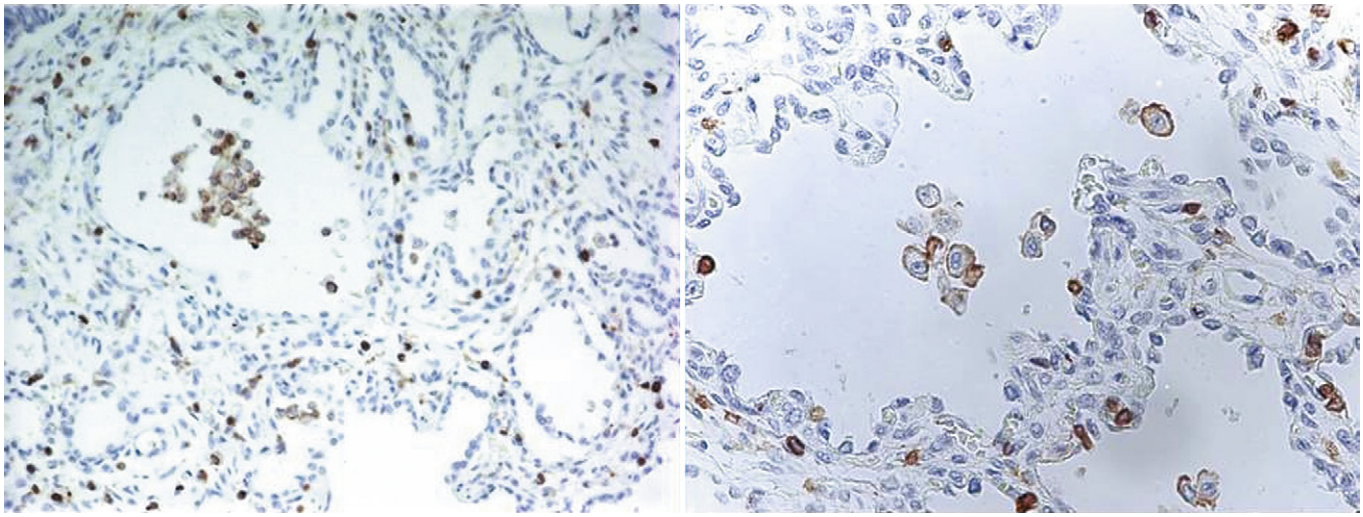

Figure 36–11. Sections obtained from infants who died with bronchopulmonary dysplasia. Pulmonary macrophages present within air spaces were immmunostained (brown stain) with anti-CD45, a general leukocyte marker. Leukocytes are also identified within the alveolar walls and capillaries (hematoxylin counterstain; ×200 *left,* ×400 *right). (Courtesy Dr. Gloria Pryhuber.)*

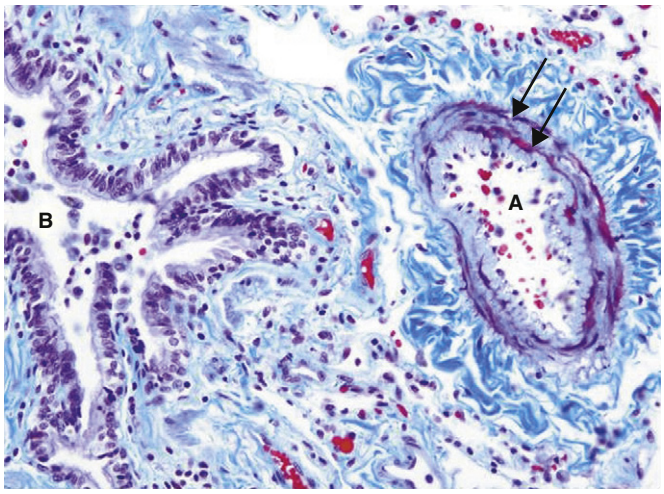

Figure 36–12. Small muscular pulmonary artery (*A*) traveling with a bronchiole (*B*). Two layers of smooth muscle cells are present in the vascular media (*arrows*). (Gomori trichrome; ×200.)

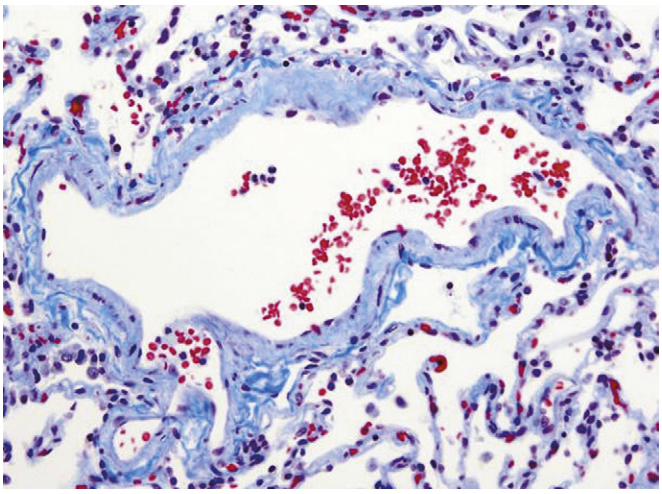

Figure 36–13. Pulmonary vein. The media is composed of loose, pale, blue-staining collage fibers with scarce smooth muscle present. (Gomori tricrome, ×200.)

and elastin, and unlike their arterial counterpart, show no clear internal and external elastic lamina (Figure 36-13).

Bronchial Vascular System

Whereas the pulmonary circulation returns all venous blood to the lung and serves some nutritive function to peripheral capillaries, the bronchial circulation is the primary blood source for the lung. Although two major bronchial arteries for each lung is a common pattern, this pattern is present less than 40% of the time. There usually are two bronchial arteries in the left lung and one in the right lung. Although variable, the left bronchial arteries usually arise from the upper portion of the descending aorta. The right bronchial artery arises from the descending aorta, one of the right intercostal branches, or subclavian or internal thoracic arteries. The bronchial arteries traverse along the dorsal portion of each bronchus. They lose their distinctness along the respiratory bronchioles and drain with the alveolar capillaries into the peribronchiolar venous network. They form a capillary plexus in the bronchi that supplies the submucosa and muscle. The capillary plexus communicates with branches of the pulmonary artery that empty into pulmonary veins. Other bronchial arteries supply the interlobular tissue and the pleura. They drain into the bronchial veins. The diameter of the bronchial artery is much smaller than that of the accompanying pulmonary artery. It has an internal elastic lamina and media but no external elastic lamina.

Pulmonary Lymphatics

Pulmonary lymphatics invariably have less elastic tissue in their walls than either arteries or veins.[11,30] They are lined by endothelium, and valves are present, especially near and in the visceral pleura. There are two lymphatic systems in the human lung: a superficial network in the pleura and a deep network around the bronchi and pulmonary arteries and veins and in the connective tissue septa between the pulmonary lobules. The two separate systems have anastomoses, both in the pleura and near the hilum. Lymphatics can be demonstrated to the level of the septal walls but are not found at the alveolar level. Lymph flow from both lower lobes drains into the infratracheal lymph nodes. The remaining right and left lung lobes drain into the tracheobronchial lymph nodes on each side of the trachea, respectively. Lymph from the right tracheobronchial nodes drains into the right bronchomediastinal trunk, whereas the left tracheobronchial nodes drain into thoracic duct.

Understanding the lymphatic drainage of the pleura is of clinical value. All lymph from the visceral pleura eventually reaches parabronchial and hilar lymph nodes by flowing either on the surface or in lymphatic trunks that course through the lung. Lymphatic vessels in the parietal pleura are in communication with the pleural space via 2- to 6-mm stomas found on the mediastinal pleura or the intercostal surfaces of the lower thorax. Because the parasternal nodes in the second and third interspaces receive lymph from a significant portion of the parietal pleura, biopsy of these nodes may reveal an etiology of the pleural effusion. The portion of lymph that drains caudally from the lower parietal pleural region into retroperitoneal nodes can explain metastases of tumor to the adrenals and kidneys.

Diaphragm

Although the diaphragm is the principal muscle of respiration, it is not essential for breathing in the awake state. It becomes essential during deep anesthesia because other muscles of respiration become inactive. The diaphragm is a musculotendinous sheet that is the main source of inspiratory muscle force. Anatomically it separates the thoracic from the abdominal cavity. It has two distinct muscular components: the sternocostal portion and the crural portion. These two portions have distinct embryologic origins and have separate segmental innervations and varying muscle fiber composition. Following birth, changes in fiber composition occur. The muscle fibers vary morphologically, physiologically, and cytochemically. The diaphragm has three openings near its central portion for the aorta, inferior vena cava, and esophagus. The vagus nerve passes through the esophageal hiatus, whereas the azygos vein and thoracic duct pass through the aortic hiatus. There are small paravertebral perforations for

splanchnic nerves. Because of the way the fibers originate from the bones and traverse to the central tendon, triangular areas may result in spaces or clefts in the diaphragm. Anteriorly these spaces or clefts are called Morgagni foramina, and posteriorly they are known as the foramina of Bochdalek. Both are potential sites for hernias. The phrenic nerve innervates the diaphragm.

During contraction in adults, the dome of the diaphragm descends and the lower ribs elevate. In infants, because of their very compliant rib cage, descent opposes elevation of the lower ribs and results in the subcostal retractions. Other muscles of respiration include the intercostals, the majority of which are arranged to enhance inspiration by elevating the lower ribs, and the abdominal muscles, which are powerful muscles of expiration but do not participate in expiration during quiet breathing. Scalenes act to elevate the first two ribs and are active even during quiet breathing. Although the sternocleidomastoid muscles usually are not active in quiet breathing, when inspiratory efforts are marked, they become the most important accessory muscles of inspiration. This phenomenon is well seen in infants with respiratory distress who elevate the upper portion of their sterna.

Summary

The respiratory portion of the lung is a complex organ with more than 40 cell types. It undergoes remodeling over the first few years of life. Altered structure, whether due to congenital abnormalities or due to injury and repair, is a critical determinant of survival and quality of life. Understanding the structure of the lung is critical to the management and treatment of lung disease in critically ill children.

Physiology of the Respiratory System

Mark J. Heulitt and Katherine C. Clement

PEARLS

- During childhood, the most important chest diseases have obstructive pictures that are best measured utilizing interrupter and oscillation techniques.
- Wheezing is a sound heard when there is flow limitation in a compliant tube. It is a sign of expiratory flow limitation. The wheezing is caused by "flutter" of the walls at the site of flow limitation secondary to the conservation of energy in the system.
- The respiratory system is not a linear system; resistance and compliance are not constants. They are dependent upon volume, volume history, and flow.
- The equation of motion changes when a spontaneously breathing patient is placed on positive pressure mechanical ventilator support. The pressure applied to the airway (P_{APP}) equals the sum of pressure generated by the patient's muscles (P_{mus}) plus the ventilator pressure (P_{vent}). Thus:

$$(P_{mus} + P_{vent} = \left(\frac{1}{C}\right)\dot{V} + RV)$$

Physiology of the Respiratory System

Because of the increasing emphasis on molecular biology today, many physicians currently in training have received limited exposure to physiologic principles that form the basis of clinical medicine. However, a resurgence of interest in translational research has occurred recently with a reemphasis on molecular research and applied animal physiology before these principles are utilized in clinical research.[1] In a recent editorial in the *European Journal of Physiology*, Rossier[1a] stated that research is refocusing itself to make a change from the past, where its mantra was "from function to the gene," to the future, where the focus must be on the "gene to function." The focus of this chapter will be to expose the reader to the important basic principles of respiratory physiology and to serve as a primer to other chapters in this book that utilize these principles.

The main function of the lungs is (rapid) gas exchange. This process is accomplished by a well-coordinated interaction of the lungs with the central nervous system, the diaphragm and chest wall musculature, and the circulatory system.

Gas exchange occurs in the alveolus, where the thin laminar blood flow and inspired air are separated only by a thin tissue layer. Gas exchange takes 0.25 seconds or one third of the total transit time of a red cell. The entire blood volume of the body passes through the lungs each minute in the resting state, approximately 5 L/min. The total surface area of the lung is about 80 meters square, equivalent to the size of a tennis court. The primary function of the lungs is to supply oxygen (O_2) and to remove carbon dioxide (CO_2) from the tissues of the body. For the lungs to do this, two interrelated processes must occur: ventilation, which is the movement of air between the outside body and the alveoli, and gas exchange, which is the transfer of O_2 and CO_2 between the alveolar gas and the mixed venous blood entering the lungs.

Approximately 10% of the lung is occupied by solid tissue, whereas the remainder is filled with air and blood. However, it should be noted that changes occur with development. A gram of lung from an infant probably represents more airway tissue and less parenchymal (alveolar and interstitial) tissue than the same amount of lung from an adult. Supporting structures of the lung must be delicate enough to allow gas exchange yet strong enough to maintain the architectural integrity needed to sustain alveolar structure. The functional structure of the lung can be divided into (1) the conducting airways (dead air space) and (2) the gas exchange portions. The two plumbing systems are airways for ventilation and the circulatory system for perfusion. Both systems are under low pressure.

Conducting Airways

The diameter of the lower airways is maintained by a balance of forces. Sympathetic impulses relax and parasympathetic impulses constrict the muscles. Airway dilatation may occur as a result of sympathomimetic agents (e.g., epinephrine or adrenaline). Narrowing forces are bronchial smooth-muscle contraction, mediated by efferent autonomic nerve control. Constriction also can occur as a result of irritants (e.g., dust, smoke, or cold), hyperventilation, and vasoactive agents (e.g., acetylcholine, histamine, or bradykinin).

Additional narrowing occurs during forced expiration, when there is dynamic airway compression caused by pleural and peribronchial pressures. This narrowing is counteracted by the intraluminal pressure and the tethering action of the surrounding lung. The luminal diameter of a branch

is related to the number of alveoli at the end of that branch (axial and lateral pathways). Because the longer airways with more branches and more alveoli usually have a wider lumen that allows greater airflow, newly inspired air reaches all of the alveoli throughout both lungs at the same time and in approximately the same amount, that is, an even distribution of inspired air throughout all lobes in a given period of time. There are approximately 23 airway divisions to the level of the alveoli. The divisions include main bronchi, lobar bronchi, segmental bronchi (to designated bronchopulmonary segments), and so on to the smallest bronchioles, which do not have alveoli and are lined completely by bronchial epithelium. These are the terminal bronchioles. Although the base airway diameter decreases with branching, the overall or total cross-sectional diameter increases tremendously so that peripheral airway resistance decreases.

Model of the Respiratory System

The respiratory system can be represented by a collection of physical components interacting with one another and with their environment. Although in vivo analysis demonstrates that the lungs do not function as a single compartment, analyzing the respiratory system in a linear model simplifies the presentation.

A single balloon on a pipe is the simplest model, although this model has its deficiencies because the airway is more complex than a simple pipe. Also, it now appears that the alveolus is not simply a single balloon or group of balloons similar to a cluster of grapes. It is now known that the alveoli are not physically independent structures but are actually interconnected.[2] An excellent review of the structure of the alveoli and the role of surfactant is offered by Gatto et al.[3] However, to lay the ground work for our understanding of respiratory mechanics, we will consider the simple model of a balloon on a pipe.

The relationship at any moment (t) between the pressure applied at the opening of the model (P(t)) and the volume in the model (V(t)) during emptying of this balloon can be described as a first-order model:

$$P(t) = E \bullet V(t) + R + \dot{V}$$

where *E* is the elastance of the balloon, *R* is the resistance of the pipe, and $\dot{V}$ is the flow through the opening. Using regression analysis, E and R can be calculated from P(t), V(t), and V′(t).

The values of R and E, as applied to the respiratory system, reflect the resistance of the airways and the elastance of the respiratory system, whereas V(t) is the volume increase from functional residual capacity (FRC) when the mouth pressure is zero.

The three important components of this linear model are the time constant (τ), compliance (C) or elastance (E), and resistance (R). The relationship of these is given by the equations:

$$\tau = C \times R \text{ or } \tau = R/E$$

Each of these components will be discussed separately.

Elastic Properties of the Respiratory System

The respiratory system is composed of a collection of elastic structures. The response to a force applied to the elastic structure of the respiratory system is to resist deformation by producing an opposing force, known as elastic recoil, to return the structure to its relaxed state.[4] In the respiratory system this opposing force produces a pressure known as the elastic recoil pressure (P_{EL}). The force required to stretch an elastic structure depends on the volume at which the outward recoil of the chest wall balances the inward recoil known as the elastic equilibrium volume. The pressure of the elastic recoil or P_{EL} divided by the lung volume (V) gives a measure of the elastic properties of respiratory system and is called elastance (E):

$$E = P_{EL} / V$$

When lung volume is plotted on the ordinate and P_{EL} is plotted on the abscissa, the slope of the static pressure-volume curve is equivalent to the reciprocal of elastance, called *compliance*.

For ventilation of the lungs to occur, the forces necessary to overcome the elastic, flow-resistive, and inertial properties of the lungs and the chest wall must be produced to create motion of the respiratory system. In normal circumstances, respiratory muscles produce these forces.

Overcoming forces to move gas into the airway can be exemplified by moving a block of wood over a surface. The movement of the block is determined by the friction between the block of wood and the surface and how fast the wood is moving. It is irrelevant what the block's position is. Similarly, the pressure required to produce a flow of gas between the atmosphere and the alveoli must overcome the frictional resistance of the airways. This pressure is proportional to the rate at which volume is changing or flow ($\dot{V}$) as follows:

$$P_{mouth} - P_{alv} = P_{fr} \alpha \dot{V} \text{ or } P_{ao} - P_A = P_{fr} \alpha \dot{V}$$

where P_{ao} is pressure at the airway opening (usually atmospheric pressure), P_A is the alveolar pressure, and P_{fr} is the pressure required to overcome frictional resistance. The pressure required to produce a unit of flow is known as flow resistance (R):

$$R = P_{fr} / \dot{V}$$

If the respiratory system is modeled as a single compartment with a single constant elastance (E) and a single constant resistance (R), then the equation of motion describes the balance of forces acting on the system is as follows:

$$P = EV + R\dot{V} + I\dot{V}$$

The inertia (*I*) is usually negligible and therefore ignored. Of the pressure produced during normal tidal respiration, most is required to overcome the elastic forces, and a minimal amount is required to overcome the flow-resistant forces.

Traditionally it was thought that little energy was dissipated by the tissues of the respiratory system and that the majority of the force developed during breathing was required to move gas through the airways. The lung parenchyma is a complex system consisting of alveolar walls composed of collagen, elastin, and proteoglycan macromolecules; an air liquid interface of surfactant; and cells that have the capacity to act in a contractile fashion, called interstitial cells. The viscoelastic behavior of the pulmonary parenchyma could potentially explain this behavior. In addition, this action is difficult to study because it is unclear where the boundary of the airways end and parenchyma begins. Airway smooth muscle exists in the terminal bronchioles and alveolar ducts, and the behavior of these structures may well influence parenchymal mechanics.

The energy expended moving the tissue is called the tissue viscance or resistance, although it is a non-Newtonian resistance. In other words, the viscosity depends upon the force applied. When measured during inspiration, the tissue resistance increases with increasing lung volume, whereas airway resistance falls. Tissue resistance comprises approximately 65% of respiratory system resistance at FRC in mechanically ventilated animals and increases as much as 95% at higher lung volumes.[5] The contribution of tissue resistance to respiratory system resistance in humans under the same circumstances is unknown.

Resistance is expressed as changes in pressure divided by changes in flow:

$$R = \Delta P / \Delta \dot{V}$$

The other part of elastic recoil depends upon the surface tension at the alveolar gas-liquid interface (surface forces). Surface tension is produced by the interface between air in the alveolus and the thin film of liquid that covers the alveolar surface. Surface tension in the alveolus is created by interacting water molecules that direct a force inward and could cause the alveoli to collapse. This action is described by La Place's equation where the pressure inside a bubble exceeds the pressure outside the bubble by twice the surface tension, divided by the radius. In other words, the smaller a bubble, the more the pressure inside exceeds the pressure on the outside. La Place's equation is defined as:

$$P = 2T / r$$

where *P* is the internal pressure, *T* is the tension in the wall of the structure, and *r* is the radius. When comparing two different alveoli with the same surface tension, the smaller the radius, the greater the pressure created by a given surface tension. Air will flow from high pressure (small alveoli) to lower pressure (larger alveoli). Thus smaller alveoli are more likely to collapse. The surface tension of the alveoli is affected by a substance produced in the alveoli called surfactant. Surfactant contains a mixture of lipids and proteins, is manufactured by alveolar type II cells, and exists as a monolayer on top of the alveolar subphase. Three surfactant-associated protein groups have been identified.[6] Surfactant acts to lower surface tension at the alveolar air-liquid interface and thereby decreases elastic recoil of the lungs.[7] Another action of surfactant is to reduce the development of pulmonary edema by diminishing one component of the pressure gradient driving transudation. In the lung there is a gradient between pulmonary capillary pressure and the interstitial pressure that surrounds the capillary. In most of the lung, the pulmonary capillary pressure is greater than the interstitial pressure; thus pulmonary edema would develop if not checked by the oncotic pressure of the plasma proteins. By reducing surface tension, the surfactant reduces the interstitial pressure and transcapillary gradient, but if there is a deficiency of surfactant and thus a rise in surface tension, pulmonary edema may develop.[8] Also, surfactant has been described as an anti-wetting agent that helps to keep the lungs dry.[9] Currently there is agreement on the fact that surfactant plays an essential role in alveolar mechanics, but its mechanism is debated. The aforementioned description outlines the classic discussion on the role of surfactant, but diverse opinions exist on its true role. Scapelli[10] has described the role of the surfactant foam bubbles within the alveoli as "inner tubes." In contrast, Hills proposes that surfactant coats the alveolar walls as a "biologic wax."[11,12] The clinical implications of a deficiency of surfactant has been described in a famous editorial by Lachman entitled "Open up the Lung and Keep the Lung Open."[13]

Compliance and Elastance

Compliance is how much a compartment will expand if the pressure in that compartment is changed. An elastic balloon has a high compliance because a small pressure increase inside the balloon will greatly expand the balloon. A rigid tube has a low compliance because a small pressure increase inside the rigid tube will not result in a significant increase in the volume of the rigid tube. Two major forces contribute to lung compliance: tissue elastic forces and surface tension forces. The compliance (C) is determined by the change in elastic recoil pressure (ΔP) produced by a change in volume (ΔV):

$$C = \Delta V / \Delta P$$

The compliance of the lungs (C_L), chest wall (C_{CW}), and respiratory system (C_{RS}) can be determined by measuring the change in distending pressure and the associated change in volume. The distending pressure represents the pressure change across the structure, where P_{ao}, P_{pl}, and P_{bs} represent the pressure measured at the airway opening, pleural pressure, and pressure at the body surface (atmospheric pressure), respectively:

$$C_L = \Delta V / \Delta (P_{ao} - P_{pl})$$
$$C_{CW} = \Delta V / \Delta (P_{pl} - P_{bs})$$
$$C_{RS} = \Delta V / \Delta (P_{ao} - P_{bs})$$

Lung volume and volume-pressure relationships (e.g., compliance) reflect parenchymal (air space) development, whereas airflow and pressure-flow relationships (resistance and conductance) predominantly reflect airway development. The lungs become stiffer (compliance decreases) at higher lung volumes.

Pulmonary compliance changes with growth and maturation depending upon the number of expanded air spaces, the size and geometry of the air spaces, the characteristics of the surface lining layer, the properties of the lung parenchyma. This shift is represented by changes in the shape of the volume-pressure curve. When these curves are corrected by expressing the volumes as a percentage of the maximal observed lung volume, they are more curved in infants than in older children (Figure 37-1).[14] It is important to note that there may be boundaries for dynamic changes in alveolar size and shape during ventilation because of the tensile forces of the connective tissue and surface tension supporting the alveoli and alveolar ducts.

The developmental change in shape of the volume pressure curve represents the maturation of alveoli and hence differences in the elastin-collagen ratio with age.[14] The lung volume (as a percent of maximal lung volume) at which airway closure occurs is higher in children younger than 7 years[15] and is closer to their functional residual volume. Pressure-volume relationships are also more curvilinear in infants.[16] Chest wall compliance is 50% greater in infants.

Elastance is defined as the change in distending pressure divided by the associated change in volume:

$$E = \Delta P / \Delta V$$

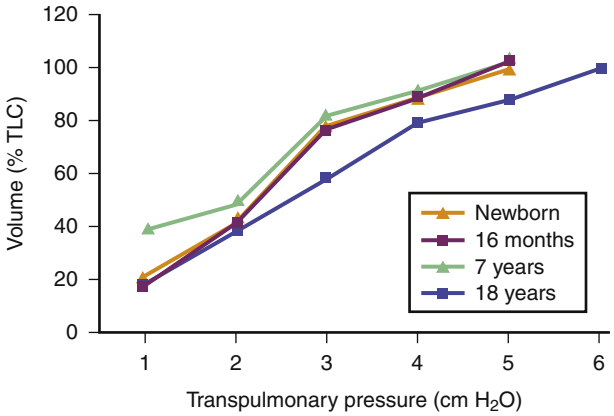

Figure 37–1. Deflation volume-pressure curves of the lung at different ages (obtained from studies on excised lungs).[8] With increasing age up to young adulthood, the curves become straighter and, at a given lung volume, elastic recoil pressure is greater. The curve from elderly individuals resembles that from a 7-year-old respiratory system. *TLC,* Total lung capacity.

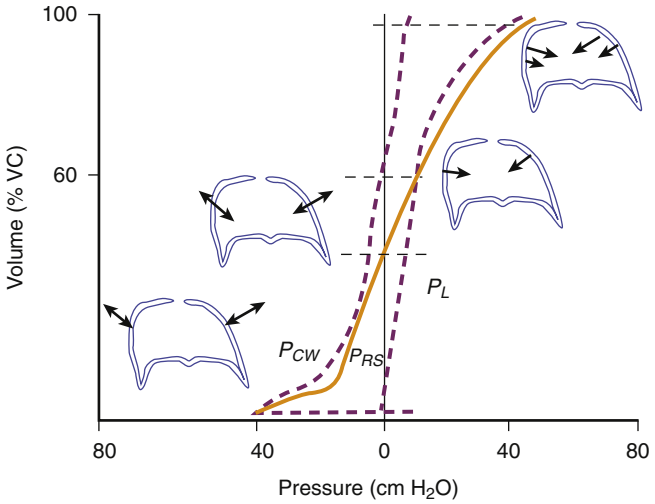

Figure 37–2. Pressure-volume relationship of the lung (P_L), chest wall (P_{CW}), and entire respiratory system (P_{RS}). *Large arrows* represent the elastic recoil of the lungs and the chest wall. *(Modified from Agostoni E, Mead J: Statics of the respiratory system. In Fenn WO, Rahn H, editors:* Handbook of physiology, respiration, vol 1, *Washington, DC, 1964, American Physiological Society, p 392.*

Elastance is therefore the reciprocal of compliance; thus stiff lungs have a high elastance.

Elastic Recoil of the Respiratory System

In the intact thorax, the inward recoil of the lungs is opposed by the outward recoil of the chest wall (when it is below its resting volume). Both the lungs and the chest wall recoil inward when chest volume exceeds its resting volume. These recoil forces act as though arranged in series.

The pressure required to balance the elastic recoil of the lungs, chest wall, and respiratory system (elastic recoil pressure) may be determined by having a subject exhale in increments from total lung capacity (TLC) to residual volume. At each volume, the subject relaxes against a fixed obstruction with glottis open, and the pressure difference across the lung, chest wall, and entire respiratory system is recorded. Pressure volume curves are derived in this way for the respiratory system, and its components are shown in Figure 37-2.[17] The static pressure-volume curves of the respiratory system, lung, and chest wall are different during inspiration and expiration. Thus lung volume at a given transpulmonary pressure is higher during deflation than during inflation. This phenomenon is called hysteresis. Hysteresis is the failure of a system to follow identical paths of response on application and withdrawal of a forcing agent, as occurs during inspiration and expiration. Hysteresis in the respiratory system depends on viscoelasticity, such as stress adaptation (i.e., rate-dependent phenomenon), and on plasticity (i.e., a rate-independent phenomenon). In the lungs, hysteresis is due primarily to surface properties and alveolar recruitment-derecruitment. In comparison, the chest wall hysteresis is related to the action of both muscles and ligaments because both skeletal muscles and elastic fibers exhibit hysteresis. Hysteresis is negligible when volume changes are minimal, such as during quiet breathing. This phenomenon is important because the area of the hysteresis loop represents energy lost from the system.

The resting volume of the respiratory system, the FRC, is the volume at which the elastic recoil of the lungs and the chest wall exactly balances each other. Above and below this equilibrium point, progressively increasing pressure is required to change the volume of the respiratory system. The total pressure required at each volume is the sum of the pressures required to overcome the elastic recoil of the lungs and chest wall.

Flow Resistance of the Respiratory System

The response of the lung to movement is governed by its response to the physical impedance of the respiratory system. The impedance can be categorized into (1) elastic resistance between the alveolar gas/liquid interface and tissue and (2) frictional resistance to gas flow. Under static conditions, pressure is required only to oppose the elastic recoil of the respiratory system. However, when the lungs and chest wall are in motion and movement of air into and out of the lungs occurs, pressure also must be provided to overcome the frictional or viscous forces. The ratio of this additional pressure (P) and the rate of air flow that it produces ($\dot{V}$) is defined as the resistance:

$$R = P / \dot{V}$$

In other words, the flow ($\dot{V}$) measured at the mouth depends on the driving pressure (i.e., the pressure difference between alveoli [P_{alv}] and mouth [P_{mo}]) and the airway resistance (R_{aw}):

$$\dot{V} = (P_{mo} - P_{alv}) / R_{aw}$$

If the mouth pressure is zero (i.e., atmospheric pressure), the driving pressure is the alveolar pressure.

Airways resistance (R_{aw}) is the sum of the peripheral airways resistance (peripheral intrathoracic airways <2 mm diameter; R_{awp}), the central airways resistance (large intrathoracic airways >2 mm diameter; R_{awc}), and the extrathoracic airways resistance (especially glottis; R_{ext}). In healthy people, R_{ext} accounts for 50% of the total R_{aw} and R_{awp} for about 15%. R_{awp} and R_{awc} are influenced by lung volume. Higher lung volumes give higher P_{el} and therefore increase airway diameter. With increasing volumes during inspiration, the increased

P_{el} is counteracted by P_{pl}, resulting in increased radial distending force. This distending force is the transmural pressure and is the difference between pressure in (P_{in}) and pressure outside (P_{out}) the airway.

At zero airflow the pressure inside the airways (P_{in}) equals atmospheric pressure and transmural pressure (P_{tm}) equals the elastic recoil pressure (P_{el}):

$$P_{in} = P_{mo},\ P_{tm} - P_{el}$$

The total respiratory resistance (R_{rs}) consists of the resistance of the airways (R_{aw}), the resistance of the lung (R_L), and the resistance of the chest wall (R_{cw}):

$$R_{rs} = R_{cw} + R_L + R_{aw}$$

In older children, R_{cw} and R_L represent only 10% to 20% of R_{rs},[18] but in newborns, R_L could be higher.[19]

Airway diameter of the intrathoracic airways approximates to a sigmoidal relationship with P_{tm}. This relationship results in volume dependency of R_{aw}. At higher lung volumes R_{awp} decreases. The specific relation between R_{awp} (or its reciprocal conductance G_{aw} [$=1/R_{aw}$]) and volume is mirrored by the specific R_{aw} (sR_{aw}) and specific G_{aw} (sG_{aw}):

$$sR_{aw} = R_{aw} / V$$

The resistance of the airways (R_{aw}), lungs (airway and parenchyma) (R_L), chest wall (R_{cw}), and entire respiratory system (R_{RS}) can be calculated by measuring the rate of air flow and the associated transstructural pressure by subtracting from the total pressure the amount required to overcome elastic recoil:

$$R_{aw} = (P_{ao} - P_{alv}) / \dot{V}$$
$$R_L = (P_{ao} - P_{pl}) / \dot{V}$$
$$R_{cw} = (P_{pl} - P_{bs}) / \dot{V}$$
$$R_{RS} = (P_{ao} - P_{bs}) / \dot{V}$$

where P_{ao}, P_{alv}, P_{pl}, and P_{bs} represent the pressure at the airways opening, alveolar pressure, pleural pressure, and pressure at the body surface, respectively. The resistance of the lung parenchyma may be derived by subtracting airway from total lung resistance.

The relationship between the flow rate and the airway pressure gradient is nonlinear because of the relative contribution of the various components of the respiratory system to the total pressure required to overcome the viscous forces and its dependence upon volume, volume history, and flow. The viscous forces increase disproportionately as the flow rate increases and as airway resistance increases. In contrast, the resistance of the chest wall and lung parenchyma remains constant over a wide range of flow rates.[20] During quiet breathing by mouth, airway resistance accounts for greater than 50% of the total respiratory system resistance.[21] However, as flow rate increases, the contribution of the airways to total resistance progressively increases.

Changing patterns of airflow result in the nonlinear flow-resistance characteristic of the airways. Subsequently, as the flow rate to the airway increases, airflow becomes progressively more turbulent. The more turbulent the flow, the greater the pressure required to overcome the viscous forces. Turbulence occurs at lower flow rates in the upper airway compared with the lower (intrathoracic) airways because of the tortuous geometry of the upper (extrathoracic) airway and the narrow glottic aperture. Therefore, the upper airway is responsible for most of the increase in airway resistance with an increase in flow rate. Studies have shown the resistance of the lower airways to be nearly constant up to flow rates of 2L per second.[20] For patients who are breathing quietly by mouth, total airway resistance is divided almost equally between the upper and lower airways. As their effort increases, flow rate increases, and the ratio of upper to lower airway resistance progressively increases as previously described.

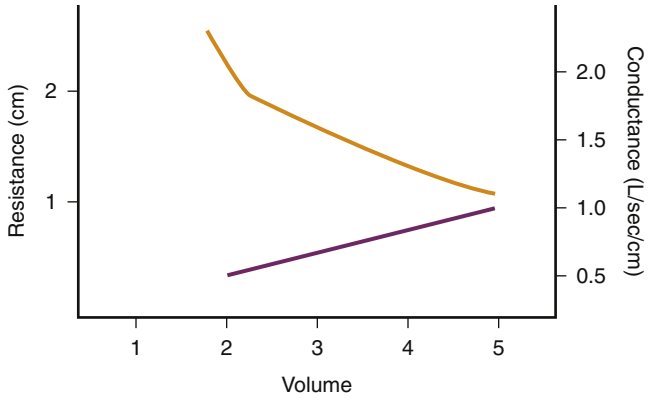

Figure 37–3. Relationship between lung volume and airway resistance (*solid line*) and conductance (*dashed line*). *(Modified from Briscoe WA, Dubois AB: The relationship between airway resistance, airway conductance, and lung volume in subjects of different age and body size,* J Clin Invest *37:1280, 1958.)*

Depending on whether laminar or turbulent flow predominates, resistance to airflow varies inversely with either the fourth or the fifth power of airway radius.[22] Therefore major changes in airway resistance are caused by factors that affect airway diameter.[23] During spontaneous lung inflation, airway diameter increases as airway resistance decreases. This change is produced by two mechanisms. First, as lung volume increases, the increasing elastic recoil of the pulmonary parenchyma provides a tethering effect that dilates the intrapulmonary airways. Second, extrapulmonary and large intrapulmonary airways are surrounded by pleural pressure, which becomes increasingly negative during inspiration. This phenomenon leads to an increasing pressure gradient across the airway wall and therefore to an increasing diameter. The change in airway resistance with lung volume is curvilinear and is illustrated in Figure 37-3.[23] When the reciprocal of airway resistance, airway conductance (G_{AW}) is plotted against lung volume, this relationship is nearly linear.

Dynamic Change in Airway Caliber During Respiration

Airway caliber is partially dependent on the transmural pressure. The transmural pressure is the difference between the interstitial pressure and the atmospheric pressure. The external airway wall for the intrathoracic airways is subjected to the interstitial pressure, which is approximately equal to the pleural pressure. In contrast, the external walls of extrathoracic airways are subjected to atmospheric pressure. The intraluminal pressure is dependent upon the generation of the airway. During inspiration, pleural pressure is negative relative to atmospheric pressure. Alveolar pressure is approximately equal to pleural pressure, and pressure at the mouth is equal to

atmospheric pressure. This pressure difference creates a gradient from the mouth to the alveoli. Extrathoracic airways tend to narrow during inspiration because the transmural pressure is positive. In contrast, the transmural pressure in the intrathoracic airways is negative, causing a tendency for these airways to dilate during inspiration. The degree of airway caliber change during inspiration depends on both the magnitude of the transmural pressure and the airway wall compliance. At the end of inspiration there is a relaxation of the inspiratory muscles, and the elastic recoil of the respiratory system produces, relative to atmospheric pressure, a positive pleural and alveolar pressure. Because of the dynamic pressure changes previously described, there is a tendency for intrathoracic airways to narrow and extrathoracic airways to dilate during expiration.

Applied Forces

Ventilation of the lungs involves motion of the respiratory system, which is produced by the forces required to overcome the flow resistive, inertial, and elastic properties of the lungs and chest wall. Under normal circumstances, these forces are produced by the respiratory muscles.

If ventilation is to occur, opposing forces must be overcome by a pressure applied to the respiratory system to create motion. At each instant, the applied pressure (P_{APP}) must equal the sum of the pressure required to balance elastic recoil (P_{ER}) and the pressure lost to viscous (resistive) forces (P_R). The maximal pressures that can be generated by the respiratory muscles are determined by both lung volume and gas flow:

$$P_{APP} = P_{ER} + P_R$$

With use of the aforementioned equations, this may be converted to:

$$P_{APP} = (1/C)V + R\dot{V}$$

This equation is known as the *equation of motion of the respiratory system.*

Figure 37-4 illustrates the pressure involved in respiration. Gradients must occur to allow for gas to flow into the lungs.

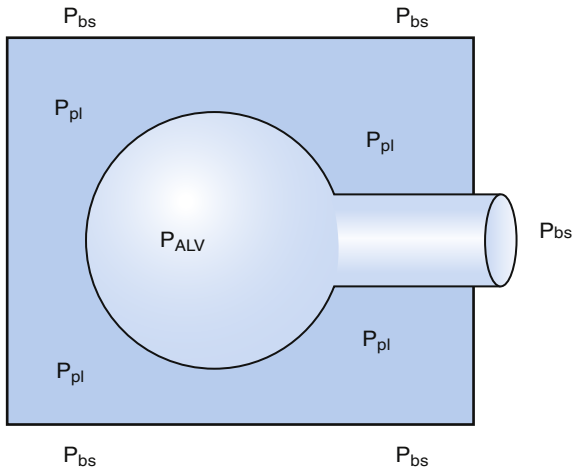

Figure 34–4. Illustration of the pressure involved in respiration. Gradients must occur to allow for gas to flow into the lungs. P_{ALV}, Alveolar pressure; P_{bs}, pressure at the body surface; P_{PL}, intrapleural pressure.

The airway pressure gradient that drives airflow into the lungs is defined as:

$$P_M - P_{ALV}$$

where P_M is the pressure at the mouth, which is normally atmospheric, and P_{ALV} is the alveolar pressure. Transpulmonary pressure (P_{TP}) is defined as:

$$P_{TP} = P_{ALV} - P_{pl}$$

where P_{ALV} is the alveolar pressure and P_{pl} is the intrapleural pressure. P_{TP} is equal to elastic recoil of the lungs when there is no airflow. P_{TP} increases and decreases with lung volume. Transchest wall pressure (P_{TC}) is defined as:

$$P_{TC} = P_{pl} - P_{bs}$$

where P_{pl} is the intrapleural pressure and P_{bs} is the pressure at the body surface that is usually atmospheric. P_{TC} and P_{pl} are equal in magnitude to the elastic recoil of the chest when there is no airflow and, like P_{TP}, increases and decreases with lung volume.

The transmural pressure (P_{RS}) is defined as:

$$P_{RS} = P_{ALV} - P_{bs}$$

where P_{ALV} is the alveolar pressure and P_{bs} is the pressure at the body surface. P_{RS} represents the transmural pressure across the entire respiratory system, including the lungs and the chest wall, and is equal to the net passive elastic recoil pressure of the whole respiratory system when airflow is zero.

During inspiration the respiratory muscles provide the applied pressure that expands the chest wall and the lungs, causing the alveolar and airway pressure to fall. The net result is that the alveolar pressure becomes less than atmospheric pressure. Once alveolar pressure is less than atmospheric pressure, air flows into the lungs along a pressure gradient and the lungs inflate, storing potential energy in the elastic structures for expiration. In order for gas flow to occur, there must be a balance of forces. Table 37-1 illustrates these forces (expressed as pressures).

Expiration is usually passive (excluding disease states where the patient actively tries to empty their lungs). That is, the energy stored in the elastic recoil of the lungs and the chest wall produces the positive alveolar and airway pressure needed to overcome flow resistance and air is forced from the lungs.

In order to inflate the lungs there must be an increase in alveolar pressure, which is usually done with positive pressure ventilation or a decrease in body surface pressure, such as in negative pressure ventilation (iron lung), or the respiratory muscles must be activated (normal breathing).

Under resting conditions, expiration is usually passive. At times of increased ventilatory requirements, such as during exercise, contraction of the abdominal and internal intercostals muscles can aid expiration.

Table 37–1 Balance of Forces

$P_{RS} + P_{MUS}$	=	$P_L + P_{CW}$
$P_{ALV} - P_{bs} + P_{MUS}$	=	$P_L + P_{CW}$
Inspiratory muscle contraction		Lung, chest wall elastic recoil
Outward acting forces when positive		Inward acting forces when positive

Interactions Between Lungs and Chest Wall

The lungs and the chest wall operate in series, and their compliance adds reciprocally to make total compliance:

$$1/C_T = 1/C_L + 1/C_{CW}$$

The chest wall is like a spring that may either be compressed or distended. Transthoracic pressure is negative at residual volume and at FRC, meaning the chest wall is smaller than its unstressed volume and its tendency is to spring out. Normal tidal breathing is entirely in the negative pressure range for transthoracic pressure. When examining the compliance curve of the chest wall (lung volume versus transthoracic pressure), pressure is 0 at about 65% of TLC. Thus the chest is at its unstressed volume and has no tendency to collapse or expand. Transthoracic pressure is positive at volumes above 65% TLC. The chest tends to collapse above its unstressed volume.

Volume-pressure loops observed during breathing are based on the flow resistance of gas and tissue. It had been previously suggested that the static volume-pressure relationship is represented by a single line, suggesting that the static pressures depend only on volume. However, the static pressure will vary depending upon the volume history of the lung. Thus if the lung is fully expanded, at deep inspiration, static pressures will be lower. This concept is important because of the hysteresis of the lungs and the tendency not to follow identical paths of response upon the application and withdrawal of forces on the lung. Hysteresis applies both to the lung and to the chest wall.

Time Constant of Emptying

The time taken for volume in the respiratory system to be reduced by 63% when the respiratory system is allowed to empty passively and the volume-time profile is measured is known as the time constant (τ) of the respiratory system.[24] If we use a model of the respiratory system with a single compartment and a single, constant elastance and a single, constant resistance, then the following occurs:

$$\tau = R/E$$

In a single compartment model the volume-time profile can be represented by a single exponential decay.

In healthy adults the time constant of the passive respiratory system is short—approximately 0.5 seconds. Such a short time constant allows the lungs to empty to the end expiratory volume (EEV) at the end of each expiration. Thus the FRC and EEV are equal. Since the respiratory system is relaxed at the end of expiration, inspiration can begin as soon as inspiratory muscle activity is initiated. The expiratory time constant is shorter in children, with values approximating 0.3 seconds reported in infants with normal lungs.[25] Infants with hyaline membrane disease have stiffer than normal lungs with expiratory time constants reported as low as 0.1 seconds. In the case of patients with obstructive airway diseases such as asthma, resistance is increased and the expiratory time constant is longer. Therefore, a longer time is required for the lungs to empty and return the respiratory system to EEV. Patients with chronic airway obstruction frequently have carbon dioxide retention and an increased respiratory drive. This phenomenon results in an increased respiratory rate with a shorter respiratory cycle and less time available for expiration. In this situation the respiratory system frequently does not have time to return to EEV before the next inspiration starts; thus FRC occurs at a volume higher than EEV, not equal to EEV, which prevents relaxation of the respiratory system at the end of expiration. This lack of relaxation of the respiratory system at the end of expiration causes a positive recoil pressure. This pressure is called intrinsic positive end expiratory pressure, or $PEEP_i$. Before inspiratory flow can begin, the patient's inspiratory muscle must produce enough force to overcome the $PEEP_i$; thus this force is "lost" to produce inspiratory flow and represents a load that must be overcome by the inspiratory muscle. In patients with severe airway obstruction, this pressure can be as high as 15 to 20 cm H_2O.

Physiology of Positive Pressure Mechanical Ventilation

Up to this point our discussion has focused on patients breathing spontaneously without artificial support. To understand the respiratory physiology principles that apply to the critically ill pediatric patients, we must briefly examine the effects of positive pressure breathing on the pediatric respiratory system.

The respiratory system, like most biological systems, is closely associated with exponential functions. An exponential function is a mathematical expression that describes an event where the rate of change of one variable is proportional to its magnitude.

For example, in a passive breath, expiratory flow will be higher at the beginning of expiration than at the end, as the lung volume decreases toward FRC.

There are various forms of exponential functions, but the two most important ones for the clinician in mechanical ventilation are the rising and the decaying exponential functions.

Rising exponential function expresses an increase of one variable as a function of time—for example, flow, pressure, or volume versus time. A rising exponential function expresses the behavior of a physical system where the rate of change of one variable is proportional to its magnitude and a constant. In this relationship, the largest rate of change is always observed at the beginning of the event, and the smallest rate of change is always observed at the end of the event.

Decaying exponential function expresses a decrease of one variable as a function of time: flow, pressure, or volume versus time. An example of this relationship can be seen with the pressure decrease during lung deflation in a passive expiration. Flow returns to a baseline during a passive expiration, reflecting a negative decaying function. This expression of a physical system is expressed where the rate is proportional to its magnitude only. Therefore the rate of change will always have the largest value at the beginning of the event, and the smallest value at the end of the event. The rate of decay is not constant over time.

As previously discussed, the respiratory system is governed by various laws of physics that describe the various dynamic forces involved in the movement of the system. In physiology, force is measured as Pressure = Force/Area, displacement is measured as Volume = Area × Displacement, and the relevant rate of change is measured as flow (e.g., Average flow

= ΔV/ΔTime; Instantaneous flow = dv/dt [the derivative of volume with respect to time]). The pressure necessary to cause flow of gas into the airway and increase the volume of the gas in the lung is the key component in positive pressure mechanical ventilation. The volume of gas (ΔV) to any lung unit and the gas flow ($\dot{V}$) is related to the applied pressure (ΔP) by:

$$\Delta P = \frac{\Delta V}{C} + \dot{V} \bullet R + K$$

where *R* is the airway resistance and *C* is the lung compliance. This equation is the same one previously described as Newton's equation of motion for the respiratory system. The applied pressure to the respiratory system measured at the inlet is the sum of the muscle pressures P_{mus} (pressure generated by the patient's spontaneous muscular forces) and the ventilator pressure $P_{applied}$ (pressure generated by ventilator). Muscle pressure is patient generated but cannot be directly measured. Muscle pressure represents the pressure generated by the patient to expand the thoracic cage and lungs. In contrast, ventilator pressure is the transrespiratory pressure generated by the ventilator during inspiration. Combinations of these pressures are generated when a patient is breathing on a positive pressure ventilator. In spontaneously breathing patients, the pressure measured at the patient's airway is a mix of the two pressures dependent upon the mode of ventilator support utilized. For example, in continuous positive airway pressure, all pressure generated will be by the patient muscles, whereas in pressure support, the pressure generated will be a mix of the pressure generated by the patient's respiratory muscles and that generated by the ventilator. When respiratory muscles are at complete rest, the muscle pressure is zero; therefore the ventilator must generate all the pressure necessary to deliver the tidal volume and inspiratory flow. The reverse is also true, and there are degrees of support depending upon the amount of force generated by the patient's respiratory muscles. The application of the equation of motion to the generation of gas flow is the next important step. Total pressure applied to the respiratory system (P_{RS}) of a patient undergoing ventilation is the sum of the pressure generated by the ventilator (measured at the airway) (P_{AO}) and the pressure generated by the respiratory muscles (P_{MUS}). Therefore:

$$P_{RS} = P_{Applied} + P_{MUS} = (V/C) + \dot{V} \times R + K$$

where P_{RS} is the respiratory system pressure, $P_{Applied}$ is the applied pressure by the ventilator, P_{MUS} is the pressure developed by the respiratory muscles, $\dot{V}$ is flow, *R* is airway resistance, *V/C* is respiratory system compliance, and *K* is the pressure. $P_{Applied}$ and $\dot{V}$ can be measured by the pressure and flow transducer in the ventilator. Volume is derived mathematically from the integration of the flow waveform.

To generate a volume displacement, the total forces have to overcome elastic and resistive elements of the lung and airway/chest wall represented by V/C and V × R, respectively. V/C depends on both the volume insufflated in excess of resting volume and the respiratory system compliance. To generate gas flow, the total forces must overcome the resistive forces of the airway and the endotracheal tube against the driving pressure gradients. At any moment during inspiration, there must be a balance of forces opposing lung and chest wall expansion measured as the airway pressure (P_{AO}). The opposing pressure can be summarized as the sum of elastic recoil pressure ($P_{elastic}$), flow-resistive pressure ($P_{resistive}$), and inertial pressure ($P_{resistance}$) of the respiratory system. Therefore:

$$P_{AO} = P_{elastic} + P_{resistive} + P_{inertance}$$

Inertial forces are usually negligible during conventional ventilation, which depends on bulk convective flow—unlike in high-frequency ventilation, where volumes are at the level of dead space. Therefore, for conventional ventilation, the forces exemplified in the equation of motion can expressed as:

$$P_{AO} = P_{elastic} + P_{resistive}$$

If elastic forces are recognized as the product of elastance and volume ($P_{elastic} = E \times V$) and the resistive forces as the product of flow and resistance (Resistive $\dot{V} \times R$), the formula can be written as:

$$P_{AO} = (\text{Elastance} \times \text{Volume}) + (\text{Resistance} \times \text{Flow})$$

If compliance (the inverse of elastance) is substituted for elastance, the equation of motion, as described in the preceding text, becomes:

$$P_{AO} = \text{Volume} / \text{Compliance} + \text{Resistance} \times \text{Flow}$$

The quotient of volume displacement over compliance of the respiratory system represents the pressure necessary to overcome the elastic forces above the resting lung volume or FRC. The resting lung represents the quantity of air remaining in the lungs at the end of a spontaneous expiration. Pressure, flow, and volume are all measured relative to their baseline values. The pressure necessary to cause inspiration is measured as the change in airway pressure above PEEP. For example, in a patient breathing spontaneously on continuous positive airway pressure, the ventilator pressure is zero; the patient must utilize his or her respiratory muscles to generate all the work of breathing. The same can be applied to the volume during inspiration or the tidal volume, which is the change in volume above FRC. The pressure necessary to overcome the resistive forces of the respiratory system is the product of the maximum airway resistance (R_{MAX}) and inspiratory flow. Flow is measured relative to its end-expiratory value, which is usually zero, unless a $PEEP_i$ is present. The ultimate result of the gas movement or flow is to allow gas to reach and be exchanged at the alveolar unit.

Gas Exchange

The basic function of the respiratory system is to supply oxygen to the body and to remove excess carbon dioxide. The following are the essential steps involved in this process:

1. Ventilation, the exchange of gas between the atmosphere and the alveoli
2. Diffusion across the alveolar-capillary membrane
3. Transport of gases in the blood
4. Diffusion of the gases from the capillaries of the systemic circulation to the cells of the body
5. Use of the oxygen and production of carbon dioxide within the cells as a by-product of metabolism

During the process of ventilation, air is transported back and forth between the outside of the body and the terminal respiratory units of the lungs. In the alveoli, the air is exposed to a thin film of blood. O_2 diffuses across the alveolar-capillary membrane, enters the blood, and combines with hemoglobin. Simultaneously, CO_2 diffuses from the blood and enters the

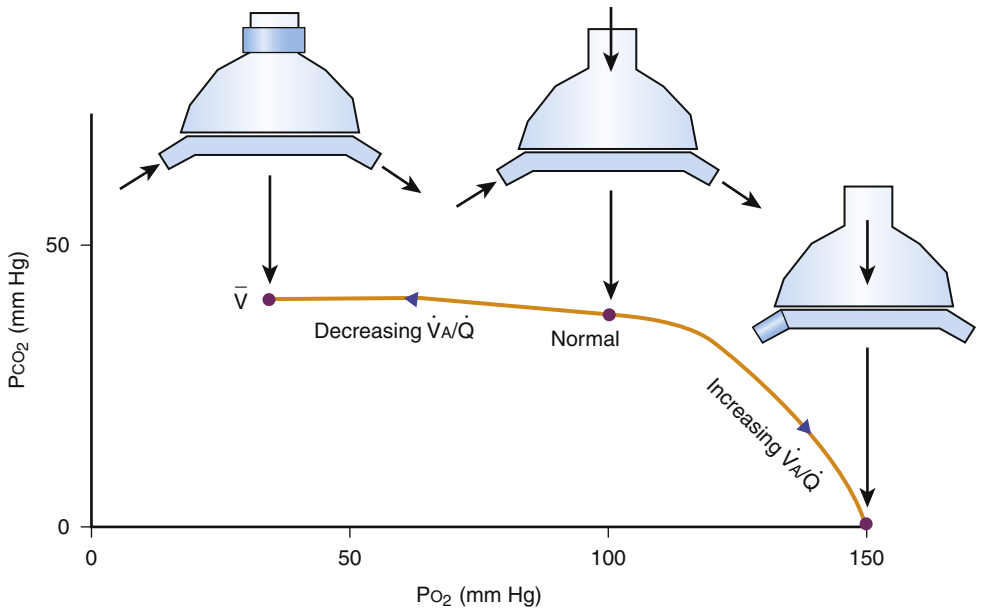

Figure 37-5. Relationship between the ventilation/perfusion ratio ($\dot{V}_A/\dot{Q}$) of an alveolus and the P_{O_2} and P_{CO_2} of the alveolar gas and end-capillary blood. The P_{O_2} and P_{CO_2} vary from the mixed venous blood ($\bar{V}$) to inspired air (I) as $\dot{V}_A/\dot{Q}$ changes from zero to infinity. *(Modified from West JB:* Ventilation blood flow and gas exchange, *ed 3, Oxford, 1977, Blackwell Scientific, p 37.)*

alveolar gas. In this way, the mixed venous blood entering the lungs is altered through the addition of O_2 and the removal of CO_2. This is the process of gas exchange.

The partial pressure of O_2 (Pa_{O_2}) and CO_2 (Pa_{CO_2}) in the arterial blood, and therefore the adequacy of gas exchange, are dependent on a number of factors. These factors include the composition of the alveolar gas and the extent to which equilibrium is reached between the alveolar gas and the pulmonary capillary blood. The alveolar gas composition is, in turn, dependent upon the content of the inspired air and the mixed venous blood, the quantity of air (ventilation) and blood (perfusion) reaching the alveoli, and the ratio of alveolar ventilation to perfusion ($\dot{V}_A/\dot{Q}$). Of the factors determining the adequacy of gas exchange, the structure and function of the lungs primarily influence the ventilation-perfusion relationships, alveolar ventilation, and diffusion of O_2 and CO_2.

Ventilation Perfusion Relationships

In the normal, upright lung, both alveolar ventilation and perfusion increase from the apex to the bases largely because of the effects of gravity. Blood flow increases more rapidly from apex to base than ventilation, and therefore $\dot{V}_A/\dot{Q}$ ratios are high at the apex and decrease progressively toward the base of the lungs. The regional differences in perfusion are called *West's zones of perfusion*.[26-28] West's zone I occurs when mean pulmonary arterial pressure is less than or equal to alveolar pressure; thus no blood flow occurs. In zone I, the apices of the lung of an upright adult, there are unperfused yet ventilated alveoli, which is dead space ventilation. (Bronchial arterial flow nourishes the lung.) In zone II, which consists of the mid lung, pulmonary artery pressure is greater than alveolar pressure. Conditions in this zone are governed by the fact that blood flow is not influenced by venous pressure but by the difference between arterial and alveolar pressures, which is a function of (hydrostatic) height. In zone III, the lower zone of the lung, pressure at the alveolus is exceeded by the pressures in both pulmonary artery and vein. Flow in this zone is a function of pulmonary artery and pulmonary venous pressures and is independent of height. At the very base of the lung, because of higher perivascular pressures and reduced lung expansion, flow again is diminished.[29]

Any disorder affecting the airways or the parenchyma of the lung will result in an increased imbalance between ventilation and perfusion and therefore a greater than normal range of $\dot{V}_A/\dot{Q}$ ratios. The presence of varying $\dot{V}_A/\dot{Q}$ ratios, whether in the normal or the diseased lung, has several important effects on gas exchange. The P_{O_2} and the P_{CO_2} of an alveolus, and therefore of the capillary blood leaving it, is dependent on the ratio of ventilation to perfusion. As this ratio decreases, the P_{O_2} decreases and the P_{CO_2} increases. The opposite occurs as the $\dot{V}_A/\dot{Q}$ ratio increases. Figure 37-5 demonstrates the relationship between the ventilation/perfusion ratios P_AO_2 and P_ACO_2.

Lung units with low $\dot{V}_A/\dot{Q}$ ratios therefore decrease arterial P_{O_2} and increase arterial P_{CO_2}. In the extreme cases in which no ventilation reaches a lung unit, $\dot{V}_A/\dot{Q}$ is zero and mixed venous blood is added unchanged to the arterial circulation. A right-to-left shut occurs. The contribution of low $\dot{V}_A/\dot{Q}$ units and shunts to arterial blood may be determined through the calculation of the venous admixture $\dot{Q}_S/\dot{Q}_T$:

$$\dot{Q}_S/\dot{Q}_T = (C_C - C_a)/(C_C - C\bar{V}),$$

where C_c, C_a, and $C\bar{V}$ are the O_2 contents of pulmonary end-capillary, arterial, and mixed venous blood, respectively. This contribution also may be assessed by calculating the difference between the alveolar and arterial P_{O_2} ($A-aDO_2$), which varies directly with the extent of venous admixture. Because of difficulties in accurately measuring it, the mean alveolar P_{O_2} (P_AO_2) is calculated from the alveolar air equation:

$$P_AO_2 = P_IO_2 - PCO_2/R,$$

where P_IO_2 represents the P_{O_2} of inspired air and R is the respiratory exchange quotient—the ratio of CO_2 production

to O_2 consumption. In healthy young subjects, the A – aDO_2 averages 8 mm Hg.[30]

When ventilation to a lung unit exceeds its perfusion (that is, $\dot{V}_A/\dot{Q} > 1$), the excess ventilation is considered to be "wasted" because it does not participate in gas exchange. The sum of the excess ventilation contributed by lung units with high $\dot{V}_A/\dot{Q}$ ratios is referred to as *alveolar dead space*.

The effects of increasing ventilation/perfusion imbalance on gas exchange is that as the amount of inequality increases, both the ratio of physiologic dead space to tidal volume and venous admixture increase and arterial P_{O_2} falls. Arterial P_{CO_2} also progressively increases.

Alveolar Ventilation

The volume of air entering the lungs each minute that actually participates in gas exchange is called the alveolar ventilation ($\dot{V}_A$). It is therefore the difference between the total volume of air entering the lungs each minute (minute ventilation, $\dot{V}_E$) and the volume of air entering the lungs that does not participate in gas exchange (dead space: $\dot{V}_D$): $\dot{V}_A = \dot{V}_E - \dot{V}_D$.

The type of dead space ($\dot{V}_D$) depends on the location of the volume not exchanged, either in the anatomic airways or in the alveolus. The anatomic dead space is equal to the volume of airways proximal to the terminal respiratory units. Approximately 25% of each tidal volume is lost in these conducting airways. The ultimate volume is dependent on body size and equals approximately 1 mL/lb.[31] This volume is divided almost equally between the upper and lower airways. An alveolar dead space is produced by all alveoli that are overventilated relative to their perfusion. Thus more gas is available then blood for diffusion. The physiologic dead space is usually expressed as a fraction of the tidal volume (V_D/V_T).

The alveolar ventilation is an important determinant of gas exchange because it, along with the rate at which tissue metabolism produces CO_2 ($\dot{V}_{CO2}$), determines the P_{CO_2} of arterial blood:

$$PCO_2 = \dot{V}_{CO\,2} / \dot{V}_A$$

When $\dot{V}_{CO2}$ is constant, P_{CO_2} varies inversely with $\dot{V}_A$. It is evident that at given minute ventilation, the P_{CO_2} will vary directly with the amount of physiologic dead space. As dead space changes, the P_{CO_2} can be kept constant only by increasing or decreasing $\dot{V}_E$ by an identical amount.

The measurement of dead space has evolved from the original description by Bohr in 1891 when dead space was considered simply the gas from the conducting airways. One can calculate the physiologic dead space as:

$$V_D/V_T = (Pa_{CO2} - P\dot{E}_{CO2})/Pa_{CO2}$$

where $P\dot{E}_{CO2}$ is end-tidal P_{CO_2}.

Diffusion of Oxygen and Carbon Dioxide

Gas must travel through a number of barriers between the alveolus and blood. These barriers include the alveolar epithelial lining, basement membrane, capillary endothelial lining, plasma, and the red blood cell. The amount of gas (Q) diffusing through a membrane is directly proportional to the surface area available for diffusion (S), the pressure difference for the gas on either side of the membrane (p1 – p2), and a constant (K) that depends on the solubility coefficient of the gas, membrane characteristics, and liquid used. This association is defined by the Fick principle of the diffusion state as follows:

$$Q/\min = K\lambda(p1 - p2)/d$$

where Q is inversely proportional to the distance it has to diffuse, whereas K is proportional to the solubility of the gas and inversely proportional to the square root of the molecular weight.

In healthy subjects at rest, equilibration of the P_{O_2} and P_{CO_2} of the alveolar gas and the pulmonary capillary blood is achieved in approximately 0.75 seconds.[32] This is about one third of the time spent by the blood in the capillary network. The rate of pulmonary blood flow can increased greatly, to the point that it prevents equilibration. For this reason, diffusion disequilibrium has been demonstrated in healthy persons, but only during strenuous exercise at high altitudes.

In the presence of parenchymal disease, diffusion impairment may occur solely as a result of thickening of the alveolar-capillary membrane. Much more commonly, however, diffusion disequilibrium is associated with destruction of the pulmonary capillary bed. This destruction results in a greatly increased blood flow velocity in the remaining capillaries, which may allow insufficient time for equilibration. Even when parenchymal disease is severe, however, diffusion disequilibrium usually occurs only when cardiac output, and therefore rate of flow, is markedly increased.

Control of Breathing and Acute Respiratory Failure

Robert K. Kanter

PEARLS

- Powerful neural regulation of breathing maintains a constant supply of oxygen to the tissue, despite wide variations of metabolic rate and respiratory system disorders, until an advanced stage of respiratory failure is reached.
- Impaired controls of breathing may interfere with respiratory cycle timing, respiratory effort, or functional patency of the airway. In some cases a disorder of respiratory regulation may be the patient's primary problem. Other patients have secondary impairment of respiratory regulation as a result of acute or chronic systemic illness.
- Sick or injured patients usually hyperventilate in compensation for their stressful disorder. Stressed patients with irregular breathing or inappropriately comfortable effort to breathe have a severely depressed respiratory drive. In these cases, immediate ventilatory support usually is warranted.
- Respiratory depression or apnea may be the clue that an underlying systemic illness requires specific treatment.

Because of the brain's ability to regulate breathing, homeostasis normally is maintained with respect to oxygen, carbon dioxide, and pH despite the presence of serious cardiorespiratory or metabolic disorders. Derangements of respiratory controls may be the primary cause of acute respiratory failure or one of a number of multifactorial causes in a critically ill or injured patient. In other patients, disorders of respiratory regulation prolong dependence on mechanical ventilation.

Respiratory control disorders may be acute or chronic. Longstanding disorders of respiratory controls may be acquired or congenital. When the patient is apneic or has a very slow respiratory rate, the depression of respiratory controls is obvious to the clinician. Functional obstruction of the upper airway may be a clue that neural controls of breathing are impaired. However, many disorders of respiratory controls depress the intensity of respiratory motor neural activity in a more subtle way. Neural depression of breathing may be difficult to distinguish from hypoventilation because of peripheral neuromuscular disease or primary respiratory tract disorders. Recognition of respiratory control disorders may allow specific interventions or, when these disorders cannot be reversed, may enable close monitoring and timely administration of general supportive care, including mechanical ventilation.

This chapter will describe normal respiratory controls, how respiratory controls may fail, and a practical clinical approach to recognition of failed respiratory controls and intervention.

Normal Regulation of Breathing

Rhythmic discharges whose timing corresponds to inspiratory and expiratory phases are generated in motor neurons of the medulla oblongata.[1] During comfortable unstimulated breathing, inspiratory motor activity includes diaphragm flattening as well as a mild increase in pharyngeal muscle tone and vocal cord abduction that keep the upper airway patent during inspiratory airflow. When inspiratory muscles relax, resting expiration is passive, driven by elastic recoil of the lung and chest wall. The respiratory rate and motor intensity are modified by a variety of neural, chemical, and mechanical stimuli (Figure 38-1). With high-intensity stimulation, accessory muscles are activated, including intercostals and neck muscles. Nasal flaring occurs. Stimulated breathing also may include end-inspiratory vocal cord closure that acts to prolong lung inflation with little energy expenditure, clinically evident as grunting when the vocal cords open at the beginning of expiration. In highly stimulated breathing, abdominal muscles contract to force expiratory airflow.

Other normal respiratory control behaviors include periodic deep inspirations, sneezing, and coughing to maintain expansion of basal lung areas and clear secretions from the respiratory tract. Breathing is normally coordinated with swallowing and airway protective reflexes to prevent aspiration. Pharyngeal muscle tone is also adjusted with neck flexion and extension to maintain airway patency.

Hypoxemia is a powerful stimulus to ventilation mediated by sensory input originating in the carotid body chemoreceptor. Peripheral chemoreceptor activity and ventilation increase slightly as Pao_2 falls below 500 mm Hg. Ventilation rises steeply as Pao_2 falls below 50 mm Hg (Figure 38-2, *A*). Low oxygen tension, rather than low oxygen, content is the ventilatory stimulus. Little carotid body response results from profound anemia. Hydrogen ion concentration and carbon dioxide tension independently activate chemoreceptors in the carotid body and in the brainstem (Figure 38-2, *B*). The simultaneous presence of hypoxia augments the hypercapnic ventilatory response (Figure 38-2, *C*).

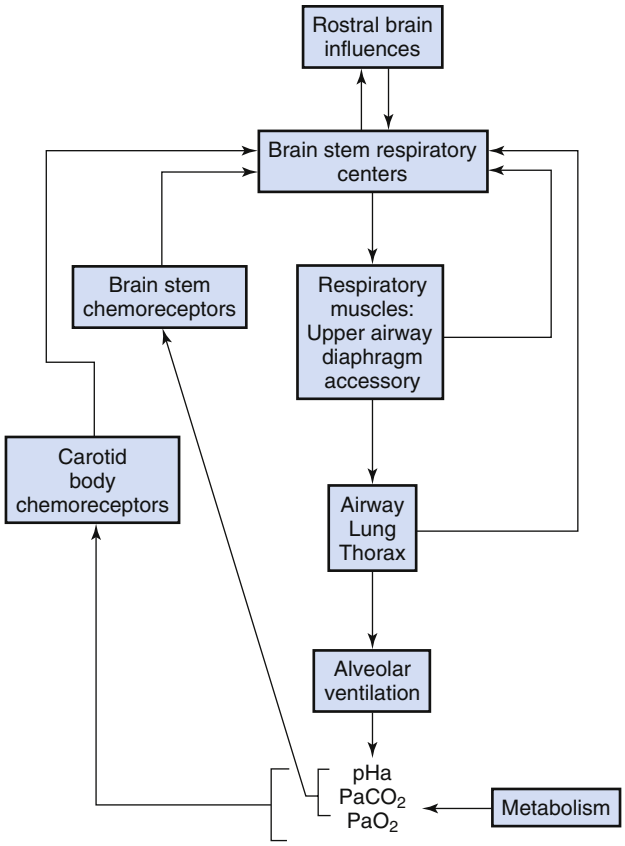

Figure 38–1. Elements of the respiratory control system.

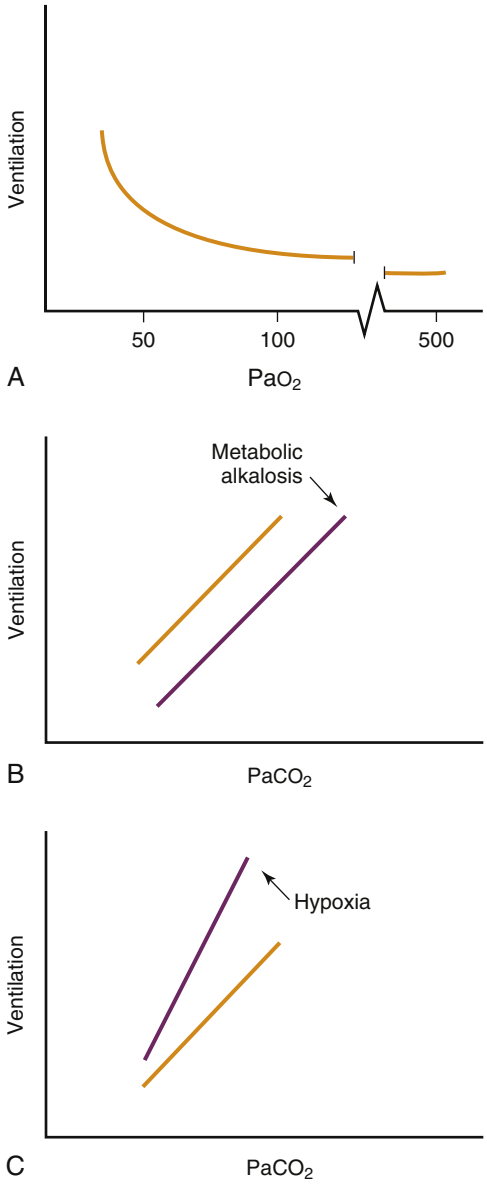

Figure 38–2. Chemoreceptor activity, as reflected by minute ventilation, varies as a function of Pao_2 (**A**), $Paco_2$ (**B**) (superimposed metabolic alkalosis inhibits breathing), and $Paco_2$ (**C**) (superimposed hypoxia stimulates breathing).

Mechanical loads on breathing influence respiratory efforts independent of chemical stimuli. Sensors for load-compensating reflexes are located in respiratory muscles and the chest wall. Reduction in lung volume also is detected by pulmonary stretch receptors. Afferent signals travel via the spinal cord, vagus nerves, and perhaps the phrenic nerves. Both conscious and reflex responses are involved in compensatory increases of effort, including the recruitment of accessory muscles in response to increased respiratory resistance or to a decrease in compliance. Stimulation to breathe is further augmented by hypercapnia or hypoxia when loaded breathing reduces ventilation. Respiratory compensation for mechanical loads accounts for the increased respiratory effort in patients who have normal blood gas tension despite acute lung disease. Dyspnea and anxiety may exacerbate the tendency to hyperventilate even without a chemical ventilatory stimulus.

Sleep modifies breathing, and compensation for respiratory illness is most likely to fail during sleep.[2] In some persons ventilatory responses to hypercapnia and hypoxia diminish during sleep. Sleep-induced reduction in upper airway tone and cough reflexes worsens the risk of obstruction and aspiration. In infants, whose thorax is compliant, awake lung volume is maintained by thoracic muscle tone and breathing at sufficiently high frequencies that expiration seldom reaches the passive resting lung volume. During sleep, inspiratory muscle tone diminishes and respiratory rate decreases, with resulting reduction in infants' expiratory lung volume. Infants' compensation for mechanical loads is compromised during the rapid eye movement stage of sleep more than during quiet sleep. Although sleep is a period of high risk for the sick infant, depriving the patient of sleep is counterproductive. Obstructive and central apnea are worsened by sleep deprivation in healthy infants.[3]

Genetic factors may account for some variation in respiratory regulation in a normal population,[4] but the clinical importance of this variation in predisposing individuals to acute respiratory failure is not clear. Although apnea is common in the premature infant, immaturity of respiratory controls does not otherwise appear to be a risk factor for respiratory failure in infant populations.

Failure of Respiratory Controls

Acute Disorders of Respiratory Controls

Patients with a critical illness or injury generally hyperventilate. At least some of the increased respiratory drive can be attributed to a higher metabolic rate. Pain, discomfort, and

fear also stimulate ventilation. When a stressed patient fails to hyperventilate, depressed respiratory controls and impending respiratory failure should be suspected.

Moderate brain injuries typically are associated with hyperventilation (Figure 38-3, *B*), whether the injury is traumatic, infectious, or hypoxic-ischemic. The hypermetabolic state, lung pathology, and loss of inhibitory cortical influences probably combine to augment ventilation. Even when the brain-injured patient does hyperventilate, airway protective reflexes usually are impaired, seizures may ensue, and subtle progression of the brain lesion may lead to hypoventilation (Figure 38-3, *A, C to E*). Resulting hypoxia may exacerbate the brain injury.

Seizures impair breathing in various ways. Apnea or slowing of respiratory rate, impairment of upper airway protective reflexes, and poor inspiratory effort are common. The clinician must have a high index of suspicion to recognize occult seizures. The seizure-induced respiratory depression may be difficult to distinguish from the brain pathology that may have caused the seizure, as well as the respiratory-depressing effects of anticonvulsant medications.

Respiratory depression by analgesic drugs, sedative agents, anticonvulsant medications, and anesthetic drugs is common. Opiates, benzodiazepines, barbiturates, and propofol all have respiratory-depressing effects. Relative effects on upper airway patency and hypoxic, hypercapnic, and loading responses may be dissociated. For example, Chloral hydrate has little effect on chemosensitivity but reduces genioglossus muscle tone and predisposes to obstructive apnea. Concern regarding respiratory depression does not warrant withholding analgesia. Rather, monitoring should be appropriate. In fact, episodic hypoxia during treatment procedures may be reduced when appropriate analgesia is provided.[5] Sedative agents and analgesic drugs that are rapidly cleared after a single dose may have a more prolonged duration of action when given repeatedly or continuously. Clearance rates for medications may vary with systemic disease, immaturity, or genetic factors. Sedation and analgesic-induced respiratory depression may prolong the need for mechanical ventilation. Substituting an agent that clears rapidly (such as remifentanil) for longer acting agents several hours before a planned extubation may facilitate weaning from mechanical ventilation. Dexmedetomidine, an α_2 adrenergic agonist, may provide sedation with less respiratory depression than other agents.

Opioid-induced respiratory depression can be reversed with naloxone. In patients with cardiovascular compromise (e.g., those who have had cardiac surgery), naloxone should be avoided in the immediate postoperative period because the stress of abruptly eliminating opioid anesthesia would be hazardous. In the patient with multiple chronic drug ingestions, naloxone may induce vomiting without improving airway protective reflexes, predisposing the patient to aspiration. The benzodiazepine antagonist flumazenil reduces the respiratory depression that results from taking benzodiazepines, but little pediatric experience with this agent has been reported. Flumazenil lowers the threshold for seizures and may cause a more hazardous condition than the initial respiratory depression. The duration of action of antagonists may be shorter than the agent that is depressing breathing. Close monitoring of the patient is essential, and repeated doses of antagonists may be necessary. In other cases of drug-induced respiratory depression, mechanical ventilation provides greater safety than do pharmacologic antagonists. This is the case with multifactorial central depression or in severely ill patients.

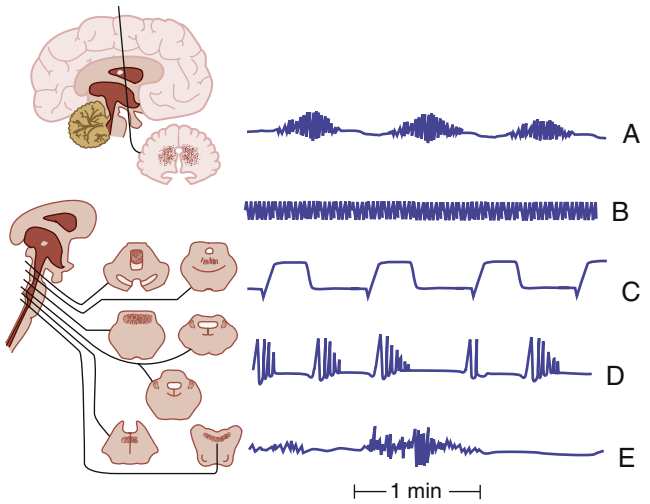

Figure 38–3. Abnormal respiratory patterns associated with lesions (shaded areas) at various levels of the brain. Inspiration reads up. **A,** Cheyne-Stokes respiration. **B,** Central neurogenic hyperventilation. **C,** Apneusis. **D,** Cluster breathing. **E,** Ataxic breathing. *(Modified from Plum F, Posner JB:* The diagnosis of stupor and coma, *ed 3, Philadelphia, 1980, FA Davis.)*

Other medications may depress breathing without alteration of consciousness. For example, prostaglandin E_1, which is given to maintain patency of the ductus arteriosus in infants with congenital heart disease, is frequently associated with respiratory depression.[6]

The respiratory inhibitory action of metabolic alkalosis may account for hypoventilation. The impact of alkalosis on breathing in sick children has not been systematically studied but may contribute to prolonged dependence on mechanical ventilation in children receiving chronic doses of diuretic agents. When metabolic alkalosis accompanies prolonged recovery from respiratory failure, correction of the alkalosis with potassium chloride and occasionally acetazolamide may promote ventilator weaning.

In the advanced stages of respiratory failure, the vigorous respiratory effort of the dyspneic patient may become counterproductive. Agitation increases oxygen consumption, and forced respiratory efforts may cause dynamic obstruction of airways. Dynamic airway obstruction in the dyspneic child may account for rapid progression of respiratory failure in some cases.

As the severely dyspneic patient decompensates, exhausted efforts may rapidly give way to periodic breathing and apnea. While this phenomenon is commonly observed in infants with lower respiratory infections[7] and pertussis,[8] observations in adults with near-fatal asthma reveal a similar tendency for respiratory arrest to precede cardiovascular collapse.[9] The mechanism of this preterminal respiratory depression is not well understood, but it appears to occur in some patients prior to the development of hypoxia and hypercapnia.

Acute Life-Threatening Events

Patients may be admitted to the pediatric intensive care unit for observation after an apparent life-threatening event (ALTE) in which caregivers perceived the need to stimulate

an infant during a sudden episode of irregular breathing or apnea, cyanosis, pallor, altered level of consciousness, or hypotonia. When the history or physical examination suggests a specific cause, diagnostic confirmation is warranted. Confirmatory studies may include a blood cell count and chemistries; screening for respiratory, bloodstream, urinary, or central nervous system infection; metabolic screening; screening for gastroesophageal reflux; a chest radiograph; brain neuroimaging; a skeletal survey; an electroencephalogram; or an echocardiogram. Studies that sometimes reveal the cause when history and physical examination are nonspecific include screening for urinary infection, brain neuroimaging, screening for gastroesophageal reflux, a chest radiograph, and a white blood cell count. In one series of patients with ALTE, 33% had infections, 28% had gastrointestinal problems, 13% had neurological disorders, 3% had airway causes, 3% had other congenital problems, 4% had other noncongenital problems, and for 16%, the cause was unknown.[10] See Box 38-1 for causes of apnea requiring specific therapy. In one sample, infants with ALTE who were more likely to have another subsequent severe event tended to be younger than 43 weeks' postconceptional age, premature, and had an upper respiratory infection.[11] The epidemiological characteristics of infants with ALTE differ from those who experience Sudden Infant Death Syndrome (SIDS). ALTE and SIDS should be regarded as distinct entities.[12] The causes and strategies to prevent SIDS continue to be an active area of investigation.

Box 38–1 Systemic Causes of Apnea that Require Specific Therapy

Central Nervous System
- Head injury, child abuse
- Seizure
- Meningitis, encephalitis
- Hydrocephalus
- Posterior fossa mass

Circulation
- Dysrhythmia
- Congestive heart failure

Infection
- Sepsis

Gastrointestinal
- Gastroesophageal reflux

Metabolic
- Poisons
- Hypoglycemia
- Many inborn errors of metabolism

Chronic Disorders of Respiratory Controls

Congenital or long-standing acquired disorders of the central nervous system may impair respiratory centers, leading to respiratory failure. Acute respiratory insufficiency may accompany progression of a central lesion. A static regulatory impairment may be revealed by failure to compensate for acute systemic illness. Primary disorders of respiratory controls may present with the following symptoms: impaired respiratory cycle generation (central apnea), deficient responses to respiratory stimuli (hypoventilation during stress and failure to arouse from sleep hypoxia), or inadequate motor control of the vocal cords or pharynx (stertor, stridor, poor swallowing, or obstructive apnea). These patterns of regulatory dysfunction may occur individually or in combination. Respiratory compromise usually is worst during sleep. Sedating medications may have an exaggerated impact on patients with primary disorders of respiratory controls. Pulmonary hypertension as a result of recurrent hypoxia, or aspiration pneumonia associated with impaired airway protective reflexes, complicate the clinical situation in some cases.

Structural Brain Disorders

Recognition of structural brain lesions as the cause of impaired respiratory regulation is important because some of the lesions are correctable. Congenital structural neurologic malformations may manifest as apnea or profound hypoventilation at birth or may be recognized later if respiratory impairment is mild. In particular, patients with Arnold-Chiari malformation often have central and obstructive sleep apnea. Surgical decompression may be associated with improvement[13] even when performed in adults.[14] Acquired lesions such as posterior fossa tumors may interfere with respiratory regulation before or after[15] surgical resection.

Nonstructural Congenital Disorders

Some genetic conditions are associated with derangements in regulation of breathing. Children with congenital central hypoventilation syndrome[16] have characteristic mutations in the *PHOX2B* gene. These patients may first come to medical attention because of growth failure, neurodevelopmental disabilities, or cor pulmonale. Abnormalities include autonomic dysfunction and cardiovascular instability as well as impaired controls of breathing. The syndrome may be recognized in the newborn period, later in childhood, and occasionally in adults. Sleep hypoventilation predominates in persons with congenital central hypoventilation syndrome, although some patients also experience respiratory insufficiency while awake. The disorder often is fatal without mechanical ventilation. Early mechanical ventilation may reduce the sequelae and improve long-term neurodevelopmental outcome.

Prader-Willi syndrome is a multigenic disorder initially presenting with hypotonia and then with progressive obesity, growth failure, neurodevelopmental disabilities, reduced ventilatory response to hypoxia and hypercapnia, sleep hypoventilation, and apnea.[17]

Rett syndrome is an X-linked disorder affecting development, behavior, and autonomic and respiratory regulation. Many patients with Rett syndrome have seizures. Abnormalities often are present in the *MECP2* gene, although some patients with characteristic clinical features have other genetic findings.[18] Multiple phenotypes exist in regard to the respiratory control disorder, with hyperventilation, hypoventilation, and apneustic breathing seen in subgroups.[19]

Many other genetic syndromes with severe neurological manifestations have impaired upper airway motor function, respiratory cycle timing, and respiratory effort nonspecifically associated with their brain disorder. Nongenetic congenital

disorders may impair respiratory controls. For example, children with cerebral palsy occasionally have neurologic deficits of pharyngeal tone, although the central drive to breathe usually is intact.

Nonstructural Acquired Chronic Disorders

Some patients with severe chronic respiratory disease have blunted ventilatory responses to hypoxia, hypercapnia, or respiratory mechanical loads. A concern regarding supplemental oxygen is sometimes raised in the care of patients with acute exacerbations of chronic respiratory disease. It is sometimes argued that administration of supplemental oxygen causes respiratory failure in patients with chronic CO_2 insensitivity who might depend on hypoxic drive to breathe. Of greater concern are the adverse effects of hypoxia. Because the hypoxic drive to breathe only increases substantially at oxygen tension below 50 mm Hg (see Figure 38-2, *A*), it is virtually impossible to maintain stable respiratory stimulation with mild and "safe" hypoxia without risking episodic life-threatening hypoxia. If a patient is so poorly compensated that removal of hypoxic drive results in hypoventilation, then mechanical ventilation may be the safest management strategy, unless end-of-life plans specifically exclude mechanical ventilation.

Obesity causes hypoventilation by a complex interaction of factors including mechanical loads on the respiratory system, reduction of lung volume, upper airway obstruction, and impaired respiratory regulation.[20] In obese patients, weight loss often improves hypoventilation.

Apparently healthy preterm infants may have postanesthetic apnea until the age of 60 weeks' postconceptional age.[21,22] Apneic events occurred within 2 hours of surgery in 72% of patients, but in the remainder, respiratory irregularity began as late as 12 hours postoperatively. Both obstructive and central mechanisms of apnea were observed. Continuous monitoring for at least 12 hours after anesthesia is warranted when surgery is required for infants born prematurely who are still younger than 60 weeks' postconceptional age.

Sleep hypoventilation tends to occur in adults with hypothyroidism and diabetes mellitus.[23] Little information is available regarding the pediatric patient or the specific role of the endocrine disorder versus obesity.

Recognition and Treatment

The Deteriorating Patient

In a patient who is sick and stressed, hyperventilation is the typical compensatory response for physiological derangements, with increased respiratory frequency and obvious use of accessory muscles of breathing. The clinician should recognize thoracic retraction, grunting respiratory sounds, nasal flaring, head bobbing, and active use of expiratory abdominal muscles as signs of increased respiratory drive.

Controls of upper airway patency and protective reflexes should be assumed to be absent in the comatose patient or the critically ill drowsy patient with stertor (i.e., snoring sounds of pharyngeal obstruction). Prompt efforts to secure the airway may avert aspiration and obstruction.

If time allows, arterial blood gas analysis may confirm suspicion of hypoventilation in a crisis. If moderate respiratory effort and hypocapnia ($Paco_2$ <35 mm Hg) accompany an acute respiratory disorder, it can be inferred that ventilatory drive is (at least temporarily) sufficient and alveolar ventilation relative to CO_2 production is satisfactory. If $Paco_2$ exceeds 40 to 45 mm Hg in a patient with an acute respiratory disorder, then lung function, the respiratory pump, or the drive to breathe is compromised. This scenario may represent a rapidly worsening trend. Close monitoring is essential, and immediate intervention may be warranted. In a sick, stressed patient with irregular breathing or inappropriately slow comfortable respiratory effort, respiratory drive is probably severely impaired, and arterial blood gas analysis is unnecessary. Immediate airway protection and ventilatory support usually is indicated.

Evaluation of patients during respiratory decompensation often is limited by their rapidly evolving state. Given the safety and effectiveness of endotracheal intubation and mechanical ventilation, support should be initiated promptly when there is substantial suspicion concerning impaired regulation of breathing in the critically ill patient. Apnea may suggest the presence of a systemic disorder requiring specific treatment (Box 38-1).

Evaluation During Recovery

Impairment of respiratory controls may contribute to prolonged dependence on mechanical ventilation during recovery from critical illness. In contrast to the limited evaluation of respiratory controls in patients during respiratory emergencies, careful study of specific ventilatory responses is feasible and may be warranted in the patient with slow recovery from respiratory failure.

Coordination of the upper airway is assessed by testing the gag reflex. If the gag reflex is vigorous in the alert patient, upper airway control will seldom be a limiting factor in the patient's recovery.

In attempting to decide whether to discontinue mechanical ventilation and remove an endotracheal tube, a trial of unassisted spontaneous breathing with the endotracheal tube still in place provides important insights. Continuous positive airway pressure may be maintained to avoid loss of functional residual capacity during the trial. Once $Paco_2$ exceeds the apneic threshold of 30 to 35 mm Hg, respiration should become regular and comfortable without apnea. $Paco_2$ less than 45 mm Hg, pH greater than 7.35, and safe oxygenation with a comfortable effort suggest that drive and other components of the respiratory system are adequate to withdraw mechanical ventilation.

If tachypnea develops or the patient breathes laboriously or complains of dyspnea, respiratory tract disease or impaired respiratory muscle strength probably is a limiting factor. Failure to cough, to at least double resting tidal volume, and to generate peak inspiratory negative pressures of at least 30 cmH_2O all suggest that respiratory muscle strength is inadequate to accomplish the necessary work of breathing. When pulmonary disease and muscle weakness are present, independent evaluation of respiratory drive is difficult.

Finally, some patients fail to increase effort despite hypercapnia and hypoxia during the trial of spontaneous breathing. Others lack a gag response. In these cases, obvious deficiency of neural controls of breathing contributes to persistence of their respiratory insufficiency.

Measuring Respiratory Drive

Except for observation of breathing pattern and rate, respiratory neural output cannot be directly measured. Interpreting baseline ventilation as a measure of the intensity of drive to breathe is confounded by dependence of ventilation on muscle weakness, respiratory system compliance, and resistance, as well as intensity of respiratory neural motor output.

However, useful and clinically feasible measurements of respiratory drive are possible. Whatever the baseline ventilation, an increase in ventilation in response to hypercapnia is evidence of at least partially intact chemosensitivity.[24,25] The pressure generated at the airway in the first 0.1 seconds of inspiration against an occluded airway (P0.1) parallels experimental direct measures of respiratory center output. Increase in P0.1 with hypercapnia indicates at least partially intact chemosensitivity. In one study, augmented P0.1 response to hypercapnia was associated with more successful extubation in a group of patients with brainstem tumors who were at risk for depressed respiratory controls.[26] These techniques are feasible for application in the pediatric critical care population, but published data are not available.

Therapy Related to Respiratory Controls

Patients with known disorders of respiratory controls should be monitored continuously during periods of severe stress and especially during sleep. Mechanical ventilation may be necessary after anesthesia and should be initiated when hypoventilation poses a substantial threat.

When tonsillar or adenoidal hypertrophy contributes to hypoventilation, surgical removal may improve ventilation. However, underlying neurological deficits of pharyngeal motor control often persist despite tonsillectomy and adenoidectomy. Noninvasive mask positive pressure may relieve upper airway obstruction resulting from pharyngeal motor dysfunction. In some cases, a tracheostomy tube may be warranted to bypass intractable upper airway obstruction in a patient with neurological motor deficits. In other cases, relief of upper airway obstruction will eliminate the need for mechanical ventilation.

Although theophylline and doxapram have been successful in alleviating apnea of prematurity, there is little evidence for the effectiveness of respiratory-stimulating drugs in other pediatric critical care applications. If a trial of respiratory stimulant therapy is used in a patient with a life-threatening disorder of respiratory regulation, such therapeutic trials should be undertaken with close observation.

Long-term management of uncorrectable disorders of respiratory controls may include home apnea monitors, positive or negative pressure ventilation, and diaphragm pacing.

Assessment and Monitoring of Respiratory Function

Emily L. Dobyns

PEARLS

- Clinical assessment of respiratory function remains invaluable in the diagnosis and management of patients with respiratory failure.
- Initial evaluation should include assessment of child's comfort and activity level and observation of child's body position, respiratory pattern, and body habitus.
- Chest x-ray films can be used to identify cardiac, vascular, bone, and lung abnormalities and to assess device placement (i.e., endotracheal tube) and the need for intervention.
- Chest computed tomography guidance can be used to drain fluid collections and obtain biopsies.
- Simple observation of the ventilator displays of an intubated patient undergoing ventilation with use of a microprocessor-equipped ventilator provides information about the respiratory mechanics of the patient.
- Flexible bronchoscopy is used to evaluate the size, patency, and compression of the airway during respiration, to evaluate the anatomy/structure of the airway, and for removing or obtaining secretions from the lung.
- Rigid bronchoscopy is used for better evaluation of vocal cord paralysis, laryngeoesophageal clefts, and H-type tracheoesophageal fistulas. Removal of foreign bodies is performed more easily and safely with a rigid bronchoscope.

The majority of children admitted to the pediatric intensive care unit (PICU) present with cardiorespiratory disease or with an acute illness that may progress to involve the respiratory system, emphasizing the need for careful monitoring of respiratory parameters. Close respiratory examination and monitoring allow titration of therapies to minimize ventilator-induced injury, optimize patient-ventilator interaction, and aid in weaning from the ventilator.[1]

Physical Examination of the Respiratory System

Clinical assessment of respiratory function remains invaluable in the diagnosis and management of patients with respiratory failure despite all the technologic advances that have occurred in monitoring. Initial evaluation begins with assessment of the child's comfort and activity level. Coexisting nonpulmonary conditions such as pain and anxiety may make this assessment difficult. Observation of the child's body position, respiratory pattern, and body habitus provides important information as to his or her level of respiratory distress.

Often children in respiratory distress assume a body position that helps them breathe more comfortably. This position may be splinting of the chest in a patient with pneumonia or assuming the "sniffing position" to maintain an open airway in a child with an upper airway obstruction. An infant is less independent and therefore often is held in position by his or her caregivers, irrespective of comfort.

The respiratory pattern provides information regarding the work of breathing in a distressed child. The respiratory rate varies with age, but an early sign of distress is tachypnea. Additional signs of increased work of breathing include grunting or irregular respirations, nasal flaring, use of accessory muscles of respiration (strap muscles of the neck), and retractions.

Inspection of the shape of the chest wall may reveal abnormalities that affect pulmonary function. Increased anteroposterior diameter can be seen in conditions associated with hyperinflation (e.g., asthma or cystic fibrosis). Scoliosis in severe cases can cause a reduction in lung volume. Neuromuscular disorders may be associated with an "A-shaped" chest and lung hypoplasia/dysplasia. Thoracic asymmetry may be associated with neuromuscular or skeletal deformities, pneumothorax, or a paralyzed diaphragm. Fingers and toes should be examined for evidence of clubbing (painless enlargement of the connective tissues of the distal phalanges), which is nonspecific but may be indicative of chronic hypoxemia. Growth parameters and neurodevelopment should be obtained and compared with age-appropriate normal subjects to assist in evaluation of long-standing or associated diseases.

Detection of cyanosis centrally (lips, tongue) or peripherally (nail beds) may be difficult. Arterial oxygen tension must drop below 80 mm Hg before cyanosis can be detected clinically. Cyanosis may be absent in patients with severe anemia or missed when lighting is poor. It also may be intermittent and be seen only with exercise or change in position. Cyanosis that does not resolve with oxygen therapy may indicate right-to-left shunting of blood in the lungs or heart or the formation of methemoglobin or sulfhemoglobin following the ingestion of certain drugs.

Evaluation of breath sounds provides assessment of airflow through the tracheobronchial tree, the presence of fluid in or

obstruction of the airways, and conditions outside the lung and pleural space. The child's chest wall is thinner than that of the adult, which allows better access to breath sounds but impedes localization of the lesion because the breath sounds can be referred. Upper airway abnormalities may present with stridor or muffling of the voice. Bronchial breath sounds suggest consolidation, whereas wheezes result from narrowed airways. Crackles may be fine or coarse. They represent air bubbling through secretions and the reopening of closed airways. A friction rub may be heard when the inflamed surfaces of the pleura move against each other through the respiratory cycle. Breath sounds may be absent if there is a significant pleural effusion or complete lobar collapse resulting from a mucus plug or pneumothorax. Heart tones often are shifted away from the pneumothorax and toward the atelectasis because of complete airway obstruction. Assessment for pulsus paradoxus (i.e., exaggerated decrease in the pulse or systolic blood pressure with inspiration) should be made during the evaluation of severe airway obstruction or pulmonary embolus.

Although each assessment should include observation and a limited physical examination, it is recognized that interobserver repeatability of physical signs is poor and independent of the experience of the observer.[2] The assessments of clubbing, wheezes, friction rub, and crackles are the most reliable and reproducible.[2,3] The lack of accuracy of repeated physical examinations and the complexity of critically ill pediatric patients require adjunctive tests/assessments to monitor these patients.

Radiography

Portable chest x-ray films are the most common films taken in the PICU. The technical quality of the chest radiograph affects the interpretation; therefore, it is important to assess the film for adequacy of penetration, degree and symmetry of lung inflation, and degree of chest rotation. Chest x-ray films can be used to evaluate for cardiac, vascular, bone, and lung abnormalities, to assess for device placement (e.g., an endotracheal tube), and to determine the need for intervention.[4] Lateral decubitus films help identify and quantify pleural effusions, pneumothorax, and the position of chest tubes/lines. Cross-table lateral films also may be used for these purposes but are harder to interpret. A chest computed tomography (CT) scan is used when details on the plain film are obscured by the superimposition of structures or an opaque hemithorax. A chest CT scan also can be used to guide drainage of fluid collections and assist in obtaining biopsy specimens. A high-resolution chest CT scan examines 1- to 1.5-mm slices at 10-mm intervals; therefore it can be used to illustrate lung parenchymal details better than a conventional CT scan, which examines 7- to 10-mm slices at 10-mm intervals.[5] This detail can be helpful in distinguishing the pathologic process causing diffuse lung diseases that appear as diffuse lung shadowing on chest x-ray films. Chest ultrasound, ventilation/perfusion scanning, spiral CT, and magnetic resonance imaging may be useful adjutants depending on the disease process.

Evaluation of Gas Exchange

Episodic hypoxemia is common in critically ill adults and has been associated with increased mortality. The frequency and impact of episodic hypoxemia in pediatrics has not been studied. Additionally, whether monitoring and early treatment of episodic hypoxemia will improve patient outcome remains unanswered, but continuous monitoring of oxygen saturation in the PICU has become the standard of care.

Noninvasive Respiratory Monitoring

Transcutaneous Oxygen and Carbon Dioxide Monitoring

Transcutaneous measurements reflect both gas exchange and skin perfusion. In this technique, a probe composed of a heater, an electrode, and a thermistor is applied to the patient's skin. The skin is warmed and softened to improve diffusion and permeability. This step also causes capillaries to dilate, resulting in better approximation of arterial oxygen values. Several disadvantages limit the use of transcutaneous monitoring to the newborn population. Skin thickness increases with age, making transcutaneous measurements less predictable. Frequent electrode site changes are required to prevent local burns. Relatively frequent calibration and comparison with arterial blood gases are necessary. Because of these limitations and the ease of application of pulse oximetry and end-tidal carbon dioxide monitoring, transcutaneous monitoring has nearly been replaced by other monitoring methods.

Pulse Oximetry

Pulse oximetry is considered a significant technologic advance that has improved patient safety.[1,6-9] Its ease of application and accuracy have resulted in widespread use. Pulse oximetry is commonly used to detect hypoxemia and to wean the oxygen concentration in patients undergoing mechanical ventilation.

Pulse oximetry is based on the principles that (1) the pulsatile absorbance detected is arterial blood and (2) oxyhemoglobin and reduced hemoglobin have different absorption spectra.[6] Red (660-nm) and infrared (940-nm) wavelengths of light are used to determine the ratio of oxygenated to deoxygenated blood. Deoxygenated blood absorbs more red light, whereas oxygenated blood absorbs more infrared light. The two wavelengths are passed through an arterial bed, and the ratio of infrared and red light transmitted to the photodetector is determined. The ratio is calibrated against measurements of arterial oxygen saturations from human volunteers and their absorbance ratios.

Several factors may affect the accuracy of pulse oximetry. Pulse oximetry measures oxygen saturation (Sao_2). Sao_2 and Pao_2 are not linearly related; the oxyhemoglobin dissociation curve is sigmoid in shape (Figure 39-1). Large changes in Pao_2 at high levels of oxygen, the upper flat portion of the oxyhemoglobin dissociation curve, may occur with little change in saturation. Additionally, a reduction in oxygenation on the steep portion of the curve may not be appreciated as significant because only a small change in saturations will have occurred.[6,7] The accuracy of pulse oximetry falls with arterial oxygen saturations less than 70%.[1,6] At arterial oxygen saturations below 70%, pulse oximetry may be more appropriate for showing trends.[6]

Abnormal hemoglobin levels (carboxyhemoglobin, methemoglobin) that have similar absorbance spectra can lead to overestimation of the true Sao_2.[6] Intravenous dyes and certain colors of nail polish may falsely lower pulse oximetry readings.

Pulse oximetry sensors may be unable to distinguish a true signal from background in low perfusion states that result in diminished pulsations (e.g., vasoconstriction, low cardiac output, and hypothermia). This situation usually is displayed as an inadequate pulse message.[1] Low peripheral perfusion and motion artifact are the most common causes of inaccurate pulse oximetry readings.[9-11] Newer designs of pulse oximeters with signal-progressing algorithms that detect and ignore motion and pulse rate interferences may overcome these limitations.[10,11]

The complications of pulse oximetry are rare. They include skin burns and pressure necrosis in newborns.[1,6] Limited understanding of pulse oximetry by health care providers may be an underrecognized problem, along with time spent determining whether alarms are false.[9,12]

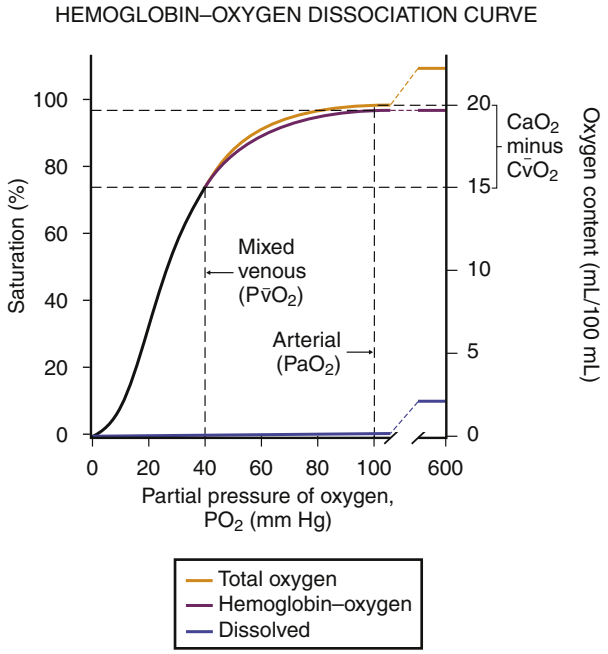

Figure 39–1. Hemoglobin-oxygen ($Hb\text{-}O_2$) dissociation curve shows the percentage saturation of hemoglobin at each P_{O_2}. When the hemoglobin concentration is known, the content of oxygen can be calculated. The total content includes the small additional content of oxygen in solution, which becomes significant at high levels of P_{O_2}. The saturation scale on the *left* applies only to the $Hb\text{-}O_2$ line. The scale on the *right* shows content values for a normal hemoglobin level of 15 g/100 mL blood. *(Modified from Hlastala MP: Blood gas transport. In Culver BH, editor:* The respiratory system, *Seattle, 1997, ASUW Publications. Redrawn in Albert RK, Spiro SG, Jett R, editors:* Clinical respiratory medicine, *ed 2, St. Louis, 2004, Mosby Elsevier.)*

Capnography

End-tidal carbon dioxide monitoring is the noninvasive measurement of exhaled carbon dioxide at the plateau of the carbon dioxide waveform (Figure 39-2). End-tidal carbon dioxide concentration reflects $Paco_2$, cardiac output, percentage of dead space, and airway time constants. In healthy subjects, the end-tidal carbon dioxide concentration is 1 to 5 mm Hg less than the $Paco_2$.[13] End-tidal carbon dioxide concentration represents the Pco_2 of all ventilated alveoli, whether or not they are perfused. Therefore any condition that reduces pulmonary perfusion of ventilated alveoli increases the difference between $Paco_2$ and end-tidal carbon dioxide. Comparison between end-tidal carbon dioxide concentration and $Paco_2$ helps to differentiate between change in alveolar ventilation, CO_2 production, or pulmonary perfusion as a cause of the change in end-tidal carbon dioxide concentration. Additionally, end-tidal carbon dioxide monitoring can be used to verify tracheal intubation, detect complete airway obstruction, and monitor ventilation during sedation.[13-16]

Sampling of exhaled carbon dioxide can be at the patient-ventilator interface (mainstream), diverted to a monitor (sidestream), or an intermediate connection.[16] The exhaled gas sample is exposed to various wavelengths of infrared light. The relative amount of light absorbed by the exhaled sample is compared with the amount of light absorbed by a sample that does not contain carbon dioxide. The difference between the

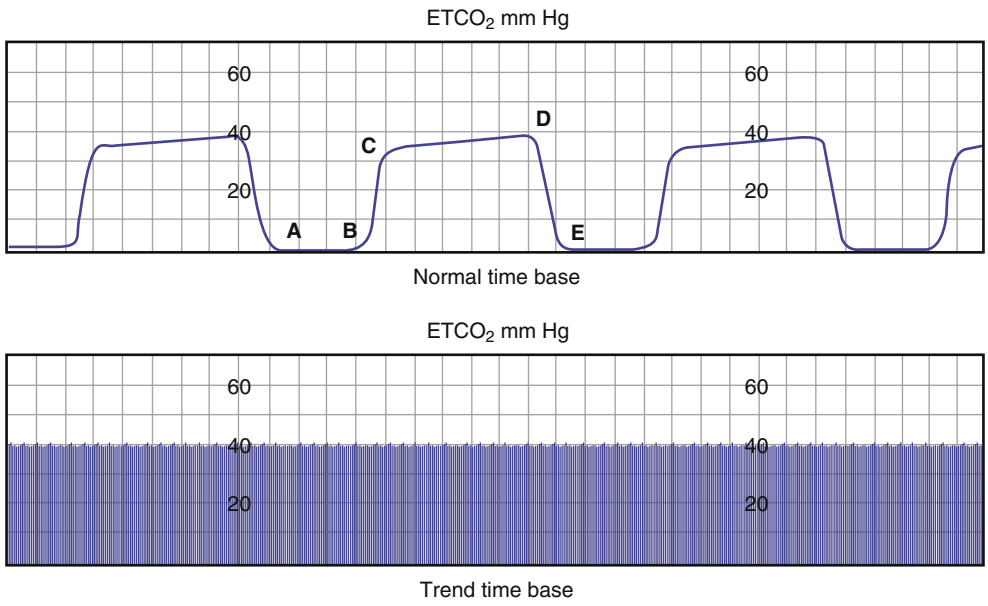

Figure 39–2. Normal capnograph. *A* to *B* is dead space, *B* to *C* is start of expiration (mix of dead space and alveolar gas), *C* to *D* is the alveolar plateau with point *D* representing the end-tidal value, and *D* to *E* is the start of inhalation.

two samples is the concentration of carbon dioxide. Carbon dioxide also can be measured semiquantitatively using a pH-sensitive indicator that changes from purple to yellow when exposed to carbon dioxide.[14]

Arterial Blood Gas Monitoring

Intermittent samples of arterial blood can be obtained from a single arterial puncture or an indwelling arterial line. Although convenient and frequently used, they offer isolated data points of continuous physiologic changes. Because of limitations such as the spontaneous variability in patients over time, the fact that blood gas is often obtained after an event has occurred, and the significant amount of lag time in therapeutic decisions that may ensue, interest in the development and use of continuous arterial blood gas monitoring exists.[17]

Evaluation of arterial blood gas provides information on the uptake of oxygen and disposal of carbon dioxide by the lung. In diseased lungs, additional information may be necessary to better understand and treat problems with gas exchange. Therefore indexes of oxygenation have been developed that use the data obtained from a blood gas to better define the efficiency of gas exchange and the causes of hypoxemia.

Venous blood that enters the arterial system without participating in gas exchange is termed "shunt." Shunt flow may be intrapulmonary or extrapulmonary. Intrapulmonary shunt occurs when alveoli are being perfused but there is no inspired alveolar ventilation because the alveolus is collapsed or filled with fluid. Extrapulmonary shunting occurs when there is drainage of venous blood into the postcapillary pulmonary circulation through either anomalous (intracardiac right to left shunts) or normal (thebesian and bronchial veins) pathways. Approximately 3% of cardiac output is shunted in a healthy individual. Most shunt flow is intrapulmonary in persons with pulmonary disease. The magnitude of the shunt can be calculated by using the following equation:

$$\frac{Q_s}{Q_t} = \frac{Cc_{O_2} - Ca_{O_2}}{Cc_{O_2} - Cv_{O_2}}$$

where Q_s is shunt, Q_t is total flow, Cc_{O_2} is pulmonary capillary oxygen content, Ca_{O_2} is arterial oxygen content, and Cv_{O_2} is mixed venous oxygen content. Applying this equation requires measurement of a mixed venous sample collected from the right ventricle or the pulmonary outflow track (i.e., placement of a pulmonary artery catheter). This equation does not identify the site or cause of the shunt.

Calculation of the alveolar-arterial oxygen tension difference ($AaD_{O_2} = PA_{O_2} - Pa_{O_2}$) helps to differentiate hypoxemia caused by hypoventilation from diffusion abnormalities, ventilation/perfusion (V/Q) mismatch, or shunt. It has the advantage of not requiring mixed venous blood sampling, but it does require alveolar $P_{A O_2}$, which is difficult to measure. Instead of direct measurement, $P_{A O_2}$ is approximated to be equal to $PA_{O_2} \sim P_{I O_2} - Pa_{CO_2}/R$, where $P_{I O_2}$ is partial pressure of inspired oxygen, Pa_{CO_2} is partial pressure of arterial carbon dioxide, and R is respiratory exchange ratio (generally assumed to be 0.8). Normally, $A_{aD O_2}$ is less than 10 mm Hg. $A_{aD O_2}$ tends to change with age and increasing fraction of inspired oxygen, and it may vary unpredictably with V/Q inequality.[18-20]

The easiest index to calculate is the arterial inspired oxygen concentration ratio ($Pa_{O_2}/F_{I O_2}$). It has been used as the basis for the definition of acute lung injury/acute respiratory distress syndrome (ALI/ARDS). One of the disadvantages of the $Pa_{O_2}/F_{I O_2}$ ratio is that it changes as a function of $F_{I O_2}$, raising the concern that it is not a precise enough measure to be used to define ALI/ARDS. That said, it remains an integral part of the ALI/ARDS definition for now.[18,20]

Respiratory Mechanics

Institution of mechanical ventilation in a patient with acute respiratory failure may result in improvement and even normalization of blood gases and measures of ventilation without improving the underlying disease process. Assessment of respiratory mechanics can provide information on the status and progression of the disease process and information that is useful for minimizing ventilator-induced lung injury.

The development of microprocessor-equipped ventilators has simplified the measurement of respiratory mechanics.[21] Simple observation of the displays of an intubated patient who is undergoing ventilation with a microprocessor-equipped ventilator provides significant information about the respiratory mechanics of the patient. Failure of expiratory flow to fall to zero (on the flow-time trace) before the onset of inspiration is the hallmark of breath-stacking, also termed autoPEEP. Inability of the patient to trigger the ventilator can be seen as "bumps" during expiration.

The simple maneuver of a rapid airway occlusion using the ventilator buttons can provide further information. The end-expiratory occlusion gives a direct measure of autoPEEP once a plateau in the airway pressure is reached.[21] The occlusion of the airway at end-inspiration for 5 seconds will measure the inspiratory plateau pressure, which approximates alveolar pressure. The risk of barotrauma is thought to increase at inspiratory plateau pressures greater than 35 cm H_2O. The inspiratory plateau pressure also can be used to calculate the static compliance. Static compliance is the change in volume over the pressure change when flow has stopped in the airways and lung, measured as plateau pressure. Therefore the calculation of static compliance is

$$C_{static} = V_t / (Pinsp_{Plateau} - PEEP)$$

where V_t is tidal volume and *PEEP* is positive end-expiratory pressure. Dynamic compliance is the change in volume divided by the change in pressure when flow in the upper airway is zero but flow continues in the lung. It can be calculated at the bedside as

$$C_{dyn} = V_t / (PIP - PEEP)$$

where *PIP* is peak inspiratory pressure. Dynamic and static compliance should be similar. Compliance may be markedly reduced in patients with ALI/ARDS because of the presence of pulmonary edema and alveolar flooding.

Studies that have used pressure-volume curves to set ventilator parameters and compared survival outcome have generated interest in the clinical application of pressure-volume curves. Three methods can be used to generate these curves.[22] All methods require that the patient be deeply sedated and usually medically relaxed. This step is necessary to eliminate the influence of the respiratory muscles. The first method used was the super syringe method.[22] In this method, the lungs are inflated in a stepwise manner using a calibrated syringe of a known volume (1.5 to 2 L) from the resting volume to a

maximum of 40 to 50 cm H_2O. The limitations of the method are that it takes a long time, the patient must be repeatedly disconnected from the ventilator, and the results may be influenced by oxygen consumption, changes in gas temperature, and humidity. Because of these limitations, its use is mainly limited to research.

The second method is the multiple occlusion technique.[22] The ventilator system is checked to ensure the absence of leaks. Multiple end-inspiratory occlusions are used to achieve different inflating volumes, each starting at the same lung volume. After several seconds of pause, the static pressure values are obtained and the exhaled volume is read off the ventilator after the occlusion is released. The volumes are plotted against the static pressures to make the pressure-volume curve. This procedure is fairly complex and may not be well tolerated by the patient. In addition, the sequential inflations at different tidal breaths may modify the lung volume history and influence the shape of the curve.

The third method is the low-flow technique.[22] This method is based on the concept that the rate of airway pressure change is inversely related to the compliance of the respiratory system during a passive lung inflation with constant inspiratory flow (15 L/min). This method is rapid and reproducible and does not require that the patient be disconnected from the ventilator.

However generated, the pressure-volume curve is an S-shaped inspiratory curve of three segments (Figure 39-3). The lower inflection point is at the transition from the initial flat segment and the linear part of the curve. It is thought to reflect reopening of collapsed airways. The upper inflection point is at the transition of the linear part of the curve and the final portion of the curve. It is thought to reflect the start of overinflation. The portion of the curve between the upper and lower inflection points represents the target for ventilation in patients with ARDS to reduce the potential for ventilator-induced lung injury.[21]

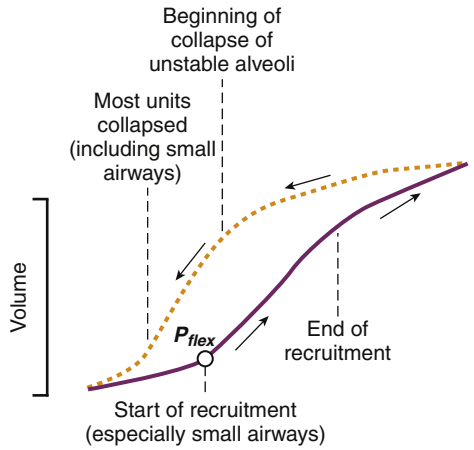

Figure 39–3. Thepressure-volume curve is an S-shaped inspiratory curve that can be divided into three sections. The lower inflection point (*P-flex*) is at the transition from the initial flat segment and the linear part of the curve. It is thought to reflect reopening of collapsed airways. The upper inflection point is at the transition of the linear part of the curve and the final portion of the curve. It is thought to reflect the end of recruitment and the start of overinflation. The portion of the curve between the upper and lower inflection points represents the target for ventilation in patients with ARDS to reduce the potential for further lung injury. *(From Albert RK, Spiro SG, Jett JR, editors:* Clinical respiratory medicine, *ed 2, St. Louis, 2004, Mosby Elsevier.)*

Endoscopy

Bronchoscopy and laryngoscopy are sometimes used in the PICU to visually examine the airway. Direct endoscopy can be performed with a flexible or rigid bronchoscope.[23,24] Flexible bronchoscopy offers the advantages of requiring little sedation and can be done through the endotracheal tube. Flexible bronchoscopy is used to evaluate the size, patency, and compression of the airway during respiration. It also is useful for evaluating the anatomy/structure of the airway and for removing or obtaining secretions from the lung. Rigid bronchoscopy continues to have a role for several reasons. Visualization of the posterior aspects of the larynx and cervical trachea is difficult using a flexible bronchoscope. Therefore better evaluation of vocal cord paralysis, laryngeoesophageal clefts, and H-type tracheoesophageal fistulas are obtained with a rigid bronchoscope. Removal of foreign bodies is performed more easily and safely with a rigid bronchoscope.

Summary

A variety of methods for assessing pulmonary status and function have been reviewed. Use of the derived information may allow ventilator settings to be altered and better matched to patient demands and comfort. Better understanding and interpretation of respiratory monitoring may result in improved patient care.

Chapter 40

Overview of Breathing Failure

Katherine Biagas, Navyn Naran, and Bradley P. Fuhrman

PEARLS

- Three pathways to breathing failure are (1) impaired neural control, (2) failure of the muscles of breathing, and (3) dysfunction of the mechanics of breathing.
- Though diverse stimuli drive respiratory cycling and effort, all must be processed by the brain to affect respiratory muscles.
- Volitional control of breathing is supratentorial and may dominate automatic control in the awake state, but may be lost in brain injury with or without loss of automatic control.
- Automatic control of breathing is integrated in the medulla and involves numerous separate brainstem regions, which are so widely dispersed that some evidence of respiratory drive may persist even after near total loss of brain function.
- Muscles of breathing include the diaphragm, intercostals, and accessory muscles. The diaphragm works like a piston to expand the thorax and displace abdominal organs caudad. Intercostal muscles participate in both inspiration and expiration. The thoracic accessory muscles (scalenes, sternocleidomastoids, pectoralis minor, and erector spinae) all elevate the ribs and facilitate inspiration. The abdominal muscles (rectus abdominis, transverse abdominis, and the obliques) facilitate expiration.
- The respiratory muscles can fail from overwork (as might occur in asthma) or from inadequate supply of blood flow, oxygen, or nutrients (as might occur in shock or sepsis, even when there is no evidence of lung disease).
- Dysfunction of the mechanics of breathing can contribute significantly to respiratory muscle workload. Abdominal distension, for example, worsens the angle of contraction of the diaphragm from the vertical, and opposes its descent.
- Assisted ventilation can (1) prevent breathing failure from progressing to respiratory arrest, (2) improve gas exchange, and (3) reduce metabolic expenditure for muscle work in the patient with limited reserve.

Respiration involves movement of air (breathing), diffusion of gases between alveolus and pulmonary circulation, circulation of blood between tissue and lung, and tissue energy metabolism. This chapter will provide an overview of spontaneous breathing and breathing gone awry, and will set the stage for later chapters on respiratory disorders. The term "breathing failure" is used in this chapter to limit consideration to mechanical failure of the respiratory pump that drives air movement. Breathing failure is arguably the most common cause of arrest in infants and children.

Physiology of Breathing

Diaphragm (Structure and Function)

The diaphragm arises from the embryologic pleuroperitoneal fold. Myoblasts migrate from cervical somites to the pleuroperitoneal fold where they arrange themselves into a sheet on a mesenchymal substrate that separates the peritoneum from the abdomen. Once fully formed, the diaphragm originates from bilateral tendinous crura attached to the spinal column and inserts as a costal tendon attached to the chest wall between the sixth and twelfth ribs. The dome of the diaphragm remains largely tendinous. This structure, a circular attachment to the thoracic wall, vertical muscle orientation adjacent to the thorax, and attachment to a flattened central tendinous dome (Figure 40-1), works like a piston during breathing to enlarge the thorax and displace abdominal contents downward.

Approximately 50% of the diaphragm consists of type I fast twitch muscle fibers, which have high endurance and are resistant to fatigue. The remainder of the diaphragm is made up of type IIA and type IIB fibers, which have different properties.[1] Type IIA fibers are important in achieving high levels of minute ventilation quickly, have good endurance, and can contract rapidly, but are not able to sustain long-term power output. Type IIB fibers cannot sustain their force of contraction because they possess lower oxidative capacity and are more susceptible to fatigue. The greater the force of contraction required, the more motor units of the diaphragm are recruited. There appears to be little difference between the activity of costal muscles and crural muscles, either during normal breathing or in response to hypoxia and hypercapnia.

When a patient lies supine, the diaphragm rests against the inner surface of the rib cage. When the diaphragm contracts and its muscle fibers shorten, the whole diaphragm moves down, lowering pleural pressure and increasing intra-abdominal pressure. The increase in intra-abdominal pressure generated by descent of the diaphragm acts as a caval pump to enhance cardiac filling.[2] Because of its alignment against the lower ribs (zone of apposition), descent of the diaphragm also expands the caudal portion of the rib cage.

The muscle of the diaphragm extends from the costal insertion onto the dome of the diaphragm. When the diaphragm is "high," it is loaded for greater force of contraction. When it is "low" or "flat," it is unloaded and disadvantaged.

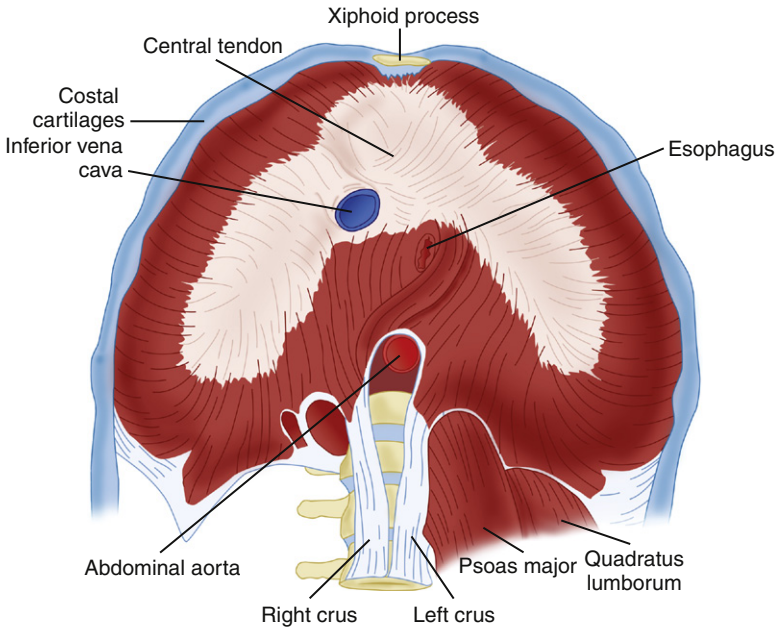

Figure 40–1. The diaphragm is attached circumferentially to the thoracic wall. Its muscular portion extends onto the dome, where it is tendinous and flattened. When the muscle contracts, the dome descends like a piston, enlarging the thorax and displacing abdominal contents downward.

The diaphragm is the major inspiratory muscle of the neonate. It increases in thickness with age (as its muscle mass increases). It also becomes appositional to a longer segment of chest wall with growth, enhancing its effectiveness as an inspiratory piston.[3] In the neonate, the muscular diaphragm has a greater angle from the vertical than that of the adult, which reduces its effectiveness as an air pump (Figure 40-2). This angle approaches zero with growth, increasing the diaphragm's effectiveness with advancing age. The importance of this angle as an impediment to diaphragmatic effectiveness becomes exaggerated at total lung capacity, with air trapping, and when the abdomen is distended, all of which flatten and unload the diaphragmatic muscle (Figure 40-3).

Intercostal Muscles

The rib cage is fixed to the spine and to the sternum. Thoracic volume is modified during breathing primarily by changing the angle of the anterior ribs to the horizontal. At rest, the ribs slope caudad from their spinal attachments. The rib cage tilts upward during inspiration. The intercostals muscles form three functional sheets. The outermost (external) sheet and the parasternal sheet act to displace the ribs cephalad as they shorten. This increases both the anteroposterior and lateral dimensions of the thorax. There is also a deep (internal) layer of intercostal muscle at right angles to the external sheet that acts to displace the ribs caudad when it contracts. Thus, the intercostals muscles play both inspiratory and expiratory roles in breathing by reshaping the thorax.

Accessory Muscles of Respiration

Though quiet expiration is largely passive, resulting mostly from elastic recoil of the lung, active expiration may be assisted by contraction of abdominal muscles (rectus abdominis, transverse abdominis, and the obliques). During quiet breathing, abdominal muscle tone elevates the diaphragm during expiration, increasing the zone of apposition and loading the diaphragm for greater inspiratory contractile efficiency.

Accessory muscles of inspiration include the scalenes, sternocleidomastoids, pectoralis minor, and erector spinae, all of which elevate the ribs during contraction. During quiet breathing, accessory muscles play a minor role, but during respiratory exertion, they may play a major role and may act to unload and unburden the diaphragm and intercostals. Even profoundly neurologically impaired children, who exhibit little volitional activity, can use accessory muscles of breathing when distressed. Children with dysfunction of the primary muscles of respiration may rely on their accessory muscles even at rest.

Integrated Control of Breathing

Control of breathing involves numerous afferent and efferent neural arcs, including volitional, sensory, and biochemical input and motor output to respiratory muscles, facial structures, and airway effectors. All of these signals are integrated, modulated, and emitted to effector organs by the brain. It is for this reason that brain death eliminates all breathing function.

The phrenic nerve arises from the cervical spinal cord (C3-C5) and migrates with the myoblasts to the pleuroperitoneal fold. Separate branches innervate the crural and costal regions of the diaphragm, and both regions include slow and fast twitch muscle fibers. These nerves secrete acetylcholine and transmission may be blocked by many drugs and toxins, including the clinically useful neuromuscular blocking agents. Phrenic motor neurons and muscle fibers continue to grow postnatally. The intercostal muscles are innervated by thoracic intercostals nerves.

The diaphragm and intercostal muscles work in unison, but also have individualized functions in breathing. When their functions are separately impaired, as in quadriplegia or

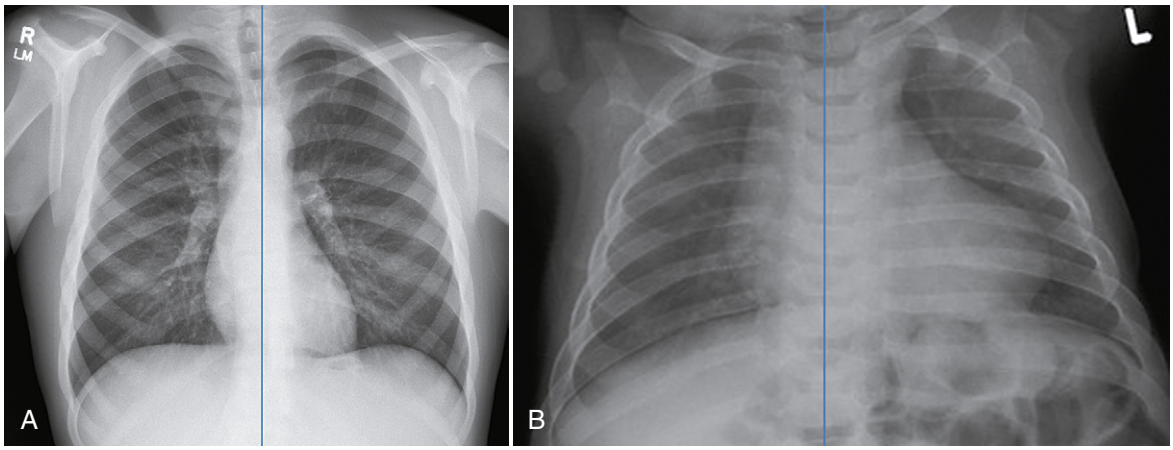

Figure 40–2. The angle of the muscular diaphragm to the vertical is narrow in the older child (**A**) and adult than it is in the infant (**B**). This more horizontal traction on the dome may be disadvantageous when the muscle of the infant diaphragm contracts. *(Courtesy Women & Children's Hospital of Buffalo, NY.)*

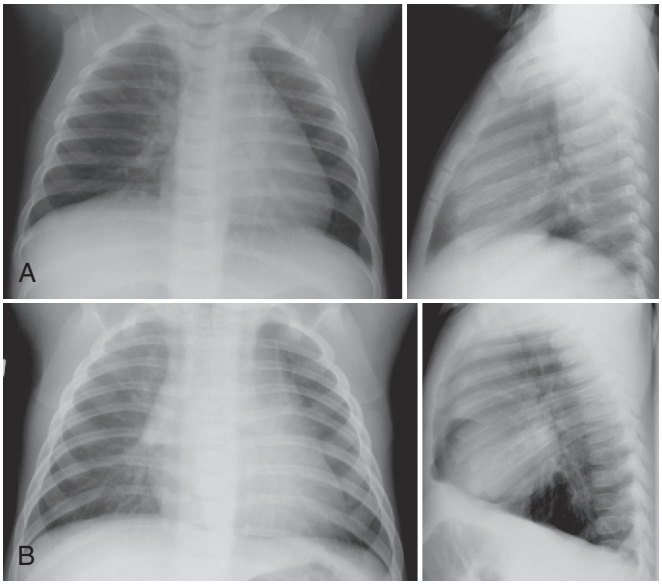

Figure 40–3. The normal position of the diaphragm (**A**) allows it to stretch or "load" during expiration. In inspiration, its muscular attachment to the thorax pulls it vertically downward. Air trapping (**B**), abdominal distension, or other disorders that cause flattening of the diaphragm interfere with "loading" and with the direction of contraction. *(Courtesy Women & Children's Hospital of Buffalo, NY.)*

diaphragm paralysis, abnormalities of gas exchange occur. DiMarco et al[4] showed that ventilation to basal lung regions is generally preserved when intercostal function alone is impaired, whereas, with isolated diaphragmatic paralysis, ventilation of more cephalad regions of the lung is relatively preserved. Costal and crural portions of the diaphragm are both responsive to hypercarbia and hypoxia.[5]

Neural Automatic Control of Breathing

The generation of respiratory patterns resides in the brainstem, in a respiratory complex consisting of the dorsal and ventral medullary and pontine respiratory groups.[6] These three neural groups coordinate and control inspiration and expiration. They modulate input from chemoreceptors, mechanoreceptors, and lung stretch receptors. In this manner, they integrate blood gas stimuli, chest wall tension, and lung stretch signals to generate and modulate an oscillatory pattern of breathing.[7]

Innervation of the laryngeal muscles modulates airway dilation and constriction. Neurons in the hypoglossal nucleus, which is the motor nucleus for the tongue, provide breath-by-breath signals to protruder muscles of the tongue to enlarge the oral airway. The trigeminal motor nucleus also plays a role in tensing the tensor palate muscle of the nasopharynx, which helps to minimize airway resistance. The alae nasi muscles, controlled by the facial motor nucleus, can actively enlarge the nostrils to facilitate inflow of breath.

The ventral medullary group functions in sleep, anesthetized, and awake states, but how organization of activity differs in these distinct states is not known. Blood pressure is tied into excitatory or depressant respiratory activity. This is thought to occur in the rostral ventromedullary area. It is also suggested that this area mediates responses to carbon dioxide (through both tidal volume and rate control), and responses to resistive breathing.[8] Lesions in the ventral medulla have been implicated in the etiology of sudden infant death syndrome and apneic episodes.[9]

Automatic control of breathing is so widely dispersed within the brainstem that it is no wonder that elements of respiratory cycling persist in many patients severely devastated by brain injury. Use of accessory muscles of respiration and motor components of respiratory distress may persist even when supratentorial function and most brainstem reflexes are absent. In the awake state, breathing patterns may be dominated by voluntary cortical activity that reaches the muscles of respiration by way of the corticospinal motor tract. Specific brain lesions may independently impair either automatic or spontaneous breathing controls.

Chemoregulation in the Physiology of Breathing

The aortic arch and the bifurcation of the common carotid artery house chemoreceptors that respond to both hypercapnia and hypoxemia. Changes in carbon dioxide are recognized by both central and peripheral chemoreceptors. The brainstem may distinguish acute from chronic hypercapnia

by sensing the acid base status of the cerebrospinal fluid. Sustained hypoxia evokes a cascade of ventilatory, neurochemical, and metabolic responses. Responses in immature animals are characterized by earlier and more marked depression of ventilation than is found in fully mature animals. Ventilation during hypoxia incorporates a number of compensatory mechanisms (stimulation or depression) from multiple systems. The time course of these responses is developmentally regulated. When hypercapnia is combined with hypoxia, the ventilatory responses are exaggerated.

The predominant drive to breathe during hypoxia and hypercarbia is mediated by stimulation of chemoreceptors of the carotid and aortic bodies. Hypercapneic drive predominates under most circumstances, but hypoxic drive may persist and predominate if the response to carbon dioxide is blunted (as in chronic respiratory acidosis). These chemoreceptors then stimulate the respiratory center in the medulla to increase minute ventilation. In the absence of brainstem function, there is no respiratory response to either hypercarbia or hypoxia.

Breathing Failure

When challenged, muscle tension can be increased either by increasing the frequency of firing or by increasing the number of motor units being fired. At low muscle tension, the *number* of motor units participating in contraction may be increased before frequency is raised. Recruitment is used to increase work. To achieve an even greater increase in force, the *frequency* of firing of individual motor units may be raised, such that while the number of motor units is held constant the *work* of each motor unit is increased.

Working skeletal muscles rely on a continuous supply of oxygenated blood. Diaphragmatic function can be impaired if blood flow or oxygenation is reduced. Diaphragmatic muscle cannot operate at optimal length (force-length relationship) to generate the appropriate contraction (force-velocity relationship) if energy demand outstrips energy supply. The combination of suboptimal force-length and force velocity relationships causes rapid, shallow breathing, largely from dysfunction of Type II B fast-twitch glycolic fibers.

Respiratory muscle fatigue develops during exhaustive exercise. Prolonged malnutrition has also been shown to affect the diaphragm's muscle structure and to impair its ability to generate force. On the other hand, it has been shown that respiratory muscle training can lessen the development of respiratory muscle fatigue.[10] Training of the diaphragm can increase capillary density, myoglobin content, mitochondrial enzyme concentration, and the concentration of glycogen, but persistent mechanical ventilation (particularly during deep sedation or paralysis) decreases muscle strength by allowing disuse muscle atrophy.

In acute illness, breathing fails if respiratory muscle demand for blood flow, metabolic substrate, and oxygen delivery outstrips supply, just as it does in exhaustive exercise.[11] The point at which this occurs is influenced by many factors, including the energy cost of breathing, duration of contraction per breath, velocity of contraction, operational length of muscle fibers, energy supply, efficiency of muscles, and state of muscle training.[12] Respiration can also fail if control of breathing is impaired. In any event, breathing failure, if untreated, may cause respiratory arrest and death.

Final Common Pathways to Breathing Failure

There are several discrete mechanisms that may cause breathing failure (Table 40-1). Each of these final common pathways may be triggered or compounded by other discrete adversities, and independent pathways of breathing failure may converge to cause respiratory arrest (or need for mechanical support of breathing).

Failure of Neural Control

The brain may fail to drive rhythmic breathing for a variety of reasons. The brain is susceptible to injury, ischemic stroke, central nervous system hemorrhage, suppression of brain function by cold, structural dysfunction, chemical suppression, signal disruption, and intrinsic disorders of respiratory control. Efferent neural pathways may be blocked by spinal cord lesions, spinal anesthesia, phrenic nerve injury, or neuromuscular disorders. Examples are cited in Table 40-2.

Table 40–1 Failure of Breathing

Mechanism	Examples
Failure of neural control	Uncal herniation, central hypoventilation
Failure of muscles of breathing	Insufficient muscle blood flow, hypoxemia
Failure of mechanics of breathing	Flail chest, diaphragmatic paralysis

Table 40–2 Causes of Failure of Neural Control of Breathing

Mechanism	Example
Brain injury	Closed head trauma
	Ischemic stroke
Severe supratentorial stroke	"Locked-in" syndrome (loss of volitional control of breathing)
Lateral medullary stroke	Ondine's curse (loss of automatic control)
Subarachnoid hemorrhage	Intracranial hypertension with uncal herniation
Brain suppression by cold	Cold water drowning
Structural brain dysfunction	Brain stem glioma
Chemical suppression	Narcotic overdose
Signal disruption	Seizure
INTRINSIC DISORDERS	
Idiopathic	Ondine's curse
Immaturity	Apnea of prematurity
Spinal cord lesion	Poliomyelitis, traumatic cord transection
Spinal anesthesia	Inadvertent spinal anesthesia
Phrenic nerve injury	Cardiac surgical phrenic nerve injury
Neuromuscular disorder	Curare poisoning, botulinum and many snake venoms

Note that volitional and automatic control of breathing may be separately and independently affected. In Ondine's curse (resulting from stroke involving the lateral medulla), automatic control is impaired, whereas volitional control may persist in the awake state. Supratentorial stroke may impair volitional control of breathing, though automatic control of breathing may be preserved. Central hypoventilation is abnormal respiratory control by the brain and results in hypercapnia. Patients with central hypoventilation may have otherwise normal neurologic functioning or concomitant neurologic injury. Unless mixed with peripheral neuromuscular disease, patients have normal muscle strength, but the essential feature is altered responses to respiratory acidosis.[13] Respiratory patterns may also be abnormal. Central hypoventilation is most apparent when patients are sleeping. Apnea of prematurity, which may persist beyond term, is still not well understood, but is clearly aggravated by concomitant infection.

Peripheral (extracranial) neural disorders include spinal cord injury, myasthenia gravis, anticholinesterase poisoning, and Guillain Barré syndrome. The hallmark of these diseases is muscle paresis or paralysis. Hypercapnia is a common feature. Depending on the extent of weakness, patients will be unable to increase their work of breathing in the face of lung disease. Clinical signs such as tachypnea and accessory muscle usage cannot be relied on. Abnormal arterial blood gases may be the only indications of worsening breathing failure, especially in patients with altered sensorium. Patients with spinal cord lesions develop muscle weakness below the level of injury. For instance, patients with lower cervical cord injury may have preservation of suprasternal muscle action but have loss of other accessory muscle function as well as diaphragmatic dysfunction or paresis. These patients will have vigorous suprasternal retractions that expand the lung apices, but have little other movement.

Failure of Muscles of Breathing

Causes of breathing muscle failure are listed in Table 40-3, along with examples. They may be crudely divided into causes of muscle exhaustion and causes of muscle plegia or paralysis and causes of muscle tetany.

In pediatric critical care, the most common cause of failure of the muscles of breathing is exhaustion. The respiratory muscles may become exhausted when responding to excessive workload. Airway obstruction (fixed or functional), lung stiffness, thoracic stiffness (e.g., anasarca), abdominal distension, air trapping, and inefficient ventilation-perfusion matching (e.g., high ventilation-perfusion mismatch, which functionally wastes ventilation) are examples. Respiratory muscles may also become exhausted if their effort is not supported by adequate nutrition, blood supply, and oxygen delivery. Respiratory distress can be likened to running a marathon. There can be a "wall" beyond which respiratory muscle metabolism is not able to sustain further respiratory effort. Without assistance, after these muscles reach their "wall," respiratory arrest occurs.

In both shock and hypoxemia, oxygen delivery to respiratory muscle may prove inadequate to meet demand on a minute by minute basis.[14] Skeletal muscle may sustain a transient oxygen debt by unloading oxygen from myoglobin, but such reserve is limited. It can also perform anaerobic metabolism to generate ATP using the Kreb cycle, but only until levels of reducing substances (diphosphopyridine nucleotide), unable to participate in oxidative phosphorylation, build up to such a degree that they inhibit the activity of Kreb cycle enzymes. Over a range of oxygen delivery, metabolic use of oxygen is insensitive to rates of supply (delivery), but below some threshold, muscle aerobic metabolism must inevitably be reduced.[15]

Mitochondrial dysfunction may aggravate deficient muscle metabolism in sepsis. Impaired oxygen utilization may contribute to failure of breathing in other mitochondrial crises as well. One of the indications for intubation and mechanical ventilation in patients with septic shock is to avert respiratory arrest from loss of oxidative metabolism with exhaustion and failure of the muscles of breathing.

There are a few conditions in which muscle contraction may be impaired by dysfunction of the myocyte. Tetrodotoxin (puffer fish) blocks the fast voltage-gated sodium channel of the muscle cell, thereby causing paralysis. Hypokalemia may impair muscle contraction and hypokalemic periodic paralysis has similar effects. Tetanus and hypocalcemia are capable of causing tetanic contraction that can impair breathing.

Failure of Mechanics of Breathing

Mechanical factors may pose acute or chronic impediments to breathing. Some place such a burden on respiratory muscles that they become exhausted (e.g., flail chest, severe thoracic dystrophy, deformity). Others cannot be overcome by any effort (e.g., foreign body, pneumothorax). Chest and spinal deformities, diaphragmatic eventration, prune belly syndrome (in which abdominal musculature is virtually absent), and deformities that flatten the diaphragm may either cause chronic respiratory insufficiency or may contribute to intolerance of intercurrent processes such as pneumonia.

Table 40–3 Causes of Muscle Failure

Mechanism	Example
Muscle exhaustion	
Overwork	Lung dysfunction, airway obstruction
Inadequate substrate	Shock, hypoxemia
Muscle plegia	Hypokalemia
Muscle tetany	Tetanus, hypocalcemia

Breathing Failure from Lung Disease

Acute lung disease may progress to breathing failure along one of several pathways. The primary mechanism is respiratory muscle exhaustion. Both excessive demand and impaired supply may come into play, and, in many children, poor thoracic mechanics and neurologic impairment contribute to breathing failure from acute lung disease.

Typically, lung disease increases the work of breathing. Hypoxia and hypercarbia drive the respiratory muscles toward exhaustion. Efficiency of the respiratory system is impaired by lung regions of high ventilation-perfusion ratio. Because these regions see scant blood flow, they actually waste ventilation and breathing effort. On the other hand, low ventilation-perfusion ratio segments cause hypoxemia, which impairs oxygen delivery to tissue and makes circulation inefficient. When oxygen delivery is too low, muscle oxygen utilization becomes

delivery dependent, and muscle work capacity declines. Add to these factors others, such as the compliance of the infant chest (which wastes breathing effort), the deformity of kyphoscoliosis (which makes breathing less efficient), the inefficiency of the infant diaphragm that operates at a wide angle to the chest wall, abdominal distension (which further widens that angle and opposes descent of the diaphragm), and the nutritional issues of chronic illness, and progression toward respiratory arrest is accelerated. Superimposed immaturity, neuromuscular dysfunction, or other comorbid conditions may also exacerbate breathing failure.

As breathing failure worsens, fatigue causes the patient's respiratory effort to deteriorate. Patients use accessory muscles less, they develop brief respiratory pauses, and they progress to apnea followed by respiratory arrest. Respiratory pauses are a subtle but helpful warning sign that should be interpreted as impending respiratory arrest. Pauses warn that respiratory support is indicated. Another helpful sign is grunting. Grunting is a low-pitched sound produced by partial or total closure of the glottis in expiration. Grunting is thought to augment expiratory lung volume (FRC) and increase arterial oxygen tension much like positive end-expiratory pressure (PEEP).[16] Grunting is also a warning of possible impending arrest in children and adults with respiratory failure,[17] though it also often occurs immediately after birth and may quickly resolve as the neonate successfully navigates transition. Patients may appear anxious and describe a feeling of air hunger. Mental status changes ranging from panic to obtundation may occur. Abrupt respiratory slowing and gasping are harbingers of respiratory arrest.

Ventilator induced lung injury (VILI) and the acute respiratory distress syndrome are histologically inseparable. Two of the mechanisms of VILI are excessive tidal volume and repeated opening and closing of diseased lung units (see Chapter 51). The distress of breathing failure drives breathing. This exertion may overdistend some lung units while contributing to closure and reopening of others. The ausculatory finding of rales in patients with pneumonia supports the contention that closure and reopening of lung units is characteristic of parenchymal lung disease. Ventilation-perfusion mismatch suggests the presence of both overdistended and collapsed alveoli. One must ask: can spontaneous breathing during respiratory failure promote an injury identical to VILI? Can spontaneous breathing of the patient with severe lung disease and breathing failure worsen lung mechanics and accelerate breathing failure?

After a patient has been intubated for breathing failure, tidal volume can be controlled, alveoli can be stinted open by PEEP, and the risk that superimposed secondary lung injury may worsen lung disease may actually be reduced (compared with the risk of an analogous injury by spontaneous breathing). Intubation also interrupts the progression from breathing failure to respiratory arrest.

Restrictive Versus Obstructive Respiratory Disease

Though restrictive and obstructive pulmonary processes act through the same final common pathways of breathing failure, their mechanics and clinical manifestations often differ. Restrictive diseases are those that limit lung expansion. These include processes that (1) fill alveoli with blood, infectious material, edema, or other debris; (2) involve expansion or swelling of the alveolar interstitium; (3) compress the lung, as with pneumothorax or effusion; or (4) impair excursion of the chest wall or thoracoabdominal region because of neuromuscular dysfunction, skeletal deformity, abdominal distension, ascites, or anasarca. These processes are characterized by a reduction in vital capacity, small resting lung volumes, but normal or near-normal airways resistance. The physical examination reflects these processes. Patients are tachypneic, taking rapid, shallow breaths. Auscultation of the chest may reveal fine inspiratory crepitations (crackles) or rales, evidence of parenchymal lung disease. Poor excursion of the chest wall is usually readily appreciated. Retractions (subcostal and intercostal) are common and indicate significant respiratory effort.

Obstructive diseases of the lung are common in childhood and are characterized by obstruction to flow in airways. Obstructive diseases may be classified as extrathoracic (above the thoracic inlet) or intrathoracic (below). Obstruction may be the result of occluding material or tissue in airways, elevated tone of the smooth muscle of airway walls (reducing caliber of the lumen), weakness of the airway wall causing collapse and impeding gas flow, or fixed extrinsic compression of airways. In some diseases, several of these processes occur simultaneously. Indeed, secondary obstruction is a common phenomenon. Obstruction in a proximal airway may cause turbulent gas flow downstream in distal airways. Turbulent gas flow causes the wall of the still developing airway to flutter, further weakening the wall's structure and exacerbating overall obstruction.

The hallmark of extrathoracic obstruction is inspiratory noise (stridor or stertor). The affected airway segment lies between the nose and the proximal trachea. Inspiratory stridor is a vibratory sound heard because the reduction of intrathoracic pressure during inspiration narrows the extrathoracic (subglottic) airway, generating an inspiratory noise. Stertor is a snoring noise generated in the nasopharynx. Airways with severe obstruction flutter in both inspiration and exhalation, causing biphasic stridor or noise heard in both phases of the respiratory cycle. Other characteristic sounds may help to identify the obstructed airway segment (Table 40-4). In extreme obstruction, patients may position themselves to maximize airway caliber (remaining upright, leaning slightly forward, and holding the head in the "sniffing position" to enhance alignment of the pharynx and larynx). It should be noted that generation of noise requires air flow. With very severe obstruction, there is little air flow and little noise is generated. Loss of noise, despite increased effort, is an

Table 40–4 Abnormal Sounds Indicative or Extrathoracic Airway Obstruction

Sound	Condition
Hoarseness	Unilateral vocal cord paralysis
Muffled voice	Supraglottic or infraglottic processes, including epiglottitis
"Hot potato" voice	Oral, retropharyngeal abscess
	Ludwig's angina
"Barking" cough	Laryngotracheobronchitis (croup)
Monotone, hurried sentences	Bilateral vocal cord paresis

ominous sign and is indicative of complete obstruction and impending respiratory arrest.

The hallmark of intrathoracic obstruction is an expiratory sound. In intrathoracic obstruction, forced expiration compresses soft airways, causing a musical wheeze. This obstruction may be largely relieved by inspiration, which tends to dilate intrathoracic airways. In severe intrathoracic obstruction, sounds may be heard during both phases of the respiratory cycle. In the classic pediatric disease of intrathoracic obstruction is asthma, high-pitched wheezes on exhalation are heard early in the episode. As airway obstruction worsens, wheezes are heard in inspiration as well. With severe obstruction, wheezes diminish because there is little gas flow.

The character of the voice and ability to speak (in words, phrases, or sentences) may be helpful in the evaluation of airway obstruction. Observation of the respiratory rate can be revealing in obstructive disease. With mild obstruction, the respiratory rate is often slower than normal, but may rise as ventilation perfusion inequality develops and increases respiratory drive. Physical examination will often reveal the use of accessory muscles of breathing.

Compensatory Mechanisms in Breathing Failure

A patient may try to compensate for the functional effects of lung disease. These compensatory mechanisms generally come into play before there is evidence of breathing failure. Many of the clinical signs of respiratory distress, discussed previously, are evidence of compensatory mechanisms. Understanding these mechanisms improves recognition of impending failure.

Compensatory Mechanisms in Restrictive Lung Disease

Tachypnea is the patient's primary compensation for the small lung volume of restrictive lung disease and is the earliest detectable clinical sign. Additional compensation is achieved by recruitment of accessory muscles. Patients with restrictive disease may take periodic sigh breaths, which are larger than tidal breaths, to recruit collapsing units. Compensatory mechanisms also operate to maximize gas exchange in diseased lungs. Hypoxic pulmonary vasoconstriction is an important mechanism to improve gas exchange in normal lungs. Hypoxic pulmonary vasoconstriction is a direct response of the vascular smooth muscle to low PaO_2 alveolar units. The precapillary arteriole of such units constricts in response to low O_2 tension in the adjacent postcapillary venule, thereby directing blood away from poorly functioning alveoli. In a lung with patchy disease, the overall effect of the hypoxic pulmonary vasoconstriction response is to shunt blood away from diseased segments and to allow flow to healthier areas. This may, paradoxically, increase pulmonary vascular resistance and oppose right ventricular ejection. Inhaled nitric oxide provides an exogenous means to improve ventilation perfusion matching (by preferentially dilating vessels to ventilated lung segments) without afterloading the right ventricle.

Compensatory Mechanisms with Obstructive Lung Disease

The major compensations in obstructive disease focus on maximizing airflow. As previously stated, patients naturally position themselves to maximize opening of their airway. If this is the case, repositioning patients, especially to the supine position, may worsen airflow. For the infant, carefully monitored prone positioning may aid gas exchange and assist spontaneous breathing.[18] Control of respiratory rate provides another means of compensation. In mild obstructive disease, the respiratory rate is lower than normal. As resistance to airflow rises, total work of breathing also rises greatly. To maximize efficiency, the respiratory rate falls. Longer respiratory cycle times allow longer times for gas flow. Having said this, the clinician will recognize that many patients with obstructive lung disease present with tachypnea, not decreased respiratory rates. The causes of tachypnea are (1) ventilation/perfusion mismatching with hypoxemia and sometimes hypercarbia driving the respiratory rate and (2) development of atelectasis in unventilated lung segments resulting in the superimposition of a restrictive process on an obstructive one. Tachypnea in such patients is counterproductive, greatly increasing the work of breathing and further diminishing gas flow.

Special Conditions

There are several conditions deserving of special note. In these, physical findings may reflect specific aberrations that generate specific compensatory mechanisms.

Infancy

The configuration of the infant's chest wall differs from that of adults. Orientation of the ribs is more horizontal in infants than in adults and they move less during breathing. The chest wall is more compliant and is composed of more cartilaginous tissues. Strength of intercostals muscles is less. In the absence of muscular action, FRC is determined by the elastic forces of the lung and the chest wall, which oppose each other. Accordingly, the infant's more compliant chest wall and weaker musculature results in lower FRC. Infants with lung disease use expiratory braking (grunting), which involves constriction of pharyngeal muscles and glottis, to increase end-expiratory lung volume. Although this promotes higher FRC, it imposes a disadvantageous increase in muscular work.

Infant respiratory muscle fibers differ from those of adults. The infant diaphragm contains a greater proportion of type II fibers, which are unable to sustain repeat strenuous activity. Hence, the infant's diaphragm fatigues more quickly than that of the adult.[19] The infant's diaphragmatic anatomy is also disadvantageous. The reduced appositional area and greater diaphragmatic angle of the infant results in lesser lung volume expansion with diaphragmatic contraction. Because pulling the rib cage cephalad produces less outward chest displacement in the infant than in the adult, the infant's tidal volume is, in the aggregate, more dependent on diaphragmatic contraction than that of the adult.

Superimposition of breathing failure on infant respiratory function exacerbates these mechanical disadvantages. In normal respiration, the chest wall and abdomen move inward and outward in synchrony. With restrictive lung disease, the respiratory pattern may be out of phase, called paradoxical breathing. Contraction of the diaphragm pulls the compliant infant chest wall inward during inspiration and pushes abdominal contents outward. This respiratory pattern is greatly exaggerated by severe restrictive lung disease. With decreased lung compliance, the pleural pressure swing is exaggerated, pulling the chest wall further inward. Prolonged respiration in

this manner can cause inward deformation of the sternum, or acquired *pectus excavatum*, and is a clinical sign of prolonged respiratory insufficiency. In the infant with severe restrictive disease, recruitment of additional diaphragmatic and accessory muscles, use of compensatory braking and grunting maneuvers, and increases in respiratory rate may be insufficient to maintain a normal FRC. Fatigue comes quickly to the stressed infant with a highly elastic rib cage and at a greatly accelerated respiratory rate. Moreover, such work is extremely energy expensive. Infants with chronic respiratory insufficiency can use as much as 50% of their caloric intake for breathing, leaving few calories for growth and other functions, and resulting in failure to thrive.

Infants are also disadvantaged with respect to obstructive lung disease. In infants and young children, a greater percent of total airways resistance is apportioned to large airways than in adults. Infants are particularly susceptible to nasal obstruction, as occurs during upper respiratory infection, because the nose may comprise as much as 50% of total airway resistance. Moreover, resistance to airflow is proportional to the inverse of the airway radius to the fourth power:

$$R = 8\eta L / \pi r^4$$

where η is gas viscosity, L is airway length, and r is radius of the airways. Resistance is greater in infants and young children because of their intrinsically small airways. Further reduction in airways caliber with obstructive disease (e.g., bronchiolitis) magnifies this problem.

The infant's airways are also less endowed with cartilage than are those of the adult and may be subject to flow limitation during active expiration. The trachea and bronchi may be pathologically compressed during expiration, causing severe obstruction that is worsened by expiratory effort. Such regions of severe and pathologic flow limitation (tracheomalacia and bronchomalacia) may be localized. Similarly, the larynx may be compressed (by atmosphere) during forced inspiration (laryngomalacia) if there is proximal (supraglottic) obstruction.

Thoracic Dysfunction

Neuromuscular disorders generally result in restrictive lung defects. Coexisting obstructive lung disease can be seen with some thoracic defects or with scoliosis. Persistent atelectasis and longstanding lung hypoplasia may lead to atrophy and may destroy supporting airway architecture resulting in air trapping. Deformities of the rib cage and spinal column result in restriction to lung expansion as occurs with isolated scoliosis.[20,21] The most severe of these are classified as "asphyxiating thoracic dystrophies" in which the chest fails to expand at all during breathing. As with the other forms of neuromuscular diseases, hypercapnia predominates. Muscle strength may be normal, but abnormal configuration of intrathoracic muscles and diaphragm may make muscle work inefficient.

With many of these disorders, patients live in a chronic state of increased work of breathing and muscle fatigue. Growth failure is common. They tend to have little ability to meet the added demands of acute respiratory processes, such as respiratory infections, and total breathing failure often ensues. They may have frequent and recurring need for positive pressure support. Yet, the usual signs of impending breathing failure may be absent in patients who are weak, nonresponsive, or have chest wall distortions. In such cases, close monitoring and measurement of arterial blood gases are essential.

Altered Nutritional States: Malnutrition and Obesity

A major functional consequence of malnutrition is altered muscle function. Protein-calorie malnutrition results in decreased muscle energetics. Protein deficiencies alone may have the same effect. Catabolism of skeletal muscle to meet body protein needs results in decreased muscle mass. Malnourished states are easy to recognize when they are the result of longstanding inadequate caloric intake, as in marasmus, but this is rarely seen in developed countries. More common are subtler forms of insufficient nutrition in children who live in a chronically high metabolic state, such as chronic congestive heart failure. Such patients may be unable to consume enough calories for effective positive nitrogen balance. Catabolism is ongoing, sacrificing muscle mass and function. Chronic respiratory insufficiency results in a cycle of progressive breathing failure, increasing work of breathing, and worsening imbalance between calorie intake and expenditure. Recognition of this cycle is imperative; metabolic demands must be decreased by treating the underlying condition, and caloric intake must be increased. In the young child, reversal of this cycle is signaled by resumption of somatic growth. The clinician should also note that in patients with malnutrition, the superimposition of an acute respiratory process, such as an intercurrent respiratory infection, will result in more rapid progression to breathing failure. The patient has little or no reserve for the added metabolic demands and added work of breathing.

At the other end of the nutritional spectrum, obesity has major respiratory consequences. As with obese adults, obese children are at risk from obstructive sleep apnea syndrome. Obstructive sleep apnea syndrome may cause frequent obstructive events. Hypercarbia and hypoxemia may occur. Obstructive sleep apnea syndrome is diagnosed by polysomnography. Treatment includes weight loss, removal of tonsils and adenoids, palatoplasty procedures in some patients, and nightly positive pressure support in others. Additionally, obesity alters lung volumes, especially when children are supine. With abdominal contents pushing up on the diaphragm, FRC and total lung capacity are reduced, representing another form of chronic restrictive disease. This effect is exaggerated in the supine (as opposed to upright) position.

Conclusion

Breathing failure occurs when neural, muscular, or mechanical challenges cannot be overcome by compensatory mechanisms. A common final pathway is muscle exhaustion, either from excessive demand on respiratory muscles or from inadequate supply to these muscles of blood flow, oxygen, or nutrients. Assisted ventilation is important, not only to improve gas exchange, but to also to prevent respiratory arrest from breathing failure. This is true both in lung disease, and in other conditions that impair neural, muscular, or mechanical breathing capacity.

Chapter 41

Ventilation/Perfusion Inequality

Thomas V. Brogan and David J. Vaughan

PEARLS

- Gravity affects the distribution of pulmonary perfusion. Both perfusion and ventilation increase down the lung. Despite these changes, perfusion is tightly matched to ventilation.
- Recent studies have shown that there is significant heterogeneity of pulmonary blood flow and ventilation in isogravitation fields. The pattern of both perfusion and ventilation is fractal in nature.
- The primary ventilation/perfusion abnormality in acute respiratory distress syndrome is intrapulmonary shunt.
- In persons with asthma, ventilation/perfusion mismatch is responsible for hypoxemia, but there is no correlation between measurements of overall airway obstruction and V/Q mismatch.
- Although positive end-expiratory pressure decreases the proportion of shunt, at high levels it also increases dead space.

The primary function of the lung is to exchange oxygen and carbon dioxide between inspired air and blood. Efficient gas exchange requires the close matching of regional ventilation and perfusion (V_A/Q). However, as the largest organ in the body, the lung is influenced by external and internal factors that affect ventilation/perfusion relationships. In children, V_A/Q mismatch and intrapulmonary shunt cause most gas exchange abnormalities (Table 41-1). Lung units that are poorly ventilated in relation to blood flow (low V_A/Q) produce blood with low oxygen content (desaturated blood), but units with high V_A/Q ratios cannot compensate, because the oxygen content of blood leaving these areas has nearly the same oxygen content as that from normal V_A/Q regions as a result of the sigmoid shape of the hemoglobin oxygen dissociation curve (Figure 41-1). Early studies supported the concept that vertical gradients of both ventilation and perfusion produced V_A/Q matching. Newer studies that achieved greater spatial resolution demonstrated that perfusion and ventilation are rather heterogeneous and that this heterogeneity serves to match ventilation and perfusion.

The alveolar gas equation helps us understand the pathophysiology of abnormal gas exchange by providing information on alveolar oxygen tension. According to the Fick equation, under steady state conditions, the quantity of O_2 taken up by the lungs equals the amount of O_2 removed from inhaled air:

$$O_2 = {}_A(F_{IO_2} - F_{AO_2}) \quad (1)$$

where O_2 is O_2 consumption, F_{IO_2} is the fraction of inspired O_2, A represents alveolar ventilation, and F_{AO_2} is the fraction of alveolar O_2. This equation can be rearranged to read:

$$F_{AO_2} = F_{IO_2} - O_2/_A \quad (2)$$

Then, by changing the fraction of gases to their partial pressures, the equation takes the following form:

$$P_{AO_2} = P_{IO_2} - (O_2/_A)(P_B - 47 \text{ mm Hg}) \quad (3)$$

where P_{IO_2} is the inspired P_{O_2} and P_B is barometric pressure. The concept underlying this equation is that alveolar oxygen level (P_{AO_2}) is the difference between what comes in (P_{IO_2}) and the amount taken up by the pulmonary capillaries $[(O_2/_A)(P_B - 47 \text{ mm Hg})]$. The ratio $O_2/_A$ can be estimated from a surrogate for the ratio between O_2 and ${}_A$. By using P_{CO_2} in arterial blood as an estimate of alveolar CO_2, $CO_2/_A$ as an estimator of F_{ACO_2}, and the respiratory quotient $R = CO_2/O_2$, the second term of Equation 3 can be estimated by P_{ACO_2}/R. The alveolar gas equation can then be derived as follows:

$$P_{AO_2} = F_{IO_2} \times (P_B - 47 \text{ mm Hg}) - (CO_2/R/_A) \times (P_B - 47 \text{ mm Hg}) \quad (4)$$

$$P_{AO_2} = F_{IO_2} \times (P_B - 47 \text{ mm Hg}) - (F_{ACO_2}/R) \times (PB - 47 \text{ mm Hg}) \quad (5)$$

$$P_{AO_2} = F_{IO_2} \times (P_B - 47 \text{ mm Hg}) - (P_{ACO_2}/R) \quad (6)$$

Table 41–1 Causes of Hypoxemia

Intrapulmonary Factors	Extrapulmonary Factors
PRIMARY	**PRIMARY**
Ventilation/perfusion mismatch	Decreased minute ventilation
Shunt	Decreased cardiac output
Alveolar-end capillary diffusion limitation	Decreased Fio_2
	SECONDARY
	Decreased P_{50}
	Decreased hemoglobin concentration
	Alkalosis

Distribution of Ventilation

Ventilation of the lung is heterogeneous and is influenced by multiple factors, including gravity, posture, and even experimental technique. Gravity has been considered predominant because of the variation in pleural pressure from the apex to the base of the lung. The lung is a viscoelastic structure encased in the supporting chest wall, with gravity imposing a globular shape on the lung. Pleural pressure is more negative at the apex of the lung compared with the base, increasing approximately 0.25 cm H_2O per centimeter of vertical distance toward the lung base. Thus transpulmonary pressure is more marked at the apex, so apical alveoli are large and at the upper end of the normal pressure volume curve. They distend less for a given pressure change, that is, they are less compliant. In the spontaneously breathing upright human, maximal gas distribution occurs at the base and progressively diminishes toward the lung apex.[1,2] This gradient also exists when inhalation occurs in the supine or lateral decubitus position, although to a lesser degree. Fast inspirations from functional residual capacity (at supranormal flow rates >1.5 L/s) may reverse this distribution with preferential ventilation of the upper parts of the lung.[3]

Heterogeneous ventilation also may occur independent of the aforementioned factors. The time constant (the product of resistance and compliance) is defined as the time required for inflation to 63% of final lung volume, inflation being indefinitely prolonged. Therefore, a given lung unit with a slow time constant will fill more slowly than one with a fast time constant and also empty more slowly. Should the time constants of different lung units vary, as frequently happens in pulmonary illness, gas distribution will be determined in part by the rate, duration, and frequency of inhalation.

Distribution of Perfusion

The predominant characteristic of the pulmonary circulation is that it is a low-pressure system. The mean pulmonary artery pressure (P_{PA}) is approximately 15 mm Hg, whereas the mean systemic arterial pressure is on the order of 100 mm Hg. This finding implies that external pressures play a greater role in determining blood flow within the lung. According to the classical model of lung perfusion, gravity affects pulmonary blood flow (PBF) in a similar fashion and to a much greater extent. In general, the dependent areas of lung receive more blood flow. The pulmonary artery pressure decreases by 1 cm H_2O per centimeter of vertical distance up the lung, so the driving pressure rapidly approaches zero with minimal blood flow to the apices, and indeed P_{PA} may become negative. In the erect human, blood flow progressively increases from apex to base.[4]

The three-zone model of PBF has been widely used to explain the heterogeneity of perfusion within the lung (Figure 41-2).[4] Three variables comprise the components of this model: pulmonary arterial (P_{PA}), alveolar (P_A), and pulmonary venous (P_V) pressures. The degree of blood flow within the lung depends on the relative magnitudes of these pressures within that zone. Zone 1 ($P_A > P_{PA} > Pv$) has negligible blood flow, as the higher alveolar pressure is believed to compress collapsible capillaries. This region is one of minimal gas exchange and "wasted" ventilation. Zone 1 conditions are rare except in cases of diminished pulmonary blood flow (e.g., hypotension or cardiac failure) or increased P_A encountered during positive pressure ventilation. Zone 2 consists of the mid portions of the lungs in which $P_{PA} > P_A > P_V$, where flow rate is determined by the difference between pulmonary arterial and alveolar pressure. Venous pressure does not influence the flow rate. Blood flow progressively increases with descent through this zone as P_a increases, whereas P_{PA} remains relatively constant.

In the lowest zone of the lung described by West et al.,[4] zone 3, $P_{PA} > P_V > P_A$, therefore the arteriovenous pressure gradient ($P_{PA} - P_V$) determines flow rate. This gradient remains relatively constant as it descends through this zone, although because pleural pressures increase less, blood flow is greater in more dependent areas of zone 3. A zone 4 region in the most dependent areas of lung also has been described. In this region, transudated pulmonary interstitial fluid increases interstitial pressures, thereby reducing blood flow; this effect is exaggerated as lung volume diminishes from total lung capacity to residual volume.

PBF in immature animals differs in several important ways from that in adult animals. Studies in piglets suggest that the pulmonary vascular bed may be fully recruited,[5,6] with no

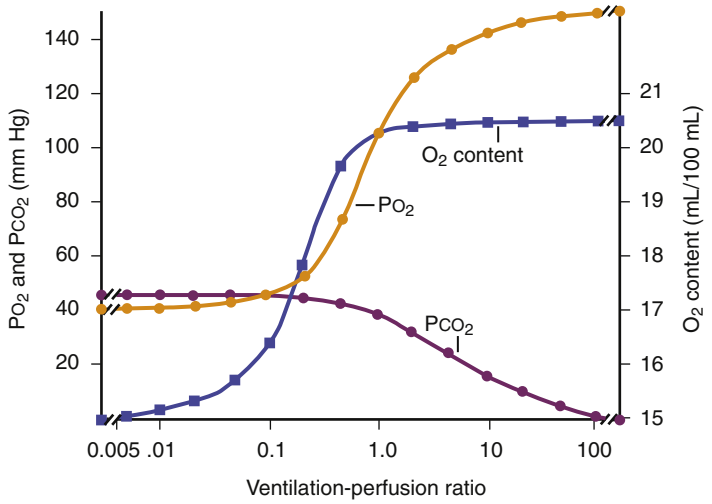

Figure 41–1. Gas exchange in a single lung unit. Changes in P_{O_2}, P_{CO_2}, and end-capillary O_2 content in a lung unit as its ventilation/perfusion ratio is increased from shunt (V/Q = 0) to dead space (V/Q = ∞). Hemoglobin concentration is 14.8 g/dL.

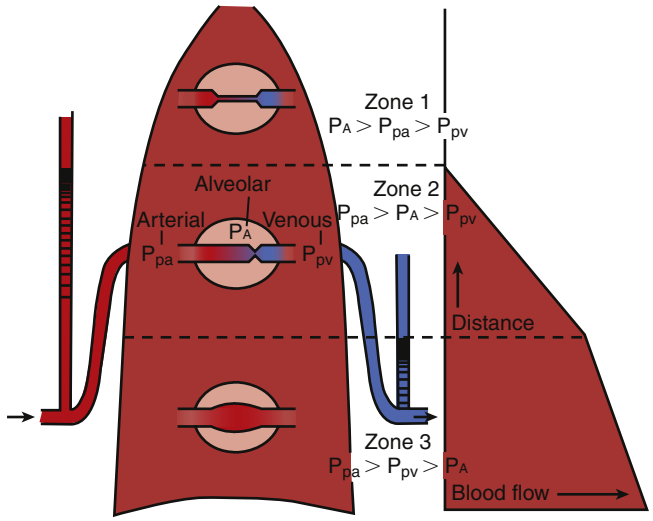

Figure 41–2. Normal distribution of pulmonary blood flow: gravitational model. According to the model, the gravitational driving force for pulmonary blood flow increases down the lung. At the apex (zone 1), flow is absent as alveolar pressure (P_A) exceeds pulmonary artery (P_{PA}) and pulmonary venous (P_V) pressures. In *zone 2,* flow is determined by the driving pressure ($P_{PA} - P_A$). Flow is constant and maximal in *zone 3* because both P_{PA} and P_V exceed P_A where the driving pressure is $P_{PA} - P_V$.

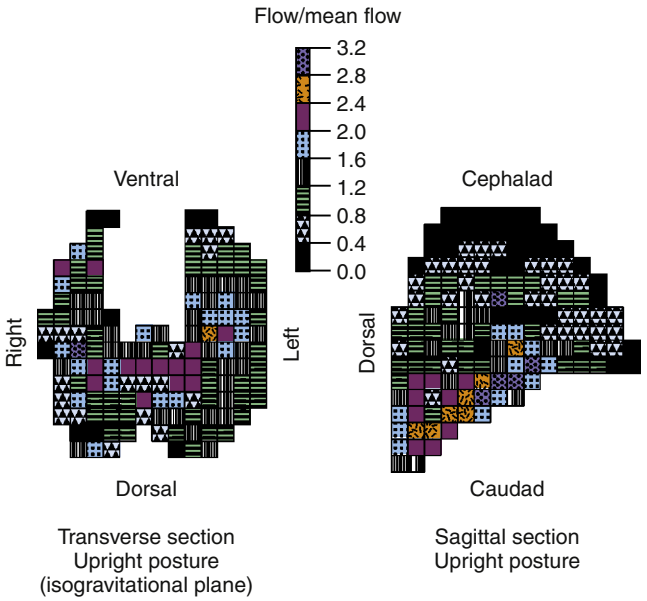

Figure 41–3. Isogravitational heterogeneity of pulmonary blood flow. Reconstruction of transverse and sagittal plane from a single baboon animal during upright posture. Each *square* depicts location and relative blood flow to a piece of lung in a given plane. Heterogeneity of blood flow is present in isogravitational planes. Flow is not random; rather, neighboring pieces tend to have similar magnitudes of flow. Cephalad-caudad (gravitational) gradient is apparent in the sagittal section.

contribution of Starling resistors in the pulmonary circulation during exposure to acute or chronic hypoxia. Furthermore, neonatal piglets show a relative hypoxemia and an increased dispersion of PBF (by the multiple inert gas elimination technique [MIGET]). This dispersion is measured as the standard deviation of PBF and is the second moment on a log scale of distribution about the blood flow mean among both high and low V_A/Q units compared with mature animals. In general, an increase in the standard deviation of PBF also occurs with lung disease.

Fractal Model of Pulmonary Blood Flow and Ventilation

The gravitational model provided a useful and accurate model of PBF. However, as studies employed increasing power of resolution, PBF was shown to have greater heterogeneity than was described by the gravitational model.[7-9] Blood flow in isogravitational planes was shown to be nearly as heterogeneous as the entire lung, yet the gravitational model predicted uniform flow in such planes (Figure 41-3). This heterogeneity in PBF was initially considered random, but the regional flow distributions were shown to be correlated with neighboring regions.[9] Thus high-flow regions were adjacent to other high-flow regions and low-flow regions bordered other low-flow regions. The distribution of PBF was shown to be independent of the scale of measurement, suggesting a fractal nature of PBF.

A fractal structure or process can be described as having a characteristic form that remains constant over a magnitude of scales (Figure 41-4).[9] This concept of self-similarity has been recognized within the topology of the bronchial and pulmonary vascular trees. The height up the lung was shown to account for only a minority of the total variability in regional perfusion.[10] In both dogs and upright baboons, gravity's contribution to overall perfusion heterogeneity was of secondary importance, although more important in upright primates than in dogs.[11] Indirect measurements of perfusion in humans under microgravity conditions showed substantial isogravitational heterogeneity of pulmonary perfusion with a hilar to peripheral gradient.[12] The asymmetry of flow at branches within the pulmonary arterial tree accounts for the heterogeneity of flow within isogravitational planes. Thus regions that share a parent or grandparent branch have more similar flows than do branches that are separated by a greater distance. This fractal pattern of PBF extends down to the subacinar level of gas exchange and is stable with growth.[13,14]

Fractal Model of the Pulmonary Ventilation

The close correlation between regional ventilation and perfusion suggests that ventilation has spatial characteristics similar to regional perfusion. Newer methods of measuring regional ventilation showed a similar pattern with similar heterogeneity to regional perfusion.[15-18] The correlation of regional heterogeneities of ventilation to those of perfusion ensures a narrow distribution of V_A/Q distributions in normal animals. Fractals possess a large area-to-volume ratio that ensures that all cells are serviced by capillaries, and hence they are well suited to the task of diffusion exchange and substrate delivery no matter what the organism's size. The high correlation between regional ventilation and perfusion may be explained by the close correlation of the developing bronchial tree and pulmonary arterial tree during organogenesis.[19]

Under normal circumstances, regional perfusion is tightly matched to ventilation.[20] Hence the innate structure of the lung itself appears to underlie the precision of V_A/Q matching. Lung basal pulmonary vascular tone is minimal, suggesting

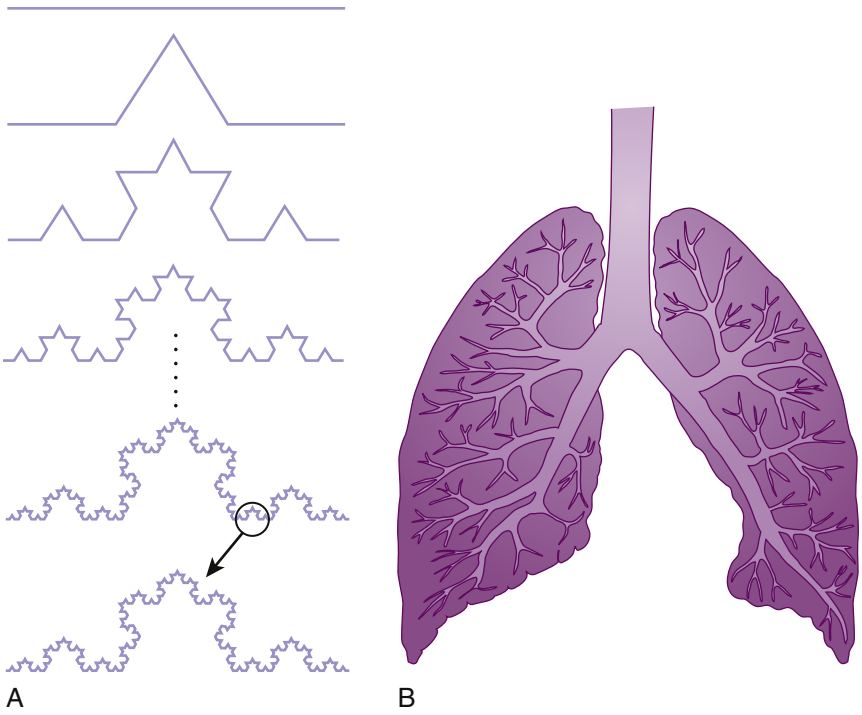

Figure 41–4. Fractal structures. **A,** This curve is produced by a simple iterative transformation beginning with a straight line. At each step the middle third of all lines is replaced with two segments, one-third length of the line, forming part of an equilateral triangle. An infinite number of iterations can be performed. Thus as increasing magnification reveals more detail, the overall appearance of the new segment remains similar to that of the previous segment. **B,** The pulmonary vascular (and bronchial) tree is a repetitive pattern of dichotomous branches that become progressively smaller and fill a predetermined area.

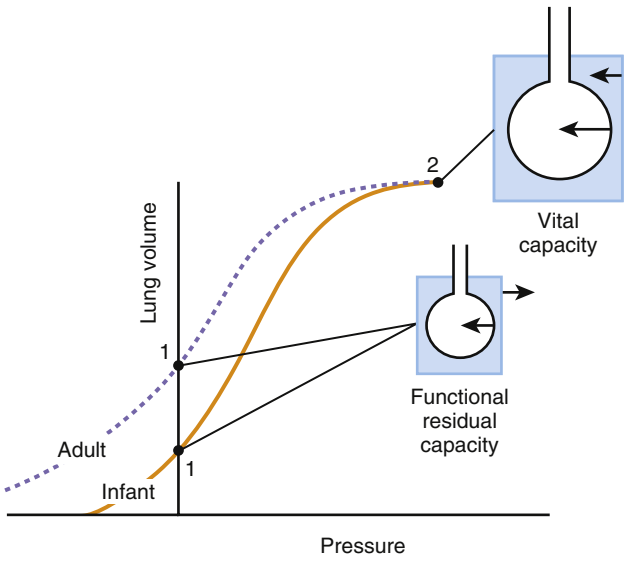

Figure 41–5. Relative ventilation and perfusion maps. Regional ventilation and perfusion scaled to the measured minute ventilation and cardiac output in the pig. Both regional ventilation and perfusion show clustering in which adjacent units have similar flows. There is strong correlation in which areas of high ventilation receive high perfusion and areas of low ventilation receive low perfusion. (These pig lungs were examined in cubes of 1.5–2.0 cm^3 volume.)

that vasoregulation is of minor importance for maintaining close V_A/Q matching in the uninjured lungs.[21,22] This concept was supported by animal and human experiments employing a variety of agents to alter baseline pulmonary vascular tone that showed little effect on ventilation/perfusion matching.[23]

Passive matching of perfusion and ventilation by pulmonary structure suggests an optimally engineered system because it requires no active feedback mechanism during normal function, which tends to develop fewer complications (Figure 41-5).[24] Furthermore, a fractal system delivers substrate with a minimum of energy expended because the fractal structure minimizes the total hydrodynamic resistance of the system. Additionally, the fractal structure appears to reduce the amount of biologic material to construct the vascular and bronchial trees while still filling the space occupied by the lung.[24] Finally, the fractal structure efficient uses the amount of genetic code to construct the vascular and bronchial structure by using a recursive construction mechanism that requires only a handful of proteins. A much greater amount of genetic code would exist if each branch in the bronchial and vascular system required unique genetic code.

V_A/Q Abnormalities in Pulmonary Disease

Hypoxemia

As previously mentioned, the primary causes of hypoxemia in children are shunt and V/Q mismatch. Shunt differs from V/Q mismatch in that it does not respond to increases in inspired O_2. Oxygen content of arterial blood represents a weighted average of the O_2 content of shunted blood (fraction of shunted blood flow within total blood flow [Q_s/Q_t]) and the remaining fraction ($1-Q_s/Q_t$) times the O_2 content of blood that participates in gas exchange (C_cO_2 or pulmonary capillary blood):

$$C_aO_2 = Q_s/Q_t \times C_vO_2 + (1 - Q_s/Q_t) \times C_cO_2 \qquad (7)$$

Q_s and Q_t represent shunt and total lung blood flow, respectively. This equation can then be rearranged to solve for shunt fraction:

$$Q_s / Q_t = \frac{C_cO_2 - C_aO_2}{C_cO_2 - C_vO_2} \quad (8)$$

By measuring arterial (C_aO_2) and venous (C_vO_2) O_2 content and by estimating C_cO_2 from the alveolar gas equation, the fraction of shunted blood can be estimated.

Regional alveolar hypoxia causes pulmonary vasoconstriction that restricts blood flow to the area.[25,26] (A similar though less robust response is seen with decreased mixed venous partial pressure of oxygen [$P_{\bar{V}}O_2$].) The response to a local decrease in Po_2 can restore the local Po_2 only to approximately half its normal level, and its efficiency is best when the alveolar Po_2 is in the 70 to 90 mm Hg range.[26] The degree of hypoxic pulmonary vasoconstriction (HPV) varies across the lung and may be affected by sepsis, vasodilators, anesthetics, and changes in inspired oxygen. Inspiration of 100% O_2 worsens V_A/Q mismatch substantially.[27] In neonatal piglets, exposure to chronic hypoxia with resultant pulmonary hypertension did not significantly alter V_A/Q matching during room air or acute hypoxic gas breathing.[5,6]

Alterations in inspired or arterial CO_2 tensions also have been shown to effect V_A/Q ratios. Low concentrations of inspired CO_2 (3% to 5%) improve V_A/Q matching and perfusion heterogeneity in normal lungs, while hypocapnia produces the opposite effect.[28,29] These changes in V_A/Q heterogeneity appear to be dependent upon changes in pH. Hypercapnia appears to improve oxygenation in injured lungs as well, but detailed analysis of V_A/Q relationships remains to be performed.[30]

Acute Respiratory Distress Syndrome

Acute respiratory distress syndrome (ARDS) is marked by gas exchange abnormalities that include profound hypoxemia refractory to high concentrations of inspired O_2.[31] Patients were found to have a bimodal distribution of lung units, one with essentially normal V_A/Q and another smaller distribution representing shunt that was proportional to cardiac output.[31] In some patients a fraction of units with very low V_A/Q ratios also was found. Areas of high V_A/Q may be observed and correlated with the level of alveolar pressure due to mechanical ventilation and the mechanical properties of the lung. The increase in shunt demonstrated with inhalation of 100% O_2 remained elevated 1 hour after returning to the original FIo_2. Inhibition of HPV in shunt units also may occur as a result of an increase in mixed venous Po_2.

The large intrapulmonary shunt accounts for the lack of response of hypoxemia in patients with ARDS to increases in inspired oxygen. The shunt results from alveolar flooding, atelectasis, and right-to-left shunt through a patent foramen ovale. The low V_A/Q units explain the increase in venous admixture with decreasing inspired fractional concentration of oxygen and may represent transient events that occur when alveoli are in the process of collapsing or reexpanding.[32] Units with low V_A/Q deteriorate to shunt as a result of absorption atelectasis, especially when exposed to high levels of inspired O_2. Diffusion impairment contributes substantially to the gas exchange abnormalities in patients with ARDS.

Pneumonia

Hypoxemia found in patients with pneumonia is multifactorial. Pure shunt was demonstrated in a canine model of pneumococcal lobar pneumonia in the first 48 hours of infection.[33] After 2 days, shunt resolved and perfusion was largely concentrated in alveoli with low V_A/Q ratios. The most common pattern of V_A/Q mismatching in patients with bacterial pneumonia severe enough to require mechanical ventilation was a combination of intrapulmonary shunt and increased perfusion to units with low V_A/Q ratios.[34] High levels of inspired O_2 did not increase in patients with intrapulmonary shunt. Similar findings also were observed in spontaneously breathing patients who had less severe cases of pneumonia.[35] MIGET studies suggested no role for other factors such as intrapulmonary oxygen consumption, diffusion abnormalities, or postcapillary shunt due to increased bronchial blood flow.

Asthma

Ventilation/perfusion abnormalities have been found across the spectrum of patients with asthma, from those in clinical remission to those who are acutely ill. Patients with asthma usually show a bimodal distribution of blood flow with normal units and large areas of low V_A/Q.[36] Patients with asthma experience little intrapulmonary shunt, indicating that collateral ventilation keeps the lung units behind severely obstructed bronchioles open. In these patients, elevated levels of cardiac output augment Svo_2, preserving arterial oxygenation.

Interestingly, patients with asthma demonstrate almost no correlation between measurements of airway obstruction and respiratory and inert gas exchange.[37] A study of serial changes of V_A/Q inequalities and spirometric measurements in patients with acute severe asthma showed that no significant inter-individual correlations existed between maximum airflow rates and V_A/Q inequalities.[37] This finding suggests that spirometric changes predominantly reflect bronchoconstriction in larger and medium-sized airways, whereas V_A/Q abnormalities are mainly related to events, edema, and/or mucus formation occurring in the distal small airways. High inspired oxygen concentrations may prevent HPV and place low V_A/Q regions at risk for absorption atelectasis, and high doses of bronchodilators may enhance the perfusion of low V_A/Q areas, exacerbating V_A/Q mismatch. However, the beneficial effects of bronchodilators on airway resistance generally outweigh the worsening in V_A/Q mismatch.

Pulmonary Embolism

By using inert beads to create a pulmonary embolism, Altemeier et al.[23] demonstrated the nature of ventilation/perfusion abnormalities in a pulmonary embolism. The embolized beads distributed preferentially to high-flow regions of the pulmonary vasculature. They produced a shift of blood toward regions that previously had been low flow. Before the embolization, the regions with high blood flow were matched with high-ventilation regions. After the embolization, regional ventilation changed little. Consequently, the areas to which blood flow shifted now became low V/Q regions, resulting in hypoxemia.

Primary Pulmonary Hypertension

V_A/Q inequalities tend to be moderate even in late stages of pulmonary hypertension.[38] Much of the cardiac output is distributed to lung units with almost normal V_A/Q ratios, while less than 10% perfused underventilated or unventilated areas. When Q is reduced, hypoxemia often occurs because of low mixed venous Po_2. Oxygen, sodium nitroprusside, isoproterenol, and nifedipine worsened V_A/Q matching, but Pao_2 did not decrease because of increased Q. The resultant increase in Svo_2 raised the end capillary Po_2.

Therapeutic Considerations

Positive End-Expiratory Pressure

Positive end-expiratory pressure (PEEP) decreases the proportion of shunt units by recruiting the nonfunctional gas exchanging units, thereby improving functional residual capacity and arterial oxygenation. Additionally, by decreasing cardiac output (Q), PEEP produces a parallel fall in intrapulmonary shunt. However, even when Q is preserved, application of PEEP results in decreased shunt due to the redistribution of blood flow from shunt units to normal units because of alveolar recruitment.[32] With constant Q, PEEP decreases venous admixture and increases mixed venous Po_2. Yet PEEP tends to increase zone 1 and 2 regions within the lung, possibly increasing the vertical gradient of perfusion.

PEEP also affects dead space. Low levels of PEEP decrease dead space by reductions in shunt and mid-range V_A/Q heterogeneity, but high levels of PEEP increase dead space. The increase in dead space with high PEEP results from overinflation of some lung units, leading to compression of capillaries and increases in anatomic dead space by distention.

Prone Positioning

The matching of perfusion and ventilation appears to be improved in the prone position.[39] MIGET analysis has suggested that the improvement in arterial blood oxygenation often seen in the prone position in normal and injured lungs is to the result of improved V_A/Q matching.[39] With use of simultaneous aerosolized and injectable fluorescent microspheres, Mure et al.[40] showed that more evenly distributed ventilation and an increase in the correlation between ventilation and perfusion occurred in the prone position. Studies in humans have demonstrated similar findings.[41]

In ARDS and other lung injury models, nonaerated or poorly aerated portions of the lung are found mainly in the dependent areas. Perfusion is largely gravity independent, especially in zone 3 conditions.[4] The majority of perfusion goes through dorsal lung regions, whether in the prone or supine position. As previously mentioned, positive pressure, especially PEEP, redistributes perfusion toward the dependent portion of the lungs by creating conditions of zones 2 and 1.[4,32] This redistribution may increase the vertical perfusion gradient in the supine position but may reduce it in the prone position.

Nitric Oxide

Nitric oxide (NO) improves gas exchange in persons with acute lung diseases by preferentially increasing blood flow to well-ventilated regions of the lung. NO reaches the well-ventilated units, producing vasodilation and reducing shunt fraction.[42] Beneficial effects appear over a wide range of doses. NO does not appear to be beneficial in persons with chronic lung diseases, possibly because the structural damage precludes rapid vascular changes or because shunt usually is not found in such diseases.

Chapter 42

Mechanical Dysfunction of the Respiratory System

J. Julio Pérez Fontán and Joel B. Steinberg

PEARLS

- The work done by the respiratory muscles and, by extension, the energy that must be supplied to these muscles are both defined by the volume-pressure relations of the lungs and the chest wall.
- Volume changes within the respiratory system are dictated primarily by the body's need to take up oxygen and eliminate carbon dioxide and therefore are determined by factors such as physical activity or metabolic rate, which are relatively independent of the condition of the lungs and chest wall. Pressure changes, on the other hand, depend on physical processes that take place in the respiratory system's constituents.
- The respiratory system has a surprising ability to compensate for mechanical dysfunction. However, compensation does not come cheap. It raises the work of breathing in almost every instance, usually by combining increases in the force of contraction of the respiratory muscles with changes in ventilatory pattern. If the increase in work is sufficient to overcome the additional restrictive and obstructive loads applied on the respiratory system, minute alveolar ventilation and arterial P_{CO_2} are maintained within normal limits and respiratory failure is averted. In contrast, if the metabolic and contractile machinery of the respiratory muscles cannot meet the greater work demands, alveolar ventilation becomes insufficient to support gas exchange and respiratory failure ensues.
- It is a common clinical observation that different types of mechanical derangement result in distinctive patterns of breathing. These patterns generally agree with the principle of minimal power expenditure and can be useful to categorize the type of derangement the patient has during the initial evaluation.

From a mechanical perspective, the mammalian respiratory system functions like a reciprocating pump that moves fresh air into the pulmonary alveoli and exhausts spent alveolar gases into the atmosphere. The pump is powered by a specialized group of skeletal muscles (the respiratory muscles) that, through their insertions on the skeletal structures of the chest and abdomen, create movements that expand and sometimes compress the lungs. As often happens with systems that contain moving parts, the respiratory system is particularly vulnerable to mechanical dysfunction. The inefficiencies imposed by this dysfunction and the attempts that the organism makes to compensate for them are indeed responsible for the majority of the signs and symptoms of respiratory disease. Moreover, whether the respiratory system overcomes the effects of disease or, on the contrary, stops fulfilling its basic gas exchange functions (respiratory failure) is a matter that can be analyzed in the pure thermodynamic terms of a balance between the work that must be done and the energy that is available to do it.

This chapter provides a basic understanding of the mechanical function of the respiratory system in health and disease, focusing on the factors that determine both respiratory work and energy expenditure. The first portion of the chapter discusses the forces responsible for the volume-pressure behavior of the lungs and chest wall and how this behavior relates to the work of breathing in both normal and disease conditions. The second portion analyzes the elements that influence the translation of the work of breathing into energy expenditure, with special attention to the factors that define the efficiency of the respiratory system. Throughout the chapter, the unique characteristics of the developing respiratory system and the mechanical features that are relevant for the diagnosis and management of respiratory disease are highlighted.

Work, Power, and Energy Expenditure in the Respiratory System

In simple intuitive terms, the variable that best sums up the function of a muscle-powered pump is the mechanical load that the contraction of the powering muscles must overcome with each pump cycle. Over time, mechanical load translates into power (the product of work by the time that it takes to carry it out) and energy expenditure. Accordingly, whether the respiratory muscles can carry a given mechanical load is ultimately determined by their ability to generate work from the limited amount of energy that they receive from their blood supply. The first law of thermodynamics stipulates that when a certain amount of energy is added to a closed system by an external source (in this case the metabolism of fuels supplied by the circulation to the respiratory muscles), the resultant change in the system's internal energy may either be applied to perform external work (W) over a period of time (t) or is dissipated as heat (Q). Implicit in this statement is the fact that only a portion of the energy that the respiratory muscles derive from metabolic substrates is transformed into respiratory work. This

proportion varies depending on the system's efficiency (E), defined as:

$$E = \frac{W \cdot t}{W \cdot t + Q} \quad (1)$$

Thus workload and efficiency define the demands that the contractile machinery of the respiratory muscles must meet and therefore are the relevant variables in the analysis of the mechanical function of the respiratory system.

Determinants of Respiratory Work

Every high school physics student learns to calculate the external work done to move an object between two points as the product of the force needed to overcome all resistances to the movement by the distance between the points. Because the force may change along the way, the same student may learn at some point that it is more precise to break the movement into many elementary components and then add up all the work components by integration, as shown in Figure 42-1, *A*.

The calculation of the external work during breathing follows the same general principle, with one caveat: allowances must be made for the fact that the lungs and the chest wall move in all the dimensions of space. In other words, their displacements are measured in terms of volume, not distance, and determined by pressure, not force.

The mathematical subtleties of this distinction may become a little clearer if we compare the breath to the action of a syringe, where, by pushing or pulling on the plunger, we create a pressure (P), positive or negative, that has the effect of changing the volume contained in the barrel (V). The work done in this process can be determined by integrating the product $P \cdot dV$, as shown in Figure 42-1, *B*. The obvious corollary is that the work done by the respiratory muscles and, by extension, the energy that must be supplied to these muscles are both defined by the volume-pressure relationships of the lungs and the chest wall.

Volume-Pressure Relationships

Before analyzing the volume-pressure behavior of the various components of the respiratory system, it is helpful to clarify the terminology. Throughout this chapter, the term "thorax" is used in reference to all the moving components of the respiratory system, including the walls of the thoracic cavity (the skeletal rib cage and its soft attachments), the abdomen, and the lungs themselves. Similarly, the term "chest wall" is used to indicate all the structures that form the enclosure of the lungs, including the thoracic wall, the diaphragm, the abdominal wall, and the abdominal organs.

The volume changes of the respiratory system can be easily measured with the help of devices such as spirometers or plethysmographs. For any breath, the thorax (defined by the suffix TH), the lungs (L), and the chest wall (W) all undergo the same change in volume, or:

$$\Delta V_{TH} = \Delta V_L = \Delta V_W \quad (2)$$

The reason for this identity is the existence of a noncompressible and nonexpandable boundary, the pleural space, which links lungs to chest wall and prevents them from changing volume independently of each other.

The pressures needed to inflate the thorax, the lungs, and the chest wall are, however, different from each other. Respiratory physiologists have traditionally approached the analysis of these pressures by taking an imaginary walk from the mouth down the airways to the alveolus, across the lung tissue and visceral pleura to the pleural space, and finally across the chest wall to the surface of the chest (Figure 42-2). The difference between the pressures measured at two consecutive stops is the driving pressure needed to cause or maintain a certain volume displacement:

$$P_{AW} = P_M - P_A \quad (3)$$

$$P_L = P_A - P_{pl} \quad (4)$$

$$P_W = P_{pl} - P_B \quad (5)$$

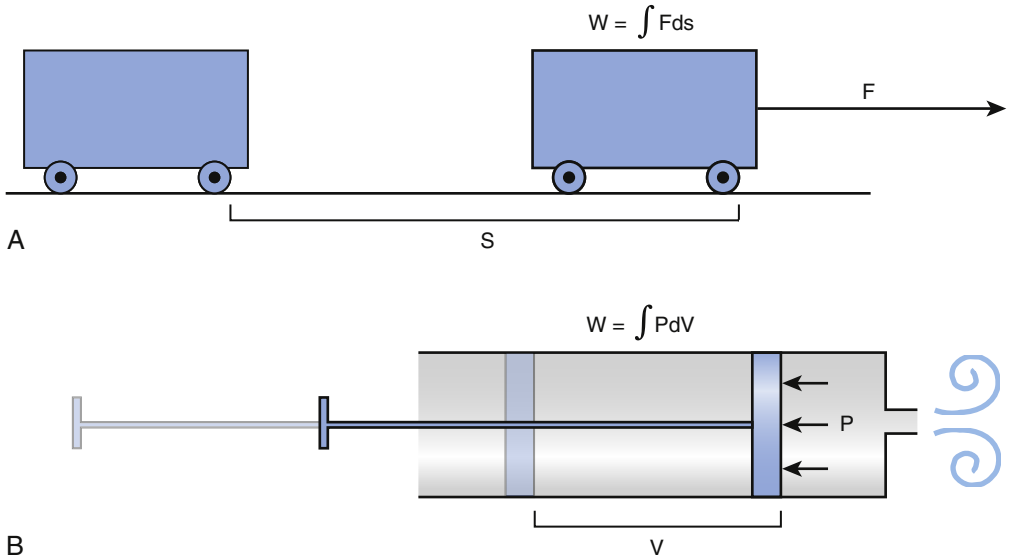

Figure 42–1. A. The amount of work that a force (*F*) must perform to move an object over a linear distance *s* is equivalent to the product $F \times s$. If the force varies during the displacement, then it is more precise to integrate the product of F by the change in *s* (*ds*). **B.** The work needed to produce a volume displacement *V* in a syringe, a better analogy for the respiratory pump, is determined as the integral of the product of the pressure inside the pump (the tridimensional analog of *F*) by *dV* (the tridimensional analog of *ds*).

where P_{AW} is the pressure gradient across the airways, P_M the pressure measured at the mouth (or, for that matter, at the connector of an endotracheal tube), P_L the lung transmural pressure or transpulmonary pressure, P_W the chest wall transmural pressure, P_A the alveolar pressure, P_{pl} the average pressure at the pleural surface, and P_B the atmospheric pressure (conventionally considered to be zero or reference).

Consider first a situation in which the lungs undergo passive distention, without participation of the respiratory muscles. This is what happens during positive airway pressure ventilation, when the pressure drive for inflation of the thorax is provided by P_M. By performing a series of substitutions in equations 3through 5 and assuming $P_B = 0$, we can easily arrive to the following equality:

$$P_M = P_{AW} + P_L + P_W \quad (6)$$

which reveals that, from a mechanical point of view, the components of the respiratory system form a *series* arrangement, whereby the total pressure needed to generate a movement is the sum of the pressures generated in the airways, the lungs, and the chest wall. Respiratory physiologists have often borrowed from electrical theory, assuming, perhaps to the dismay of many readers, that the black and white simplicity of electrical circuitry is less intimidating than the complexities of Newtonian mechanics. When speaking of electrical circuits, the term *series* indicates that every element in the circuit experiences the same current as the circuit as a whole, but the total voltage across the circuit is the sum of the voltages across the individual elements. Because current is the electrical analog of flow (volume per unit of time) and voltage is the analog of pressure, it is easy to see how Equations 2 and 6 justify the overall electrical analogy, even though many readers may be less impressed by how much conceptual clarity it sheds for them.

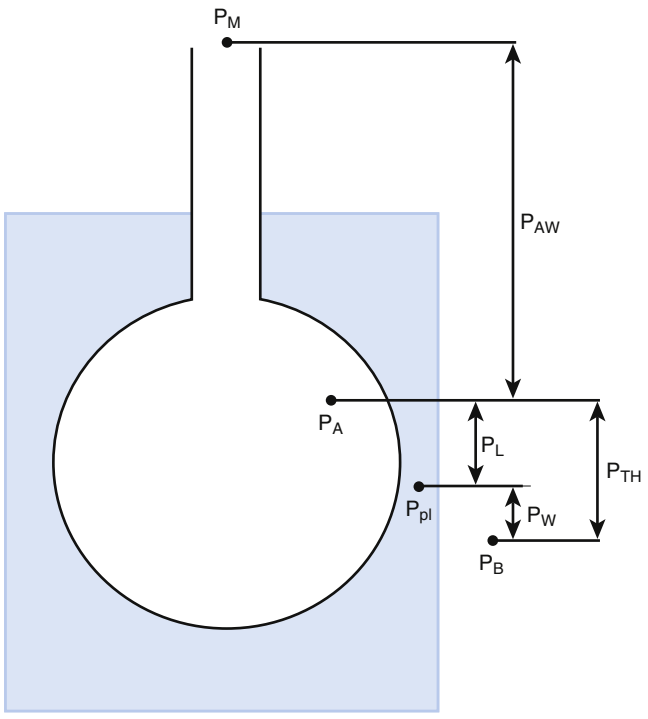

Figure 42–2. Schematic representation of the thorax demonstrating the relevant pressure gradients generated during breathing (these are the gradients that one would encounter during an imaginary walk from the mouth, through the airways, and across the walls of the lungs and the chest wall). The difference (P_{AW}) between the pressure at the mouth (P_M) and the pressure at the alveoli (P_A) drives gas flow between the airspaces and the atmosphere. The transpulmonary pressure (P_L) is the pressure that distends the lungs and is calculated as the difference between P_A and pleural pressure (P_{pl}). The transmural pressure of the chest wall (P_W) is the effective pressure distending the rib cage and abdomen defined as the difference between P_{pl} and atmospheric pressure (P_B). The transmural pressure of the thorax as a whole (P_{TH}) is the difference between P_A and P_B.

The mechanical behavior of the airways and the lungs does not change substantially during muscle-powered breathing. The behavior of the chest wall, on the other hand, is greatly influenced by the contraction of the respiratory muscles. Because the muscles not only act on the wall but are also part of the wall itself, any attempt to define mathematically the behavior of the chest wall during a spontaneous breath becomes a futile exercise. For our purposes here, however, it may suffice to say that, during spontaneous breathing, equation 6 can be modified as:

$$P_{mus} = P_{AW} + P_L + P_W \quad (7)$$

where P_{mus} represents the pressure generated by the muscles' contraction, inclusive of the effects that this contraction has on the behavior of the chest wall itself. Thus every time we take a breath, the neural output to the respiratory muscles is adjusted to overcome as precisely as possible the opposing pressures generated by the respiratory system.

Nature of the Mechanical Forces Acting on the Respiratory Pump

Volume changes within the respiratory system are dictated primarily by the body's need to take up oxygen and eliminate carbon dioxide and therefore are determined by factors such as physical activity or metabolic rate, which are relatively independent of the condition of the lungs and chest wall. Pressure changes, on the other hand, depend on physical processes that take place in the respiratory system's constituents. For instance, elastic pressures result primarily from the tendency of tissue components such as collagen and elastin fibers to recover their original shape after being stretched during lung inflation. Airway resistive pressures relate to friction and overcome the adherence of the moving gas molecules to the airway walls (viscous pressures) and, to a lesser extent, compensate for the loss in gas kinetic energy at points where the movement and direction of the gas vary randomly (turbulence). Tissue-resistive pressures are applied primarily to produce molecular rearrangements in the tissue and at the gas/liquid alveolar interface as the lungs inflate and deflate. Finally, inertial pressures derive from the acceleration and deceleration of the gas and tissue contained in the thorax during breathing. (Inertial pressure losses are negligible in children during normal breathing and therefore need no more than a passing reference here.)

Disease induces alterations in these physical processes and therefore also in the forces and pressures that result from them. To relate these alterations to the disease's clinical manifestations, it is helpful to classify both processes and pressures into nondissipative and dissipative, depending on whether the energy consumed stays in or leaves the system. For instance, elasticity is typically a nondissipative process because the energy needed to produce elastic deformation during inspiration is accumulated in the tissues and then used to empty

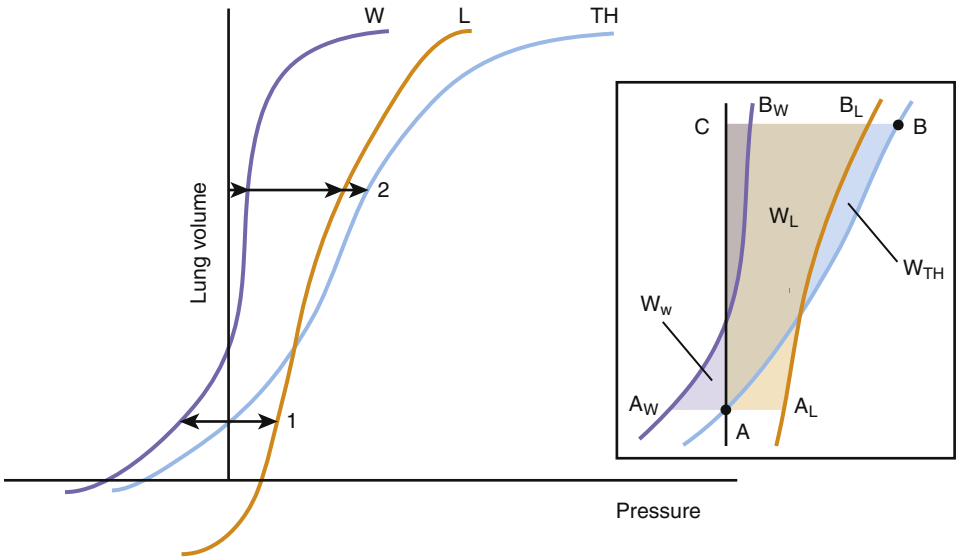

Figure 42–3. Idealized representation of the static volume-pressure relationships of the thorax (TH), lungs (L), and chest wall (W). Pressure, on the abscissa, represents the pressure across the thorax as a whole ($P_{TH} = P_A - P_B$), lungs ($P_L = P_A - P_L$), and chest wall ($P_W = P_{pl} - P_B$; see Figure 42-2). The *arrows* indicate the magnitude and direction of the pressures acting on the thorax and its components at two volumes: (1) the relaxation volume of the thorax, where the recoils of the lung and the chest wall neutralize each other; and (2) an arbitrary volume where the recoils of the lungs and the chest wall act both in the direction of reducing thoracic volume. *Inset:* Detail of the same curves, indicating the elastic work done on the thorax as a whole and each of its components for a volume displacement starting at a volume *A* (the relaxation volume of the thorax) and ending at a volume *C*. The work done on the thorax as a whole is represented by the area *A-B-C*; the work done on the lungs by $A\text{-}A_L\text{-}B_L\text{-}C$; and the work done on the chest wall by $A_W\text{-}A\text{-}B_W\text{-}C$. A portion of the work done on the chest wall (the *triangular area in purple* between A_W and the ordinate axis) is contributed by the recoil of the chest wall, which between those points facilitates the action of the respiratory muscles.

the lungs during expiration. In contrast, all resistive processes are dissipative: the energy liberated by the friction of the gas against the airway walls or by the molecular interactions within the tissue is transformed into heat and transported outside of the system by the blood or the expired gas.

Nondissipative Phenomena: Elastic Behavior of the Respiratory System

Elastic pressures result from the tendency of the components of the lungs and chest wall to recover their original shape after undergoing deformation. Because this tendency increases proportionally to the magnitude of the deformation, elastic pressures are volume-dependent. Thus they are most easily studied when the volume of the thorax is kept constant, a situation in which the absence of movement renders all resistive pressures irrelevant. This can be accomplished by inflating the lungs passively to the desired level or by asking the subject to inspire to a given volume and then to close the glottis while relaxing the respiratory muscles (something that a trained individual can do). In such circumstances, $P_{AW} = 0$, and

$$P_A = P_L + P_W \tag{8}$$

By obtaining measurements at various volumes and then plotting volume against P_A, P_L, and P_W, we can compare the volume-pressure relationships of the thorax as a whole with those of the lungs and the chest wall. Not unexpectedly given the heterogeneous composition of the structures involved, the relationships are complex and cannot be described in a simple mathematical equation (Figure 42-3). In all three cases, the plotted curve has a sigmoidlike shape, with pressure increasing rapidly relative to volume at low and high volumes and more slowly at middle volumes.[1]

Being a continuous function, each volume-pressure relationship has a defined slope at any given volume (dV/dP). This slope defines the *compliance* of the thorax, lungs, or chest wall for that particular volume, depending on whether dP is replaced by dP_A, dP_L, or dP_W. Although a cursory examination of Figure 42-3 reveals that both the lung and chest wall compliances defined in this manner vary markedly over the entire range of volumes, on closer inspection, the ratio dV/dP is relatively constant at normal breathing volumes. Thus for these volumes, it is safe to write:

$$\Delta P_{el} = \Delta V/C \tag{9}$$

where ΔP_{el} represents the change in elastic recoil pressure of the thorax (ΔP_A), lungs (ΔP_L), or chest wall (ΔP_W) for a lung volume excursion ΔV, and C is the compliance of the corresponding component. As lung volume decreases or increases beyond this linear range, dV/dP starts to decrease in a volume-dependent manner, and the respiratory muscles must generate progressively larger pressures to produce the same volume change. Disease frequently causes the lungs to operate outside of their linear volume-pressure range, thereby increasing both the work of breathing and the energy needed to do it.

At any given volume, the lungs, the chest wall, and the thorax each generate a certain elastic pressure or recoil. This recoil can act to increase or decrease volume (as indicated by the direction of the arrows in Figure 42-4). By definition, elastic recoil drives the thorax and its individual components to adopt a volume, known as the *relaxation volume,* at which recoil itself is extinguished. The relaxation volumes of the lungs and the chest wall are the volumes that each of these

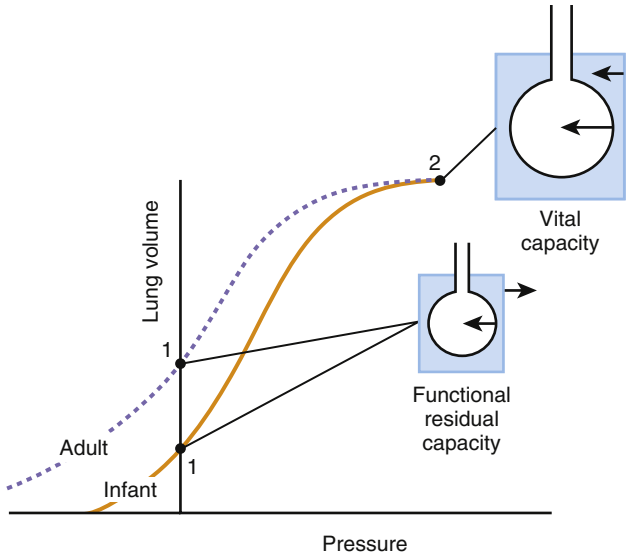

Figure 42–4. Idealized volume pressure relationships illustrating the differences in the elastic behaviors of the infant and adult thoraxes (normalized for vital capacity). The difference between the two points (labeled *1*) highlights the effect of maturation on the relaxation volume of the thorax. In the infant the chest wall is considerably more compliant than in the adult and, as a result, the opposite recoils of the lungs and the chest wall neutralize each other at a lower relaxation volume. Thus infants tend to have a lower functional residual capacity (*FRC*) than do adults. At volumes higher than the relaxation volume of the chest wall, the recoils of the lungs and the chest wall act in the same direction, opposing further increases in volume (as highlighted here at vital capacity, labeled *2*).

components would adopt if all the mechanical constraints imposed by their mutual attachments and interactions were removed. The relaxation volume of the thorax, in contrast, is defined by the mechanical interaction of the lungs and the chest wall. It coincides with the point at which the opposing elastic recoils of these two components neutralize each other (as shown by the equal magnitude but opposite pressure vectors in Figure 42-4).

In the adult, the relaxation volume of the lungs is lower than the residual volume (the volume of gas contained in the lungs at the end of a forced expiration). The relaxation volume of the chest wall, by contrast, exceeds 50% of the vital capacity (the maximal volume of gas that can be inhaled from residual volume). This discrepancy in the relaxation volumes of the lungs and chest wall has three important consequences. First, it forces the relaxation volume of the thorax as a whole to occupy a position intermediate between the relaxation volumes of the lungs and the chest wall (at approximately 35% of vital capacity). Under most circumstances, this volume coincides with the functional residual capacity (FRC), which is the volume contained in the lungs at the end of a tidal expiration. Second, as the thorax starts to rise above its relaxation volume during inspiration, the outward recoil of the chest wall contributes to the expansion of the lungs, thereby reducing the work that the respiratory muscles need to perform during normal breathing (see Figure 42-3, *inset*, where the work done by the chest wall at the beginning of a breath is represented by W_W). Finally, at normal breathing volumes, the opposing actions of the lungs and chest wall recoils create a negative pressure at the boundaries of the lung tissue with the chest wall and the other intrathoracic structures. This negative pressure is an important contributor to the return of venous blood to the chest. The static volume-pressure relationships of the lungs and chest wall vary depending on their state of maturation and health (see Figure 42-4). In the infant, the chest wall generates remarkably little outward recoil within the normal range of breathing volumes.[2-5] Because the inward recoil of the lungs varies little with respect to lung size and age during development,[6-8] the relaxation volume of the infant's thorax is proportionally smaller than that of the adult (as shown in Figure 42-4 by the lower intercept of the volume-pressure relationship of the thorax and the ordinate axis). If, as occurs in the adult, the FRC coincided with this relaxation volume (15% of vital capacity compared with 35% in the adult), then the infant would be at a definite disadvantage in terms of alveolar stability and oxygenation. The newborns of most mammalian species, however, have developed physiologic strategies to maintain their FRC above the relaxation volume of the thorax.[9] These strategies are generally directed at interrupting expiratory flow before expiration is complete and include shortening of the expiratory time,[10] contraction of adductor muscles of the glottis to retard exhalation,[11,12] and persistence of the tonic activity of the inspiratory muscles during expiration.[13] Being so dependent on the pattern of breathing, the FRC of the newborn and small infant is very vulnerable to changes in muscle coordination and tone. As an example, the decrease of tonic activity of the respiratory and laryngeal muscles associated with rapid eye movement sleep[13] may cause a substantial reduction in thoracic lung volume at these ages. Similarly, muscle weakness, anesthesia, deep sedation, and central nervous system depression in general tend to lower FRC below levels compatible with alveolar stability. Under such circumstances, alveoli close, and both the shunt fraction and the work of breathing increase.

In addition to its effects on the FRC, the reduced outward recoil of the chest wall in the infant reduces the chest wall's contribution to lung expansion. It also limits the amplitude of the pleural pressure variations as the lungs expand, an effect that helps to explain the surprising cardiovascular tolerance of many infants to the application of high levels of positive airway pressure.

Lungs/Chest Wall Interactions

Although, considered in isolation, the lungs and the chest wall have different volume-pressure relationships, their mechanical linkage at the pleural space prevents them from changing volume independently. By sharing a common boundary, the lungs and chest wall are also influenced simultaneously by variations in the pressure at this boundary. The resultant interplay is well illustrated by the effects of a pneumothorax, a complication that is quite familiar to readers who practice intensive care medicine. When a certain volume of air enters the pleural space, the most immediate effect is an increase in the pleural pressure (ΔP). This increase causes the effective transmural pressures of the lungs and chest wall to change by the same absolute amount, but in opposite direction: transpulmonary pressure ($P_A - P_{pl}$) decreases by $-\Delta P$, whereas chest wall transmural pressure (P_{pl}) increases by ΔP. No longer held together by a rigid boundary, the lungs and the chest wall respond to the change in transmural pressure by decreasing and increasing volume along their respective volume-pressure relationships (Figure 42-5). Consequently, one could say that the volume of air originally introduced in

the pleural cavity is partitioned into two components, one the volume by which the lungs collapse and the other the volume by which the chest wall expands. The relative sizes of the lung collapse and the chest wall expansion are dictated by the volume-pressure relationships of the lungs and chest wall. If the compliance of the chest wall exceeds the compliance of the lungs (as is usually the case in the infant), then the chest wall expands more than the lungs collapse. The difference is even greater when lung compliance is reduced by disease (Figure 42-5, *B*). Then the chest wall absorbs the majority of the volume change while the lungs barely decrease their volume. This simple analysis explains why noncompliant lungs show surprisingly little collapse when a pneumothorax develops, a finding that is often mistakenly attributed to the "stiffness" of the lung parenchyma. It also provides an opportunity to point out that the magnitude of the chest wall expansion, although frequently overlooked in radiographs, relates more directly to the true malignancy of a pneumothorax (compression of vascular structures) than does the usually more apparent collapse of the lungs.

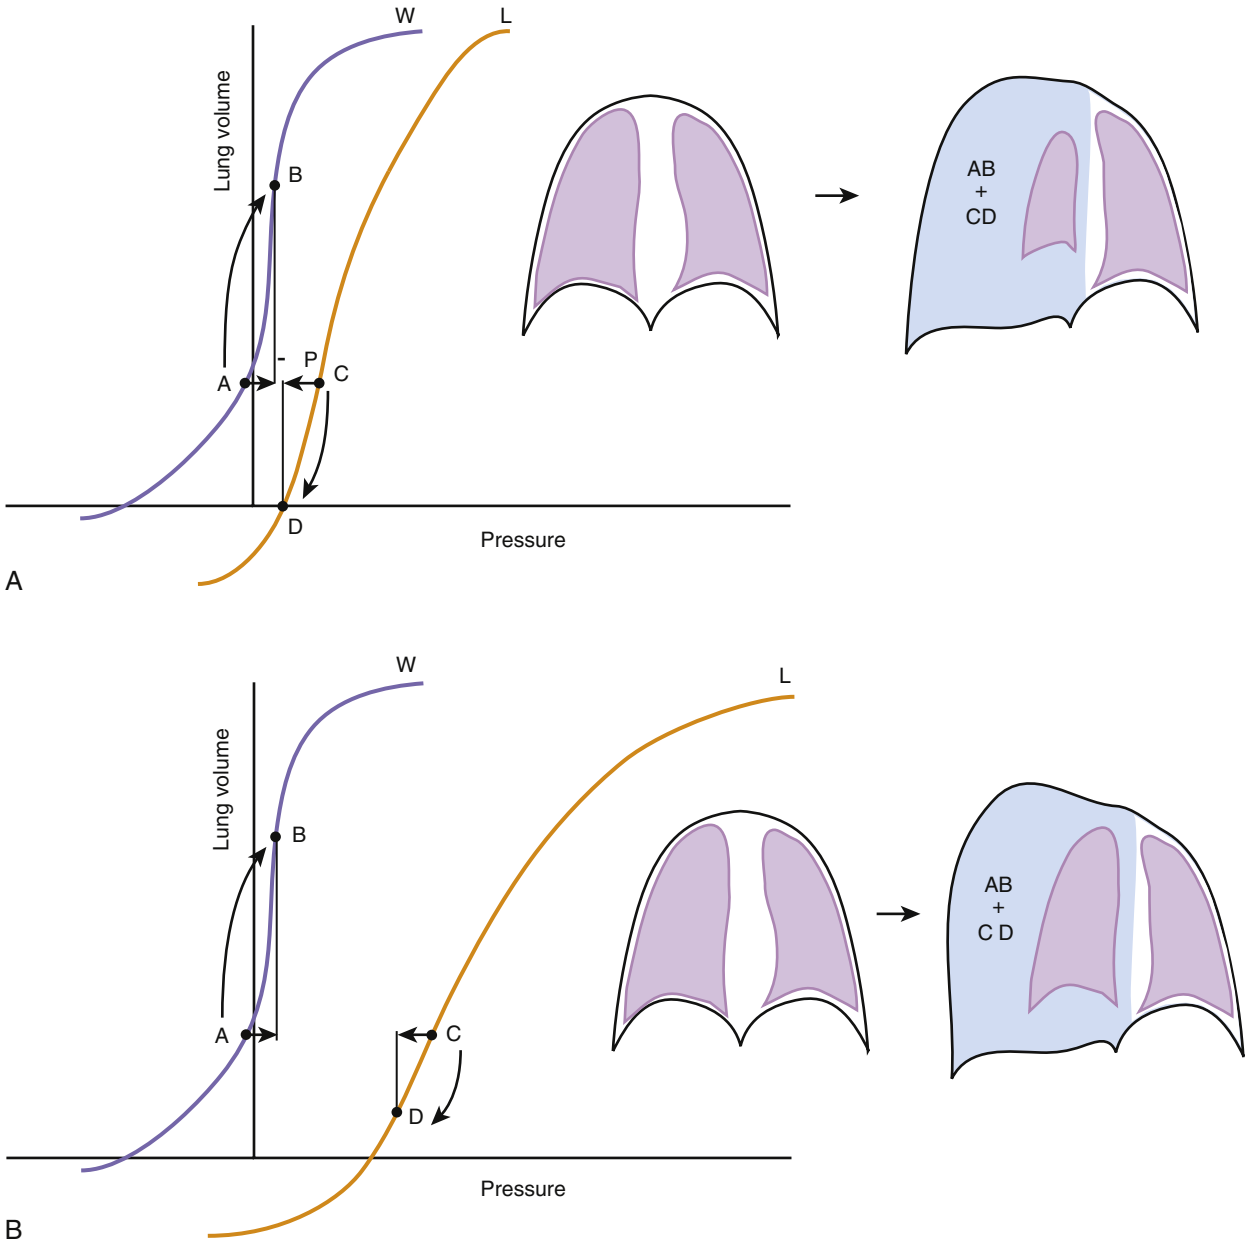

Figure 42–5. **A,** The effects of a pneumothorax are used here to illustrate the interdependence between the elastic recoils of the lungs and the chest wall. Pressures, on the abscissa, represent the transmural pressures of the lungs (*L*, $P_A - P_{pl}$, see Figures 42-2 and 42-3) and chest wall (*W*, $P_{pl} - P_B$). The introduction of a volume of gas into the pleural space raises pleural pressure by a magnitude ΔP, which changes both transmural pressures by the same absolute magnitude, but in opposite directions. Lungs and chest wall respond to the change in transmural pressure by decreasing (*C*→*D*) and increasing their volume (*A*→*B*) along their respective volume-pressure relationships. The volume of the pneumothorax is thus partitioned between the lungs and the chest wall according to their relative compliances. **B,** When lung compliance is decreased by disease, the volume pressure relationship of the lungs is displaced to the right and has a lower slope. Under these circumstances, the chest wall is forced to accommodate the majority of the volume change introduced by the pneumothorax (*AB* >> *C'D'*), giving perhaps the wrong impression that the stiffness of the lungs prevents them from collapsing further.

One important idea to emerge from these considerations is that, respiratory muscle activity aside, the pressure inside the pleural space is really determined by the elastic recoil of the chest wall and the volume of the thoracic contents. As long as lung volume is not forced above its normal range and chest wall compliance is unaltered by disease, pleural pressure (and thus the pressure around the major vessels and the heart) remains low, regardless of the airway pressures. Conversely, excessive lung distension (e.g., in asthma) is always associated with a high pleural pressure and is, for that reason, less well tolerated from a cardiovascular point of view. The dependence of pleural pressure on chest wall compliance explains why premature infants and newborns, who have very large chest wall compliance, have limited changes in this pressure during positive pressure ventilation, even if physiologic lung volumes are exceeded. Disease-induced reductions in chest wall compliance, on the other hand, always increase pleural pressure and reduce venous return to the heart. This is one reason why patients with abdominal distension typically have low cardiac output and why relief of the distension (e.g., by paracentesis in patients with ascites) reduces pleural pressure and increases cardiac output.

Dissipative Forces

Dynamic Volume-Pressure Relationships

Analysis of the volume-pressure relationships of the thorax and its components becomes more complicated when we consider the pressure changes generated by gas flow and by the movement of the lung and chest wall tissue as the lungs inflate and deflate. These pressure changes result from molecular interactions between the gas and the airway walls, within the gas stream itself, and among the components of the gas-liquid interface and the tissue. The same interactions are responsible for well-known physical phenomena such as viscosity (the internal resistance of a fluid to flow), turbulence (the development of chaotic movements within a flowing fluid), or viscoelasticity (a property of tissues and fluids that causes their deformations to be time-dependent rather than instantaneous; ketchup provides a good example when it hangs stubbornly to the bottle before being released after multiple taps).[14-17]

Regardless of their ultimate physical nature, all the phenomena that occupy our attention at this point have two characteristics in common. The first is that they always result in a net loss or dissipation of energy from the respiratory system. The lost energy can no longer be used to perform work, and consequently dissipative pressure losses cause the volume-pressure relationships of the respiratory system to follow a different trajectory depending on the direction of the volume change. This property, known as *hysteresis*, is responsible for the development of loops when the volume-pressure relationships are plotted continuously during a breath (Figure 42-6). In this graphic representation, the dissipative pressures can be easily identified as the horizontal distance between the volume-pressure tracing and the corresponding point on the elastic volume-pressure relationship. The work done against these pressures can be quantified as the area enclosed by the loop.

The second common characteristic of dissipative pressures losses is that they occur only when there is volume change or flow in or out of the lungs (flow is the first derivative of volume with respect to time, dV/dt, and is usually represented with the engineering symbol $\dot{V}$). The relationship between resistive pressure loss (P_{res}) and $\dot{V}$ is, under many circumstances, simple enough to be summarized with a linear equation:

$$P_{res} = R \times \dot{V} \qquad (10)$$

where the coefficient R defines the flow resistance of the thorax, lungs, or chest wall. While the concept of resistance is useful as a pulmonary function assessment and reporting tool, the idea of assigning a fix value to R involves a gross oversimplification. Indeed, resistive pressure losses are influenced by factors other than the absolute flow rate, including among others lung volume, flow direction (inspiratory or expiratory), and breathing pattern. An understanding of the role played by these factors during normal breathing provides valuable insights for the recognition and treatment of airway obstruction.

Effect of Flow Rate and Pattern on the Dynamics of the Gas Stream

The airway tree is a complex fractal structure. A particle traveling in the gas stream from the mouth to the alveolus would be likely to encounter obstacles and bifurcations and to experience periods of acceleration and deceleration along the way. Thus in real life, the pressure losses, and thus the amount of work that needs to be done to sustain these losses, is a complex function of flow and geometry. In the simplest of circumstances, a tube with a uniform diameter, gas flow tends to adopt a *laminar* arrangement with a *parabolic velocity profile*, whereby the gas molecules in the middle move faster than the ones near the wall, which are slowed down by their viscous interaction with the wall (in fact, the molecules next to the wall do not move at all). Under these

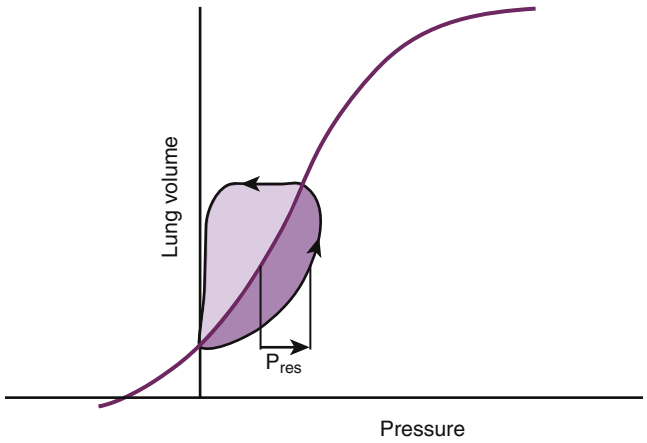

Figure 42–6. Idealized representation of the dynamic or real-time volume-pressure relationship of the respiratory system during a single breath (the *arrows* indicate the direction of the movement). Because energy is dissipated as the lungs change volume, the relationship follows a different trajectory during inspiration and expiration, forming a loop (hysteresis). The horizontal distance between any point in the loop and the line describing the elastic volume-pressure relationship of the respiratory system (*black*) is the pressure needed to overcome the dissipative forces present at the point in the breath (P_{res}). The area enclosed by the loop (*shaded area*) is the amount of energy in overcoming these forces. The inspiratory portion of this work (*darker shading* between the loop and the elastic volume-pressure relationship) must be performed by the respiratory muscles. The expiratory portion of the work (lighter shading) is typically done by the elastic recoil of the lungs and chest wall and requires no muscle effort or energy consumption. The resistance of the respiratory system is calculated by dividing P_{res} by the airway flow.

circumstances, energy dissipation is minimal and the pressure loss in the tube can be estimated with Pouiselle's law:

$$P_{res} = \frac{128 \times \mu \times L}{\pi \times d} \times \dot{V} \quad (11)$$

where μ is the viscosity of the gas, L the length, and d the diameter of the tube. It is easy to see that the fraction on the right side of this equation corresponds to the coefficient R in Equation 10.

Considerable theoretical and empirical evidence exists that although laminar flow is common, Pouiselle flow conditions are rare in the airways. The reason for this phenomenon is that airway segments are generally too short to allow the development of velocity differences between layers and thus the establishment of a parabolic profile. The resultant blunt velocity profile (i.e., the molecules move at similar speed in the center lines as in the vicinity of the airway wall) results in greater friction and causes the relationship between P_{res} and $\dot{V}$ to become nonlinear. Or, put in a different way, the value of R becomes dependent on $\dot{V}$.

The dependence of R on $\dot{V}$ becomes even more pronounced when an obstacle disturbs the laminar organization of the flow stream. Under these circumstances, the velocity and direction of the gas molecules can vary vigorously and randomly and a turbulent flow pattern is created. When this pattern is created, energy dissipation increases exponentially with flow and the density of the gas becomes more relevant than its viscosity in determining both pressure losses and work. This is the reason why helium, which has a much lower density than air, can decrease the work of breathing substantially in patients with some forms of airway obstruction (even though its viscosity is slightly greater than the viscosity of air). The development of turbulence in pipe systems and airway casts has been the subject of considerable study. Turbulence can be predicted when the ratio of inertial (density-dependent) to viscous (viscosity-dependent) forces acting in the flow stream exceed a certain value. This value is best exemplified by the Reynolds number (Re), a dimensionless quantity calculated as $\varrho \times d \times \dot{V}/\mu \times A$, where ϱ is the density of the gas. In general, Reynolds numbers lower than 2300 are associated with laminar flow and those greater than 4000 are associated with turbulent flow.

Airway Dynamics

The airways provide a distribution network to transport gas to and from the gas-exchanging units of the lungs. Although often idealized as a system of passive pipes, the airway network is in reality a highly specialized organ. Each airway segment, from the nose to the alveoli, has evolved not only to serve specific functions such as humidification and phonation but also to ensure maximal patency under the changing mechanical conditions present during breathing.

Indeed, the activity of the respiratory muscles exposes the airways to nonnegligible transmural stresses (or pressures) during breathing (Figure 42-7). The caliber and length of the airways change in response to these stresses in a manner that is only limited by the passive rigidity of its wall tissues and by the tone of the airway intrinsic muscle. Thus airway transmural pressure (the difference between the pressures measured on the inside and outside surface of the airway wall) and airway wall compliance (defined both as compressibility and distensibility) are the two determinants of airway caliber and ultimately also the determinants of airway resistance.

Airway transmural pressure varies during breathing. Its variations result from the fact that inspiration and expiration have very different effects on the pressures inside and outside the airways. The pressure inside all airways undergoes qualitatively similar changes during each phase of the breathing cycle. During inspiration, for instance, there is a gradient of increasingly negative pressures from the mouth, where pressure is atmospheric (or the zero reference), to the alveolar spaces, where the pressure must be negative (or subatmospheric) for gas to flow in. This negative pressure is of course driven by the actions of the respiratory muscles and transmitted to the lungs via the link between the chest wall and lungs at the pleural space. During expiration, alveolar pressure becomes positive and the gradient is inverted, with the pressures inside the airways being always positive but diminishing toward the mouth.

The pressure outside the airways is influenced in a different fashion by inspiration or expiration depending on whether the airways are extrathoracic or intrathoracic. Extrathoracic airways are included in the tissues of the neck, where the pressure can be considered to be atmospheric (at least in nonobese individuals, in whom tissue gravitational forces are neutralized by the skeletal support of the neck). Most of the intrathoracic airways are embedded in the lung tissue, where multiple tethering elements transmit the stresses (or pressures) generated by the tissue recoil to the airway wall (a phenomenon known as *pulmonary interdependence,*[18,19] which is explained visually in Figure 42-8). Therefore the pressure outside the intrapulmonary airways approximates the pleural pressure and, as we have seen, relates to lung volume in a manner that depends on the pressure-volume characteristics of the chest wall (see the section on Lungs/Chest Wall Interactions).

Taking these considerations altogether, it follows that the effect of inspiration and expiration on airway caliber is very different depending on whether the airway is outside or inside the chest cavity. During inspiration, the extrathoracic airways (i.e., the pharynx, larynx, and extrathoracic portion of the trachea) become narrower because the pressure inside their lumen decreases while the pressure immediately outside their walls is constant (pulling the airway wall in, as shown by the direction of the arrow acting on the wall of the trachea in Figure 42-7, *top panel A*). The intrathoracic airways, however, become dilated because the pressure outside their walls (the pleural pressure) decreases more than the pressure inside their lumen (Figure 42-7, *top panel B, C,* and *D*). Conversely, during expiration the extrathoracic airways increase their caliber as their inside pressure becomes positive with respect to atmospheric pressure (pushing the wall out, as also shown by the direction of the arrow in Figure 42-7, *bottom panel A*) and the intrathoracic airways narrow as their inside pressure decreases with respect to pleural pressure (Figure 42-7, *bottom panel B, C,* and *D*).

It is important to understand that the narrowing of the intrathoracic airways during expiration is contingent on the existence of a pressure gradient from the alveoli to the mouth. As predicted by Equation 4, alveolar pressure (P_A) must always exceed pleural pressure (P_{pl}) by a magnitude equivalent to the elastic recoil of the lungs. As the gas progresses downstream during expiration, frictional pressure losses lower the pressure inside the airways. Eventually the cumulative pressure losses can be as large as the pulmonary elastic recoil, and the

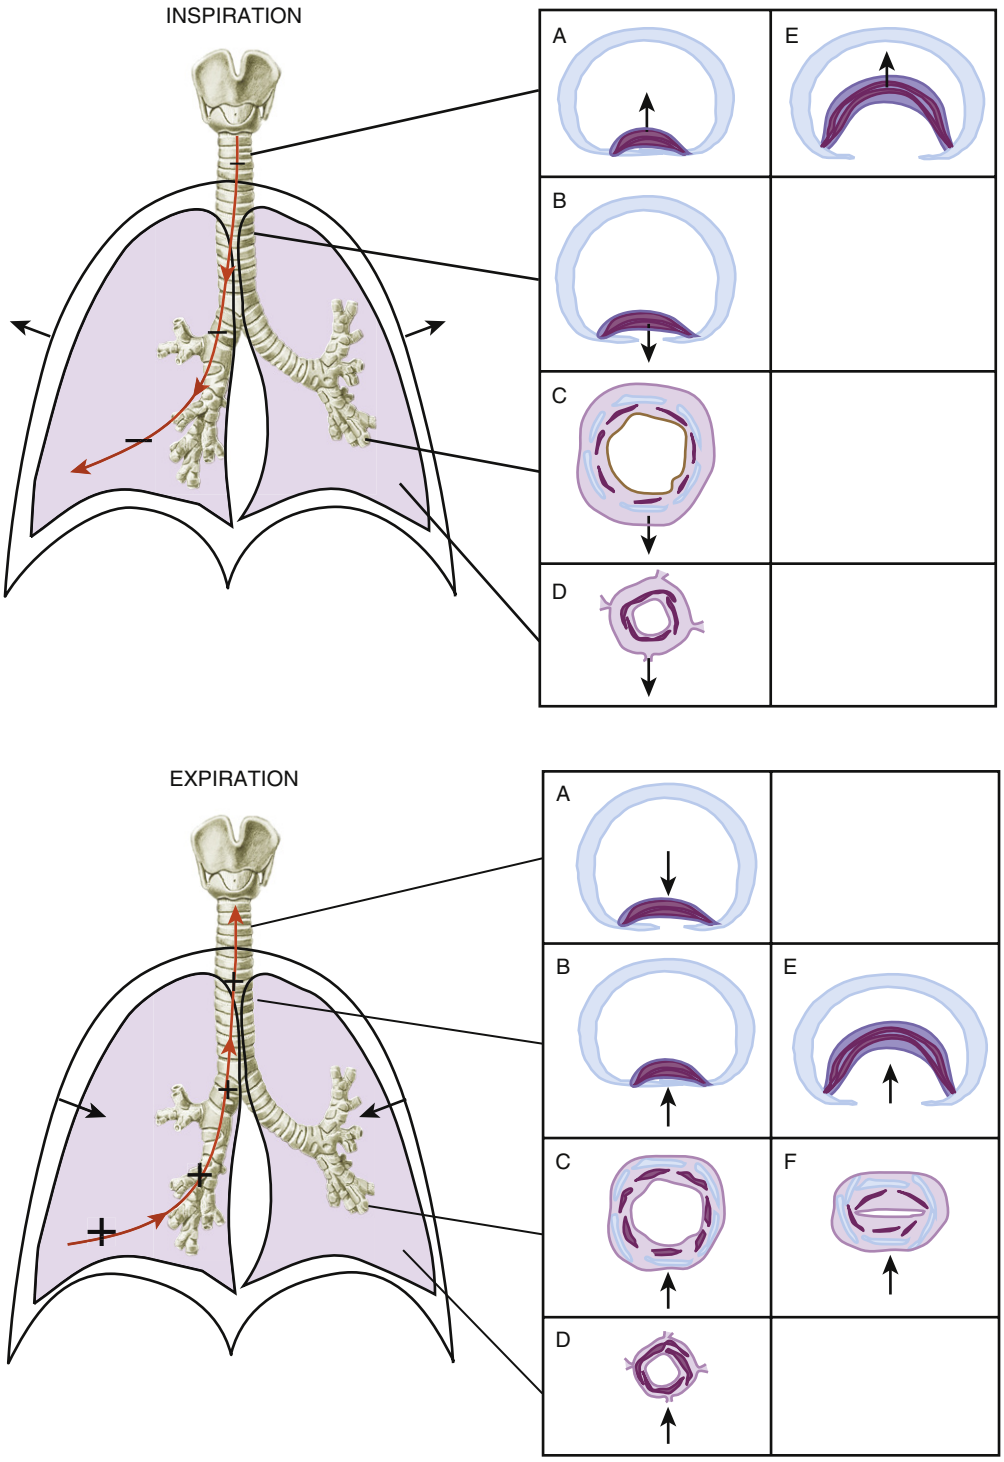

Figure 42–7. Schematic representation of the effects of inspiration and expiration on the dimensions of the extrathoracic and intrathoracic airways. During inspiration, the contraction of the respiratory muscles creates a negative pressure (relative to atmospheric) in the alveoli. This pressure drives inspiratory flow and, depending on the flow itself and the resistance of the airways, results in progressively less negative—but negative nonetheless—pressures in the direction of the mouth (as shown by the smaller size of the negative signs in the picture). During expiration, the recoil of the thorax (and, at times, the contraction of the expiratory muscles) reverses the situation, and pressures are more positive in the alveoli than in the more proximal airways. The caliber of the airways is determined by the difference between airway pressure and the pressure acting on the outside surface of their walls (airway transmural pressure). The latter approximates atmospheric pressure (zero reference) for the extrathoracic airways and pleural pressure for the intrathoracic airways. Thus, during inspiration, the transmural pressure acts to decrease the caliber of the extrathoracic airways (*A*) and to increase the caliber of the intrathoracic trachea (*B*), bronchi (*C*), and bronchioles (*D*). During expiration, transmural pressure has the opposite effect. Abnormalities in the tone of the airway muscle or the stiffness of the airway cartilage exaggerate these effects and promote collapse of the extrathoracic airways during inspiration (shown here for the trachea in *E*) and the intrathoracic airways during expiration (*E* and *F*).

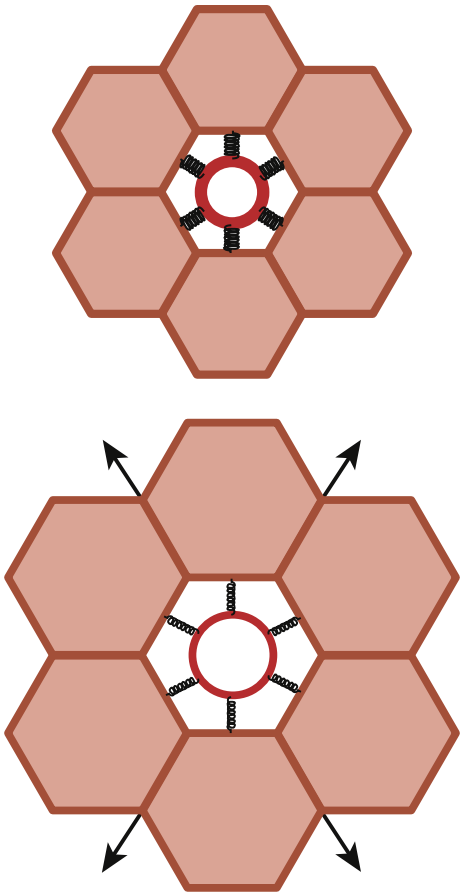

Figure 42–8. Schematic representation of the mechanical interdependence of airways and their surrounding structures. Airways and blood vessels (represented by the *red circle* in the middle of the figure) are tethered to their surrounding parenchyma by elastic elements (shown here as *small springs*). During inflation, these elements transmit the stress (or pressure) generated by the elastic recoil of the alveolar walls and pulmonary septa to the airway wall. As long as the airway changes volume proportionally to the rest of the lung, the normalized stress acting on the airway wall approximates pleural pressure. However, if the airway is stiffer than the rest of the lung (for instance, if the airway smooth muscle contracts vigorously), the tethering elements and the anchoring tissues can undergo considerable nonuniform strain (or deformation).

pressure inside the airways becomes equal to P_{pl}. Beyond this equal pressure point, airway transmural pressure becomes negative (i.e., the pressure outside exceeds the pressure inside the airway) and acts to collapse the airway. Depending on the airway's rigidity or compliance (see the following section) and diameter, the interplay between dissipative pressure loss, which increases with flow (Equation 10), and airway collapse, which depends on dissipative pressure loss, can lead to the development of a condition known as *flow limitation*,[20,21] whereby gas flow can no longer increase even if the subject makes a greater effort to raise alveolar pressure. Because the majority of the dissipative pressure losses are related to gas viscosity, this type of flow limitation is known as *viscous* flow limitation (Figure 42-9).

Flow limitation is an important concept that is pertinent to many clinical situations in which flow is both decreased and effort-independent. It occurs in persons with asthma and other forms of intrathoracic airway obstruction[22,23] when the increased effort to exhale does not accelerate lung emptying and is therefore wasted. It also occurs in persons with croup and other forms of extrathoracic airway obstruction when the increased effort to inhale only succeeds in creating more stridor and early respiratory muscle fatigue. However, it is important to point out that not all situations of flow limitation relate to dissipative pressure losses. For more than 30 years we have known that flow in a compliant tube, such as an airway, cannot exceed the minimum flow at which the velocity of a particle suspended in the flow equals the local wave-speed for the tube. The wave-speed is the velocity at which a disturbance travels through the tube, a concept that is familiar to clinicians because the wave-speed is the velocity at which the pulse waveform travels through arteries. Wave-speed flow limitation ultimately results from the coupling of airway compliance and convective acceleration (see Figure 42-9). As the respiratory gas moves through areas of decreasing cross-section, the kinetic energy of the gas increases at the expense of the total energy contained in the flow stream. As a result there is a decrease in the pressure acting on the inner surface of the airway (this decrease is the basis for the Venturi effect), and the transmural pressure of the airway decreases. Once again, if the airway is sufficiently compliant, there is a maximum flow beyond which the inside pressure would decrease faster than can be accommodated by the decrease in cross-sectional area, and flow becomes limited. Regardless of its causal mechanism (viscous or wave-speed), flow limitation occurs at lower flows in the presence of airway obstruction and at low lung volumes, when airway diameter is minimal.

Airway Muscle and Compliance of the Airways

The effect of transmural pressure on the caliber of an airway depends on the mechanical characteristics of the airway itself or, more specifically, on its ability to undergo collapse or distension, a property that is often described as airway wall compliance. The structure of each segment of the airway tree has evolved to minimize luminal distortion in response to the varying stresses that act on the airway wall during breathing. The pharynx and larynx, for example, contain skeletal muscle, which stiffens their walls or dilates the pharyngeal lumen and the glottis during inspiration under the control of cranial nerves IX and X.[24] Loss of pharyngeal or laryngeal tone during sleep or after pharmacologic inhibition or injury of the controlling neurons is the most important cause of upper airway obstruction during inspiration.

The smooth muscle of the trachea and bronchi has a similar function. For instance, the trachea is composed of a series of incomplete cartilaginous rings forming a relatively rigid arrangement that resists the collapsing effects of positive intrathoracic pressures during expiration. The rings leave a dorsal gap, where the wall of the trachea is soft. This weak point is bridged by the trachealis muscle, which, upon contracting, can approximate the edges of the cartilage rings and prevent the soft portion of the wall from bulging into the airway lumen (see Figure 42-7). Like the smooth muscle in other airway segments, the trachealis muscle is innervated by local parasympathetic ganglia. The ganglia in turn receive inputs from parasympathetic preganglionic neurons located in the medulla via nerve fibers carried by the vagus nerves.[25,26] The medullary preganglionic neurons are anatomically and functionally integrated in the control of breathing.[24] As a result,

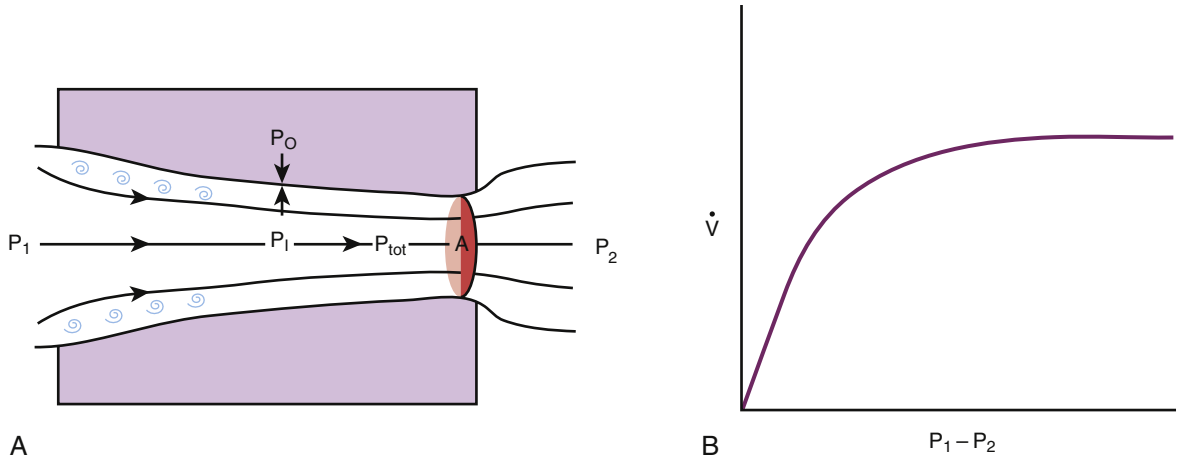

Figure 42–9. **A,** Flow limitation develops when the transmural pressure $(P_I - P_O)$ of a collapsible tube (such as an airway) and the flow in the tube interact in such a manner that the cross-section of the tube (*A*) cannot support an increase in the flow rate, independent of the pressure driving the flow ($P_1 - P_2$). Viscous flow limitation occurs when viscous friction (illustrated by the eddies at the edge of the flow stream) causes the pressure acting on the inner surface of the tube wall (P_I) to decrease faster than can be accommodated at any given flow. Wave-speed flow limitation takes place when the increase in the kinetic energy of the fluid or gas at a point of narrowing causes P_I to decrease relative to the head pressure (P_{tot} or the pressure that we would register with a probe facing the direction of flow) so that any further increase in flow cannot be supported by a further reduction in *A*. **B,** Regardless of the mechanism, when flow is limited, any increase in the driving pressure (or, in the case of the airways, the effort of the respiratory muscles) cannot increase flow ($\dot{V}$).

the traffic of impulses reaching the airway ganglia (and thus the tone of the muscle) varies with the phase of the breathing cycle and increases when the respiratory drive is increased, such as during exercise, hypercapnia, or hypoxemia.[24,27] Malformations or physical or pharmacologic interventions that disrupt the trachealis muscle or its nerve supply lead to tracheal obstruction when the intrathoracic pressure increases during expiration or when the child cries or exhales forcefully.[28] This form of tracheal obstruction often is attributed to tracheomalacia, even though no true softening of the tracheal cartilage occurs.

The bronchial smooth muscle also is innervated by the parasympathetic system.[26,29] In cartilaginous bronchi, the stiffening effect of the muscle contraction is augmented by the cartilage and prevents the bronchial lumen from collapsing when the transmural pressure decreases during expiration, coughing, or crying. In bronchioles, which in humans lack cartilage, contraction of the smooth muscle stiffens the airway walls as well. However, in these smaller airways, smooth muscle contraction may have a more important function of preventing excessive airway distension during inspiration, when the stressed transmitted to the airway wall may disrupt the delicate bronchiolar structure.

Airway Obstruction

Airway obstruction causes an exaggeration of the normal breathing changes in airway caliber. Thus the clinical manifestations of the obstruction depend on its location (extrathoracic or intrathoracic) and the direction of flow (inspiratory or expiratory). When the obstruction is extrathoracic (e.g., as occurs with croup, glossoptosis, and tonsil or adenoid hypertrophy), the subject must create a more negative pressure inside the airway segment downstream from the obstruction to overcome the increased resistance during inspiration. Therefore this segment of the airway tends to collapse, worsening the obstruction and producing a characteristic turbulent noise (inspiratory stridor) as gas accelerates through the narrowest point and induces vibrations in the airway mucosa, creating in the process a decrease in inside pressure that approximates the walls of the airway even further. The obstruction is relieved during expiration because the pressure inside the airway segment, now upstream from the obstruction, must become more positive with respect to atmospheric pressure to force gas flow through the obstruction.

When the obstruction is intrathoracic (e.g., as occurs with extrinsic compression of the trachea and bronchi, tracheobronchomalacia, and asthma), during inspiration the pressure inside the airways downstream from the obstruction has to become more negative than that inside the airways upstream. However, no matter how negative it is, the pressure inside the airways still must be less negative than the pleural pressure (Equations 3 and 4) because otherwise the lung recoil ($P_A - P_{pl}$) would be negative, which is unimaginable. Thus during inspiration the transmural pressure of intrathoracic airways remains always positive. In contrast, during expiration the pressure inside the airway segment located between the obstruction and the thoracic outlet may become lower than pleural pressure at some point (see the section on Airway Dynamics). This situation, coupled with the convective acceleration of flow at the obstructed segments, causes these airways to collapse and produce high-pitched vibrations (wheezing), expiratory delay, and dynamic hyperinflation.

A Specific Case Study in Airway Mechanics: Mechanical Ventilation

The application of positive pressure in the airways changes the balance of pressures that determines airway caliber. When positive end-expiratory pressure (PEEP) is used, pressure inside the airways is positive (relative to atmospheric pressure) during the entire respiratory cycle. As a result, any portion of the extrathoracic airway that is not bypassed by an endotracheal tube (or the entire extrathoracic airway when mask

ventilation is used) is exposed to transmural stresses that cannot have anything but a dilating effect during both inspiration and expiration. The pressure inside the intrathoracic airways also increases with respect to pleural pressure, with the difference between these two pressures varying as a function of the increase in elastic lung recoil produced by the inflation. For this reason, PEEP has been proposed as a therapy to decrease airway resistance and gas trapping in patients with intrathoracic airway obstruction.[30-33] Although PEEP is beneficial in some of these patients, in others, it increases lung volume,[34] interferes with cardiovascular function, and ultimately decreases oxygen delivery to the tissues.[35] The individual variations in the response to PEEP of patients with airway obstruction may simply reflect differences in the mechanisms of dynamic hyperinflation.[32] In patients who have gas trapping without expiratory flow limitation, proximal airway pressures (and thus also PEEP) are transmitted faithfully to the alveoli. As a result, their lung hyperinflation worsens. By contrast, in patients who have both gas trapping and expiratory flow limitation, PEEP may not affect the pressures upstream of the flow-limiting point; therefore, alveolar pressure and lung volume may not increase as much. The pressures inside the airways and downstream of the flow-limiting point increase, dilating the airway cross-section and thereby increasing the rate of lung emptying. Although PEEP is not recommended in every patient, its judicious use may be considered, under careful monitoring, to improve the mechanical function of the lungs of some selected infants and children with severe obstructive airway disease.

Determinants of Regional Gas Flow Distribution in the Lungs

From a mechanical perspective, the lungs form a parallel arrangement of acinary or multialveolar units, each supported by a conducting airway. The development of inequalities in the mechanical and gas-exchanging functions of these units is a fundamental factor in the manifestations of lung disease. To understand how mechanical inequality affects the distribution of ventilation in the lungs, it is essential to realize that the potential filling volume of any alveolar unit is determined by the unit's compliance. However, the actual filling volume during a breath depends on the rate at which the unit can fill relative to other units.[36] This rate is a function of the unit's compliance and resistance and often is defined by their product, a constant with the dimension of time known as the time constant (represented by the Greek letter τ).

The mathematical formulations that describe the distribution of flow among units with different time constants can be very complex. However, it is possible to make some basic predictions of how a certain flow pattern will influence the distribution of tidal volume among these units.[17,37] Imagine a simplified lung composed of three units (Figure 42-10), one with a normal compliance and resistance (normal τ), another with a low compliance and a normal resistance (short τ), and the third with a normal compliance and a high resistance (long τ). As long as the inspiratory time is sufficiently long to allow equilibration of alveolar pressures within the lungs, a decelerating inspiratory flow pattern (pressure-controlled ventilation) will inflate all three units proportionally to their compliances, thus favoring the two units with normal compliance. If the inspiratory time is shortened, however, gas is still flowing at the end of inspiration. This situation results in pressure and inflation inequalities among the units, with a disproportionate portion of the tidal volume being directed to units with a short time constant (once again proportionally to their compliance) and away from the unit supplied by an obstructed airway. The effect of such redistribution on gas exchange depends on the blood supply received by each type of unit and therefore is difficult to predict in diseased lungs. However, the astute clinician may derive some insight into the mechanism of a given patient's gas exchange abnormalities by observing carefully the changes induced by variations in the flow rate and duration of inspiration during mechanical ventilation.

Restrictive and Obstructive Respiratory Disease

As seen, inertial pressure losses are relatively insignificant at normal breathing frequencies in children, and viscoelastic pressure losses usually are small and lumped together with other dissipative pressure losses. Therefore the pressure that the respiratory muscles must generate to produce a certain volume excursion of the thorax can be simply considered the sum of elastic and resistive pressures that need to be overcome in the process (see Equations 6 and 7). Because work is calculated by integrating these pressures relative to the same volume change, it immediately follows that the total work done by the respiratory muscles is the sum of the works done to overcome elastic and resistive pressures.

When applying these formulations, it is important to realize that elastic and resistive forces do not always act in the same direction. During inspiration, the respiratory muscles must generate the force to overcome both elasticity and flow resistance. Thus both elastic and resistive works have the same sign and their effect on total work is additive. During expiration, however, the elastic recoil of the lungs normally provides the force needed to overcome resistance. Elastic and resistive works are of similar magnitude and opposite sign, and the total work done by the muscles is zero. When there is intrathoracic airway obstruction, however, the absolute value of resistive work often exceeds that of elastic work. Under these circumstances the expiratory value of total work is no longer negligible and the expiratory muscles must do the balance of the expiratory work.

The term *restrictive respiratory disease* encompasses all conditions in which elastic or nondissipative work is primarily increased. One could also say that restrictive disease is caused by a decrease in thoracic compliance. Whether originating in the lungs or the chest wall, a decrease in thoracic compliance has two important mechanical consequences. First, the work of breathing increases, but only during inspiration; expiration continues to be passive and, in fact, takes place at a faster rate as elastic recoil increases. Second, the relaxation volume of the thorax and the FRC decrease. The resultant decrease in lung volume, which may further reduce lung compliance, may be more pronounced in the infant, whose resting relaxation volume is already low. At low lung volumes, alveoli lack the support provided by the recoil of neighboring structures at higher volumes (mechanical interdependence[18]) and become inherently unstable, particularly if the surfactant system is affected by the disease and surface tension is increased. To prevent alveolar collapse, infants and small children with restrictive respiratory disease often close their glottis toward the end of

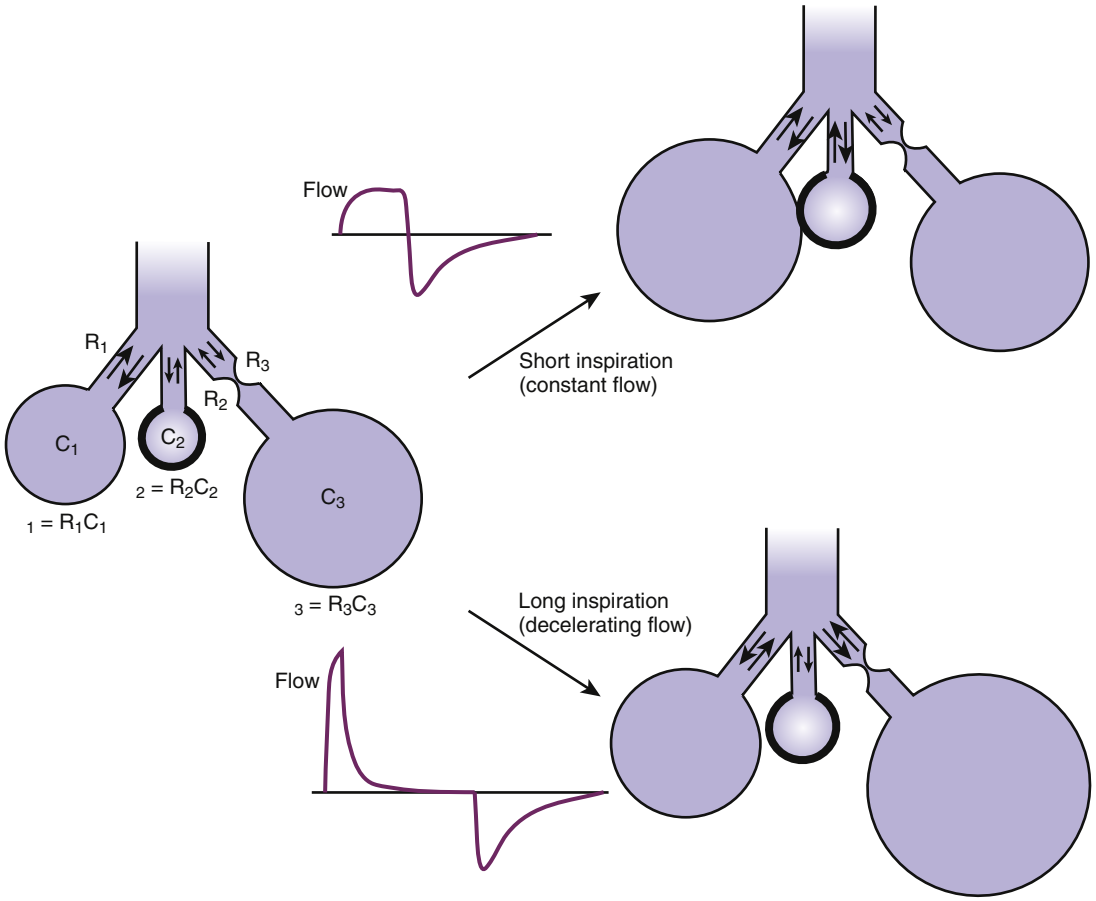

Figure 42–10. Schematic representation of the lung showing the effects of ventilatory pattern on the distribution of inspiratory gas flow. The rate of inflation or deflation of an airway-alveolar unit can be characterized by a time constant (τ) equal to the product of its resistance (*R*) and compliance (*C*). Three types of units are represented in the scheme (each identified by the corresponding numerical subscript): (1) a normal unit with normal compliance and resistance (normal τ); (2) a restrictive unit with decreased compliance and normal resistance (short τ); and (3) an obstructed unit with normal compliance and increased resistance (long τ). Inflation with a decelerating pattern of flow (typical of modern pressure-controlled ventilator modes) favors units with normal compliance (1 and 3). Inflation with a short inspiratory time and a constant flow (more typical of volume-controlled modes) directs flow away from the unit with a long time constant (3), causing the tidal volume of the other units (1 and 2) to be disproportionately larger relative to their compliance.

expiration, causing each breath to end in a grunt. PEEP and continuous positive airway pressure are effective therapeutic modalities to achieve the same objective of preserving the end-expiratory inflation volume.[38-41] Deep lung inflations during positive pressure ventilation (often described as recruitment maneuvers) also may maintain unstable alveoli open for a period. This effect of volume history on alveolar volume decreases the work needed for spontaneous breaths following the inflation and explains some of the beneficial effects of intermittent mandatory ventilation in patients with restrictive lung disease.

Obstructive respiratory disease includes all conditions in which resistive or dissipative work is predominantly increased. The small caliber and high wall compliance of the developing airways render the infant and child more vulnerable to the development of airway obstruction.[42,43] Under normal breathing conditions the small caliber of the airways represents no mechanical disadvantage because there is good correspondence between airway cross-sectional area and gas flow. When obstruction develops, however, airway resistance increases as an exponential function of the reduction in airway diameter (see Equation 11). Because the same absolute decrease in caliber causes a much greater proportional reduction in airway diameter in a small than in a large airway, obstructive lesions tend to have more severe consequences in children than in adults.

Determinants of Respiratory Efficiency

The respiratory system has a surprising ability to compensate for mechanical dysfunction. However, compensation does not come cheap. It raises the work of breathing in almost every instance, usually by combining increases in the force of contraction of the respiratory muscles with changes in ventilatory pattern. If the increase in work is sufficient to overcome the additional restrictive and obstructive loads applied on the respiratory system, minute alveolar ventilation and arterial P_{CO_2} are maintained within normal limits and respiratory failure is averted. In contrast, if the metabolic and contractile machinery of the respiratory muscles cannot meet the greater work demands, alveolar ventilation becomes insufficient to support gas exchange and respiratory failure ensues.

In the final analysis, the success or failure of the compensatory effort is a simple matter of balance between the energy resources available to the respiratory muscles and the energy demands imposed on these muscles. The energy resources are

relatively well defined and limited by the blood supply of the muscles, their ability to metabolize substrates, and the internal efficiency of the muscle's metabolic apparatus. The energy demands on the respiratory muscles are more variable, however, and depend on the workload these muscles must perform per unit of time (i.e., the power they must generate) and the overall efficiency with which the work is performed.

In thermodynamic terms, efficiency is defined as the proportion of the free energy available within a system that is transformed into external work (Equation 1). In the case of the respiratory system, this notion can be reshaped to define efficiency as the quotient of breathing power ($W \times t$) divided by respiratory muscle energy consumption.

In practice, the breathing power has to be calculated from the volume-pressure relationships of the lungs in spontaneously breathing subjects. The energy consumption of the respiratory muscles is in turn estimated from their oxygen consumption,[44] computed as the difference between the total body oxygen consumptions measured during spontaneous and supported ventilation. Some obvious sources of energy consumption, which are not included in the breathing power, reduce the respiratory system's efficiency. For example, the work of breathing does not account for isometric activity of the respiratory and postural muscles, which is not proper work in a physical sense (no volume change) but consumes energy. Other forms of volume-pressure work usually are not taken into account when calculating respiratory efficiency, so they also become sources of apparent inefficiency. The work performed to inflate the chest wall, for instance, cannot be determined during spontaneous breathing when contraction of the muscles changes the wall's passive properties (see the section on Volume-Pressure Relationships). Similarly, the work done to deform the rib cage is difficult to measure and often is ignored. Thus it is not surprising that the published efficiencies tend to be artifactually low.[45,46]

As defined here, the poor overall efficiency of the respiratory system implies that, during each breathing cycle, a substantial amount of energy derived from metabolic substrates is dissipated as heat and cannot be converted into volume-pressure work. Respiratory disease can increase this energy dissipation by various mechanisms, leading to efficiency values as low as 1% to 3%.[45,47,48] Disease-induced alterations in chest wall configuration, for example, can limit force generation by the muscles, thus interfering with the transformation of chemical energy into mechanical energy.[49] Changes in the geometry of the chest wall also modify the spatial relationships of the muscles and can interfere with the transformation of mechanical energy into work. Finally, disease-related anomalies in the contractile state of the muscles produced by fatigue or poor nutrition further decrease muscle force and the work of breathing without decreasing muscle energy demands.[50-52]

Power of Breathing and Breathing Frequency

Unlike work, which is a function of the volume-pressure characteristics of the thorax, respiratory power (work/time) is influenced by the pattern of breathing. It has been held for some time that, at any given time, each subject has an optimal breathing frequency at which minimum power, and thus a minimum energy consumption, is necessary to attain a certain minute alveolar ventilation (Figure 42-11).[46,53,54] Although this view has been challenged by those who believe that breathing frequency is adjusted to minimize average muscle force rather than power (after all, there are no known energy or power receptors anywhere in the body),[55] it is a common clinical observation that different types of mechanical derangement result in distinctive patterns of breathing. These patterns generally agree with the principle of minimal power expenditure. For instance, patients with restrictive lung disease breathe rapidly and shallowly. In contrast, patients with airway obstruction breathe more slowly and prolong their inspiration or expiration, depending on whether the obstruction is extrathoracic or intrathoracic. By simply inspecting the effort and frequency of the breathing movements, the clinician can therefore assess not only the severity but also the specific nature of a patient's respiratory dysfunction. It is important to remember, however, that the high ratio of dead space to minute ventilation in infants and small children mandates a relatively high breathing frequency at rest, even in the presence of airway obstruction. Nevertheless, severe tachypnea in a child with obstructive airway disease should always raise suspicions of an associated restrictive impairment. This distinction is best clarified by the following examples. A breathing frequency of 40 breaths/min can be considered low for a 3-month-old infant who has severe respiratory difficulty from bronchiolitis and is consistent with a predominantly obstructive dysfunction. On the contrary, a frequency of 100 breaths/min in the same infant would be indicative of a predominantly restrictive dysfunction, caused by either parenchymal involvement in the

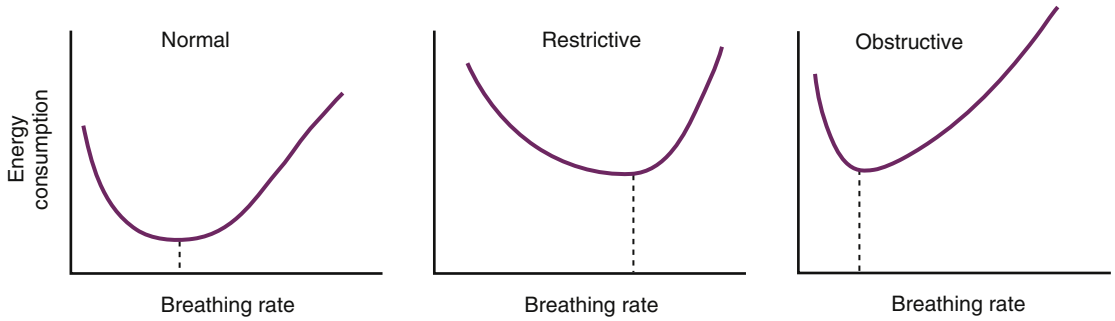

Figure 42–11. Each combination of mechanical conditions is associated with an optimal breathing rate for which the power (work × time) and thus the energy consumption of breathing are minimal. Restrictive disease increases the optimal rate, while obstructive disease decreases it. Actual breathing rates adhere remarkably to predictions based on minimal power. Consequently, it is safe to assume that, under most circumstances, the presence of tachypnea is indicative of a restrictive derangement and that a decrease in respiratory rate or, more precisely, a prolongation of inspiration or expiration indicates an obstructive derangement.

disease (e.g., pneumonitis or collapse) or severe distension of the lungs and chest wall caused by pulmonary hyperinflation.

Alterations in Chest Wall Configuration

Diaphragmatic Configuration

The amount of force developed by a muscle depends on its resting length. An optimal resting length for which maximal force is developed can be defined for each muscle. In the case of the diaphragm, the optimal length is attained at thoracic volumes close to the normal FRC. At these volumes, the muscle has the shape of a dome-capped cylinder, a configuration that has several advantages. First, diaphragmatic contraction shortens the cylinder in the axial direction,[56] producing a pistonlike motion that displaces more volume than if the diaphragmatic dome simply became flatter (assuming the same degree of fiber shortening). Second, the descent of the diaphragmatic dome increases the surface of contact between the rib cage and the lungs. Therefore the increase in lung surface produced by lung inflation can be accommodated without changing the shape of the lung or the chest wall. Finally, at normal breathing volumes, the sides of the diaphragmatic cylinder are apposed to the internal surface of the rib cage. This area of apposition establishes a mechanical link between intraabdominal pressure and lung volume.[52,57] As the diaphragm contracts during inspiration, intraabdominal pressure increases, pushing the lower portion of the rib cage forward and laterally. Thus diaphragmatic contraction has an additional contribution to lung inflation at low energy cost and may help to stabilize the lower rib cage against inspiratory distortion.[58]

The configuration of the chest in the infant and small child minimizes these advantages. At these ages, the lower portion of the infant's rib cage has large anteroposterior and lateral diameters. As a result, the insertions of the diaphragm are spread out, thereby reducing the axial shortening range of the muscle. Moreover, the lack of a substantial area of apposition of the diaphragm and rib cage abolishes the inspiratory and stabilizing effects of intraabdominal pressure on the rib cage.[52]

Thoracic hyperexpansion and abdominal distension exaggerate these limitations by widening the diameters of the lower portion, spreading out the diaphragmatic insertions. The length of the muscle fibers is diminished to a suboptimal length, and the force generated during inspiration is decreased. Abdominal distension has the additional disadvantage of raising intraabdominal pressure, which opposes diaphragmatic contraction and raises the work that the muscle has to do.

Rib Cage Distortion

Until now, we have assumed that the rib cage and abdomen have the same configuration during spontaneous breathing and passive inflation-deflation maneuvers. This assumption implies that all the various parts of the chest wall move with a single degree of freedom and that there are no volume shifts between parts. However, it has been known for quite some time that, under certain conditions, the rib cage and abdomen can change volume independently of one another and even in opposite directions.[59] In other words, the chest wall has multiple degrees of freedom and can undergo regional distortion.

Regional chest wall distortion results from the coupling of changes in pressure (pleural or intraabdominal) and the local compliances of the rib cage and abdominal wall. Rib cage distortion is more pronounced during inspiration, when pleural pressure decreases with respect to atmospheric pressure or the diaphragm pulls the rib cage by its costal insertions, forcing the thoracic wall inward in the expiratory direction. This inward movement of the rib cage causes visible retractions in areas where the chest wall has no bony support (intercostal, subcostal, or suprasternal spaces) or where the support has been abnormally weakened (e.g., costal fractures). Abdominal distortion, in contrast, usually involves alterations in the contractile state of the diaphragm or the abdominal wall muscles. When one hemidiaphragm becomes paralyzed, for example, the negative pleural pressure generated by other inspiratory muscles pulls the paralyzed muscle upward, into the rib cage, during inspiration. As a result, the abdominal wall of the affected side moves paradoxically in the inward direction, and the chest wall becomes distorted. As another example, contraction of the abdominal muscles stiffens the abdominal wall, raising intraabdominal pressure and shifting all volume changes to the rib cage during both inspiration and expiration.

The developing chest wall is particularly susceptible to distortion. As we have seen, the rib cage is very compliant in the newborn.[3,5,60] Although this high compliance facilitates passage through the birth canal, it also promotes distortion of the rib cage during inspiration. In addition, the intercostal muscles, whose main contribution to breathing is to stabilize the rib cage by contracting simultaneously with the diaphragm, appear to have decreased tone at early ages, especially during rapid eye movement sleep and in preterm infants.[61] Finally, the lack of a substantial area of apposition between the diaphragm and the rib cage removes the stabilizing effect of the intraabdominal pressure on the lower rib cage. Accordingly, in infants chest wall retractions tend to develop in the presence of minimal mechanical lung dysfunction.

Chest wall distortion represents a pressure-induced change in volume, and therefore it constitutes a form of work. Distortional work usually is not computed as part of the work of breathing. However, it has a measurable energy cost, and therefore it needs to be viewed as a source of respiratory inefficiency. Both the distortional work and its energy cost can be better understood if we analyze the volume-pressure relationships of the thorax in the particular case of rib cage retractions during inspiration. Regardless of whether such retractions are present, at any point in time, the volume change of the lungs (ΔV_L) must be equivalent to the sum of the volume changes of the rib cage (ΔV_{rc}) and abdomen (ΔV_{ab}):

$$\Delta V_L = \Delta V_{rc} + \Delta V_{ab} \tag{12}$$

Consequently, if ΔV_L is to remain constant, decreases in ΔV_{rc} caused by rib cage retractions during inspiration must be accompanied by a proportional increase in ΔV_{ab} (Figure 42-12). If, as often occurs, ΔV_{rc} is negative, then ΔV_{ab} becomes greater than ΔV_L. Because the volume displacement of the diaphragm approximates ΔV_{ab}, chest wall retractions inevitably result in an increase in the diaphragmatic excursion.

The amount of work done by the diaphragm is calculated by integrating the pressure developed by the muscle relative to the volume displacement produced by the diaphragmatic contraction. In practical terms, the pressure developed by the diaphragm or transdiaphragmatic pressure is defined as the

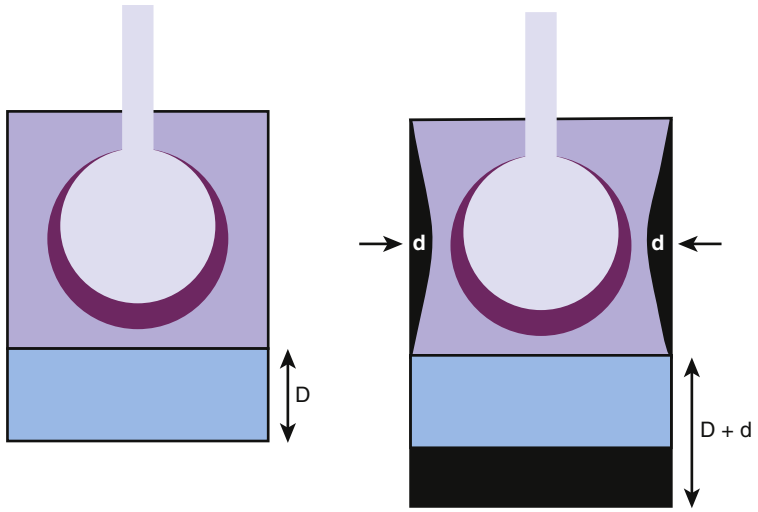

Figure 42–12. Effect of inspiratory rib cage distortion on the volume displacement of the diaphragm. When the rib cage caves inward during inspiration, to generate the same tidal volume in the lungs (shown in *red*), the diaphragm must increase its volume excursion above the non-distorted value (*D*) by an amount equivalent to the volume of the inward movement of the rib cage (*d*). Rib cage distortion usually relates to the combination of an increased rib cage compliance and increased respiratory effort, which translates into more negative pleural pressures acting on the inner surface of the rib cage. However, it can occur without apparent increase in effort, especially in premature infants, or as a result of disease- or trauma-induced chest wall distortion (e.g., rib fractures or unilateral phrenic palsy).

difference between the intraabdominal pressure (P_{ab}, often estimated from measurements of gastric pressure) and the pleural pressure (P_{pl}, estimated from the esophageal pressure). The volume displaced by the diaphragm is estimated as ΔV_{ab} in Equation 12.[62] Thus diaphragmatic work (W_{di}) can be computed as:

$$W_{di} = \int (P_{ab} - P_{pl}) \cdot dV_{ab} \qquad (13)$$

The work done on the airways and lungs to move gas in and out of the alveoli (see Equations 3 and 4) is:

$$W_L = \int (P_M - P_{pl}) \cdot dV_L \qquad (14)$$

P_{ab} is generally greater than P_M (which is 0 in the absence of positive airway pressure), particularly in a recumbent subject. In the presence of rib cage retractions, dV_{ab} greatly exceeds dV_L, and consequently W_{di} substantially exceeds W_L. The volume displacement of the diaphragm may be up to twice the tidal volume of the lungs in premature infants without apparent lung disease,[63] an increase that could be responsible for the poor weight gain and development of fatigue of infants recovering from the respiratory distress syndrome.

Alterations in Contractile State of the Respiratory Muscles

Respiratory efficiency is affected by the functional state of the respiratory muscles. Sustained increases in activity likely will eventually result in decreased contractile force and lower minute alveolar ventilation, a condition often classified as muscle fatigue. When muscle fatigue is present, the energy consumption of the muscle may be increased with respect to the actual work performed. Similar decreases in contractility without a decrease in energy consumption can be present in a variety of clinical situations. Some result from an imbalance between the energy demands of the muscle's contractile machinery and its substrate availability (e.g., shock[64,65]). Others are simply the expression of the inadequate coupling of the excitation-contraction processes inside the muscle cell, changes in the recruitment of specific fiber populations within the muscle,[66] or chronic depletion of the muscle's energetic resources as a result of malnutrition.[50-52]

Conclusion

Although the developing respiratory system has obvious mechanical disadvantages, the reader should not be left with the idea that infants and children are constantly on the brink of respiratory failure. Quite the contrary, they have a remarkable capability to tolerate respiratory disease. This capability is in great part based on a very proficient system of mechanical compensation. The information contained in this chapter is intended to provide an overview of the factors involved in both mechanical dysfunction and its compensation. Unfortunately, the physiological principles underlying the basic concepts presented here are receiving less and less attention in our training programs. The reader is encouraged to visit and study the many classical references contained in the bibliography. While many of them certainly show the signs of age, they provide the critical foundation for a more rational approach to the therapy of respiratory disease in the critically ill child.

Chapter 43

Noninvasive Monitoring in Children

Sally E. Rampersad, Kenneth A. Schenkman, and Lynn D. Martin

PEARLS

- Many patients in the pediatric intensive care unit are unusually sensitive to environmental temperature fluctuations. Temperature fluctuations in these patients may occur rapidly and may have important effects on physiology and metabolism.
- Most pulse oximeters measure only oxyhemoglobin and deoxyhemoglobin and ignore other forms of hemoglobin, such as methemoglobin and carboxyhemoglobin. However, blood cooximeters and recently developed noninvasive cooximeters account for these other species.
- The accuracy of the capnogram depends on the sampling site. If the tidal volume is small and the sample flow rate is large, the gas sample may be diluted by entrained fresh gas.
- Capnography can be a good global indicator of the patient's condition.
- The bispectral index monitor is a form of processed electroencephalogram that integrates various electroencephalographic descriptors into a single unitless number that gives an indication of the brain's response to hypnotic agents.

The purpose of monitoring is to obtain frequent, repetitive, or continuous measurement of vital functions that are displayed at the bedside to allow prompt recognition of clinical problems and early initiation of therapy. No single physiologic measurement or group of measures can completely convey the clinical condition of the patient. Monitoring provides objective criteria for the evaluation and treatment of physiologic deficiencies and is an invaluable supplement to clinical judgment, which is more subjective and less easily quantified.

Noninvasive monitoring in the form of vital signs (i.e., heart rate, respiratory rate, noninvasive blood pressure, fluid intake and output, and temperature) has been used routinely for all patients receiving care in the intensive care unit (ICU) since the birth of the specialty. Guidelines for equipment and monitoring and for levels of care for pediatric ICUs (PICUs) were specified by the American College of Critical Care Medicine in 2004.[1] It has become increasingly apparent that accurate and continuous core temperature management may significantly influence outcomes in pediatric critical care. Admission temperature is inversely related to both mortality and late-onset sepsis in low birth weight infants.[2] Cold stress may lead to or worsen hypoglycemia in late preterm infants.[3]

Pulse oximetry and capnometry have significantly affected the practice of critical care medicine and are now standards of care. New technologies currently under development to noninvasively monitor physiologic function may significantly decrease the need for more invasive monitoring and lessen the associated risks of such modalities.

Vital Signs

Heart and respiratory rate, noninvasive blood pressure, fluid balance, and temperature are the simplest, most easily measured, and most commonly monitored and recorded physiologic variables. Heart rate and respiratory rate are continuously recorded and displayed electronically. Changes in these variables alert the ICU team to cardiovascular and respiratory physiologic responses and to changes in clinical conditions and/or responses to pharmacologic interventions.

Electrocardiographic Monitoring

The electrocardiogram (ECG) evaluates the electrical events of cardiac contraction by sensing and recording voltage changes at the body surface. The body is assumed to be a homogeneous volume conductor with uniform geometry. The heart is represented by two charged electrodes: a dipole with one positive pole and one negative pole. This dipole is surrounded by a hypothetical equilateral triangle. The electrical activity of the heart (i.e., changes in magnitude and orientation) are measured throughout the cardiac cycle. The sides of the triangle, which represent the axes of the three standard limb leads, provide a triaxial frame of reference for spatial orientation of the cardiac electrical activity. When combined with the chest (V lead) recordings, the model provides frontal, sagittal, and horizontal components. Continuous ECG monitoring enables the ICU team to be aware of the rate and rhythm of the cardiac contractions. By tracking transthoracic impedence, the ECG leads also monitor respiratory rate and regularity.

Blood Pressure Measurement

Accurate, continuous measurement of noninvasive blood pressure (NIBP) in infants and children can be challenging. Current methods of measuring NIBP are limited to auscultation, oscillometry, ultrasound, and the flush or return to flow.[4] Because of technical difficulties, routine, reliable

measurements of NIBP in infants and children did not become possible until approximately 4 decades ago. Auscultatory determinations, even on an intermittent basis, can be difficult to obtain in infants. In the flush or return to flow technique, the distal extremity is compressed, facilitating blood drainage. An occluding cuff is inflated proximally on the limb and gradually deflated. The systolic pressure is the pressure at which flow returns to the compressed distal extremity.

Numerous subjective influences play a major role in accuracy. Sensitive sound amplification systems have been used, but not commonly in the ICU setting. The most popular method used is based on the principle of oscillometry (e.g., Dinamap, Critikon, Tampa, Fla.), which automatically inflates and deflates the cuff and uses crystal microphones and piezoelectric crystals and the Doppler principle to measure and display systolic, mean, and diastolic pressures. During oscillometry, blood flow through an artery during cuff deflation causes the arterial wall to oscillate.[5] The rapid increase in oscillation amplitude represents systolic pressure, whereas the sudden decrease in oscillation represents diastolic pressure. The period of maximum oscillation is used to estimate mean blood pressure.

The needle bounce technique is another oscillometric method commonly practiced by flight nurses/physicians. An inflated distal or proximal extremity circumferential cuff is slowly deflated, and the first visible bounce corresponds to systolic pressure. Automatically obtained blood pressures by the oscillometric method compare favorably with those obtained via arterial cannulas in infants and children.[6-8] Oscillometric devices do not perform well if there is significant limb movement or in the presence of dysrhythmias.[4] Occlusive systems using frequent measuring intervals can be associated with problems such as skin breakdown after prolonged use.[4,9]

Doppler devices are extremely useful for determining blood pressure in small babies, particularly when shock is present. First, a small Doppler probe is placed over an extremity artery. Blood movement causes changes in exquisitely sensitive ultrasound reflectance, and thus, as a cuff on the proximal extremity is slowly deflated, systolic pressure is signaled by the appearance of the first Doppler effect signal. Diastolic pressure is read when the strength and quality of the signal decrease. Correlation of these two pressures with arterial catheter pressures is good.[10] However, it is important to place the Doppler probe directly over an artery. When an arterial catheter is not available and the automatic oscillometric device is not able to provide pressure readings, the Doppler technique can be used to obtain intermittent blood pressure measurements in the ICU setting.

When measuring blood pressure in babies and children, it is important to select the appropriate-sized blood pressure cuff. Numerous cuff sizes are available, including neonatal sizes. For the upper extremity, the cuff should occupy at least two thirds of the upper arm.[11] The cuff bladder circumferential dimension should be 20% greater than that of the extremity.[11] A cuff that is too small will result in falsely increased readings.[7,11] In contrast, an oversized cuff will artificially decrease blood pressure readings, but the magnitude of this error is small.[7]

Temperature Monitoring and Routine Temperature Management

Body temperature can dramatically alter physiology and metabolism. Monitoring of temperature is a routine part of the practice in the ICU. The accepted normal range of rectal temperature in children is from 36.1° C to 37.8° C.[12] This range is closely guarded by an intact thermoregulatory system that controls heat production and loss. However, many ICU patients can be considered poikilothermic, meaning they are unusually sensitive to environmental temperature fluctuations. A number of factors may contribute to this poikilothermic tendency, including the presence of either endogenous or exogenous vasoactive influences, hypothalamic dysfunction, the administration of drugs that blunt the normal regulation of body temperature, and depression of the central nervous system (CNS), either endogenous or exogenous from administration of sedatives at moderate to high doses. Temperature fluctuations in such patients may occur rapidly. For this reason, the continuous monitoring of core temperature can be particularly useful in selected patients, including those with increased intracranial pressure or status epilepticus who are managed with high-dose CNS depressants and mechanical ventilation; those with unstable hemodynamics after open heart surgery; those experiencing respiratory failure and extreme mechanical ventilation support; and, of course, those being observed for the development of malignant hyperthermia.[13]

Temperature Monitoring Sites

Because core temperature is the principal thermoregulatory controller, monitoring core temperature is more useful than monitoring peripheral skin temperature. Commonly used core temperature monitoring sites include the distal esophagus, tympanic membrane, pulmonary artery, and nasopharynx. These sites detect core temperature changes rapidly, in contrast to urinary bladder or rectal measurements, which are good reflections of core temperature during steady-state conditions.[14] Cutaneous temperature monitoring is the least reliable indicator of rapid core temperature changes. However, monitoring peripheral temperatures can be useful in defining core peripheral gradients in temperature and assist in tracking vasoconstriction and vasodilation. Oral probes are used as thermometers, and some have been attached to pacifiers. A thermometer that scans the temporal artery is also available.[15]

The ideal spot for continuous core temperature monitoring is a pulmonary artery via a catheter, but because of the invasive nature of this monitor, it would never be placed for temperature monitoring alone. An esophageal temperature probe positioned in the lower third of the esophagus is a good alternative. In this position, the temperature sensor is immediately behind the left atrium and accurately tracks core temperature without significant time lag in the majority of situations. If a gastric tube with applied suction is present next to the temperature probe, it must be on the low intermittent setting or the temperature readings will be falsely lowered.

Nasopharyngeal and tympanic membrane temperatures are good indicators of cerebral temperature but can be inaccurate as a result of sensor positioning. Furthermore, trauma to the nasopharynx or tympanic membrane may result in troublesome bleeding, especially when coagulation and platelet function are abnormal.

Axillary and peripheral skin probably are the most convenient sites for monitoring temperatures, although they also provide the most inaccurate readings because of skin perfusion. These sites may be monitored through use of a

wearable continuous-read precision phase change thermometer, which is a dot matrix system of heat-responsive indentations that is secured to the patient via an adhesive backing. In a dot matrix thermometer color changes occur in the dots at specific temperatures related to the melting point of the specific chemical materials in each dot.[15] When continuous core temperature monitoring is desirable, the most reliable and convenient device is the lower esophageal temperature probe.

Pulse Oximetry

Pulse oximetry has become a standard monitoring modality for many aspects of medical care. In the ICU, pulse oximetry is routinely and continuously used to monitor most patients. Of all of the advances in medical monitoring during the past several decades, pulse oximetry has undoubtedly had the largest positive impact on the clinical care of hospitalized patients.

Takuo Aoyagi, working for the Nihon Kohden Corporation in Japan, first proposed the theory for pulse oximetry in 1972. His idea was developed into a working oximeter, which subsequently was patented in Japan in 1974 and marketed as the world's first commercial pulse oximeter. In 1977 a fiberoptic-based pulse oximeter with improved accuracy was marketed by Minolta, and in 1982 Nellcor began marketing a pulse oximeter that ultimately became an industry standard.[16] Since then numerous companies have produced and marketed pulse oximeters, and improvements in technology continue to improve the accuracy and reliability of these devices. Most recently, Masimo Corporation (Irvine, Calif.) introduced pulse oximeters with signal extraction technology[17] that minimizes motion artifact and interference from ambient light and is able to function in relatively low perfusion states. This approach has improved the accuracy of pulse oximetry readings and has decreased the frequency of false alarms in clinical settings.[18-22]

There is also a "blue" sensor that is particularly sensitive in patients with cyanotic congenital heart disease.[23] Standard pulse oximeters are not accurately calibrated for the low saturations seen with some congenital cardiac lesions. Accurate pulse oximetry is especially vital in the neonatal population, who benefit from tight control of oxygenation in order to minimize oxidative stress and to decrease the risk of retinopathy of prematurity.[24]

Principles of Pulse Oximetry

Pulse oximetry is based on the elegant observation that the attenuation of light passing through blood-perfused tissue changes with pulsation of blood and that the alternating component of the light attenuation results from the composition of arterial blood.[25] Figure 43-1 is a schematic diagram showing that the component of light attenuation as a result of pulsatility comes from arterial blood. This information can be analyzed to determine the hemoglobin saturation in the arterial blood. Absorption of light as a result of other tissue components and capillary and venous blood in the static portion of the signal is ignored in the analysis.

Light passing through a turbid media such as tissue is attenuated by absorption and scattering. If light scattering in tissue is assumed to be fairly constant, then measured changes in the attenuation of the transmitted light can be assumed to result from changes in absorption. Beer's law describes the theoretical absorption of light as follows:

$$\text{Absorbance (OD)} = -\log_{10}(I/I_O) = \varepsilon bc \qquad (1)$$

where I is light emerging from the sample, I_o is incident light illuminating the sample, ε is molar extinction coefficient of the specific absorbing species at a specific wavelength, b is path length (in centimeters) the light traverses, and c is molar concentration of the absorbing species. Thus changes in the concentration of an absorber, that is, oxyhemoglobin, results in changes in absorbance.

Hemoglobin has characteristic light-absorbing properties that change with oxygen binding. Figure 43-2 shows absorption spectra of oxyhemoglobin and deoxyhemoglobin in the visible and near-infrared spectral region. At any given wavelength there is a difference in absorption between oxyhemoglobin and deoxyhemoglobin except where the spectra cross at wavelengths called isosbestic wavelengths, where the absorption is the same for each state. At nonisosbestic wavelengths, the difference in absorption can be used to determine

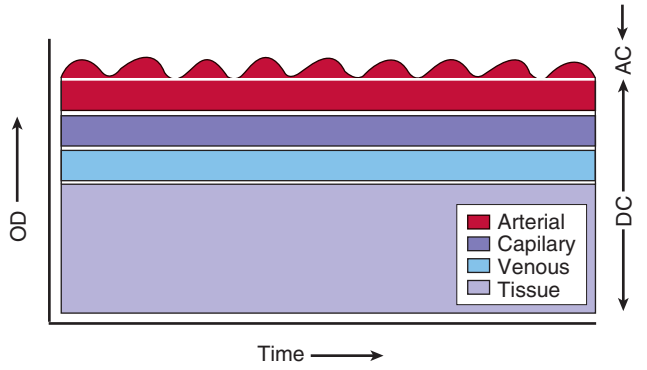

Figure 43–1. Light passing through a pulsating tissue will be absorbed by multiple components of tissue and blood. The alternating component (*AC*) is composed only of arterial blood.

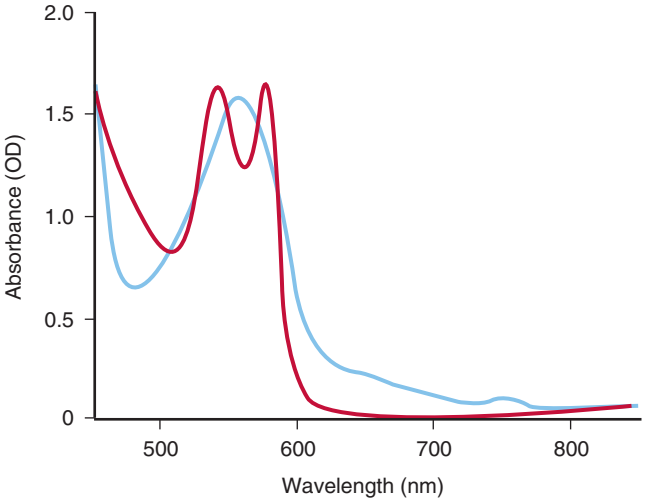

Figure 43–2. Absorption spectra of hemoglobin in the visible and near-infrared spectral region. The deoxy form of hemoglobin (*blue*) has a single peak in the visible and near-infrared region. Oxyhemoglobin (*red*) has two peaks in the visible region but no significant peak in the near-infrared region.

the fraction of oxyhemoglobin. Saturation of hemoglobin is defined as follows:

$$Hb_{sat} = [OxyHb] / ([OxyHb] + [DeoxyHb]) \quad (2)$$

where Hb_{sat} is fractional saturation of hemoglobin, [*oxyHb*] is concentration of oxyhemoglobin, and [*deoxyHb*] is concentration of deoxyhemoglobin. Hemoglobin percent saturation, as commonly reported, is determined by multiplying Hb_{sat} by 100.

Pulse oximeters typically use two wavelengths of light to determine the saturation of hemoglobin, usually one around 660 nm in the visible light region and one around 940 nm in the near-infrared region.[17] The absorption around 940 nm is relatively low and fairly constant over the range of saturations; thus a change in absorbance at 660 nm can be referenced to the absorption at the 940-nm wavelength and is used to determine the saturation. Each pulse oximeter uses a complex algorithm to convert the change in absorbance at the two wavelengths to an absolute saturation value. More wavelengths can be used to improve the accuracy of the measurement.

In the presence of other forms of hemoglobin, primarily carboxyhemoglobin or methemoglobin, the saturation of hemoglobin is correctly determined by the more complex relationship:

$$Hb_{sat} = [OxyHb] / ([OxyHb] + [DeoxyHb] + [MetHb] + [CarboxyHb]) \quad (3)$$

where [*metHb*] is concentration of methemoglobin and [*carboxyHb*] is concentration of carboxyhemoglobin. Most pulse oximeters usually cannot accurately account for the presence of these other forms of hemoglobin. Blood cooximeters, however, do account for these species, as do the newer Masimo pulse oximeters.

Validation

Numerous studies have been performed to validate existing pulse oximeters.[26,27] Pulse oximeters also must be subjected to extensive testing prior to obtaining U.S. Food and Drug Administration (FDA) approval for marketing in the United States. Despite all of the current testing, difficulties in both calibration and validation remain. One of the most significant issues surrounding calibration is the development of an appropriate universal test that will accurately test the pulse oximeter for a wide range of potential clinical applications. Pulse oximeters must be accurate for a wide range of skin thickness and color and over a wide range of saturations. In general, pulse oximeters are most accurate at higher saturations, usually above 75%.[28-30]

Sources of Error

Although pulse oximetry is widely accepted as a valid clinical monitor and provides valuable minute-to-minute clinical data, pulse oximeters are subject to multiple potential sources of error. The most clinically significant source of error usually results from movement or "motion artifact," which, as most clinicians recognize, results in frequent and annoying false alarms. Other sources of error include dyshemoglobinopathies, interfering dyes or other pigments in the blood, ambient light,[31] and poor tissue perfusion. The extent of ambient light interference has been questioned for some of the pulse oximeters studied,[32] but shielding of the probe from ambient light is often used clinically to improve performance. Hypoperfusion also may limit the ability of pulse oximeters to adequately detect a pulsatile signal and can adversely affect reported saturation values.[31]

The presence of interfering dyes or dyshemoglobinopathies is an infrequent clinical problem but can result in erroneous pulse oximetry readings. In methemoglobinemia, the iron in the heme groups in hemoglobin becomes oxidized from the ferrous (Fe^{2+}) state to the ferric (Fe^{3+}) state. The oxidized form of hemoglobin, called methemoglobin, cannot bind oxygen. Thus the presence of significant quantities of methemoglobin leads to tissue hypoxia because these molecules no longer participate in oxygen transport. However, light absorbance by methemoglobin more closely resembles oxyhemoglobin than deoxyhemoglobin at the measured wavelengths, erroneously leading the pulse oximeter to indicate a higher percentage of oxygen saturation than expected.[33,34] Similarly, the presence of carboxyhemoglobin may result in erroneous reading in pulse oximetry because carbon monoxide–bound hemoglobin also does not participate in oxygen transport.[35]

Masimo has recently introduced a pulse oximeter, known as the Masimo Rainbow SET, that uses eight wavelengths of light (Figure 43-3) and thus is able to determine carboxyhemoglobin and methemoglobin levels in addition to oxygenated and deoxygenated hemoglobin.[36] Because these other species of hemoglobin are recognized, it is also possible to have a continuous readout of total hemoglobin. The Rainbow oximeter will be useful not only for monitoring patients with dyshemoglobinemias but also in situations where occult blood loss may be occurring because of its ability to report total hemoglobin. Because the technology is relatively new, confirmation with laboratory samples may still be needed, but trends can then be followed with the oximeter, minimizing the need for blood sampling.[37]

Because cooximeters account for the presence of both carboxyhemoglobin and methemoglobin, blood gas samples sent for cooximetry should correctly measure hemoglobin saturation in cases where measurable levels of either methemoglobin or carboxyhemoglobin are present or suspected. Fetal hemoglobin has a sufficiently similar absorbance spectrum to adult hemoglobin, such that the presence of fetal hemoglobin does not significantly affect the determined saturation.[38] The presence of bilirubin also does not appear to significantly affect pulse oximetry readings.[39]

Probe Placement

Pulse oximetry probes typically are placed on fingers or toes, with the light-emitting diodes placed across the digit, opposite from the detector. For premature and small infants, the probe often is placed around the entire palm or foot with good results. Because of scattering of light in tissue, pulse oximeter probes also can be used in a reflectance mode. In this manner, both light-emitting diodes and detectors are on the same surface and can be placed, for example, on the forehead.[40,41] Transesophageal probes have been designed and are used for care of operative or critically ill patients with potentially poor peripheral perfusion.[42-44]

Cerebral Oximetry

The basic principles underlying pulse oximetry have been extended to determine hemoglobin saturation in the brain. Currently a small number of devices for determination of

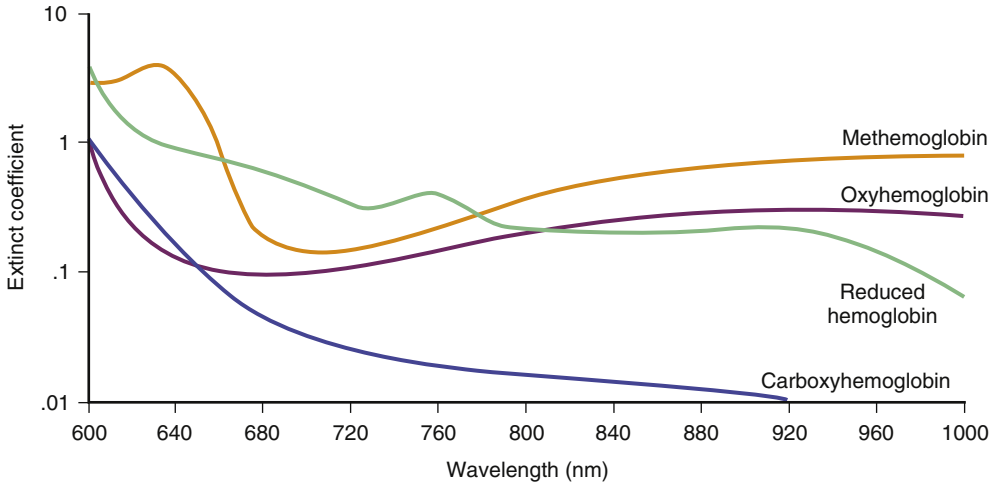

Figure 43–3. Absorption spectra for carboxyhemoglobin, deoxyhemoglobin, oxyhemoglobin, and methemoglobin used in the Masimo SET Rainbow pulse oximeter. *(Modified with permission from the Masimo Corporation.)*

cerebral oxygenation are commercially available. Somanetics and Casmed both have FDA-approved devices available for pediatric use. Hamamatsu also makes a device, the NIRO 300, but it currently has not been approved by the FDA.[45] These devices take advantage of the relative transparency of the skull and brain in the near-infrared spectral region. However, because these devices do not restrict analyses to a pulsatile component, the information provided comes from light absorption of hemoglobin in arterial, venous, and capillary blood and is contaminated to some extent by the presence of other light-absorbing molecules, primarily the cytochromes. Thus these devices provide a "relative" saturation value of cerebral oxygenation, which may have some correlation with clinical conditions,[46] but these devices currently do not report an absolute saturation value in the way that pulse oximeters do. Technical advances likely will improve the clinical utility of cerebral oximetry as the information provided becomes more reliable.

Somatic Regional Oximetry

Near infra-red spectroscopy (NIRS) also has been used to measure somatic regional oxygen saturation (rSO_2). In one resusucitation study of children with moderate dehydration, NIRS probes were placed on the forehead to reflect cerebral rSO_2 and on the flank to reflect somatic rSO_2. In children with moderate dehydration the cerebral rSO_2 was preserved but the somatic rSO_2 demonstrated regional hypoperfusion when the patients were dehydrated and showed an increase with rehydration.[47] Similarly, NIRS was used to provide cerebral and somatic oxyhemoglobin data for a group of neonates with hypoplastic left heart who were awaiting palliation, and it was found to simplify management, allowing more accurate assessment of systemic perfusion.[48]

Muscle Oximetry

Optical spectroscopy has been used to assess muscle oxygenation with increasing success. Earlier approaches for determining muscle oxygenation have been limited by the similarity between optical absorbance spectra from hemoglobin and myoglobin. Many reports of tissue oxygenation as a combined hemoglobin plus myoglobin saturation have been reported.[49] Because hemoglobin and myoglobin have vastly different oxygen dissociation relationships,[50] a combined saturation may have little clinical significance. Successful distinction of myoglobin saturation from hemoglobin saturation has been reported, using a complex multiwavelength spectra analytic approach.[51,52] Because myoglobin is an intracellular oxygen-binding molecule in cardiac and skeletal muscle, myoglobin saturation can be used to determine intracellular oxygen tension. This approach has led to the determination of intracellular oxygen tension measurements in both cardiac and skeletal muscle in laboratory studies.[53-55] Technical advances using this approach likely will have a significant impact on clinical monitoring of critically ill and injured patients.

Capnometry and Capnography

Another monitoring technology routinely used in the critical care unit is the measurement of carbon dioxide (CO_2). Capnometry is the measurement of the partial pressure (or concentration) of CO_2 in the patient's airway during the entire ventilatory cycle. A capnometer provides a numerical measurement of inspired and expired, end-tidal CO_2. Capnography is the graphic display of the partial pressure or concentration of CO_2 as a waveform (capnogram), usually plotted as P_{CO_2} versus time. When the waveform display is calibrated, capnography includes capnometry.

Physiologic Basis

When ventilation and perfusion are well matched throughout the lung, the arterial partial pressure of CO_2 ($Paco_2$) and the partial pressure of end-tidal CO_2 ($Petco_2$) are nearly equal, normally 40 mm Hg. If a discrepancy between ventilation and perfusion exists, a difference between the $Paco_2$ and $Petco_2$, also known as (a-et)ΔPco_2, occurs.

The capnogram displays the CO_2 concentration in the patient's airway over time (Figure 43-4). The essentials of a normal capnogram are (1) zero baseline during early exhalation, which reflects gas exhaled from the anatomic dead space;

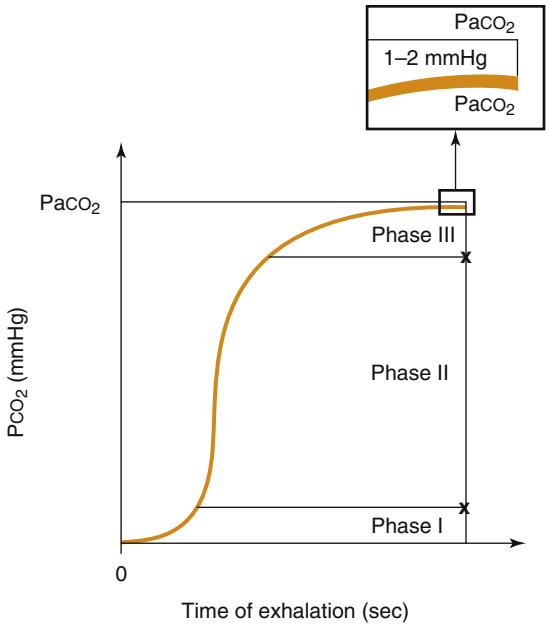

Figure 43–4. Normal capnogram.

(2) sharp upstroke during mid exhalation, which reflects the transition to alveolar gas; (3) relatively horizontal alveolar plateau (the final peak is also known as $Petco_2$ because it reflects the end of expiration; prolonged exhalation caused by obstructive lung disease causes a steeper plateau); and (4) sharp down stroke and return to a zero baseline at the start of inhalation. A capnogram without these normal attributes suggests an anomaly in the patient's cardiopulmonary system, a malfunction in the airway, or a malfunction in the gas delivery system.[56]

Operating Principles of Capnometry

To measure the partial pressure of CO_2 in the airway, respiratory gas must be sampled. In the most common sampling method, gas is diverted from the airway and aspirated through a tube (sidestream) to the CO_2 monitor. Diverting capnometers allow true zero-P_{CO_2} reference measurements, which tend to produce dependable, drift-free performance and thus accurate CO_2 measurements. An alternative to the diverting instrument is the nondiverting or "mainstream" capnometer in which a special flow-through adapter and CO_2 monitor are placed on the patient's airway.

In the majority of stand-alone capnometers, CO_2 concentration is measured by infrared spectroscopy. By comparing absorption by the sample gas with absorption by the reference gas, the capnometer determines the amount of CO_2 in the sample gas, which it then displays as the CO_2 concentration. Raman scattering and mass spectrometry are alternative methods of P_{CO_2} measurement.

Clinical and Technical Issues

Both physiologic anomalies and technical factors can result in $Petco_2$ values that do not approximate $Paco_2$. For $Petco_2$ to approximate $Paco_2$, two assumptions must be met: (1) the lung units must empty synchronously with uniform time constants, and (2) ventilation and perfusion must be well matched in the lung units. Additionally, technical variables can produce $Petco_2$ values that do not approximate $Paco_2$. These include the design of the gas sampling system, the distance the gas must be transported, and the instrument's calibration methods.

Gas Sampling Issues

The gas sampling method used by a capnometer affects the accuracy of the capnogram and $Petco_2$ measurements. Relevant factors include the location of the ventilatory circuit from which the gas is sampled, the distance over which the gas is transported before analysis, and the sample flow rate of the instrument. With a nondiverting or mainstream device, the CO_2 monitor is placed on the airway, so there is no need to divert gas from the airway. This sampling configuration typically is available only in infrared capnometers because only infrared CO_2 monitors can be designed small enough to fit on the airway. A study comparing mainstream proximal end-tidal CO_2 to a novel method that sampled distal end-tidal CO_2 via a special double lumen tube found that the distal end-tidal samples had the best correlation with $Paco_2$ and remained reliable even when severe lung disease was present.[57] Another sampling configuration is seen in the proximal-diverting device. A lightweight, low-profile airway adapter is placed on the patient's airway and gas is sampled from the airway and transported to the sensor, which is placed near the patient but not on the airway itself. A third sampling configuration is found in the distal-diverting device, the classic "sidestream" capnometer. In a distal-diverting system, gas is sampled from the airway and transported to the CO_2 monitor, which is located in the display unit distal to the patient.

The accuracy of the capnogram, the $Petco_2$ measurements, and the displayed values depends on the sampling site (Figure 43-5). In continuous gas flow circuits, sampling in or at the endotracheal tube results in the most accurate values because there is little contamination with fresh gas from the breathing circuit (point A). The Y-connector of the breathing circuit is the next best sampling site (point B). However, if the fresh gas flow is large compared with the expiratory flow rate of the patient (as may be the case in neonates and small children), the capnogram and the $Petco_2$ values may be distorted as a result of dilution with the fresh gas flowing through the Y-connector. If gas is sampled "downstream" from the patient, the waveform and $Petco_2$ are increasingly diluted by fresh gas from the circuit (points C and D). If gas is sampled "upstream" from the patient in the fresh gas supply, none of the exhaled CO_2 is detected and the measured $Petco_2$ is zero (point E). Therefore the best sampling site is within the patient's endotracheal tube or at the tube connector, as far as possible from the Y-connector of the breathing circuit.[58]

In breathing circuits with intermittent flow (demand-valve ventilators) and in larger children with large exhaled tidal volumes, the capnogram and $Petco_2$ values usually are unaffected by minor changes in sampling location. If the tidal volume is small (e.g., as in infants and children) and the sample flow rate is large (i.e., >150 mL/min), the capnogram and $Petco_2$ measurements may be significantly diluted by the entrainment of fresh gas. Using a capnometer system with a low sample flow rate, typically less than 75 mL/min, restores the waveform and $Petco_2$ readings to more accurate values.

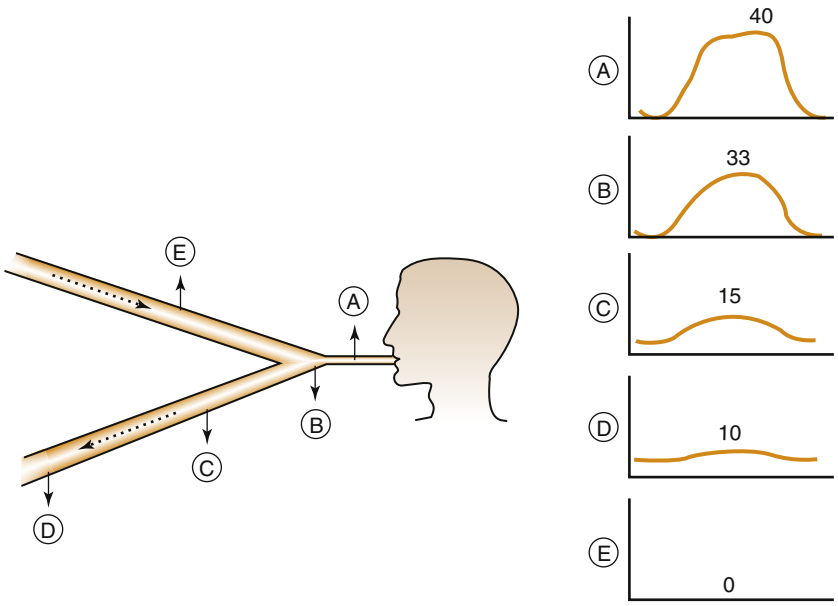

Figure 43–5. Accuracy of end-tidal CO_2 measurements is highly dependent on obtaining good samples of expiratory gas from the patient. If sampled gas is contaminated with fresh gas from the breathing circuit, the measured values will not be accurate. The best samples are obtained from a site nearest to the source of CO_2, the patient (*point A*).

Dead-Space Ventilation

Dead space is the volume of gas in the airways and lung that participates in tidal breathing but does not participate in gas exchange. Obvious examples are the volume of the endotracheal tube and ventilator circuit (apparatus dead space) and the volume of the tracheal lumen and central airways (anatomic dead space). A less obvious, but still important, source of error in critically ill patients is alveolar or physiologic dead space. This dead space is attributable to lung units in which ventilation greatly exceeds perfusion. Gas exchange in these overventilated, relatively underperfused lung units is less efficient than normal.

The fraction of the tidal volume that is delivered to all dead spaces taken together can be calculated using the Bohr equation. A sample of mixed expired air collected over numerous breaths is analyzed for mixed P_{CO_2} (PE_{CO_2}). The total fraction of dead space per tidal volume is given by:

$$V_D/V_T = (Pa_{CO_2} - PE_{CO_2}) / Pa_{CO_2} \quad (4)$$

Physiologic dead space (VD/VT) can be determined from a variant of the Bohr equation:

$$V_D/V_T = (Pa_{CO_2} - Pet_{CO_2}) / Pa_{CO_2} \quad (5)$$

or

$$V_D/V_T = 1 - (Pet_{CO_2} / Pa_{CO_2}) \quad (6)$$

where Pet_{CO_2} is used in place of a sample of mixed expired air.

In many clinical situations, dead-space ventilation is an appreciable fraction of tidal breathing, including severe respiratory dysfunction,[59] pulmonary hypoperfusion, pulmonary thromboembolism, and cardiac arrest (Box 43-1). In these conditions, the clinician using a capnometer may see a large arterial to end-tidal P_{CO_2} gradient (typically >10 mm Hg). This gradient can be used as an indicator of severity of disease, and Pet_{CO_2} can be used to evaluate trends rather than as a specific measure of alveolar P_{CO_2}.

Box 43–1 Clinical Conditions Associated with Abnormalities in ET_{CO_2}

Increases in ET_{CO_2}

Sudden
Sudden increase in cardiac output
Release of a tourniquet
Injection of sodium bicarbonate

Gradual
Hypoventilation
Increased metabolism (carbon dioxide production)

Decreases in ET_{CO_2}

Sudden
Sudden hyperventilation
Sudden decrease in cardiac output
Massive pulmonary embolism
Air embolism
Ventilator disconnection
Ventilator circuit leakage
Obstruction of the endotracheal tube

Gradual
Hyperventilation
Decrease in metabolism (carbon dioxide production)
Decreased pulmonary perfusion

Absent ET_{CO_2}

Esophageal intubation
Accidental extubation

Differential Diagnosis of Abnormal Capnograms

The capnogram probably is the single most reliable and effective monitor of pulmonary ventilation. The integrity and function of the patient's cardiopulmonary system and the

breathing circuit both affect the capnogram, and malfunctions often can be detected by changes in the capnogram.[57,60]

Gradually Decreasing End-Tidal CO_2 Concentration

When the capnogram retains its normal morphology but there is a slow, progressive drop in $ETco_2$ (Figure 43-6), the possible causes include falling body temperature, slowly decreasing systemic or pulmonary perfusion, and hyperventilation. Sedation and neuromuscular blockade attenuate the normal body mechanisms for generating heat to preserve body temperature. As body temperature falls, the patient's rate of metabolism and CO_2 production also fall. If ventilation is controlled and kept constant as body temperature decreases, alveolar CO_2 concentration and arterial Pco_2 decrease. This decrease is reflected in the capnogram as a slow decrease in $Petco_2$ over many minutes. Another cause of decreasing $Petco_2$ is a fall in total body perfusion associated with blood loss or cardiovascular depression. As systemic and pulmonary perfusion decrease, alveolar dead space increases with a resultant fall in $Petco_2$.

Sustained Low End-Tidal CO_2 Concentrations Without Plateaus

Occasionally, with no apparent malfunction in the breathing circuit or in the patient's cardiopulmonary status, the capnogram shows sustained low $Petco_2$ values without a good alveolar plateau. In this situation, $Petco_2$ is not a good estimate of alveolar Pco_2. The absence of a good alveolar plateau suggests that either full exhalation is not occurring before the beginning of the next breath or the patient's tidal volume is being diluted with fresh gas because of a small tidal volume, high aspirating sample rate, or high fresh gas dilution from the circuit. Several maneuvers are available to distinguish between these possibilities.

Incomplete emptying of the lungs may be suggested by adventitial sounds such as wheezing or large airway rhonchi with compromise of small airway patency caused by bronchospasm or secretions. If rhonchi are present, tracheal suctioning often corrects the partial obstruction and restores full exhalation. Bronchospasm may be treated with a variety of bronchodilators. An endotracheal tube that is kinked or partially obstructed by secretions may prevent full exhalation. Passing a suction catheter down the endotracheal tube usually confirms or eliminates this possibility. Gently squeezing the child's chest to assist with a forced exhalation often produces a waveform in which the CO_2 concentration continues to rise toward an alveolar plateau. If the plateau is present, the "squeeze end-tidal CO_2" value may be taken as a good estimate of alveolar CO_2 concentration.

When no signs of partial airway obstruction are present, another explanation for this type of capnographic waveform should be considered. In infants and other patients who have small tidal volumes, the aspirating sample rate may exceed the expiratory flow rate near the end of exhalation. When this occurs, the aspirating sample is diluted with fresh gas from the breathing circuit, resulting in a drop-off of the plateau and a fall in $Petco_2$ as a result of dilution. Reducing the flow rate of fresh gas or moving the sampling site closer to the endotracheal tube connector usually corrects the problem. In very small newborns, a sample rate of 100 to 250 mL per minute may be too high to result in good plateaus despite instituting the preceding corrective measures. Then either a capnographic system having a very low sampling rate (50 mL/min) can be used or the capnogram can be used as a gross monitor of the integrity of the ventilatory circuit and trends in cardiopulmonary function rather than as an accurate estimate of alveolar ventilation.

Sustained Low End-Tidal CO_2 Concentration with Good Plateaus

In some circumstances, the capnogram demonstrates a low $Petco_2$ with a widened (a-et)ΔPco_2 and preservation of a good alveolar plateau. This discrepancy may indicate that the capnograph is malfunctioning or miscalibrated. The clinician can evaluate this possibility by sampling his or her own exhaled CO_2 and verifying that the $Petco_2$ concentration is between 5% and 6% (equivalent to approximately 38 to 46 mm Hg). If the instrument is functioning properly and is well calibrated, a wide (a-et)ΔPco_2 is an indication of excessive dead-space ventilation in the patient.

Exponential Decrease in End-Tidal CO_2

An exponential drop in $Petco_2$ that occurs within a short time (e.g., a dozen or so breaths) almost always signals a sudden and probably catastrophic event in the patient's cardiopulmonary

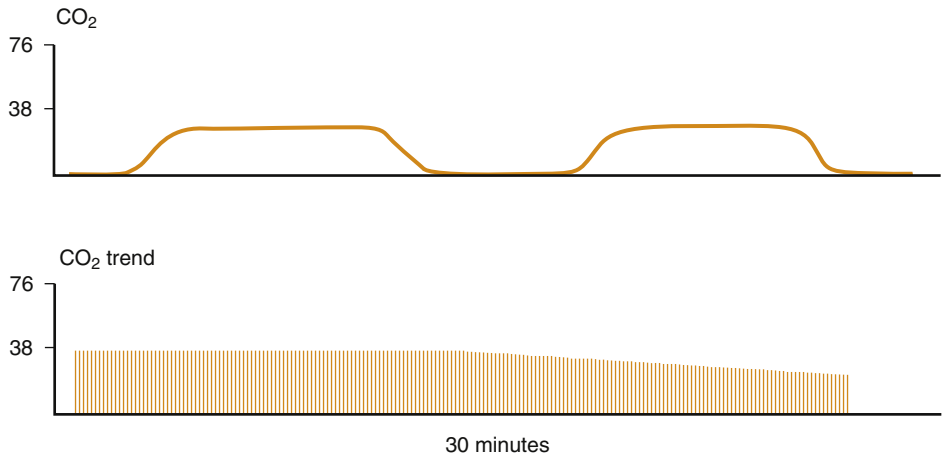

Figure 43–6. Slow, progressive fall in end-tidal CO_2 occurs when CO_2 elimination exceeds CO_2 production or wasted ventilation increases slowly.

system (Figure 43-7). The basis for this capnogram is a sudden and dramatic increase in alveolar dead-space ventilation. Possible causes include sudden hypovolemia, circulatory arrest with continued pulmonary ventilation, and pulmonary embolus with thrombus or air. Only after ruling out these catastrophic events and determining that the patient is hemodynamically stable should more mundane explanations for the exponential decay in $Petco_2$ be considered. The most common noncatastrophic cause is an accidental increase in ventilation attributable to an incorrect ventilator adjustment, resulting in a gradual decrease in $Petco_2$. However, it is important to note that even doubling the alveolar ventilation decreases the $Petco_2$ to only half of the preadjustment value, not to the near-zero values that may accompany catastrophic cardiopulmonary events.

Gradual Increase in both Baseline and End-Tidal CO_2

A gradual rise in both baseline and $ETco_2$ value indicates that previously exhaled CO_2 is being rebreathed from the circuit (Figure 43-8). In this situation, the inspiratory portion of the capnogram fails to reach the zero baseline, and there may actually be a premature rise in CO_2 concentration during the inspiratory phase of ventilation. $Petco_2$ usually increases until a new equilibrium alveolar CO_2 concentration is reached, when excretion once again equals production.

Transcutaneous Monitoring

The development of portable, miniaturized electrodes led to the use of this technology to continuously measure both oxygen and carbon dioxide tension transcutaneously. This technology works under the assumption that transcutaneous values reflect those from the arterial circulation. Heating the skin allows more rapid diffusion of both oxygen and carbon dioxide from the subcutaneous tissues to the surface of the electrode. However, the heating affects both tissue and blood by decreasing oxygen solubility, shifting the oxyhemoglobin dissociation curve to the right, and dilating local arterioles. Temperatures of 44° C to 45° C

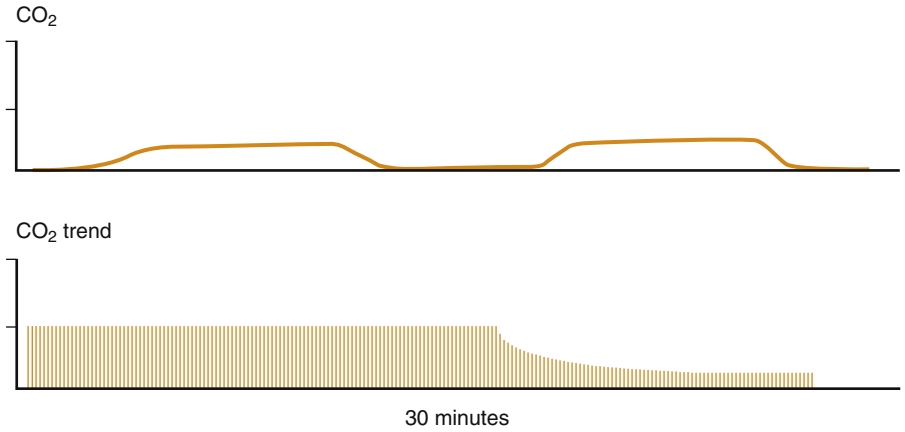

Figure 43–7. Sudden, exponential decay in end-tidal CO_2 values almost always signals a potential catastrophe in the cardiopulmonary function of the child. The causative factor is a dramatic increase in wasted ventilation or dead space. Possible causative events include sudden hypotension such as that resulting from massive blood loss, circulatory arrest with continued pulmonary ventilation, and pulmonary embolism with thrombus or air.

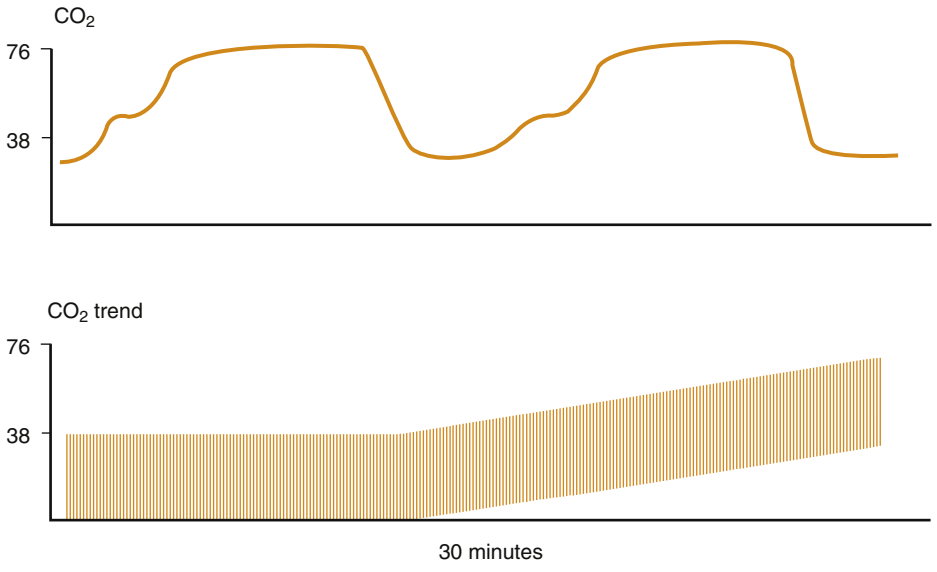

Figure 43–8. Persistent elevation of the inspired CO_2 baseline and a rising end-tidal CO_2 value suggest that the child is rebreathing previously exhaled CO_2. In the intensive care unit, this pattern is often seen when the fresh gas supply to a breathing circuit becomes disconnected from the source.

increase diffusion and prevent vasoconstriction in the local area of the skin.[61]

Oxygen Monitoring

Transcutaneous Clarke electrodes measure oxygen tension in a local segment of the heated skin. Because skin is the organ most responsive to adrenomedullary-induced vasoconstriction, local oxygen tension may not be the same in all skin segments or other tissues. In essence, transcutaneous oxygen tension ($TcPO_{2)}$ is only an indirect reflection of arterial oxygen tension; it is more directly related to local tissue perfusion and oxygenation.

This technology has several limitations. Electrode placement must be changed every 4 to 6 hours to prevent thermal injury to the site of measurement or when readings become unstable. A thermal neutral environment to limit peripheral vasoconstriction increases the correlation between transcutaneous and arterial tensions. Finally, the electrode membranes must be calibrated before each use and each change of measurement site. However, displaying the $TcPO_2$ was shown to result in less time spent hyperoxemic and less time spent hypoxemic than displaying the SpO_2.[62]

Carbon Dioxide Monitoring

Transcutaneous carbon dioxide tension using a Stowe-Severinghaus electrode has been widely used in the neonatal population to approximate $Paco_2$. Transcutaneous CO_2 values parallel but consistently overestimate $Paco_2$ values in hemodynamically stable neonates and adults.[63] The difference in arterial and transcutaneous values reflects accumulation of carbon dioxide in the tissues as a result of inadequate perfusion. Transcutaneous monitoring of CO_2 more closely approximates arterial CO_2 tension in infants and children who are experiencing respiratory failure than does end-tidal CO_2.[64] This technology also is useful in settings where nonconventional forms of ventilation (high-frequency ventilation) preclude the use of end-tidal monitoring.

Cerebral Function Monitoring

Clinical assessment of the level of consciousness is a sensitive indicator of cerebral function. Unfortunately, the assessment can be subjective, particularly in the pediatric population. Standardization of clinical methods, such as the Glasgow Coma Scale, with modifications for infants and children,[65] can decrease but not eliminate the subjective nature of the assessment of consciousness. During the past decade, efforts to use electroencephalographic signals as a more objective measure of cerebral function have been pursued.

Bispectral Index Monitoring

The bispectral index (BIS) monitor uses a processed electroencephalogram (EEG) that integrates various electroencephalographic descriptors, as an assessment of the brain response to hypnotic agents, into a single unitless number on a scale from 0 to 100. The technology processes and evaluates via fast Fourier transform analysis the common characteristic changes and waveform relationships that are seen on the EEG in response to the administration of sedative, hypnotic, and anesthetic agents.

Historical Perspective and Development of the Electroencephalogram

Attempts to monitor the brain have a long history. Dr. Richard Caton, an English physician, described the first recognition of the EEG while mapping brain waves in animals.[66] The physiologic basis for the origin of the EEG potentials comes from the extracellular current flows associated with postsynaptic activity in the upper layers of the cerebral cortex.[67] A psychiatrist, Dr. Hans Berger, went on to describe the human EEG in a series of reports in 1929.[68] In 1937, Gibbs et al.[69] reported that the EEG responded to administration of potent inhaled anesthetic agents.

The electrical signal from the brain is measured in microvolts and is easily acquired using technologically advanced sensors.[70] Advances in computer processing of electrical signals has led to the development of electroencephalographic technology that allows rapid processing of real-time complex waveforms in a small, inexpensive, compact, easy-to-use electroencephalographic monitor. The computer analyzes the complex waveforms using a technique called bispectral analysis, a mathematical procedure originally used for describing wave motion in the ocean. Barnett et al.[71] described the first clinical applications of bispectral analysis of the EEG waveform during natural sleep and waking. Kearse et al.[72] were the first to report that bispectral analysis may predict anesthetic depth.

Age-Related Maturation of the Electroencephalogram

Development of the normal EEG in infants and young children parallels brain maturation, with the most abrupt changes occurring between the last few weeks of gestation and the first 3 months of life. Synapse formation continues after birth up to age 5 years, with the majority occurring (with gradual loss of neonatal patterns) in the first 3 months of life.[73] Wide variations and developmental differences exist in the EEG of infants and children because of progressive development of the immature brain. Developmental maturation of the pediatric EEG, including changes in power and frequency, progresses to an adult pattern in late adolescence. Data on EEG changes produced by anesthetic drugs in the pediatric population are not available.[73,74] Bispectral index monitoring has yet to be validated for all pediatric patient age groups, particularly because age-related maturation differences in the EEG may affect the BIS algorithm.[75] Some evidence supports the validity of the algorithm in infants, but further studies in children younger than 1 year are needed.

Validation Studies

The BIS is a continuous form of complex processed EEG derived parameterthat has been validated in adults as a quantifiable, objective measure of the sedative, hypnotic drug effect on the CNS.[70,76] It has been shown to correlate with loss of consciousness, recall, and return to consciousness during general anesthesia. Glass et al.[77] established the strong correlation between the BIS value and level of sedation, as quantified

by the Observer's Assessment of Alertness/Sedation Scale. This same study also demonstrated the correlation between BIS values and measured plasma concentrations of propofol, alfentanil, midazolam, and isoflurane. The investigators also tested for responsiveness and memory recall at targeted plasma concentrations. Another study demonstrated a relationship between the pre-incision BIS value and the likelihood of purposeful movement with skin incision.[78]

Several studies have attempted to determine the clinical validity in infants and children; however, methods used to validate BIS performance in adults are difficult to replicate in children. The BIS range guidelines were developed based largely on responsiveness and recall data that were obtained from studies of adult volunteers who were maintained at various steady-state plasma concentrations of anesthetic, hypnotic agents. These studies cannot easily be conducted in children. The first report comparing the dose responses of sevoflurane to BIS values in infants and children scheduled for elective surgery showed that both pediatric and adult populations had awake BIS values between 90 and 100 that decreased precipitously after induction of anesthesia.[79] A second study found that the correlation between BIS and end-tidal sevoflurane concentration in children is very similar to that observed in adults.[80] No differences in BIS values between infants (0 to 2 years) and children (2 to 12 years) at similar clinical levels of anesthesia were seen. An end-tidal concentration-response difference between the two age groups is consistent with existing data regarding minimum alveolar concentration required to prevent movement with stimulus. The same age-related difference has been demonstrated for halothane minimum alveolar concentration.[81]

Utility Studies

The utility of the BIS as a clinical parameter to measure the depth of sedation or hypnosis has been well established through a multitude of adult clinical studies using inhalation anesthesia.[78,82] The titration of propofol to a specific BIS range during surgery resulted in a wide range of patient benefits compared with a standard practice (non–BIS-titrated) group. These benefits included a reduction in the amount of anesthetic agent used, faster emergence and shorter time to postanesthesia care unit discharge eligibility, and higher levels of patient orientation on arrival in the postanesthesia care unit as assessed by blinded observers. Similar results were achieved in a variety of studies conducted using all of the commonly administered anesthetic, hypnotic agents.[83-85]

A growing number of observational and clinical utility studies in the pediatric population have demonstrated promising results with use of the current BIS algorithm in both infants and children. Experience to date suggests that BIS monitoring in children and infants could provide similar benefits to those achieved in the adult population, with respect to improved sedative, hypnotic drug administration and recovery profiles.[86-88] However, not all persons agree. A subsequent study showed a weaker correlation between BIS and sevoflurane concentration in infants.[89] BIS values have been recorded at various clinical endpoints during cardiac surgery with cardiopulmonary bypass in children with results similar to those observed in adults.[90] A later study revealed large interpatient variability of BIS at different levels of anesthetic depth, which may limit the applicability of BIS to pediatric anesthesia.[91]

Summary of Bispectral Index–Related Studies in Critical Care

After the clinical introduction of BIS into operating rooms, this technology naturally found its way into the ICU. Numerous studies in both adults and children have been published. Initial reports in both populations suggested good correlation between objective sedation scores and BIS.[92,93] One such study in children showed that the BIS and COMFORT scale measurements were highly correlated ($R^2 = 0.89$).[94] Others demonstrated a strong correlation between the Ramsay Sedation Score and BIS in nonparalyzed children for sedation monitoring.[95] They also noted that, in the presence of chemical paralysis, the Ramsay Sedation Score and bedside nursing assessment were not able to accurately recognize adequate or inadequate sedation states. Other researchers found that the correlation between sedation scores and BIS was suboptimal and inconsistent in the heterogeneous ICU population.[96,97] Reliance on the BIS as the sole monitor of sedation may result in excessive sedation, primarily because of high levels of muscular activity.[98]

Although BIS monitoring is a well-established clinical parameter in the adult surgical population, its use and application in the critical care and pediatric arenas is still under investigation. Several preliminary clinical studies of BIS monitoring in both the operating room and the ICU have demonstrated possible clinical utility and efficacy for improved sedation titration, decreased drug usage, strong sedation score correlation, and greater accuracy and reliability in sedation assessment for paralyzed children.

Conclusion

Noninvasive monitors, such as pulse oximetry and capnometry, are standards of care in the pediatric critical care environment. It is therefore important to understand key clinical and technical issues that determine how these instruments can be used most effectively. These noninvasive technologies provide early warning of potential catastrophic events and facilitate early intervention, with potential for better outcomes. Concerns for complications related to invasive monitors will continue to drive the search for newer and better devices for noninvasive physiologic monitoring. Promising recent advances have been made in the technology of pulse oximeters, allowing measurements of all types of hemoglobin, including dyshemoglobins and total hemoglobin, with less artefact resulting from patient movement, which is a vital consideration in the PICU patient population. However, with all of the technological advances, we must remember the importance of basic vital sign monitoring and clinical observation, such as heart rate, respiratory rate, temperature, and fluid balance.

Specific Diseases of the Respiratory System: Upper Airway

David Jardine, Omar J. Bhutta, and Andrew Inglis

PEARLS

- Diseases leading to compromise of the airway are the most frequent cause of cardiac arrest in pediatric patients. A small reduction in the caliber of the child's airway may lead to a life-threatening reduction of airflow.
- Laryngomalacia is the most common congenital anomaly of the larynx. Infants tend to outgrow this problem during the first year of life; however, the condition may be of sufficient severity in some infants that activities such as feeding are compromised.
- The trachea may be compressed by the presence of an abnormal vascular structure. Children affected by this problem may have such diverse symptoms as stridor, wheezing, lobar atelectasis, or recurrent pulmonary infections.
- The practice of treating laryngotracheobronchitis with corticosteroids is standard of care, especially for hospitalized patients. A meta-analysis in which the efficacy of corticosteroids was evaluated suggests that corticosteroids may reduce the need for endotracheal intubation and hasten improvement when given in the first 24 hours of illness.
- Epiglottitis, a bacterial infection of the supraglottic tissues historically caused by *Haemophilus influenzae* type B, is now most frequently caused by group A β-hemolytic streptococcus.
- Patients with bacterial tracheitis usually do not respond to inhaled racemic epinephrine, have a high fever, and appear very ill.

Diseases leading to compromise of the airway are the most frequent cause of cardiac arrest in pediatric patients. Prompt recognition of these illnesses can lead to timely intervention and improve the outcome of these patients. The small size of the infant's trachea makes airway obstruction more likely and particularly dangerous. The normal anteroposterior diameter of the infant's glottis is 4.5 mm. One millimeter of circumferential tracheal edema reduces the glottic lumen to 30% of its normal size. Poiseuille's law stipulates that laminar flow of gas through a tube is inversely proportional to the fourth power of the radius of the lumen:

$$R = \frac{8ln}{\pi r^4}$$

where R is the resistance to gas flow, l is the length of the tube, n is the viscosity of the gas, and r is the radius. Unfortunately, airflow through a narrowed trachea is usually turbulent, which worsens the situation because resistance to turbulent flow of gas past an obstruction is inversely proportional to the fifth power of the radius of the lumen.[1,2] Gas exchange will be dramatically reduced by minor degrees of impingement on an infant's trachea. Consequently, a child will not tolerate lesions that would not even produce symptoms in an adult.

Initial Management

Once the diagnosis of upper airway obstruction is made, efforts should be undertaken to minimize disturbing the patient unless the respiratory embarrassment is severe enough to be life-threatening. Airway obstruction often worsens when infants and children are alarmed during a diagnostic evaluation. Humidified oxygen should be administered through a nasal cannula or facemask. These devices may frighten younger children who may more readily accept oxygen delivered through flexible tubing held by the parent. If the child will tolerate placement of a pulse oximeter probe, this provides a noninvasive way of evaluating oxygenation. If oxygen saturation by pulse oximeter measurement is within an acceptable range (>95%), arterial blood gas determination may be unnecessary. An arterial blood gas is useful to identify the patient who may be hypercapnic, but to obtain these data may further upset the child.

After upper airway obstruction has been diagnosed, a combination of physical and radiographic findings may help localize the lesion. With identification of the anatomic site of the lesion, the diagnostic possibilities are greatly narrowed. During the diagnostic evaluation, the child may sit in the parent's lap if this reduces anxiety. This position usually does not interfere with diagnostic evaluation, like lateral neck and chest radiography. The dose of radiation to a nonpregnant parent is small and should be of little concern.

If it is thought to be safe, examination of the patient's head and neck may reveal the cause of the illness. Depending on the patient's condition, the degree of respiratory embarrassment may be quantified with a rating scale (Table 44-1). One of the primary benefits of using such a scale is that signs of respiratory obstruction are systematically sought and objectively documented. This information may be valuable in helping

Table 44–1 Subjective Assessment of Clinical Severity of Laryngotracheobronchitis

	0	1	2	3
Stridor	None	Mild	Moderate at rest	Severe on inspiration and expiration or none with markedly decreased air entry
Retractions	None	Mild	Moderate	Severe, marked use of accessory muscles
Air entry	Normal	Mild decrease	Moderate decrease	Marked decrease
Color	Normal	Normal (0 score)	Normal (0 score)	Dusky or cyanotic
Level of consciousness	Normal	Restless when disturbed	Anxious, agitated; restless when undisturbed	Lethargic, depressed

From Davis HW, Gartner JC, Galvis AG, et al: Acute upper airway obstruction: croup and epiglottitis, Pediatr Clin North Am 28:859, 1981.

to define the course of the patient's illness and the response to treatment. During the initial evaluation, an assessment may be made regarding the likely location of the obstruction. Extrathoracic airway obstruction usually results in stridor (the obstruction is most severe during inspiratory phase), while intrathoracic airway obstruction usually results in wheezing (the obstruction is most severe during expiratory phase). Localizing the obstruction in this manner helps to narrow the diagnostic possibilities.

The initial evaluation should allow one to make important triage decisions about management and further evaluation of the patient with upper airway compromise. Depending on the severity of the illness, a decision must be made about which diagnostic tests will be undertaken. In the case of severe respiratory compromise, it may be necessary to plan for invasive procedures (endotracheal intubation or operative intervention) while the diagnostic evaluation is being performed. Finally, it should not be forgotten that pulmonary edema might follow relief of severe upper airway obstruction.[3] Postobstructive pulmonary edema may be severe enough to require vigorous therapy, including endotracheal intubation, mechanical ventilation, and positive end-expiratory pressure.

Congenital Malformations

A variety of congenital malformations can affect the pediatric airway. Many of these become evident in the delivery room. Some congenital malformations do not present until the child is older and somatic growth has made the airway impairment more evident.

Choanal Atresia

Choanal atresia is estimated to occur about once in every 5000 to 9000 live births.[4] Choanal atresia is seen commonly with other defects, especially CHARGE syndrome, which accounts for 25% of all patients with choanal stenosis.[5] Unilateral choanal atresia, the most common form, is often seen without accompanying congenital defects and may not be diagnosed at the time of delivery. Bilateral choanal atresia almost always occurs in the presence of other congenital defects.[5] For the first 5 months of life, many infants breathe only through their noses and do not open their mouths when the nasal passages are occluded; consequently, bilateral choanal atresia often results in respiratory distress shortly after birth. Bilateral choanal atresia (Figure 44-1) is diagnosed through examination of the naris with the mouth closed. If no airflow is present, a presumptive diagnosis of choanal atresia is established. Some authorities advocate passing a thin, flexible catheter through the naris. This will confirm the diagnosis of choanal atresia; however, if the symptoms are resulting from choanal stenosis, edema formation following even minor trauma of the nasal mucosa after catheter placement may lead to complete occlusion of the nasal airway and worsening of respiratory distress. Surgery is indicated for the correction of bilateral choanal atresia if the infant has symptoms[6] (Figure 44-2). Infants with bilateral choanal atresia generally have surgery within the first 3 months of life, while infants with unilateral choanal atresia typically have surgery after the second year of life.[7] Topical application of mitomycin to inhibit fibroblast proliferation has been shown to be an effective adjunct to surgical repair of choanal atresia.[8] Although choanal atresia is the most common cause of nasal airway obstruction, midline nasal masses such as meningoencephaloceles, gliomas, or dermoid tumors can also cause obstruction. Because these lesions may originate from within the cranial vault, computed tomography (CT) scanning or magnetic resonance imaging (MRI) should be performed before a biopsy or surgical correction of the abnormality is attempted.[9]

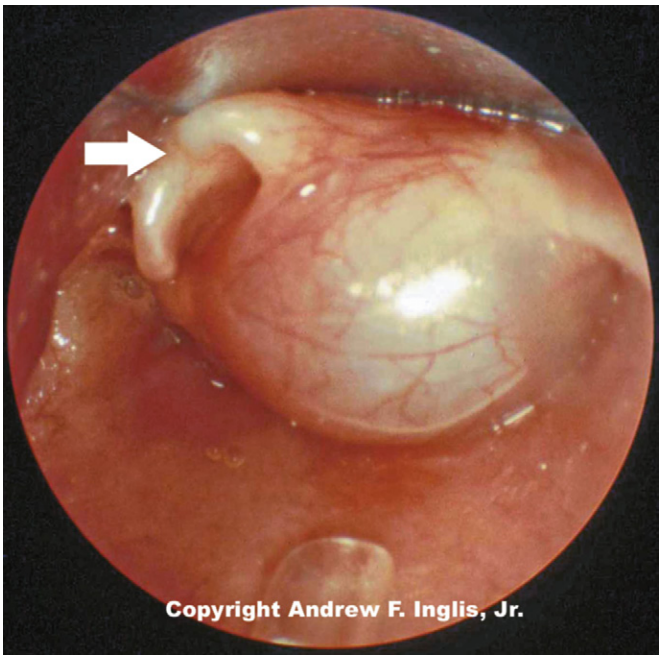

Figure 44–4. A large laryngeal cyst protrudes from the lateral wall of the trachea, just below the level of the glottis. *(Copyright Andrew F. Inglis Jr.)*

Laryngomalacia

Laryngomalacia is the most common congenital anomaly of the larynx. The infant has inspiratory stridor that is exacerbated by crying or distress. Although no gross anatomic abnormalities are present, the laryngeal cartilages lack their usual rigidity. When the larynx is observed during fiberoptic examination of the glottis, the arytenoid cartilages and supraglottic structures collapse inward (toward the glottis) during inspiration, leading to inspiratory stridor. The negative intrathoracic pressure generated during inspiration contributes to a high incidence of gastroesophageal reflux[10] and pulmonary aspiration.[11,12]

These abnormalities can be graphically observed with fiberoptic laryngoscopy, which shows the dynamic component, with obstruction during inspiration and full airflow during expiration. In some patients with laryngomalacia, gastroesophageal reflux may be the primary cause of the airway compromise, whereas in others it may be a significant cofactor exacerbating preexisting neurologic or anatomic abnormality.[13] The respiratory embarrassment associated with this problem is usually minor and self-limited, although hypoxia and hypercapnia have been documented.[14] Infants tend to outgrow this problem during the first year of life; however, the condition may be severe enough in some infants that activities such as feeding are compromised. In the most severe cases, surgical intervention may be necessary.[15] The goal is to relieve airway obstruction by excision of tissue that collapses into the glottis during inspiration.

Laryngeal Webs, Stenosis, and Tumors

Laryngeal webs usually occur at the level of the glottis and are usually located anteriorly. These may be congenital or acquired and are generally thin membranes of soft tissue that partially occlude the tracheal opening, producing symptoms of feeble cry and dyspnea shortly after birth (Figure 44-3).[16] Surgical lysis of these lesions corrects the problem. Laryngeal cysts and laryngoceles are soft tissue masses that protrude into the glottic lumen (Figure 44-4). The resulting respiratory compromise is usually recognized as inspiratory stridor. Treatment is surgical excision of the lesion.[17]

Another lesion presenting as inspiratory stridor is congenital laryngotracheal (subglottic) stenosis. This is the second most frequent cause of stridor in infants.[18] The infant with this

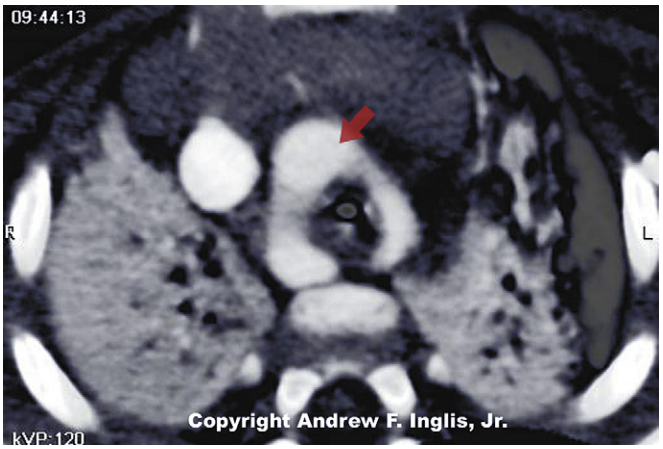

Figure 44–6. Contrast CT scan showing vascular ring encircling and compressing the trachea (arrow indicates vascular ring encircling trachea). *(Copyright Andrew F. Inglis Jr.)*

problem may have symptoms when newborn but often comes to medical attention later when the tracheal edema produced by a minor respiratory infection causes severe inspiratory stridor. This may be initially diagnosed as croup (laryngotracheobronchitis) but is noted to recur with each subsequent upper respiratory infection. Although the diagnosis of laryngotracheal stenosis may be made radiographically, it is usually established with bronchoscopy. If endotracheal intubation is necessary, a smaller than normal endotracheal tube should be used to reduce trauma and ischemia of the subglottic tissues. Depending on the severity of the lesion, surgical intervention may be necessary (see the discussion about acquired laryngotracheal [subglottic] stenosis for details of the surgical procedures).

Soft tissue masses may reduce the caliber of the tracheal lumen, either by extrinsic compression, as happens with a cystic hygroma, or by growth into the tracheal lumen from the tracheal wall, as happens with a hemangioma. Although these lesions may be present at birth, they often do not produce symptoms for the first few months until the growing

lesion further impinges on the trachea. Although surgery is frequently used for treatment of tracheal hemangiomas,[19] pioneering work by Judah Folkman was instrumental in demonstrating that some of these lesions respond to steroid therapy.[20]

Vascular Impingement on the Trachea

The trachea may be compressed by the presence of an abnormal vascular structure (Figure 44-5). The innominate artery is the most common vessel causing tracheal compression. Vascular rings and enlarged pulmonary arteries are also known to cause tracheal compression, as are a variety of other vascular abnormalities.[21] These lesions may present with physical findings such as stridor or wheezing. Alternatively, the patient may be symptom-free, but may suffer respiratory problems such as recurrent lobar atelectasis or frequent pulmonary infections. Because of this, it is difficult to recognize a vascular ring as the underlying cause of illness.[22] Careful inspection of the chest radiograph may reveal indentation of the trachea, but often this sign is absent. Barium swallow has been the historic method of diagnosing vascular impingement of the trachea. CT scanning and MRI have become the diagnostic modalities of choice (Figures 44-6 and 44-7).[23,24] These noninvasive methods are effective at showing complex three-dimensional cardiovascular anatomy, especially the extracardiac morphology. Treatment involves surgical correction of the vascular anomaly, in severe cases. Respiratory distress may persist postoperatively because prolonged compression of the trachea has made the affected segment softer and collapsible. In severe cases, the tracheomalacia may severely compromise the patient and may be improved by surgical intervention to prevent tracheal collapse.[25]

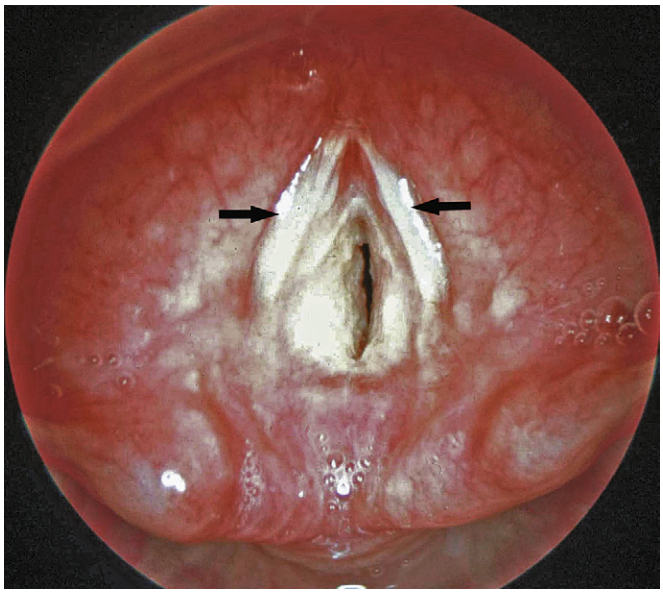

Figure 44–8. Laryngotracheobronchitis: below the level of the vocal cords the trachea appears swollen and the tracheal walls are covered with purulent material (vocal cords are indicated by *arrows*).

Bronchomalacia and Intrathoracic Tracheomalacia

During normal respiration, the upper airway is subject to cycles of positive and negative intraluminal pressure. The cartilaginous components of the upper airway are rigid ringlike structural elements that resist the tendency to collapse caused by the cycling of pressure within the airway lumen. When these structures lack their characteristic rigidity, the mechanics of breathing are altered.[26] The symptoms produced by these changes depend on the location of the damaged cartilages. Characteristically, intrathoracic cartilaginous lesions such as bronchomalacia or tracheomalacia impede exhalation. Diagnosis of this problem may be made through observation of collapse of the upper airways during active exhalation, such as occurs while crying. Collapse can be observed with several diagnostic modalities including fluoroscopy, flexible or rigid bronchoscopy, and ultrafast CT scanning.[27]

Although these lesions may be congenital, many of the cases of tracheomalacia and bronchomalacia seen in the pediatric intensive care unit (PICU) are the result of an infectious or mechanical insult to the trachea. Infants with bronchopulmonary dysplasia and persistent respiratory problems may be affected by bronchomalacia alone or in combination with tracheomalacia.[28] The obstructive symptoms produced by these lesions may be relieved by continuous positive airway pressure to maintain patency of the airway during exhalation.[29] The level of continuous positive airway pressure necessary to improve respiratory function may be assessed clinically (relief of obstructive symptoms), mechanically (measurement of flow-volume loops), or bronchoscopically (maintenance of airway patency throughout the respiratory cycle).[30] With sufficient time, many of these infants outgrow their respiratory difficulties. As an alternative to tracheostomy and positive airway pressure, some have advocated surgical intervention with pericardial flap aortopexy[31] or, in extreme situations, metallic airway stents.[32]

Infectious Processes

A variety of infectious processes may affect the pediatric airway. Poiseuille's law dictates that airway compromise from the swelling that accompanies an infectious process is greater in infants and young children than it is in adults. A small reduction in the caliber of the smaller child's airway may lead to a life-threatening reduction of airflow.

Laryngotracheobronchitis

Laryngotracheobronchitis (croup) is a common childhood infection. It is caused by a variety of infectious agents; parainfluenza virus, coronavirus, and rhinovirus are the most common.[33] This is a seasonal illness, occurring predominately during winter months, and most commonly affecting children from age 6 months to 3 years. There is frequently a history of prodromal infection accompanied by an unusual cough (described as sounding like the bark of a seal). Swelling of the tracheal mucosa in the subglottic region causes airway compromise (Figure 44-8). Medical attention is usually sought when the child develops inspiratory stridor and respiratory distress. Various scales have been devised to quantify the severity of the stridor to document the progression of the illness and the response to therapy. One of the most commonly employed scales is the Westley scale,[34] which has been validated (see Table 44-1).[35]

When a chest radiograph is obtained during an episode of laryngotracheobronchitis, the trachea is seen to have a gradual progressive narrowing of its lumen, reaching the narrowest point just below the vocal cords (the "steeple sign") (Figure 44-9). The upper glottis, as seen on a lateral neck radiograph, is normal.

Many care providers believe that exposing the child to cold or misty air often dramatically improves the symptoms; although evidence in support of this therapy is lacking.[36,37] When the illness is refractory to these measures, racemic epinephrine has been shown to produce dramatic reduction of airway obstruction. This probably is accomplished by stimulation of the α-adrenergic receptors, producing vasoconstriction and resulting in diminished tracheal edema. Rebound tracheal edema may occur several hours later as the effect of the racemic epinephrine dissipates. Because this problem is unpredictable, the child should be admitted to the hospital for observation after racemic epinephrine has been used.

The practice of treating laryngotracheobronchitis with corticosteroids is widespread, especially for hospitalized patients.[38] Oral, intramuscular, and nebulized corticosteroids have been shown to be beneficial in randomized, blinded trials.[39,40] Meta-analyses in which the efficacy of corticosteroids was evaluated suggest that corticosteroids reduced the need for endotracheal intubation or inhaled epinephrine, hasten improvement in the first 24 hours of illness, shorten the duration of hospitalization, and reduce the frequency of readmission.[41-44]

Mixtures of 70% helium and 30% oxygen (heliox) may be beneficial because the characteristics of this mixture permit greater gas flow past areas of airway narrowing. Some authors suggest that this therapy is as efficacious as racemic epinephrine[45]; however, this therapy has not been conclusively demonstrated to be superior to the administration of supplemental oxygen by itself.[46]

Table 44–2 Characteristics of Laryngotracheobronchitis, Bacterial Tracheitis, and Epiglottitis

	Laryngotracheobronchitis	Bacterial Tracheitis	Epiglottitis
Age	3 mo to 3 yr	6 mo to 12 yr	12 yr (average)
Onset	Gradual	Intermediate	<24 hr
Fever	Usually low	Usually high	High
Cough	Characteristic "barking"	Characteristic "barking"	None
Sore throat	None	Usually absent	Often severe
Drooling	No	No	Usually
Posture	Any position	Any position	Sitting forward, mouth open, drooling
Voice	Normal	Normal or hoarse	Muffled
Appearance	Nontoxic	Toxic	Toxic
Seasonal distribution	Usually winter, epidemic	Throughout the year	Throughout the year

Endotracheal intubation is occasionally necessary when laryngotracheobronchitis proves refractory to medical intervention. Unless merited by special circumstances, such as severe subglottic stenosis in association with laryngotracheobronchitis, tracheostomy offers no advantages over endotracheal intubation. The endotracheal tube should be of a smaller size than would normally be used, to avoid additional injury to the swollen tracheal mucosa. If the tracheal edema is severe, even a small tube may fit tightly in the trachea.

Later, when an audible leak around the endotracheal tube is present, the trachea may be extubated with a high probability that reintubation will not be necessary.[47] If a leak does not become audible after 2 to 4 days, it is our practice to extubate the trachea, because prolonged intubation may increase the risk for subglottic injury. Racemic epinephrine is commonly needed to treat stridor after extubation. If a patient should have especially severe or recurrent laryngotracheobronchitis, an anatomic lesion causing tracheal narrowing should be suspected.

Epiglottitis

Epiglottitis caused by *Haemophilus influenzae* type B was once a common cause of serious respiratory illness in pediatric patients, but the widespread use of *H. influenzae* type B vaccine has reduced the frequency of this problem by more than 90% in young children.[48] Patients who present with epiglottis are now older, with an average age of 11.6 years, as opposed to an average age of 5.8 years before the advent of Hib vaccination.[49] Although cases of *H. influenzae* epiglottis continue to occur, even among vaccinated patients,[50] other causes of epiglottitis have assumed greater importance in the postvaccination era. Group A β-hemolytic *Streptococcus* is now identified as the cause of epiglottitis in many patients and is clinically indistinguishable from epiglottitis caused by *H. influenzae* type B.[51] Thermal injury to the epiglottis from ingesting hot liquids can also cause epiglottitis.[52] Several points serve to distinguish epiglottitis from laryngotracheobronchitis (Table 44-2).

Figure 44–10. Lateral radiograph of the neck of a patient with epiglottitis. Note the large, swollen epiglottis.

Figure 44–11. Epiglottitis causing a severely swollen epiglottis (between the *arrows*). In the lower portion of the picture, the endotracheal tube can be seen. *(Copyright Andrew F. Inglis Jr.)*

Management of epiglottitis in young children is a multidisciplinary undertaking, involving pediatric intensive care specialists, anesthesiologists, and otolaryngologists. When a child with presumed epiglottitis is admitted to the emergency department, this team should be notified in anticipation of taking the child to the operating room to secure his or her airway. As the team members are being notified, lateral radiographs of the neck may be obtained if tolerated by the patient. This may be done with the child sitting on the parent's lap to minimize the child's anxiety. In epiglottitis, the anteroposterior view of the trachea appears normal, but a lateral neck radiograph shows a markedly swollen and edematous epiglottis (Figure 44-10). The diagnostic evaluation of the patient should proceed expeditiously, while care is taken to disturb the patient as little as possible. For this reason, fiberoptic examination of the epiglottis in the awake patient is usually not advisable. Attempts to examine the oropharynx directly or to start an intravenous line should be discouraged. The apprehension caused by these events may lead to tracheal obstruction by the enlarged epiglottis. If the patient will tolerate it, humidified oxygen should be administered, preferably through a plastic hose held by the parent.

If the diagnosis of epiglottitis is strongly suspected or confirmed on the lateral neck x-ray film, the child should go to the operating room as quickly as possible. In the operating room, the patient is anesthetized with an inhaled anesthetic (sevoflurane) and oxygen while the patient is spontaneously breathing. Once the patient has been anesthetized, an intravenous catheter is inserted. Laryngoscopy is then performed (Figure 44-11). It may be exceedingly difficult to obtain a direct view of the glottis and trachea because of the large swollen epiglottis. Nevertheless, it is almost always possible to pass an endotracheal tube through the edematous tissues and into the trachea. Nasotracheal intubation is preferred to orotracheal intubation because the tube is more readily secured to the face, the patient cannot bite the tube, and salivation is decreased. An otolaryngologist should be in the operating room and ready to do an emergency tracheostomy if an airway cannot be secured by endotracheal intubation, although this is rarely necessary. As with laryngotracheobronchitis, endotracheal intubation is preferred to tracheostomy because it has been shown that complications are more common when a tracheostomy has been routinely used to treat epiglottitis. After the airway is secured, blood cultures and cultures of the epiglottis are obtained, and antibiotic therapy is initiated with a penicillinase-resistant antibiotic because of the high incidence of *H. influenzae* resistance to ampicillin.[53]

In the PICU, patients usually require endotracheal intubation for 24 to 72 hours while the swollen epiglottis returns to normal size. The patient may be allowed to breathe spontaneously through the endotracheal tube or may undergo mechanical ventilation. Variable amounts of sedation are usually necessary. Extraepiglottic sites of *H. influenzae* infection are common. In one series, pneumonia occurred in 25% of patients with epiglottitis.[54]

The management of epiglottitis depends upon the patient's age. Adults and teenagers with epiglottitis usually present with severe pharyngitis, but usually have mild or absent airway obstruction. In contrast to younger unsedated children, teenagers and adults may tolerate examination of the airway with a small fiberoptic bronchoscope. This procedure may have superior diagnostic sensitivity compared to lateral neck radiographs. Although the management of epiglottitis in young children is almost always accomplished with placement of an endotracheal tube, teenagers and adult patients may be admitted to the hospital for close observation and expectant airway management. Endotracheal intubation is reserved for those patients who develop respiratory compromise.[55,56]

Peritonsillar Abscess

The initial presentation of peritonsillar abscess may resemble that of epiglottitis. The child usually has a severe sore throat and may also have a muffled voice and drooling. If the abscess is of sufficient size, the child may also experience respiratory distress. Unlike epiglottitis, children with peritonsillar abscess often experience trismus and usually do not have respiratory embarrassment. If the abscess is fluctuant, surgical incision and drainage may be indicated. Although trismus may be of concern in evaluation of the patient for anesthesia, there is usually no anatomic restriction of jaw movement. Once the patient has been anesthetized, the mouth may be easily opened. Extubation is almost always possible after the abscess has been drained, unless there is severe inflammation and swelling extending well beyond the tonsillar bed. Intraoral ultrasound examination has been suggested to be a useful test to differentiate abscess from cellulitis.[57] The most commonly encountered microorganism is Group A *Streptococcus*.[58]

Retropharyngeal Abscess

Almost 90% of children with retropharyngeal abscess are younger than 6 years.[59] Patients may have fever, stiff neck, sore throat and, in severe cases , respiratory distress. During examination of the oropharynx, the posterior pharyngeal wall may be observed to bulge, but most commonly, the findings are unremarkable. Palpation of the posterior pharyngeal wall should be avoided because it may cause rupture of the abscess with possible spillage of the contents into the tracheobronchial tree. An inspiratory radiograph of the lateral neck may show thickening of the prevertebral soft tissue, and occasionally an air-fluid level may be present (Figure 44-12). A chest radiograph should be obtained to evaluate possible mediastinal extension of the infection. CT scanning is commonly employed to evaluate these infections; however, evidence of abscess on CT scan does not reliably predict the quantity of purulent material obtained at the time of surgical drainage.[60]

A trial of antibiotic therapy is often indicated before any decision is made to proceed with surgical drainage of the abscess,[61] as between 30% and 90% of patients treated with antibiotic therapy can be cured without surgical intervention.[62,63] Surgical treatment of this lesion is drainage of the abscess, after the patient has been anesthetized and an endotracheal tube has been inserted to protect the patient from pulmonary aspiration of the purulent fluid. The organisms most often isolated are group A β-hemolytic *Streptococci* and *Staphylococcus aureus*.[59,64]

Bacterial Tracheitis

The peak incidence of this infection occurs in the fall and winter and tends to affect children between 6 months and 8 years of age. Bacterial tracheitis is a secondary infection that begins during a viral upper respiratory infection.[65-67] Frequently, but not always, bacterial tracheitis will resemble viral laryngotracheobronchitis (croup). Children will frequently complain of a severe sore throat or pain during coughing. In contrast to viral laryngotracheobronchitis, patients with bacterial tracheitis usually have a high fever and may appear very ill at the time of presentation (see Table 44-2). Because of the clinical similarity between bacterial tracheitis and viral

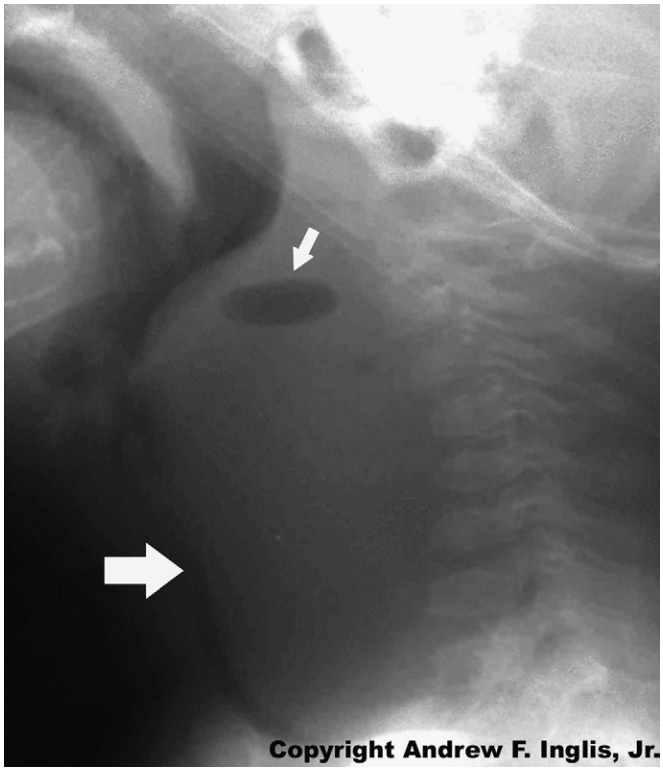

Figure 44–12. Lateral radiograph of the neck of a patient with retropharyngeal abscess. Note the thickening of the prevertebral soft tissue and the radiolucent area caused by the presence of air in the tissue. *(Copyright Andrew F. Inglis Jr.)*

laryngotracheobronchitis, these patients are treated with racemic epinephrine but fail to respond. If bronchoscopy is performed, it shows normal supraglottic structures, and diffuse inflammation of the larynx, trachea and bronchi,[68] with adherent or semiadherent purulent membranes in the trachea.[69] Endotracheal intubation is often necessary because of severe, progressive respiratory distress. Following endotracheal intubation, aggressive tracheobronchial toilet may be necessary because thick, tenacious purulent debris may rapidly occlude the endotracheal tube.

A variety of bacterial agents have been reported in association with this illness, including *Moraxella catarrhalis*, *Staphylococcus aureus*, *Haemophilus influenzae* type B, and *Pneumococcus*.[70,71] The injury to the respiratory epithelium caused by the virus may predispose the patients to bacterial superinfection. The most common complication of bacterial tracheitis is pneumonia, which is observed in approximately 60% of patients with this illness. Antibiotics are an important aspect of therapy and should be directed by the results of bacterial cultures obtained during bronchoscopy or immediately after endotracheal intubation.

Laryngeal Papillomatosis

The laryngeal papilloma is the most common benign tumor of the larynx during childhood. The agent causing this disease is human papilloma virus, with types 6 and 11 causing the vast majority of cases.[72] Despite its nonmalignant structure, the propensity of this tumor to cause respiratory obstruction may result in injury to the patient or death. The onset of symptoms occurs between infancy and 4 years of age. New onset of

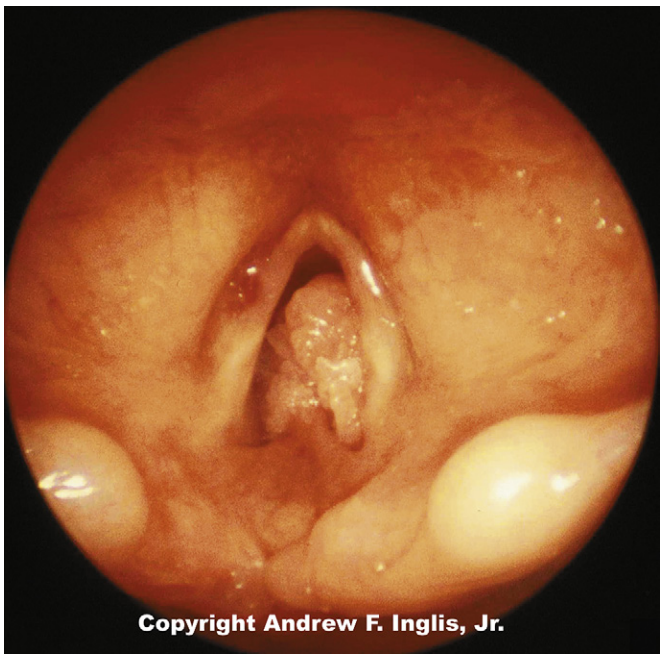

Figure 44–13. Large, pedunculated papilloma is seen just below the vocal cords. These papillomae almost completely occluded the tracheal lumen and produced marked respiratory distress. *(Copyright Andrew F. Inglis Jr.)*

infection is less frequent after age 5 years. The most common medical complaint in these children is voice change, which occurs in more than 90% of the patients. Airway obstruction is present in almost half of the patients, although it is mild in many of these. The presence of inspiratory stridor may misdirect the diagnostician to think that the child has laryngotracheobronchitis. The diagnosis is typically made with laryngoscopy (Figure 44-13).

Little is known about the immunological mechanisms involved in laryngeal papillomavirus infection, but cellular immunity is considered a more important mechanism than humoral immunity.[73] Better understanding of human papillomavirus infection is hampered by the lack of a good experimental model in which the entire viral life cycle can take place.

The treatment for this illness is surgical excision of the polyps. Induction of anesthesia in the child with severe airway obstruction may be hazardous, because it may be difficult or impossible to ventilate the child's lungs after loss of consciousness. Although patients characteristically require multiple surgical resections of these lesions (an average of 11 resections over the course of the disease), the mortality with this illness is low. Carbon dioxide laser vaporization of the papillomata is widely used. During laser excision of lesions caused by a similar viral agent, anogenital condylomas, medical personnel have become infected with the virus, presumably from viable virus particles carried in the smoke plume.[74] Although this has caused concerns about the spread of infection after excision of laryngeal papillomatosis, test results of the smoke plume have been negative for viral DNA.[75] Despite this, careful scavenging of the plume is routine in most centers where this operation is performed.

Despite modern surgical treatments, recurrence of laryngeal papillomata is relatively common and has prompted the search for other treatment options. Adjunctive treatment with interferon-α has been shown to reduce the relapse rate in both children and adults.[76] Molecular analysis has shown that patients infected with human papillomavirus-11 were sensitive to interferon treatment as opposed to those with human papillomavirus-6.[77]

Vocal Cord Paralysis

The bulk of the motor innervation to the larynx is supplied by the recurrent laryngeal nerves. These nerves originate in the nucleus ambiguous in the brainstem, travel to the chest with the vagus nerve, and then loop back up to the larynx in the tracheoesophageal groove. The left recurrent laryngeal nerve loops under the ductus arteriosus in the chest, and thus is vulnerable to injury during ligation of this vessel, and with other thoracic vascular procedures.[78]

Symptoms associated with even complete unilateral vocal cord paralysis vary greatly in severity. In infants, they may range from merely a mildly diminished cry up to a severely disabled larynx with significant stridor, feeding difficulties from aspiration, and loss of voice.[79] Bilateral vocal cord paralysis almost always produces significant stridor with varying degrees of airway distress. Stridor in these instances is typically inspiratory, and may be confused with laryngomalacia, a much more common entity. Diagnosis can usually be made at the bedside by fiberoptic laryngoscopy.[80]

Congenital vocal cord paralysis is usually idiopathic, and often resolves spontaneously over several months. This is the most common cause of bilateral vocal cord paralysis in children.[81] Other neurological causes, such as Arnold-Chiari malformation, are occasionally seen, and workup usually includes an MRI. The cause of acquired vocal cord paralysis is usually obvious, with most cases coming after thoracic or cervical surgery.[82]

The treatment of vocal cord paralysis in the critical care setting is primarily supportive. Airway support may include temporizing with high-flow nasal oxygen or continuous positive airway pressure/biphasic positive airway pressure (CPAP/BiPAP). Longer-term interventions include tracheotomy, or various procedures aimed at enlarging the glottic airway, including vocal cordotomy, arytenoidectomy, vocal cord lateralization, and posterior cricoid split and cartilage grafting.[80] If a specific lesion may be addressed medically or surgically (such as decompression of the brainstem in Arnold-Chiari malformation), such therapy should be undertaken.

Intrathoracic Mass Lesions Causing Respiratory Obstruction

The intrathoracic trachea may be compressed by a variety of anterior mediastinal masses. Because the symptoms produced by a malignant mass impinging on the trachea can worsen dramatically over several days, the child with respiratory compromise resulting from a mediastinal mass deserves rapid evaluation and aggressive medical therapy.

Before caring for a child with this problem, the parents should be asked if the child refuses to lie in certain positions. The child's reluctance to recline in a given position may be caused by airway compromise from the mass. Forcing the child to lie down may result in airway obstruction or even cardiac arrest.[83] Endotracheal intubation is indicated only if respiratory function becomes severely compromised. Unfortunately,

this measure may be of little benefit, because the lesion may compress the bronchi distal to the tip of the endotracheal tube requiring advancing the endotracheal tube into the mainstem bronchi.[84] In addition, it may be impossible to ventilate the child's lungs after muscle relaxants have been administered to facilitate placement of the endotracheal tube. Mechanical support with ECMO has been used to support patients with large mediastinal masses; however, the mass may distort the great vessels and pose unusual challenges for the ECMO team.[85] Obtaining tissue for a pathologic diagnosis can be a challenge, as these patients are at significant risk for anesthetic complications.[86] Factors associated with airway compromise are (1) anterior location of the mediastinal mass, (2) histological diagnosis of lymphoma, (3) symptoms and signs of superior vena cava syndrome, (4) radiological evidence of vessel compression or displacement, (5) pericardial effusion, and (6) pleural effusion.[87]

Trauma

Postextubation Stridor

After endotracheal intubation that lasts more than a few hours, postextubation stridor is a relatively common problem in small children and is most frequently caused by laryngeal edema. Estimates of the frequency of postextubation stridor in children vary widely. Most authors cite figures of less than 2% to 9%,[88,89] although the incidence may be as high as 37% in patients with trauma or burns.[90]

In addition to audible stridor, patients with this problem show decreased air movement; flaring of the alae nasi; and in more severe cases, decreased arterial oxygen saturation and mental status changes. The severity of these signs reliably indicates the severity of airway obstruction.[91]

Several risks are associated with the development of postextubation stridor. Endotracheal tube size plays an important role, because too large an endotracheal tube may compress the tracheal mucosa, causing submucosal ischemia. When the endotracheal tube is removed, the injured tissue may swell and partially obstruct the larynx. Endotracheal tube movement within the trachea may produce trauma to the tracheal mucosa, resulting in tissue injury and swelling. Whether stridor occurs depends on the extent of the swelling and the diameter of the child's airway. Small patients are more likely to have postextubation stridor because a larger proportion of their airway is obstructed with a given degree of swelling and because of the unfavorable characteristics of turbulent flow through small passages. Lack of an audible leak of air around the endotracheal tube is frequently used as a predictor of postextubation stridor in children; however, one study suggests that this measure may be valid only in children ages 7 years and older.[92]

Uncuffed endotracheal tubes are often recommended for children younger than 8 years because of concern that the presence of an endotracheal tube cuff may contribute to the risk of postextubation stridor. The subglottic region is the narrowest portion of the airway in this age group and will often provide an adequate seal around the endotracheal tube. Although historically, cuffed endotracheal tubes were not frequently used in children younger than 8 years, there are increasing data suggesting the safety of such endotracheal tubes. Data regarding the harmful effects of cuffed endotracheal tubes were derived from tubes with high-pressure, low-volume cuffs, which are likely to cause submucosal tracheal ischemia. These endotracheal tubes have been replaced by low-pressure, high-volume cuffs that seal the trachea by providing a larger area of contact with the mucosa at a lower pressure, resulting in less submucosal ischemia. When such endotracheal tubes are used, the risk of postextubation stridor appears no greater than when uncuffed endotracheal tubes are used.[88,89,93] Because cuffed endotracheal tubes may provide a better seal than uncuffed endotracheal tubes, they can be useful in delivering higher pressures needed in patients with noncompliant lungs who require mechanical ventilation. A large multicenter randomized control trial also suggests there is a significant reduction in endotracheal tube exchanges when cuffed tubes are used.[88]

Postextubation stridor has a greater risk of developing in children with trisomy 21; as many as one third of these patients have stridor after extubation. There appear to be several causes for this problem, including hypotonia and facial abnormalities, such as a large tongue.

Although most cases of postextubation stridor are caused by laryngeal edema, when this problem persists, other causes should be sought. Anatomical airway anomalies, which may not be visible during endotracheal intubation (such as tracheal hemangioma), may cause persistent postextubation stridor. Vocal cord paralysis is one of the more common causes of persistent postextubation stridor and may be caused by increased intracranial pressure, brainstem compression,[94] trauma to the brainstem after neurosurgery, or recurrent laryngeal nerve during thoracic surgery.[95]

The therapy of postextubation stridor is aimed at reducing airway edema. Racemic epinephrine and dexamethasone are the most widely used therapeutic agents. Racemic epinephrine, delivered by aerosol nebulizer, probably works by stimulation of α-adrenergic receptors; this stimulation causes vasoconstriction, which, in turn, reduces tracheal edema. Racemic epinephrine works rapidly, so improvement, when it occurs, should be observed within a few minutes of completion of therapy. Mixtures of helium and oxygen have also proven helpful in the treatment of postextubation stridor.[96]

The practice of using dexamethasone to treat postextubation stridor is widespread,[97] although the efficacy of this therapy remains controversial. Although data from animal studies suggest that corticosteroid use at the time of extubation may reduce tracheal edema, inflammation, and capillary dilation, a recent meta-analysis of prior studies has failed to show reduction of postextubation stridor after corticosteroid use.[98] Nevertheless, many practitioners think that dexamethasone (or an equivalent dose of another steroid) will ameliorate postextubation stridor, especially if the medication is administered several hours before extubation.

In most cases, postextubation stridor is self-limited, but occasionally, endotracheal intubation may be necessary. If the degree of airway obstruction before reintubation was severe, postobstructive pulmonary edema may be observed and should be treated with positive end-expiratory pressure. When reintubation is contemplated, the size of the previous endotracheal tube should be determined, and a smaller endotracheal tube should be selected in the hope of preventing additional tracheal injury. Ideally, the trachea should remain intubated until a leak around the endotracheal tube is observed, indicating resolution of the laryngeal edema.

Laryngotracheal (Subglottic) Stenosis

Laryngotracheal stenosis is most commonly seen as a complication of prolonged endotracheal intubation, and as such is of special interest to the critical care practitioner (Figure 44-14). Injury most commonly occurs in the larynx at the level of the cricoid cartilage, just below the vocal cords, the only part of the airway below the nose that is surrounded by a complete circumferential ring of cartilage. This region cannot expand under pressure and is thus more susceptible to pressure necrosis and scarring (subglottic stenosis). Airway stenosis also can occur at the level of the vocal cords (glottic stenosis) when scarring occurs within the cricoarytenoid joints (cricoarytenoid ankylosis) or between the arytenoid cartilages (interarytenoid fibrosis). Glottic stenosis prevents vocal cord abduction and occasionally may be confused with bilateral vocal cord paralysis. Rarely, tracheal stenosis may be seen as a result of endotracheal tube (ETT) cuff injury, often in the setting of infection requiring high pressure ventilation.

Laryngeal intubation injury appears to result from an interaction of several elements, including individual susceptibility, movement of the endotracheal tube, size of the ETT, presence of infection, and duration of intubation. Fortunately, the incidence of this complication in neonates appears to be decreasing.[99] The odds of prevention will be enhanced by choosing the smallest tube that allows adequate ventilation and pulmonary care; this reduces the risk of subglottic stenosis. It is also thought that nasotracheal intubation may reduce movement of the ETT within the airway and thus diminish trauma, although this benefit comes with an increased risk of sinusitis secondary to obstruction of drainage from the sinus cavities. Gastroesophageal reflux is frequently present, and perhaps plays a significant role in the development of laryngotracheal stenosis.[99] The role of early intervention with a tracheotomy for the prevention of laryngeal stenosis is controversial.[100]

Clinically, laryngeal stenosis presents initially as postextubation stridor. It may be successfully managed with steroids or racemic epinephrine. Some patients may benefit from noninvasive positive-pressure breathing therapies such as BiPAP or CPAP. If reintubation is necessary, the larynx may heal successfully if a smaller endotracheal tube is used. Multiple failed attempts at extubation may require treatment with either an anterior cricoid split and cartilage graft, or tracheotomy.

Chronic laryngeal stenosis can be managed a variety of ways.[101] The obstruction may be bypassed with a tracheotomy, or may be managed with endoscopic excision of scar, cricoid expansion via cricoid split and cartilage grafts, and excision of the stenotic segment and reanastomosis via partial cricotracheal resection. Postoperative management of these patients is frequently complicated by the need to allow the larynx to heal for 5 to 14 days while maintaining a patent airway with an endotracheal tube. Management of the patient during this critical period is controversial. Some favor heavy sedation including the use of neuromuscular blocking agents to minimize the chance of movement of the ETT and accidental extubation. Others favor the opposite, actually allowing the patient to be alert and active with the ETT in place.[102] Fortunately, improvements in postoperative care have resulted in improved outcomes after laryngotracheal reconstruction.[103]

Ideally, reconstruction will be performed at a young age (younger than 25 months) to minimize the time period the child is exposed to the hazards of being dependent on the tracheotomy airway, and so that the child's speech and language development is not impaired.[104] Earlier laryngotracheal reconstruction may, however, be more prone to failure and requirement for revision procedures.

Foreign Body Aspiration

Airway obstruction may be produced by aspiration of a variety of foreign bodies, with nuts being one of the most frequent offenders in children.[105] Most of the patients aspirating foreign bodies are aged 1 to 3 years, with more than 95% being younger than 10 years. Fewer than 30% of patients aspirating foreign bodies receive medical attention within the first 24 hours, with many patients experiencing a significant delay before seeking medical attention. A clear history of foreign body aspiration may be elicited from 40% to 80% of the patients.[106] Patients with an aspirated foreign body may initially be symptom-free or may have a cough, wheezing, and evidence of respiratory embarrassment. Patients without symptoms who do not seek medical attention may have a persistent cough and may develop pneumonia distal to the obstructed bronchus. Recurrent bouts of pneumonia may lead to bronchiectasis if the foreign body is not removed.

Foreign bodies may become lodged in the airway anywhere from the posterior pharynx to the bronchi. The symptoms produced by foreign body aspiration vary according to the site of the foreign body and the degree of obstruction it produces. Foreign bodies of the extrathoracic airway characteristically produce inspiratory stridor. Foreign bodies lodged in the intrathoracic trachea and bronchi tend to produce expiratory stridor and wheezing.

Radiographic evaluation should include inspiratory and expiratory radiographs because a single anteroposterior radiograph will be unremarkable in 18% of children with an aspirated foreign body (Figure 44-15).[106] If the foreign body

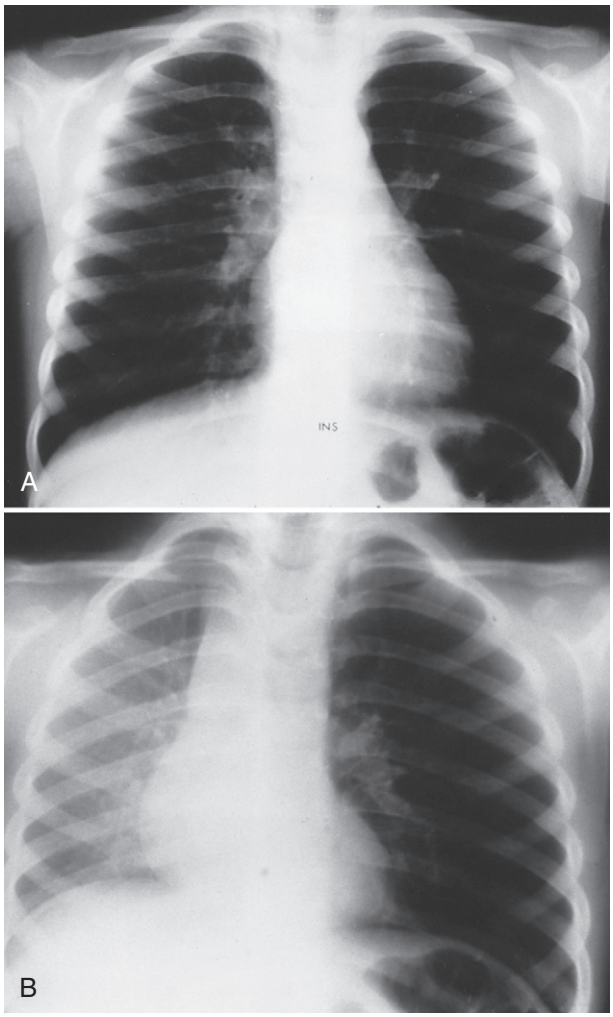

Figure 44–15. **A,** Inspiratory chest radiograph with foreign body present in left mainstem bronchus. The left lung is slightly hyperinflated but could be considered normal. **B,** Expiratory chest radiograph with foreign body present in left mainstem bronchus. The left lung is clearly hyperinflated because of air trapping by the foreign body. *(**A** and **B**, Courtesy Eric Effmann, MD.)*

is producing ball-valve bronchial obstruction, hyperinflation of the involved lung will be seen during the expiratory radiogram. Many foreign bodies are not radiopaque,[107] so failure to see a foreign body on the chest radiograph cannot exclude this diagnosis. If a suspicion of an aspiration is high, a bronchoscopy is warranted (Figure 44-16).

Foreign bodies are removed from the tracheobronchial tree with a bronchoscope.[108] Depending on the material, this may be a difficult procedure, although improvement in bronchoscopes in recent years has greatly facilitated this undertaking. Cardiopulmonary bypass has been successfully used to support a patient who had extensive foreign body aspiration. Occasionally, bronchoscopic extraction is unsuccessful, and a pulmonary lobectomy is required.

Traumatic Injury to the Airway

Traumatic injury to the upper airway may be divided into two broad categories: oral facial trauma and laryngeal/tracheal trauma. Patients with obvious oral facial trauma may be at

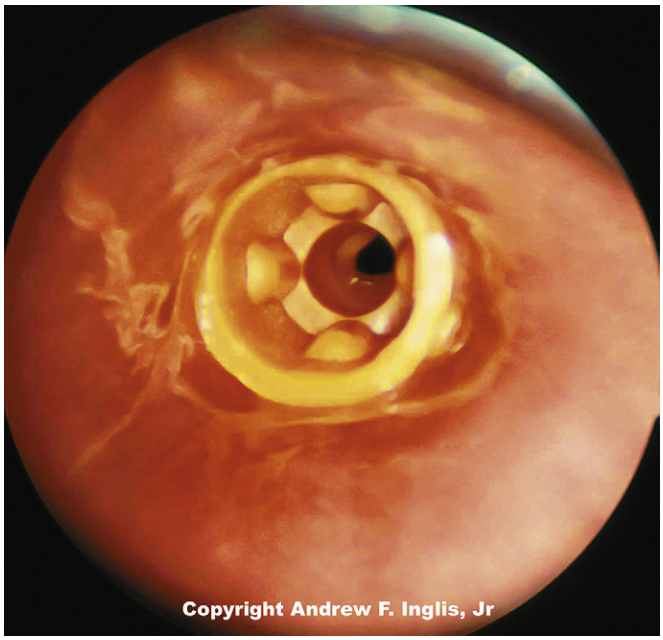

Figure 44–16. Hollow plastic foreign body in patient's trachea. Because the lumen of the foreign body was aligned with the tracheal lumen, severe respiratory embarrassment did not occur. *(Copyright Andrew F. Inglis Jr.)*

risk for upper airway obstruction. Even if the patients have no sign of respiratory distress at the time of presentation, swelling of soft tissues and hemorrhaging to the airway may lead to airway compromise.

Patients who must undergo operative intervention to treat their traumatic injuries need careful evaluation of their airway, including radiographs and CT scan examination. Traumatic injuries may make intubations in the trachea difficult in these patients. For this reason, sedation is to be avoided and endotracheal intubation with the patient awake should be considered. This may be accomplished with direct laryngoscopy after local anesthesia has been applied to the patient's oropharynx. In more difficult cases, it may be necessary to use a fiberoptic bronchoscope to guide the ETT into the trachea.

Postoperatively, patients undergoing repair of facial trauma may have their jaw wired shut and the ETT sutured in place to prevent accidental extubation. These patients should undergo extubation only when fully awake, and after resolution of their airway and facial edema. Instruments to open the wires should always be kept at the patient's bedside. Emesis may present a grave hazard in these patients.

Injury to the larynx and trachea may occur after blunt trauma such as automobile accidents, after penetrating trauma, or with crush injuries such as hanging. Blunt trauma to the neck may lead to fracture of the cartilaginous rings supporting the trachea or to disruption of the tracheal mucosa. In the latter case, attempted endotracheal intubation may worsen a partial tracheal transection and create an airway emergency.[109] Signs of laryngeal injury include dyspnea, altered phonation, pain on swallowing, hoarseness, swelling, and subcutaneous emphysema of the neck. The development of subcutaneous emphysema after blunt trauma to the neck suggests that a laryngeal fracture or tracheal tear has occurred. The quantity of air in the subcutaneous tissues does not correlate with the severity of the injury. Establishment of an adequate airway is

an essential consideration. Acute trauma of the larynx is often treated with placement of a tracheostomy before surgical repair of the larynx.

Blunt thoracic trauma can cause tracheal or bronchial disruption. Most commonly, these are "blowout" injuries that result in tracheobronchial disruption. These injuries usually occur near the carina, and most involve mainstem bronchi.[110] Because children have flexible ribs, severe intrathoracic injuries can occur without rib fractures. The signs of tracheobronchial disruption include persistent air leak, failure to expand the lung with thoracostomy tube drainage, and massive atelectasis (from failure to conduct gas through an injured bronchus). Diagnosis of these injuries is usually made with bronchoscopy. Although small tracheobronchial disruptions may be managed conservatively, most of these lesions require surgical repair.[110]

Burn Injury to the Upper Airway

Thermal injury to the upper airway may complicate the management of a patient with burns. The presence of facial burns and singed nasal hairs, hoarseness, or inspiratory stridor should suggest the possibility of burn injury to the upper airway. Although respiratory compromise may not be present at the time of admission, it may develop later as swelling of the injured airway becomes more severe. Because of the efficient cooling capacity of the upper air passages, thermal injury to the airway below the vocal cords is uncommon, occurring in less than 5% of all hospitalized patients with burns.

Evidence of respiratory embarrassment in a patient with burns should be rapidly evaluated. Neck radiographs and fiberoptic examination of the larynx may show swelling of the soft tissues of the airway. If these findings are present, endotracheal intubation should be expeditiously performed to secure the airway before obstruction occurs. Because of the risk of infection, attempts are made to avoid tracheostomy placement in the patient with burns, and data suggest this is a safe practice.[111] Upper airway embarrassment is often accompanied by smoke inhalation injury to the lower airway, resulting in hypoxemia and hypercapnia. The products of combustion result in severe carbon monoxide intoxication or cyanide poisoning, both of which have nonspecific symptoms but require prompt medical therapy.[112]

Angioedema

Angioedema is a well-demarcated localized edema involving the deep layers of skin, including the subcutaneous tissue. Angioedema may occur in response to a variety of systemic disorders, including allergic reactions that are mediated with immunoglobulin E, anaphylactic and anaphylactoid reactions, and other illnesses. Angioedema may lead to swelling of the soft tissue of the face, particularly the eyes and lips. If this should involve the soft tissues of the upper respiratory tract, laryngeal obstruction may result. Administration of subcutaneous epinephrine may dramatically reduce swelling caused by this condition. Compared to adults, children often have a rapid response to antihistamines and steroids.[113] Occasionally, respiratory embarrassment caused by this condition is so severe that endotracheal intubation is warranted. The evaluation of patients with this disorder should be directed at (1) the identification of the causative agents so that the patients can avoid these in the future and (2) the anatomic site of presentation to allow stratification of airway risk and planning of appropriate triage for airway intervention.[114]

Tracheostomy

Indications for the placement of a tracheostomy fall into three broad, frequently overlapping categories: airway obstruction, assisted ventilation, and pulmonary toilet. Pediatric anatomical anomalies that may necessitate tracheostomy are most often manifested in the neonatal period or in infancy, although some may not appear until childhood. The most common abnormalities include vocal cord paralysis (congenital and postbirth injury), subglottic stenosis, tracheal stenosis, cystic hygroma, tracheal hemangioma, and laryngeal cyst. The accurate diagnosis of these problems is frequently made during bronchoscopic examination of the larynx and trachea while the patient is anesthetized. If the obstruction is of sufficient magnitude, consideration should be given to doing a tracheostomy at the time of bronchoscopy.

Infants may require a tracheostomy because of the need for prolonged periods of assisted ventilation. The advent of neonatal intensive care has enabled small preterm infants to survive despite severe respiratory illness. Many of these patients will need lengthy periods of mechanical ventilation to treat infant respiratory distress syndrome and bronchopulmonary dysplasia. Prolonged intubation may lead to subglottic stenosis.[115] For a reduction in the frequency of this complication, a tracheostomy may be performed. The optimal timing of tracheostomy for children who need long-term intubation is controversial. In many neonatal ICUs, infants needing mechanical ventilatory support for more than 30 to 45 days will undergo a tracheostomy. Placement of a tracheostomy is not a trivial matter, with several large studies showing a tracheostomy-related mortality rate of 0.5% to 0.7%.[116,117] One recent study provided evidence that long-term tracheostomy is associated with airway inflammation (number of cells, neutrophils), more frequent bacteria, and reduced concentration of surfactant protein-D.[118] The decline of polio in the United States during the decade following 1950 dramatically decreased the number of tracheostomies performed to facilitate mechanical ventilation and pulmonary toilet. Nevertheless, several pediatric diseases predictably lead to prolonged neuromuscular failure. Infants with infant botulism may have prolonged neuromuscular weakness and may undergo a tracheostomy to simplify management of mechanical ventilation. Similarly, older children with Guillain-Barré syndrome and respiratory failure may need a tracheostomy if a lengthy course of mechanical ventilation is expected. The use of tracheostomy has been advocated to promote pulmonary toilet and improve ventilation during the treatment of flail chest.

The timing of the tracheostomy will depend on several issues, including the patient's underlying illness and the severity of the condition that makes tracheostomy necessary. If possible, emergency tracheostomy under unfavorable conditions should be avoided because the complications are more common in this setting. Percutaneous placement of a tracheostomy has been widely used in the adult population; however, experience in children remains limited. One small retrospective series suggests that placement in the ICU can be done safely with adherence to sound techniques and prudent patient selection.[119]

Postoperative Nursing Care

Care from attentive, trained nurses is essential for the well-being of the patient with a tracheostomy. Until a tract of granulation tissue has formed in the stoma between the cervical and tracheal epithelium, precautions should be taken to prevent the accidental displacement of the tracheostomy tube. Although stay sutures simplify replacement of the tracheostomy tube, this procedure may be difficult, especially in an emergency situation with a struggling patient. A hastily replaced tube may be incorrectly located in the pretracheal soft tissue, resulting in asphyxiation. If positive-pressure ventilation is attempted with the tube in this position, subcutaneous and mediastinal emphysema may be followed by a life-threatening tension pneumothorax. Because of these risks, patients routinely stay in the ICU for 5 to 7 days postoperatively. Smaller children have arm restraints placed to prevent them from pulling at the tracheostomy tube. If necessary, sedation is given until the child grows accustomed to the tracheostomy and the tract matures with the formation of granulation tissue. If accidental displacement of the tracheostomy tube does occur, replacement may be facilitated with a gentle insertion of a 0 Miller laryngoscope blade into the stoma and the identification of the tracheal lumen before the tube is passed.

Besides avoiding accidental displacement of the tracheostomy, the nurse must constantly monitor the patient for obstruction of the tracheostomy tube. The tube may be obstructed by dried tracheal mucus. Sometimes the patient's chin may obstruct the tube. Humidified gas may be administered to prevent drying and inspissation of secretions.

Complications

Any operation on the airway involves risk. The complication rate after tracheostomy has been reported to be 10% to 30%, with a death rate of 3%. Early postoperative complications include air leak, hemorrhage, and aspiration. Air leak is seen more often in children than in adults and may be life-threatening. The risk of complications declines as the patient ages. Some life-threatening complications, such as accidental decannulation or tracheostomy tube obstruction, may occur anytime after the placement of a tracheostomy. The safety and well-being of patients with a tracheostomy require constant vigilance to prevent these mishaps.

Swallowing dysfunction after tracheostomy may lead to aspiration of saliva and food. This may be due in part to anchoring of the trachea to the skin of the neck, preventing the cephalad movement of the trachea during swallowing. Children who have a tracheostomy often have difficulty learning to eat. The high frequency of pneumonia observed after tracheostomy may be in part due to the problem of recurrent aspiration. Aerophagia, another form of swallowing dysfunction, occurs with modest frequency in pediatric patients after tracheostomy.

Late complications include granulation tissue formation, tracheal stenosis, infection of the stoma, pneumonia, fused vocal cords, and distal tracheomalacia. Although infection of the stoma and distal tracheomalacia may be evident before decannulation, granulation formation and fused vocal cords may not be apparent until decannulation is attempted. An uncommon, but particularly dangerous late complication is erosion of the tracheostomy tube into the innominate artery.

Decannulation

Problems at the time of decannulation occur in up to 36% of children. These difficulties are most frequent in patients younger than 1 year. Structural abnormalities that result in decannulation problems include subglottic stenosis, tracheomalacia at the tracheostomy site, granuloma tissue obstructing the trachea, and fused vocal cords. If respiratory distress is encountered during decannulation, it should not be attributed to the patient's psychological dependence on the tracheostomy tube. Evaluation of the airway with bronchoscopy or a lateral neck radiograph is important. Psychological factors should not be considered until structural causes of respiratory embarrassment have been eliminated.

Asthma

Alexandre T. Rotta, Veda L. Ackerman, and Howard Eigen

PEARLS

- Patients with severe acute asthma exacerbations should be aggressively managed in the emergency department with inhaled β-agonist agents, ipratropium bromide, and systemic corticosteroid drugs. Patients who fail to improve or who further deteriorate should be admitted to the intensive care unit for a higher level of monitoring and escalation of therapy. Standard treatments include administration of fluids, oxygen, β-agonist agents by intermittent or continuous nebulization, ipratropium bromide, parenteral corticosteroid drugs, and intravenous infusion of a β_2-agonist agent. Other therapies available in the intensive care unit include intravenous infusions of magnesium sulfate and methylxanthine agents, and breathing helium-oxygen mixtures.
- Failure to respond to treatment can lead to further deterioration and the development of respiratory insufficiency, necessitating intubation and mechanical ventilatory support. Ventilation should be initiated with a strategy that avoids dynamic hyperinflation. Select patients may benefit from inhalational anesthetic agents for bronchodilatation or from bronchoscopy to relieve airway obstruction or atelectasis resulting from mucous plugging.
- Aggressive medical treatment and a mechanical ventilation strategy that minimizes dynamic hyperinflation result in low morbidity and near-zero mortality rates in patients with severe acute asthma.

Asthma is a highly prevalent chronic disease that affects both children and adults and is the most common medical emergency in the pediatric population. Despite adequate treatment and access to medical care, patients with asthma are at risk for episodic acute deteriorations in pulmonary function, commonly known as reactive airway disease exacerbations or asthma attacks. These attacks vary greatly in severity, ranging from mild episodes that are easily managed in the outpatient setting with intensification of corticosteroid and bronchodilator therapy to severe episodes with intense airway obstruction that rapidly evolve to respiratory failure.

The term *status asthmaticus* has been used to denote a more severe form of asthma attack, but its definition varies widely among different authors. To some authors, status asthmaticus is an asthma attack that does not respond to initial treatments with bronchodilators,[1,2] whereas to others it indicates severe asthma that leads to respiratory failure and requires mechanical ventilatory support.[3] For the purposes of this text, status asthmaticus is defined as an asthma attack that fails to respond to initial doses of nebulized β_2-adrenergic and anticholinergic agents and systemic corticosteroid drugs and that requires admission to the hospital for continuation of treatment. Patients who experience relentless progression of respiratory signs and symptoms and require admission to the intensive care unit (ICU) are reported as having near-fatal asthma.[4]

Epidemiology and Risk Factors

Asthma is the most common chronic illness in childhood, affecting approximately 6.7 million children and adolescents in the United States, or 9.1% of persons younger than 18 years.[5] Asthma is also a very common discharge diagnosis in children's hospitals, accounting for approximately 5.6% of all hospital admissions and more than 150,000 admissions each year in the United States alone.[5] The prevalence of asthma worldwide is highly variable, with greater than twentyfold differences in prevalence of symptoms encountered among centers located in various parts of the world.[6] The highest prevalence rates for asthma are found in the United Kingdom, Australia, New Zealand, and the Republic of Ireland; very low prevalence rates occur in eastern Europe, the Indian subcontinent, and China.[6] Race is a significant factor in determining prevalence and severity of asthma in children and young adults. African Americans are 4.1 times more likely to require treatment for asthma in the emergency department, two times more likely to be hospitalized for asthma, and 7.6 times more likely to die compared with white persons.[5] Socioeconomic status also has been shown to negatively correlate with asthma prevalence, morbidity, and mortality in the United States.[7]

Asthma prevalence has increased steadily during the past 27 years in the United States.[5] However, while the rate of nonurgent asthma-related outpatient visits continues to increase, emergency department visits and death rates have steadily declined during the past decade.[5]

The incidence of asthma-related respiratory failure requiring mechanical ventilation is difficult to determine because of variability in diagnostic criteria and reporting practices. Nonetheless, up to 36% of adult patients admitted to an inner-city medical ICU with near-fatal asthma require invasive mechanical ventilation.[8] This figure appears to be significantly lower for children, considering that only 22 (10.2%) of 237 patients treated for near-fatal asthma underwent mechanical ventilation during a 2-year period in the pediatric ICU (PICU) of a tertiary

children's hospital (A.T. Rotta, unpublished data), and that only 14 (8.6%) of 163 patients required intubation in another study.[9]

The majority of patients with asthma who experience respiratory failure or arrest do so during the first stages of therapy or prior to arrival in the emergency department.[9] Therefore early identification and close monitoring of patients at high risk for near-fatal asthma could be advantageous. High-risk patients often have a history of ICU admissions,[10] mechanical ventilation,[2,10] seizures or syncope during an attack,[11] $Paco_2$ greater than 45 torr,[2,10] attacks precipitated by food,[10] or a history of rapidly progressive and sudden respiratory deterioration.[1] These patients are likely to use more than two canisters of β-agonist metered-dose inhalers per month[12] and often are poorly compliant or are receiving insufficient steroid therapy.[13,14] Denial or failure to perceive the severity of an attack are factors frequently associated with near-fatal asthma.[15,16] Although unquestionably some patients at risk for near-fatal asthma simply ignore early warning signs and do not seek adequate therapy, a subgroup of patients actually lacks normal perception of disease severity. Some patients with near-fatal asthma exhibit reduced chemosensitivity to hypoxia and blunted perception of dyspnea.[17] Other patients have a decreased perceptual sensitivity of inspiratory muscle loads and display abnormal respiratory-related evoked potentials.[18]

Although many of these high-risk factors are commonly present in patients with near-fatal asthma, they fail to identify a significant number of cases. In one study, 33% of patients who died of asthma were judged to have a history of trivial or mild asthma, whereas 32% had never been admitted to the hospital with an asthma exacerbation.[1] Some of these patients may in fact have what likely represents a distinct clinical entity known as sudden asphyxial asthma, a condition marked by acute onset of severe airway obstruction and hypoxia that rapidly leads to cardiorespiratory arrest in patients known to have only mild asthma or no asthma history at all.[19,20]

Pathophysiology

Asthma is primarily an inflammatory disease and, as such, it is marked by highly redundant pathways and complex interactions among inflammatory cells, mediators, and the airway epithelium[21] (Figure 45-1). Functionally, asthma is characterized by variable airflow obstruction and airway hyperresponsiveness associated with airway inflammation. Pathologically, it is marked by mast cell degranulation, accumulation of eosinophils and CD4 lymphocytes, hypersecretion of mucus, thickening of the subepithelial collagen layer, and smooth muscle hypertrophy and hyperplasia.[22]

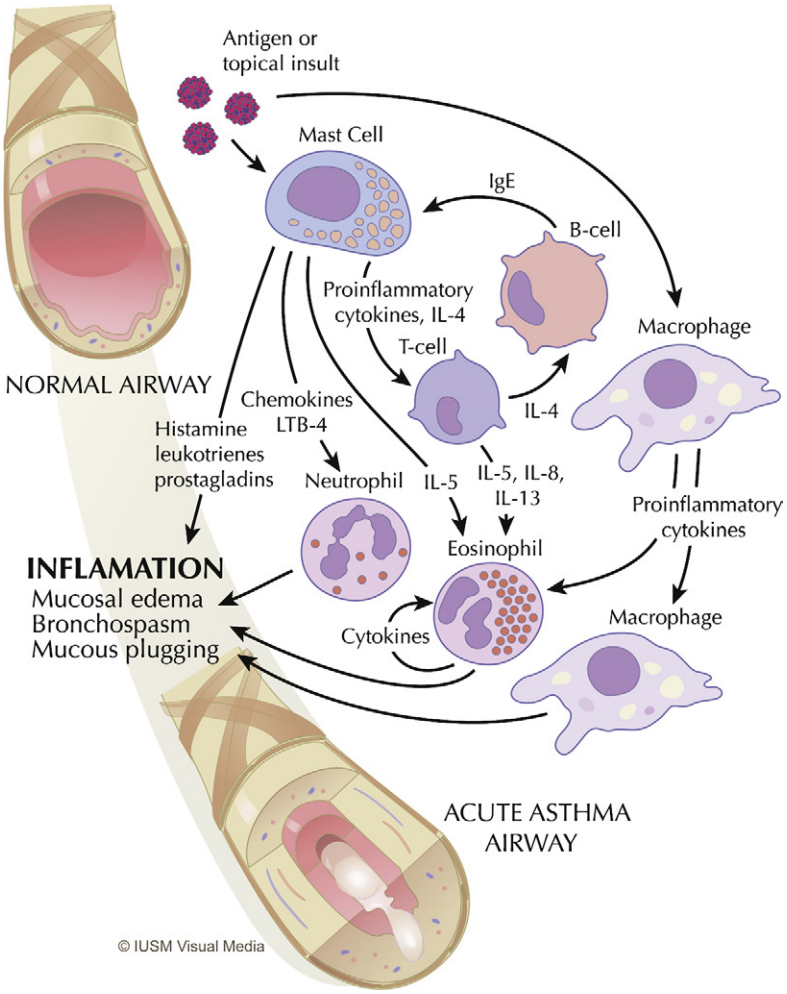

Figure 45–1. Cellular and humoral mediators that lead to mucosal edema, bronchospasm, and mucous plugging in patients with acute asthma. *IL*, Interleukin; *LTB-4*, leukotriene B-4. *(Modified with permission from Indiana University School of Medicine Visual Arts Media.)*

Mast cells, eosinophils, macrophages, and T lymphocytes are central to the derangements that occur during an acute attack (see Figure 45-1). The usual cascade begins with the activation and degranulation of mast cells in response to allergens or topical insults. The mast cells in turn promote activation of T lymphocytes by presenting these cells to the allergenic particles. The inflammatory process is then amplified by T-lymphocyte release of cytokines and chemokines. Increasing evidence exists that airway inflammation in asthma is the result of T-lymphocyte activation with the production of T_H2 cytokines, such as interleukin (IL)-4, IL-5, IL-8, and IL-13.[23] The presence of these T_H2 cytokines leads to further augmentation of the inflammatory process through overexuberant production of immunoglobulin E (IgE) by B cells, stimulation of airway epithelial cells, and eosinophil chemotaxis. IgE stimulates mast cells to release leukotrienes, whereas interleukins (particularly IL-5) promote maturation and migration of activated eosinophils into the airway.[24] This highly inflammatory milieu results in stimulation of airway epithelial cells and continued augmentation of the inflammatory process by further release of leukotrienes, prostaglandins, nitric oxide, adhesion molecules, and platelet-activating factor. This process results in overproduction of mucus and epithelial cell destruction that lead to airway plugging and denudation of the airway surface. Epithelial denudation is known to expose nerve endings, resulting in hyperirritable airways[25] that become more susceptible to spasm and obstruction when challenged by subsequent exposure to allergens,[26] inhaled irritants such as cigarette smoke and pollution,[27] respiratory tract infections,[28] psychological stress,[29] and exercise,[30] among other insults. Mucus itself is pathological in content,[31,32] and mucus hypersecretion has been underappreciated as a cause of respiratory failure in persons with severe asthma, when in fact strong evidence exists that it may be a principal cause.[31-33]

Inflammation-mediated edema, mucus hypersecretion, airway plugging, and bronchospasm lead to the severe airway obstruction seen in patients with status asthmaticus and near-fatal asthma. The resulting obstruction and increased airway resistance create an impediment for inspiratory and expiratory gas flow, which leads to deranged pulmonary mechanics and increased lung volumes.[32]

Airway plugging can result in ventilation/perfusion mismatching and increased oxygen requirements. Hypoxemia is common in patients with a severe asthma attack, but it is generally easily corrected with supplemental oxygen[34] and is only weakly correlated with pulmonary function abnormalities.[35] More frequently, airway plugging and obstruction lead to regional alveolar hyperinflation associated with reduced perfusion, resulting in a significantly increased pulmonary dead space. Most patients with this condition exhibit an increased respiratory rate in attempt to achieve a higher minute volume and compensate for the ventilation abnormality. Unfortunately, in patients with more severe disease, airway obstruction also results in significant prolongation of expiratory time, which, coupled with initiation of inspiration prior to completion of the previous exhalation, leads to dynamic hyperinflation, gas trapping, and the development of abnormally high lung volumes[36] (Figure 45-2).

The higher lung volumes that result from incomplete alveolar emptying and dynamic hyperinflation serve as an adaptation mechanism to allow for higher expiratory flows than would have been possible at lower, more physiologic lung volumes. This higher expiratory flow is accomplished, however, at a high energy cost. Expiration becomes an active process, and the use of accessory muscles is required to overcome the high resistances to airflow both during inspiration and exhalation.[37] During a severe attack, inspiratory transpulmonary pressures in excess of 50 cm H_2O may be generated, compared with approximately 5 cm H_2O during normal breathing.[38] The increased muscle work is accompanied by an increase in blood flow to the diaphragm, but this flow often is insufficient to meet the much greater metabolic demands.[39] Failure to promptly relieve the airway obstruction and reduce the work of breathing eventually leads to respiratory muscle fatigue, inadequate ventilation, and respiratory failure.

States of advanced airway obstruction and dynamic hyperinflation typical of severe asthma attacks have a significant impact on the circulatory system. The highly negative intrapleural pressures generated by spontaneously breathing patients during inspiration favor transcapillary edema fluid movement into the air spaces.[37] They also cause a phasic increase in left ventricular afterload and a decrease in cardiac output[40] that is clinically manifested as pulsus paradoxus.[41] Right ventricular afterload may be increased during severe asthma as a result of pulmonary vasoconstriction related to hypoxia and acidosis. A state of increased pulmonary vascular resistance resulting from dynamic hyperinflation also can increase right ventricular afterload, further affecting cardiac output.[41-43]

Clinical Assessment

History

The child with an asthma exacerbation usually presents with complaints of difficulty breathing and shortness of breath. The presence of these complaints in a child known to have had previous asthma exacerbations is highly suggestive of the diagnosis. A significant percentage of children have a history of a coexisting viral upper respiratory infection, whereas some describe exposure to known allergic triggers. Circumstances permitting, time should be taken to inquire about the presence of high-risk factors (Box 45-1) for near-fatal asthma and the adequacy of maintenance intercrisis therapy.

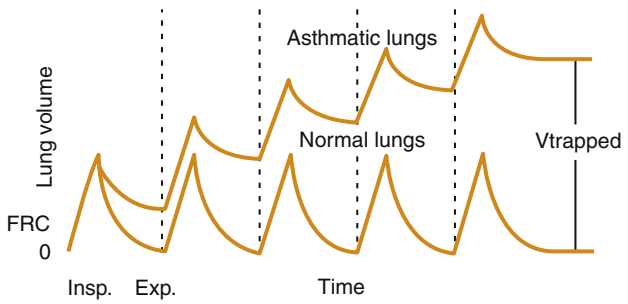

Figure 45–2. Mechanics of dynamic pulmonary hyperinflation in the setting of severe airflow obstruction. The next inspiration begins before complete exhalation, leading to gas trapping and increased end-expiratory lung volume. *Exp.,* Expiration; *FRC,* functional residual capacity; *Insp.,* inspiration; *Vtrapped,* volume of trapped gas above FRC. *(From Levy BD, Kitch B, Fanta CH: Medical and ventilatory management of status asthmaticus,* Intensive Care Med *24:105-117, 1998.)*

Box 45–1 Risk Factors for Near-Fatal Asthma.

Medical Factors

Previous asthma attack with:

- Admission to intensive care unit
- Respiratory failure and mechanical ventilation
- Seizures or syncope
- $Paco_2$ >45 torr
- High consumption (>2 canisters per month) of β-agonist metered-dose inhalers
- Underuse of corticosteroid therapy

Psychosocial Factors

- Denial of or failure to perceive severity of illness
- Associated depression or other psychiatric disorder
- Noncompliance
- Dysfunctional family unit
- Inner-city residents

Ethnic Factors

- Nonwhite children (black, Hispanic, other)

Data from Werner HA: Status asthmaticus in children: a review, *Chest* 119:1913-1929, 2001.

Table 45–1 Clinical Asthma Evaluation Score*

	0	1	2
Pao_2 (torr) *or*	70–100 in 21% O_2	<70 in 21% O_2	<70 in 40% O_2
Cyanosis	None	In 21% O_2	In 40% O_2
Inspiratory breath sounds	Normal	Unequal	Decreased to absent
Accessory muscles used	None	Moderate	Maximal
Expiratory wheezing	None	Moderate	Marked
Cerebral function	Normal	Depressed or agitated	Coma

*A score of 5 or more is thought to be indicative of impending respiratory failure. A score of 7 or more with $Paco_2$ >65 torr indicates existing respiratory failure.

Data from Wood DW, Downes JJ, Lecks HI: A clinical scoring system for the diagnosis of respiratory failure. Preliminary report on childhood status asthmaticus, *Am J Dis Child* 123:227-228, 1972.

Physical Examination

Children with severe forms of acute asthma commonly present with tachypnea, diaphoresis, increased use of accessory muscles, and nasal flaring. Sick nonverbal children may appear anxious, agitated, or simply unable to be distracted from the task of breathing. Older children often assume a tripod sitting position and may voice a sensation of impending doom. Speech flow is truncated by the need to inspire. The presence of intercostal, subcostal, and suprasternal retractions, nasal flaring, inability to speak in sentences, and agitation are signs of impending respiratory failure. Evolution or persistence of these signs is followed by slower labored breathing, confusion or obtundation, and respiratory arrest.

Wheezing, which is a common clinical finding in patients with acute asthma exacerbations, is the audible manifestation of the transmitted turbulence to airflow in the intrathoracic intrapulmonary airways. Wheezing may be predominantly expiratory as a result of the dynamic phasic compression of conducting airways, but it also can be biphasic. Wheezing in persons with severe asthma usually is symmetrical. An asymmetrical distribution suggests regional mucous plugging, atelectasis, pneumothorax, or the presence of a foreign body. The degree of wheezing correlates poorly with disease severity,[44] because wheezes are heard only in the presence of airflow. As such, a patient with severe airway obstruction and very limited airflow may have a silent chest upon arrival at the emergency department, but loud wheezes may develop after effective therapy is instituted. Likewise, in a patient with loud wheezes that continue to worsen, a silent chest may develop as a prelude to respiratory failure.

An objective assessment of disease severity is important in evaluating a patient's response to therapy. Wood and colleagues[45] developed a practical clinical asthma score composed of five variables with three different grades that allows for semiquantitative assessment of disease severity (Table 45-1). This clinical asthma score has been shown to correlate well with the need for prolonged bronchodilator therapy and hospitalization.[46] However, although clinical asthma scores seem to be useful for assessing the severity of an attack, they are not as effective in prospectively identifying patients who require prolonged hospitalization or in whom complications and subsequent disability develop.[47,48]

A less frequently used but more objective method of assessing disease severity and progression in patients with severe asthma is measurement of the pulsus paradoxus. Originally described by Adolf Kussmaul[49] in a patient with constrictive pericarditis, pulsus paradoxus also is observed in conditions in which pleural pressure swings are exaggerated, such as status asthmaticus and near-fatal asthma. The simplest definition of pulsus paradoxus is an exaggeration of the physiologic inspiratory decrease in systolic blood pressure[50] (Figure 45-3). It has been suggested that the term pulsus paradoxus is inappropriate to describe this phenomenon,[51] because an accentuated inspiratory decrease in systolic pressure in the same direction as the normally occurring change cannot be described as a paradox. However, the true paradox described by Kussmaul[49] was "the presence of a pulse slight and irregular, disappearing during inspiration and returning upon expiration despite the continued presence of the cardiac impulse during both respiratory phases."[50] Several mechanisms have been implicated in the occurrence of pulsus paradoxus in persons with asthma, and it is likely that various mechanisms contribute differently depending on the adequacy of intravascular volume, the magnitude of pleural pressure swings, the degree of pulmonary hyperinflation, and the state of cardiac contractility. These mechanisms include increased left ventricular afterload from highly negative intrapleural pressure[52]; decreased left ventricular preload as a result of inspiratory blood pooling in the pulmonary vasculature[53]; impaired left ventricular diastolic filling caused by a leftward shift of the interventricular septum resulting from increased venous return to the right heart[54]; constraint of cardiac filling because of longitudinal inspiratory deformation of the pericardium[41]; and increased right ventricular afterload with decreased filling of the left ventricle as a result of hyperinflation, acidosis, and hypoxia.[55] The pulsus paradoxus can be measured easily in a patient who is spontaneously breathing by transducing pressure signals from an indwelling arterial catheter or by using a manual sphygmomanometer. In the

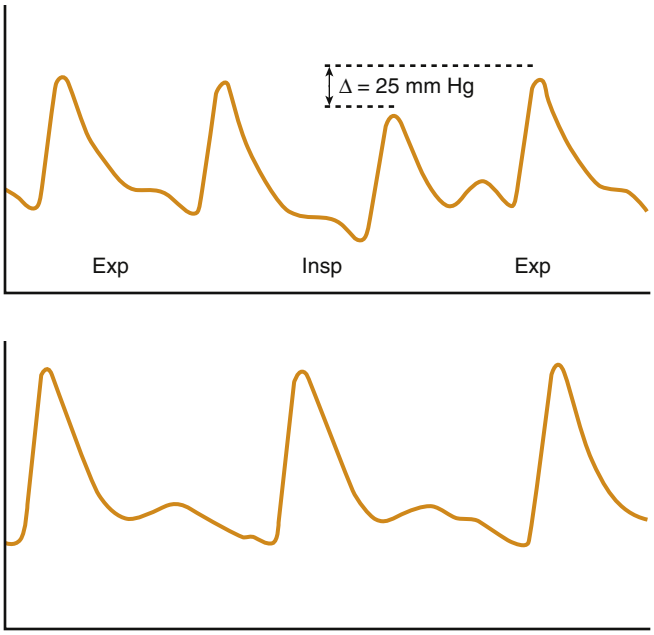

Figure 45–3. Pressure recording from a radial artery catheter of a spontaneously breathing patient with airway obstruction. *Upper panel:* Abnormally high pulsus paradoxus of 25 mm Hg is measured as the difference (Δ) in systolic blood pressure between expiration (Exp) and inspiration (Insp). *Lower panel:* Normal slight physiologic variation of the systolic blood pressure as a function of the respiratory cycle 12 hours after onset of treatment. *(Modified with permission from Indiana University School of Medicine Visual Arts Media.)*

latter technique, the cuff is inflated 20 mm Hg above the systolic pressure and then deflated until the first Korotkoff sounds are heard (systolic blood pressure). Initially, Korotkoff sounds are heard only during expiration. The cuff is then carefully deflated until the point where the sounds are heard equally during both inspiration and expiration. The difference between the highest systolic pressure and the pressure at which all Korotkoff sounds are heard is the magnitude of the pulsus paradoxus. During normal breathing, this difference is less than 5 mm Hg, but it is generally greater than 10 mm Hg during acute asthma exacerbations and greater than 20 mm Hg in patients with more severe disease.[56] Changes in the magnitude of pulsus paradoxus during the course of therapy are good indicators of disease severity and clinical response to treatment.[41,56]

Patients with status asthmaticus frequently have a palpable liver with normal liver span on physical examination. This sign is more pronounced in patients with significant hyperinflation and is explained by caudal displacement of the liver by the flattened diaphragm.

Radiography

Chest radiography is not routinely indicated in spontaneously breathing patients known to have asthma. However, it is a valuable diagnostic tool in patients suspected of having a pneumothorax or pneumomediastinum, pneumonia, or clinically important atelectasis and in children presenting with a first episode of wheezing in whom anatomic abnormalities (such as vascular rings or a right-sided aortic arch) or foreign bodies are suspected. One should consider obtaining a chest radiograph in patients who are sick enough to require monitoring and treatment in the ICU to exclude the possibility of unsuspected extrapulmonary air and airspace disease.

Laboratory Data

Arterial Blood Gas Analysis

Arterial blood gas measurements provide objective information on the adequacy of ventilation and oxygenation of the patient with asthma. The typical blood gas abnormality encountered in the early phase of asthma is relative hypoxemia with hypocapnia ($Paco_2$ <35 torr), reflecting hyperventilation.[57] With worsening of airway obstruction, $Paco_2$ measurements return to the normal range of approximately 40 torr. However, this "normal" $Paco_2$ should not be viewed as reassuring when taken in the context of prolonged expiratory time, tachypnea, and accessory muscle use.[58] In fact, $Paco_2$ greater than 40 torr in a patient with status asthmaticus should be interpreted as a sign of evolving respiratory muscle fatigue and warrants close clinical observation. Sicker patients often exhibit a mixed respiratory and metabolic acidosis.[59] Lactic acidosis is frequently encountered in these patients and is thought to represent exaggerated lactate production by the respiratory muscles and tissue hypoxia.[60]

The decision of whether to intubate a child with asthma should not be made on the basis of arterial blood gas measurements but on the basis of the overall clinical status. As such, routine arterial blood gas determinations are not a critical component of the evaluation of a spontaneously breathing child with status asthmaticus. In contrast, children with asthma undergoing mechanical ventilation require frequent blood gas measurements to monitor disease progression and the adequacy of ventilatory support.

Electrolytes and Complete Blood Cell Count

Routine chemistry results and blood cell counts generally are not revealing in patients with status asthmaticus. Children who present with a protracted asthma attack may have evidence of dehydration with elevated blood urea nitrogen as a result of decreased oral fluid intake and increased insensible water losses. Patients undergoing repeated treatments with nebulized or intravenous (IV) β-agonist agents might show evidence of hypokalemia from the potassium shift to the intracellular space. The blood cell count usually is normal, although some patients who are atopic may exhibit elevated eosinophil counts. The presence of leukocytosis in some patients does not necessarily indicate infection and likely is related to adaptive stress or the administration of exogenous corticosteroid agents.

Muscle Enzymes

At least one third of patients with acute severe asthma exhibit an elevated plasma creatine kinase (CK) level.[61] Although such elevations seem to be more pronounced in patients with marked acidemia or in those presenting with more severe respiratory insufficiency, a convincing correlation between disease severity and CK elevation has not been established.[61] Myoglobin, a heme protein present in skeletal and cardiac muscle, is often also elevated in patients with near-fatal asthma.[61] Elevations of CK-myocardial bound (CK-MB) isoenzyme develop in some patients with near-fatal asthma, suggesting a possible

myocardial injury. This scenario certainly is plausible, considering that many patients are hypoxemic, acidotic, have high myocardial energy demand, and are receiving medications with adverse cardiac effects. However, plasma myoglobin and CK-MB elevations cannot be solely attributed to myocardial injury because the lungs and respiratory muscles are also known sources of these substances.[62] Cardiospecific troponin T is a very sensitive and specific marker of myocardial cell damage[63] and should be used preferentially to address the question of cardiomyocyte involvement in patients with severe asthma.

Electrocardiography

Patients with status asthmaticus or near-fatal asthma with significant airway obstruction and hyperinflation may exhibit a change in the mean frontal P-wave vector. A P-wave axis greater than 60 degrees has been associated with hyperinflation in both pediatric and adult patients with airway obstruction and is thought to represent positional atrial changes caused by inferior displacement of the diaphragm.[64]

Twelve-lead electrocardiography and continuous cardiac monitoring are valuable tools in the care of patients with near-fatal asthma in the ICU environment. These patients usually receive high doses of β-agonist drugs and may show evidence of hypokalemia (low-voltage T waves) or cardiac arrhythmias.[65,66] The already increased myocardial energy demand resulting from airway obstruction is compounded by the chronotropic and vasodilatory effects inherent to β-agonist drugs and may lead to myocardial ischemia, particularly in adult patients with restricted coronary perfusion. Pediatric patients also may exhibit electrocardiographic (ECG) and enzymatic evidence of myocardial ischemia, particularly during treatment with intravenously administered isoproterenol.[67] However, despite the fact that a study reported that a high percentage (66%) of patients exhibited nonspecific ST segment changes or other criteria suggestive of ischemia, these changes were not well correlated with initiation of terbutaline therapy or elevations in cardiac troponin T.[68]

Spirometry

Measurement of peak expiratory flow rates can be used to estimate the degree of airway obstruction and response to therapy in patients presenting to the emergency department with an acute asthma attack. Use of this simple technique is less ubiquitous to the pediatric ICU environment because sick patients with severe respiratory distress simply may be unable to perform an adequate forced expiratory maneuver. Measurements also may not be reliable in younger patients who are incapable of coordinating a rapid forced expiratory effort.

Treatment

Initial Management in the Emergency Department

Pediatric patients with mild acute asthma exacerbations generally are treated in the emergency department with one or more doses of an inhaled β-agonist, such as albuterol (salbutamol). Most of these patients also should receive a systemic-acting corticosteroid, such as prednisone, and generally are sent home to complete a 3- to 5-day course of therapy. Patients with mild disease generally respond well to initial treatment and do not require the attention of a pediatric intensivist.

Patients with moderate or severe acute asthma attacks require aggressive treatment from the outset, including the prehospital setting. Because most patients with moderate or severe attacks have enough intrapulmonary shunt to result in clinically measurable hypoxemia, supplemental oxygen therapy should be initiated in patients with an oxygen saturation measured by pulse oximetry (Spo_2) of lower than 91%. It should be obvious that use of supplemental oxygen will cause an increase in Spo_2 but will have no impact on ventilation. Therefore one must not incorrectly assume that ventilation is adequate in a patient with normal Spo_2 during administration of supplemental oxygen therapy.

Nebulized β-agonist agents, such as albuterol (salbutamol), are the most commonly used first-line therapy in the emergency department. The usual albuterol dose ranges between 0.05 and 0.15 mg/kg, diluted with 1 or 2 mL of normal saline solution. However, from a practical standpoint, patients weighing 20 kg or more usually are administered 5-mg doses, whereas patients weighing less than 20 kg receive 2.5-mg doses. Albuterol doses are repeated every 20 minutes during the first hour, with the need for additional doses dictated by clinical response.

Patients with moderate or severe acute asthma also should receive a dose of systemic corticosteroid in the emergency department, which usually is administered prior to the second dose of albuterol. Prednisone (2 mg/kg) can be administered orally and is generally well tolerated. Oral prednisone is superior to inhaled fluticasone in children with severe asthma as evidenced by greater improvement in pulmonary function and lower hospitalization rates.[69] The role of corticosteroid drugs in reversing an acute asthma attack in the emergency department has been the subject of debate, considering that these drugs require at least 4 to 6 hours for peak effects to be manifested.[70] However, regardless of considerations about onset of action, acute suppression of inflammation is a cornerstone of acute asthma treatment and should be initiated as early as possible. Sicker patients with severe asthma exacerbations, those unable to tolerate oral medication because of respiratory distress or emesis, or those with a history of nausea during intensive β-agonist therapy should be given parenteral corticosteroid drugs such as methylprednisolone (2 mg/kg administered intravenously, followed by 0.5 to 1 mg/kg/dose administered intravenously every 6 hours).

Inhaled or nebulized anticholinergic agents such as ipratropium bromide are now considered an important adjunct in the treatment of persons with moderate and severe asthma exacerbations in the emergency department. In patients treated with one dose of a corticosteroid, use of ipratropium bromide (500 μg/2.5 mL) in conjunction with the second and third albuterol (salbutamol) doses has been associated with greater clinical improvement[71] and reduced hospitalization rates compared with corticosteroid and albuterol (salbutamol) alone.[72]

Admission Criteria

The majority of patients with an acute asthma exacerbation respond to treatment in the emergency department and are discharged home. Among patients whose symptoms persist despite initial treatment, most can be safely managed in the

general pediatric inpatient ward. Indications for hospitalization after treatment in the emergency department are loosely defined but may include (1) an inadequate response to three or four aerosol treatments; (2) relapse within 1 hour of receiving treatment with aerosols and steroids; (3) persistent Spo_2 measurements of less than 91% in room air; (4) the need for oxygen therapy; (5) a significant reduction in peak expiratory flow rate; (6) having unreliable family support or being unable to comply with outpatient treatment; and (7) multiple visits for the same episode.[73,74] Patients who require higher levels of monitoring or more invasive and aggressive treatment or who deteriorate during hospitalization in the general pediatric ward should be admitted to the PICU.

Management in the Intensive Care Unit

General

Patients with near-fatal asthma who are admitted to the ICU represent a heterogeneous group and, as such, require different levels of monitoring, technology, and treatments. However, all patients who are sick enough to warrant admission to the ICU should be attached to a monitor capable of displaying continuous ECG tracing, respiratory rate, noninvasive blood pressures, and Spo_2. Sicker patients who require blood samples to be obtained frequently or who require monitoring of pulsus paradoxus will benefit from an indwelling arterial catheter. Patients in respiratory failure requiring mechanical ventilation should have adequate central venous access and a Foley catheter in addition to the more basic instrumentation.

Oxygen

Sick patients with asthma are likely to exhibit hypoxemia as a result of intrapulmonary shunts caused by mucus plugging and atelectasis. Treatment with β-agonist agents also can contribute to hypoxemia by abolishing regional pulmonary hypoxic vasoconstriction and increasing intrapulmonary shunt.[75,76] Therefore humidified oxygen should be offered both as a carrier gas for nebulizations and continuously between treatments.[77] Supplemental oxygen can be safely incorporated into the treatment algorithm because, unlike in some adult patients with severe chronic obstructive pulmonary disease[78] or asthma,[79] no evidence exists to suggest that supplemental oxygen suppresses the respiratory drive in children with near-fatal asthma.

Fluids

Patients with near-fatal asthma usually present in a state of decreased total body water because of decreased oral fluid intake and increased insensible water losses. Therefore most patients require some degree of volume expansion. This need should be carefully balanced with the need to avoid overhydration because of the propensity for transcapillary fluid migration and alveolar flooding that is exhibited by some patients with large swings in intrathoracic pressures. The need for rapid fluid expansion often becomes obvious shortly after intubation of patients with low intravascular volumes who are receiving IV β-agonist agents.

Corticosteroids

Corticosteroid drugs play a central role in the treatment of patients with status asthmaticus and near-fatal asthma, considering that these conditions are predominantly inflammatory in nature. Glucocorticosteroid agents modulate airway inflammation by a number of mechanisms, including direct interaction with cytosolic receptors and glucocorticosteroid response elements in gene promoters and indirect effects on binding of transcription factors, such as nuclear factor–κB, and on other cell signaling processes, such as posttranscriptional events.[80] Gene products suppressed by glucocorticosteroid agents include a wide range of cytokines (IL-1, IL-2, IL-3, IL-4, IL-5, IL-6, IL-7, IL-8, IL-11, IL-12, IL-13, tumor necrosis factor-α, and granulocyte-macrophage colony-stimulating factor), adhesion molecules (intracellular adhesion molecule-1 and vascular cell adhesion molecule-1), and inducible enzymes, including NO synthase and cyclooxygenase-2.[81] Transcription of other genes, such as lipocortin-1 and the β_2-adrenergic receptor, may be enhanced.[81] Glucocorticosteroid agents also decrease airway mucus production, reduce inflammatory cell infiltration and activation, and attenuate capillary permeability.[82-85]

In children with status asthmaticus or near-fatal asthma, glucocorticosteroid drugs should be administered by the IV route. The oral route can be used in selected cases, but inhaled glucocorticosteroid drugs play no role in the treatment of the sick hospitalized patient.[21,69] The most common agent used in the United States is methylprednisolone because of its wide availability as an IV preparation and lack of mineralocorticoid effects. The usual dose of methylprednisolone is 0.5 to 1 mg/kg/dose, administered intravenously every 6 hours. Hydrocortisone, an agent with both glucocorticoid and mineralocorticoid activity, can be used as an alternative at doses of 2 to 4 mg/kg/dose, administered intravenously every 6 hours. Short courses of steroids usually are well tolerated without significant adverse effects.[84] However, hypertension, hyperglycemia, mood disorders, and serious viral infections, such as fatal varicella, have been reported in previously well patients with asthma who have received glucocorticosteroid drugs.[84,86,87] Duration of corticosteroid therapy is dictated by the severity of illness and the clinical response. Once initiated, treatment in patients with status asthmaticus or near-fatal asthma is generally continued for 5 to 7 days. Longer treatment courses necessitate gradual weaning of the drug to decrease the chances of symptomatic adrenal insufficiency or relapse. Prophylaxis with an H_2 blocker should be considered because of the possibility of steroid-associated gastritis and gastric perforation.[88]

β-Agonists

The β-agonist properties of the sympathomimetic agents cause bronchial smooth muscle relaxation and hence bronchodilatation. These agents also can increase diaphragmatic contractility, enhance mucociliary clearance, and inhibit bronchospastic mediators from mast cells.[89] Therefore β-agonists, along with systemic corticosteroids, are the mainstay of pharmacotherapy in persons with near-fatal asthma. β_2-receptor selectivity is desirable to avoid adverse effects of nonselective α- and β_1-adrenergic receptor stimulation. However, despite β_2 selectivity, cardiovascular adverse effects remain a dose-limiting factor. The relative potency of various agents

for the β_2 receptor is as follows: isoproterenol > fenoterol > albuterol > terbutaline > isoetharine > metaproterenol.[90] Of these agents, only albuterol and terbutaline are widely used in clinical practice, with some centers still using isoproterenol in selected occasions.

Once bound to the β-adrenergic receptor, β-agonists activate adenyl cyclase, resulting in increased intracellular cyclic adenosine monophosphate (cAMP) levels, which leads to bronchial and vascular smooth muscle relaxation. Dose-response curves demonstrate that large dose increases fail to enhance bronchodilation significantly; however, as the degree of bronchial constriction increases, the bronchodilation dose-response curve shifts to the right, indicating the need for a higher dose to achieve the desired response.[90]

In persons with near-fatal asthma, parenteral and aerosol routes of administration are used exclusively. Traditional therapy for persons with acute asthma previously included subcutaneous doses of epinephrine, but epinephrine is no longer widely used because of the development of newer, more selective β-agonist agents with longer duration of action and fewer adverse effects.

The most frequent untoward adverse effects of β-agonist agents are skeletal muscle tremor, nausea, and tachycardia. These adverse effects are common to both nonselective and selective β-agonist drugs administered by IV and inhalational routes. Other cardiovascular adverse effects include blood pressure instability (predominantly diastolic hypotension) and cardiac dysrhythmias.[91,92] Myocardial ischemia has been well documented as a complication of IV isoproterenol administration to children with near-fatal asthma.[67,93] However, continuous IV infusions of terbutaline appear to be safe and are not associated with significant cardiotoxicity.[68] Prolongations of the QTc interval and hypokalemia have been observed during IV infusions of β-agonist drugs.[94] Hypokalemia occurs in the setting of relatively stable total body potassium and is the result of intracellular potassium shifting that results, at least in part, from an increased number of sodium-potassium pumps and not from augmented potassium elimination.[95] Therefore supraphysiologic potassium supplementation is rarely necessary. A less frequently recognized adverse effect of β-agonist agents is hypoxemia, which is likely related to decreased regional hypoxic pulmonary vasoconstriction in areas of atelectasis and the resultant increased intrapulmonary shunt.[75,76]

Albuterol (Salbutamol)

Albuterol is the most β_2-specific aerosol agent available in the United States. It usually is administered every 20 minutes during the initial phase of treatment at a dose of 0.05 to 0.15 mg/kg. The optimal dose and frequency of albuterol are controversial because less than 1% of the nebulized drug is deposited in the lung.[96] Moreover, spontaneous tidal volume, breathing pattern, and technique are unpredictable yet major determinants of drug delivery. After the initial series of three albuterol treatments, continuous albuterol nebulization should be started for patients who require nebulization treatments more frequently than every 1 hour.

Continuous albuterol nebulization appears to be superior to repeated intermittent dosing and has not been shown to cause significant cardiotoxicity.[97-99] A small prospective randomized study in children with near-fatal asthma and impending respiratory failure indicated that children treated with continuous albuterol nebulization had more rapid clinical improvement and shorter hospitalizations compared with children treated with intermittent albuterol doses.[98] Continuous administration of albuterol also was associated with more efficient allocation of respiratory therapists' time[98] and could offer the added advantage of more hours of uninterrupted sleep to patients who often are already exhausted.[100] The usual dose of continuously administered albuterol ranges between 0.15 and 0.45 mg/kg/h, with a maximum dose of 20 mg/h. Higher doses of albuterol have been used in patients who are unresponsive to standard treatment.[51] However, we do not support this practice, because the intensification of adverse effects can outweigh any small incremental gain in bronchodilatation.

The availability of levalbuterol has generated some controversy. Albuterol is a 50:50 mixture of R-albuterol (levalbuterol), the active enantiomer that causes bronchodilation, and S-albuterol, which was thought to be inactive in humans. The U.S. Food and Drug Administration has approved levalbuterol, the pure R-isomer, as a preservative-free nebulizer solution.[101] The purported advantage of using levalbuterol over albuterol stems from the fact that S-albuterol may not be completely inert and has a longer elimination half-life than R-albuterol.[102,103] However, the notion that S-albuterol is not inert and that it is capable of clinically significant adverse effects is not universally accepted.[104-106] A large randomized controlled trial of levalbuterol versus racemic albuterol in children with asthma demonstrated a decreased rate of hospitalization in patients treated with levalbuterol. However, this study had methodological problems, as the primary outcome variable (rate of hospital admission) was left to the discretion of the treating physicians and none of the secondary outcome variables were significantly different between treatment groups once the patients had been admitted to the hospital.[107] More recent randomized clinical studies in children with asthma failed to show definitive evidence that levalbuterol is superior to a regular racemic albuterol.[108,109] Furthermore, although the cost of levalbuterol has decreased significantly in the past few years, this drug continues to be more expensive than albuterol (C. A. Thomas, PharmD, Riley Hospital for Children, personal communication, 2011). Considering the lower cost of albuterol and the paucity of clinical evidence supporting the superiority of levalbuterol, we continue to favor albuterol as the routine bronchodilator of choice in children with near-fatal asthma.

Intravenously administered albuterol is not available in the United States. However, the efficacy of albuterol infusions in patients with severe asthma has been well established in countries where the IV preparation is available.[110-112]

Terbutaline

Terbutaline is a relatively selective β_2-agonist with a mechanism of action that is similar to that of albuterol. It is the most commonly used parenteral β-agonist in the United States and is available for nebulization, subcutaneous injection, and IV use. Because of its lower β_1-receptor affinity, subcutaneous administration of terbutaline has largely supplanted the use of epinephrine in persons with severe acute asthma. The use of subcutaneous terbutaline is limited in the PICU environment; it is reserved for patients with acute worsening of the respiratory status who do not have vascular access and in whom access cannot be easily obtained. Subcutaneous terbutaline is more commonly used in the acute management of sick patients in the emergency department and in the prehospital

setting. The usual subcutaneous terbutaline dose is 0.01 mg/kg/dose (maximum 0.25 mg) subcutaneously every 20 minutes for three doses, as necessary.

Terbutaline is more commonly used in the ICU environment through the IV route. This therapy is indicated for patients with near-fatal asthma who fail to improve or show signs of deterioration during treatment with nebulized β_2-agonists, ipratropium bromide, and steroids. The usual IV terbutaline doses are 0.1 to 10 μg/kg/min as a continuous infusion,[91] prepared in 0.9% normal saline solution or D_5W. In our clinical experience, however, most patients are started on a dose of 1 μg/kg/min and the dose is titrated to effect, with doses higher than 4 μg/kg/min rarely necessary. Patients receiving doses lower than 1 μg/kg/min can be given a loading dose of 10 μg/kg over 10 minutes to accelerate the onset of action.

Anticholinergic Agents

Anticholinergic agents have become an important part of the treatment of children with severe acute asthma. The prototypical anticholinergic agent used in treating patients with asthma is ipratropium bromide, a quaternary ammonium compound formed by the introduction of an isopropyl group to the N atom of atropine. Unlike atropine (a tertiary ammonium compound), ipratropium bromide does not cross the blood-brain barrier, thus preventing the occurrence of central anticholinergic adverse effects. Considering that bronchial smooth muscle tone is influenced by the parasympathetic tone, ipratropium bromide can produce bronchodilation by inhibition of cholinergic-mediated bronchospasm.[113] An unexpected but important property of ipratropium bromide is the lack of negative effect on ciliary bronchial epithelium, unlike the marked inhibition of ciliary beating and mucociliary clearance produced by atropine.[113]

Nebulized ipratropium bromide (250- to 500-μg doses) can be used every 20 minutes during the first hour in the emergency department. The recommended dose for continuation therapy is 250 to 500 μg, given every 6 hours. After inhalation, peak responses usually develop over 30 to 90 minutes, and clinical effects may persist for more than 4 hours.[113] Systemic effects are minimal because less than 1% of an inhaled dose of ipratropium bromide is absorbed into the circulation. However, extrapulmonary effects such as mydriasis and blurred vision have been reported as a result of topical ocular absorption of the drug.[114,115]

The addition of ipratropium bromide to nebulized albuterol in the treatment of bronchospasm makes pharmacological sense, because albuterol causes bronchodilatation by increasing cAMP levels, while the effect of ipratropium bromide is mediated by a decrease in cyclic guanosine monophosphate. The combined use of ipratropium bromide and nebulized albuterol in treating children with asthma who present to the emergency department has proved to be cost effective and reduces the rate of admission to the hospital.[71,72] However, the routine addition of repeated doses of nebulized ipratropium bromide to a standard regimen of β_2-agonist agents and systemic steroid drugs in hospitalized children with status asthmaticus does not appear to confer a significant benefit.[116,117] Considering the high safety profile of inhaled ipratropium bromide treatments, the benefits of its use in the emergency department, and the lack of data specific to the PICU population, we find it reasonable to administer ipratropium bromide along with standard therapy for critically ill patients with status asthmaticus until definitive evidence becomes available.

Magnesium Sulfate

Magnesium is a physiologic calcium antagonist that causes smooth muscle relaxation as a result of inhibition of calcium uptake. It has been known for more than 60 years that magnesium causes bronchorelaxation in patients with asthma,[118] but its incorporation as an adjunct in the treatment of patients with severe asthma has occurred only recently. Numerous reports, case series, and randomized controlled trials have suggested clinical improvement when asthmatic patients with severe airway obstruction receive IV magnesium sulfate infusions in the emergency department or ICU.[119,120] Magnesium appears to be as effective as albuterol when delivered by nebulization[121] and has been used successfully by some practitioners as a liquid vehicle for albuterol nebulization.[122]

The indication for IV magnesium sulfate in children with status asthmaticus or near-fatal asthma is still controversial because of the paucity of randomized controlled trials. Some studies suggest that magnesium sulfate infusions are associated with significant improvements in short-term pulmonary function,[123-126] whereas another study failed to show improvement in disease severity or a reduction in hospitalization rates.[127] The usual dose of magnesium sulfate in children with status asthmaticus or near-fatal asthma is 25 to 40 mg/kg/dose, intravenously, infused over 20 to 30 minutes.[126] The onset of clinical response is rapid (occurring in minutes) and is generally observed during the initial infusion. During the infusion patients should be carefully monitored for adverse effects, which include hypotension, nausea, and flushing. Serious toxicity involving cardiac arrhythmias, muscle weakness, areflexia, and respiratory depression has not been reported with the use of magnesium sulfate in persons with acute asthma, when used as directed. The IV infusion of magnesium sulfate under controlled conditions appears to be safe, and a subset of patients with status asthmaticus and near-fatal asthma clearly responds to this mode of therapy.[123-126] A systematic review of the published randomized controlled trials supports the use of magnesium sulfate in addition to β_2-agonist agents and systemic steroid drugs in the treatment of persons with severe acute asthma.[128]

Methylxanthine Agents

Methylxanthine agents, as the name implies, are substances formed by the methylation of xanthine, such as caffeine, theobromine, and theophylline. The water solubility of methylxanthine agents is very low but can be greatly enhanced by formation of complexes with a variety of compounds. Most notably, the combination of theophylline and ethylenediamine yields aminophylline, a water-soluble salt. A large number of methylxanthine derivatives have been developed, but only theophylline and aminophylline are relevant to the treatment of patients with asthma.

The exact molecular mechanism of theophylline-mediated bronchodilation is unclear but is thought to involve, at least in part, its action as a phosphodiesterase-4 inhibitor, reducing the degradation of cAMP, which in turn mediates

cellular responses that result in bronchial smooth muscle relaxation.[129] Other mechanisms of action have been proposed, including inhibition of phosphoinositide 3-kinase activity,[130] adenosine receptor antagonism,[131] increasing histone deacetylase activity,[132] stimulation of endogenous catecholamine release,[133] prostaglandin antagonism,[134] and alterations in intracellular calcium mobilization.[135] Theophylline is also known to cause inhibition of afferent neuronal activity,[136] thereby leading to inhibition of bronchospasm mediated by reflex activation of cholinergic pathways. Theophylline has antiinflammatory and immunomodulatory actions[137] and is known to augment diaphragmatic contractility and increase respiratory drive.[138]

The bronchodilator effects of theophylline in isolated human bronchial preparations in vitro occur at concentrations greater than 70 μmol/L, which is capable of inducing a 50% reversal of bronchoconstriction.[139] Such high local concentrations presumably would be achieved with plasma levels greater than 10 to 20 μg/mL.[140] In clinical practice, however, this range poses a difficult problem because of the narrow window between therapeutic levels and toxicity, which often overlap. The half-life of theophylline ranges from 3 to 7 hours.[141] Therefore theophylline is generally administered as a continuous IV infusion to avoid significant fluctuations in serum concentrations. Aminophylline is equivalent to 80% theophylline and also is administered by continuous IV infusion. When a decision is made to initiate therapy with theophylline or aminophylline, a loading dose is given to achieve serum levels between 10 and 20 μg/mL. Assuming a normal average volume of distribution, a 1 mg/kg dose of theophylline (1.25 mg/kg of aminophylline) raises the serum concentration by 2 μg/mL. The loading dose should be administered over 20 minutes and should be followed immediately by the continuous infusion of the drug. Empiric doses can be started for patients with normal hepatic and cardiac function as follows: infants younger than 6 months: 0.5 mg/kg/h; infants aged 6 months to 1 year: 0.85 to 1 mg/kg/h; children aged 1 to 9 years: 1 mg/kg/h; and children older than 9 years: 0.75 mg/kg/h. Patients with compromised hepatic and cardiovascular function should be started at a dose of 0.25 mg/kg/h. Obese patients should have doses calculated by ideal body weight to prevent toxicity. Serum drug levels should be monitored 30 to 60 minutes after the loading dose and frequently during the continuous infusion, considering that steady-state concentrations are not achieved until approximately five half-lives, which corresponds to 24 to 36 hours of infusion.

A number of studies in adults and children with acute asthma indicate that therapy with theophylline or aminophylline is of no clinical benefit.[142-144] More recently, randomized, placebo-controlled trials tested the efficacy of aminophylline[9] and theophylline[145] in children with near-fatal asthma in the ICU environment. Aminophylline treatment resulted in significantly improved physiologic outcomes, such as oxygenation and pulmonary function testing, but did not decrease ICU length of stay and was associated with adverse effects such as nausea and vomiting.[9] Theophylline was associated with faster clinical improvement, but it had no effect on PICU length of stay and led to a significantly higher frequency of vomiting compared with control subjects.[145]

Considering that the narrow therapeutic window (10 to 20 μg/mL) often overlaps the toxicity (>15 μg/mL), that there is questionable evidence of clinical efficacy, and that methylxanthine agents have been associated with serious adverse effects ranging from nausea, vomiting, and fever to dyskinesias, seizures, and death, enthusiasm for these agents has decreased significantly in the past decade. Although methylxanthine agents are still used as first-line agents in many parts of the world, in North America they have been reserved for occasional selected patients who fail to respond to maximal therapy with β-agonist agents, steroids, anticholinergic drugs, and other adjuncts.

Helium-Oxygen Mixtures

Helium is a biologically inert gas that is less dense than any other known gas except hydrogen and is about one seventh as dense as air. The medicinal application of helium and oxygen mixtures (heliox) in the treatment of asthma and extrathoracic airway obstruction has been known for approximately 7 decades.[146] Because of its low density, heliox reduces the Reynolds number. This effect is associated with a reduced likelihood of turbulent gas flow while facilitating laminar gas flow in the airways, thus decreasing the work of breathing in situations associated with high airway resistance.[147] Heliox provides a theoretical benefit to patients with obstructive lesions of the extrathoracic and intrathoracic airways. Several reports advocate the benefit of heliox in the management of children with extrathoracic airway obstruction.[147,148] The role of heliox in patients with asthma is less clear.

Research using heliox mixtures has demonstrated a greater percentage of lung particle retention and a greater delivery of albuterol from both metered-dose inhalers and nebulizers,[149,150] suggesting that one of the beneficial effects of heliox use in patients with asthma is improved deposition of aerosolized drugs. A recent study in children with moderate to severe asthma exacerbations showed that 70%/30% heliox-driven continuous nebulized albuterol treatments were associated with a greater degree of clinical improvement compared with oxygen-driven continuous nebulized albuterol.[149]

Heliox has been recommended by some persons as a useful adjunct in adult patients with severe asthma, both during spontaneous breathing and during mechanical ventilation.[151-154] Anecdotal reports suggest that heliox is associated with improvement in pulmonary function in children with acute asthma.[155,156] However, a small randomized crossover trial of heliox in spontaneously breathing patients with severe asthma failed to show improvement in pulmonary function or dyspnea scores.[157] Additionally, a systematic review of seven prospective, controlled trials in children and adults failed to provide support for the use of heliox in patients with moderate or severe acute asthma.[158] The paucity of well-executed, randomized, controlled studies makes it impossible to assess the therapeutic effect of heliox in children with asthma at this time. In addition, should heliox be beneficial in some patients, the duration of administration and optimal helium-oxygen mixture remain undetermined. Until more sound information emerges, heliox remains an unproved therapy for pediatric asthma, and its use should be restricted to individual attempts in selected patients with severe refractory near-fatal asthma who did not respond to more conventional treatments.[159] The need to use 80:20 or 70:30 helium-oxygen mixtures to take full advantage of the lower gas density properties may further thwart the use of heliox in sicker patients who exhibit significant hypoxemia.

Ketamine

Ketamine hydrochloride is a dissociative anesthetic agent available in a solution for IV or intramuscular administration. The term *dissociative anesthetic* is derived from the strong feeling of dissociation from the environment that is experienced by the subject to whom it is administered. After IV administration, a sensation of dissociation is generally experienced within 15 seconds, and unconsciousness becomes apparent after another 30 seconds. This reaction is followed by intense analgesia that lasts approximately 40 to 60 minutes and amnesia that may persist for up to 2 hours. Some patients, particularly older children, may experience a postanesthesia emergence reaction with confusion, agitation, and hallucinations. Usual ketamine doses do not significantly affect hypoxic or hypercarbic respiratory drive.[160] Pharyngeal and laryngeal reflexes are maintained, and although the cough reflex is somewhat depressed, airway obstruction does not normally occur. Aside from its anesthetic properties, ketamine exerts a number of other effects, including sialorrhea. It increases airway secretions, cardiac output, heart rate, blood pressure, metabolic rate, cerebral blood flow, and intracranial pressure.[161] Pulmonary vascular resistance is not altered, and hypoxic pulmonary vasoconstriction is preserved. Ketamine inhibits bronchospasm and lowers airway resistance, presumably through blockage of *N*-methyl-D-aspartate receptors in airway smooth muscle.[162] The bronchodilatory effect of ketamine makes it an attractive agent in patients with asthma who require sedation and anesthesia for intubation or mechanical ventilation.[163,164] However, the bronchodilatory effects of ketamine are often obliterated by the significant observed increase in airway secretions and sialorrhea.

Some controversy exists regarding the use of ketamine in nonintubated patients with near-fatal asthma, with the goal of avoiding the need for mechanical ventilation. Limited evidence suggests that this strategy may be viable in selected patients.[165] In our experience, the administration of ketamine to nonintubated children with severe refractory asthma frequently precedes the need to intubate and is rarely associated with significant and noticeable clinical improvement. For this reason, attempts at administering ketamine to nonintubated children with severe refractory asthma should always take place in the ICU under strictly monitored conditions and with personnel capable of rapidly establishing an airway for initiation of ventilatory support.

Ketamine usually is administered as an IV bolus of 2 mg/kg, followed by a continuous infusion of 1 to 2 mg/kg/h. The resulting sialorrhea and increased airway secretions can be attenuated by administration of glycopyrrolate or atropine. The concurrent use of benzodiazepines may attenuate the agitation and hallucinations in patients who experience emergence reactions following ketamine anesthesia.

Mechanical Ventilation

Indications

Only a small minority of patients with near-fatal asthma admitted to the PICU (approximately 8% to 10%) require endotracheal intubation. The indications for intubation are not precisely defined, and the decision to proceed with intubation is largely based on clinical judgment. Absolute indications are obvious and include cardiac or respiratory arrest, profound hypoxemia refractory to supplemental oxygen administration, and respiratory failure. The decision to intubate should not be based solely on blood gas results. However, the presence of a mixed respiratory and metabolic acidosis, persistent hypoxemia, and agitation or obtundation, despite adequate therapeutic efforts, indicate impending respiratory arrest and signal the urgent need to proceed with intubation and mechanical ventilation.

Some patients may benefit from attempts to attenuate respiratory muscle fatigue with a trial of noninvasive ventilation.[132] However, the use of bilevel positive airway pressure requires patient cooperation and a well-fitted and sealed mask, which may prove difficult, if not impossible, to achieve in an anxious and agitated child with impending respiratory failure.

Intubation

The intubation of patients with severe near-fatal asthma is complicated by the fact that these patients are, by definition, fatigued, acidotic, and often also hypoxemic or agitated. Once the decision to intubate is reached, the procedure should be performed promptly by someone skilled and experienced in rapid sequence intubation. Intubation should be preceded by the administration of an anesthetic, such as an opiate, propofol, or ketamine; a benzodiazepine; and a neuromuscular blocker. Ketamine is the preferred anesthetic because of its bronchodilatory properties. Our preference is to use ketamine with a benzodiazepine, such as midazolam or lorazepam, to ensure adequate sedation and reduce the risk of hallucinations during emergence from anesthesia. Propofol may cause bronchodilatation and could be used as an alternative to ketamine, although this drug currently is not approved in the United States for continued use for anesthesia in the PICU after induction. Among the opiates, fentanyl is a widely available choice; morphine should be avoided because it is associated with histamine release and could, at least in theory, contribute to the allergic and inflammatory process. A rapid-acting neuromuscular blocker such as succinylcholine can be used to induce chemical paralysis. More commonly, a nondepolarizing neuromuscular blocker such as vecuronium, rocuronium, or cisatracurium can be used. The patient should be preoxygenated with 100% oxygen by face mask during spontaneous breathing. Assisted breathing with a bag-mask apparatus should be avoided, and cricoid pressure should be maintained throughout the procedure to reduce the risk of aspiration. Whenever possible, a nasogastric tube should be placed in advance to decompress the stomach.

A cuffed endotracheal tube should be introduced and its placement confirmed by a colorimetric method or capnography, auscultation, and chest radiograph. Special attention to the manual ventilation technique is needed to avoid fast rates that often are inadvertently applied immediately following intubation. Rapid respiratory rates applied to intubated children with severe airway obstruction lead to a state of high lung volume, significant dynamic hyperinflation, hypoxemia, and hemodynamic instability (hypotension). These patients require slow respiratory rates with very prolonged expiratory times to allow for adequate gas exchange and lung volumes. A helpful maneuver is to establish the timing of the next inspiration by using a stethoscope to auscultate for the disappearance of expiratory wheezes, thus marking the end of the previous exhalation. The occurrence of desaturation and hypotension

following intubation should prompt an equipment check and confirmation of tube placement. A tension pneumothorax must be considered in patients with hypoxemia and hypotension who fail to improve rapidly after administration of fluids and optimization of ventilation (or brief endotracheal tube disconnection), particularly when unequal breath sounds are present.

Ventilator Settings

The goal of mechanical ventilation in patients with acute asthma should be to reverse hypoxemia (if present), relieve respiratory muscle fatigue, and maintain a level of alveolar ventilation compatible with an acceptable pH, while avoiding iatrogenic hyperinflation and levels of intrathoracic pressure that could adversely affect cardiac output. Therefore the choice of mechanical ventilator settings must take into consideration the significant derangements of lung mechanics and function that are inherent to persons with severe acute asthma. Ill-advised attempts to achieve a normal $Paco_2$ would require fast respiratory rates, high minute volumes, and very high airway pressures, which are associated with the development of barotrauma (pneumothorax and pneumomediastinum) and high mortality rates.[166-168]

A paradigm shift in the ventilatory management of patients with asthma occurred with the introduction of a strategy of controlled hypoventilation reported by Darioli and Perret.[169] Their strategy resulted in no mortality in 34 episodes of mechanical ventilation in 26 patients and significantly lower complication rates in comparison with historical controls.[169] This approach used tidal volumes between 8 and 12 mL/kg and targeted peak airway pressures up to 50 cm H_2O. Tidal volumes were further reduced if the peak pressure limit could not be respected and higher $Paco_2$ measurements were tolerated.[169] A similar approach using respiratory rates lower than 12 breaths/min, tidal volumes between 8 and 12 mL/kg, peak inspiratory pressures of 40 to 45 cm H_2O, and permissive hypercapnia also resulted in very few complications and no mortality or long-term morbidity in 19 mechanically ventilated children with near-fatal asthma.[170]

From a simplified perspective, the modes of ventilatory support for patients with severe acute asthma can be divided between pressure and volume preset. No definitive evidence exists to suggest that one particular mode of ventilation is superior to the other. However, to safely ventilate a patient with asthma, the characteristics of each mode must be understood. Pressure control modes use a decelerating gas flow and have the advantage of ensuring that a particular inspiratory pressure limit is respected. The main disadvantage of pressure control modes is that tidal volumes can vary greatly with changes in airway resistance and the state of hyperinflation. Volume control modes deliver a constant tidal volume, provided there is no significant air leak. An added advantage of volume control is that it allows for comparison of peak inspiratory pressure and plateau pressure measurements (peak-to-plateau pressure), which can serve as a longitudinal indicator of airway resistance and response to therapy. For these measurements, the plateau pressure is obtained by performing an inspiratory hold (a feature ubiquitous to most ventilators) and is then compared with the peak inspiratory pressure (Figure 45-4). An increasing peak-to-plateau pressure indicates increasing airway resistance, whereas a decreasing peak-to-plateau pressure suggests response to therapy. A disadvantage of volume control ventilation is that very high lung volumes can develop if exhalation is incomplete, because tidal volumes remain constant breath to breath. The option of using pressure-regulated volume control, a mode available in some ventilators, offers some of the advantages of pressure control and of volume control, including optimal inspiratory gas flow, assured tidal volumes, and minimized airway pressures.

The peak-to-plateau pressure difference (*double-headed arrow*) is obtained after an inspiratory hold by comparing the peak pressure and the measured plateau pressure. *(Modified with permission from Indiana University School of Medicine Visual Arts Media.)*

Use of positive end-expiratory pressure (PEEP) in intubated patients with asthma has been the focus of controversy. Externally applied PEEP may benefit patients with expiratory flow limitation resulting from dynamic compression of small airways by moving the equal pressure point, stenting collapsed or severely narrowed airways, and enabling decompression of upstream alveoli.[171] The application of low levels of PEEP that are, by definition, lower than the level of auto-PEEP also may relieve dyspnea by facilitating ventilator triggering and synchronization for intubated patients capable of drawing spontaneous breaths.[171,172] However, as elegantly demonstrated by Tuxen,[173] use of PEEP in chemically paralyzed patients with severe airflow obstruction was uniformly associated with higher lung volumes, increased airway and intrathoracic pressures, and circulatory compromise (Figure 45-5).

Our personal preference is to use the volume control synchronized mandatory ventilation mode or the pressure regulated volume control mode, with tidal volumes of 8 to 12 mL/kg, which can be reduced as needed to generate peak inspiratory pressures of 45 cm H_2O or less and plateau pressures 30 cm H_2O or less. The initial tidal volume target of 8 to 12 mL/kg might seem high, particularly in the era of lung protective ventilation with reduced tidal volumes for patients with acute respiratory distress syndrome. However, it is important to note that the prototypical patient with near-fatal asthma does not have significant parenchymal lung injury or the heterogeneously decreased lung compliance typical of patients with acute respiratory distress syndrome and that tidal volumes are often reduced as needed to target conservative peak and plateau pressure goals, as previously discussed. Respiratory rate is initially set between 6 and 12 breaths/min, and inspiratory time is set between 1 and 1.5 seconds, allowing for expiratory times between 4 and 9 seconds. PEEP is set at zero for the patient under neuromuscular blockade. With intensification of therapy and clinical improvement, neuromuscular blockade

is stopped and trigger sensitivity for spontaneous breaths is optimized. A low level of PEEP (lower than the measured auto-PEEP and never in excess of 8 cm H_2O) is applied to facilitate synchronization between patient and machine, and spontaneous breaths are aided by the application of pressure support.

Use of high-level pressure support in the management of spontaneously breathing intubated patients with asthma with the goal of reducing inspiratory work while allowing the patient to actively assist with exhalation is an intriguing strategy that warrants further study.[174]

Ventilatory Monitoring

Regardless of the chosen mode of ventilation, patients with near-fatal asthma undergoing mechanical ventilation require very close monitoring. Frequent auscultation can provide valuable information regarding symmetry of breath sounds (e.g., pneumothorax or mucus plugging) and optimal length of exhalation. Monitoring modules capable of analyzing and displaying permutations of important variables, such as pressure, volume, flow, and time, can provide important information that assists in the optimization of ventilatory settings (Figure 45-6). Monitoring peak-to-plateau pressure differences allows for inferences regarding airway resistance and response to treatment. The shape of the capnography curve also may provide insights regarding adequacy of lung emptying (Figure 45-7), while integrated volumetric capnography can track changes in alveolar dead space over time.

Analgesia, Sedation, and Muscle Relaxation

Patients with near-fatal asthma who are undergoing mechanical ventilation require adequate analgesia and sedation to avoid tachypnea, breath stacking, and ventilator dyssynchrony, particularly in the setting of hypercapnia. Ketamine is the anesthetic agent of choice because of its bronchodilatory properties. Its use with continuous infusions of midazolam or lorazepam can provide deep sedation while decreasing the chance of postanesthetic emergence hallucinatory reactions. Despite its bronchodilatory effects, the use of ketamine may not be favored by many practitioners because of concerns about the negative impact of increased secretions on an already hypersecretory and narrowed airway. When opiates

are used instead, fentanyl is the preferred agent because morphine can cause histamine release and theoretically aggravate an acute attack.

Muscle relaxation with neuromuscular blockers should be maintained following initiation of mechanical ventilation until satisfactory gas exchange and clinical stability are achieved. Patients who exhibit hypercapnia during mechanical ventilation require continuation of neuromuscular blockers to abolish spontaneous respiratory movements that could worsen dynamic hyperinflation. However, use of neuromuscular blockers should be discontinued as soon as feasible to reduce the likelihood of serious neurologic complications, such as prolonged muscle weakness or paralysis, from the association of these agents and corticosteroid drugs.[175,176] Reports of prolonged paralysis and myopathy after the concomitant use of corticosteroid drugs and aminosteroid-based agents, such as vecuronium and pancuronium, led to the preferential use of benzylisoquinolinium compounds, such as cisatracurium, in patients with asthma. However, this combination may not be completely safe, because prolonged muscle weakness has

been observed in a patient treated with cisatracurium and corticosteroids.[177]

Inhalational Anesthetic Agents

Inhalational anesthetic agents have been used for their bronchodilatory effects in the treatment of mechanically ventilated patients with near-fatal asthma that is refractory to more conventional treatment modalities.[178] The exact mechanism responsible for bronchodilatation during inhalational anesthesia is unknown but may involve direct inhibition of vagal tone.[179] Various agents have been used successfully in both adult and pediatric patients with refractory near-fatal asthma, including halothane,[180] isoflurane,[181] enflurane,[182] and sevoflurane.[182,183] Although halothane is often recommended as an agent of choice, little evidence exists in humans to suggest that it is more effective than other agents.[184] Sevoflurane compares favorably with halothane and appears to be less noxious to human airways than isoflurane or enflurane.[185]

Inhalational anesthetic agents can be delivered by means of an anesthesia machine that feeds into the low-pressure gas port of a conventional mechanical ventilator or via a dedicated anesthesia ventilator with its own vaporizer. Attention should be taken to ensure proper disposal of exhaled gases into a scavenger system to prevent release of the anesthetic agent into the ICU environment. A monitor capable of continuously analyzing inspiratory and expiratory drug concentrations is helpful in ascertaining the actual amount delivered and signaling interruptions in therapy, such as those caused by an empty vaporizer reservoir or inadvertent failure to resume therapy after a refill. Usual doses range from 0.5% to 2% (isoflurane) and should be titrated for effect. Clinical response usually can be observed within 15 to 30 minutes of initiation of treatment.

Therapy for persons with refractory near-fatal asthma with an inhaled anesthetic agent should be performed only in a well-monitored ICU environment, under the direction of personnel experienced in the administration of these agents and their adverse effects. Patients treated with halothane can experience significant hypotension as a result of myocardial depression and require rapid fluid expansion and inotropic support.[186,187] Halothane is associated with cardiac arrhythmias, particularly during concurrent administration of epinephrine,[188] which explains why many physicians prefer a nonarrhythmogenic alternative such as isoflurane. Isoflurane does not have negative inotropic effects but may still cause hypotension because of vasodilatation.[159] Considering that halothane and isoflurane result in equivalent bronchodilation, isoflurane is preferred for use in children because of its less significant adverse effects. The use of subanesthetic doses of inhalational anesthetic agents in attempts to avoid mechanical ventilation in spontaneously breathing patients with severe asthma during maximal medical treatment is an intriguing strategy that warrants further study.[189]

Antibiotics

In children, acute asthma exacerbations frequently are triggered by a concurrent viral infection. As such, antibiotic agents are not indicated as part of the standard treatment strategy. A subset of school-aged children may present to the hospital with shortness of breath, accessory muscle use, hypoxemia, and expiratory wheezing caused by *Mycoplasma pneumoniae* pneumonia that simulates an acute asthma exacerbation. These patients usually are shown to have bilateral interstitial disease on a chest radiograph and should be treated with appropriate antibiotic agents such as a macrolide.

Patients with near-fatal asthma who require intubation and prolonged mechanical ventilation should be monitored for the development of nosocomial infections. The presence of fever and abundant thick white or purulent tracheal secretions should warrant a protected Gram stain and cultures to guide appropriate antibiotic coverage.

Bronchoscopy

Increased bronchial secretions and mucus plugging play a major role in the continued deterioration observed in some patients with severe acute asthma who fail to respond to maximal therapy.[31-33] Mucous plugging and casts can cause atelectasis of large segments and worsen the heterogeneity of ventilation and dynamic hyperinflation (Figure 45-8). Thus a small percentage of mechanically ventilated patients with severe near-fatal asthma may require selective suction of mucus plugs, casts, or thick secretions by bronchoscopy.[190] The combination of bronchial lavage with mucolytic agents such as *N*-acetylcysteine[191] or recombinant human deoxyribonuclease[192] and aggressive selective suction through a bronchoscope may be beneficial in patients with clinically significant mucous plugging who fail to respond to maximal therapy and traditional tracheal suction.

Extracorporeal Life Support

The use of extracorporeal life support (ECLS) has been reported in the management of the very few patients with near-fatal asthma who continue to exhibit a profound degree of clinical instability despite maximal therapy.[193,194] Such cases

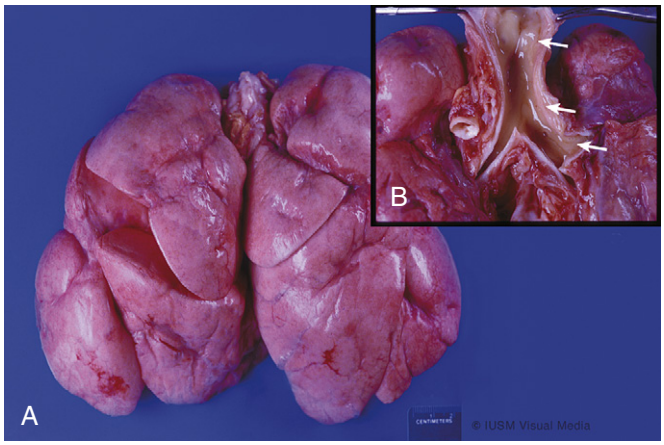

Figure 45–8. Excised lung block obtained from autopsy of a patient with fatal asthma. Despite equilibration with atmospheric pressure, the lungs retain their severely hyperinflated appearance (**A**) because of widespread airway plugging from viscous and tenacious secretions, which are also evident (*white arrows*) in the more proximal airways (**B**). *(Reprinted with permission from Indiana University School of Medicine Visual Arts Media.)*

are most unusual, as indicated by the very small number of patients with acute asthma as the primary diagnosis in the Extracorporeal Life Support Organization registry (1.36%, i.e., 173 of 12,763 pediatric and adult ECLS runs).[195] Interestingly, the survival rate for persons with near-fatal asthma supported by ECLS is approximately 78%,[195] which is remarkable considering that the vast majority of these patients were extraordinarily sick and had not responded to all forms of aggressive treatment.

Prognosis

The prognosis of patients with status asthmaticus or near-fatal asthma who receive proper medical therapy is excellent. Better understanding of the pathophysiology of airway obstruction and dynamic hyperinflation, coupled with improved mechanical ventilation strategies and aggressive pharmacologic treatment, has reduced the ICU mortality rate to nearly zero in these patients.[196,197] Asthma fatalities still occur in patients with sudden onset of severe airway obstruction who do not come to medical attention prior to the development of respiratory failure or cardiorespiratory arrest.[198,199] The treatment plan for patients admitted to the hospital with status asthmaticus or near-fatal asthma should be carefully reviewed prior to discharge to ensure adequate outpatient therapy, education, and follow-up in an attempt to reduce the likelihood of a preventable recurrence.

Chapter 46

Neonatal Respiratory Disease

Waleed Maamoun, Amber E. Fort, and James J. Cummings

PEARLS

- Pulmonary or nonpulmonary disorders can lead to respiratory distress or failure.
- Respiratory distress presenting in the first hours of life is a common reason, second only to low birth weight, for admission to the intensive care nursery.
- The following factors are important in reducing complications and improving the outcome of neonates with respiratory distress: early recognition of respiratory distress, the ability to distinguish respiratory disorders from normal neonatal transition, and prompt intervention as indicated.
- Fetal lung fluid must be cleared from the airways to allow normal breathing after birth.
- As a group, pulmonary air leaks are more common during the neonatal period than at any other time of life. The two most common leaks are pneumothorax and pneumomediastinum.
- In most cases, what is called pulmonary hemorrhage is actually the most severe manifestation of pulmonary edema rather than vascular disruption. True pulmonary hemorrhage in a neonate is rare and is almost always terminal.
- In addition to respiratory distress syndrome, many other clinical disorders may be associated with "functional" surfactant deficiency.
- Infants with "classic" bronchopulmonary dysplasia typically require a high degree of ventilatory and oxygen support beyond age 1 week, are slow to wean, and have episodes of bronchospasm or desaturation. The goal of treatment is to promote growth while simultaneously supporting respiratory needs and minimizing further injury to the lungs.
- In the neonate, significant congenital heart disease typically presents in one of two ways: (1) cyanosis with minimal or no respiratory distress or (2) cardiorespiratory failure.

Effective gas exchange within the lung requires both adequate ventilation and perfusion. Determinants of ventilation include the ventilatory "pump" (e.g., central drive, muscle strength, and chest wall recoil),[1] compliance of the lung and chest wall, and resistance to airflow within the airways. Determinants of perfusion include the circulatory pump (right ventricular output) and pulmonary vascular resistance. A disorder in any one or a combination of these determinants can lead to respiratory insufficiency. Clearly then, a variety of disorders, either pulmonary or nonpulmonary, can lead to respiratory insufficiency.

Acute or Early-Onset Respiratory Disorders

Respiratory distress presenting in the first hours of life is a common reason, second only to low birth weight, for admission to the intensive care nursery. Even in the current era of surfactant replacement, high-frequency ventilation (HFV), extracorporeal membrane oxygenation (ECMO), and nitric oxide inhalation, morbidity and mortality resulting from acute respiratory disorders can be high. Early recognition of respiratory distress in the neonate, the ability to distinguish respiratory disorders from normal neonatal transition (addressed later in this chapter), and prompt intervention when indicated are all important in reducing complications and improving the outcome of neonates with respiratory distress.

Delayed Clearance of Fetal Lung Liquid

Fetal lung fluid, which is actively produced by the lung and is critical for normal fetal lung development,[2] must be readily cleared from the airways to allow normal breathing after birth. On the basis of results from animal studies, the relative volume of liquid within potential airspaces, which remains constant in utero, is approximately 20 to 30 mL/kg near term and is the result of a balance between net accumulation within the lung (production minus reabsorption) and efflux out the trachea into the amniotic cavity.[3] In the hours to days before delivery, net accumulation diminishes, and during labor, reabsorption predominates.[4] As a result, extravascular lung liquid (i.e., liquid within the airspaces and interstitium) decreases. Any excess fluid remaining within the airspaces at the time of delivery is further removed as air entry into the lung displaces liquid from the airways into the interstitium. Residual liquid within the interstitium is then taken up into the circulation during the next several hours. Excessive extravascular liquid will lead to impairment of gas exchange, interstitial liquid pressure can compress small airways leading to atelectasis and gas trapping, and excess liquid within airspaces will impair alveolar gas exchange.[5]

Fetal lung liquid production and reabsorption are the result of active ion transport[6] and are presumably hormonally regulated (Figure 46-1). Chloride ions enter the lung epithelial cell across the basolateral membrane via a Na/K/2CL cotransporter (the transporter on which furosemide acts). The mechanism of transepithelial movement of lung fluid at the time of birth is passive movement of sodium through epithelial

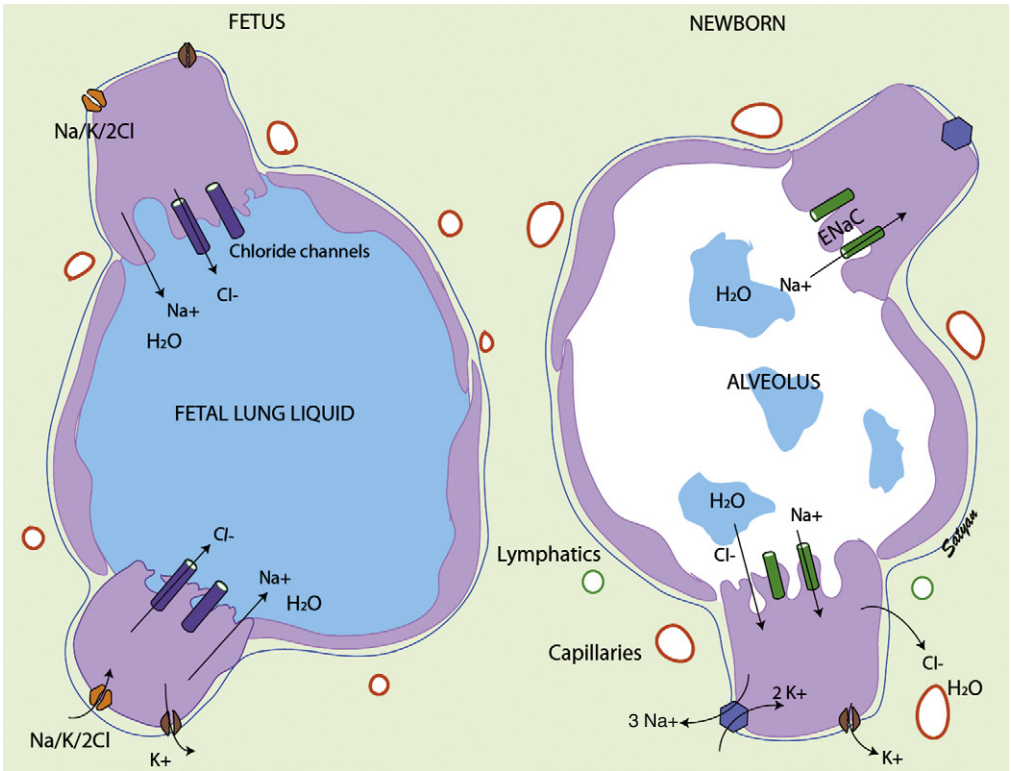

Figure 46–1. Mechanism of fetal and neonatal lung fluid transport. *(Modified from Guglani L, Lakshminrusimha S, Ryan RM: Transient tachypnea of the newborn,* Pediatr Rev *29:e59-e65, 2008. Copyright Satyan Lakshminrusimha.)*

sodium channels (ENaC), which are closed during fetal life; adrenergic stimulation during parturition activates these channels.[7] Although β-adrenergic agents such as terbutaline and epinephrine enhance Na ions and thus liquid reabsorption,[7,8] β-adrenergic blockade does not inhibit the reabsorption of lung liquid during spontaneous labor and delivery in animal studies.[9,10] Other hormones of parturition, such as vasopressin, may be important as well.[11,12]

The pulmonary circulation is also a key factor in fetal lung fluid clearance; not only does interstitial liquid drain directly into the circulation,[13,14] but the dramatic increases in pulmonary blood flow seen after birth may enhance reabsorption of liquid from fetal airspaces.[15] The onset of breathing not only increases the surface area for liquid reabsorption but also is associated with the opening of pores through which liquid can readily enter the interstitium.[16] Drainage of interstitial liquid is generally complete by the end of neonatal transition (4 to 6 hours). Interstitial liquid appears to be directly absorbed into the microcirculation, and this process is governed by Starling forces; the contribution of lymphatic drainage is negligible.[3]

Interference with this process of liquid removal from the airspaces and interstitium leads to impaired gas exchange and respiratory distress with a variable clinical presentation. Excess liquid within the airspaces reduces compliance and increases intrapulmonary shunting, which results in tachypnea and mild to moderate hypoxemia. The chest radiograph may show opaque areas similar to neonatal pneumonia or surfactant-deficient respiratory distress syndrome (RDS). This picture is often described as "prolonged neonatal transition" or "delayed extrauterine adaptation." Excess interstitial liquid reduces compliance and compresses small airways, which leads to the clinical signs of tachypnea and air trapping. The chest radiograph may show streaky densities within the lung, fluid collection within interlobar fissures, or even small pleural effusions; the lungs will also appear hyperinflated because of gas trapping. This clinical picture is often labeled retained fetal lung liquid or transient tachypnea of the newborn.[5,17]

Taken together, these clinical entities resulting from delayed fetal lung liquid clearance represent the most common type of respiratory disorder in the neonate and occur in 5% to 10% of all neonates. Typically, affected infants are term or near term and have persistent tachypnea beyond the immediate perinatal period. Infants born precipitously, or by cesarean delivery, are at highest risk for this disorder. With the increasing incidence of cesarean section deliveries worldwide, a record number of term and near-term newborns are now being admitted to neonatal intensive care units (NICUs) for transient respiratory difficulty.

Several additional points are worth noting. Infants who have been stressed in utero or whose mothers have been receiving β-mimetic agents are less likely to have retained lung liquid. Preterm infants with this condition may be mistakenly assumed to have surfactant-deficient RDS; supportive treatment is similar, although surfactant therapy has not been studied in infants with this condition. Because neonatal pneumonia also can present with tachypnea, an oxygen requirement, and a "wet" chest radiograph, infants with retained lung liquid who have symptoms often are treated with antibiotics. The clinical severity of this disorder can vary widely, and although most infants need only supplemental oxygen, others may require intubation and mechanical ventilation for 12 to 24 hours. Supplemental oxygen should be required for

no more than 24 to 48 hours, but tachypnea may persist for several days.

It is of interest to note that infants born to mothers who have asthma are at increased risk of transient respiratory difficulty immediately after birth.[18,19] In addition, reactive airway disease is more likely to develop later in life in newborns who present with transient respiratory distress.[20,21]

Pulmonary Air Leak Syndromes

Pulmonary air leak syndrome encompasses a spectrum of disease including pneumothorax, pneumomediastinum, pneumopericardium, subcutaneous emphysema, pneumoperitoneum, and pulmonary interstitial emphysema (PIE). As a group, pulmonary air leaks are more common during the neonatal period than at any other time of life. The two most common types of air leaks—pneumothorax and pneumomediastinum—occur spontaneously in 1% to 2% of term neonates.[22] Preterm infants with surfactant-deficient respiratory distress had previously reported rates of air leaks in excess of 30%[23]; these rates fell rapidly with the advent of surfactant therapy in the 1980s but still remain around 5%.[24] Infants with meconium aspiration or hypoplastic lungs have much higher rates of air leaks. Although techniques such as HFV and ECMO have markedly reduced the incidence of air leaks associated with these disorders, the rates still remain high, at 25% to 30%.[25,26]

The pathophysiologic cause of pulmonary air leaks has been hypothesized for many years as the uneven filling and redistribution of air in the lung; overdistension of more compliant air spaces leads to rupture. The alveoli most susceptible to this injury are those that border on arterioles and other structural elements of the lung; uniform protection by surrounding alveoli is lacking. After rupture of the alveolus or terminal airspace, air escapes into the lung interstitium and tracks along the vascular sheaths toward the hilum. For reasons that remain unclear, in the preterm infant the air may dissect within the interstitium (PIE).[27] More commonly, the air breaks through the pleural reflections at the hilum (pneumomediastinum) and from there gains access to various potential compartments: the pleural cavity (pneumothorax), the pericardial reflection (pneumopericardium), and the soft tissue planes of the neck (subcutaneous emphysema), or across the diaphragmatic apertures and into the peritoneal space (pneumoperitoneum).

In the past, pulmonary air leaks most commonly occurred as a result of excessive ventilatory pressures due to either aggressive mechanical ventilation (barotrauma) or air trapping caused by partial airway obstruction with meconium or other debris (ball valving). Now, air leaks are more commonly seen during the recovery phase of acute respiratory disease, when lung compliance dramatically improves and pressure-limited ventilation leads to excessive tidal volumes (volutrauma). This phenomenon explains the clinical observations that air leaks tend to occur during the recovery phase of RDS[28] and that the incidence of air leaks actually increased during early trials of surfactant therapy.[29] Both observations underscore the need to closely monitor ventilatory volumes and wean pressure aggressively as compliance improves; these observations also suggest that volume-limited ventilation may be safer during the recovery phase of acute neonatal respiratory disease, although this theory has not been studied.

Pneumomediastinum is one of the most common air leaks and, considering the pathways by which air will track, is often the harbinger of further air leaks. Infants with isolated pneumomediastinum generally have few or no symptoms other than low-density widening of the mediastinum, which is visible on chest x-ray film. Distention of the mediastinum has the potential to compress the great vessels and compromise circulation. This situation rarely occurs in clinical practice because air will usually track into the soft tissues of the neck or rupture into the pleural spaces before reaching the pressure needed for circulatory compromise.

Pneumothorax is a clinically common and more worrisome form of pulmonary air leak. The initial signs of pneumothorax reflect compression of the lung and diminished lung compliance. If compromise is minimal, the infant will maintain minute ventilation by simply increasing ventilatory rate (tachypnea); if that is insufficient, the infant will increase the use of accessory muscles (retractions) in an effort to improve tidal volume. If positive pressure within the pleural space builds to the point of vascular compromise (i.e., tension pneumothorax), cardiac return will decrease, and the heart rate will rise in an attempt to compensate for diminished stroke volume. Eventually, blood pressure may fall, and if oxygen delivery cannot be maintained, bradycardia and arrest will ensue.

Pneumopericardium is a rare but often life-threatening form of pulmonary air leak. The clinical signs closely resemble those of tension pneumothorax, but diminished heart sounds are invariably present. Clinical deterioration is often sudden and severe, and differentiation from pneumothorax is often difficult because usually no time is available to obtain a chest radiograph. The incidence of mortality may be as high 80%.

Pneumoperitoneum occurs when air dissects from the chest through a foramen of the diaphragm. This condition generally results in few if any symptoms or problems, other than possible confusion with a perforated viscus. Pneumoperitoneum is usually distinguished from bowel perforation by the clinical history of a prior pneumomediastinum or pneumothorax, especially with a lack of gastrointestinal symptoms. Although it usually requires no treatment, pneumoperitoneum can compromise ventilation. In that case, aspiration of air from the pneumoperitoneum is not only therapeutic but also diagnostic; oxygen tension in ventilatory gas is markedly higher than that in bowel gas.

PIE is a more severe manifestation of the same pathophysiologic process that leads to the rest of the air leak syndromes. In this case, the air accumulates in the interstitial space instead of tracking toward the hilum. This accumulation produces compression of the airways and vasculature, making ventilation more difficult. This situation creates a need for higher airway pressures to maintain open airways, which increases the air leak, and therefore the PIE. Avoiding this escalation of therapy has become the primary principle in the treatment of PIE.

The approach to management of air leaks in infants is similar to that in older children. Pneumothorax, pneumopericardium, and occasionally pneumoperitoneum are acute, life-threatening emergencies because they can seriously impair cardiac output by decreasing venous return. A high degree of suspicion for air leaks in a patient who has a sudden cardiovascular deterioration for no apparent reason is critical for prompt diagnosis. Transillumination of the relatively translucent neonatal chest wall with an intensely focused light source is a quick and useful tool for diagnosing a large pneumothorax.

Immediate aspiration of the air, preferentially with a large-bore angiocatheter, should be done without radiographic confirmation if the infant is severely compromised. Clinical signs of compromise, not the radiographic interpretation of percent size or extent, should dictate treatment, and many cases can be managed expectantly.[30] An unstable or recurrent pneumothorax may require a thoracostomy tube; however, tube thoracostomy may have significant complications, including parenchymal lung injury, phrenic nerve paralysis, chylothorax, and hemorrhagic pericardial effusion.[30] Penetration of the chest tube into the pulmonary parenchyma is a complication that often is not appreciated by chest radiographs; one study of autopsies of infants with pneumothorax reported a lung perforation rate of 25%.[31] Cardiac tamponade resulting from a pneumopericardium may be suggested by distant heart tones and hypotensive shock with a normal-appearing electrocardiogram tracing (so-called *electromechanical dissociation*). Pneumomediastinum often is asymptomatic and rarely benefits from drainage, even in the presence of symptoms. PIE occurs predominantly in preterm infants and often leads to a vicious cycle of increasing ventilator delivery pressures to open alveoli compressed by extrinsic air, which in turn leads to more extravasation of air and further collapse. Conventional treatment of PIE, including positioning, selective mainstem intubation, and steroids, has been unsatisfactory.[27,32] HFV, which may maintain alveolar patency while reducing inspiratory airway pressure, appears to be the ventilatory mode of choice in managing infants with PIE[33] and refractory pneumothoraces.[34]

Pulmonary Hemorrhage

The term *pulmonary hemorrhage* is often misapplied in the neonatal intensive care setting. True pulmonary hemorrhage in a neonate is rare and almost alwaysresults in death. In most cases, what is called pulmonary hemorrhage is actually the most severe manifestation of pulmonary edema rather than vascular disruption.[35] This distinction has been drawn by measuring the hematocrit of hemorrhagic fluid suctioned from the airway.[36] The airway fluid generally will be 15 to 20 points lower than whole blood in the same patient at that time. Finding whole blood in the airway is rare and is usually a result of trauma from suctioning.

Similar to older children and adults, factors that alter Starling forces within the pulmonary microcirculation will predispose the lung to hemorrhagic pulmonary edema. These factors include increased perfusion pressure (e.g., left ventricular failure), increased blood flow (e.g., from a left-to-right shunt across a patent ductus arteriosus [PDA]), increased microvascular permeability (e.g., associated with sepsis or oxygen toxicity), and decreased oncotic pressure (e.g., protein malnutrition or water overload). Most infants who have pulmonary hemorrhage will have more than one risk factor present. In the neonate, the factors most commonly associated with hemorrhagic pulmonary edema are those that increase pulmonary blood flow, such as a left-to-right shunt or treatment with surfactants.[35,37] Clinical features that increase the risk of hemorrhagic pulmonary edema or even frank pulmonary hemorrhage in neonates include extreme preterm gestation, asphyxia, hypothermia, certain types of congenital heart disease, and underlying coagulopathies.[38] Pulmonary hemorrhage also has been associated with neurologic disorders, including seizures, stroke, subarachnoid hemorrhage, and massive intraventricular hemorrhage. This association has led some researchers to suggest that pulmonary hemorrhage may have a neurogenic origin and that neonates with known or suspected neurologic injury represent a particularly high risk group.[39]

The diagnosis of hemorrhagic pulmonary edema is presumptively made when the appearance of bloody secretions within the endotracheal tube coincides with acute respiratory deterioration that requires increased oxygen and ventilatory support. The chest radiograph is the key to diagnosis; homogeneous, diffuse haziness, or fluffy infiltrates are signs that best indicate hemorrhagic pulmonary edema. Focal opacities on a radiograph require an alternative explanation such as pneumonia or upper airway trauma with subsequent aspiration of blood.

Although the diagnosis of hemorrhagic pulmonary edema is relatively straightforward, management can be challenging. The most important approach to managing hemorrhagic pulmonary edema is to establish high positive end-expiratory pressure (PEEP); this not only effectively reduces alveolar flooding but also improves oxygenation and left ventricular function. Although the airway must be kept clear, frequent suctioning not only may be traumatic but also can aggravate the condition by reducing PEEP. High mean airway pressures, which can be safely achieved with HFV, can be effective in massive pulmonary hemorrhage with rapid improvement in oxygenation.[40]

Some persons have advocated administration of epinephrine or iced saline solution via the endotracheal tube, but the efficacy of this method is questionable, and epinephrine may worsen the condition by elevating pulmonary vascular pressures. Aggressive volume resuscitation also should be avoided for the same reason. Antibiotics should be considered if sepsis is clinically suspected, but the efficacy of prophylactic antibiotics to prevent bacterial contamination of the airways is unproven. If an underlying cause such as a PDA or coagulopathy is suspected, it should be treated accordingly. Additional therapies under investigation include surfactant[41] and recombinant activated factor VII.[42] Prevention also may be possible in some cases; in preterm infants at high risk of the development of hemodynamically significant PDA, indomethacin prophylaxis appears to reduce the incidence of severe hemorrhagic pulmonary edema.[43] In a recent randomized trial of hemocoagulase given to preterm newborns requiring mechanical ventilation, the incidence of pulmonary hemorrhage (suspected or proven) was reduced by 70%[44]; however, in that study, the definition of "pulmonary hemorrhage" was rather broad and occurred in more than 40% of control infants, a much higher rate than is typically reported for this condition.

Even with aggressive management, the incidence of mortality from hemorrhagic pulmonary edema can exceed 25%, and surviving infants are at increased risk for neurodevelopmental impairment (e.g., cerebral palsy or cognitive delay) and neurosensory impairment (e.g., hearing loss requiring amplification or bilateral blindness).[43]

Pneumonia

The lungs represent the most commonly affected organ in neonates with sepsis. Bacterial or viral infection of the neonate may begin in utero, either by transplacental passage

or, more commonly, ascending infection from the maternal genital tract. A delay from the time of rupture of the amniotic membranes until delivery increases the risk of an ascending infection, although some organisms may invade through intact membranes. Cervical bacterial colonization with group B streptococci or primary herpesviral cervical infection during pregnancy increases the risk of transmitting those diseases; however, routine cervical cultures taken during pregnancy often do not reliably predict the actual flora at the time of delivery. Also, infants born vaginally are invariably colonized with organisms from the vaginal canal and typically swallow organisms during vaginal passage. Cesarean delivery is not necessarily protective because fetuses may swallow contaminated amniotic fluid or aspirate organisms in utero. Infection occurring during the perinatal period may not present clinically for several days; thus infections congenitally acquired may be indistinguishable from infections postnatally acquired (i.e., nosocomial).

Organisms that cause perinatal pneumonias, then, typically are those found in the genital tract of the mother and include streptococci (groups A, B, and D), gram-negative rods (e.g., *Escherichia coli* and Klebsiella species), *Listeria monocytogenes*, Ureaplasma, genital hemophilus, and herpesvirus. Less commonly, maternal viral infections due to adenovirus, enteroviruses, or varicella can be vertically transmitted to the fetus. Although perinatal tuberculosis is rare compared with other causes of neonatal pneumonia, the increasing prevalence of this disease in women of child-bearing age increases the likelihood of new cases[45]; in congenitally acquired cases, the mother may be symptom free.[46] Perinatal infection with other organisms, most typically chlamydia, may not present for several weeks.

Pneumonia as a nosocomial infection may develop in neonates, particularly those who require mechanical ventilation for other critical illness. Although reported rates vary widely, in part because of the lack of a diagnostic gold standard in this population, some authors have suggested that the incidence of ventilator-associated pneumonia may be as high as 30% in selected NICU populations.[47,48] In addition to the presence of an endotracheal tube, risk factors for ventilator-associated pneumonias include low birth weight, prolonged mechanical ventilation, sedation with opiates, frequent endotracheal tube suctioning, and the crowding that is typical in some units.[47,49] If a ventilator-associated pneumonia is suspected, typical nosocomial pathogens such as staphylococcus, Klebsiella and Pseudomonas species, and the pathogens previously listed for congenital pneumonias should be considered as possible causes.

Congenital pneumonia can be difficult to diagnose because clinical symptoms and radiographic signs may be nonspecific. Although congenital infections are generally introduced through the respiratory tract, symptoms are rarely limited to those of pneumonia; the neonate is particularly prone to rapid dissemination of either bacterial or viral infections and typically has signs of sepsis or meningitis in addition to respiratory distress. The chest radiograph initially may appear normal, except for some slight streakiness or hyperinflation, or may be so opaque as to be confused with surfactant-deficient RDS. Meconium aspiration with resultant severe chemical pneumonitis may be indistinguishable radiographically from bacterial pneumonia. Heart failure, or obstructed anomalous pulmonary venous drainage, also can present with a clinical and radiographic picture similar to pneumonia/sepsis.

Congenitally acquired pneumonia/sepsis can be a rapidly fatal disease, especially in the case of group B streptococcal or herpesviral infections, for which mortality rates as high as 50% have been reported.[50,51] A high degree of suspicion is therefore important because prompt treatment may be lifesaving. Although antibiotics are routinely used in neonates with suspected pneumonia or sepsis, antiviral therapy should be considered if the infant has systemic signs such as shock or disseminated intravascular coagulation or is not responding to initial therapy.

In regard to group B streptococcus (GBS) infection, guidelines for antenatal screening and antepartum prophylaxis published by the Centers for Disease Control and Prevention in 1996, and revised in 2002, have been followed by a significant decrease in GBS-related neonatal morbidity and mortality in the United States.[52] However, because of the inability of current microbiologic screening to identify all carriers, the failure in some cases to administer adequate intrapartum prophylaxis, and the need to deliver some infants prior to scheduled screening, GBS continues to be an important cause of early onset sepsis.[53] Given the complications and potential limitations associated with maternal screening and intrapartum prophylaxis, vaccines may be the most effective means of preventing neonatal GBS disease and are currently under development.[53]

Meconium Aspiration Syndrome

Passage of meconium in utero is generally considered a sign of fetal distress. The stress can be acute, as in the case of cord compression during labor, or chronic, as in the case of preeclampsia. Moderate distress occurring during labor results in passage of meconium during the final stages of delivery (terminal meconium), whereas more severe or chronic distress results in passage in utero, with resultant staining of the amniotic fluid and fetus. The incidence of meconium staining as a more significant marker of fetal distress occurs in 10% to 20% of all deliveries and is most common in postmature infants.[54] There also appears to be a maturational aspect to the ability to pass meconium because it is rarely observed in fetuses younger than 36 weeks' gestation.[54]

Not only is meconium-stained amniotic fluid a sign of antenatal distress, but it also can cause subsequent difficulties in the neonate. The contaminated amniotic fluid may be aspirated by the fetus, either in utero or during passage through the birth canal, and lead to subsequent respiratory distress. Meconium is a lipid and protein-rich substance that is highly irritating to mucous membranes of the distal airways, resulting in a chemical pneumonitis.[55] Dissolved meconium may travel down the respiratory tree and inactivate pulmonary surfactant; this inactivation leads to a functional surfactant deficiency.[56,57] In addition, meconium induces a potent inflammatory response, further impairing lung function.[58,59] As inflammatory markers improve, so too does pulmonary function.[60] More particulate meconium will remain trapped in small airways, and this leads to a ball-valve type of gas trapping. In most cases the meconium is gradually removed from the respiratory tract through phagocytosis, and normal pulmonary function returns in 5 to 7 days. In more severe cases, meconium aspiration syndrome may lead to respiratory failure, and even death, despite aggressive intervention.

Infants with meconium aspiration are typically postmature, with elongated nails, peeling skin, and staining of the umbilical cord, skin, and nails. Respiratory distress develops soon after birth, although the infant's respirations initially may be depressed if meconium passage occurred in response to a recent asphyxial episode in utero. Gas trapping may lead to a barrel-shaped appearance to the chest, and signs of respiratory distress may be severe. Chest radiographs often show characteristic patchy densities, hyperinflation, and areas of collapse. Air leaks are especially common. Aspiration of blood during delivery results in a similar clinical and radiographic picture; however, blood aspiration usually has a much milder course.[61]

An important step in the treatment of meconium aspiration syndrome is prevention. This has led to the routine practice of aggressive suctioning, beginning with clearing of the infant's nose and mouth while still at the perineum and before delivery of the infant's chest, followed by endotracheal intubation once the infant is delivered. A couple of large, randomized clinical trials have brought these practices into question and have even raised concerns that such interventions may produce harm, particularly in the vigorous infant.[62,63] On the basis of these trials, current recommendations are that suctioning should be limited to infants who are not vigorous at delivery.[64] Another intervention aimed at reducing disease as a result of meconium aspiration has been amnioinfusion, that is, the introduction of fluid transcervically during labor. The theoretical benefits of this approach include dilution of thick meconium and reducing cord compression by providing support to the umbilical cord. However, a recent large, randomized clinical trial has put this practice into question.[65] As with tracheal suctioning, it can be argued that distressed fetuses may aspirate in utero, long before delivery, and that severe complications such as persistent pulmonary hypertension are more likely the result of the antecedent stress and are not due to meconium aspiration per se.

The treatment of meconium aspiration syndrome is to provide supportive care; infants are recognized as being at increased risk for having persistent pulmonary hypertension (see section on "Persistent Pulmonary Hypertension of the Neonate"). Supplemental oxygen support to maintain arterial oxygen saturation, endotracheal suctioning to clear remaining meconium, and ventilatory techniques to minimize gas trapping are techniques that are commonly used. HFV may be helpful in preventing subsequent air leaks. Antibiotics are commonly used because distinguishing the clinical and radiographic picture from sepsis may be difficult and because damage to the airways may predispose to subsequent bacterial infection. Surfactant therapy has been recently explored as an adjunctive therapy, following promising results from two small pilot studies.[66,67] A recent systematic review of four clinical trials in term and near-term infants concluded that surfactant administration significantly reduced the need for extracorporeal life support, although the overall incidence of mortality was not affected[68]; in many centers, surfactant replacement has been added to other therapies routinely use in this condition, including high-frequency ventilation and inhaled nitric oxide.

A recent modification of surfactant replacement has been to lavage the lung with relatively large volumes of diluted surfactant to facilitate removal of meconium and improve surfactant function.[69,70] While this approach has merit, more clinical work needs to be done to determine the optimal approach, because some infants do not tolerate the procedure.[70]

Despite the intense inflammatory nature of meconium aspiration, the utility of steroid administration remains unclear[54]; although a recent small, randomized, controlled trial showed some clinical improvements, the mortality rate remained high.[71]

Because meconium passage in utero and meconium aspiration syndrome per se often are associated with an hypoxic event, long-term outcome remains guarded, particularly with regard to neurodevelopment.[72] In addition, a recent study has suggested that meconium aspiration during the perinatal period may be associated with increased risk of reactive airway disease in early childhood.[73]

Surfactant-Deficient Respiratory Distress Syndrome

For years, infants born preterm were recognized as being at increased risk for severe, occasionally lethal respiratory distress that presented within minutes to hours of age. In the past, the term commonly used to describe acute neonatal lung disease was hyaline membrane disease, a pathologic description of abnormal protein deposition in the alveolar linings of preterm infants who died after the onset of this disease. Today this disorder is commonly referred to as RDS; this term emphasizes the clinical instead of the pathologic presentation because hyaline membranes generally develop only in those now rare infants who eventually succumb to the disease. Recognizing that this disorder is primarily due to inadequate surfactant production, some authors prefer the term surfactant-deficient RDS to differentiate the pathophysiologic origins of this disorder from other types of neonatal respiratory distress such as transient tachypnea or retained fetal lung liquid.

Pulmonary surfactant disperses at the air-liquid interface on the inner surface of the alveolus, reduces surface tension at that interface, and prevents alveolar collapse at end-expiration. Surfactant is produced by type II alveolar epithelial cells and is a phospholipid and glycoprotein composite with phospholipid as the surface-active agent and glycoproteins aiding in surface adsorption, spreading, and metabolism of surfactant.[74] Maturation of the pulmonary surfactant system is generally not complete until the latter part of the third trimester of fetal life, but it can be induced by intrauterine stress, by maternal steroid therapy, and after preterm delivery. The incidence of surfactant deficiency at birth is inversely related to gestational age; approximately 50% of infants born between 30 and 36 weeks' gestation will be surfactant deficient, and virtually all infants born before 28 weeks' gestation will be affected to some degree.[75]

Surfactant-deficient alveoli are more prone to collapse, and this leads to diffuse atelectasis, reduced ventilatory compliance, and intrapulmonary shunting. Infants with surfactant deficiency have stiff, noncompliant lungs and require significant distending pressure for the lungs to be ventilated. Neonates will have tachypnea, retractions, and expiratory grunting; these symptoms indicate RDS. Preterm infants with RDS have significant morbidity, although some complications may primarily be a result of prematurity per se. Short-term complications can be life-threatening and include pulmonary air leaks, pulmonary hemorrhage, and intracranial hemorrhage. Infants with RDS are at risk for later complications including necrotizing enterocolitis and chronic lung disease. Infants who require prolonged intubation and mechanical ventilation also

are at risk for subglottic injury including subglottic stenosis and tracheomalacia. Before surfactant therapy, the mortality rate from RDS exceeded 20%[76]; now infants rarely succumb to RDS unless severe complications develop.[77-79]

Assessment of fetal lung maturity using phospholipid analysis of amniotic fluid and maternal steroid therapy, both introduced in the mid 1970s, have reduced the incidence of RDS in infants born before term. Treatment with surfactants in neonates with symptoms during the first few days of life has significantly reduced the clinical severity of RDS and improved survival.[24]

Unfortunately, although surfactant therapy has reduced some short-term complications such as pulmonary air leaks, the incidence of long-term morbidity remains unchanged, in part because of the increased survival rate of preterm infants with extremely low birth weight (<1000 g).[78,79]

Surfactant Protein B Deficiency

Pulmonary surfactant consists of surface-active phospholipid and a small amount (approximately 10% by weight) of protein.[74] Various surfactant-associated proteins (SPs) have been identified. SP-A and SP-D are large molecular weight, hydrophilic glycoproteins. Although these larger proteins have no surface tension–lowering ability per se, SP-A regulates surfactant phospholipid synthesis, secretion, and recycling and blocks the inhibition of native surfactant by plasma proteins that may leak into the alveolus during lung injury. SP-D does not appear to be involved in surfactant function but does play a key role in host defense of the lung. Despite having little to do with surfactant function, a recent study found that certain SP haplotypes for SP-A and SP-D conferred protection against newborn RDS.[80] In contrast to SP-A and SP-D, SP-B and SP-C are small, hydrophobic glycoproteins that promote spreading of surfactant across an air-liquid interface, which is an essential prerequisite for surfactant to function. A deficiency of either SP-B or SP-C markedly interferes with natural surfactant function in animal models.[74]

Congenital alveolar proteinosis is a rare disease entity with histopathologic similarities to alveolar proteinosis in older children and adults.[81] The clinical course of congenital alveolar proteinosis, however, is markedly different, characterized by rapid progression to death within several hours to days. A clustering of cases within families has suggested a genetic basis for this disorder; the condition in older children and adults is thought to result from a nonspecific alveolar injury. Pulmonary lavage has been helpful in adults and some children with alveolar proteinosis, but it has not been studied in infants with congenital disease.[82] Extracorporeal support has not altered the long-term prognosis of infants with this condition.[83]

In the early 1990s, several cases of congenital alveolar proteinosis were described in which SP-B and its messenger protein have been shown to be totally absent.[84,85] Since then, more than 25 loss of function mutations have been identified in patients with SP-B deficiency, the most common being a single gene mutation (121 ins2).[86] Adult humans heterozygous for this mutation have normal pulmonary function,[87] whereas homozygous cases are uniformly lethal within days of life. Affected infants respond only transiently to exogenous surfactants that contain SP-B[88]; to date, the only survivors are those who have undergone a lung transplant. Molecular techniques can identify affected infants and even predict fetal outcome, allowing us to provide specific counseling for parents whose infants have this fatal disorder.[89]

Congenital Malformations of the Lung

In utero, the organ of gas exchange is the placenta. As such, fetal viability does not depend on a functioning lung. Not surprisingly, substantial abnormalities of the lung can exist antenatally with little or no clinical indication until delivery of the neonate, when the lung must assume the placental function of gas exchange.

Pulmonary Hypoplasia

Both static and dynamic expansion of the fetal lung appears to be an important determinant of normal fetal lung development.[90] Static lung expansion occurs as a result of fetal lung liquid production. Epithelial cells within the lung actively secrete fluid into the lung lumen, distending the future airspaces. An intraluminal pressure gradient above amniotic fluid pressure is maintained by glottic regulation of fluid efflux from the trachea into the amniotic cavity, thus keeping the lungs expanded at a fluid volume that approximates postnatal functional residual capacity.[91] Failure to maintain this distention, either by inadequate production or excessive drainage of fetal lung liquid, leads to developmental hypoplasia. Dynamic lung expansion occurs during fetal breathing movements, which are rhythmic in nature and occur with increasing frequency during the latter part of gestation.[92] Absent or abnormal fetal breathing also appears to result in pulmonary hypoplasia.[90]

Pulmonary hypoplasia, unlike pulmonary agenesis or aplasia (discussed later in this chapter), can occur any time during gestation. Hypoplastic lungs are small in volume, and DNA content relative to body size have reduced numbers of alveoli, bronchioles, and arterioles per unit mass.[90] Although the pathophysiologic origin is not well understood, pulmonary hypoplasia is thought to result from impairment of normal fetal lung expansion and generally occurs in conjunction with one of the following conditions: (1) space-occupying lesions within the hemithorax, such as a diaphragmatic hernia, or massive pleural effusions associated with fetal hydrops; (2) an inadequate thoracic cage, as in asphyxiating thoracic dystrophy or achondrogenesis; (3) a deficiency of amniotic fluid (oligohydramnios), either because of leakage (e.g., preterm rupture of fetal membranes) or underproduction (e.g., renal dysplasia) [25]; (4) inadequate vascular supply to the developing lung, as may be seen with pulmonary artery atresia, hypoplastic right heart, or tetralogy of Fallot; (5) lack of the fetal breathing movements that normally occur throughout the latter part of gestation; and (6) chromosomal anomalies such as trisomy 13 or 18. Pulmonary hypoplasia may occur in the absence of any of these conditions, but such cases of primary isolated pulmonary hypoplasia are rare.[90]

Infants with pulmonary hypoplasia generally have signs of respiratory failure in the immediate newborn period. Reduced lung volumes impair ventilation and lead to hypercarbia, and decreased surface area for gas exchange (due to decreased alveoli) leads to hypoxemia. A decreased cross-sectional area of the vasculature makes these infants particularly susceptible to pulmonary hypertension, which further exacerbates the hypoxemia. The chest radiograph in infants with pulmonary

hypoplasia should show low lung volumes but may otherwise be unremarkable. The severity of the respiratory distress depends on the degree of hypoplasia and the presence of associated problems such as fetal hydrops or cyanotic heart disease. The most common association is renal dysplasia or agenesis; in these cases infants have a history of moderate to severe oligohydramnios and have severe respiratory distress and compression deformities of the face and extremities (Potter's syndrome).[93]

Treatment of infants with pulmonary hypoplasia is supportive, and outcome depends on the severity of the hypoplasia and the presence of any associated lethal anomalies such as renal agenesis or achondrogenesis. The lungs of infants with severe pulmonary hypoplasia may be extremely difficult to ventilate, and pneumothoraces are common because of the need for high distending pressures. HFV may be an effective means of ventilating these infants' lungs through a combination of high ventilatory rates with extremely low tidal volumes.

Congenital Diaphragmatic Hernia

Failure of the pleuroperitoneal canal to close at 6 to 8 weeks' gestation results in a diaphragmatic defect that allows gastrointestinal structures to travel into the thoracic cavity as the intestines return from outside the fetus to the abdominal cavity.[94] The resulting mass effect in the chest exerts a negative influence on ipsilateral lung growth, characterized by a quantitative reduction in airways and their associated preacinar arteries. Congenital diaphragmatic hernia (CDH) occurs in approximately 1 in 3000 births and is the most common cause of pulmonary hypoplasia in the neonate.[95] The defect occurs on the left side in 80% to 85% of cases; the reason is that closure of the right pleuroperitoneal membrane normally precedes the left during fetal development. Because herniation often occurs before the tenth week of gestation when normal gut rotation occurs, malrotation is common. Nongastrointestinal anomalies are found in approximately 25% of cases; the most common involve the cardiovascular system, where virtually any kind of defect has been reported.[94-96] Other associated anomalies include esophageal atresia, trisomies (13, 18, and 21), Turner's syndrome, neural tube defects, and renal anomalies. While it has been assumed the pulmonary hypoplasia seen with CDH is secondary to mechanical forces, studies in newborns and animals have found that CDH may be associated with nutritional deficiencies.[97,98] In the rat model of nitrofen-induced CDH, prenatal retinoic acid improves alveologenesis[99]; the experimental data regarding vitamin E supplementation has yielded conflicting results.[100-102]

Clinical presentation of CDH depends on the degree of pulmonary hypoplasia present (see section on "Pulmonary Hypoplasia"). In addition, the abdomen is often scaphoid because of a paucity of abdominal contents. As the infant cries and swallows air, the degree of lung compression may worsen, and an infant who appears healthy at delivery may undergo decompensation within minutes. The chest radiograph will show a cystic lesion in the lower lung field, often extending upward along the lateral chest wall. Initially, while the intestines remain fluid filled, the radiograph may be similar to that seen with pulmonary sequestrations or fluid-filled cysts (discussed later in this chapter); as the infant swallows more air, the radiographic findings can be confused with congenital emphysema or even a pneumothorax. Small or right-sided defects in infants may not present for weeks or even months; indeed, occasional cases have been diagnosed incidentally during childhood when chest radiographs are obtained for other reasons. Today, with the widespread use of antenatal sonography, most cases are diagnosed before birth, and significant confusion is avoided in the delivery room. In cases where sonographic findings are equivocal, prenatal magnetic resonance imaging may be particularly useful.[103]

Initial management focuses on stabilization, including immediate intubation and gastrointestinal decompression. Ventilation by bag and mask should be avoided because this intervention will only introduce more gas into the gastrointestinal tract. As with pulmonary hypoplasia, the clinical course is usually complicated by persistent pulmonary hypertension, which has accounted for mortality rates as high as 80%.[104] With the advent of ECMO this number has dropped somewhat but is still significant.[105] High-frequency ventilation appears to have particular merit for this condition and may improve mortality rates independent of bypass technology.[96,106] In a lamb model of CDH the contralateral nonhypoplastic lung is functionally immature, leading some investigators to suggest that surfactant therapy may be beneficial,[107] but this suggestion has not been borne out in a recent review of a large, national CDH registry.[108] Attempts at intrauterine intervention, either to close the defect or to encourage lung growth through temporary blocking of the fetal lung liquid egress at the trachea, have been disappointing; fetal surgery is associated with an unacceptably high incidence of complications, including recurrence of the defect, preterm delivery, and miscarriage.[96,109] In infants with significant pulmonary hypoplasia who require ECMO, distending the lung with perfluorochemical can promote lung growth, but further study is needed.[110]

Although early corrective surgery had been advocated in the past, recently a paradigm shift toward delayed repair has occurred, in large part because of the observation that respiratory function often worsens in the immediate postoperative period.[95,96,111,112] Thus early, aggressive cardiorespiratory stabilization followed by surgery has become the recommended approach and is associated with improved outcome.[95,113] An alternative to an initial period of attempted stabilization has been an ex-utero intrapartum therapy procedure, in which the delivering fetus is orally intubated and placed on a mechanical ventilator prior to umbilical cord ligation. In this approach, a brief trial of ventilation may be given; if oxygen saturation does not improve during the trial, the fetus is cannulated and ECMO is begun, followed by delivery of the infant. This approach may be helpful in selecting infants who are least likely to respond to initial stabilization in the NICU, and reported outcomes with this approach have been favorable, although the mortality rate for infants with this condition remains quite high.[114]

Cystic Adenomatoid Malformation

Cystic adenomatoid malformation (CAM) is a relatively infrequent lesion, estimated at 1 in 30,000 pregnancies.[115] It results from abnormal mesenchymal proliferation and failure of maturation of bronchiolar structures early in gestation.[116,117] The resultant adenomatous overgrowth leads to the development of cysts and suppression of alveolar growth. The cysts are almost always multiple, and in more than 95% of cases the cystic malformations lie within a single lobe. No lobar

predilection exists. Histologically, the lesions are notable for the preponderance of elastic tissue and for a lack of cartilage. The cysts communicate directly with the tracheobronchial tree and with each other.

CAMs have been divided into three types, which vary both in anatomic and clinical characteristics. According to the traditional Stocker classification scheme, Type 1 CAM, which accounts for about half the cases, occurs as a few large (>2 cm) cysts, usually one to four in number, or a single large cyst surrounded by much smaller "satellite" cysts. Type 2 CAM, which accounts for about 40% to 45% of the cases, consists of multiple, small (<2 cm), evenly spaced cysts scattered throughout the affected area. Compared with type 1 CAM, type 2 cysts are associated with a much higher incidence (about 25%) of anomalies in other organs, particularly within the genitourinary tract (e.g., renal dysgenesis). Type 3 CAM, which accounts for less than 10% of cases, occurs as large collections of numerous tiny cysts; the affected area can be large, and this type often leads to early cardiovascular compromise, resulting in fetal hydrops or immediate postnatal complications. The Stocker classification scheme is based primarily on postnatal lung examinations; recent studies of fetal lung specimens suggests that a different classification scheme may be needed, particularly as this condition is now detected antenatally in most cases.[118,119]

Depending on the type, CAM presents during the neonatal period in 50% to 85% of infants, but presentation can be delayed for up to several years. Occasionally cases are discovered on chest radiographs taken for other reasons; many lesions are now detected prenatally during routine sonography. The most common presentation is respiratory distress that results from obstruction, although infection of the cyst leading to recurrent lobar pneumonias can occur as well. The elastic walls of the cyst allow easy expansion on inspiration, but the lack of cartilaginous support results in premature closure during exhalation, leading to a ball-valve type of respiratory compromise.

Chest radiograph findings are variable and depend somewhat on the type of CAM. In the neonate a solid, space-occupying mass will appear, becoming air-filled over the next several hours or days. In types 1 and 2, multiple air-filled cysts may become apparent. This appearance can be confused easily with diaphragmatic hernia; placement of a nasogastric tube to determine the location of the stomach and intestines and absence of a scaphoid abdomen will help rule this out. The multiple small cysts of type 3 CAM cannot be delineated on a chest radiograph; in this case a computed tomography (CT) scan of the chest can be helpful.

Treatment of infants with symptoms may require positive pressure ventilation; in some infants PEEP may facilitate emptying of the cysts. Definitive treatment is surgical removal of the affected lobe, which can be done thoracoscopically in many cases.[120] Even if an infant is asymptomatic, surgical resection is recommended by 3 to 6 months of age because of the high risk of expansion or infection if the cysts are left untreated.[115,121]

Prognosis depends on the type and extent of the CAM. The large type 3 lesions are more likely to cause immediate distress and carry a higher incidence of mortality, especially if associated with pulmonary hypoplasia or fetal hydrops.[115,121] The prognosis in type 2 CAM depends on the presence and nature of associated anomalies. In addition, malignant transformation of CAM has been reported.[94,116,121] Most cases of CAM, however, carry a good prognosis.[115,117,121]

Bronchogenic Cysts

Bronchogenic cysts occur as a result of anomalous budding of the ventral or tracheal diverticulum of the foregut during the sixth week of gestation, with subsequent separation from the normally developing bronchi by the sixteenth week of gestation.[116,117] If separation occurs early (<12 weeks), the bronchogenic cyst tends to be located in the mediastinum (which is the most common type); if separation occurs later, it is more likely to occur in the peripheral pulmonary parenchyma. The cyst walls are cartilaginous and receive either systemic or pulmonary blood supply depending on their location. Bronchogenic cysts are more common in male infants, are usually singular, are more commonly right sided, and are generally less than 10 cm in diameter. They generally do not communicate with the airway and remain fluid filled, which differentiates them from pulmonary parenchymal cysts.

Bronchogenic cysts generally do not present in the neonatal period unless they are large, expand rapidly, or are located near major airways; in these cases infants may have moderate to severe respiratory distress. More commonly the young child will have recurring episodes of wheezing or infection. Occasionally, asymptomatic bronchogenic cysts are visualized on chest radiographs taken for other reasons.

Chest radiographs can readily disclose most bronchogenic cysts.[122] The cyst typically appears as a round or oval water-density mass, commonly in the mediastinal or perihilar area; if the cyst has been infected, an air-fluid level may be present. Mediastinal bronchogenic cysts usually appear just beneath the carina and extend to the right. Pulmonary bronchogenic cysts are usually sharply circumscribed and appear toward the periphery; two thirds of these cysts will be located in the lower lobes, with no right or left predilection. About 25% of bronchogenic cysts may be difficult to visualize with a chest radiograph; in these cases CT scans cannot only delineate the lesion but can also discern associated anomalies, such as a pulmonary sequestration (see later).[116,122]

Treatment may require ventilatory support for infants with symptoms. In all cases, surgical resection is indicated. Prognosis for infants with bronchogenic cysts, whether mediastinal or pulmonary, is good.[123]

Pulmonary Parenchymal Cysts

Pulmonary parenchymal cysts are thought to represent a disorder of bronchial growth,[116,117] although they also may be acquired.[124] Like adenomatoid malformations and bronchogenic cysts, congenital cysts arise early in fetal life; pulmonary parenchymal cysts are thought to develop at a time when completion of the terminal bronchioles and development of the alveoli are occurring. Pulmonary cysts are typically thin walled, singular, multilocular, and located in the periphery. Unlike bronchogenic cysts, some communication usually exists between the pulmonary cyst and the tracheobronchial tree, and thus approximately 75% will become filled with air. Like adenomatoid malformations, pulmonary cysts contain mostly elastic tissue and little or no cartilage.

Although pulmonary cysts are generally small (1 to 2 cm in diameter), they can expand dramatically and thus are much

more likely to be symptomatic than are bronchogenic cysts. As with adenomatoid malformations, the lack of cartilaginous support leads to trapping of air. Unlike adenomatoid malformations, pulmonary cysts are rarely associated with other anomalies. Rupture of a peripheral cyst can result in a pneumothorax. Rarely, multiple cysts can occur and involve both lungs in an extensive fashion; these cases are generally fatal within the perinatal period.

Chest radiographs typically reveal thin-walled, round cysts with an air density. Often faint strands of lung tissue can be seen within the cysts. A large pulmonary cyst may be confused with congenital lobar emphysema; in this case a CT scan should easily distinguish the cystic nature of the former condition.[122]

Reports of spontaneous resolution of pulmonary cysts have been infrequent. As with other cystic lesions of the lung, however, surgical resection of the affected lobe is usually indicated.[116,124]

Pulmonary Sequestrations

Like bronchogenic cysts, pulmonary sequestrations are thought to result from an abnormal budding of the foregut, which retains its embryonic systemic arterial connections.[116,117] Thus a sequestration is a mass of nonfunctioning, ectopic pulmonary tissue with its own blood supply. Pulmonary sequestrations are divided into two types, which are histologically similar. Extralobar sequestrations are surrounded by their own separate pleura, and intralobar sequestrations have no separate pleural covering.

Extralobar sequestrations account for about 25% of cases, are more common (90%) on the left side, are more common in males (80%), and are usually located in a subpulmonic location. Extralobar sequestrations have a high (50% to 60%) association with other anomalies, including direct esophageal communication, bronchial atresia, colonic duplication, cystic adenomatoid malformation, pulmonary hypoplasia, and diaphragmatic hernia. Most cases of extralobar sequestration become evident in infancy; presentation ranges from fetal hydrops with massive pleural effusions and pulmonary hypoplasia to recurrent lower respiratory infections (particularly if there is a gastrointestinal communication).

Intralobar sequestrations are the more common type (75%); they are usually left sided (65% to 70%) and typically occur in the lower lobes. Unlike extralobar sequestrations, they are rarely associated with other anomalies.[125] Most cases are asymptomatic and are found on chest radiographs obtained for other reasons. Symptomatic cases typically present in late childhood with recurrent infections.

Distinguishing between extralobar and intralobar sequestrations on chest radiographs may be difficult. Both can appear as either solid or cystic structures, although extralobar lesions are more often solid and intralobar lesions are more often cystic.[122] Delineation of the vascular supply to the sequestration is important, not only to differentiate extralobar sequestrations from adenomatoid malformations, but to guide surgical management; in the past few years, magnetic resonance imaging has replaced arteriography for obtaining this information.[122] Some authors recommend a study of the gastrointestinal tract, particularly if communication with the sequestration is suspected.

As with other cystic lesions of the lung, surgical removal is indicated and may be done thoracoscopically.[126-128] Whereas extralobar sequestrations can be removed en bloc because of their separate pleural covering, intralobar sequestrations require lobectomy.[94] Recently, success with a nonsurgical approach using transumbilical artery embolization during the newborn period has been reported.[129]

Congenital Lobar Emphysema

Congenital lobar emphysema is an unusual disorder characterized by overdistension of a pulmonary lobe caused by air trapping. The term *emphysema* is misapplied because usually no emphysematous destruction of the alveoli occurs; thus many authors favor the term *congenital lobar overinflation*.[94,116,117] Although clinical and radiographic findings are typical of a ball-valve type of obstruction, evidence for this is found in less than 25% of cases. In most cases the cause for the air-trapping is unknown. Intrinsic bronchial obstruction may be the result of a deficiency of cartilaginous support or an intraluminal mass such as a mucous plug. Extrinsic bronchial obstruction usually results from an underlying cardiovascular abnormality, such as a vascular sling or, rarely, a PDA. Intrathoracic masses, such as an enlarged lymph node or a bronchogenic cyst, can lead to extrinsic obstruction as well.

Congenital lobar emphysema is more common in male infants and typically occurs in the upper lobes or the right middle lobe; fewer than 1% of cases occur in the lower lobes. Up to 20% of the cases have bilateral involvement. Associated cardiovascular anomalies are common; rib cage anomalies and aplasia/dysplasia of the kidneys have been reported in a small percentage of cases. In most infants with congenital lobar emphysema, the condition presents within the first month of life, and about one third of infants have symptoms within hours of birth. Symptoms relate directly to the degree of overinflation. Typically, infants have mild to moderate tachypnea, asymmetric inflation of the chest, and cyanosis. A chest radiograph reveals the overinflated lobe with ipsilateral atelectasis and flattening of the hemidiaphragm; also, a mediastinal shift away from the affected side may be observed. A CT scan may be helpful in identifying the cause of obstruction, if one is present. Lobectomy is the definitive treatment and may be done thoracoscopically.[130] Surgery should be limited to symptomatic cases; favorable outcomes reported in asymptomatic or minimally symptomatic cases in which surgery was not conducted suggests that a less aggressive approach may be warranted.[131]

Pulmonary Agenesis and Aplasia

Pulmonary agenesis and aplasia, which are both rare and highly lethal disorders, have similar underlying causes that differ from those of pulmonary hypoplasia.[117] Pulmonary agenesis and aplasia result from an arrest of development of the primitive lung during embryonic life. Obviously, the earlier in development that the arrest occurs, the more severe the defect. In pulmonary agenesis, the bronchial tree, pulmonary parenchyma, or pulmonary vasculature does not develop. In pulmonary aplasia there is a rudimentary bronchial pouch. The resulting lesion may involve one lobe or the entire lung; focal or bilateral defects are rare. Pulmonary agenesis or aplasia may be associated with other nonpulmonary anomalies including microphthalmia/anophthalmia, cleft palate, cardiac

defects, congenital diaphragmatic hernia/eventration, and limb abnormalities.[132]

The clinical presentation is variable. If the defect is focal and isolated, the infant may not have any symptoms, but usually some mild respiratory distress is present. A chest radiograph reveals unilateral lung or lobar collapse with a shift of mediastinal structures, which leads to a suspicion of bronchial or bronchiolar obstruction. Misdiagnosis may subject the infant to the unnecessary risks of bronchoscopy when CT is readily diagnostic.[133] Associated anomalies in the cardiovascular, gastrointestinal, genitourinary, central nervous, and musculoskeletal systems have all been described.[117]

If the defect is isolated to a single lobe, surgical resection will reduce symptoms and lessen the chance for infection.[134] If the defect is extensive but the fetus is considered salvageable, an ex-utero intrapartum therapy procedure may be performed.

Prognosis depends on the degree of pulmonary involvement, a history of recurrent pulmonary infections, and the presence of associated anomalies.[117] Bilateral defects are invariably lethal. If the defect is focal, the remaining normal lung tends to hypertrophy to compensate. Still, mortality rates exceed 50%, generally because of the presence of associated malformations, which are common. Right-sided defects have a poorer prognosis than left-sided lesions, partly because of a higher association with other anomalies and partly because of an increased risk for disseminating infection. It also has been suggested that right-sided lesions produce a greater mediastinal shift, distorting the trachea and great vessels.[135,136] Repeated lower respiratory infections result in progressive pulmonary debilitation and also increase the risk for death.

Special Treatment Considerations for Acute Respiratory Failure

Surfactant Replacement

Exogenous surfactant therapy has significantly decreased the incidence, severity, and morbidity of RDS and improved the survival of low-birth-weight infants.[137] Exogenous surfactants in current clinical use are considered "natural" because they are derived from either bovine or porcine lungs. Because of concerns for animal protein sensitization and for ease of standardization, newer surfactants under development and not yet commercially available contain no animal proteins but consist of surface active phospholipids and recombinant proteins that exhibit properties similar to the natural surfactant proteins, either B or C. While these surfactants may prove to have advantages over surfactants derived from animals, the earlier concerns regarding sensitization to foreign animal proteins have not been substantiated in more than two decades of clinical use. Human surfactant, purified and concentrated from pooled amniotic fluid, also has been studied clinically and is effective, but it is too expensive and sparse in supply to allow general use.

The three animal-derived surfactants are compositionally different from each other, even though two of them come from the same animal source. These differences are in large part due to the way in which the surface-active components are either extracted, or supplemented, in the different preparations. While most compositional differences are of little biophysical or clinical importance, differences in SP-B content appear to translate into clinical differences such as onset and duration of activity and resistance to inhibition.[138] This difference is important because many other clinical disorders besides RDS can be associated with "functional" surfactant deficiency. Increasing evidence exists that conditions such as meconium aspiration, persistent pulmonary hypertension, hemorrhagic pulmonary edema, congenital diaphragmatic hernia, pulmonary hypoplasia, acute respiratory distress syndrome (ARDS), pneumonia, bronchiolitis, and asthma are associated with surfactant dysfunction and inactivation and that persons with these conditions might theoretically benefit from exogenous surfactant therapy [67,139-145] Treatment of these conditions may prove to be an appropriate niche for synthetic products that contain protein analogues.[146]

High-Frequency Ventilation

Two types of HFV are commonly used in neonates.[34,147-150] The first type uses a highly pressurized intermittent jet of gas that is delivered at rates of 120 to 600 Hz and is called high-frequency jet ventilation. The second type uses an oscillating diaphragm or piston to provide active instillation and withdrawal of gas and is called high-frequency oscillatory ventilation (HFOV).

Although the effects of ventilator settings have been well studied in HFV, the actual mechanics of gas exchange during HFV are less well understood. Similar to conventional ventilation, oxygenation is affected primarily by inspired oxygen concentration and mean airway pressure. Although ventilation is affected by volume and frequency, the effect of volume is much more pronounced than with conventional ventilation, and the effect of frequency is contrary to what would be expected because it inversely affects tidal volume.[34,147,150] In general practice, frequency is not a critical variable within the ranges afforded by the high-frequency ventilator and is not further adjusted during HFV use.

One key advantage to HFV of particular use in the neonate is the ability for high-end expiratory pressures to be used without the need for high-inspiratory pressures to maintain normal tidal volumes, allowing adjustment of mean airway pressure more or less independently of volume. This ability is particularly desirable when a significant V/Q mismatch exists, such as with the neonate who has idiopathic persistent pulmonary hypertension and whose lungs may be easy to ventilate but who is marginally oxygenated with 100% oxygen. Another advantage of HFV is the ability to use low, usually subphysiologic tidal volumes. The use of low volumes prevents overdistension and rupture of more compliant alveoli, thereby reducing the risk of pneumothorax. Furthermore, HFV reduces airflow across existing air leaks, not only promoting their closure but also enabling more effective ventilation in situations such as severe PIE or a bronchopleural fistula.[34,147,148] Still, a specific advantage of HFV over conventional pressure ventilation in preterm infants with RDS, other than managing air leaks, has yet to be demonstrated.[34,147,148] Rehospitalized NICU graduates with chronic lung disease frequently require mechanical ventilation following upper airway infection, particularly with organisms such as respiratory syncytial virus (RSV). The use of HFV may attenuate additional lung injury by allowing higher PEEP while minimizing volutrauma in these babies; however, this advantage is theoretical and not well studied to date.

Complications that have been reported with HFV use include hypotension, pulmonary hypertension, tracheobronchitis, and in preterm infants, intraventricular hemorrhage.[34,147-150] Because the use of excessive airway pressures may impede cardiac return and increase pulmonary vascular resistance, hyperinflation must be avoided. Reports of necrotizing, sometimes lethal tracheobronchitis, a complication recognized during the early years of HFV use, are now rare, presumably because of better attention to humidification and avoidance of excessive mean airway pressures. While some studies have suggested that infants of very low birth weight (less than 1500 g) treated early with HFOV have a lower incidence of chronic lung disease,[151] others have suggested that HFOV increases the risk of intracranial hemorrhage in preterm infants, perhaps because of alterations in cerebral blood flow and drainage.[152-154] Researchers in several other clinical studies have found no such association,[106,151,155-160] and researchers in two studies in animals found no differences in the effects of HFV and conventional ventilation on the cerebral circulation.[161,162]

Extracorporeal Membrane Oxygenation

ECMO evolved from classic bypass technology with the advent of membrane oxygenators that could operate for days without significantly disrupting blood cells and plasma proteins. However, when applied to premature neonates with RDS, ECMO initially was disappointing.[163] ECMO did not reduce mortality rates in patients with ARDS and was associated with a high risk of intracranial hemorrhage in preterm infants. Nevertheless, subsequent use in term infants with cardiorespiratory failure, particularly those with persistent pulmonary hypertension and congenital diaphragmatic hernia for whom conventional therapies had failed, has led to its increasing application in this area, despite the absence of controlled clinical trials.[164] In neonates with respiratory failure, compared with other indications for ECMO, RSV/lower airway disease has a far higher survival rate (96%) and very low rate of neurologic sequelae.[165,166] Most causes of neonatal respiratory failure in the newborn are self-limited, and ECMO allows time for the lung to recover from the underlying disease process and for reversal of pulmonary hypertension, which frequently accompanies respiratory failure in the newborn.[167] In addition, the use of ECMO in older children and adults also has received a resurgence of interest see Chapter 53. The technical description, aspects of clinical management, and potential complications of ECMO are covered elsewhere in this book and are not detailed here.

Nitric Oxide Inhalation

In mammals, vascular smooth muscle relaxation is in large part induced by nitric oxide, which is released by adjacent endothelial cells in response to flow and shear stimuli and stimulates guanylate cyclase to produce cyclic guanosine monophosphate, a potent vasodilator. Inhaled nitric oxide causes significant pulmonary vascular vasorelaxation without a significant systemic effect because it is rapidly scavenged by hemoglobin as it enters the pulmonary microvascular circulation. In addition, inhaled nitric oxide selectively vasodilates the lung units that are better ventilated, optimizing ventilation-perfusion matching. Inhaled nitric oxide is approved for use in term and near-term (≥34 weeks' gestation) infants with persistent pulmonary hypertension; although it does not alter the long-term outcome in patients with this condition, it significantly reduces the need for rescue treatment with ECMO.

While nitric oxide inhalation has received much interest in the management of term infants with persistent pulmonary hypertension, other applications continue to be evaluated. Animal studies suggest that nitric oxide may have a significant role in the successful perinatal transition to breathing of air.[168,169] Clinical studies suggest that inhaled nitric oxide may be beneficial in infants with surfactant-deficient RDS, particularly those who do not respond to exogenous surfactant therapy.[170,171] The basis for these studies lies in the observation that pulmonary hypertension is not confined to term neonates but has been reported in preterm infants with RDS as well.[172,173] In addition, recent work has shown that nitric oxide production modulates basal pulmonary vascular tone in preterm animals.[174]

Many questions regarding nitric oxide use remain to be answered before it can be approved for clinical use in preterm infants with RDS. Recognized clinical complications include methemoglobinemia (because of its high affinity for hemoglobin) and prolonged bleeding times[175];the toxicity of nitric oxide metabolites includes the potential for injury to the pulmonary epithelium and surfactant system as well.[176] In time, the intense amount of ongoing basic research in nitric oxide biochemistry and clinical trials in both adults and children will begin to answer important questions about dosing, safety, and efficacy.[177,178]

Liquid Ventilation

Liquid ventilation with perfluorochemicals, a complete departure from traditional ventilation with gases, is one of the latest advances in ventilatory management for the neonate. Specific advantages of liquid instead of gas expansion of the lungs were first demonstrated in the 1920s, but application to the clinical setting was hampered by the poor solubility of most liquids for oxygen and carbon dioxide and technical difficulties in achieving liquid tidal volume exchange. The introduction of perfluorochemicals, which have high solubility for respiratory gases, and the development of specific liquid ventilators enabled researchers to study liquid ventilation in animals in the 1970s.[179] The demonstration that complete tidal liquid movement was not necessary to capitalize on the advantages of liquid ventilation[180] made liquid ventilation a clinical reality in the 1990s. Partial liquid ventilation is the term applied to conventional gas tidal volume ventilation superimposed on liquid-filled alveoli (i.e., alveoli filled to functional residual capacity).

Though gas exchange can be impaired by too rapid liquid ventilation in the healthy lung in animal studies,[181,182] it is clearly improved in many injured lung models. Possible mechanisms for this improvement includes reducing surface tension and maintaining alveolar stability, thus eliminating the need for alveolar surfactant by filling the alveoi with liquid and thereby removing the air-liquid interface normally present. Perfluorochemicals also may act as a mechanical PEEP, holding the alveoli open because of the higher density of the liquid. Therefore partial liquid ventilation offers the potential

to manage infants with respiratory distress resulting from surfactant deficiency or dysfunction, in which exogenous surfactant replacement has failed or becomes impractical (e.g., heterogeneous lung disease such as ARDS). In animal models, perfluorochemicals also reduce neutrophil accumulation and inflammatory responses to lung injury[183-186] and inhibit hydrogen peroxide and free radical production by macrophages.[187] Studies in animals also show that partial liquid ventilation leads to marked improvements in respiratory mechanics compared with conventional ventilation strategies.[188-192] In 13 premature infants with severe RDS for whom conventional mechanical ventilation had failed and who had a high predicted risk of mortality, 10 of 13 received partial liquid ventilation for 24 to 72 hours,[193,194] resulting in dramatically improved oxygenation and compliance; 8 of 10 survived to 36 weeks gestational age without significant complications. Large randomized human trials have been limited by the dose-dependent risk of hypoxia and barotrauma associated with perfluorocarbon.[195] No studies of perfluorochemical liquid ventilation have been conducted in term neonates with respiratory disease; however, other limited clinical trials and individual case reports have been encouraging.[194,196-200]

Chronic Pulmonary Disease

Chronic Lung Disease (Bronchopulmonary Dysplasia)

The first description of a chronic respiratory disease in neonates was in 1967 by Northway et al.,[201] who reported long-term radiographic and clinical outcomes of 32 low-birth-weight infants with acute respiratory disease. The infants described by Northway and colleagues progressed from acute respiratory disease (typically, hyaline membrane disease) requiring mechanical ventilation to a chronic phase with persistent oxygen requirement and respiratory distress, often resulting in right ventricular failure and death. Northway et al. coined the term bronchopulmonary dysplasia (BPD) to describe the patho logic findings in these infants at autopsy.

Over the years, this term has been loosely applied to include a wider variety of infants with chronic lung disease, most of whom survive.[202,203] Because of improvements in the management of severe RDS, pulmonary hypertension, and pulmonary hypoplasia and because of increased survival rates of infants born between 23 and 26 weeks' gestation, the BPD characterized in the original description by Northway and colleagues is relatively rare. The pathophysiology of BPD has evolved to encompass a new population of infants with chronic lung disease: extremely-low-birth-weight infants (weighing less than 1000 g) who without today's advancements in medicine and technology could not have survived at the time of the investigations by Northway et al. These infants typically have a relatively mild course of acute respiratory disease and usually wean to minimal ventilatory support, oxygen support, or both within the first 72 hours of life. The oxygen requirement, however, tends to persist for weeks, months, or even years, and these infants are at extreme risk for respiratory exacerbations. Although the incidence of mortality is rare, those with this "new" type of BPD who die typically do not show severe lung injury with marked fibrosis and cellular proliferation, as seen in infants with classic BPD. Instead, one finds arrested lung development, with evidence of both impaired vascular and alveolar growth.[204-207]

The pathophysiologic cause of chronic lung disease after relatively mild acute respiratory disease in these extremely-low-birth-weight infants may, in part, relate to an increased sensitivity and abnormal responsiveness of the immature airways to injury.[205,206,208-219] It has been suggested that preterm birth during the late canalicular stage (24 to 27 weeks' gestation) leads to an arrest of normal lung development[213]; this suggestion is consistent with the observation that "normal" preterm infants (i.e., those without clinical evidence of lung disease) have dysfunction of terminal respiratory units and higher elastic recoil than do term infants at comparable postmenstrual ages.[212] This arrested development sets the stage for disordered repair when the immature lung is subjected to postnatal injury, perhaps by oxidants, infection, or ventilatory trauma.[209] Inflammation clearly plays a role in the development of BPD[210]; indeed, evidence exists that it may begin in utero.[213] Mediators of epithelial lung injury include a variety of cytokines, including interleukin-1β (IL-1β), IL-6, and IL-8[218]; in addition, impaired signaling of growth factors such as vascular endothelial growth factor has been implicated.[208,215] Given these considerations, it is likely that the pathogenesis of BPD, particularly in the extremely-low-birth-weight infant, is multifactorial in nature.

Generally, the incidence of BPD increases with decreasing gestational age: at less than 28 weeks' gestation the incidence is approximately 40%, and it approaches 90% for infants at less than 26 weeks' gestation.[202,203] Additional risk factors include maternal infection, neonatal sepsis, and PDA.[219] Although better monitoring, improved ventilation strategies, and new technologies have all had a positive impact on reducing the incidence and severity of BPD in the more mature neonate, increased survival of extremely-low-birth-weight infants has increased the overall prevalence of this condition in NICU graduates.

The clinical presentation of BPD depends on the severity and extent of the acute lung injury. In cases of classic BPD, infants typically require a high degree of ventilatory and oxygen support beyond the age of 1 week. These infants are slow to wean, require supplemental oxygen for weeks to months, and have episodes of bronchospasm or desaturation. Infants with severe BPD can have varying degrees of right ventricular failure or, in less severe cases, simply display fluid intolerance. Findings of chest radiographs for these infants will be abnormal, showing areas of increased density interspersed with areas of hyperinflation or even cystic development.

In the new type of BPD, onset is much more insidious. For the first 2 to 3 weeks of life, these extremely-low-birth-weight infants appear stable on minimal ventilatory and oxygen support, but then their need for increased ventilatory and oxygen support slowly develops. These infants often have episodes of apnea, desaturation, or carbon dioxide retention. Increased secretions from the endotracheal tube may occur as well. The chest radiograph may show areas of atelectasis, but more commonly it is clear in the early stages or simply shows a minimal, homogeneous increase in density in both lung fields. Depending on clinical signs, confounding conditions such as a PDA, pneumonia, or aspiration must be considered and ruled out.

Treatment of infants with BPD is generally supportive. The goal of treatment is to promote lung growth while simultaneously supporting respiratory needs and minimizing further injury to the lungs. Supplemental oxygen should be used for infants with oxygen saturations below 93% in room air.

Bronchodilators may be helpful particularly during exacerbations because often there is a large airway component to BPD. Fluid restriction or diuretics may be helpful in infants with evidence of cor pulmonale or fluid intolerance. At initial presentation infants often receive a few days of antibiotics until infection is ruled out. Infants with pulmonary insufficiency have increased energy needs,[211] making nutritional support particularly important, although it is often overlooked.[220]

An approach aimed at reducing the inflammation and ongoing fibrotic injury is the use of steroids. However, although earlier study results have shown that intravenous dexamethasone reduces the severity of BPD and improves respiratory outcome in older premature infants,[221,222] concerns have been raised regarding long-term safety, particularly from studies that included younger and more immature infants.[223-225] Because of these observations and a growing body of data that questions the safety of high-dose steroids in extremely premature animals, the Academy of Pediatrics Committee on the Fetus and Newborn has recommended that steroid use for infants with BPD be within the context of well-designed, randomized trials until issues of long-term efficacy and safety are more clear.[226] Given the rapid and sustained response that many infants with BPD have to steroids, significant controversy exists regarding this recommendation, particularly as it applies to older or less premature infants with significant pulmonary disability.

What is clear is that infants who receive long courses of steroids for BPD usually show chemical evidence of adrenal suppression, which may last for several months;[221] infants who receive steroids for more than several days also should receive supplementation at times of increased stress (e.g., surgery and infection). It also is apparent that the inhaled method of administering steroids offers no particular advantage over the intravenous route, except for ease of administration.[227] Potential new therapies to prevent or reduce the severity of BPD include synchronous mode ventilation, HFV, antioxidants, nitric oxide, antiproteases, vitamin A, and antenatal therapy with steroids and thyrotropin-releasing hormone; however, to date, study results have been inconclusive.[151,155,157,217,228-231]

The long-term outcome for infants with classic BPD has improved over the years, although these infants remain at risk for significant morbidity and mortality.[219,232] Infants typically require supplemental oxygen for the first several months of life, and some may require chronic diuretic and bronchodilator use. High-caloric formulas should be considered for infants who cannot tolerate fluid loading. Rehospitalizations as a result of respiratory exacerbations, which often are brought on by infection, are common during the first 2 years of life.[233] Persons with relatively uncomplicated courses will gradually improve and by school age often have normal lung function.[219]

The long-term outcome for extremely-low-birth-weight infants with new BPD is less clear. Although these infants often require little or no respiratory support at the time of discharge from the NICU, fewer data exist on long-term outcome because extremely-low-birth-weight infants rarely survived to discharge from the hospital before the advent of surfactant replacement therapy in the 1980s. If these infants indeed have an arrest of lung epithelial and vascular development as a result of preterm birth, long-term cardiorespiratory function remains unclear. As with infants with classic BPD, these infants are at increased risk for rehospitalization as a result of pulmonary infection and reactive airway disease,[234] but they also may be at increased risk for long-term pulmonary dysfunction.[235-237]

Mortality as a result of BPD has markedly improved during the past decade but remains high in infants with complicating conditions (such as cardiovascular disease) or in those with intercurrent respiratory infections, particularly RSV or adenovirus. Passive immunization against RSV is now possible and is recommended for high-risk premature neonates[238]; however, it is costly and is not uniformly protective.[239,240] Minimizing exposure to environmental hazards, whether infectious or irritant (e.g., from kerosene burners or cigarette smoke), cannot be overemphasized.[230]

Congenital Defects of the Lymphatics

Chylothorax is not an uncommon entity encountered in the pediatric ICU because it can be a complication of cardiothoracic surgery; however, postoperative chylothorax has a different natural history and prognosis than does congenital chylothorax, which is thought to be due to a failure of peripheral and central lymphatic channels to fuse, or perhaps a rupture of inadequately fused channels at birth.[241] Most affected infants have symptoms within hours of birth and require mechanical ventilation. Congenital chylothorax, in contrast to the postoperative variety, can be associated with chromosomal abnormalities and other malformations, as described by a recent case series of 11 newborns. Familial cases are especially common in babies with associated congenital pulmonary lymphangiectasis with bilateral chylothoraces.[242] Progressive respiratory compromise develops as fluid accumulates in the hemithorax. Drainage is both diagnostic and therapeutic; initially the lymphocyte-rich fluid is clear, but it becomes opaque when milk feedings are introduced. Nutritional support is critical because of the tremendous loss of protein in the chylous drainage. Most cases self-resolve in 2 to 3 weeks; occasionally, a several-day course of a somatostatin-analog, which reduces chyle flow, or an attempt at surgical closure of the thoracic duct is indicated. Whether congenital or postoperative, common complications include nosocomial infection, hemodynamic disturbance, and protein loss.[243] In the congenital variety, length of time to resolution is significantly affected by additional underlying problems.[242]

Pulmonary lymphangiectasia is a very rare condition that can be a primary condition or a secondary dilation of pulmonary lymphatics resulting from obstructed pulmonary venous flow.[241,244] A primary lymphangiectasia can be isolated, which is termed congenital pulmonary lymphangiectasia, or it can be part of a generalized condition that includes intestinal lymphangiectasia, in which pulmonary involvement is less severe. Congenital pulmonary lymphangiectasia is thought to result from failure of connective tissue elements to normally regress during fetal lung development. In some cases, a hereditary pattern has been suggested. Affected infants usually have symptoms soon after birth; however, some infants may remain symptom free for several weeks. Affected infants are usually born at term and may appear normal except for mild tachypnea, or they may be more severely affected with cyanosis or be frankly hydropic[245]; infants born preterm may be mistaken as having surfactant-deficient RDS. Radiographs generally reveal streaky reticular densities as a result of engorged lymphatics, and occasionally a finer, "ground-glass" appearance

may be confused with surfactant deficiency. Pleural effusions have been reported but are unusual. The condition is progressive and untreatable; most infants die within days, but an occasional survivor beyond infancy has been reported.

Nonpulmonary Conditions that Result in Respiratory Disease

Many nonpulmonary disorders may present with respiratory distress in the neonate (Box 46-1). Conditions that affect the control or mechanics of breathing, the patency or integrity of the upper airway, perfusion to and from the lung, or acid-base balance can present with increased respiratory effort or signs of respiratory insufficiency (i.e., respiratory acidosis or hypoxemia). The clinical and radiographic picture may be consistent with an underlying pulmonary pathologic condition, but nonpulmonary causes must be considered, particularly if an infant is gravely ill or not responding to conventional treatments. In many of these nonpulmonary conditions, a delay in diagnosis can lead to irreversible injury and death.

Apnea of Prematurity

Apnea is one of the most common respiratory problems encountered in the neonatal population. The incidence of apnea is inversely proportional to the gestational age at birth, and more than 75% of infants born before 27 weeks will have apnea at some point in their NICU stay. Apnea can be broadly classified as physiologic (i.e., apnea of prematurity) or pathologic (i.e., resulting from an underlying disorder such as sepsis).

Three main types of apnea exist. The first is central apnea, which results from decreased central responsiveness to respiratory stimuli, such as hypoxia and hypercarbia. This responsiveness improves as the infant matures and approaches term. This type of apnea is characterized by cessation of respiratory effort, which usually occurs at the end of exhalation. The second type of apnea is called obstructive apnea because of an anatomical or physiologic restriction of the airway. Common examples include tracheomalacia or Pierre Robin syndrome. The respiratory pattern of obstructive apnea demonstrates increasing respiratory effort with little to no air movement. Mixed apnea represents the third type of apnea. Initially the infant has what appears to be a central apnea, but when a respiratory effort is made, an obstructive pattern is revealed. The obstructive pattern is thought to result from gradual airway collapse during the initial central apneic portion of the episode. Most apneic episodes lasting longer than 20 seconds fall into this category.

Although apneic spells are a common cause of rehospitalization following NICU discharge, apnea of prematurity is a diagnosis of exclusion. Most infants with apnea of prematurity achieve complete resolution of symptoms by 34 to 36 weeks after conceptual age. Once apnea of prematurity has resolved, it does not come back,[246] and pathologic causes such as hypoglycemia, hypoxemia, hypothermia or hyperthermia, infection, left-to-right shunt, and intracranial hemorrhage should be ruled out. Of particular concern is new-onset apnea in a previously symptom-free infant. Apnea also increases in response to less stressful stimuli, such as immunizations or an ophthalmoscopic examination. Apnea in a term or near-term infant is almost always pathologic.

Isolated apnea may be treated with simple tactile stimulation in many cases. Infants who remain apneic after stimulation may require blow-by oxygen, nasal cannula therapy, nasal continuous positive airway pressure, nasal intermittent mechanical ventilation, or even re-intubation and mechanical ventilation depending on the severity, recurrence, and presence of underlying pathology. Caffeine is the pharmacologic agent of choice to treat apnea because of a long plasma half-life and low toxicity. It is interesting to note that whereas high neonatal serum levels of magnesium resulting from maternal magnesium therapy have been associated with apnea, magnesium deficiency can also cause apnea. In one retrospective study of premature infants receiving supplemental magnesium because of low serum levels, reduction in apneic episodes was noted[247]; however, because of a narrow therapeutic index, using magnesium to treat preterm neonatal apnea would require frequent serum levels that are not necessary when using caffeine.

Box 46–1 Nonpulmonary Conditions that Cause Respiratory Distress in the Newborn

Disorders of Respiratory Control
- Central hypoventilation disorder
- Apnea

Airway Obstruction/Patency
- Choanal stenosis/atresia
- Mandibular hypoplasia/micrognathia
- Laryngomalacia
- Laryngeal web/stenosis
- Vocal cord injury
- Subglottic hemangioma
- Tracheobronchomalacia
- Tracheoesophageal fistula
- Vascular compression

Interference with Respiratory Mechanics
- Neuromuscular disorders
- Phrenic nerve injury
- Eventration of the diaphragm
- Pleural effusion
- Chest wall anomalies

Perfusion Abnormalities
- Persistent pulmonary hypertension of the newborn
- Hyperviscosity
- Congenital heart disease

Disorders of Acid-Base Balance
- Metabolic disorders (e.g., organic acidemias)
- Intestinal bicarbonate wasting
- Renal bicarbonate wasting
- Sepsis
- Iatrogenic metabolic acidosis/alkalosis

Choanal Atresia/Stenosis

Choanal obstruction resulting from failure of bony or membranous regression is the most common supralaryngeal congenital defect. It occurs in approximately 1 in 4000 live births. Choanal atresia is often associated with defects in other organs or with syndromes that include other craniofacial anomalies, especially CHARGE syndrome (i.e., coloboma of the eye, heart anomaly, choanal atresia, retardation, and

genital and ear anomalies). Choanal atresia is usually unilateral, typically on the right side; a 2:1 excess of choanal atresia has been reported in girls, though a recent review suggests equal sex predilection.[248] Unilateral choanal atresia occurs more frequently in isolated cases, whereas bilateral choanal atresia is an indication for further evaluation for other congenital anomalies. This phenomenon may be partly explained by the idea that genetic factors are more likely to result in symmetric errors of embryogenesis.[249] Associated findings include a high-arched palate, thickening of the vomer, and medial bowing of the lateral wall of the nose. Clinical presentation depends on the degree of obstruction; bilateral choanal atresia or severe bilateral stenosis will present in the newborn period, whereas unilateral cases or mild stenosis may not present for weeks, months, or years. Infants with symptoms are typically distressed during times of sleep or feeding, when nasal breathing is preferential. Clinical presentation in infants with unilateral obstruction or mild stenosis may occur only when the nares become obstructed, as with the passage of a nasogastric tube or inflammation during an upper respiratory infection. With occlusion of the patent nares, an infant can suddenly decompensate, with signs of severe respiratory distress.

Infants in severe distress may require elective intubation if an oral airway is insufficient or cannot be easily maintained. Direct visualization of the obstruction is best performed by an otolaryngologist using a fiberoptic scope. A cranial CT scan can determine the presence and thickness of the bony plate within the nasal cavity, which is an important surgical consideration. Definitive treatment generally involves drilling through the bony plate and stenting the nasal passage with tubes for 6 weeks to allow proper healing. A high degree of suspicion is key to diagnosing and properly treating this disorder, and if true bilateral choanal atresia is present, associated anomalies must be ruled out.

Laryngomalacia

Laryngomalacia is the most common cause of stridor in the neonate. It is thought to result from redundant soft tissue or delayed development of neuromuscular control. Similar to infants with mandibular hypoplasia, infants with laryngomalacia tend to have more symptoms in the supine position because this allows relatively unsupported anterior tissue to drop into hypopharynx, causing obstruction. Affected infants may be stridulous, however, only during periods of crying or distress. Treatment includes prone positioning, and resolution is common by age 1 to 2 years.

Vocal Cord Paralysis

Vocal cord paralysis can be unilateral or bilateral. Unilateral cord paralysis usually presents with a weak or sometimes hoarse cry. Obstructive symptoms, such as stridor or retractions, are less severe and less common. The infant may also cough or choke while feeding because of an inability to prevent aspiration while swallowing. The most common causes are stretch injury during delivery or recurrent laryngeal nerve injury during ductus ligation; thus left-sided paralysis or paresis is most common. Symptoms from unilateral cord paralysis usually improve over a few weeks or months with no intervention.

Bilateral cord paralysis represents a more serious problem and is usually the result of an intracranial pathologic condition, such as Chiari malformation, intracranial hemorrhage, or hypoxic-ischemic encephalopathy. These infants may have near total airway obstruction and will have moderate to severe stridor. Most will require tracheostomy to maintain a patent and reliable airway.

Subglottic Hemangioma

Congenital hemangiomas just below the level of the vocal cords are another relatively uncommon cause of stridor, with or without expiratory wheeze, in the neonate. As they enlarge they can threaten the airway. Positional changes tend to have little effect on the severity of the symptoms. Superficial, capillary hemangiomas on the skin of the neck are often present, suggesting the diagnosis. For acute exacerbations, systemic steroids may be used to reduce tissue swelling and improve airway patency; however, symptomatic infants eventually require surgical removal of the lesions. The availability of laser surgery has markedly reduced the need for tracheostomy in children with subglottic hemangioma.

Tracheobronchomalacia

Tracheobronchomalacia is characterized by abnormally compliant airway cartilage, leading to intermittent collapse of the airways during normal respiration. Specific classification depends on the area(s) involved (e.g., tracheomalacia, tracheobronchomalacia, and bronchomalacia). Infants can be mildly or severely affected, depending on the extent of involvement and the ability of surrounding supporting tissues to maintain airway patency. Affected infants generally have symptoms in the newborn period, but presentation may be delayed for many days or weeks if the defect is mild. In these milder cases, infants may remain symptom free until an intercurrent infection leads to increased airway secretions and increased work of breathing. Symptoms include expiratory wheezing and respiratory distress including tachypnea and retractions, and the infant may receive a mistaken diagnosis of reactive airway disease; however, the use of bronchodilators may actually worsen the condition. A chest radiograph may show hyperinflation. Definitive diagnosis is made by direct visualization, typically with flexible bronchoscopy. Treatment is supportive because airway compromise generally lessens as the infant grows; however, more severe cases may require stenting with continuous positive airway pressure or even surgical plication. Tracheostomy alone may not be helpful if the affected area extends beyond the proximal trachea. A high association with other congenital anomalies, including vascular rings or tracheoesophageal fistula (discussed later in this chapter) also must be kept in mind; a history of recurrent coughing or choking requires further investigation.

Tracheoesophageal Fistula

Tracheoesophageal fistula (TEF) occurs in approximately 1 in 4500 live births, making it one of the most common congenital malformations. Usually isolated, it can be associated with other anomalies including complex syndromes like VATER (vertebral defects, anal atresia, TEF, esophageal atresia, and renal anomalies), VACTERL (VATER plus cardiac and upper

limb defects), and CHARGE (coloboma, heart defect, choanal atresia, mental retardation, genital hypoplasia, ear anomalies, and deafness). In the absence of a more generalized syndrome, TEF is also associated with isolated cardiac defects, which may present in up to 50% of cases. Whether as part of a syndrome or an isolated anomaly, TEF usually is associated with esophageal atresia; however, in 5% to 7% of cases there is no associated esophageal atresia (H-type TEF).

TEF and an associated esophageal atresia and TEF as part of a more general disorder invariably present in the immediate newborn period; infants with an isolated H-type fistula can remain clinically silent for many weeks or even months. Although relatively rare (approximately 1 in 100,000 live births), an H-type fistula must be suspected in any infant who coughs during feedings and has recurrent pneumonitis. In preterm infants it can present as apnea spells with no other signs. The diagnosis of an H-type fistula can be difficult but is best found by a cine esophagram; in cases in which this study is inconclusive, bronchoscopy may be necessary. Successful repair and preservation of pulmonary function depends on early diagnosis.

Vascular Compression

Vascular compression of the trachea or mainstem bronchus can result from improper regression of the embryonic branchial arch arteries during fetal development. The most common anomaly is a vascular "ring" consisting of a double aortic arch, in which the vessel completely encircles the trachea and esophagus. Other variants include an ectopic aortic arch (passing behind the esophagus) or an aberrant origin of the right brachiocephalic artery.

Vascular rings will cause inspiratory stridor and expiratory wheezing, neither of which change appreciably with the infant's position. Intermittent worsening of symptoms is sometimes seen when feeding as boluses passing down the esophagus, further compressing the trachea. Feeding difficulty also may be present because of esophageal compression. When a previously undiagnosed child first presents with these symptoms, the child may be misdiagnosed as having tracheomalacia, bronchomalacia, or tracheobronchomalacia, until further imaging confirms the cardiovascular abnormality. This condition also can be detected antenatally.

The presence of an abnormally shaped mediastinum on a chest film often provides a clue to this diagnosis. Endoscopy may identify tracheal or esophageal compression. An echocardiogram may define the nature of the vascular anomaly; cardiac catheterization is sometimes necessary. Decisions regarding surgical correction of this defect depend on the relative compromise of the trachea and esophagus; however, the degree of compression may actually worsen as the infant grows.

Phrenic Nerve Paralysis

Stretch injury to the cervical nerve roots C3 to C5 during delivery can lead to temporary paralysis of the hemidiaphragm, and avulsion of the nerve roots will lead to a permanent injury. Most commonly on the right, this type of injury is associated with birth trauma; brachial plexus injury or Horner's syndrome is present in 70% to 80% of cases, and clavicular fracture is common. Infants at highest risk are those with estimated birth weights of more than 4 kg, shoulder dystocia, or difficult breech presentations. Diminished ventilation is present on the affected side, and the infant may have tachypnea or even be cyanotic if severely compromised. The chest radiograph will show a varying degree of atelectasis with a raised hemidiaphragm on the affected side and the heart and mediastinum shifted toward the contralateral side. Fluoroscopy will show that the paralyzed diaphragm elevates during inspiration and descends on expiration (paradoxical movement). Treatment is supportive in most cases because function usually returns spontaneously in several weeks; in cases of avulsion or permanent dysfunction, surgical plication may be necessary.

Eventration of the Diaphragm

The normal diaphragm consists of three layers: a muscular layer sandwiched between the pleural and peritoneal layers. Congenital dysplasia or absence of the muscular layer is a rare disorder that results in a nonfunctioning diaphragm that is highly stretchable. Partial defects are more common and appear most often on the right side; complete defects are more common on the left side and often are associated with anomalies of other organs. Under normal abdominal pressure, viscera easily push the affected diaphragm upward into the hemithorax. In utero this phenomenon may lead to pulmonary hypoplasia (although this is usually mild), whereas after birth it will cause respiratory compromise by affecting lung expansion. Radiographic and fluoroscopic findings are similar to those of a paralyzed diaphragm, but the clinical history of birth trauma or associated injuries is usually absent. With large defects the appearance of bowel apparently in the thoracic cavity on a chest radiograph may be mistaken for a diaphragmatic hernia; however, close inspection will reveal the thin, overlying diaphragmatic pleura. Treatment is supportive; defects that remain symptomatic beyond the neonatal period may require plication.

Pleural Effusion

Collection of fluid within the pleural cavity, if excessive, can result in significant respiratory embarrassment. Pleural effusions in the neonate can result from inflammation, transudation, or frank leakage from disrupted vessels (either vascular or lymphatic). Small pleural effusions are normal during the first hours of life, as fetal lung liquid is cleared from the airspaces, but large effusions or persistence beyond the first day of life is abnormal. Large effusions can result in significant respiratory compromise; although initial management is similar regardless of the cause, successful long-term management depends on accurately identifying the source of the pleural effusion.

Congenital Anomalies of the Chest Wall

Thoracic cage abnormalities represent a group of uncommon but often overlooked causes of respiratory distress in the neonate and can be classified as either structural or functional. Structural abnormalities may be limited to the sternum or involve the entire thoracic cage. Sternal deformities include pectus excavatum, a relatively common but usually benign condition, and complete separation of the sternum, which usually leads to ectopia cordis and usually is lethal. Generalized

structural abnormalities invariably involve some degree of thoracic restriction and pulmonary hypoplasia; many of these abnormalities are intrinsically lethal or are part of a more generalized lethal disorder. Some conditions, however, such as achondroplasia and Ellis-van Creveld syndrome, are compatible with normal life. Functional anomalies result from dysfunction of the chest wall musculature. Like structural defects, they can be isolated to the thoracic cage, but more often they are part of a systemic disorder, such as congenital muscular dystrophy, glycogen storage disease, or myasthenia gravis.

The condition of most infants with thoracic cage abnormalities is recognized in the immediate newborn period, although a relatively protuberant abdomen may distract the clinician from the primary problem. Infants with restricted thoracic cages (either structural or functional) will have tachypnea and retractions; the radiograph will show a narrow, elongated thoracic cage with high clavicles and low hemidiaphragms. Treatment is supportive, and in the absence of severe pulmonary hypoplasia or an underlying lethal disorder, infants may do relatively well, although they often require mechanical ventilation for a limited duration.

Persistent Pulmonary Hypertension of the Neonate

In the fetus, the organ of gas exchange is the placenta, not the lung. Thus placental blood flow is high, whereas pulmonary blood flow is minimal. To achieve this gas exchange, blood returning to the right side of the heart must be directed to the systemic (and thus placental) circulation. This blood flow is accomplished by two principal right-to-left shunts in the fetus: the foramen ovale, which shunts blood from the right to left atrium, and the ductus arteriosus, which shunts blood from the pulmonary artery to the descending aorta. These shunts result in less than 10% of the combined fetal ventricular output going to the lungs.

At birth, dramatic changes must occur within the lung if the fetus is to make a successful transition from placental to pulmonary gas exchange. Not only must liquid be removed from potential airspaces (see the section on Delayed Clearance of Fetal Lung Liquid in this chapter), but blood flow also must be redirected. After inflation of the lungs with air and dramatic increases in oxygen tension within the lungs, a marked increase in cyclic nucleotides occurs within the pulmonary vascular smooth muscle, leading to vasodilatation.[250,251] The resultant drop in pulmonary vascular resistance leads to a tenfold increase in pulmonary blood flow,[252] which causes left atrial pressure to exceed right atrial pressure, allowing the one-way flap across the foramen ovale to close. Flow across the ductus arteriosus reverses, and this, combined with the increase in oxygen tension in the blood, leads to gradual closure of the ductus over the first few hours of life.

In the syndrome of persistent pulmonary hypertension of the newborn (PPHN), this transition of the pulmonary circulation fails to occur normally (see Chapter 48). Pulmonary vascular resistance and pulmonary arterial pressure remain high and blood flow continues to bypass the lungs as in fetal life. (This is why the term persistent fetal circulation has been used, although it is not strictly correct because there is no longer any placental/umbilical circulation as in the fetus.) PPHN is associated with many neonatal disorders, including RDS, meconium aspiration, air leak syndromes, perinatal asphyxia, congenital sepsis, and structural lung disease such as pulmonary hypoplasia or alveolar-capillary dysplasia. PPHN can also be idiopathic. Infants with PPHN can be moderately or severely affected, depending on the degree of shunting. PPHN is often a self-limited disease, but this process may take several days; meanwhile, severe hypoxemia can lead to significant morbidity. The incidence of mortality can be as high as 50% to 60%; it has improved significantly with the advent of new treatment modalities such as HFV, inhaled nitric oxide, and extracorporeal bypass, which allow the infant more time to spontaneously recover.[105,106,149,163,164,253-256] Because nitric oxide works by increasing cyclic guanosine monophosphate levels, there has been recent interest in using selective phosphodiesterase inhibitors such as sildenafil, particularly in infants with a prolonged course of PPHN, or in whom PPHN develops beyond the newborn period, either idiopathic or as a result of underlying cardiorespiratory disease. However, the long-term benefits and risks of sildenafil are unknown, and its use should still be considered experimental.

Hyperviscosity Syndrome

Neonates with polycythemia (i.e., a central hematocrit greater than 65%) are at risk for abnormally high blood viscosity, which interferes with perfusion to vital tissues. Polycythemia can occur in several situations, including twin-twin transfusion, maternal-fetal transfusion, delayed cord-clamping, home delivery, maternal diabetes, small-for-gestational-age infants, postmature infants, and infants with Down syndrome or Beckwith-Wiedemann syndrome. Symptoms generally relate to the degree of hyperviscosity and can range from tachypnea to apnea, listlessness to irritability, and jitteriness to seizures. Hyperviscosity syndrome presents in the first few hours of infants' lives, and the presentation can mimic that in infants with congenital pneumonia, meconium aspiration, persistent pulmonary hypertension, or congenital heart disease. Affected infants are at risk for ongoing thrombotic injury unless the condition is reversed by partial blood volume exchange.

Congenital Heart Disease

In the neonate, significant congenital heart disease typically presents in one of two ways: (1) cyanosis with minimal or no respiratory distress or (2) cardiorespiratory failure. Cyanotic lesions, such as transposition of the great vessels or tetralogy of Fallot, usually present in an infant who is blue but comfortable. Characteristically, congenital cyanotic heart disease is suspected in such an infant, even if a murmur is absent, particularly if the infant remains desaturated or hypoxemic in 100% oxygen. Less common in the neonate are those conditions that lead to early failure, such as an atrioventricular canal defect or a large ventricular septal defect. These infants are generally not cyanotic but are pale with marked respiratory distress and often a loud murmur; chest radiographs may show the classic signs of cardiomegaly and pulmonary vascular congestion.

In some types of congenital heart disease there is an overlap in presentation, and infants will appear cyanotic and have signs of respiratory distress such as tachypnea and perhaps even retractions. This type of presentation, which is common with hypoplastic left heart syndrome and total obstructed anomalous pulmonary venous return, may initially be confused with

sepsis, pneumonia, meconium aspiration, or even RDS. Total anomalous pulmonary venous return (TAPVR) deserves particular mention because it cannot be detected in utero; it is often missed postnatally, even on repeated echocardiograms. In fact, this condition is the most common potentially correctable cardiac lesion for which neonates are mistakenly placed on ECMO. To diagnose TAPVR, one must keep a high index of suspicion, particularly in a term or near-term infant who has a clinical and radiographic picture of surfactant-deficient respiratory distress or group B streptococcal sepsis. If TAPVR is suspected and echocardiograms are not confirmatory, these infants must have a cardiac catheterization to make the diagnosis.

Metabolic Disorders

Several hundred inborn errors of metabolism (IEM) have been identified. Because they are a heterogeneous group, variable in presentation and relatively rare, they are frequently overlooked. Even with expanded newborn screening in many states, covering anywhere from 4 to 36 disease entities, results can be unavailable or difficult to interpret. An infant with an IEM may present with deep, labored respirations (Kussmaul breathing), if the underlying condition is associated with metabolic acidosis or increased intracranial pressure from cerebral edema. In many cases, this situation will rapidly progress to respiratory failure and apnea. Other manifestations of IEM result from either accumulation of a toxic product or deficiency of a necessary substrate. Although often present in the later course of the illness, many times these infants will not present with dysmorphic features, seizures, or vomiting. Rather, they display a pattern of worsening but nonspecific symptomatology that may not respond to routine intervention. It is important to maintain a high index of suspicion for IEMs, especially if there is no identified risk factor for respiratory distress, because a delay in diagnosis and treatment can be catastrophic.[257]

Intestinal and/or Renal Bicarbonate Wasting

Low plasma bicarbonate represents a metabolic acidosis that may present as tachypnea and respiratory distress in the neonate, although usually not in isolation. It is worth noting that metabolic acidosis with a normal anion gap may be a feature of neonatal diabetes or may be indicative of bicarbonate loss through the kidneys or intestines; gastroenteritis, renal tubular acidosis, and mineralocorticoid insufficiency are common causes.[258] Differentiating the source of the acidosis is important because bicarbonate therapy may actually be harmful depending on the underlying problem.

Pneumonitis and Interstitial Disease

Jeffrey C. Benson, Daiva Parakininkas, and Tom B. Rice

PEARLS

- Most pediatric pulmonary parenchymal disease occurs as the result of an infectious agent.
- Clinical evaluation for parenchymal lung disease in the pediatric patient should include a search for symptoms and signs associated with pulmonary disease, such as difficulty with feeding, exercise intolerance, chest pain, cough, tachypnea, dyspnea, cyanosis, orthopnea, clubbing of the nail beds, weight loss, and lethargy.
- Factors predisposing a child to bacterial pneumonia include having numerous siblings, having parents who smoke, preterm delivery, living in an urban environment, poor socioeconomic status, presence of an airway foreign body, impaired immune response, congenital and anatomic lung defects, abnormalities of the tracheobronchial tree, cystic fibrosis, and congestive heart failure.
- Viral agents are the leading cause of lower respiratory tract infection in infants and children.
- Three major clinical syndromes are associated with lower respiratory tract viral illness are (1) bronchitis, (2) bronchiolitis, and (3) pneumonia.
- Fungal infections are important in the differential diagnosis of pulmonary infections, particularly in children whose immunity is compromised and in healthy children who are exposed to pathogens in a particular geographic or environmental setting.
- Three forms of disease patterns in pneumocystosis are (1) childhood/adult, (2) infantile, and (3) chronic fibrosing observed in some patients infected with the human immunodeficiency virus.
- Chemical pneumonitis and/or pneumonia may be acquired by (1) aspiration, (2) inhalation, (3) ingestion, or (4) injection.
- Pulmonary hemorrhage is a potentially life-threatening event that can occur at any age. Clinical presentation varies from massive fatal hemoptysis to silent bleeding with respiratory distress and anemia.

Pneumonitis, or inflammation of the lung parenchyma, is perhaps the most common cause of life-threatening lower respiratory tract disease in pediatric patients. Although pneumonitis may result from noninfectious processes (Box 47-1), most pediatric pulmonary parenchymal disease occurs as the result of an infectious agent. Pneumonitis may involve the pleura, interstitium, and airways; pneumonia by definition must include alveolar consolidation. Whereas early parenchymal lung injury is associated with increased cellularity with minimal fibrosis, advanced disease is characterized by extensive fibrosis and destruction of gas exchange units. Physiologic changes may include the following: low lung volumes, diminished lung compliance, impaired gas exchange, and airflow limitation. This chapter addresses the principal potential causes of pediatric pulmonary parenchymal disease, including alveolar and interstitial disorders.

Pathogenesis

Regardless of the cause, pneumonitis often follows a common pathogenesis. The initial parenchymal injury can result from mechanisms that directly damage the endothelium or epithelial cells. Other agents may injure the lung indirectly by one or more of the following processes:

1. Generation of toxic radicals
2. Recruitment of inflammatory cells (e.g., neutrophils)
3. Activation of complement and/or release of chemotactic factors

If these processes go unchecked, alterations may occur in the lung parenchyma and connective tissues leading to end-stage fibrosis. This condition is characterized by severe destruction of gas exchange units and airways and the development of parenchymal cystic lesions.

Pathophysiology

Changes in lung volumes in pulmonary parenchymal disease depend primarily on the intensity of the alveolitis and stage of the disease process. Acute severe pneumonitis with an intense alveolitis is characterized by moderate to severe reduction in both vital capacity (VC) and total lung capacity. It also is associated with a reduction in pulmonary compliance. In the early stages, patients with chronic interstitial diseases involving the lung parenchyma often have normal VC and total lung capacity. Subsequent reduction in lung volumes and pulmonary compliance occurs as the disease progresses and pulmonary fibrosis ensues.[1] Expiratory flow rates usually are preserved in persons with pneumonitis involving the lung parenchyma, and major obstructive

defects, although reported, are rare. The carbon monoxide diffusing capacity, one of the earliest and most sensitive tests of parenchymal inflammation, is diminished in persons with interstitial lung disease (ILD). A reduction in the carbon monoxide diffusing capacity is not specific and may be found with other parenchymal disorders. Early in the course of parenchymal disease, resting arterial oxygen tension may be normal, but there is often mild alveolar hyperventilation with reduction in alveolar carbon dioxide tension and widening of the alveolar-arterial oxygen gradients ($P_{AO_2} - Pa_{O_2}$). With exercise, hypoxemia and an increased $P_{AO_2} - Pa_{O_2}$ become exaggerated because of ventilation/perfusion (V/Q) imbalance. V/Q mismatch is attributed to regional alterations of flow, altered parenchymal compliance, and increased obstruction to pulmonary airflow. Progressive alveolitis and subsequent derangement of gas exchange lead to deterioration of ventilatory efficiency and markedly increased work of breathing. Adequate oxygenation may become impossible even with the use of high-flow supplemental oxygen. Resting hypercapnia, pulmonary hypertension, and eventual right ventricular dysfunction with heart failure are common sequelae.[2-4]

Diagnosis

Diagnosing parenchymal lung disease in the pediatric patient may be quite challenging because of extreme variability in the presentation of disease. Clinical evaluation of the child should include a search for symptoms and signs associated with pulmonary disease, such as difficulty with feeding, exercise intolerance, chest pain, cough, tachypnea, dyspnea, cyanosis, orthopnea, clubbing of the nail beds, weight loss, and lethargy. In the child with diffuse alveolar disease, auscultative findings may be normal unless significant consolidation or small airway involvement is present. Fine crackles that may be heard throughout the chest late in inspiration are a characteristic finding of small airway disease. These rales are produced by the opening of occluded small peripheral airways.

Laboratory Diagnosis

The chest radiograph is critical in the diagnosis and management of pulmonary parenchymal disease. In children with ILD the classic radiographic features that are present in adults may be absent. Computed tomography scanning,[5-7] gallium lung scanning, and bronchoalveolar lavage (BAL)[8-10] are useful techniques in the diagnosis and management of diseases involving the lung parenchyma. Pulmonary function testing is important and usually can be performed reliably in children who are older than 4 years.[1,11]

Bacterial Pneumonitis

Bacterial infections of the lower respiratory tract continue to account for a significant number of hospital admissions. The frequency of bacteria as etiologic agents of lower respiratory tract infection varies from 10% to 50%, depending on the study population and the methods of evaluation used.[12,13] In a large study of pediatric patients with lower respiratory tract infection, an etiologic agent was identified in nearly 50% of the patients. Bacteria accounted for 10% to 15% of the causative agents identified.

Factors predisposing to bacterial pneumonia include having numerous siblings, having parents who smoke, preterm delivery, living in an urban environment, and poor socioeconomic status. Hospitalization also increases the risk of contracting bacterial pneumonia because of the clustering of ill patients in confined areas, administration of immunosuppressive therapy, and various medical and surgical interventions that enhance the opportunity for colonization and infection. Additional factors that increase susceptibility to bacterial pneumonia include the presence of an airway foreign body,[14] impaired immune response,[15-19] congenital and anatomic lung defects, abnormalities of the tracheobronchial tree, cystic fibrosis,[20] and congestive heart failure.

Definition

Bacterial pneumonia is an inflammatory process of the lungs that may involve interstitial tissue and pleura in its evolution but always progresses to alveolar consolidation.

Pathophysiology

Pneumonia occurs when pulmonary defense mechanisms are disrupted and bacteria invade the respiratory system by aspiration or hematogenous spread. In most instances pneumonia

appears to be a consequence of aspiration of a high inoculum of pathogenic bacteria. Viruses often are responsible for enhancing the susceptibility of the respiratory tract to bacterial infection. Less frequently, bacterial pneumonia may be the result of defects in host immunity because of young age, underlying immune dysfunction, or immunosuppressive therapy. Pneumonia also may occur when host defenses are mechanically disrupted because of tracheostomy or endotracheal intubation. The presence of respiratory pathogens in the terminal bronchioles and alveoli induces an outpouring of edema fluid and large numbers of leukocytes into the alveoli.[2,21] Macrophages subsequently remove cellular and bacterial debris. The infectious process may extend further within the lung segment, or it may disseminate through infected bronchial fluid to other areas of the lung. The pulmonary lymphatic system enables bacteria to reach the bloodstream or visceral pleura.

With consolidation of lung tissue, VC and lung compliance markedly decrease and intrapulmonary right-to-left shunt and V/Q mismatch occur, resulting in hypoxia. Subsequently, pulmonary hypertension may occur because of significant oxygen desaturation and hypercapnia, often leading to cardiac overload.

Clinical Features

Signs and symptoms of bacterial pneumonia vary with the individual pathogen, the age and immunologic condition of the patient, and the severity of the illness. Clinical manifestations, especially in newborns and infants, may be absent. General or nonspecific complaints include fever, chills, headache, irritability, and restlessness. Individual patients may have gastrointestinal complaints including nausea, vomiting, diarrhea, abdominal distension, or pain. Specific pulmonary signs include nasal flaring, retractions, tachypnea, dyspnea, and occasionally apnea.

Tachypnea is the most sensitive index of disease severity. The sleeping respiratory rate is often a valuable guide to diagnosis. On auscultation, diminished breath sounds are frequently noted. Fine crackles that may be heard in children and older patients are commonly absent in infants. Because of the relatively small size of the child's thorax and the thin chest wall, broad transmission of the breath sounds occurs, and the classic findings of consolidation are often obscured. Pleural inflammation may be accompanied by chest pain at the site of inflammation. This pleuritic pain may cause "splinting," which restricts chest wall movement during inspiration and reduces lung volume.

Extrapulmonary infections that may be present in some children include abscesses of the skin or soft tissue (*Staphylococcus aureus*); conjunctivitis, sinusitis, otitis media, and meningitis (*Streptococcus pneumoniae* or *Haemophilus influenzae*); and epiglottitis (*H. influenzae*).

Radiographic Features

Bacterial pneumonia typically is characterized by defined areas of consolidation with either segmental or lobar involvement. Lobar consolidation is the most characteristic, but multilobed disease is not unusual. The findings of pleural effusion, pneumatocele, or abscess are also strongly indicative of a bacterial infection. Staphylococcal pneumonia is suggested by rapid clinical and radiographic progression of disease, particularly in a young infant. Evidence of an abscess or pneumatocele further suggests a diagnosis of staphylococcal or gram-negative pneumonia such as Klebsiella. Group A streptococcal pneumonia may initially present with a diffuse interstitial pattern prior to the development of consolidation. Except for *Pseudomonas*, which may have a diffuse nodular appearance in the lower lobes, pneumonias caused by gram-negative organisms have no specific radiographic pattern. Anaerobic pulmonary infection is also associated with lung abscesses or air fluid levels.

Diagnosis

Bacterial pneumonia is suggested by fever, leukocytosis (>15,000 white blood cells), and increased band forms on the peripheral blood smear. Examination of the sputum may be helpful in establishing the diagnosis of bacterial pneumonia; however, it often is difficult to obtain a satisfactory sputum sample in pediatric patients unless transtracheal aspiration or bronchoscopy is used. Transtracheal aspiration, although useful in adolescents and adults, is associated with significant complications in infants and young children. If a sputum sample is obtained (an adequate specimen must have >25 polymorpho-nuclear cells and <25 epithelial cells per high-power field), the Gram stain should be examined for a predominant bacterial pathogen, and cultures should be performed with the appropriate antibiotic susceptibility studies. Counterimmune electrophoresis (CIE) performed on sputum specimens has proved helpful in establishing the diagnosis in both adults and children. Bacterial pneumonia is accompanied by bacteremia in a significant number of cases; hence blood cultures should be obtained prior to initiation of antibiotic therapy. Circulating antigens in *S. pneumoniae* and *H. influenzae* may be detected in the blood with CIE,[22] polymerase chain reaction (PCR),[23-25] or latex agglutination.[26,27]

If a significant pleural effusion is present, a diagnostic thoracentesis should be performed for the purposes of Gram stain and culture. Culturing pleural fluid has a relatively high yield in patients who have not received previous antibiotic therapy. If the Gram stain of pleural fluid is negative, CIE or latex agglutination should be performed because bacterial antigen may be detected in the fluid even after the initiation of antibiotics.

BAL should be considered in the management of a severely ill child in order to make a prompt diagnosis.[9,10] Making a prompt diagnosis is essential for the patient with progressive disease that has responded poorly to initial therapy or for the child with underlying immunodeficiency for whom empirical antibiotic treatment may be hazardous. In such instances, if the BAL is nondiagnostic, then lung aspiration or biopsy should be considered.[28] Material may be obtained through closed-needle biopsy, percutaneous needle aspiration, or an open lung biopsy. Positive results for such procedures in carefully selected cases identify an etiologic agent in 30% to 75% of cases, with open lung biopsy having the highest yield.[18,29]

Specific Pathogens

Group B Streptococci

Group B streptococci can cause infection in people of any age; however, these organisms are common pathogens in infants younger than 3 months.[30] Early-onset illness often is associated

with maternal fever at the time of delivery, prolonged rupture of membranes, amnionitis, prematurity, and low birth weight.

Infected neonates usually manifest clinical symptoms within the first 6 to 12 hours of life. Symptoms include fever, respiratory distress, apnea, tachypnea, and hypoxemia. By 12 to 24 hours of age, signs of cardiovascular collapse often are apparent. Frequently, the syndrome of pulmonary hypertension of the newborn is present, and pulmonary or intracranial hemorrhage may become the terminal event.

Isolation of the organism establishes the diagnosis. Cultures from blood and cerebrospinal fluids must be obtained in all instances of suspected group B streptococcal pneumonia. Rapid diagnostic techniques have been helpful in providing early diagnoses. The radiographic findings in neonates with group B streptococcal pneumonia can be either a lobar (40%) or a diffuse reticulonodular pattern with bronchograms similar to findings of respiratory distress syndrome.

Aggressive cardiovascular and ventilatory support is usually required, particularly in the early stages of the disease. Antibiotic therapy should include a combination of ampicillin or penicillin and an aminoglycoside agent.

Although in the past the mortality rate of patients with group B streptococcal pneumonia could be as high as 50% to 60%, recent studies suggest improvement with prompt initiation of therapy and even better outcomes with maternal prophylaxis.[31] Some infants experience a second episode of infection 1 to 2 weeks after discontinuation of antibiotic therapy. Infants with group B streptococcal pneumonia and meningeal involvement (30%) may demonstrate significant neurologic deficits (20% to 50%).

Streptococcus Pneumoniae

S. pneumoniae is a gram-positive diplococcus with at least 84 sera types; however, 80% of the serious infections are caused by only 12 sera types. Streptococci are a major cause of pneumonia in the United States. Victims are usually infants younger than 2 years, with a peak age between 3 and 5 months. Patients with asplenia, functional hyposplenia, or malignancy or those receiving immunosuppressive drugs are at special risk of the development of invasive disease.[32]

The radiographic finding in infants often is a patchy bronchopneumonia. Lobar consolidation is not uncommon. Penicillin is the drug of choice in the treatment of persons with streptococcal pneumonia. However, organisms relatively resistant to penicillin occur in 3% to 40% of culture-positive patients recorded in studies from different parts of the United States.[33] In such instances, pneumonias have been effectively treated with vancomycin or high-dose β-lactam cephalosporin agents such as cefuroxime, ceftriaxone, or cefotaxime. Disease resulting from penicillin-resistant pneumococci should be considered in patients who received therapy with β-lactam antibiotics.[33-35]

The heptavalent pneumococcal conjugate vaccine is recommended for all children aged 2 to 23 months. It also is recommended for certain children aged 24 to 59 months. Pneumococcal polysaccharide vaccine is recommended in addition to pneumococcal conjugate vaccine for certain high-risk groups.[36]

Haemophilus Influenzae

Haemophilus organisms are small, nonmotile, gram-negative rods that occur in both encapsulated and nonencapsulated forms. Approximately 90% to 95% of invasive disease is caused by the encapsulated sera type B. A pleural effusion or empyema is detected in nearly 40% of patients with *H. influenzae* pneumonia. There is an extremely high incidence of bacteremia in this disease. Serious complications such as epiglottitis, meningitis, and pericarditis can be diagnosed in 15% to 20% of patients. Cellulitis, anemia, and septic arthritis occur infrequently.

In a hospitalized patient, administration of the combination of ampicillin and chloramphenicol or a single cephalosporin such as cefuroxime, cefotaxime, or ceftriaxone generally is effective therapy.[33,37] The mortality rate in appropriately treated patients is generally considered less than 5% and often is related to associated meningitis, epiglottitis, or pericarditis rather than the pneumonic process itself. Hib conjugate vaccine is an important measure in reducing the incidence of *Haemophilus*-related disease and should be administered to all children.[33,38,39]

Staphylococcal Pneumonia

Primary *S. aureus* pneumonia has decreased in frequency in recent years but still accounts for approximately 25% of cases in young infants. The incidence of secondary or metastatic dissemination has increased since 1972. Patients with primary pneumonia present with fever and respiratory symptoms, whereas those with metastatic disease often present with fever, generalized toxicity, and musculoskeletal symptoms. In patients presenting with primary staphylococcal pneumonia, the disease often is preceded by an upper respiratory tract infection.[40,41] Pleural effusion or empyema develops in nearly 80% of the patients with primary staphylococcal pneumonia and is extremely common in patients with metastatic disease. It is not unusual for patients with staphylococcal pneumonia to remain bacteremic long after the initiation of appropriate antibiotic therapy.

Radiographic findings of *S. aureus* pneumonia differ according to the stage of disease. They vary from minimal changes to consolidation (most common) and are associated with pleural effusion (50% to 60%) or pneumothorax (21%). Pneumatoceles usually appear during the convalescent stage and may persist for prolonged periods in asymptomatic patients. Antibiotic therapy should be administered intravenously and include a drug that is resistant to inactivation. Strong consideration should be given to providing antibiotic coverage for methicillin-resistant *S. aureus*, which can account for 1% to 30% of isolates, depending on the prevalence in the area.[42] The duration of therapy usually is lengthier in patients with staphylococcal disease than for patients with other bacterial pneumonias and consists of 21 days or more of treatment. The mortality rate of staphylococcal pneumonia varies from 23% to 33%. An increased incidence of mortality usually is associated with younger age, inappropriate initial antimicrobial therapy, or failure to drain an empyema appropriately.

Mycoplasma Pneumonia

Mycoplasma organisms are the smallest free-living microorganisms. They lack a cell wall and are pleomorphic. Mycoplasma is an uncommon cause of pneumonia in children younger than 5 years but is the leading cause of pneumonia in school-aged children and young adults. Illness can range from a mild upper respiratory tract infection to tracheobronchitis to pneumonia. Symptoms include malaise, low-grade fevers, and headache. In 10% of children a rash develops that usually

is maculopapular. Cough, if it develops, usually occurs within a few days and may continue for 3 to 4 weeks. Initially the cough is nonproductive but then it may become productive and usually is associated with widespread rales on physical examination. Roentgenographic abnormalities vary but usually are bilateral and diffuse.[33]

Isolation of *Mycoplasma* by culture is complicated by the requirement for special enriched broth or agar media, which are not widely available; it is successful in only 40% to 90% of cases and requires 7 to 21 days. A fourfold increase in antibody titer between acute and convalescent sera is diagnostic but the time involved is lengthy, providing only a retrospective diagnosis. Complement fixation and immunofluorescent and several enzyme immunoassay antibody tests have been developed but have been of limited diagnostic value.[33] Serum cold agglutinins with titers of 1:32 or greater are present in more than 50% of patients with pneumonia by the beginning of the second week of illness. A PCR test has been developed but is not widely available. Where available, the PCR test has become an important means of diagnosing *M. pneumoniae* infections in clinical practice and allows for institution of therapy directed at the causative pathogen.[43] Treatment of upper respiratory tract infections or acute bronchitis is rarely indicated, but treatment with erythromycin or another macrolide such as azithromycin is indicated for persons with pneumonia or otitis media.

Miscellaneous Etiologic Agents

Pneumonia resulting from group A streptococcus accounts for less than 1% of all bacterial pneumonias. This disease is found in older children (median age 5 to 6 years), and nearly all patients are bacteremic and toxic at the time of diagnosis. Associated findings may include anemia, hyponatremia, and respiratory distress often accompanied by pleural effusion or empyema. Often a positive history of a preceding viral infection is noted.

Gram-Negative Bacteria

Pneumonia caused by gram-negative enteric bacteria, especially *Pseudomonas,* almost always is found in patients with underlying pulmonary disease, compromised immune status, or those receiving prolonged respiratory therapy.[44,45] Gram-negative enteric bacteria are a frequent cause of nosocomial infection in critical care units. These organisms can produce a severe necrotizing pneumonia that is associated with an increase in morbidity.[46]

Legionella Pneumophila

Pneumonia that occurs as a result of *Legionella pneumophila* has been reported infrequently in the pediatric age group.[47-50] The onset of this disease is characterized by high unremitting fever, chills, and a nonproductive cough.[48] Extrapulmonary manifestations include gastrointestinal symptoms such as diarrhea, liver involvement, and confusion. Chest radiographs typically consist of peripheral nodular infiltrates and pleural effusions. Cavitation occurs only in immunosuppressed individuals. Death in the normal host is unusual if prompt therapy with azithromycin or erythromycin is initiated.

Anaerobic Bacteria

Pneumonia resulting from anaerobic upper respiratory flora is uncommon in healthy children. When it does occur, it is frequently associated with risk factors such as underlying pulmonary disease, a central nervous system disorder (including seizures), a postanesthetic state, and aspiration of a foreign body. Lung abscess and empyema are frequent complications in persons with anaerobic bacterial pneumonias.

Complications

The mortality rate in persons with uncomplicated bacterial pneumonia is less than 1%. Death is more common in children with complicated disease or an underlying disorder. The most frequent complications of bacterial pneumonia are pleural effusion and empyema (Table 47-1). Thoracentesis should always be performed if fluid is present to facilitate an etiologic diagnosis and to establish the character of the fluid. Tube thoracostomy is indicated if a large amount of fluid is present and is producing respiratory compromise or if purulent fluid is obtained by thoracentesis. Empyema may extend locally to involve the pericardium, mediastinum, or chest wall. Evidence of empyema extension should be considered in the child who is unresponsive to antibiotic therapy.[28]

When tube thoracostomy/surgical drainage is required, it should be discontinued as soon as drainage has substantially decreased. For patients with staphylococcal empyema, streptococcal pneumonia, or *H. influenzae* empyema, 3 to 7 days of drainage usually is sufficient. Patients with empyema require prolonged antimicrobial therapy and careful follow-up.

Pneumothorax and pneumatoceles can be seen with almost any bacterial pneumonia but are especially common with staphylococcal disease.[40] Such pneumatoceles require no special therapy and usually resolve. Lung abscess is an infrequent complication of *H. influenzae* and pneumococcal pneumonia and is most often encountered with staphylococcal disease or anaerobic bacteria.

Table 47–1 Major Sequelae/Life-Threatening Complications Associated with Bacterial Infections

Complication/Sequelae	Organism
Necrotizing pneumonia	Anaerobic, GNB
Respiratory failure	GBS
Shock	GBS, SP, H. flu, GNB
Apnea	GBS
Pneumothorax	H. flu
Pneumatoceles	H. flu, anaerobic, staph, SP, GAS
Abscess (lung)	Staph, SP, anaerobic
Pleural effusion	H. flu, GAS, SP, staph
Empyema	H. flu, staph, SP
Epiglottitis	H. flu, GAS
Meningitis	H. flu, GBS, SP
Encephalopathy	*Legionella*
Pericarditis	H. flu
Bone/joint	H. flu, staph
Kidneys	Staph

GAS, Group A streptococcus; *GBS,* group B streptococcus; *GNB,* gram-negative bacteria; *H. flu, Haemophilus influenzae; SP, Streptococcus pneumoniae; Staph, Staphylococcus aureus.*

Prognosis usually is excellent even in persons with severe bacterial pneumonia complicated by empyema. Long-term follow-up of children with empyema has demonstrated remarkably few, if any, residual pulmonary function abnormalities and remarkable clearing of chest roentgenograms. In contrast to adults with empyema, children seldom require surgical procedures such as decortication. However, follow-up chest radiographs should be obtained on all patients with bacterial pneumonia to document complete resolution. Such radiographic follow-up studies probably are not indicated until at least 6 to 8 weeks following the initiation of antibiotic therapy.

Therapy

Therapy for persons with bacterial pneumonia should include appropriate intravenous antibiotic treatment directed toward the specific pathogen, if it is known (Table 47-2). Localized or compartmental complications such as empyema, lung abscess, pericarditis, or septic joints require appropriate surgical drainage and antibiotic therapy. Prevention via immunization or chemoprophylaxis has changed the incidence and epidemiology of pneumonitides significantly. Options for immunization, active or passive, and chemoprophylaxis for various etiologic agents are listed in Table 47-3.

Viral Pneumonitis

Infection is the most common cause of pulmonary interstitial disease in children, and viral agents are the leading cause of lower respiratory tract infection in infants and children. The viral agents listed in Table 47-4 account for the greatest percentage of pediatric pulmonary disease. Nearly 85% of all hospitalizations of children younger than 15 years occur during outbreaks of respiratory syncytial, parainfluenza, or influenza virus.

The diagnosis of a viral pneumonia in children is frequently based on the clinical presentation, epidemiologic setting, and exclusion of bacterial pathogens by negative cultures. A specific agent is identified in only approximately 50% of cases of presumed viral pneumonia. Pediatric viral respiratory tract infections occur most commonly during the winter, with distinct peaks during midwinter and early spring in temperate climates. Closed population groups provide for greater spread of respiratory viruses and increased recognition of viral pneumonias.

Pathophysiology

The mechanism of infection for most respiratory viruses appears to be a progressive spread from the larger airways to the alveoli. The respiratory epithelial cell is the major target of cytopathic effect. The normal ciliated columnar epithelium may become markedly dysplastic with loss of the overlying cilia.[51,52] Areas of ulceration then occur as segments of the mucosal surface desquamate into the bronchial lumen. Impaired mucociliary clearance occurs and altered stimulation of nerves mediating bronchial smooth muscle tone leads to increased airway resistance.[53] Enhanced mucus formation along with mucosal debris may lead to obstruction of the bronchioles, luminal narrowing, distal air trapping, and hyperinflation of various lung segments. In advanced disease with complete small airway obstruction, atelectasis results, causing hypoxemia as a result of intrapulmonary shunting and V/Q imbalance.

In persons with severe viral pneumonia, widespread parenchymal injury caused by a necrotizing alveolitis may occur. Alveolar round cell infiltrates occur often, with subsequent hyaline membrane formation and intraalveolar hemorrhage, which produces extensive parenchymal destruction and diminished lung compliance, decreased lung volumes, and intrapulmonary shunting.[54]

Table 47–2 Bacterial Pneumonia Therapy

Disease/Organism	Therapy
UNDETERMINED ORGANISMS	
Serious, life-threatening pneumonia, nonsuppressed host	Cefotaxime or ceftriaxone + azithromycin
	Bronchial lavage or needle aspiration of lung may be necessary to establish diagnosis
Suppressed neutropenic host	Imipenem/meropenem *or* Piperacillin or ceftazidime + aminoglycoside ± clindamycin
	Vancomycin not included in initial therapy unless high suspicion, ampho not used unless still febrile after 3 days/high suspicion. Bronchial lavage, needle/open biopsy may be necessary to establish diagnosis
Lung abscess	Clindamycin *or* Ticarcillin/clavulanate *or* Piperacillin/tazobactam
SPECIFIC ORGANISMS	
Pneumonia with Empyema	
Streptococcus pneumoniae, group A strep	
Penicillin susceptible	Cefotaxime or ceftriaxone + chest tube drainage
Penicillin resistant	Vancomycin ± rifampin + chest tube drainage
Staphylococcus	
Methicillin sensitive	Nafcillin or oxacillin + chest tube drainage
Methicillin resistant	Vancomycin ± chest tube drainage
Pneumonia without Empyema	
Haemophilus influenzae	Ampicillin or cefotaxime or ceftriaxone + chloramphenicol
Klebsiella pneumonia	Cefotaxime or ceftriaxone
Escherichia coli, Enterobacter	Aminoglycoside or cephalosporin
Legionella	Azithromycin or erythromycin ± rifampin
Pseudomonas	Aminoglycoside + anti-*Pseudomonas* penicillin *or* Aminoglycoside + ceftazidime
Mycoplasma pneumoniae	Erythromycin or azithromycin *or* Clarithromycin

Diagnosis

Although the clinical presentations of illness by respiratory viruses overlap, presumptive diagnosis of the specific etiology is based on clinical presentation, setting, and, most importantly, epidemiologic information. In the past, virus isolation or seroconversion was necessary for a definitive diagnosis. Today many respiratory viral infections can be diagnosed through the use of new techniques.

Viral specimens should be obtained as early as possible during the period of greatest viral excretion. Nasopharyngeal washings or swabs of the throat are most widely used. Cultures may be negative in up to 40% of patients during acute viral respiratory tract disease; failure to isolate a virus is not definitive evidence against the diagnosis of viral pneumonia. Serologic tests including complement fixation, hemagglutination inhibition, enzyme-linked solid-phase assays (enzyme-linked immunosorbent assays), and antibody assays have been used in the diagnosis of viral infection. Histologic evidence of infection in biopsy or postmortem specimens may be helpful, particularly when intranuclear inclusions are documented. Rapid diagnostic techniques focus on detection of the virus or its components in the sample. These new techniques include refinements in the use of immunofluorescence, enzyme immunoassay, time-resolved fluoroimmunoassay, latex agglutination assays, and use of nucleic acid hybridization methods, such as deoxyribonucleic acid (DNA) probes and PCR.[55-58]

Three major clinical syndromes are associated with lower respiratory tract viral illness:

1. Bronchitis: Acute bronchitis is a febrile illness associated with a new productive cough. Symptoms of upper respiratory tract infection may be present. Acute bronchitis can adversely affect respiratory function, particularly in patients with chronic pulmonary impairment, leading to hospitalization of persons with marginal lung function.
2. Bronchiolitis: Symptoms result from airflow obstruction caused by localized inflammation of the terminal respiratory bronchioles. The development of cough, tachypnea with intercostal retractions, fine, moist, inspiratory crackles, and expiratory wheezes are characteristic. Hypoxemia and cyanosis are often present.[59]
3. Pneumonia: Primary viral pneumonia is frequently a mild illness characterized by a mild cough and one or more segmental infiltrates on chest radiograph. Although it is usually a self-limited process, in some persons the pneumonic process may progress with extensive parenchymal injury, diffuse interstitial alveolar infiltrates, and severe hypoxemia. Bacterial superinfection is heralded by increased temperature, change in sputum, and signs of localized consolidation several days after the initial onset of symptoms.

Table 47–3 Preventive Measures

Organism	Immunization	Chemoprophylaxis
Cytomegalovirus	IVIG: prophylaxis in seronegative transplant recipients	Ganciclovir or valganciclovir
Haemophilus influenzae type b	Capsular polysaccaride vaccine *or* Conjugate vaccine	Rifampin in the face of incomplete immunization and exposure
Influenza	Inactivated virus produced in chicken embryos	Oseltamivir (A or B) *or* Amantadine/rimantadine (A)
Measels	Live virus vaccine *or* IVIG for immunocompromised patients	None
Streptococcus pneumonia	Purified capsular polysaccharide antigens of 23 pneumococcal serotypes vaccine *or* Multivalent protein conjugate vaccine	Penicillin VK for functional or anatomic aspleia until age 5 years
Pneumocystitis carinii	None	Trimethoprim-sulfamethoxazole *or* Pentamidine or dapsone
RSV	RSV-IVIG *or* Palivizumab (monoclonal antibody)	None
Group B strep	None	Intrapartum antibiotics

IVIG, Intravenous immunoglobulin; *RSV,* respiratory syncytial virus.

Table 47–4 Viral Agents Associated with Pediatric Interstitial Lung Disease

Agent	Frequency
Respiratory syncytial virus	+++++
Parainfluenza virus	++++
Adenovirus	+++
Influenza virus	+++
Cytomegalovirus	+
Enterovirus	+
Rhinovirus	+
Measles	+

Radiographic Findings

Differentiation of bacteria from viral pneumonia cannot be made solely on the radiographic appearance. Children with presumed viral pneumonia, however, may have several radiographic findings, including the following:

1. Peribronchial thickening and perihilar linear densities
2. Partial lobar or patchy involvement in multiple areas of the lung
3. Shifting regional infiltrates
4. Areas of hyperinflation and atelectasis

Hilar adenopathy is usually absent. Diffuse bilateral infiltrates similar to those reported in acute respiratory distress syndrome (ARDS) have been found in persons with severe influenza, adenovirus, and respiratory syncytial virus (RSV) pneumonias.[60] Pleural effusions can occur in both adenovirus and parainfluenza pneumonias. Pulmonary calcifications/nodules have been described in the convalescent phase of varicella and measles.

Specific Pathogens

We will review the most common viral pathogens that cause pneumonitis in children but have elected to exclude such viruses as Hantavirus that are beyond the scope of this

chapter. Please refer to more up-to-date journal articles for specific pathogens of interest (see also Chapter 102: Neuroendocrine-Immune Mediator Cooordination and Disarray in Critical Illness.).[25, 61]

Respiratory Syncytial Virus

RSV is the most common cause of bronchiolitis and pneumonia in the United States in children between the ages of 6 months and 3 years. The disease produced by RSV varies from upper respiratory tract infection to severe bronchiolitis and pneumonia with wheezing and respiratory failure.[59] Higher mortality rates and greater severity with prolonged symptoms occur in infants and children younger than 6 weeks of age and in those who have a history of prematurity, chronic lung disease, cardiopulmonary disease, congenital heart disease, pulmonary hypertension, or neuromuscular impairment and in those receiving chemotherapy or immunosuppressive therapy. [16,62-70] Signs of RSV pneumonia include wheezing, dyspnea, pulmonary infiltrates, and areas of atelectasis and hyperinflation on the chest radiograph. RSV infection may result in increased airway reactivity and airway resistance that persists for months. Significant respiratory tract shedding of virus continues for up to 21 days from the onset of illness. Nosocomial spread of RSV infection is common, and early diagnosis and appropriate isolation techniques are critical in hospitalized patients.

Methods for diagnosis of RSV include viral isolation in cell culture, immunofluorescence of exfoliated nasopharyngeal epithelial cells for detection of RSV antigens, and enzyme immunoassay for detection of RSV antigens in nasal secretions.[71,72] PCR technology is now available for diagnosis of RSV illness.

All hospitalized patients with bronchiolitis and RSV pneumonia should be monitored for hypoxia, hypercarbia, and the need for ventilatory assistance. Supportive care includes the use of humidified oxygen, secretion clearance, and hydration.[73,74] Mechanical ventilation for respiratory failure usually is well tolerated. Extracorporeal membrane oxygenation has been used successfully in infants who do not respond to conventional ventilation.[75,76] The routine administration of bronchodilators and corticosteroids is not warranted; use should be individualized based on clinical reponse.[74,77] Ribavirin, an antiviral agent, has been used to treat children with severe RSV pneumonitis, but its clinical effectiveness remains controversial.[66,78-89] Passive immunoprophylaxis has proved useful in high-risk populations in preventing RSV infection, as has palivizumab, a humanized mouse monoclonal antibody. [33,90-94] The incidence of bacterial superinfection in persons with RSV disease is low; therefore prophylactic antibiotics are not recommended for RSV disease.[63,95,96] It is not unusual for an infant with RSV to require hospitalization for 7 to 10 days following the onset of illness. Long-term complications of RSV infection may include persistent bronchial reactivity, with lower respiratory tract symptoms in more than 70% of infants in the year following hospitalization.[88] Whether moderately severe RSV infection predisposes a person to asthma later in life remains controversial.[97-101]

Parainfluenza Virus

Parainfluenza virus (types 1 and 2) is more often associated with laryngotracheobronchitis and croup than with pneumonia (usually type 3). Parainfluenza is second only to RSV as an etiology of lower respiratory tract disease responsible for the hospitalization of children.[102-107] The pneumonia associated with parainfluenza is typically mild; however, fatal cases with prolonged viral shedding have been reported in patients with severe combined immunodeficiency disease.[108-111] Conferred immunity following infection is low; repeat infection occurs in nearly 50% of patients by age 30 months, although they result in progressively milder illness. Parainfluenza virus, like RSV, has demonstrated ability to elicit an immunoglobulin IgE-specific antibody response.[104] Rapid identification of parainfluenza virus by either fluorescent and enzyme-linked immunologic techniques is possible, but results are variable depending on the viral type and antisera used. Viral culture may take up to a week. PCR methods are available for detection and differentiation, with high sensitivity and specificity. Treatment is supportive.

Adenovirus

Adenoviruses are responsible for approximately 3% of the pneumonias occurring in children. Clinical features are similar to other viral pneumonias except that the onset of illness is often gradual, occurring over several days. Of the 51 serotypes, types 3, 4, and 7 are the most common causes of lower respiratory tract disease in children. Adenovirus type 7 is most commonly associated with severe pneumonitis in infants and children and has a significant incidence of mortality and morbidity.[41,112-116] In 2007, a new strain of adenovirus 14 was isolated in previously healthy infants and young adults in the United States in whom fatal pneumonia developed.[117] A clinical presentation similar to that of bacterial pneumonia, with massive pleural effusion, rhabdomyolysis, and myoglobinuria, has been reported with adenovirus type 21.[118] In many infants with documented adenovirus respiratory tract infection, chronic pulmonary disease develops that manifests as persistent atelectasis, bronchiectasis, and recurrent pneumonitis with areas of hyperinflation and interstitial fibrosis. Bronchiectasis and restrictive lung disease have been documented in children following acute adenovirus infection. Adenovirus pneumonia is the most common cause of bronchiolitis obliterans in children, and unilateral hyperlucent lung syndrome has been reported.[119-124] Disseminated adenovirus occurs and usually is associated with infection by serotype 3, 7, or 21. It occurs most frequently in infants younger than 18 months and usually involves the heart, pericardium, liver, pancreas, kidneys, central nervous system, and skin.[125] Fatal cases of adenovirus and pneumonia can occur in previously healthy young individuals. Diagnosis is made by cell culture, and antigen and DNA detection by PCR. Adenovirus typing is available from some reference and research laboratories. Treatment is supportive.

Influenza

Three antigenically distinct influenza viruses exist—types A, B, and C. All three have hemagglutinin surface antigen, but only types A and B have neuraminidase surface antigen. Antigenic drift for types A and B produce minor changes in the surface antigens, resulting in endemic illness. Antigenic shift only occurs with influenza type A, resulting in a major change or new surface antigen, for which there may be low or no immunity in the population. Influenza type A is subtyped by its surface antigens, and currently three influenza strains are circulating world wide, including influenza A/H1N1, H1N2, and H3N2.[33,126]

Clinical signs of uncomplicated influenza pneumonia include coryzal symptoms followed by dyspnea, fever, cyanosis, cough, and wheezing. Children with influenza typically have a more sudden onset of "toxic" signs than do those with other viral diseases. Infection is associated with myalgia, encephalopathy, and cardiac involvement. Pathologically, influenza virus infection is similar to RSV in that the virus destroys ciliated respiratory epithelial cells with subsequent edema and an acute inflammatory response. Influenza has been associated with Reye syndrome and with significant bacterial suprainfections.[127] In patients in whom bacterial infection develops, there often is a period of apparent improvement before a sudden worsening that is heralded by the production of purulent sputum, return of fever, and development of pulmonary consolidation.[128] Fatal outcomes have been reported in previously healthy children as well as in high-risk groups.

Prevention of influenza disease is possible with either administration of multivalent influenza vaccine (influenza A/H1N1, A/H3N2, and B) or chemoprophylaxis with Oseltamivir and Zanamivir (influenza A, B, and A/H1N1) or amantadine hydrochloride and its closely related analogue rimantadine (influenza A). One study showed efficacy of aerosolized ribavirin in the treatment of persons with influenza B.[129,130] Diagnosis of influenza pneumonia may be made by a culture of the virus from respiratory secretions or with serologic techniques. Rapid diagnosis by means of immunofluorescence of exfoliated nasopharyngeal cells may be helpful, as well as by PCR, which may be available at some institutions. Treatment includes supportive care, monitoring of respiratory status, and administration of antiviral medications.

Measles

Measles is a highly contagious disease that is preventable by vaccine; the incidence fell below the endemic threshold in the United States in 2000.[131] Endemic outbreaks continue in developing countries and when international travelers import measles to nonimmunized persons in the United States.[33,131] Typical disease manifests as high fever, cough, runny nose, and generalized rash. Respiratory symptoms are nearly universal in this illness, making the prevalence of measles pneumonia difficult to determine. Moist crackles develop in most children, and approximately 20% have expiratory wheezes and hypoxia. In cases in which radiographs have been obtained, a fine reticular infiltrate was present, compared with the nodular infiltrates in children with atypical measles. Although the clinical syndrome usually resolves over 1 to 2 weeks, both radiographic and pulmonary function abnormalities may persist for months. Severe life-threatening tracheitis may occur during the course of measles or bacterial suprainfection.[132-134] In fatal cases, severe respiratory and nervous system disease is manifested, and lung tissue demonstrating interstitial pneumonitis with diffuse endothelial cells, pneumatocyte degeneration, and presence of multinucleated giant cells has been reported.[135]

Diagnosis is made by isolation of the virus, standard serology, or identification of viral ribonucleic acid by reverse transcription-PCR. All suspected cases should be reported to local and state health departments. No antiviral agent is available; treatment is supportive. Two doses of vitamin A (200,000 International Units) on consecutive days) has been shown to reduce pulmonary-specific and overall mortality rates in patients up to 2 years of age.[136] Administration of intravenous immunoglobulin may be of benefit to high-risk or immunosuppressed patients when it is started within 6 days of exposure.[33]

Human Immunodeficiency Virus

Human immunodeficiency virus (HIV) infection in children most commonly presents with recurrent bacterial infections. The major morbidity and mortality in pediatric acquired immune deficiency syndrome (AIDS) is associated with lung disease, ranging from opportunistic infections such as *Pneumocystis carinii* pneumonia to entities such as chronic interstitial pneumonitis.[137,138] Treatment for specific pulmonary pathogens are discussed throughout this chapter, but specific guidelines for HIV/AIDS treatment are lengthy, rapidly changing, and beyond the scope of this chapter. More specific and current information regarding HIV/AIDS are available at www.aidsinfo.nih.gov/guidelines. This Web site provides the most current information regarding HIV/AIDS clinical research, HIV treatment and prevention, and medical practice guidelines. This information also can be obtained by phone at 1-800-HIV-0440 within the United States or at 1-301-519-0459 outside the United States or by mail at AIDS Info, P.O. Box 6303, Rockville, MD 20849-6303.

Complications

The actual mechanisms by which viruses predispose the lung to secondary bacterial infection are not precisely understood. Viruses are capable of altering both cellular and noncellular defenses of the respiratory tract.[52,53,139] Viral infection of the epithelial cells appears to predispose the upper respiratory tract mucosa to bacterial colonization by allowing bacterial pathogens to adhere to injured cells.[51,52] Viral infection may cause significant impairment of both intracellular killing and ingestion of bacteria by the pulmonary macrophage. Significant defects in polymorphonuclear leukocyte chemotaxis and phagolysosome fusion occur during acute viral infection. The greatest impairment of macrophage function occurs 1 week after the onset of viral infection, which correlates with the peak incidence of bacterial suprainfection. Thus suprainfection during the course of viral lower respiratory tract disease appears to be the result of a combination of the cytopathic effects of the virus on the respiratory mucosa and various alterations in host immune response.

Significant life-threatening complications of viral lower respiratory tract disease are noted in Box 47-2. Respiratory failure with viral pneumonitis resembling ARDS is frequently seen in patients in the pediatric critical care unit. It often is associated with influenza or adenovirus but can occur with varicella, cytomegalovirus, and RSV.[60]

Diagnosis

A number of techniques are available for establishing a viral diagnosis. In the critical care setting, the decision to undertake these diagnostic measures should be guided by how awareness of the specific viral illness will affect the clinical management. Potential benefits include (1) a guide to selection of appropriate antiviral therapy and avoidance of unnecessary treatments with antibiotics and (2) initiation of appropriate infection control measures and use of vaccine or drug prophylaxis. Direct isolation of viruses is a sensitive method of diagnosis early in the course of disease when a

Box 47–2 Major Sequelae/Life-Threatening Complications Associated with Viral Pneumonitis

- Subacute sclerosing panencephalitis: measles
- Guillain-Barré syndrome: influenza, varicella
- Reye syndrome: influenza, VZV
- Encephalitis: adenovirus, measles, RSV, CMV
- Seizures: influenza
- Bacterial superinfection: influenza, VZV, Epstein-Barr virus, measles
- Asthma: RSV, parainfluenza, rhinovirus
- Apnea: RSV, influenza
- Bronchiolitis obliterans: influenza, adenovirus, measles
- Chronic obstructive pulmonary disease: RSV
- Fatal pneumonitis: influenza, measles, adenovirus, RSV, parainfluenza, CMV
- Tracheitis, life-threatening: measles, parainfluenza
- Appendicitis: adenovirus, measles
- Intussusception: adenovirus, CMV
- Hepatitis: adenovirus, influenza measles, CMV
- Nephritis: adenovirus, influenza, measles
- Myocarditis: adenovirus, influenza, measles
- Pericarditis: adenovirus, influenza, measles
- Arthritis: adenovirus
- Deafness: adenovirus
- Keratoconjunctivitis: adenovirus
- Myositis: influenza
- Stevens-Johnson syndrome: measles
- Coagulopathy: measles
- Thrombocytopenia: measles, CMV

CMV, Cytomegalovirus; *RSV,* respiratory syncytial virus; *VZV, Varicella zoster* virus.

large number of infectious particles are present in respiratory secretions. Nasopharyngeal washings are the preferred specimens for viral cultures because large quantities of secretions for culture are easily available. Unfortunately, viral isolation may require up to 2 weeks for positive culture results. Serologic testing or diagnosis depends upon demonstration of a rising antibody titer between acute and convalescent sera. Although serologic data may provide a diagnosis, they are of little value in guiding therapeutic critical care interventions. The more commonly used methods for viral diagnosis involve detection of viral antigens present in the respiratory secretions. These antigen-detection techniques using radioimmune or enzyme-linked assays can detect all riboviruses and adenoviruses that commonly produce lower respiratory tract infections. Antibody detection also has been used successfully in the diagnosis of lower respiratory tract viral disease (cytomegalovirus pneumonia).[140] A major advantage of tests capable of detecting viral components is that these studies can be performed rapidly and the results made available to the critical care physician in hours, thus allowing timely management.

Prevention and Treatment

Guidelines for influenza chemoprophylaxis and treatment are lengthy and rapidly changing. Specific and current information regarding the use of antiviral drugs is available at www.aapredbook.org/flu or www.cdc.gov/flu/professionals/antivirals/index.htm.

Vaccination

Influenza vaccine is directed at the currently circulating antigenic types of seasonal influenza A and B and influenza A/H1N1 and A/H3N2. Because of antigenic drift, it is necessary to vaccinate on a yearly basis to prevent seasonal influenza A and B. The Centers for Disease Control and Prevention recommends administration of influenza vaccine to groups at special risk for complications of influenza such as children with chronic cardiac, pulmonary, neurologic, or metabolic disorders and health care workers capable of nosocomial spread to high-risk patient groups.

Palivizumab is a monoclonal antibody vaccine directed against RSV that provides passive immunity. Current recommendations are to administer this vaccine to high-risk infants during the RSV season.[33] Passive immunization also is available for some viruses that can be associated with pneumonitis (see Table 47-3 for further details).

Chemoprophylaxis

Amantadine, rimantadine, oseltamivir, and zanamivir are approved for prophylaxis of viral respiratory tract infection caused by influenza. Amantadine and rimantadine have been shown to be effective prophylaxis for influenza type A; however, they are not active against influenza type A/H1N1 or influenza type B. Amantadine resistance has been reported in persons with influenza type A/H3N2. Oseltamivir and zanamivir have activity against influenza types A, B, and A/H1N1. Oseltamavir resistance has been reported among persons with influenza type A/H1N1 strains globally, but no significant resistance has been reported among persons with influenza type A/H1N1 strains circulating in the United States. All four drugs are recommended for persons at high risk for serious influenza infection who have not been vaccinated or who have received the vaccine within 2 weeks of the onset of an epidemic. They also are recommended for persons in whom appropriate immune response may not develop following vaccination and for persons who cannot receive the influenza vaccine because of allergic reactions.[33,141,142]

Therapy

A number of antiviral agents inhibit the replication of respiratory viruses in vitro, and some of these drugs have been used clinically in both experimental and naturally occurring respiratory infections (Table 47-5). Amantadine can be used to treat seasonal influenza A virus infections. Numerous studies have demonstrated that amantadine shortens the course of illness in uncomplicated influenza infections in otherwise healthy children if initiated within the first 48 hours of the disease. Amantadine is not effective against influenza type B or A/H1N1.[143] Rimantadine is effective against influenza type A, but it has not been approved for therapeutic use in children younger than 13 years and is not effective against influenza type B or A/H1N1. Oseltamivir and zanamivir both are effective against influenza type A, B, and A/H1N1.[144] These neuraminidase inhibitors have been shown to reduce the severity and duration of illness.[145-148] Resistance to oseltamivir has been reported in persons with influenza type A/H1N1 strains, but not A/H3N2 or B strains.[149-153] Zanamivir is effective against influenza type A, B, and A/H1N1, but it has not been approved for therapeutic use in children younger than 7 years.[33] Authorization

Table 47–5 Antiviral Agents Used in Viral Pneumonia

Agent	Indication	Route	Side Effects
Acyclovir	HSV, varicella Prophylaxis/treatment	IV, PO	Phlebitis, seizures, leukopenia, renal dysfunction
Valacyclovir renal	HSV, varicella Prophylaxis/treatment	PO	Bone marrow suppression, renal failure
Ganciclovir	CMV in immunocompromised host Prophylaxis/treatment	IV, PO	Renal failure, bone marrow suppression, seizure
Valganciclovir	CMV prophylaxis	PO	Same as ganciclovir
Amantadine	Influenza A Prophylaxis/treatment	PO	Nausea, dizziness, ataxia, diarrhea
Rimantadine	Influenza A Prophylaxis	PO	Similar to amantadine
Zanamivir	Influenza A and B Treatment, prophylaxis under study	Diskhaler	Bronchospasm
Oseltamivir	Influenza A and B Prophylaxis/treatment	PO	Nausea, vomiting, vertigo
RSV-IVIG	RSV prophylaxis (high-risk population)	IV	Allergic, fluid overload, not approved for CCHD
Palivizumab	RSV prophylaxis	IM	Anaphylaxis
Ribavirin	RSV (parainfluenza, influenza A and B, measles)	Small-particle aerosol	Conjunctival edema
Foscarnet	CMV retinitis, HSV resistant to acyclovir	IV	Renal dysfunction, nausea, bone marrow suppression
Pieconaril (under investigation)	Enterovirus and rhinovirus Prophylaxis/treatment	PO	Under investigation

CCHD, Cyanotic congenital heart disease; *CMV,* cytomegalovirus; *HSV,* herpes simplex virus; *IVIG,* intravenous immunoglobulin; *RSV,* respiratory syncytial virus.

for emergent use of intravenous Peramivir for confirmed A/H1N1 or nontypeable influenza A has been issued for pediatric patients who are not responding to current therapy, for whom the enteral or inhalation delivery route is prohibited, or who are allergic to amantadine. Peramivir is a neuraminidase inhibitor and should not be administered if the patient has a severe allergy to oseltamivir, zanamivir, or one of their metabolite components.

Ribavirin is a synthetic nucleoside analogue licensed for use in aerosol form for treatment of persons with severe RSV infection. This therapy may shorten the course of the illness and improve oxygenation in high-risk patients. A few children with severe combined immune deficiency have been treated with ribavirin with resulting clinical improvement and decrease in viral shedding. Ribavirin aerosol may be effective in shortening the course of both influenza type A and B in infections in college students, and it is possible that parainfluenza and the measles virus can be treated with ribavirin.[154] Various case reports of treatment in seriously ill adults with complicated viral infections suggest that ribavirin may be an effective treatment. Overall, the documented therapeutic benefit of antiviral agents has been inconclusive. Improvement is most apparent when the therapy was initiated early after the onset of infection. Future investigations are necessary to define the optimum dose/route of antiviral agents for each respiratory virus/pneumonia and to clarify the ability of antiviral therapy to modify serious lower respiratory tract infection in high-risk infants and children.

In persons with varicella or zoster, acyclovir reduces the period of viral shedding and the time needed to heal skin lesions, and it can prevent dissemination of localized zoster in immunocompromised children. Thus the use of acyclovir in immunosuppressed patients can be justified by the low toxicity of the drug and the potential severity of the illness. Ganciclovir (DHPG) is an antiviral drug with significant activity against cytomegalovirus.[155] It has been used successfully in immunocompromised patients with disseminated cytomegalovirus and pneumonia.[156] Symptomatic infection of the lower airway with herpes viruses is rare. When it occurs, it usually does so in an immunosuppressed child. Antiviral therapy for herpes viruses includes acyclovir, foscarnet, and adenine arabinoside.[157]

Fungal Pneumonitis

Fungal infections are becoming increasingly important in the differential diagnosis of pulmonary infections, particularly in immunocompromised hosts. The majority of pulmonary mycotic infections occur in two microbiologic and clinical groups (Box 47-3). In general, different patient groups are at risk for infection because of either opportunistic or pathogenic dimorphic pulmonary fungi. Primary pulmonary mycotic infections generally infect healthy children exposed to the pathogen in a particular geographic or environmental setting, whereas the opportunistic mycoses occur in children whose immunity is compromised.[158-160] The increase in opportunistic fungal infections can be attributed to numerous factors, including the following:

1. Selection of fungal organisms as flora by the use of broad-spectrum antibiotics
2. Leukopenia secondary to use of cytotoxic agents

Box 47–3 Major Pulmonary Mycoses

Primary (Endemic; Pathogenic to Normal Children)

Dimorphic Soil

- Histoplasmosis
- Blastomycosis
- Coccidioidomycosis
- Paracoccidioidomycosis
- Sporotrichosis

Nondimorphic Soil

- Cryptococcosis

Opportunistic (Ubiquitous; Abnormal Host)

- Aspergillosis
- Mucormycosis
- Candidiasis

3. Suppression of humoral and cell-mediated immunity by cytotoxic and suppressive therapy
4. Increased use of immunosuppressive drugs in patients with organ transplant or collagen vascular disease
5. An increasing number of patients with AIDS
6. An increased number of invasive surgical procedures in hospitalized children, which create portals of entry for fungi[19]

Primary Pulmonary Fungi

Fungi that cause primary pulmonary infection in otherwise healthy hosts are generally endemic mycoses found in a particular geographic distribution. The four major mycoses in this group are histoplasmosis, blastomycosis, coccidiomycosis, and paracoccidiomycosis.[15,161] Chemiluminescent DNA probes are available for identification of blastomycosis, coccidioidomycosis, and histoplasmosis. We review these primary pulmonary mycoses in the following section but exclude paracoccidiomycosis because this infection occurs primarily in South America, Central America, and Mexico. For information regarding paracoccidiomycosis infections, please refer to up-to-date journal articles.[162]

Pathogenesis

The dimorphic fungi cause infection following inhalation of spores (conidia) into the pulmonary system. In the lower respiratory tract the conidia transform into the yeast phase, which is susceptible to phagocytosis by the pulmonary macrophages. These yeast forms may persist in the nonimmune host. As the yeast-laden macrophages are transported via the lymphatics to the peribronchial and mediastinal lymph nodes, hematogenous dissemination may occur. However, with the primary pulmonary infection in the immunocompetent host, extrapulmonary infection is rare.

Progressive primary pulmonary infection in the absence of host defenses (such as in a patient who is immunocompromised or an infant) may lead to seeding of extrapulmonary sites, dissemination, and death if left untreated. Cellular immunity is the primary host defense against these deep mycoses, many of which are subclinical and require no therapy. However, children with severe life-threatening infections should be treated (Table 47-6).

Histoplasmosis

Histoplasmosis is caused by *Histoplasma capsulatum*, which is endemic in the east-central United States, particularly the Mississippi and Ohio River valleys. Primary pulmonary histoplasmosis is asymptomatic in more than 50% of patients. Patients usually become ill 2 weeks following exposure, manifesting influenza-like illness with fever, chills, myalgia, headache, and a nonproductive cough. Occasionally children have a skin rash, arthritis, and erythema nodosum.

The chest radiograph may show patchy areas of pneumonitis and prominent hilar adenopathy. After exposure to an usually heavy inoculum, a more diffuse pulmonary involvement may occur with extensive nodular infiltrates. Children with this condition frequently have significant dyspnea and may progress to respiratory failure. The chest radiograph frequently returns to normal after a primary pulmonary infection; however, a number of residual abnormalities may be seen, including multiple nodules with a dense core of calcium (a target lesion), scattered calcifications within lymph nodes, and occasionally small "buckshot" calcifications scattered throughout both lung fields.[163]

Diagnosis

The skin test is of epidemiologic value but is useless in individual case diagnosis because a positive test only indicates prior exposure to this disease. Neither are direct smears of the sputum helpful for diagnosis. Most cases are recognized by serologic studies and include immunodiffusion (M and H bands) and complement fixation. Unfortunately, the immune diffusion test is relatively insensitive, and a response may be delayed following a primary infection. The complement fixation test is more sensitive but less specific.[164] A titer of 1:32 or higher against the yeast antigen is diagnostic if the clinical picture suggests histoplasmosis. Children with rapidly progressive pneumonia that is not responding to antibacterial antibiotic therapy or those in impending respiratory failure need urgent diagnosis, and invasive procedures such as bronchoalveolar lavage (BAL), diagnostic lung aspiration, or open lung biopsy are necessary to obtain the required information.

Complications

Disseminated histoplasmosis refers to progressive extrapulmonary infection that occurs most frequently in children younger than 2 years and in patients with altered cellular immunity.[17,165] The clinical features of disseminated disease include fever, weight loss, hepatosplenomegaly, cough, diarrhea, gastrointestinal ulcers, and skin lesions. Anemia, leukopenia, and thrombocytopenia may occur as a result of bone marrow involvement in young children and may lead to rapid death. Chronic disseminated disease, which is uncommon and insidious, may present as a nonspecific afebrile illness without cough or radiographic abnormalities. Occasionally, disseminated histoplasmosis presents as a localized infection involving the central nervous system. Chorioretinitis and pleural effusion, along with isolated gastrointestinal findings involving terminal ileum, can occur.

Treatment

The usual primary pulmonary infection requires no treatment. Amphotericin B should be used for persons with a severe infection, especially if it is life-threatening or associated with

Table 47–6 **Antifungal Therapy**

Drug	Indications	Route	Side Effects
AmB	All life-threatening mycoses, empirical therapy in febrile granulocytopenic patients	IV	Fever, chills, nephrotoxicity, anemia, hypokalemia, thrombophlebitis
AmB lipid complex, AmB cholesteryl sulfate, AmB liposomal	Failure or intolerance to AmB, organ transplantation with renal insufficiency	IV	Same as AmB with decreased nephrotoxicity and infusion-related adverse events
Flucytosine (5-FC)	With AmB for life-threatening infections with *Cryptococcus, Candida* (central nervous system, ophthalmitis, disseminated, renal) or invasive disease refractory to AmB	PO	Neutropenia with elevated serum levels (if levels are not available, this agent should not be used)
Ketoconazole	Not indicated for acute treatment of severe invasive disease; alternative for mild blastomycosis, histoplasmosis, *Candida*, or coccidiomycosis	PO	Nausea, vomiting, hepatotoxicity, testosterone synthesis blockade
Miconazole	Deep infection: *Pseudallescheria* and *Scedosporium*	IV	Cardiac dysrhythmias, cardiovascular collapse with rapid infusion
Fluconazole	*Cryptococcus, Candida* (question in critically ill), coccidiomycosis	PO	Nausea, vomiting, dizziness
Itraconazole	Non–life-threatening blastomycosis, sporotrichosis, histoplasmosis, paracoccidioidomycosis	PO	Pediatric dosage not yet established; nausea, hypokalemia, edema, hypertension, adrenal insufficiency, epigastric pain
Voriconazole	*Apergillus* and *Cryptococcus,* resistant *Candida* spp.	IV	Visual changes, fever, nausea, vomiting, elevated liver enzymes
Caspofungin	Treatment for resistant *Aspergillus* and possible combination therapy for *Candida* and endemic mycoses	IV	Fever, phlebitis, nausea, headache, elevated liver enzymes

AmB, Amphotericin B.

respiratory failure. Upon clinical improvement, itraconazole should be given to complete the course of therapy. Chronic cavitary histoplasmosis can be treated with intravenous amphotericin B or a long-term course of oral itraconazole or ketoconazole. Pericarditis therapy should include antiinflammatory agents such as indomethacin or aspirin. Failure of pericarditis to improve with nonsteroidal antiinflammatory medication should not prevent use of a brief course of steroids because steroid use does not appear to predispose to dissemination.[166-168]

Blastomycosis

Blastomycosis is endemic to the southeastern region of the United States but extends northward along the western shores of Lake Michigan across to northern Wisconsin and Minnesota and into Canada. An intimate exposure to an infected site is required for infection rather than the casual exposure often found with histoplasmosis and coccidioidomycosis.[169-171] Most pediatric cases of blastomycosis occur in older children and adolescents in rural areas.

The pathophysiology is similar to that of histoplasmosis. The clinical course of primary pulmonary blastomycosis is variable. The symptoms are similar to those of acute bacterial pneumonia and include high fever, cough with productive purulent sputum, occasional pleuritic chest pain, and myalgias. Such symptoms generally last 2 to 3 weeks.

The chest radiograph frequently demonstrates patchy areas of alveolar consolidation affecting one or both lower lobes. Pleural effusions and cavitation can occur but are unusual. A rather dense lobar infiltrate similar to pneumococcal pneumonia is uncommon but occurs more frequently in pulmonary blastomycosis than with other pulmonary fungi. Clearing of the chest x-ray film may take 3 to 4 months.

Blastomycosis is not always self-limited, and progressive pulmonary infection can occur with acute dissemination to distant sites. In such instances the child remains febrile and toxic with rather rapid progression. Diffuse pulmonary involvement with acute miliary spread can lead to rapid respiratory failure and radiographic findings of ARDS.

Children may have asymptomatic primary pulmonary blastomycosis that is diagnosed only with reactivation blastomycosis involving the skin, bones, or other distant organ sites. Reactivation blastomycosis appears to be most common in the first 1 or 2 years immediately after the initial pulmonary infection and probably occurs in less than 5% of all infected patients. A chronic form of pulmonary blastomycosis may occur in patients who have no significant history of acute pneumonia but present with respiratory symptoms that have persisted for weeks or months. These persons have a chronic cough, productive sputum, nocturnal fevers, night sweats, weight loss, and dyspnea. Chest radiographs in persons with chronic blastomycosis may reveal a single large mass, often perihilar in location. A more common finding is a fibronodular infiltrate with small cavities and fibrosis radiating toward the hila. Such findings mimic tuberculosis.

Diagnosis

No reliable skin test exists for pulmonary blastomycosis. Sputum and material aspirated from BAL, lung aspiration, skin, or bone lesions may be examined directly after potassium

hydroxide digestion, and the pathognomonic yeast forms are identified. Such positive direct smears provide a rapid, accurate, inexpensive test. Serologic tests include immunodiffusion using purified antigen. The complement fixation test is less sensitive and less specific than the immunodiffusion test.[172] Most acute cases are diagnosed by direct sputum smears or from BAL. Needle aspiration under fluoroscopy usually is diagnostic in a child who is severely ill; a lung biopsy (either needle biopsy or open lung biopsy) and histopathology are necessary in some instances.

Complications

Patients whose illnesses are clinically similar to bacterial pneumonia frequently have a self-limited process. Life-threatening progressive respiratory failure similar to ARDS can occur. In such instances, diagnosis and therapy including mechanical ventilation must be initiated promptly. Dissemination occurs only in the most severe cases.[173,174] With dissemination, characteristic skin lesions (i.e., raised and crusted) may occur on the face and upper extremities. In persons with disseminated disease, bone involvement often includes the spine, ribs, and skull. The prostate, epididymis, or testes may be involved.

Treatment

Acute pulmonary blastomycosis does not require treatment in all cases. Treatment with intravenous amphotericin should be given if the patient is severely ill or if progressive illness occurs. Oral itraconazole and ketoconazole have been used for treatment of chronic pulmonary blastomycosis (similar to tuberculosis) but should not be used for severe life-threatening infections.[175,176]

Coccidioidomycosis

Coccidioidomycosis is a relatively common infection that occurs primarily in the southwestern United States. Sixty percent of patients with primary pulmonary infection have no symptoms or minimal symptoms. The pathogenesis is similar to that of histoplasmosis and other dimorphic fungi infections. Children 5 years or younger have a higher frequency of progressive disease than do older children and healthy adults. The clinical course of coccidioidomycosis is a flulike illness usually associated with fever, cough, and chest pain. There may be a transient maculopapular eruption similar to erythema nodosum in children. Radiographic abnormalities range from hilar adenopathy to patchy infiltrates with pleural effusion.

Diagnosis

Diagnostic studies include skin testing, which has some usefulness if the patient has compatible respiratory illness and a past negative skin test. Direct smears of potassium hydroxide-digested sputum are helpful if characteristic spherules are found. Antibody detection through complement fixation may be a useful measure of severity of disease.[172] In cases of suspected coccidioidal meningitis, complement fixation tests on cerebrospinal fluid should be obtained because many patients have a negative spinal fluid culture with positive complement fixation studies. Use of chemiluminescent DNA probes may aid in rapid diagnosis.

Complications

Complications include chronic progressive coccidioidal pneumonia, which is similar to tuberculosis but is uncommon in pediatric patients. Disseminated coccidioidomycosis does occur and is often accompanied by persistent fever and rapid progression with development of meningitis, bony lesions, and skin and soft tissue disease. A fulminant primary miliary spread of disease with severe respiratory failure and diffuse lung involvement has been observed in patients with altered immune status. The disseminated disease frequently has an insidious onset, following the primary pulmonary infection by weeks. The meninges are the most worrisome site of extrapulmonary involvement because coccidioidal meningitis requires intrathecal amphotericin B therapy, and cure is unlikely.[174,177-181]

Treatment

If the infection causes prolonged fever, progressive pulmonary disease, significant mediastinal adenopathy, or disseminated lesions, antifungal therapy with amphotericin B should be initiated. Ketoconazole has been used in skeletal, cutaneous, and other localized infection but not for meningitis. Coccidiomeningitis is the most difficult complication of this disease to treat; it requires intrathecal and systemic therapy with amphotericin B.

Opportunistic Pulmonary Mycoses

Pulmonary Aspergillosis

Invasive pulmonary aspergillosis occurs almost exclusively in immunocompromised patients.[15,182-185] Despite treatment, unless the underlying immune defect is ameliorated, invasive pulmonary aspergillosis is often fatal. Many cases are nosocomially acquired, usually in hospitals undergoing renovation or new construction.[171] Children with hematologic malignancies (e.g., myelogenous and lymphocytic leukemia) or organ transplantation are at the highest risk for development of invasive disease, presumably because of the abnormal immune cells and the cyclic neutropenia induced by repeated doses of chemotherapy. Persons with cheart and bone marrow transplants are at higher risk for aspergillosis infection than are persons with kidney transplants.

Neutropenia is an important risk factor for the development of aspergillosis because both the absolute neutrophil count and the duration of neutropenia have been related to the incidence of infection. Use of steroids and immunosuppressive drugs also appears to predispose to invasive aspergillosis.[186] Immune and myelosuppressed patients exposed to heavy aerosol concentrations of aspergillosis spores have an increased chance of the development of invasive pneumonia. Efforts should be made to eliminate the risk of airborne conidiospores in patient areas. If such elimination is not possible, then susceptible patients should be moved away from areas of excavation or construction.

Clinical signs of invasive aspergillosis are nonspecific. The usual presentation includes pulmonary infiltrates and fever that do not respond to empirical antibacterial therapy. Patients may exhibit dyspnea, a nonproductive cough, pleuritic chest pain, and pleural friction rubs. Symptoms usually are difficult to identify in small children, and auscultatory changes usually are found only with advanced disease. Hemoptysis is uncommon in children.

Diagnosis

Radiographs of the chest reveal virtually any infiltrative pattern, including patchy infiltrates, necrotizing pneumonitis, miliary nodules, and lung abscesses. Early findings may include

a round, patchy pneumonia that progresses to a wedge-shaped density characteristic of pulmonary infarctions.[187] Definitive diagnosis of invasive pulmonary aspergillosis requires histopathologic identification of fungus in tissue specimens.[188] Positive sputum cultures do not prove the presence of invasive disease even in compromised hosts, although isolation should be taken seriously and multiple positive cultures should be considered strong evidence of fungal infection in patients whose immunity is compromised. Serologic antibody tests have no value in the diagnosis of invasive aspergillosis. In severely ill children, fiberoptic bronchoscopy with bronchial lavage is the initial diagnostic test of choice in patients with suspected pneumonitis. If the results of fiberoptic bronchoscopy are nondiagnostic, a lung biopsy (open or needle) may be required.

Complications

Untreated invasive pulmonary aspergillosis usually is fatal in immunocompromised patients. Fatality rates greater than 80% are reported; however, survival may improve if appropriate therapy is initiated early in the disease. Death usually results from progressive pneumonitis, pulmonary infarction, and massive hemoptysis. On rare occasions, endocarditis, osteomyelitis, meningitis, or infection of the eye or orbit occurs.

Treatment

Therapy with amphotericin B should be initiated early in the course of the disease. Surgical resection usually is not indicated in the treatment of critically ill patients with uncontrolled disease. However, it may be considered in patients who have only partial response to antifungal therapy or with relapsing disease in a well-defined lung segment or in those identified with massive hemoptysis. In critically ill patients who are unresponsive to therapy or in whom aspergillosis develops while they are receiving amphotericin B, the addition of flucytosine or rifampin may be helpful.[189] Use of the lipid formulations of amphotericin is indicated in patients who are intolerant of or refractory to conventional amphotericin for reasons such as renal toxicity or persistent infusion-related adverse events.[190] Itraconazole is an option for use after an initial course of amphotericin B.[191] Change from amphotericin to the oral itraconazole must take into account the patient's status. New antifungal agents such as voriconazole have shown in vitro activity against aspergillus and are in phase II or III trials.[192,193]

Pulmonary Candidiasis

Of all the opportunistic pulmonary mycoses, candidiasis may be the most difficult to diagnosis and treat effectively because the *Candida* organism routinely colonizes the upper respiratory tract, resulting in positive cultures without significant disease. The prevalence of *Candida pneumonitis* has increased remarkably in the past 3 decades as a result of the increased use of broad-spectrum antibiotic therapy, immunosuppressive drugs, indwelling vascular lines, prosthetic devices, and organ transplantation.

Pathogenesis

Pulmonary candidiasis may occur by hematogenous seeding of the lung parenchyma from a distal infected site or through direct invasion of inhaled or aspirated organisms. *Candida* acquired through the hematogenous route demonstrates pulmonary lesions that are diffuse, bilateral, and miliary. The endobronchial form of infection does not have a significant interstitial component such as that seen with a hematogenous form. The endobronchial form radiographically demonstrates pulmonary lesions that are small, asymmetrical, patchy, and frequently found in the lower lobes.

Diagnosis

There are no pathognomonic signs and symptoms of pulmonary candidiasis. The diagnosis should be considered in an immunocompromised febrile patient with a pulmonary lesion, particularly if broad-spectrum antibiotics were used without a response. Oral pharyngeal involvement (thrush) indicates that the patient is harboring the organism in an invasive stage. Retinal lesions on ophthalmoscopic examination may help identify invasive *Candida*. A cutaneous lesion often seen in persons with invasive *Candida* is a discrete erythematous papule with an erythematous halo. The radiographic findings of *Candida* pneumonia are nonspecific. Early in the course of infection, patients have normal chest radiographs. The isolation of *Candida* in culture from an otherwise sterile body fluid or tissue and the identification of the organism in a biopsy specimen are diagnostic of invasive *Candida*. Serologic studies are of no diagnostic value. Tests for antibody, antigen, and metabolite detection remain investigational at this time. Proof of *Candida* pneumonia requires tissue examination or evaluation of alveolar lavage or protected brush samples from bronchoscopy as direct evidence of tissue invasion. If these studies fail to identify the disease process, the diagnosis of pulmonary candidiasis may be established with a lung biopsy.

Complications

As with other mycoses, pulmonary candidiasis may be complicated by systemic dissemination affecting other organs. Concomitant infection with other organisms, particularly bacteria, is not uncommon.

Treatment

Effective treatment includes correction of the patient's immunosuppression in addition to administration of amphotericin B. The concomitant and synergistic effect of flucytosine has been demonstrated with amphotericin B for most *Candida* species and is recommended for use in critically ill patients.

Pneumocystis Carinii Pneumonia

Pneumocystis carinii, which probably is a protozoan, produces a unique infection. In the early stages of the infection with cysts, trophozoites are found distributed within the alveoli, most commonly adjacent to the alveolar septum. Usually in this phase no clinical signs or symptoms are evident. With extension of infection, the number of organisms increases and bilateral diffuse distribution occurs throughout the lungs. Eventually desquamation of the alveolar septal cells occurs, with subsequent phagocytosis of the organisms by the alveolar macrophages. Minimal inflammation occurs in discrete areas of the alveolar septum at this stage of the disease, and a child may or may not be symptomatic. Ultimately the alveolar septum becomes thickened with inflammatory cells producing the clinical manifestations of childhood pneumocystosis.[194] In the infantile form there is extensive involvement of alveolar septa

with plasma cell and lymphocyte infiltration. The normal septal thickness may be increased 5 to 20 times, which results in occupation of much of the alveolus by the distended septum.

Clinical Features

The three forms of disease patterns in pneumocystosis are the childhood/adult form, the infantile form, and a more chronic fibrosing form observed in some HIV-infected patients.[195] The typical child/adult type of pneumocystosis occurs in children beyond infancy who have congenital or acquired immunodeficiency disorders or malignancies and in organ transplant recipients.[196-198] Clinical symptoms of pneumonitis include fever, cough, tachypnea, cyanosis, flaring of the nasal ala, and retractions. Chest auscultation usually reveals no adventitious sounds until the terminal stage of infection, at which time bilateral crackles may be present. The chest roentgenogram initially may be normal and changes may be seen only late in the course of the disease.[199]

In the infantile form of pneumocystosis, symptoms often begin insidiously, and presentations include poor feeding, failure to thrive, and diarrhea. Increasing tachypnea may be detected, with respiratory rates frequently in the range of 80 to 120 breaths per minute. A dry, nonproductive cough with increased retractions and flaring of the nasal alae becomes prominent. Diffuse crackles may be heard bilaterally on auscultation of the chest, and most infants remain afebrile. The clinical course in neonates and infants may be quite rapid, with progressive cyanosis and death resulting from respiratory failure within days. More commonly, however, the course extends over a period of several weeks, with a mortality rate varying from 20% to 50% without treatment.[198,200]

The chronic fibrosing type of *Pneumocystis* pneumonia identified in patients with HIV is associated with the presence of long-standing symptoms, localized radiologic changes, and interstitial fibrosis.[195]

Diagnosis

A definitive diagnosis requires documentation of *P. carinii* in lung tissue. The standard surgical open lung biopsy provides histologic details; however, the necessity for general anesthesia presents additional risk, particularly in the critically ill child. Identification of the organism in sputum is sufficient for the diagnosis, but inducing and obtaining sputum in young children often are difficult; in such cases bronchoscopy should be considered.[201] Fiberoptic bronchoscopy with BAL, although not achieving yields as high as open lung biopsy, offers a useful and safe alternative to open lung biopsy.[9,10,29] Transthoracic percutaneous needle aspirate and thoracoscopy have been used successfully and can be obtained without the use of a general anesthetic.[202,203] However, pneumothorax can be expected in up to 30% of children. Once a specimen is obtained, it can be stained with one of the array of preparations by which the organism can be confidently identified. Molecular techniques have been developed for detection of the organism based on PCR techniques amplifying *P. carinii* DNA and have been shown to be sensitive and specific detection methods. PCR assays can be applied to BAL samples, sputum, and nasopharyngeal aspirates with success.[204] Serum lactate dehydrogenase usually is elevated in patients with *P. carinii* pneumonia and appears to be related to the degree of lung injury.[205] The chest radiograph often may be normal early in the course of *P. carinii* pneumonia. However, as the disease progresses, the pattern demonstrates a diffuse bilateral alveolar disease process with hyperinflation and eventually development of air bronchograms. The bilateral densities frequently are more intense in the middle and lower lung fields. Only late in the course of disease do the upper lung fields become involved. Atypical lesions have been reported, including pneumonitis limited to lobar areas. Pneumatoceles and pleural effusions have been reported.[206]

Complications

P. carinii usually remains localized to the lungs, even with extensive disease. A disseminated form has been documented, with recovery of the organism from extrapulmonary sites including bone marrow, liver, and spleen. Life-threatening complications that can arise in patients with *P. carinii* pneumonitis include pneumothorax and pneumomediastinum. Pneumothorax, both spontaneous and iatrogenic, occurs frequently in patients with *P. carinii* pneumonitis. Some evidence indicates that upper lobe predominance of pneumothorax may be more frequent in those previously treated with inhaled pentamidine. Pneumomediastinum, with associated respiratory failure, may be noted in patients receiving assisted ventilation.

Treatment

Therapy for *P. carinii* should include specific anti-*Pneumocystis* chemotherapy, inhibition of the pulmonary inflammatory response, and enhancement of the immunologic status of the patient.[207-212] Several drugs have been used for treatment of pneumocystosis (Table 47-7).

Trimethoprim-sulfamethoxazole may be administered either orally or intravenously and is the drug of choice for treatment of this disease.[3,180] The second most widely used drug for treatment of *P. carinii* pneumonitis is pentamidine isethionate.[211,213] Its effectiveness has been well documented over several years, but it has an increased number of undesirable adverse effects and treatment failures compared with trimethoprim-sulfamethoxazole.[197] Administration of a

Table 47–7 *Pneumocystis Carinii* Pneumonitis Therapy

Drug	Route	Duration of Therapy (Days)	Comments
TMP-SMX	IV/PO	21	DOC
Pentamidine isethionate	IV	21	DOC
TMP dapsone	PO	21	Alternative
Trimetrexate folinic acid	IV	21	Alternative
Clindamycin primaquine	PO	21	Alternative
Atovaquone	PO	21	Alternative
Prednisone	IV/PO	21	Adjunctive agent

corticosteroid such as prednisone should occur at the initiation of specific anti-*Pneumocystis* therapy to improve survival and attenuate or prevent the initial decline in oxygenation. In addition to the specific therapies, efforts should be made to reverse the immune dysfunction that allowed occurrence of *P. carinii*, that is, reduce or discontinue immunosuppressive medications.

Chemical Pneumonitis

A large number of chemical and physical agents may produce intense inflammation of the lower respiratory tract in children. Chemical pneumonitis and/or pneumonia may be acquired in several different ways, such as by aspiration, inhalation, ingestion, or injection.

Aspiration Pneumonia

Aspiration pneumonia is composed of a diverse group of disorders that have in common the soiling of the lower respiratory tract by foreign, nongaseous substances. For purposes of this chapter, neither the solid foreign body nor the infectious component of aspiration is discussed.

Gastroesophageal reflux (GER) has been defined as the retrograde passage of stomach contents into the esophagus. This condition may be asymptomatic or it may be associated with significant regurgitation and vomiting, esophagitis, failure to thrive, and anemia.[214] Aspiration into the pulmonary tree can cause significant complications including apnea, pulmonary fibrosis, severe necrotizing pneumonias, recurrent bronchospasm, and death. Diminished lower esophageal sphincter pressure is often the result of physiologic immaturity; hence GER is more frequent in younger infants. This disorder also occurs in older children, especially those with central nervous and neuromuscular dysfunction. Other high-risk pediatric populations include patients with congenital abnormalities of the tracheal-bronchial tree and those with severe chronic pulmonary disease (Box 47-4).

Box 47–4 Pulmonary Aspiration and Gastroesophageal Reflux: Associated Disorders

Associated Disorders
- Bronchopulmonary dysplasia
- Asthma
- Cystic fibrosis
- Infantile apnea

Central Nervous System
- Convulsive disorders
- Anoxic encephalopathy
- Neurologic impairment
- Myopathies

Congenital Malformations
- Tracheoesophageal fistula
- Hiatal hernia

General
- Failure to thrive
- Achalasia
- Cardiopulmonary resuscitation
- Emergency surgery

Pathophysiology

The association of GER and lung disease has been well documented; however, the actual cause and effect of the relationship has not been firmly established. Massive aspiration of gastric fluid produces direct injury to the mucosal surface of the respiratory tract, resulting in diffuse alveolar damage, hemorrhage, and necrotizing bronchiolitis. This may be followed by a rapid interstitial reaction resulting in an acute inflammatory polymorphonuclear cell infiltration involving the interalveolar septa. Bronchiolitis obliterans and fibrosis can occur. In severe instances the initial onset of disease closely resembles that of ARDS with similar outcomes. Repeated aspiration of small amounts of gastric contents may lead to recurrent pneumonia, airway hyperreactivity, bronchitis, and bronchiectasis with eventual fibrosis and involvement of the pulmonary interstitium.

Clinical Findings

Clinical symptoms of GER vary with age.[214,215] In older children, heartburn, acid/bitter taste, retrosternal pain, or abdominal pain may be reported. Infants may be irritable and exhibit stridor, poor sleeping patterns, or intermittent apnea. Esophagitis can lead to microcytic anemia because of repeated episodes of gastrointestinal blood loss. Chronic respiratory symptoms may include coughing, wheezing with choking episodes occasionally resulting in apnea, or life-threatening events similar to those seen in infants with sudden infant death syndrome. In the hospitalized pediatric patient, significant aspirations may occur during or after general anesthesia. Severe aspiration may be seen in patients receiving tube feedings as a result of displacement of the feeding catheter.

Findings on a chest radiograph may vary from slight hyperinflation to a pattern of diffuse interstitial and alveolar densities. In mild cases a picture of bilateral diffuse infiltrates compatible with ARDS may be seen. Although a barium esophagogram can help to evaluate esophageal motility and detect esophagitis, it reflects only a single point in time. Therefore a negative study does not rule out the presence of GER. Radionuclide scans permit observation of esophageal function following administration of a radioactive tracer. Thus the frequency and severity of reflux and information on esophageal and gastric dysmotility may be obtained. If delayed aspiration occurs, the radionuclide may be observed in the lung fields on a delayed scan.[216] Esophageal motility and intraluminal pressures may be measured by esophageal manometry. Intraesophageal pH measurement is helpful in that it allows long-term monitoring of acid reflux by detecting frequency, duration, and intensity of reflux.[217,218] Esophagoscopy also is useful for assessing the extent of mucosal injury by allowing direct visualization and obtaining a mucosal biopsy. Use of BAL for assessment of lipid-laden macrophages has been useful in establishing or corroborating the diagnosis of aspiration in complex patients.[217,218]

Treatment

Treatment of patients with GER frequently includes placing the patient in an upright prone position and using thickened feedings. Use of antacid preparations, omeprazole, cimetidine, ranitidine, and other inhibitors of H_2 gastroreceptors may be helpful in decreasing acid production and neutralizing its effects on the esophageal mucosa. Omeprazole has on rare

occasions been associated with electrolyte disturbances. It also has been reported to possibly result in atrophic gastritis with prolonged use, but its use continues to increase despite these possible adverse effects.[219-223] Metoclopramide is used prior to meals to help improve lower esophageal function and aid gastric emptying. With the suspension of cisapride from the marketplace as an effective prokinetic agent because of potentially fatal toxicity, interest in erythromycin as a prokinetic agent has resurfaced, and many trials evaluating its dose and efficacy are under way.[224] Bronchodilators are used frequently to treat bronchospasm associated with GER. Because theophylline decreases the lower esophageal sphincter pressure, therefore aerosolized β_2 agonists are preferred. In instances where medical therapy was attempted and failed or in life-threatening situations, antireflux surgery is indicated. In such instances a fundoplication, partial plication, or percutaneous gastrojejunostomy is the appropriate treatment of choice.[214,215] The most favorable outcome and lowest incidence of morbidity in such instances are achieved when surgery is delayed until the patient is adequately nourished and optimal pulmonary status has been obtained.

Inhalation Injury

Acute inhalation injuries are a leading cause of fatalities in pediatric patients. Smoke inhalation accounts for the largest number of pediatric lives lost to inhalation injury each year. A significant number of inhalation injuries as a result of irritant gases occur through industrial or household accidents.[225] Serious pulmonary inhalation injury may be manifested immediately or delayed in onset (Table 47-8).[226-228]

Pathogenesis

Direct injury to the mucosal surface is the most common mode of pulmonary injury. Inhalation of noxious substances may cause extensive physical damage to the lungs and seriously impair subsequent gas exchange. The epithelial cells of air passages may become necrotic and desquamate, causing marked airway obstruction. Bronchospasm caused by irritation from the inhaled gases or particles may lead to further airway obstruction. Severe damage to the basement membrane may occur and cause subsequent leakage of intravascular fluid and blood into the alveolar and interstitial spaces. Injury may occur at all levels of the respiratory tract, depending on the physical and chemical properties of the irritant, the agent concentration, duration of exposure, and breathing pattern of the person exposed.[226,229,230] The clinical course usually has three phases: (1) the acute phase, which occurs within minutes or hours of the insult, resulting in pulmonary edema, hypoxemia, and respiratory failure; (2) the delayed phase, which occurs within the first few days and may include continuing effects of the lung injury such as pulmonary edema, airway obstruction, and superinfection; and (3) the phase in which long-term sequelae may be noted because of the hypoxic or ischemic injury to other organ systems and recurrent pulmonary problems resulting from reactive airways disease or interstitial fibrosis.

Table 47–8 Irritant Gases

Agent	Exposure/Environment
DIRECT MUCOSAL INJURY	
Acrolein	Plastic, rubber, textiles
Ammonia	Fertilizer, refrigerants, explosives
Chlorine	Bleaching, disinfectant
Formaldehyde	Disinfectant, paper, photography
Hydrogen chloride	Refining, dye making
Hydrogen fluoride	Etching, petroleum
Nitrogen dioxide	Welding, fertilizer, farming
Phosgene	Insecticide, dyes, chemicals
Sulfur dioxide	Bleaching, refrigeration
ASPHYXIATION INJURY	
Carbon dioxide	Mining, foundry
Carbon monoxide	Smoke, foundry, mining
Natural gas	Mining, petroleum

Clinical Findings

Clinical manifestations are nonspecific for inhalation of various irritant gases and may differ, depending on the individual child. Injury of the airways may be manifested as upper airway obstruction resulting in laryngotracheitis, bronchitis, and upper airway edema. More peripheral airway obstruction may present with classic findings of asthma and airway edema with hypersecretion. In cases of massive exposure the presenting symptoms may be those associated with acute respiratory distress syndrome, manifested by profound V/Q mismatch, cyanosis, dyspnea, and respiratory failure. Severe nasopharyngeal and laryngeal edema with hypersecretion may present as stridor.[227,229] Chest radiograph findings are nonspecific, ranging from scattered areas of atelectasis and infiltrate to dense bilateral alveolar infiltrates.

Treatment

Prompt physical removal from the offending agent and maintenance of upper airway patency are imperative. Endotracheal intubation is a high-risk procedure, and meticulous attention must be directed toward maintaining proper pulmonary toilet and removal of upper airway secretions and debris from the artificial airway once it is secured.

Oxygenation should be closely monitored. High oxygen concentrations, mechanical ventilation, and use of positive end-expiratory pressure may be necessary in the event of acute respiratory failure because the diminished compliance and formation of pulmonary edema occur rapidly. Use of steroids may be justified in the treatment of patients who have been exposed to oxides of nitrogen; however, use after exposure to other irritant gases has not been validated.

Bronchoscopy may be indicated and useful in assessing the severity of airway injury and as an aid to endotracheal intubation and treatment of major areas of atelectasis. However, use of BAL usually is not indicated except in instances in which significant particulate or carbonaceous material is likely. Humidification of air and oxygen mixtures to thin secretions is necessary, and chest percussion/postural drainage may help to mechanically clear the airways.

Use of prophylactic antibiotics in persons with inhalation injuries is not recommended. If pulmonary infection is suspected, prompt therapy with broad-spectrum antimicrobial agents should be started. Use of bronchodilators is advocated because of a high incidence of bronchospasm. No critical studies

have evaluated this therapy in persons with an inhalation injury; however, the risk associated with its use is low, and administration to the child with obvious airflow obstruction is warranted. Use of aerosolized β_2 agonists is preferred. Special attention is required in the presence of smoke inhalation with regard to treatment of carbon monoxide poisoning. Hyperbaric oxygen, if available, or sustained administration of 100% oxygen is recommended in the initial treatment of patients with significant carbon monoxide intoxication. Development of upper or lower airway edema may necessitate intubation and mechanical ventilatory support.[226,230,231] Administration of artificial surfactant may be beneficial in patients in whom ARDS develops.[232] Use of prophylactic steroids and antibiotics for persons affected by smoke inhalation is not recommended, especially if burn injuries are present, because complications are more frequent.

Prognosis

The prognosis of children with acute pulmonary injury produced by inhalation of toxic gases is generally good. Restrictive and obstructive pulmonary function abnormalities have been observed following recovery. Residual defects such as bronchiolitis obliterans, bronchiectasis, and reactive airways disease have been observed following smoke inhalation.

Ingestion/Injection of Pharmacologic Agents

Several chemotherapeutic agents and other commonly used drugs have potentially serious pulmonary toxicity (Box 47-5). Pulmonary toxicity is thought to be a direct effect in most instances, but immunologic and hypersensitivity mechanisms also may be involved. Toxicity may occur during therapy or after discontinuation of the agent.[233] The development of blebs in the capillary endothelium is followed by an interstitial fibrinous edema and mononuclear cell response with eventual hyaline membrane formation. Some studies have shown a significant decrease in type 1 pneumocytes with evolution of type 2 pneumocytes, septal thickening, and a proliferation of fibrous tissue with a decrease in the number of alveolar septa. Pleural thickening may accompany the pneumonitis.

Diagnosis/Clinical Findings

Characteristic clinical features of drug-induced pulmonary disease include fever, malaise, dyspnea, and a nonproductive cough. Initial radiographic studies may be normal but usually demonstrate a diffuse alveolar and/or interstitial involvement. Pulmonary function studies may be of either an obstructive or restrictive pattern. Hypoxemia enhanced by exercise is an early and clinically important finding because interstitial pneumonitis and pulmonary fibrosis constitute a major portion of drug-induced pulmonary disease. Histologic examination of lung tissue is frequently indicated to confirm the clinical diagnosis and to rule out other potential causes of pneumonitis such as *Pneumocystis*, viral, or fungal infections that often occur in children treated with these agents.

Other complications such as hypersensitivity lung disease, noncardiogenic pulmonary edema, bronchiolitis obliterans, alveolar hemorrhage, and pleural effusion may occur in these patients. Persistent and fatal lung dysfunction may follow drug-induced pulmonary damage. Therapy should be directed at early recognition of the problem, discontinuation of the offending agent, and supportive therapy. The benefit of steroid use for treatment of lung injury caused by pharmacologic agents has not been well defined. In persons with severe life-threatening disease, steroids are frequently used.

Box 47–5 Pharmacologic Agents Associated with Pulmonary Toxicity

Cytotoxic Agents

Antibiotics
- Bleomycin: IP/PF, H, PEFF
- Mitomycin C: IP/PF, PE, PEFF

Alkylating Agents
- Cyclophosphamide: IP/PF, PE, B
- Chlorambucil: IP/PF
- Melphalan: IP/PF

Antimetabolites
- Methotrexate: IP/PF, PE, H, PEFF
- Azathioprine: IP/PF
- G-mercaptopurine: IP/PF
- Cytosine arabinoside: IP/PF, PE
- Nitrosoureas
- Carmustine: PF

Noncytotoxic Agents
- Amiodarone: IP/PF
- Carbamazepine: H, B
- Gold salts: IP/PF, H
- Nitrofurantoin: AH, PEFF, H, B, IP/PF
- Diphenylhydantoin: H
- Sulfasalazine: H, FA, BO, B
- Penicillamine: DA, AH, H, BO

AH, Alveolar hemorrhage; *B,* bronchospasm; *BO,* bronchiolitis obliterans; *DA,* diffuse alveolitis; *FA,* fibrosing alveolitis; *H,* hypersensitivity lung reaction; *IP,* interstitial pneumonitis; *PE,* pulmonary edema; *PEFF,* pleural effusion; *PF,* pulmonary fibrosis.

Idiopathic Interstitial Lung Disease

ILD of undetermined etiology is rare in adults but is even more uncommon in children. Histologic classification of the idiopathic type of ILD can be somewhat confusing, and in past years, pediatric classification mirrored the adult classification scheme. As research progressed, some overlap was noted, but it was found that pediatric interstitial lung diseases have features that are very unique to pediatrics. Usual interstitial pneumonitis has never been identified in children as the diagnostic fibroblastic foci were not found in any of the cases that had initially been labeled UIP. Other interstitial pneumonias such as desquamative interstitial pneumonitis (DIP) and lymphocytic interstitial pneumonias (LIP) are seen in children but remain quite rare and have some features that are different from their adult counterparts. DIP in children is not associated with smoking, and the histologic picture is one of macrophage being the primary inflammatory cell that fills the alveolus, although histiocytes, lymphocytes, eosinophils, and plasma cells are also present. Hyaline membrane formation is not seen in DIP and the structural integrity of the alveolar unit usually is maintained. DIP tends to be responsive to steroids.[234] LIP is seen mostly in patients with immune deficiencies and connective tissue disorders. LIP tends to be insidious in onset and appears as a result of infiltration of the

interstitium by plasma cells, mature lymphocytes, and histiocytes. Nonspecific interstitial pneumonitis histologically is a mixture of inflammation and fibrosis. This entity has been identified in children. Cryptogenic organizing pneumonia (previously bronchiolitis obliterans organizing pneumonia) has been identified in children either as an isolated phenomenon or with infection, asthma, drug reactions, malignancies undergoing chemotherapy, bone marrow transplantation, and autoimmune disorders. Prognosis is usually excellent and patients have an excellent response to corticosteroids. Acute interstitial pneumonia is a rapidly progressive disorder with a histologic appearance consistent with the organizing form of diffuse alveolar damage. This diagnosis generally has a poor prognosis. Some interstitial lung diseases that are unique to infancy most likely in the past had been labeled under the aforementioned interstitial lung diseases but truly belong in their own classification scheme. These syndromes are persistent tachypnea of infancy (neuroendocrine cell hyperplasia of infancy), follicular bronchitis, cellular interstitial pneumonitis (pulmonary interstitial glycogenosis), chronic pneumonitis of infancy, and genetic abnormalities of surfactant function.[234] Detailed discussions of these disorders of infancy or the other interstitial lung diseases and their management is beyond the scope of this chapter but can be found in various review articles.[235-240] Patients who do not respond to medical therapy should be considered candidates for lung transplantation.

Pediatric Pulmonary Hemorrhage

Pulmonary hemorrhage (PH) is a potentially life-threatening event that can occur at any age. The clinical presentation varies from massive fatal hemoptysis to silent bleeding with respiratory distress and anemia. Rapid determination of the etiology of the PH and institution of specific therapy are often difficult. This section examines the less common causes of PH. PH resulting from trauma and infection will not be discussed.

Definition

PH is defined as extravasation of blood into airways and/or lung parenchyma. Massive PH in adults is defined as blood loss of 600 mL or more in 24 hours.[241-243] In infants, Esterly and Oppenheimer[244] characterized massive PH as the involvement of at least two pulmonary lobes by confluent foci of extravasated erythrocytes. Loss of 10% of a patient's circulating blood volume into the lungs regardless of age causes a significant alteration in cardiorespiratory function and should be considered massive. The diagnosis of PH following an episode of silent bleeding is established by pulmonary hemosiderosis, which is the abnormal accumulation of iron within lung parenchyma and alveolar macrophages.

Pathophysiology

Accumulation of blood in the airways following a significant episode of PH creates multiple problems. These problems include production of a diffusion barrier resulting in hypoxemia and reduction in the diameter of involved airways, which in turn increases airway resistance and may lead to airway obstruction.

Reduction in pulmonary compliance and impairment of ventilation may occur.[245,246] These changes in respiratory function increase both the ventilatory and myocardial work necessary to maintain a normal arterial oxygen tension. Interstitial fibrosis that develops following repeated episodes of PH results in reduced carbon monoxide diffusion and diminished static and dynamic lung compliance.

Etiology

Classification of the etiologies of PH provides a simple framework to proceed with diagnostic and therapeutic interventions (Box 47-6). Diffuse PH usually is associated with less total blood loss and can occur from either immune or nonimmune mechanisms. Diffuse, immune PH typically affects adolescents and, less commonly, school-aged children. Focal PH is commonly responsible for massive PH and carries a mortality rate greater than 50%.[243,247] Focal PH typically affects preschool-aged children but may occur in infancy.

Diffuse/Nonimmune Pulmonary Hemorrhage

PH in the neonate occurs in 0.7 to 4 per 1000 live births and is present in 6% to 26.3% of neonates at postmortem examination. Risk factors associated with PH in the neonate include asphyxia, infection/sepsis, central nervous system injury, weight less than 1500 g and/or small-for-gestational age, male sex, congenital heart disease, idiopathic respiratory distress syndrome, and coagulation disorders.[248,249] Intraalveolar hemorrhage appears to occur more commonly in neonates of older gestational age. Pulmonary hemorrhage in neonates as a primary occurrence is uncommon.[248] Pathogenesis of PH in the neonate is considered to result from the development of persistent pulmonary hypertension with right-to-left

Box 47–6 Causes of Pulmonary Hemorrhage

Diffuse

Nonimmune
- Neonatal
- Congenital heart disease
- Hematologic

Immune
- Lower respiratory and renal
  - Goodpasture syndrome
  - Idiopathic rapid progressive glomerulonephritis
- Upper and lower respiratory and renal
  - Wegener granulomatosis
- Multisystem organ involvement
  - Systemic lupus erythematosus
  - Polyarteritis nodosa
  - Behçet syndrome
  - Henoch-Schönlein syndrome
  - Rheumatoid arthritis

Focal
- Foreign body aspiration and chronic retention
- Sequestration
- Arteriovenous fistula
- Bronchogenic and gastroenteric cysts
- Thrombus or embolus
- Neoplasms: angiomas, adenomas

intracardiac shunting of blood, resulting from hypoxia and acidosis. Left ventricular failure ensues, causing an increase in pulmonary capillary pressure and subsequent disruption of pulmonary capillary and alveolar membranes. Severe central nervous system injury may indirectly affect cardiac function, causing increased left ventricular end-diastolic pressure.[250]

Severe hemoptysis and life-threatening PH are very rare in the preadolescent child with congenital heart disease. However, a drastic increase in pulmonary capillary pressure in children with pulmonary atresia, unilateral pulmonary venous atresia, total anomalous pulmonary venous drainage, mitral stenosis, cor triatriatum, or hypoplastic left heart syndrome may result in massive PH.[250,251]

Although the lungs are an infrequent site for early manifestations of primary bleeding disorders,[241,244] a coagulopathy should be ruled out during the management of any patient with PH. In patients with leukemia, PH occurs most frequently when the platelet count is lower than 10,000/mm.

Diffuse/Immune Pulmonary Hemorrhage

The classic clinical triad of hemoptysis, microcytic hypochromic anemia, and diffuse alveolar-filling opacities on a chest radiograph (Figure 47-1) is found in most episodes of PH in this category. Although the lung may be the only organ affected, more frequently multiple organs are involved. In patients with PH, establishing which extrapulmonary organs are involved by the disease helps to narrow the differential diagnosis of which of the immune-mediated disorders is most likely present.

Diffuse parenchymal bleeding without evidence of extrapulmonary involvement occurs in patients with idiopathic pulmonary hemosiderosis, Heiner syndrome, and drug-induced PH. Idiopathic pulmonary hemosiderosis, a disease of childhood, is a diagnosis of exclusion. Clinically, episodes of PH recur, with 30% to 50% of patients eventually dying of exsanguination and/or respiratory failure.[252,253] Microscopic examination of the lungs is compatible with nonspecific injury rather than a specific cause such as vasculitis or immune deposits.[254] Heiner syndrome, which affects children between the ages of 6 months and 2 years, usually manifests as other symptoms, such as chronic rhinitis, recurrent otitis media, and growth retardation.[242,250] Tests for precipitating antibodies to milk proteins are positive. Symptoms resolve when milk and milk products are eliminated from the diet.[250]

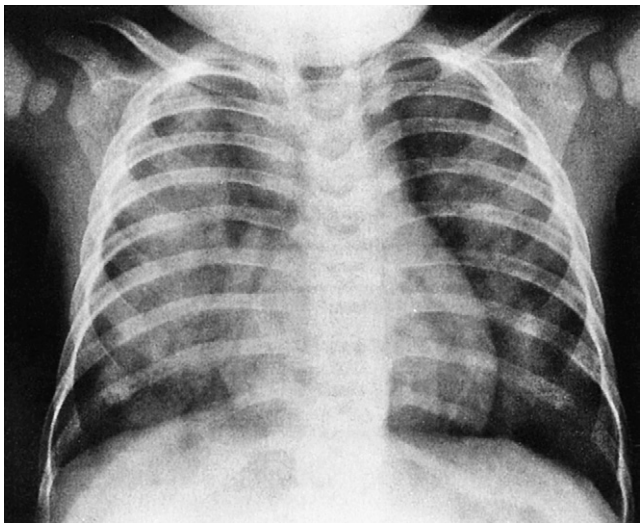

Figure 47–1. Chest radiograph of a patient with diffuse immune pulmonary hemorrhage.

Although uncommon, exposure to or inhalation of D-penicillamine, lymphangiography dye, trimellitic anhydride, cocaine, and exogenous surfactant[255-257] has been associated with development of PH. Acute PH of an undetermined etiology occurring in infants has been reported.[258,259]

Idiopathic rapidly progressive glomerulonephritis is usually a disease of older adults (mean age, 55 to 60 years).[253] In children with PH and either proteinuria, hematuria, or red cell casts, Goodpasture syndrome is the most likely etiology. The presence of a linear immunofluorescent staining of Ig and C3 along glomerular capillary walls and antibasement membrane antibody (ABMA) in the serum confirms the diagnosis of Goodpasture syndrome. Renal biopsy is the preferred primary method of confirming the diagnosis because an ABMA assay is not readily available at most institutions. AMBA is a cytotoxic plasma Ig that reacts immunologically with components of alveolar and glomerular basement membrane. Stress failure of pulmonary capillaries because of alteration of the alveolar and glomerular basement membrane may contribute to the likelihood of PH in these patients.[260] Fifty percent of patients with Goodpasture syndrome die of asphyxia as a result of massive PH. The presence of sinusitis and/or bilateral, multiple cavitary pulmonary nodules and evidence of glomerulonephritis in patients with PH help distinguish Wegener granulomatosis from the other vasculitides.[261] The immune-mediated causes of PH with multisystem organ involvement often have characteristic physical findings to suggest the diagnosis. Serositis, arthritis, facial erythema, fever, and glomerulonephritis are present prior to the development of PH in patients with systemic lupus erythematosus (SLE).[253,262] Ten percent of all cases of immune-mediated PH are associated with SLE.[253] The onset of PH in patients with SLE is abrupt. Pulmonary histology may or may not reveal a small vessel vasculitis characterized by neutrophilic infiltration of vessel walls and necrosis of capillaries and alveolar septa. Renal histology shows a vasculitis represented by focal and segmental glomerulonephritis with absent or minimal immune deposits.[263] The majority of patients who have SLE and PH die.[254] PH has been reported with most of the vasculitides, but the incidence is much lower than in the SLE population. Constitutional signs and symptoms, such as musculoskeletal involvement, blood dyscrasias, and dermatitis, are the predominant clinical features of polyarteritis nodosa, the second most likely vasculitis-associated disease to cause PH.[254] A segmental necrotizing (granular pattern) vasculitis is the characteristic lesion of polyarteritis nodosa, with PH a dominant feature.[264,265] Recurrent uveitis, mucocutaneous ulcerations, and genital ulcerations in a patient with PH suggests Behçet syndrome as the etiology. Other clinical features seen with Behçet syndrome include arthritis, gastrointestinal disease, cardiovascular involvement, and central nervous system disease.[266,267] A necrotizing vasculitis of small- to medium-sized arteries and veins and thromboses of the terminal vascular beds or vena cava confirm the diagnosis.

Although PH is an extremely rare complication of Henoch-Schönlein purpura or syndrome (when abdominal pain and

arthritis precede the purpura), it should be treated aggressively because it may be fatal. In a few patients with rheumatoid arthritis syndromes resembling idiopathic pulmonary hemosiderosis without evidence of vasculitis or renal disease have developed.[254]

Focal Pulmonary Hemorrhage

Congenital malformations that may be responsible for PH during infancy include angiomas and bronchogenic and gastroenteric cysts.[250] Angiomas are located in the subglottic area and present with symptoms of airway obstruction by age 6 months in almost 90% of cases. Bronchogenic cysts arise from abnormal branching of the tracheobronchial tree, are lined with ciliated columnar epithelium, are filled with mucoid fluid, and if they are in communication with the airway, they may demonstrate an air-fluid level. They are prone to infection and may bleed if contiguous vessels erode. Gastroenteric cysts, which are enteric duplication cysts lined with gastric mucosa, produce acid peptic secretions that may erode through adjacent vessels to cause bleeding. Pulmonary sequestration, arteriovenous fistula, and bronchial adenomas are congenital malformations that may present in childhood or later life with PH. With its tendency to become recurrently infected, a sequestered lobe may suffer erosion into its systemic arterial supply, causing massive PH.[250] Pulmonary arteriovenous fistula with or without telangiectasia (isolated or familial) may produce massive PH during childhood, but this usually does not occur until adulthood.[268,269] Adenomas are highly vascular tumors that, with minor trauma or inflammation, can cause PH. Acquired causes of focal PH include aspiration of an organic foreign body and development of a pulmonary arterial thrombus or embolus.[241,250] A patient presenting with PH and wheezing should lead the clinician to suspect a diagnosis of foreign body aspiration. Prolonged retention of an organic foreign body leads to hyperplasia of tortuous bronchial vessels, varicosities, and bronchiectasis, any of which may cause PH. Thrombi or emboli may develop in postoperative immobile children with central venous or pulmonary catheters, in female adolescents using oral contraceptives, or in patients with homozygous deficiency of antithrombin III, protein S, and protein C. Focal PH may develop in children with cystic fibrosis as a result of bronchiectasis.

Treatment

General

The primary objectives in treatment of PH are twofold: (1) to rapidly control the bleeding to prevent tissue hypoxia and/or ischemia resulting from airway obstruction and exsanguination and (2) to stabilize hemodynamics to prevent further damage to the kidneys or other extrapulmonary organs by the underlying disorder.[245,270] Initial management of the patient with severe PH should occur in the setting of a critical care unit because of the potential lethality of this event (Box 47-7). General care measures include use of the Trendelenburg position as tolerated, oxygen supplementation, mechanical ventilation, and hemostasis therapy when indicated. The Trendelenburg position may help clots propagate superiorly and exit the airway. This position may not be well tolerated by patients with respiratory or cardiac embarrassment.

Box 47–7 Treatment of Pulmonary Hemorrhage

General

- Admission to pediatric intensive care unit
- Positioning (intermittent Trendelenburg)
- Oxygen supplementation
- Mechanical ventilation (positive end-expiratory pressure)
- Hemodynamic monitoring
- Hemostasis replacement therapy
- Endobronchial tamponade (Fogarty catheter, cuffed endotracheal tube)

Specific

Immune

- Corticosteroids
- Other immunosuppressive agents (azathioprine, cyclophosphamide)
- Plasmapheresis (Goodpasture syndrome)
- Bilateral nephrectomy
- Deferoxamine, milk-free diet

Focal

- Surgical resection
- Selective embolization of bronchial vessels

Positive end-expiratory pressure during mechanical ventilation may become necessary to reverse hypoxemia and may provide a measure of tamponade to the site of hemorrhage.[243] Coagulation factors should be administered when indicated to lessen the severity of bleeding. Hemodynamic monitoring with a pulmonary arterial catheter may be beneficial in some instances because high pulmonary artery occlusion pressure may worsen PH of any etiology. Short-term control of bleeding may be obtained with insertion, under direct vision, of a balloon-tipped (Fogarty) catheter into the affected portion of the airway. Right upper lobe bleeding is best managed by intubating the left main stem bronchus with a cuffed endotracheal tube and inflating the cuff of the tube. Utilization of a "double lumen" or Carlens-type endotracheal tube also may be helpful in isolating the bleeding segment. However, the diameter of these tubes precludes their use in smaller children, and proper positioning may prove difficult.[245,271] Rigid bronchoscopy not only is the best means of identifying the source and type of bleeding but also has therapeutic applications.[245,272] The rigid scope readily establishes an adequate airway and can be used for large-volume isotonic saline solution lavage and for suctioning large volumes of blood. Fiberoptic bronchoscopy should be reserved for diagnostic purposes, including definitive identification of the bronchopulmonary segments involved and BAL. BAL provides useful information by permitting culture of the lavage for bacteria, fungi, mycobacteria, and viruses and quantitative assessment of the hemosiderin content of the alveolar lavage. Interpreting the presence or absence of hemosiderin-laden macrophages should be done cautiously because they may not appear for up to 48 hours following an acute episode of bleeding and usually disappear by 2 weeks.

Specific

Despite the different etiologies in the category of immune-mediated PH, the response to corticosteroid therapy is swift (within 24 to 48 hours) as assessed by transfusion requirements, hemoglobin concentration, hemoptysis, and absence

of new infiltrates.[254] Although controlled clinical trials have not been performed to validate this temporal relationship suggestive of therapeutic benefit, the risk of administering a short course of high-dose corticosteroids in this setting is low. Hence, the corticosteroids adrenocorticotropic hormone (10 to 25 units/day), methylprednisolone (2 to 4 mg/kg/day), or hydrocortisone (4 mg/kg/day) should be administered early in a patient with an acute, life-threatening episode of immune-mediated PH. Once remission is achieved, corticosteroids should be tapered until they are discontinued or until symptoms recur. In cases of inadequate response to corticosteroids alone, other immunosuppressive agents (e.g., azathioprine, cyclophosphamide, and chlorambucil) have been administered with some success in persons with the immune-mediated PH syndromes.[250] Azathioprine (1.2 to 5 mg/kg/day) with prednisone (5 to 20 mg every 6 hours) is a typical treatment combination. Cyclophosphamide is the drug of choice for treatment of patients with Wegener granulomatosis.[263,273-275] Once a specific diagnosis is made for the various etiologies of immune-mediated PH, directed therapies are available, including immunosuppression and plasmapheresis. These therapies are beyond the scope of this chapter and are discussed in the literature.[263,274,275] Administration of intravenous vasopressin to a patient with massive hemoptysis may temporarily control the bleeding. Surgical resection of a bleeding focus remains the procedure of choice if feasible. Surgical resection is the generally recommended treatment of uncorrectable, unilateral pulmonary vein atresia, bronchiectatic lung resulting from a foreign body, recurrent infection, and vascular tumors.[245] Severe bleeding at the time of resection resulting in single lung ventilation increased the mortality rate from 12% to 25% in one series. Pulmonary embolectomy should be considered for patients with an acute large embolus, especially if fibrinolysis is contraindicated.[245,276,277] For focal PH resulting from increased bronchial circulation, selective embolization or occlusion of bronchial vessels with glass microspheres, small pledgets of absorbable gelatin sponge, or polyvinyl alcohol sponge may provide temporary hemostasis. Embolization should be considered in the unstable or poor surgical candidate with focal PH. Complications of embolization include inadvertent central nervous system or coronary artery occlusion and transverse myelitis with resulting paraplegia.

Summary

PH that does not occur in the familiar setting of trauma or infection can be classified according to extent of pulmonary involvement, that is, diffuse or focal. PH occurs most commonly during the neonatal period as a result of diffuse nonimmune mechanisms. PH in the neonate is a preterminal complication of severe disorders of the cardiovascular and respiratory systems. The best initial approach to diagnosis and specific therapy in the older child is determining the extent of extrapulmonary organ involvement. Diseases that lead to focal hemorrhage are more likely to cause massive hemoptysis, typically affect younger children, and may be amenable to surgical resection. If the suspected cause of PH is a diffuse, immune-mediated process, a trial of corticosteroids should be administered early because of the rapid, dramatic response seen in patients with some disorders. A systematic approach to diagnosis in persons with PH will improve the odds of a favorable outcome for patients with this rare phenomenon.[245,271]

Chapter 48

Diseases of Pulmonary Circulation

Satyan Lakshminrusimha and Vasanth H. Kumar

PEARLS

- The onset of breathing and lung inflation at birth with a resultant increase in oxygen tension decreases pulmonary vascular resistance, which is essential for establishing a normal postnatal circulatory pattern.
- Elevated pulmonary vascular resistance relative to systemic vascular resistance, which may result from either vasoconstriction or structural remodeling of the pulmonary vasculature, characterizes persistent pulmonary hypertension of the newborn (PPHN).
- An increase in pulmonary vascular smooth muscle can occur in utero or after birth and result in peripheral extension of the smooth muscle onto vessels that do not normally have muscle layers. This process may contribute to the pathology of PPHN.
- The gold standard in defining PPHN rests on the echocardiographic findings of right to left shunting of blood at the foramen ovale and/or ductus arteriosus, as well as evidence of elevated pulmonary arterial pressures.
- High-frequency oscillatory ventilation, surfactant therapy, and nitric oxide have decreased considerably the need for extracorporeal membrane oxygenation in infants with PPHN.
- In children, it is important to establish an accurate diagnosis with respect to etiology, because therapy may depend on the etiology of pulmonary hypertension.
- Echocardiography is a useful screening tool in children with suspected pulmonary arterial hypertension (PAH). Before committing to therapy specific to childhood PAH, diagnosis needs to be confirmed by catheterization.
- Calcium channel blockers are useful only for patients who respond to vasodilator testing during cardiac catheterization.
- Overall exercise capacity, symptoms as assessed by World Health Organization classification, and hemodynamic parameters of right ventricular function help not only in the management of these patients but also correlate well with survival.
- Recent advances in the medical management of PAH has widened the therapeutic modalities available for children including prostanoids, oral endothelin receptor antagonists, PDE-5 inhibitors, and some forms of combination therapies.
- Aggressive medical therapy combined with prompt and meticulous follow-up will improve quality of life and survival of children with pulmonary hypertension.

Early referral to expert centers is crucial to patient survival.

Etiology and Treatment of Pulmonary Hypertension

This chapter addresses the neonatal and pediatric aspects of pulmonary hypertension (PH). First, unique aspects of fetal and postnatal development of pulmonary vasculature, transitional circulation, and developmental regulation of pulmonary vascular tone are discussed. This background helps in understanding the pathophysiology and treatment of pulmonary vascular disorders in newborns and children.

Developmental Pulmonary Vascular Anatomy

Embryology

The vascular network of the developing endodermal pair of lung buds is derived from the surrounding mesenchyme of the splanchnic mesoderm beginning at 4 weeks of gestation. These vessels accompany the developing airways, differentiate into arteries, and join the larger pulmonary arteries that originate from the sixth aortic arch. The veins arise separately within the loose mesenchyme of the lung septa and subsequently connect to the developing left atrium.

Distinctions can be recognized between the proximal and distal pulmonary vasculature both in terms of their embryonic origins and the morphogenetic processes by which they develop. The sixth branchial arch is the embryonic origin of the proximal pulmonary vasculature, and it develops by the process of vasculogenesis. Vasculogenesis is the differentiation and segregation of angioblasts within the mesenchyme, which forms early vascular channels (arteries, veins, and lymphatics), depending on local influences from the epithelium and the mesenchyme. The lung mesenchyme is the embryonic origin of the distal vasculature, which develops by angiogenesis. Angiogenesis is the formation of new vessels from preexisting vascular channels by proliferation and migration of endothelial cells at the tips, which form multiple capillary sprouts. Abnormal maturation or maturational arrest in pulmonary arterial development is reflected in functional derangement that can appear in the newborn period. Persistent pulmonary hypertension of the newborn (PPHN) has been reported in association with pulmonary arterial maturational arrest at week 5 of gestation.[1] Normal growth and development of the pulmonary circulation in utero is critical for achieving successful transition to postnatal life.

Multiple factors influence development and growth of pulmonary vasculature in utero, including growth factors. Growth factors such as vascular endothelial growth factor[2] and fibroblast growth factor[3] appear to be responsible for orderly growth and branching morphogenesis of blood vessels. Quantity, timing, and location are critical determinants of the net effects of these agents. The mechanical stress that endothelial cells must withstand may be the predominant force responsible for development of large vessels after onset of circulation.[4]

Vascular Smooth Muscle

In the normal fetal and term lung, fully muscularized thick-walled preacinar arteries extend to the level of terminal bronchioles, whereas the intra-acinar arteries (i.e., those accompanying respiratory bronchioles) are partially muscular (surrounded by a spiral of muscle) or nonmuscular. Arteries at alveolar ducts and alveolar walls are nonmuscular. Preacinar arteries in the fetus late in gestation and in the newborn have thicker coats of smooth muscle relative to the arterial diameter than do similar arteries in adults, although the fetus actually has less distal extension of smooth muscle in smaller arteries than do older children or adults.[5] Figure 48-1 shows the diagrammatic representation of the extension of arterial smooth muscle within the acinus in a normal term newborn and in infants with severe PPHN.[6] An increase in intrauterine vascular smooth muscle, resulting from peripheral extension of smooth muscle into vessels that do not normally contain muscle layers, may contribute to the pathophysiology of PPHN[7] (see Figure 48-1). Increased muscularization of the pulmonary arteries has been described in infants with severe meconium aspiration syndrome (MAS) with PPHN.[8] Neonates who die of PPHN may have a striking distal extension of smooth muscle in the intra-acinar region, thickening of the media and adventitia, and excessive accumulation of the matrix protein in the pulmonary vessels.[9] The increase in vascular smooth muscle and its peripheral extension can occur either prenatally or postnatally. In utero ductal ligation 1 to 2 weeks prior to delivery results in severe PPHN at birth associated with distal extension of vascular smooth muscle in newborn lambs[10] (Figure 48-2) similar to the changes seen in human infants dying with severe PPHN.

Developmental Pulmonary Vascular Physiology

Hemodynamic Features of Fetal Circulation

Oxygenated blood (Pao_2 approximately 30 to 40 mm Hg) returning from the placenta in the umbilical vein[11] splits in the liver with slightly more than half passing through the ductus venosus to the inferior vena cava (IVC). The oxygenated blood streams along the medial aspect of the IVC as it enters the right atrium (Figure 48-3). Approximately two thirds of the IVC flow is directed toward the foramen ovale by the eustachian valve and the septum primum and enters the left atrium. The remaining third of the IVC flow mixes with the blood from the superior vena cava and enters the

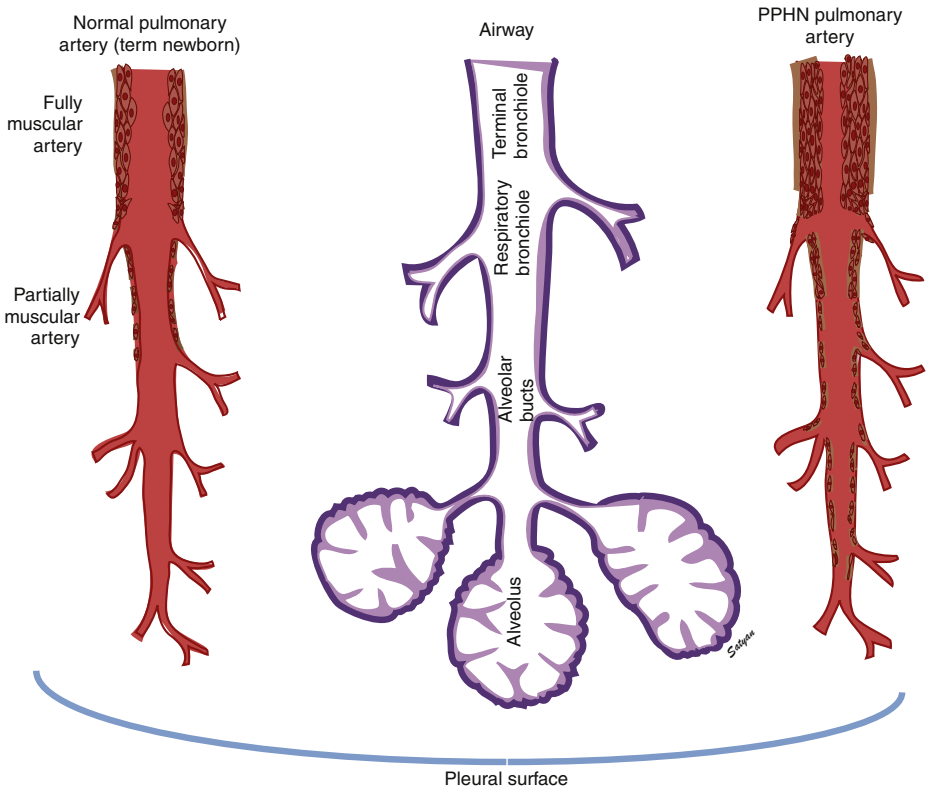

Figure 48–1. Diagrammatic representation of a normal pulmonary artery from a term newborn infant showing a fully muscular media to the level of the terminal and respiratory bronchiole. A partial muscular layer extends further distally but the terminal portion of the arterial tree is devoid of smooth muscle. right ventricle. The majority of the right ventricular (RV) output enters the ductus arteriosus and the descending aorta. A small portion enters the lungs via the pulmonary arteries.[12] The ratio of blood flow to the pulmonary arteries to the flow that traverses the ductus arteriosus is determined by the fetal pulmonary vascular resistance (PVR).

The fetal pulmonary circulation fulfills a unique function. Close to term, fetal lungs in the lamb receive about 5% to 10% of combined ventricular output to meet the metabolic demands of an actively growing organ. More recent data in human fetuses using Doppler echocardiography suggest that approximately 25% of combined ventricular output may enter the lungs near term.[13] The presence of large fetal shunts, the foramen ovale and the ductus arteriosus (see Figure 48-3), allows the fetal lung to regulate the amount of blood flow it receives by active vasoconstriction. The distribution of combined ventricular output, measured in fetal lambs ranging from 60 to 150 days gestational age, indicates that the lungs receive only about 3.5% of total output at 0.4 term, but the fraction increases to almost 8% at term.[14] This remarkable

increase in fetal pulmonary perfusion presumably is related to growth of the fetal lung. The lung increases in weight by sixfold from midgestation to term, and the number of pulmonary vessels increases more than tenfold.[15,16] Thus the tremendous increase in cross-sectional area of pulmonary vasculature permits pulmonary blood flow (Qp) to increase throughout gestation. However, Qp remains relatively constant when corrected for wet lung weight with advancing gestation.[17] A gradual increase in pulmonary arterial pressure (PAP), accompanied by a relatively constant flow per unit lung tissue, results in increasing fetal PVR with advancing gestation.[17] A major part of this increase comes from elevated pulmonary vascular tone associated with low Po_2 in the fetal lung.[18,19] Maintaining high PVR in utero is important because the function of gas exchange is performed not by the lungs but by the placenta.

Regulation of Pulmonary Vascular Tone in Utero

Low oxygen tension and various mediators play a crucial role in maintaining elevated fetal PVR.[20] Vasoconstriction in response to low oxygen tension contributes to high PVR in the fetal lamb as it approaches term.[18,19] Decreasing oxygen tension in fetuses at 103 to 104 days of gestation does not increase PVR, but it doubles resistance in fetuses at 132 to 138 days. Conversely, increasing oxygen tension does not change PVR before 100 days of gestation, but it decreases resistance markedly and increases blood flow to normal newborn levels at 135 days of gestation.[17]

Arachidonic acid metabolites are some of the most powerful vasoconstrictors known. Prostaglandin (PG) $F_{2\alpha}$ and thromboxane A_2 (TXA_2) are synthesized by the fetal lung via the cyclooxygenase pathway[21] and are pulmonary vasoconstrictors in the fetal and newborn lungs. However, TXA_2 does not appear to be responsible for maintenance of high PVR in the fetus.[22] Blocking PG or thromboxane synthesis does not decrease fetal PVR but prevents the decrease in PVR in response to rhythmic distension of the lung in fetal lambs.[23] The cytochrome P450 metabolism of arachidonic acid results in the formation of epoxyeicosatrienoic acids, dihydroxyeicosatetraenoic acids, and 20-hydroxyeicosatetraenoic (HETE) acids. Of these compounds, HETE acids have been shown to constrict pulmonary circulation in newborn piglets.[24] However, inhibition of 20-HETE did not reduce basal PVR in fetal lambs.[25] Thus it does not appear that cyclooxygenase and CYP450 metabolites of arachidonic acid cause the high vascular tone of the fetal lung.

Leukotrienes are formed from arachidonic acid through the 5-lipooxygenase pathways. Lipoxygenase activity has been demonstrated in human fetal lung as early as 12 to 18 weeks of gestation.[26] Leukotriene inhibition has been shown to decrease PVR in fetal lambs by 45%.[27] It also reverses hypoxic pulmonary vasoconstriction in newborn lambs but not in newborn piglets.[28,29] The specific role of leukotrienes in maintaining high PVR in immature fetuses is unclear. It is possible that they play a role in pathologic states such as hypoxia or inflammation.

Endothelins (ETs) are 21-residue peptides[30,31] whose role in regulating vascular tone and vasomotor responses has been studied intensively in the past decade. Three distinct ET isoforms have been described: endothelin-1 (ET-1), endothelin-2 (ET-2), and endothelin-3 (ET-3), cleaved from ET precursors big ET-1, big ET-2, and big ET-3, respectively, by an ET-converting enzyme. ET-1 synthesized by vascular endothelial cells is a potent vasoconstrictor,[32] and its effects in both animal and human studies vary with the tone of the pulmonary vessels, dose of ET-1, and the maturation of vessels.[33,34] Of the ETs, ET-1 is the best characterized, and its actions of fetal pulmonary circulation are best studied. Both ET-1 and ET-2 have been shown to dilate the fetal (normally high tone) pulmonary vasculature and constrict the bed when the tone is reduced by ventilation.[35] Thus it appears that the response of the pulmonary vasculature to ETs is tone-dependent. In contrast, infusion of big ET-1, the precursor of ET-1, into fetal lambs causes sustained pulmonary vasoconstriction,[36] suggesting that this might be the predominant effect of endogenous ET-1.[37] Currently at least two receptor subtypes, ET_A and ET_B, are thought to mediate responses to ETs (Figure 48-4). The ET_B receptor plays a role in vasodilation and the ET_A receptor plays a role in vasoconstriction. Selective blockade of the ET_A receptor causes fetal pulmonary vasodilation.[38-40] Some investigators suggest a significant role for an endothelial ET_B receptor in vasodilation and a smooth muscle ET_B receptor and ET_A receptor in vasoconstriction.[41,42] Vasoconstriction induced by ET-1 is mediated by calcium,[43] whereas the vasodilator properties are mediated by endothelium-derived nitric oxide (NO).[42,44] ET-1 may play a role in the change that occurs in the pulmonary vasculature at birth. It is possible that prenatally, endogenous ET-1 primarily stimulates ET_A receptors to cause vasoconstriction and that ET_B receptors are less active in fetal life.[38] However, ET_B receptors mediate the vasodilator

responses to ET-1 in the fetus, and there is a suggestion that an abundance of ET_B receptors may be of physiologic importance in decreasing PVR at birth.[40]

Transitional Circulation

The first stage of transitional circulation is essentially a fetal pulmonary circulation that is characterized by high pressure and low flow because of both passive and active elevation of PVR (Figure 48-5, *A*). The passive resistance most likely is related to compression of pulmonary capillaries by fetal lung liquid, but there is also a high degree of active vasomotor tone resulting from various mediators and hypoxic stimuli. Thus PVR exceeds systemic vascular resistance (SVR), resulting in right atrial and ventricular pressures exceeding left atrial and ventricular pressures. High PVR results in right-to-left shunting of blood across the foramen ovale, and most of the blood ejected by the right ventricle flows across the ductus arteriosus into the descending aorta. Persistence of elevated PVR after birth without the benefit of placental oxygenation results in the profound hypoxemia that characterizes PPHN.

The second stage of normal transition is accomplished when the fluid-filled fetal lungs are distended with air during the first breath (Figure 48-5, *B*).[20] A rapid decrease in PVR occurs with mechanical distension of the pulmonary vascular bed. The entry of air into the alveoli improves oxygenation of the pulmonary vascular bed, further decreasing PVR.[45] At birth PVR decreases dramatically, which leads to an eightfold increase in Q_p. The increase in Q_p raises left atrial pressures above right atrial pressures, closing the foramen ovale. SVR increases at birth, in part because of removal of the low resistance bed of the placenta. As PVR becomes less than systemic, flow across the ductus reverses. Within the first 5 minutes after birth, oxygen-induced vasodilation and lung expansion decrease PVR to approximately half of systemic resistance. Over the first few hours after birth, the ductus arteriosus closes, largely in response to the increase in oxygen tension. At this point the normal postnatal circulatory pattern is established.

The third stage of the transitional circulation occurs for 12 to 24 hours after birth and accounts for the greatest reduction in PVR. In the final phase of neonatal pulmonary vascular transition, further decline in PVR is accompanied by rapid structural remodeling of the entire pulmonary bed from the main pulmonary arteries to the capillaries.[46] During this remodeling, changes in the shape and geometric orientation of endothelial and smooth muscle cells cause luminal enlargement. Maturation of smooth muscle function, thinning of endothelial cells (Figure 48-5, *C*), and more gradual changes in elastic and connective tissue occur during the next few weeks.

Factors Responsible for Decrease in Pulmonary Vascular Resistance at Birth

The onset of ventilation with rhythmic inflation of the lungs at birth with a resultant increase in oxygen tension in the lungs leads to a decrease in PVR. Each of these stimuli has been shown to decrease vascular resistance and increase blood flow in the lungs of fetal lambs.[45] Increasing oxygen tension alone by using a hyperbaric chamber decreased PVR and increased

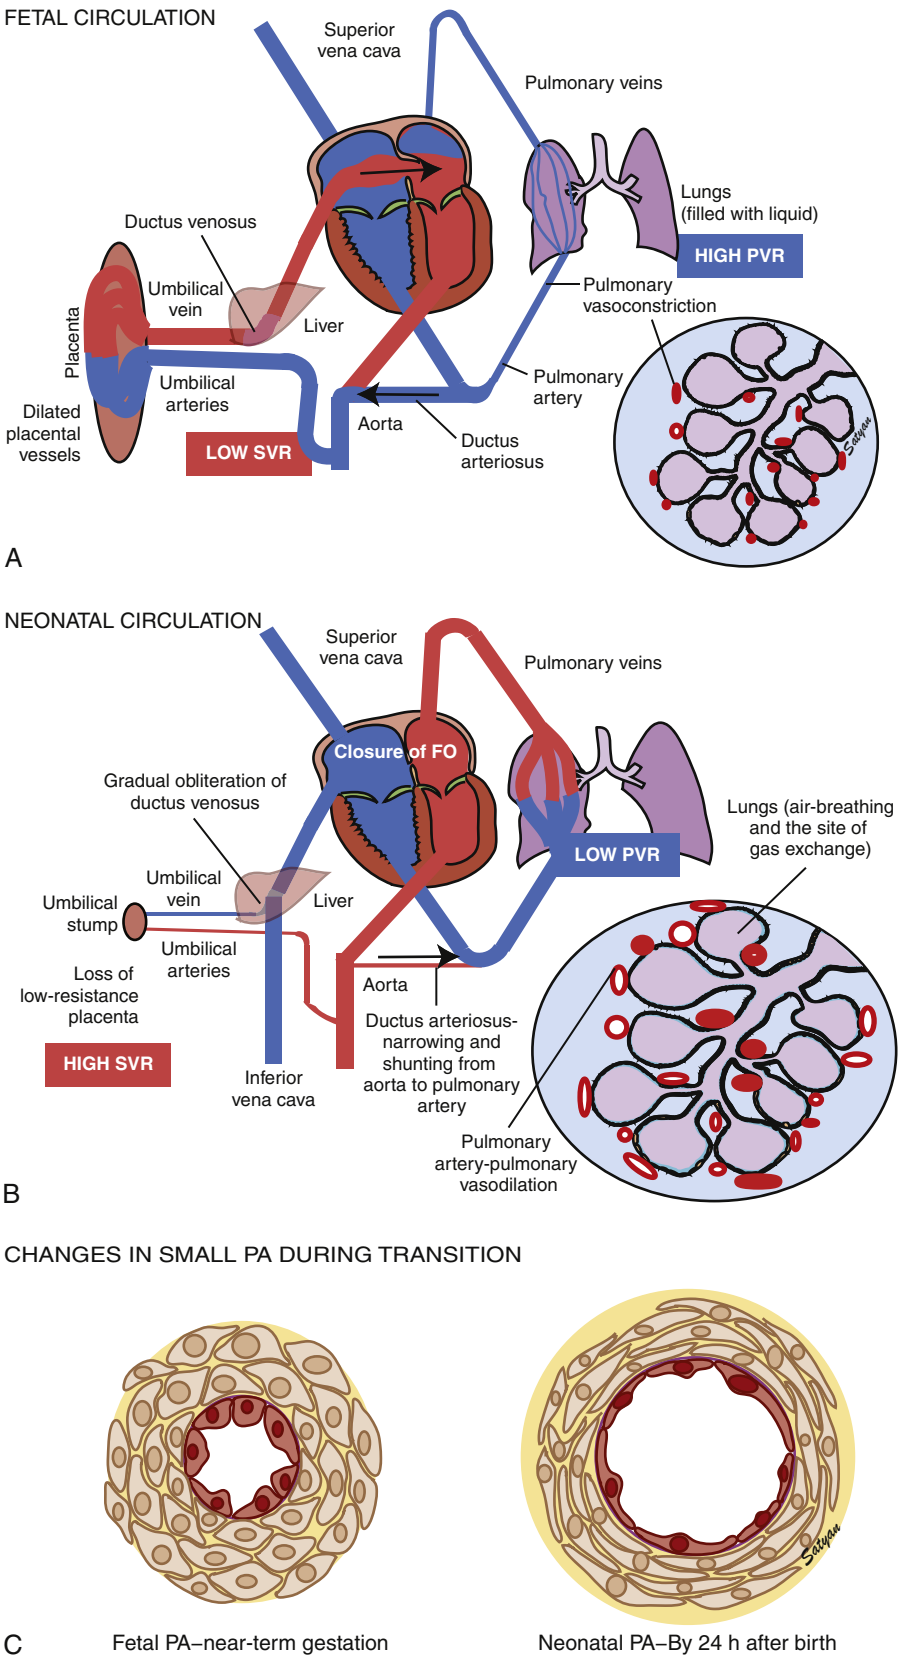

Figure 48–5. Transitional circulation. Fetal circulation (**A**) is characterized by high pulmonary vascular resistance (PVR), low pulmonary blood flow, and low systemic vascular resistance (SVR). After birth, with the clamping of the umbilical cord, low resistance placental circulation is removed and SVR increases and with pulmonary vasodilation, PVR decreases (**B**). During the first few hours of postnatal life, morphologic changes occur in the pulmonary arterial endothelial cells and smooth muscle cells. These changes contribute to further reduction in PVR (**C**). *(Copyright Satyan Lakshminrusimha.)*

Q_p by tenfold in mature fetal lambs.[17] Inflation of lungs with gas may decrease resistance, at least in part by mechanical effects. Oxygen may dilate in part by direct effects on vascular endothelial and smooth muscles.[20,47]

The drop in PVR soon after birth is accompanied by production of prostacyclin (PGI_2) and NO. Arachidonic acid metabolites such as PGs, generated through the cyclooxygenase pathway, are potent pulmonary vasodilators in the fetus. PGI_2 synthesized by endothelial cells appears to relax smooth muscle by producing cyclic adenosine monophosphate (cAMP). PGI_2 and its metabolites are more potent vasodilators than PGE_2. Even though blockade of PG synthesis, either by indomethacin[48,49] or meclofenamate,[23] blunts the decrease in PVR, it does not completely disrupt the transition to gas exchange. In addition, cyclooxygenase through the PGE_2 pathway plays an important role in maintaining patency of the ductus arteriosus. PPHN has been observed in infants of mothers receiving aspirin or nonsteroidal antiinflammatory drugs (NSAIDs) that inhibit cyclooxygenase activity.[50] In this situation, the inhibitor acts through prenatal constriction of the ductus arteriosus or by decreasing PGI_2 synthesis at birth.[51] The cAMP signal transduction pathway is shown in Figure 48-6.

Acetylcholine,[52] bradykinin,[53] and histamine[54] are fetal pulmonary vasodilators, which in many species act by an endothelium-dependent mechanism (see Figure 48-4). They stimulate the production of NO by vascular endothelium. NO activates soluble guanylate cyclase to produce the second messenger cyclic guanosine monophosphate (cGMP). cGMP induces relaxation of vascular smooth muscle through activation of a cGMP-dependent protein kinase that produces a lowering of cytosolic ionic calcium, in part through activation of potassium channels.[55] There is strong evidence that NO is an important mediator of the decrease in PVR at birth. NO is a potent dilator of the fetal pulmonary circulation.[56] The dilation of the fetal pulmonary circulation caused by an increase in oxygen tension is mediated in large part by endogenous synthesis of NO.[57] In late gestation lambs, prolonged administration of nitric oxide synthase (NOS) inhibitors, which blocks endogenous NO synthesis, does not affect basal PVR but markedly blunts the decrease in PVR observed at birth.[58]

Evidence suggests that many other mediators can act as pulmonary vasodilators during fetal life and at birth. The purines adenosine triphosphate and adenosine are potent pulmonary vasodilators in the fetal lamb that may also be involved at birth.[59-63] Natriuretic peptides such as atrial natriuretic peptide, B-type natriuretic peptide, and C-type natriuretic peptide dilate fetal pulmonary vasculature by increase cGMP through particulate guanylate cyclase.[64] Arachidonic acid metabolites such as epoxyeicosatrienoic acids, which are generated through the cytochrome P450 pathway, are potent pulmonary vasodilators.[65] Because pulmonary vasodilation at birth is a vital step in establishing postnatal life, it is logical that there would be sufficient redundant vasodilators to compensate for failure or inadequacy of any single pathway.[37]

Persistent Pulmonary Hypertension of the Newborn

PPHN is a serious clinical condition that can result from diverse etiologies and is characterized by failure of the pulmonary circulation to adapt to extrauterine life.

Pathophysiology

Elevated pulmonary to systemic vascular resistance ratio (PVR/SVR) resulting from either vasoconstriction, structural remodeling of the pulmonary vasculature, intravascular obstruction, or lung hypoplasia (Figure 48-7) characterizes PPHN. This leads to right-to-left shunting of blood across the foramen ovale and ductus arteriosus, resulting in hypoxemia. Numerous disease states with diverse etiologies can result in a similar final pathophysiology. About 10% of cases with PPHN are idiopathic, with no associated pulmonary airspace pathology. However, PPHN is usually associated with other acute respiratory conditions, such as MAS, respiratory distress syndrome (RDS), pneumonia, or congenital diaphragmatic hernia (CDH) (Figure 48-8). Hypoxemia in these conditions can be due to ventilation/perfusion (V/Q) mismatch

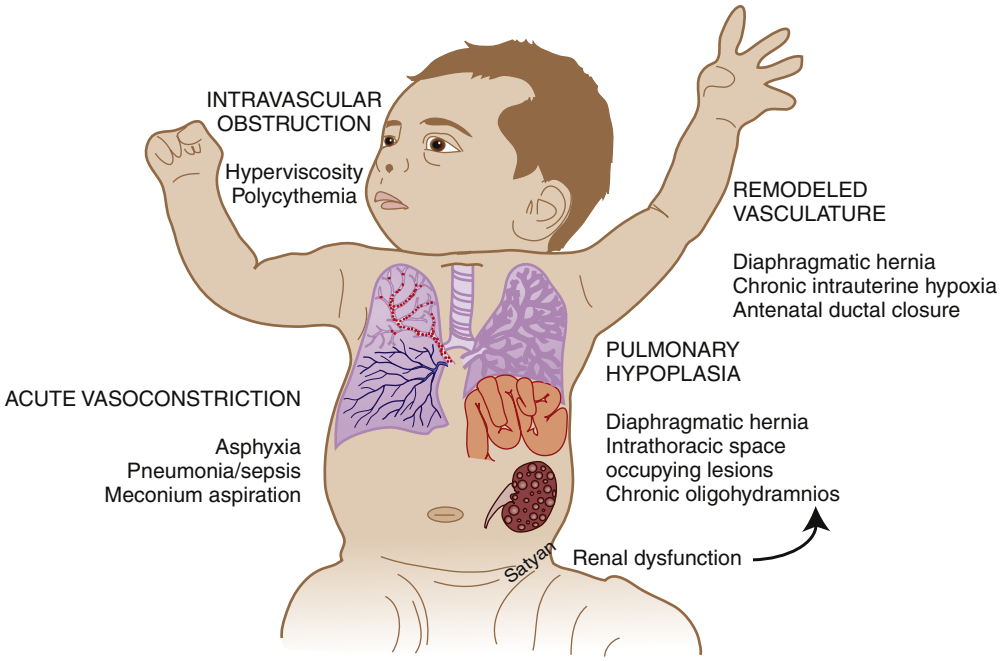

Figure 48–7. Mechanisms of persistent pulmonary hypertension of the newborn. *(Copyright Satyan Lakshminrusimha.)*

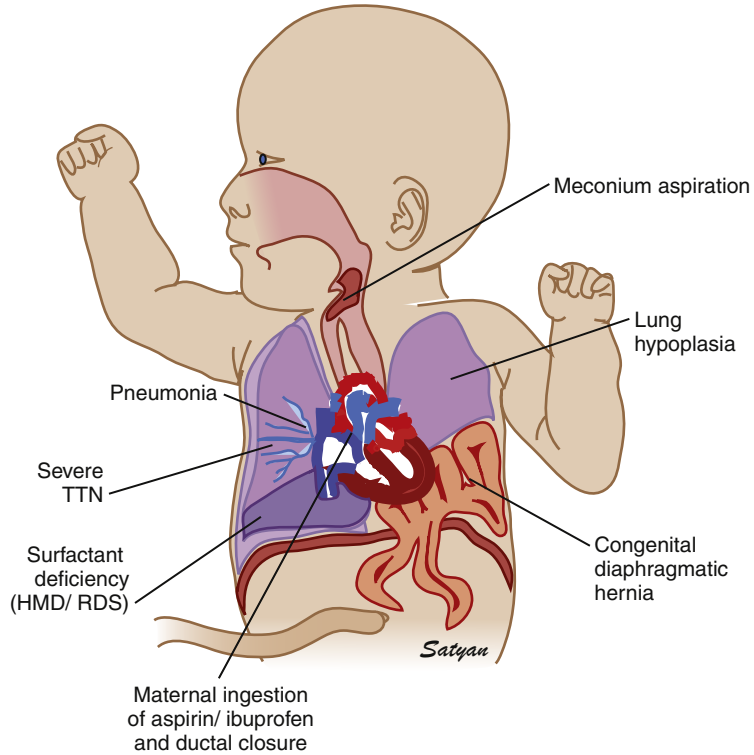

Figure 48–8. Clinically common conditions associated with persistent pulmonary hypertension of the newborn. *(Copyright Satyan Lakshminrusimha.)*

and intrapulmonary, as well as extrapulmonary, right-to-left shunting of blood. In some newborns with hypoxic respiratory failure, a single mechanism predominates (e.g., extrapulmonary right-to-left shunting in idiopathic PPHN). However, more commonly, several of these mechanisms contribute to hypoxemia. In MAS, obstruction of the airways by meconium results in decreasing V/Q ratios and increasing intrapulmonary right-to-left shunt. Other segments of the lungs may be overventilated relative to perfusion, causing increased physiologic dead space. The same patient also may have severe PPHN with extrapulmonary right-to-left shunting at the ductus arteriosus and foramen ovale. The PPHN in patients with MAS may result from the alveolar hypoxia, from inflammatory mediators, or from abnormal pulmonary vascular muscularization.

Pneumonia or meconium aspiration may release inflammatory mediators that induce vasoconstriction. Vasoconstrictors such as leukotrienes, platelet-activating factor, thromboxanes,[66] and ET-1[67] have been found to be elevated in patients with PPHN. Chronic intrauterine ET_A receptor blockade following ductal ligation decreases pulmonary arterial pressure in utero and decreases RV hypertrophy, and distal muscularization of small pulmonary arteries increases the fall in PVR at delivery in newborn lambs with PPHN.[39] Thus ET-1 acting through the ET_A receptor stimulation might contribute to the pathogenesis and pathophysiology of PPHN. Derangements in the NO pathway of vasodilation also can result in the physiologic characteristics of PPHN. Pulmonary endothelial nitric oxide synthase (eNOS) gene and protein expression and enzyme activity are decreased in fetal lambs with PPHN induced by antenatal ductal ligation.[68] In addition, the response to stimulators of eNOS is lost.[69] In these lambs with PPHN, the vascular response to NO itself is also diminished,[70] whereas the response to cGMP is normal. Thus the decreased responsiveness appears to result from decreased vascular smooth muscle sensitivity to NO at the level of soluble guanylate cyclase. The cGMP pathway of signal transduction is shown in Figure 48-4. Because NO both vasodilates and inhibits vascular smooth muscle growth, diminished eNOS expression may contribute to both abnormal vasoreactivity and excessive muscularization of pulmonary vessels in patients with PPHN.

PH sometimes occurs because of an abnormal pulmonary vascular bed despite the absence of alveolar hypoxia and hypercapnia and of lung inflammation. These infants can be grouped according to the degree of muscularization and the number of pulmonary arteries.[71] In infants with hypoplastic lungs, as in those with congenital heart disease (CHD) and oligohydramnios sequence, PPHN may arise primarily as a consequence of a decreased number of vessels causing a decreased cross-sectional area of the pulmonary vascular bed, leading to flow restriction (see Figure 48-7). Patients with alveolar capillary dysplasia may have a similar vascular hypoplasia. These cases may be complicated by increased muscularization of the vessels.

Antenatal exposure to NSAIDs such as aspirin and ibuprofen has been associated with PPHN.[50] More recently, an association between the use of selective serotonin reuptake inhibitor class of antidepressants after 20 weeks of gestation and PPHN has been found.[72,73] Prenatal exposure to fluoxetine (a selective serotonin reuptake inhibitor) induced fetal PH in rats.[74] The exact mechanism of this association is not clear. Polycythemia and hyperviscosity also may increase PVR and contribute to PPHN. Similarly, hypothermia, acidosis, and hypoxemia can aggravate PPHN.

Clinical Presentation

PPHN must be included in the differential diagnosis of hypoxic respiratory failure in term or near-term infants. Prenatal and perinatal history may provide clues to the etiology of PPHN. These clues include the presence of meconium, acidosis, and asphyxia at delivery, maternal risk factors for infection such as prolonged rupture of membranes, maternal fever, or positive group B streptococcus status. Maternal use of over-the-counter medications that contain PG synthesis inhibitors such as aspirin may be important. Postmaturity also appears to be a risk factor.

Labile hypoxemia is the hallmark of PPHN (Figure 48-9). A newborn infant who is extremely labile, with frequent desaturation episodes and wide swings in arterial Po_2 without changes in ventilator settings, should suggest the possibility of PPHN. Lability also can occur in the face of significant parenchymal disease when V/Q mismatch is severe. Auscultation of the heart in babies with PPHN may reveal a single S2, which can be loud, and a systolic murmur of tricuspid regurgitation. Chest radiograph findings may vary depending on the etiology of PPHN. Hypoxemia out of proportion to the degree of parenchymal disease severity on chest radiography should suggest PPHN. Measurement of preductal and postductal arterial oxygenation can confirm PPHN. A difference in arterial Po_2 20 mm Hg or greater or oxygen saturation 10% or greater should be considered significant. Minimal or no difference in oxygen tension does not exclude PPHN because shunting at the atrial level produces no ductal gradient and probably is the most common site of shunting. Thus in clinical practice, the gold standard in defining PPHN rests on the echocardiographic findings of right-to-left shunting of blood at the foramen ovale and/or the ductus arteriosus, as well as estimates of PAP. Doppler measurements of atrial and ductal level shunts provide essential information when managing a newborn with hypoxic respiratory failure.[75] For example, left-to-right shunting at the foramen ovale and ductus arteriosus with marked hypoxemia suggests predominant intrapulmonary shunting, and interventions should be directed at optimizing lung inflation. Similarly, presence of right-to-left shunting at the ductal level and left-to-right shunting at the atrial level suggests PPHN with left ventricular dysfunction with some pulmonary venous hypertension (see Table 48-1). This finding may be associated with CHD.[76]

Treatment

General Measures

Understanding the dynamic pathophysiology underlying right-to-left shunting is important to the successful management of PPHN. In patients with PPHN, even mild stress can cause Po_2 to plummet within minutes. Vigorous and persistent resuscitative measures are often necessary to promote pulmonary vasorelaxation. Accordingly, neonates and children with PPHN are often very sensitive to activity and agitation. Minimal stimulation and sedation with narcotics such as fentanyl and morphine are commonly used to achieve this goal. However, paralysis should be avoided because it is associated with

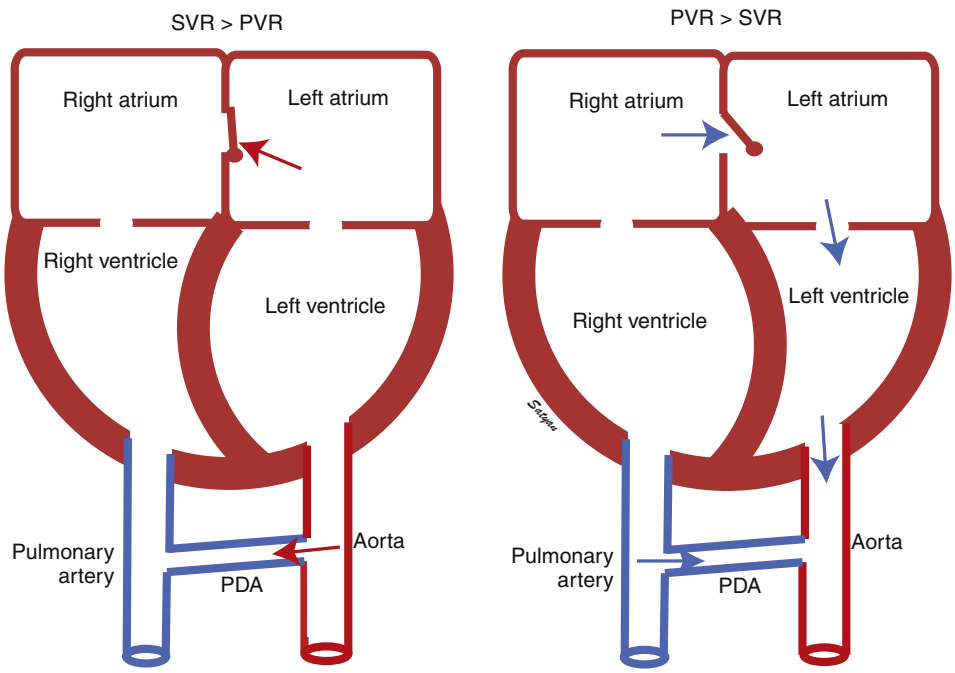

Figure 48–9. Physiology of labile oxygenation in persistent pulmonary hypertension of the newborn. When systemic vascular resistance (SVR) is higher than pulmonary vascular resistance (PVR), there is no right-to-left shunt. When PVR is close to or exceeds SVR, variable right-to-left shunt at foramen ovale and ductal levels results in labile hypoxemia. *(Copyright Satyan Lakshminrusimha.)*

increased mortality.[77] The lability in Pao_2 may result from the fact that when pulmonary and systemic arterial pressures are similar, small alterations in the ratio of the two can produce large changes in extrapulmonary shunting (see Figure 48-8).[78] Systemic blood pressures should be maintained at a high normal range for age and gestation, because an increased systemic resistance may decrease the degree of right-to-left shunting. Hypotension resulting from hypovolemia should be treated aggressively with volume replacement. If hypotension persists despite volume replacement, inotropic support with dopamine, dobutamine, and epinephrine may be required. All patients with PPHN benefit from a core group of therapies that includes management of hypothermia, hypocalcemia, acidosis, hypoglycemia, and polycythemia. In cases of PPHN resulting from perinatal asphyxia, correcting alveolar hypoxia, hypercarbia, and metabolic acidosis with administration of oxygen, conventional ventilation, and a buffer should restore normal pulmonary vasodilation. Surprisingly, few prospective randomized trials have been conducted of most of the therapeutic modalities advocated for the treatment of PPHN. Older therapies such as hyperventilation and alkalosis were introduced into clinical practice based on animal studies or short-term studies that included very small numbers of patients and used physiologic response rather than patient outcome as the end point. Only the newer therapies of inhaled nitric oxide (iNO) and extracorporeal membrane oxygenation (ECMO) have been rigorously evaluated in controlled clinical trials. In a National Institute of Child Health and Human Development (NICHD) observational study,[77] the use of hyperventilation varied among the 12 NICHD centers from 33% to 92%, and alkali infusion ranged from 27% to 93%. Similar variation was seen in the use of inotropic agents (46% to 100%) and intravenous vasodilators (13% to 81%). High-frequency ventilation (HFV) use ranged from 0% to 73%, and ECMO use varied

from 0% to 85%. Some of the variation is expected given the wide range of pathophysiology contributing to PPHN. A more likely explanation for the wide variation seen, however, is the overall lack of proven efficacy of many of these therapies.

Hyperventilation and Alkali Infusion

Animal studies documented the sensitivity of the pulmonary vasculature to both hypoxia and acidosis.[79] Short-term studies during cardiac catheterization showed reductions in PAP and elevation of oxygen tension following hyperventilation.[78,80] Based on these studies, hyperventilation became the mainstay of ventilation of term infants with hypoxic respiratory failure and PPHN. In some patients the benefits of hyperventilation may be outweighed by risks of barotrauma or volutrauma. Moreover, subsequent observations have raised concern of impaired cerebral perfusion and neurosensory deafness at extremes of alkalosis.[81,82] Studies of infants with PPHN maintaining normal Pco_2 (40 to 60 mm Hg) indicate similar or better outcomes and with less chronic lung disease.[83,84] Many neonatologists have moved away from the practice of hyperventilation in neonates with PPHN. Animal studies have shown that the beneficial effects of hyperventilation result from altered pH rather than from changes in Pco_2 or minute ventilation.[85,86] At one time alkali infusion to maintain alkaline pH to induce pulmonary vasodilation was a standard practice. In the aforementioned NICHD observational study, the group treated with alkali had a greater chance of treatment with ECMO compared with those treated with hyperventilation and an increased rate of supplemental oxygen at 28 days.[77] Alkali infusion with bicarbonate increases CO_2 production, necessitating higher ventilator support. Lack of patient outcome data with both hyperventilation and alkali infusion and availability of better therapeutic options have led to less use of these outdated management strategies.

Oxygen

Oxygen is a specific and potent pulmonary vasodilator, and increased oxygen tension is an important mediator of reduction in PVR at birth. Alveolar hypoxia and hypoxemia increase PVR and contribute to the pathophysiology of PPHN. Avoiding hypoxemia by mechanical ventilation with high concentrations of oxygen continues to be the mainstay of PPHN management. However, exposure to hyperoxia may result in formation of oxygen free radicals and lead to lung injury. Recent evidence suggests that brief exposure to 100% oxygen in newborn lambs results in increased contractility of pulmonary arteries[87] and reduces response to inhaled NO.[88,89] The biological half-life of endogenous NO is related to the local concentration of superoxide anions (see Figure 48-4).[90] Administration of intratracheal recombinant human superoxide dismutase (an antioxidant that breaks down superoxide anions) results in improved oxygenation in lambs with PPHN.[91,92] Based on these studies, it appears that avoiding hyperoxia is as important as avoiding hypoxia in the management of PPHN.

The optimal Pao_2 in the management of PPHN is not clear. Wung and colleagues[84] have suggested that gentle ventilation with avoidance of hyperoxia and hyperventilation results in good outcome in neonates with respiratory failure. Decreasing Pao_2 below 45 to 50 mm Hg results in increased PVR in newborn calves[79] and lambs.[89] In contrast, maintaining Pao_2 greater than 70 to 80 mm Hg does not result in additional decrease in PVR in both control lambs and lambs with PPHN. In animal studies, hypoxemia results in pulmonary vasoconstriction and normoxemia reduces PVR but hyperoxemia does not result in additional pulmonary vasodilation. However, to date, randomized studies comparing different Pao_2 targets have not been conducted in infants with PPHN.

Lung Recruitment Strategies

Surfactant. Clinical reports suggest that surfactant therapy improves oxygenation in term infants with RDS, pneumonia, and MAS.[93,94] Surfactant administration results in reduced need for ECMO in infants of 36 weeks or greater gestation at birth. Near-term and term infants delivered by elective repeat cesarean section may be one subset of patients who are at risk for deficiency or dysfunction of surfactant and progressive hypoxic respiratory failure.[95] If the cause of PPHN is parenchymal lung disease such as RDS, meconium aspiration or pneumonia, exogenous surfactant may be beneficial in improving oxygenation and reducing the need for ECMO.[94]

High-Frequency Ventilation. Many clinicians use HFV to manage infants with PPHN. Considering the important role of parenchymal lung disease in specific disorders resulting in PPHN, adequate lung inflation and optimal ventilation are as essential as pharmacologic vasodilator therapy. In the case of inhaled vasodilators, optimal inflation and ventilation may be necessary for drug delivery.[96] Infants with PPHN from a variety of causes have been successfully treated with HFV.[97] High-frequency oscillatory ventilation (HFOV) decreases $Paco_2$ and increases oxygenation in infants with PPHN. HFOV may improve oxygenation through safer use of higher mean airway pressures to maintain lung volume and prevent atelectasis. Two studies have evaluated the effectiveness of HFV compared with conventional ventilation in rescuing infants with respiratory failure and PPHN from potential ECMO therapy.[98,99] Neither mode of ventilation was more effective in preventing ECMO in these infants. In clinical pilot studies using iNO, combination of HFOV and iNO resulted in the greatest improvement in oxygenation in some newborns who had severe PPHN complicated by diffuse parenchymal lung disease and underinflation.[100] A randomized controlled trial demonstrated that treatment with HFOV and iNO was often successful in patients who failed to respond to HFOV or iNO alone in severe PPHN, and the differences in responses were related to the specific disease associated with PPHN. Infants with RDS and MAS benefit most from a combination of HFOV and iNO therapy.[101,102]

Nitric Oxide. In 1996 the Food and Drug Administration (FDA) approved iNO for use in neonates who are 35 weeks' gestation and older with PPHN. The physiologic rationale for using iNO for treatment of PPHN[103,104] is based on its ability to achieve potent and selective pulmonary vasodilation without decreasing systemic vascular tone (Figure 48-9). Once iNO enters the intravascular space, it combines with hemoglobin to form methemoglobin and does not exert a vasodilator effect on the systemic circulation. Inhaled NO also exerts a microselective effect and reduces V/Q mismatch. Being an inhaled vasodilator, NO enters only ventilated alveoli and redirects pulmonary blood by dilating adjacent pulmonary arterioles and reduces V/Q mismatch (Figure 48-10). Studies

in newborn lambs have shown that prolonged administration of NO increased survival rates without increasing the incidence of acute lung injury in lambs with PPHN.[105]

Three randomized trials on the use of iNO in newborns with PPHN and respiratory failure were published in 1997. In a randomized controlled clinical trial of patients with PPHN reported by Roberts and colleagues,[106] oxygenation doubled in 58% of treated patients in response to 80 ppm iNO. In addition, twice the proportion of the treated group avoided ECMO compared with the control group. In the Neonatal Inhaled Nitric Oxide Study, 235 infants older than 34 weeks' gestation who were diagnosed with hypoxic respiratory failure were randomly assigned to receive 20 ppm iNO or were assigned to a control group. Infants whose partial pressure of arterial oxygen increased by 20 mm Hg or less were studied for a response to 80 ppm iNO or control gas. The end point of this trial was death or ECMO. Although the mortality rate was no different in either treatment arm, there was a 40% reduction in the need for ECMO among infants treated with iNO compared with control subjects.[107] Only 6% of infants who failed to respond to treatment with 20 ppm of iNO responded to the higher dose in this study. In a study by Kinsella and colleagues,[102] 205 infants with PPHN were randomly assigned to receive iNO and conventional ventilation or to receive HFOV alone. Those who did not respond to either therapy received the combination of iNO and HFOV. Treatment with HFOV in combination with iNO was successful in some patients who did not respond to one treatment alone. The differences were partly related to the specific disease (RDS and MAS) associated with PPHN.[102] Because adequate lung inflation appears to be necessary for optimal response to iNO, lung recruitment strategies with HFOV should augment the response to iNO. Clark and colleagues[108] reported a 38% reduction in ECMO and no difference in mortality among 248 infants randomly assigned to receive 20 ppm iNO for 24 hours followed by 5 ppm for no more than 96 hours. A meta-analysis of the results of seven randomized trials of iNO use in newborns with PPHN demonstrated that 58% of hypoxic near-term and term infants responded to iNO within 30 to 60 minutes.[109] Mortality was not reduced in any of the NO studies analyzed, but use of ECMO as a rescue therapy in nonresponders was significantly decreased.

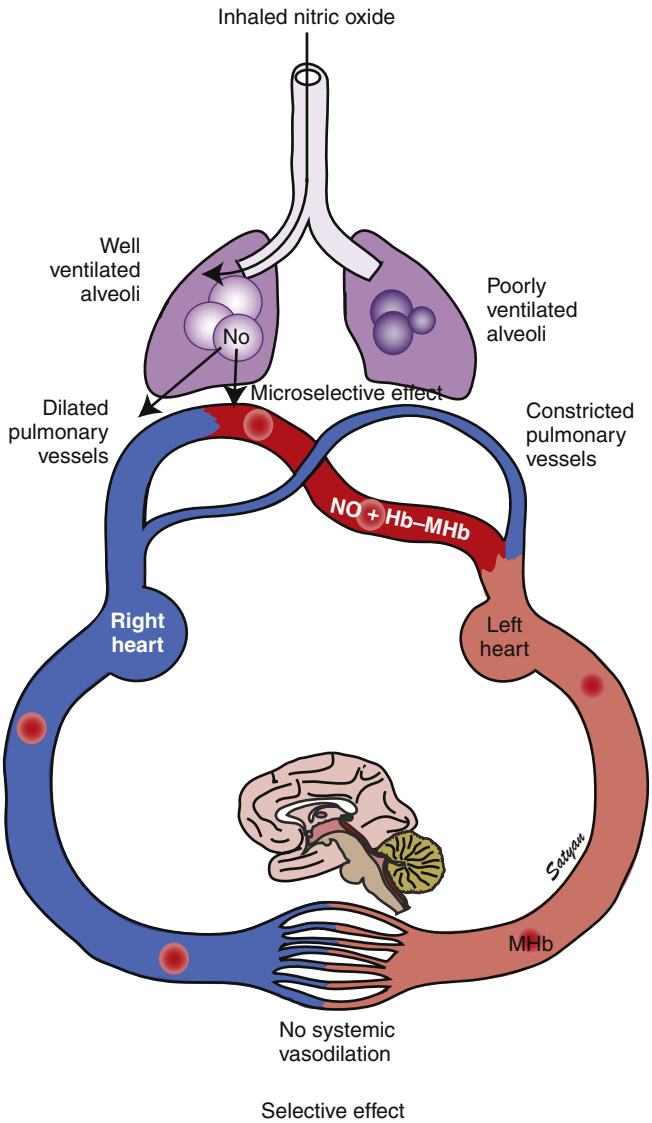

Figure 48–10. Selective and microselective action of inhaled nitric oxide (NO). Inhaled NO is a selective dilator of the pulmonary circulation without any significant systemic vasodilation because it combines with hemoglobin to form methemoglobin (MHb). Because it is an inhaled vasodilator, it selectively goes to the well-ventilated alveoli and improves blood flow to these alveoli and reduces ventilation/perfusion mismatch (microselective effect). *(Copyright Satyan Lakshminrusimha.)*

Inhaled NO by itself is toxic at higher concentrations. Potential adverse effects include methemoglobinemia, pulmonary edema, and platelet dysfunction. NO reacts with superoxide anion to form peroxynitrite, which causes lipid peroxidation and other oxidative injury to cell membranes. NO_2 is even more toxic. Careful monitoring of both NO and NO_2 levels during administration is mandatory. Because the optimal dosing and timing of iNO administration remains unclear and the potential toxicities are dose-related, lower doses might afford both safety and efficacy in the management of these infants. Two studies using 2 ppm iNO yielded contradictory results. In one study, 2 ppm iNO diminished the clinical response to 20 ppm.[110] In the other study, the initial exposure to a very low dose did not compromise the response to higher doses.[111] In a study involving direct measurements of PAP during cardiac catheterization, iNO produced peak improvement in oxygenation at 5 ppm, whereas peak improvement in the pulmonary-to-systemic arterial pressure ratio did not occur until an iNO dose of 20 ppm, which suggests that an initial dose of 20 ppm is optimum for the treatment of PPHN.[112] The use of higher doses of iNO is associated with increased methemoglobin levels, especially at 80 ppm but not at 40 or 20 ppm.[113] The results of randomized controlled trials support the use of iNO at starting does of 20 ppm in near-term and term infants. In summary, iNO offers substantial benefit to a large proportion of near-term and term newborns with hypoxic respiratory failure who do not respond to ventilatory support, lung recruitment, and oxygen.

The timing of initiation of iNO in patients with hypoxic respiratory failure is not clear. Severity of hypoxemia in neonates is measured by oxygenation index (OI = Mean airway pressure in cm of water × FIO_2 × 100/PaO_2 [in mm Hg]). An OI of 40 is often used as an indication for ECMO therapy. An OI of 25 is associated with a 50% risk of requiring ECMO or dying.[37] Thus the acceptable indication for treatment with

iNO include an OI greater than 25 with echocardiographic evidence of PPHN or a higher OI with or without evidence of right-to-left shunt. However, it has been suggested that initiating iNO at a lower OI may be associated with reduced need for ECMO.[114] Konduri and colleagues[115] randomly assigned neonates who were born at 34 weeks' gestation or later, required assisted ventilation, and had an OI of 15 or greater and less than 25 to receive early iNO or to receive simulated initiation of iNO (control). Infants who had an increase in OI to 25 or more were given iNO as standard therapy. Arterial oxygen tension increased by more than 20 mm Hg in 73% of infants who received early iNO (n = 150) and in 37% of infants in the control group (n = 149) after study gas initiation. Infants in the control group received standard iNO and deteriorated to an OI score greater tha 40 more often than did infants who were given early iNO. The incidence of death (early iNO group, 6.7% vs. control group, 9.4%), ECMO (10.7% vs. 12.1%), and their combined incidence (16.7% vs. 19.5%) were similar in both groups.[115] Follow-up evaluations showed no differences between the 2 groups in the incidence of neurodevelopmental impairment (early iNO group, 27%; control group, 25%) and hearing impairment (early iNO group, 23%; control group, 24%). Mental development index scores were similar in the two groups; however, psychomotor developmental index scores were significantly higher in the control group (early iNO group, 89 ± 17.7; control group, 93.5 ± 18.4).[116] These findings suggest that caution must be exercised while initiating iNO at lower OI levels.

Inhaled NO should be weaned gradually to avoid rebound PH.[117] A flow diagram showing the protocol for weaning iNO at The Women and Children's Hospital of Buffalo is shown in Figure 48-11.

The outcome of infants treated with iNO collectively supports both the efficacy and safety of this mode of treatment. Reports identify significant medical and neurodevelopmental sequelae of PPHN with or without iNO and point out the necessity for coordinated multidisciplinary follow-up for these infants. The overall rate of neurodevelopmental handicap in infants treated with NO was 46%, with 25% mildly affected and 21% severely affected at age 1 year in one study.[118] In another study, mild and severe neurodevelopmental handicaps were 14% and 12% at age 1 year and 9% and 12% at age

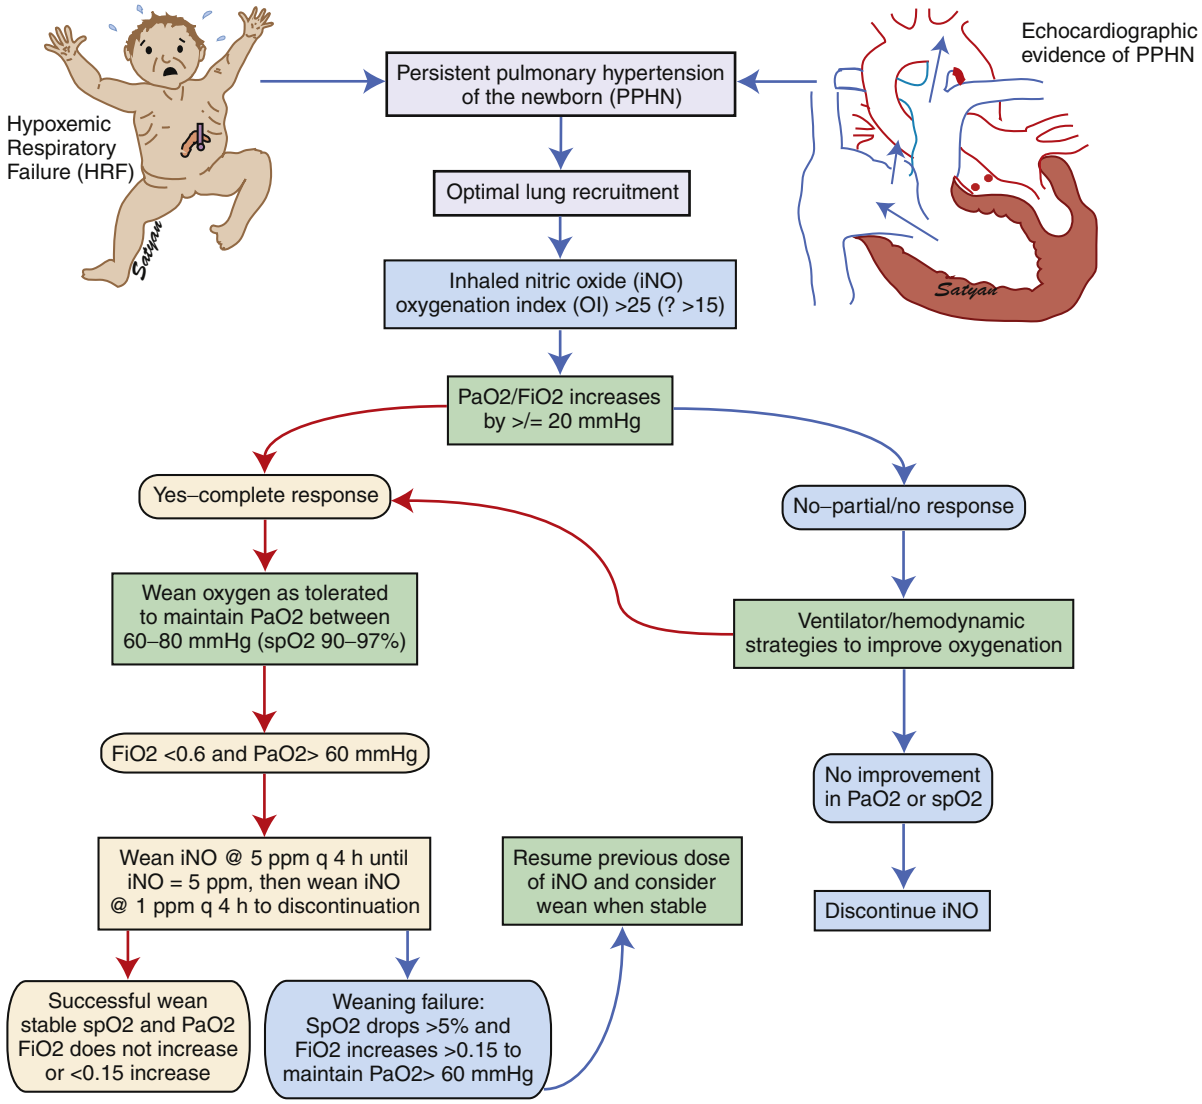

Figure 48–11. Weaning protocol for inhaled nitric oxide in use at The Women and Children's Hospital of Buffalo, NY.

2 years.[119] In these studies sensorineural hearing loss was present in 6% to 19% of infants with PPHN treated with iNO. No difference was noted between control and treatment groups for these outcomes. Published reports on the use of iNO in ECMO centers have not substantiated early concerns that iNO would adversely affect outcome by delaying ECMO utilization. Inhaled NO treatment may play an important role in stabilizing patients before ECMO is initiated, thus improving the chances of ECMO cannulation without further clinical deterioration. The Committee on the Fetus and Newborn of the American Academy of Pediatrics has suggested that iNO use be limited to tertiary care centers where ECMO is available.[120] In non-ECMO centers, a system should be in place to continue iNO during transport even if a response occurs, because not all physiologic responders avoid ECMO. For the same reason, the combination of HFOV and iNO should be used cautiously in non-ECMO centers.

Inhaled NO is contraindicated in the treatment of neonates known to be dependent on right-to-left shunting of blood (such as hypoplastic left heart syndrome). Also, patients with preexisting left ventricular dysfunction treated with iNO, even for short durations, have a high risk of pulmonary edema (package insert, INOmax, 2009).

Phosphodiesterase Inhibitors

Vasodilators such as NO and prostacyclin relax vascular smooth muscle by increasing intracellular concentrations of the second messengers cGMP (see Figure 48-4) and cAMP, respectively (see Figure 48-5). However, nearly 40% of patients with PPHN do not demonstrate a sustained improvement in oxygenation with this management. Because iNO is not universally effective, there has been considerable interest in understanding and targeting other biochemical pathways that regulate pulmonary vasoconstriction in PPHN. Inhibition of the cGMP degrading phosphodiesterase (PDE_5) by sildenafil and inhibition of the cAMP degrading phosphodiesterase (PDE_3) by milrinone offer additional tools to achieve pulmonary vasodilation in patients with PPHN. Two studies have evaluated the use of oral sildenafil in PPHN.[121,122] In centers lacking iNO therapy, oral sildenafil (dose range 1 to 3 mg/kg every 6 hours) has been shown to improve oxygenation and reduce mortality. A recent study showed that intravenous (IV) sildenafil was effective in improving oxygenation in patients with PPHN with and without prior exposure to iNO.[123] Systemic hypotension was the most common adverse effect. Administration of a loading dose slowly over 3 hours followed by a maintenance dose of sildenafil reduced the risk of systemic hypotension. These data suggest a beneficial effect for oral as well as IV sildenafil in patients with PPHN. Because oral or IV agents are not selective to pulmonary circulation, caution must be exercised about the risk of systemic hypotension with oral sildenafil. IV sildenafil is not available currently in the United States, but the same caution regarding systemic hypotension exists. The use of oral sildenafil for treatment of PH is approved by the FDA for adults but not for children.

Milrinone is the prototype PDE_3 inhibitor and is commonly used in adult and pediatric intensive care settings as an inotropic vasodilator. Agents that increase cAMP levels in pulmonary arterial smooth muscle cells (such as milrinone and prostacyclin) provide an alternate pathway of pulmonary vascular relaxation and potentially result in improved oxygenation in patients with poor response to iNO. In newborn lambs with PPHN, milrinone effectively relaxes pulmonary arteries[124] and improves oxygenation.[125] There is a marked increase in PDE_3 activity and reduced cAMP in pulmonary arteries following ventilation of lambs with iNO.[126] Milrinone can be effective in PPHN by inhibiting PDE_3 and increasing cAMP, causing direct pulmonary vasodilation and a synergistic effect with iNO. Milrinone may also improve cardiac function by positive inotropy (improved contraction), lusitropy (improved relaxation), and reduced ventricular afterload. Bassler and colleagues[127] and McNamara and associates[128] described 13 patients with PPHN refractory to iNO from Ontario, Canada, who were treated effectively with intravenous milrinone. This therapy is associated with a risk of hypotension and intraventricular hemorrhage and is not currently approved by the FDA.

Extracorporeal Membrane Oxygenation

If the heart and lungs cannot support the newborn, they can be bypassed with ECMO. Several randomized trials have indicated improved survival of infants supported with ECMO. In a large prospective trial conducted in the United Kingdom, 121 infants with severe respiratory failure were randomly assigned to ECMO or conventional management.[129] Survival in the patients treated with ECMO was significantly greater than in the control group (68% vs. 41%). Neurologic outcome was similar among survivors of either treatment arm, indicating that ECMO likely did not contribute to morbidity in this group of critically ill infants. ECMO has been shown to be both clinically[129] and economically[130] justifiable for mature newborn infants with severe respiratory failure. ECMO is not a specific treatment for any disease but rather a method of supportive treatment, in which the patient is kept alive while the lungs and their vasculature recover. As newer treatment modalities including HFOV, surfactant therapy, and NO have become available for treatment of hypoxemic respiratory failure, ECMO use in newborns has decreased considerably.[131,132] Because of serious inherent risks, such as systemic and intracranial hemorrhage, for infants with PPHN, the procedure presently is reserved for newborn infants with reversible pulmonary disease in whom alternative therapies have failed. However, ECMO should be initiated before the infant is moribund.

Considerable progress has been made in the last two decades in understanding the pathophysiology of PPHN and its management. While the need for ECMO for neonates with PPHN is decreasing, this syndrome continues to be associated with high mortality and morbidity, emphasizing the need for novel treatment strategies to improve outcome in PPHN. Vascular mediators such as phosphodiesterase inhibitors currently are being used experimentally in infants. Newer experimental therapies such as antioxidants, Rho-kinase inhibitors, L-citrulline, and inhaled prostacyclin analogs are under investigation.

Pulmonary Arterial Hypertension in Children

After the newborn period, pulmonary arterial hypertension (PAH) in children is an uncommon disease characterized by elevated PAP either at rest or during exercise. Progressive obliteration of the pulmonary vascular bed is the hallmark

of PAH. Primary pulmonary hypertension (PPH) is a rare disease in children that predominantly affects adolescents and young people in whom no apparent cause for PAH can be identified. In secondary PAH, a coexisting disease can be identified that presumably explains the PAH. As per World Health Organization (WHO) classification,[133] the term PAH refers to a disease spectrum with a similar clinical and pulmonary histopathology that includes PPH and PAH, which cannot be distinguished from PPH. This includes patients with PPH, both sporadic and familial, as well as pulmonary arterial hypertension associated with collagen vascular disorders, congenital systemic to pulmonary shunts, human immunodeficiency virus, CHD, portal hypertension, hemoglobinopathies, myeloproliferative disorders, and appetite suppressants (Box 48-1). Familial PAH often results from a mutation in the bone morphogenic protein receptor-2 and is inherited as an autosomal dominant disease with incomplete penetrance. These groups together comprise WHO Group I PAH. Other WHO categories include Group II, PH with left heart disease; Group III, associated with lung disease and/or hypoxemia; Group IV, PH due to chronic thrombotic and/or embolic disease; and Group V, miscellaneous cause of PAH. Despite recent advances leading to early recognition and new therapies, PAH remains a serious life-threatening condition. Most of the abnormalities in PAH have been linked to the recent advances in our understanding of smooth muscle cell physiology, endothelial and platelet dysfunction, vascular remodeling, and genetics to provide insight into its pathophysiology. It is important to establish an accurate diagnosis with respect to etiology of PAH because therapy may vary with etiology. For instance, thromboembolic disease is often amenable to surgery with excellent results from thromboendarterectomy. Similarly, secondary PAH may result from a left-sided heart lesion with pulmonary venous hypertension.

Box 48–1 Revised WHO Classification of PH

1. Pulmonary arterial hypertension (PAH)
   - 1.1. Idiopathic (IPAH)
   - 1.2. Familial (FPH)
   - 1.3. Associated with (APAH):
     - 1.3.1. Connective tissue disorder
     - 1.3.2. Congenital systemic-to-pulmonary shunts
     - 1.3.3. Portal hypertension
     - 1.3.4. HIV infection
     - 1.3.5. Drugs and toxins
     - 1.3.6. Other (thyroid disorders, glycogen storage disease, Gaucher's disease, hereditary hemorrhagic telangiectasia, hemoglobinopathies, chronic myeloproliferative disorders, splenectomy)
   - 1.4. Associated with significant venous or capillary involvement
     - 1.4.1. Pulmonary veno-occlusive disease (PVOD)
     - 1.4.2. Pulmonary capillary hemangiomatosis (PCH)
   - 1.5. Persistent pulmonary hypertension of the newborn
2. Pulmonary hypertension with left heart disease
   - 2.1. Left-sided atrial or ventricular heart disease
   - 2.2. Left-sided valvular heart disease
3. Pulmonary hypertension associated with lung diseases and/or hypoxemia
   - 3.1. Chronic obstructive pulmonary disease
   - 3.2. Interstitial lung disease
   - 3.3. Sleep disordered breathing
   - 3.4. Alveolar hyperventilation disorders
   - 3.5. Chronic exposure to high altitude
   - 3.6. Developmental abnormalities
4. Pulmonary hypertension due to chronic thrombotic and/or embolic disease (CTEPH)
   - 4.1. Thromboembolic obstruction of proximal pulmonary arteries
   - 4.2. Thromboembolic obstruction of distal pulmonary arteries
   - 4.3. Nonthrombotic pulmonary embolism (tumor, parasites, foreign material)
5. Miscellaneous (sarcoidosis, histiocytosis X, lymphangiomatosis, compression of pulmonary vessels (adenopathy, tumor, fibrosing mediastinitis)

Pathophysiology

PAH is a syndrome resulting from restricted flow through the pulmonary arterial circulation, which leads to pathologic increases in PVR and ultimately to right heart failure. The mechanisms responsible for the development of PAH are complex and incompletely understood. In persons with PPH, hyperreactive lung vessels in which various stimuli initiate vasoconstriction may explain the subsequent development of characteristic vascular lesions.[134] The vascular endothelium is regarded as an important source of locally active mediators that contribute to the control of vasomotor tone. The thromboxane/PGI_2 and NO/ET-1 system are two of the important balances that control pulmonary vasomotor tone. Endothelial injury/dysfunction may lead to vascular remodeling and progressively increasing vascular obstruction and loss of vascular luminal cross-section and obliteration (Figure 48-12). Risk factors that are associated with PPH include the use of anorexic drugs, family history of PH, infection with human immunodeficiency virus, cirrhosis, and the use of cocaine or intravenous drugs.[135]

ET-1 is a potent vasoconstrictor and stimulates pulmonary artery smooth muscle cell (PASMC) proliferation. Plasma levels of ET-1 are increased in patients with PAH and correlate with the severity of PAH and prognosis.[136] Of the two ET-1 receptors, ETa receptors, which are expressed mainly in the smooth muscle, mediate vasoconstriction and cell proliferation, whereas ETb receptors, which are expressed mainly in the endothelial cells, are important for clearance of ET-1, release of NO and PGI_2, and inhibition of endothelin-converting enzyme-1.[30,137] In experimental studies of hypoxia-induced[138] and monocrotaline-induced PH,[139] chronic ET receptor blockade lowered PAP and the incidence of vascular and pulmonary injury and improved NO-mediated pulmonary vasodilation. Studies with L-ω-nitroarginine methyl ester–induced PH suggest that ET-1 is linked to the dysfunction of the L-arginine/NO pathway[140] because ETa selective[141] but not combined ET blockade[142] improves endothelial function. Thus selective inhibition of ETa receptors improves the endothelial L-arginine/NO pathway that agrees with observations in humans.[143] ET-1 expression in pulmonary arteries is increased in patients with primary and secondary PH.[144,145] ET-1 increases at high altitudes in mountaineers and correlates

with pulmonary pressures and oxygen tension.[146] ET increases even more in mountaineers prone to high altitude pulmonary edema.[147] Increased local production[145] and elevated circulating levels of endothelin[148] have been demonstrated in patients with Eisenmenger syndrome,[149] PPH,[150] and in PAH associated with CHD.[151]

PGI_2 is a powerful vasodilator and an inhibitor of platelet aggregation, whereas TXA_2 is a vasoconstrictor and induces platelet aggregation leading to microvascular thrombus formation and hence vascular injury. Because TXA_2 and PGI_2 have opposing effects on platelet aggregation and pulmonary vascular smooth muscle, an imbalance in their biosynthesis could contribute to the progressive increase in PVR seen in older untreated patients with pulmonary hypertensive CHD.[152] Decreased urinary excretion of 2,3-dinor-6-keto prostaglandin $F_{1\alpha}$, a metabolite of PGI_2, occurs in patients with PPH.[153] In patients with PAH, the balance between these two molecules is shifted toward TXA_2,[153] favoring thrombosis, proliferation, and vasoconstriction. A decrease in expression of the enzyme PGI_2 synthase (PGI_2-S) in the lung may be an important manifestation of pulmonary endothelial dysfunction in patients with severe PH. PGI_2-S is decreased in small- and medium-sized pulmonary arteries, and the loss of expression of PGI_2-S may represent one of the phenotypic alterations present in the pulmonary endothelial cells in patients with severe PAH.[154] Pulmonary PGI_2-S overexpression in transgenic mice protects against development of hypoxic PH.[155] PGI_2-S may play a major role in modifying the pulmonary vascular response to injury. Intratracheal transfer of human PGI_2-S gene has been shown to augment pulmonary prostacyclin synthesis, ameliorate monocrotaline (MCT)-induced PH and improve survival in MCT rats.[156]

Potassium (K+) channels play an important part in smooth muscle cell electrophysiology, which has implications for the development of PAH. The inhibition of voltage-gated K+ (Kv) channels results in an accumulation of positively charged K+ ions within the cell, hence depolarizing the cell and activating the voltage-gated, L-type calcium channel.[157] Calcium then enters the cell, activating the contractile apparatus, leading to vasoconstriction, and possibly initiating cell proliferation. Acute hypoxia seems to initiate vasoconstriction in part by inhibiting the Kv channel in PASMC.[157] In humans with PPH, Kv1.5 messenger ribonucleic acid (mRNA) levels are reduced in PASMC.[158] This down-regulation of Kv1.5 is associated with inhibition of the K+ current, membrane depolarization, and elevation of cytosolic Ca++. Thus decreased expression or function of K+ channels in PASMC in patients with PPH could initiate and/or maintain pulmonary vasoconstriction and play a role in the pathogenesis of PPH.[158] The use of anorexic agents like aminorex, fenfluramine, and dexfenfluramine is associated with the development of PPH,[135] and these agents are thought to act by blocking the Kv channel.[159] Kv2.1 is inhibited by dexfenfluramine, a weight-loss drug that is associated with the development of PAH.[159] Anorexigen-induced Kv channel inhibition and membrane depolarization can contribute to pulmonary vasoconstriction.[160,161] Fenfluramine reduces the Kv1.5 mRNA levels by 50% in PASMC from normotensive patients,[162] suggesting that inhibited gene transcription and expression of Kv channels may play an important role in anorexigen-induced PAH.

Matrix metalloproteinases (MMP) and extracellular matrix are thought to be important in vascular remodeling and hence proliferation of SMCs. Endothelial abnormalities early in the course of PAH may permit extravasation of factors that stimulate SMC production of vascular serine elastase.[163,164] This results in the liberation of matrix-bound SMC mitogens, such as basic fibroblast growth factor, and enhances matrix degradation by activating other MMPs. The MMPs stimulate the production of mitogenic cofactor, tenascin, leading to phosphorylation of growth factor receptors and smooth muscle cell (SMC) proliferation. When MMPs are inhibited, tenascin levels fall, leading to apoptosis.[163] Direct inhibition of MMP-2 and serine elastases lead to complete regression of experimental PH in rats,[165] suggesting that they regulate vascular tone. MMP-2 and MMP-9 can activate platelets,[166] and intravascular MMP-2 can enhance the formation of vasoconstrictors and inhibit the action of endogenous vasodilators.[167]

A number of other less well-studied factors potentially are involved in the pathogenesis of PH. Abnormalities of the thrombomodulin/protein C anticoagulant system with a decrease in soluble thrombomodulin and an increase in fibrinolytic inhibitor plasminogen activator 1 have been noted in patients with PPH.[168] Whether hypercoagulability occurs in response to PAH or can actually initiate PAH is unclear, but it likely contributes to disease progression. Serotonin (5-hydroxytryptamine or 5-HT) and serotonin transporter (5-HTT) have been shown to promote development of hypoxic PH by stimulating PASMC growth.[169] 5-HTT activity may play a role in the pathogenesis of PASMC proliferation in PPH, and a 5-HTT polymorphism may confer susceptibility to PPH.[170] Mutations in the 2 genes in the transforming growth factor-β receptor pathway BMPR2 and activin-like kinase 1, have been implicated in the pathogenesis of familial PAH.[171,172] Many different BMPR2 mutations occur in familial PAH. These mutations, which lead to loss of function in the SMAD signaling pathway, are prevalent in familial PAH.[171] Activin-like kinase-1 mutations, detected in a group of patients with hereditary hemorrhagic telangiectasia and PAH,[172] are also thought to result in growth-promoting alterations of SMAD-dependent signaling.

Pulmonary Vascular Histopathology

PAH is a panvasculopathy predominantly affecting small pulmonary arteries and is characterized by a variety of arterial abnormalities, including intimal hyperplasia, medial hypertrophy, adventitial proliferation, thrombosis in situ, varying degrees of inflammation ,and plexiform arteriopathy (Figure 48-13). Heath-Edwards introduced the first comprehensive classification of PAH based on the histopathology of pulmonary vasculature[173] in children with CHD or idiopathic PH (Table 48-2). Grade I referred to changes seen in patients with CHD associated with PH from birth. Grades II to IV were classified as a result of raised PAP. Grades V and VI often overlap and represent advanced disease. Rabinovitch[174] introduced a morphometric classification system in 1978 by studying lung biopsies of 50 patients with CHD (Table 48-3). The presence and severity of pathologic lesions correlated with increased pulmonary blood flow (PBF), elevated PAP, and elevated PVR. The most familiar patterns of pulmonary vascular lesions begin with medial hypertrophy followed by cellular proliferation and concentric laminar intimal fibrosis. Eventually dilatated lesions, fibrinoid necrosis, and plexiform lesions develop, and the disease is referred as Eisenmenger syndrome.[175] The

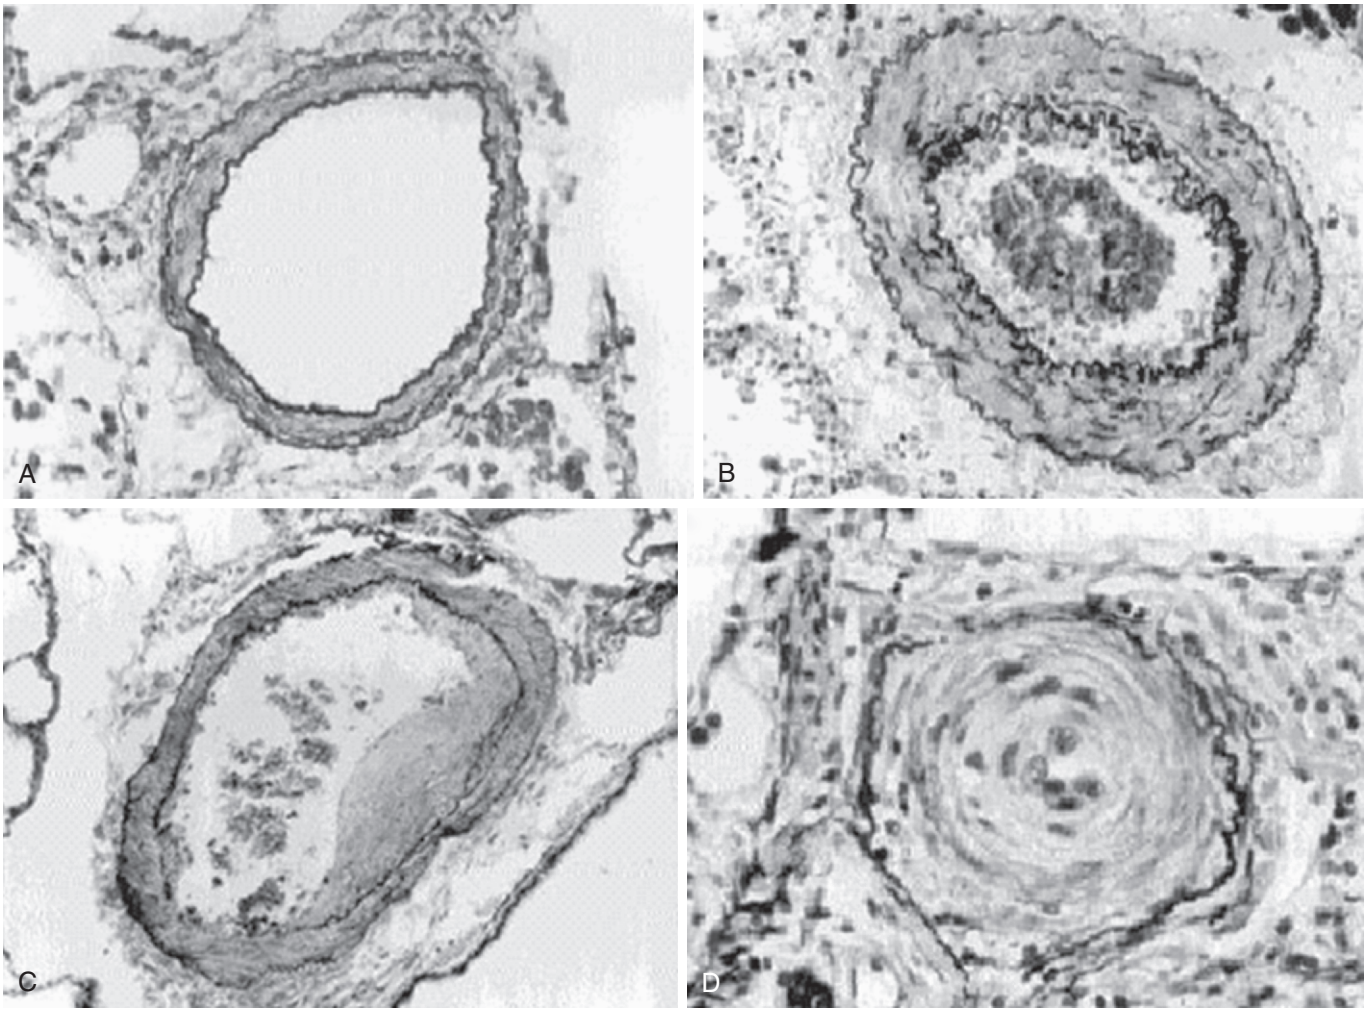

Figure 48–13. **A,** Normal small pulmonary artery with typically thin muscular wall. **B** through **D** show some of the changes that can occur in primary pulmonary hypertension. **B,** Wall or small pulmonary artery thickens. **C,** Fibrous or scarred tissue appears on inner wall of small pulmonary artery. **D,** Bands of scarred tissue build up on inner wall of small pulmonary artery, substantially narrowing the blood vessel.

Table 48–2 Heath-Edwards Classification of Pulmonary Vascular Disease

Grade	Pulmonary Vascular Pathology
I	Retention of fetal-type pulmonary vessels
II	Medial hypertrophy with cellular intimal proliferation
III	Medial hypertrophy; intimal fibrosis; early generalized vascular dilatation in severe instances
IV	Progressive generalized arterial dilation and occlusion by intimal fibrosis with the formation of complex dilation lesions (plexiform lesions)
V	Chronic dilation with formation of numerous dilation lesions including veinlike branches of hypertrophied arteries, cavernous and angiomatous lesions, and pulmonary hemosiderosis
VI	Necrotizing arteritis

Table 48–3 Morphometric Classification of Pulmonary Vascular Disease

Grading	Vascular Pathology
Grade A	Abnormal extension of smooth muscle along smaller peripheral arteries with intra-acinar extension (arteries accompanying respiratory bronchiole, alveolar duct and alveolar wall) (corresponds to Heath-Edwards grade I); associated with ↑ PBF without evidence of ↑ PAP
Grade B	In association with abnormal extension of the muscle, the medial muscular coat of the intra-acinar and preacinar arteries is thicker than normal (corresponds to Heath-Edwards grade I); when mild not associated with PAH; when more than twice normal is associated with PAH
Grade C	In association with abnormal extension and increased thickness of the muscular coat, the number of intra-acinar and preacinar arteries are reduced in number (high alveolar-arterial ratio); associated with moderate to severe elevation in PVR

PAH, Pulmonary arterial hypertension; *PAP,* pulmonary artery pressure; *PBF,* pulmonary blood flow; *PVR,* pulmonary vascular resistance.

progressive vascular lesions that occur in patients with PPH are identical to those that occur with CHD involving systemic to pulmonary shunts.[173] Based on these findings, similar therapeutic approaches have been used in children who have PPH and those who have PAH associated with CHD.

In patients with CHD, morphologic criteria[175] and pulmonary hemodynamics are both used to determine the stage beyond which surgical correction is no longer indicated because established disease will cause an unacceptable high operative risk or will continue to progress despite surgical repair.[176] Abnormalities in muscularization and growth of pulmonary arteries obtained at biopsy during surgical repair from patients with CHD correlated with preoperative hemodynamic data of increased pulmonary blood flow, pressure, and resistance.[175] Pulmonary vascular structural changes assessed by morphometry[175] (see Table 48-3) and Heath-Edwards classification[173] (see Table 48-2) in lung tissue obtained by biopsy at the time of surgical repair correlated with the postoperative hemodynamic findings of PAP and PVR measured 1 day and 1 year after surgery. One year after repair, mean PAP and PVR were normal in all patients whose conditions were surgically corrected before 9 months of age regardless of the severity of pulmonary vascular changes. PAP and PVR were increased in all patients whose conditions were repaired after 2 years of age with grade C morphometric findings and to a severe degree if associated with Heath-Edwards grade III. Thus although Heath-Edwards grade usually can be used to identify patients at risk for PH in the early postoperative period, both the morphometric and Heath-Edwards grades as well as age of the patient at the time of repair can be used to determine whether PAP and PVR eventually return to normal or remain elevated.

Congenital Heart Disease

Pulmonary vascular disease remains a significant cause of morbidity and mortality in children with CHD. Congenital heart lesions resulting in increased PBF or pulmonary venous obstruction produce pulmonary artery smooth muscle hypertrophy and hyperplasia and pulmonary vasoconstriction.[178] Unless PH is treated either by medical or surgical means, pulmonary vasoconstriction may persist, progress to vascular obliteration, and produce a high morbidity. Pulmonary hypertensive crisis in the immediate postoperative period is a life-threatening complication in children with certain types of CHD, despite a good surgical repair.[179] Even though early surgical repair has been advocated to prevent later pulmonary vascular obstructive disease, it does not abolish the occurrence of PH in the immediate postoperative period.[180] Microemboli, platelet aggregation, compliment activation, pulmonary leukosequestration, excess production of vasoactive mediators, atelectasis, and hypoxia during cardiopulmonary bypass all contribute to elevated PVR in the immediate postoperative period. The effects on the pulmonary vasculature may be insidious over several hours, presenting as low cardiac output and right heart failure or more acutely as pulmonary hypertensive crisis. In such situations, the PAP increases to systemic or suprasystemic levels, systemic blood pressure falls, and the arterial oxygen saturation drops. In one large center, half of the postoperative cardiac children who had pulmonary hypertensive crises died during their hospitalization.[181] In the newborn, parenchymal lung disorders including pulmonary edema, intrapulmonary shunting, and pneumonia may coexist with heart disease, resulting in hypoxic respiratory failure following cardiopulmonary bypass.

Pulmonary endothelial damage is an early histological event in children with CHD and pulmonary hypertension.[182] Reduced pulmonary vasodilation to acetylcholine demonstrates a physiologic impairment of endothelial function in these children.[183] Loss of local endothelial NOS activity may be one of the contributing factors in postoperative pulmonary hypertensive crisis. It has been suggested that cardiopulmonary bypass also may contribute to endothelial dysfunction. Arteries with endothelial damage are particularly sensitive to exogenous NO, and response to inhaled NO in the postoperative period suggests that the capacity for smooth muscle relaxation and pulmonary vasodilatation is intact in these children.[184] Even though NO-induced vasodilation varies among children with PH and elevated PVR, a decline in selective

response seems to parallel the progression of established vascular disease and thus may help in selecting patients to undergo surgery.[185] An increase in the number of ETa receptors in lung arteries and lung parenchyma has been noted in patients with increased PVR and low PBF.[186] Up-regulation of the ET-1 system may play a role in the pathogenesis of secondary PH associated with CHD in children.[186]

Clinical Presentation

Often no correlation exists between the time PPH is thought to have started, the age at which it is diagnosed, and the severity of symptoms. The disease seems to progress fairly rapidly, especially in children. Frequent tiredness, dyspnea, dizziness, and fainting spells are the typical early symptoms. Some of the other symptoms include edema of legs, cyanosis, palpitations, and chest pain. Exertional dyspnea, chest pain, and syncope result from the inability to increase cardiac output in the presence of increased oxygen demand. Examination findings compatible with PH in children include jugular venous distention, systolic murmur of tricuspid regurgitation, loud second heart sound at the base of the heart, and a diastolic murmur of pulmonary regurgitation (Graham Steel murmur). In patients with PAH and right heart failure hepatomegaly, ascites and peripheral edema may be seen. Initially the RV hypertrophies to maintain cardiac output at rest, although the ability to increase cardiac output during exercise may be impaired. As pulmonary vascular disease progresses, RV dysfunction ensues, resulting in right heart failure. Although the left side of the heart is not directly affected by pulmonary vascular disease, progressive right heart dilatation can impair left ventricular filling.[187] Depending on the degree of physical limitation by symptoms, the functional level of patients is graded from I to IV, with higher grades representing severe disease and worse prognosis. The New York Heart Association (NYHA) classification of dyspnea has been modified by the WHO to categorize PH by the severity of symptoms that, unlike PAP, correlate well with survival (Table 48-4).

Table 48–4 WHO Functional Classification for Pulmonary Hypertension (Modified After NYHA Classification)

WHO Class	Description
Class I	Patients with pulmonary hypertension but without resulting limitation of physical activity; ordinary physical activity does not cause undue dyspnea or fatigue, chest pain, or near syncope
Class II	Patients with pulmonary hypertension resulting in slight limitation of physical activity; they are comfortable at rest; ordinary physical activity causes undue dyspnea or fatigue, chest pain, or near syncope
Class III	Patients with pulmonary hypertension resulting in marked limitation of physical activity; they are comfortable at rest; less than ordinary activity causes undue dyspnea or fatigue, chest pain, or near syncope
Class IV	Patients with pulmonary hypertension with inability to carry out any physical activity without symptoms; these patients manifest signs of right heart failure; dyspnea and/or fatigue may be present even at rest; discomfort is increased by any physical activity

Diagnostic Approach

The diagnosis of PAH is made based on a clinical and a comprehensive diagnostic evaluation. Chest radiographs, pulmonary function tests, and sleep study will help in ruling out pulmonary causes of PH. Chest radiographs may demonstrate enlarged central pulmonary arteries, right heart enlargement, or evidence of a left-sided heart lesion. Etiologic clues of parenchymal lung disease or an airway lesion may be demonstrated. Pulmonary function tests and exercise testing are important not only for diagnosis but also for monitoring progression of the disease. Other tests that may help in the diagnosis include autoantibody testing for collagen vascular disorders, HIV testing, and liver function tests in cases of portopulmonary hypertension. An electrocardiogram will show right axis deviation and RV hypertrophy with strain. If PH is suspected based on history, risk factor assessment, and physical examination, an echocardiogram is the next appropriate study.

Doppler echocardiography may offer clues to the potential etiologies of PH, particularly left-sided heart lesions. RV systolic pressures greater than 35 to 40 mm Hg in a patient with unexplained dyspnea may warrant further evaluation of PAH. Common echocardiographic findings of PAH include right atrial and rRV enlargement, reduced RV function, tricuspid regurgitation, flattening of intraventricular septum, and underfilling of the left ventricle. In a clinical setting, findings of Doppler echocardiography suggest the diagnosis of PAH, but right heart catheterization (RHC) may eventually be required for an accurate assessment of PVR to confirm the diagnosis. Other noninvasive modalities such as computed tomography (CT) and/or magnetic resonance imaging (MRI) should be explored before subjecting the patient to a catheterization procedure. CT scanning may suggest an etiology of PAH such as a severe airway or parenchymal lung disease. Chronic thromboembolic pulmonary hypertension (CTEPH) is a form of PH and should be sought in all patients with clinically significant PH because it is curable with surgery. CT and V/Q scans help in the diagnosis of CTEPH. Presence of ground-glass opacities, particularly with a centrilobular distribution, septal lines, and adenopathy on a CT scan are suggestive of pulmonary venoocclusive disease in a patient displaying symptoms of PH.[188] Pulmonary venoocclusive disease is an unusual form of PH, characterized by elevated PAP with a normal pulmonary capillary wedge pressure and evidence of venous congestion on chest radiograph. Cardiac MRI accurately assesses size and function of the RV with a high degree of reproducibility and hence is used as a prognostication tool in the management of PAH.[189] Despite the aforementioned noninvasive investigations, catheterization may be needed to define the hemodynamic profile, to confirm the diagnosis of PAH, to perform vasoreactivity testing on confirmation of diagnosis, and most important, to begin a specific management plan for the treatment of PAH.

The current hemodynamic definition of PAH is a mean PAP greater than 25 mm Hg; a pulmonary capillary wedge pressure, left atrial pressure or left ventricular end-diastolic pressure of 15 mm Hg or less and a PVR greater than 3

Wood units.[190] Any patient with suspected PAH requires a careful invasive assessment of pulmonary hemodynamics. Many causes of elevated PA pressure (PH) are not caused by pulmonary vascular disease. Pulmonary hypertension commonly occurs with high transpulmonary flow states such as exercise, anemia, pregnancy, sepsis, portopulmonary syndrome, or thyrotoxicosis. In these states, the pulmonary vascular bed is anatomically normal and the PH resolves when the cardiac output returns to normal levels. The consensus document on PH requires elevated PVR as opposed to simply elevated mean PAP in the setting of a normal left heart filling pressures. PVR is a more robust diagnostic criterion for PAH because it reflects the influence of transpulmonary gradient and cardiac output and is only elevated if the vascular obstruction occurs within the precapillary pulmonary circulation. PVR is a useful measure to apply to patients with increased mean PAP. PVR distinguishes passive PH (i.e., elevated mean PAP and normal PVR) from PPH caused by pulmonary vascular disease (i.e., elevated mean PAP and elevated PVR). By definition, PVR and PAP are both elevated in PAH.[133]

All patients suspected of having PAH after noninvasive evaluation should undergo RHC prior to initiation of therapy specific to PAH. Although RHC and pulmonary angiography are invasive, they can be performed safely by experienced operators even in patients with severe PH and right heart failure. In a recent review of 7218 RHC procedures collected retrospectively and prospectively, 76 serious events (1.1%) were reported. Most of them were related to venous access (e.g., hematoma or pneumothorax), followed by arrhythmias and hypotensive episodes related to vagal reactions or pulmonary vasoreactivity testing with a overall procedure-related mortality of 0.05% (4/76).[191]

Acute Vasodilator Testing

Vasoreactivity testing in an essential component in the diagnostic evaluation of PAH, because this has therapeutic implications. Responders are more likely to respond to oral calcium channel blockers (CCB) than are nonresponders and seem to have a better prognosis.[192] Acute vasodilator testing (AVT) is usually performed during the same procedure as the diagnostic RHC. AVT is performed using iNO, intravenous PGI_2,[194] or intravenous adenosine.[195] Inhaled NO is the commonly used drug for AVT at doses of 20 to 40 ppm for 5 minutes. Hemodynamic measurements are recorded prior to and after administration of iNO, and the drug is discontinued completely. Based largely on the data from Sitbon and colleagues,[192] the European Society of Cardiology and American College of Chest Physicians guidelines propose that the acute response to vasodilator testing be defined as a decrease in mean PAP by at least 10 mm Hg to an absolute level of less than 40 mm Hg without a decrease in cardiac output.[196] While these criteria are insufficient to capture all patients who may be responsive to long-term CCB therapy, it will reliably identify those who are least likely to benefit from oral CCB therapy and therefore provide the greatest degree of safety.[133] Patients with PAH due to conditions other than idiopathic PAH, such as BMPR2 genotype or anorexigen-induced PAH, have a very low rate of long-term responsiveness to oral CCB therapy. Accordingly, the decision to proceed with AVT in such patients should be individualized. AVT is not indicated and may be harmful in patients with significantly elevated left heart filling pressures.[133]

Treatment

General Measures

Treatment of PAH has evolved considerably during the past decade, and treatment algorithms have been formulated by the American College of Chest Physicians for adult patients.[196] Unfortunately, because of limited data in children with PAH, management decisions often are extrapolated from adult studies. Without treatment, the natural history for children with idiopathic PAH is worse than that for adults; however, with treatment, the outcome appears better in children than in adults. In the absence of studies specifically reporting the clinical response of children to PAH therapy, similar clinical strategies have been suggested for the management of PAH in children. Treatment goals in children are similar to those in adults. They include improvements in patient symptoms such as dyspnea, enhancing exercise capacity measured objectively by an assessment of exercise endurance in older children (such as a 6-mile walk test), improving hemodynamic profile (lowering PAP), preventing the progression of the disease, and improving survival rates.

Treatment of PPH is usually treatment for life. The therapeutic regimen has to be tailored in a given child and adjusted according to the clinical and hemodynamic response. Optimizing the management in these children will improve the quality of life and survival. Most important is the avoidance and treatment of hypoxemia. Patients are advised to avoid heavy physical exercise because this may evoke exertional syncope. Exposure to high altitude may contribute to hypoxic pulmonary vasoconstriction and may not be well tolerated. Because hypoxemia is a potent pulmonary vasoconstrictor, most experts recommend supplemental oxygen to maintain oxygen saturation greater than 90%. A sodium-restricted diet is advised and is particularly important to manage volume status in patients with RV failure. Routine immunizations, such as against influenza and pneumococcal pneumonia, are advised. The hemodynamic fluctuations of pregnancy, labor, and delivery are potentially devastating to patients with PAH with a demonstrated maternal mortality of 30% to 50%.[197] Current guidelines recommend that pregnancy be avoided or terminated early in women with PAH.[196] It is important to discuss effective methods of birth control with women with PAH who have child-bearing potential, although the preferred method is not clear. It also is advisable to avoid elective major surgeries, especially during periods of progression or bad control of the disease. Conventional treatment of children with PPH consists of an anticoagulant and an oral vasodilator, usually a CCB and supplemental oxygen.[198] Anticoagulation with Warfarin has been shown to be beneficial in these patients.[199] In a more recent study, anticoagulant therapy had a positive influence on long-term survival and a significantly improved quality of life in patients with PPH, particularly in patients with a history of anorectic drug intake.[200]

Therapy in secondary PH is directed at the cause of PAH. Closure of the heart defect will resolve the PAH resulting from increased PBF. Management of pulmonary venous hypertension includes controlling left ventricular failure and relieving the cause of venous obstruction (commonly

left heart obstructive lesions). Medical management includes administering oxygen, diuretics, and digoxin. Vasodilator therapy is the mainstay in the management of pulmonary vascular obstruction. Even small reductions in RV afterload following vasodilator therapy will produce substantial improvement in RV output in patients with PH. The goal of vasodilator therapy in patients with PAH is to reduce PAP and increase cardiac output without symptomatic systemic hypotension. The response to vasodilators is important in making a decision for surgical correction (lung or heart/lung transplantation). Patients with severe intractable cases of left ventricular dysfunction may need heart transplantation.

Pulmonary Vasodilators

Calcium Channel Blockers. CCBs are the drugs most frequently used in the treatment of PH outside of the neonatal period. The response to CCBs is better in children than in adults with PPH. Acute response to the vasodilator drug during cardiac catheterization will help in determining the desirability of using chronic oral CCBs. A positive response to a vasodilator is taken as a decrease in mean PAP of 20% or more with no fall in cardiac index. Patients who meet criteria for oral CCBs should be followed closely for both safety and efficacy of CCB therapy. If the patient meets the definition of an acute response but does not improve to functional class I or II while receiving CCB therapy, the patient should not be considered a chronic responder and alternative PAH therapy should be considered. Long-acting nifedipine, diltiazem, or amlodipine are the most commonly used CCBs. Verapamil should be avoided because of its potentially negative inotropic effects. The response to acute vasodilator testing is higher in children compared with adults (41% vs. 12% in adults).[201] The acute response in children is also age dependent. Oral CCBs help in reducing PAP in about 40% of children with PPH.[202] In the remaining 60%, acute vasodilator testing with agents such as iNO or intravenous PGI_2 failed to demonstrate responsiveness, and these children have not benefited from chronic oral CCB therapy.[202] Chronic CCB therapy improved survival and quality of life in children who acutely respond to vasodilator drug testing.[203] A 5-year survival rate for patients treated with chronic oral CCB who respond acutely to vasodilator testing was 97%, versus 35% for those who do not respond acutely.[202] Chronic use of CCBs in patients with fixed PVR and unfavorable hemodynamics may worsen right heart failure. Regular, noninvasive monitoring of PAP and cardiac function is as essential part of the management of these patients.

Prostanoids. PGI_2 is reduced in patients with PAH, and administering PGI_2 or its analogues (prostanoids) has been the mainstay in the management of these patients. Currently three prostanoids are commercially available: epoprostenol, treprostinil, and iloprost.

Epoprostenol. Prostacyclin (sodium epoprostenol) has been studied extensively during the past decade in patients with PPH[201,202,204,205] and secondary pulmonary hypertension.[206] Chronic administration of prostacyclin is usually well tolerated with minimal decrease in systemic pressures and modest decrease in PAP. Higher doses can lead to high cardiac output states, suggesting that it has important positive inotropic effects.[204] In patients who are nonresponders to vasodilator testing and responders who fail to improve while taking CCBs, continuous intravenous infusion of PGI_2 improves survival.[202] Long-term, continuous IV administration of PGI_2 has been shown to improve survival, quality of life, and exercise capacity and to significantly reduce PAP in children with PPH.[202,207] Ongoing studies suggest that in some children who were previously believed to have fixed pulmonary vascular disease with irreversible obstruction, their condition may be reversible with long-term IV administration of prostacyclin, perhaps via remodeling of the pulmonary vascular bed.[202,208] Although in the late 1980s and early 1990s the aim of chronic prostacyclin therapy was to act as a bridge to lung or heart/lung transplantation,[209] continuous prostacyclin now is being used as an alternative therapy to transplantation in selected children.[201] Chronic PGI_2 infusion improves hemodynamics and quality of life in patients with PH associated with CHD for whom conventional therapy fails.[210] Continuous IV PGI_2 is the only one of the "specific" therapies currently approved for use in patients with chronic PH. However, drawbacks to this therapy exist. Tolerance develops in some patients, requiring dose escalation, which results in additional adverse events and increased drug costs. More importantly, complications are associated with administration of PGI_2, such as risk of serious infections, catheter thrombosis, and rebound PAH due to pump failure with subsequent interruptions in therapy. Given its considerable complexity, epoprostenol use should to limited to centers experienced with its administration and with systematic follow-up of patients.

Treprostinil. The propensity for serious catheter-related infections with epoprostenol administration led to the development of treprostinil, a stable prostacyclin analogue for subcutaneous infusion with a half-life of about 4 hours. Chronic subcutaneous infusion of treprostinil improved indices of dyspnea, signs and symptoms of PH, and hemodynamics and had an acceptable safety profile in patients with PAH.[211] Dosage used in this study was 1.25 ng/kg/min to 22.5 ng/kg/min via subcutaneous infusion with use of a micro infusion pump with a catheter placed in the subcutaneous tissue. The FDA approved subcutaneously administered treprostinil in 2002 for use in persons with functional class II, III, and IV PAH. More recently, IV treprostinil has been studied in an open-label, uncontrolled fashion. Even though the drug proved to be of benefit in the treatment of persons with PAH,[212] a Centers for Disease Control and Prevention report recently raised concern for an increased risk of bloodstream infections, particularly with gram-negative organisms, in patients receiving IV treprostinil.[213] Given the complexity of administration of both IV and subcutaneous treprostinil, administration should be limited to centers experienced with this agent.

Iloprost. Iloprost is a stable prostacyclin analog with a serum half-life of 20 to 25 minutes. Aerosolization of prostacyclin or its stable analog iloprost causes selective pulmonary vasodilatation, increases cardiac output, and improves venous and arterial oxygenation in patients with severe PH.[214] Thus it may offer a new strategy for treatment of this disease. Long-term treatment with aerosolized iloprost has been shown to be safe and has sustained effects on exercise capacity and pulmonary hemodynamics in patients with PPH.[215] In a placebo-controlled trial, iloprost inhalation (2.5 μg or 5 μg per inhalation; median dose of 30 μg per day) improved pulmonary hemodynamics and quality of life in patients

with severe PH.[216] Inhaled iloprost represents a significant advance from intravenous PGI_2 in the management of PAH. Aerosolized iloprost might be an alternative to iNO for early testing of vascular reactivity and for the postoperative treatment of acute PH in children with CHD.[217] Common adverse effects of inhaled iloprost include cough, headache, flushing, and jaw pain. Iloprost was approved by the FDA in 2004 for use in persons with functional class III and IV PAH. Its short half-life and frequent inhalations do not make it an ideal candidate for chronic treatment of PPH in children.

Beraprost. Beraprost is a prostacyclin analog for oral administration. It has been shown that beraprost reduces PVR in patients with PPH[218-220] and also may be effective in the treatment of secondary precapillary pulmonary hypertension.[221] Oral administration of beraprost sodium also may improve exercise capacity and ventilatory efficiency in patients with both primary and chronic thromboembolic pulmonary hypertension.[222] Limited studies suggest the efficacy of oral beraprost in infants and children with PH resulting from congenital heart defects.[223]

Endothelin Receptor Antagonists. ET-1 mediates vasoconstriction and smooth muscle cell proliferation contributing to the development of PAH. Its action is mediated mainly through the ET_A receptor. Both nonselective (ET_A and ET_B receptor) and selective (ET_A receptor) antagonists are being evaluated in animal and clinical studies.

Bosentan. Bosentan (Tracleer), an oral antagonist of both ET_A and ET_B receptors, is the most widely studied endothelin receptor antagonist in clinical trials. In a placebo-controlled randomized trial, bosentan increased exercise capacity and improved hemodynamics in patients with PH.[224] Patients given bosentan had a reduced Borg dyspnea index and an improved WHO functional class indicating exercise tolerance.[224] In another large double-blind, placebo-controlled multicenter study, bosentan given for 16 weeks was well tolerated, improved exercise tolerance, and increased time to clinical worsening.[225] Similar improvements in exercise capacity, symptoms, and clinical worsening were seen in the larger Bosentan Randomized Trial of Endothelin Antagonist Therapy of Pulmonary Hypertension study.[226] Bosentan was well tolerated at a dose of 125 mg twice daily in these adult patients. Studies in children of the physiologic and long-term effects of bosentan appear to be warranted. Potentially serious hepatotoxicity and teratogenicity has been reported with bosentan that requires close monitoring and cautious use. Because of the risk of hepatic toxicity, the FDA requires that liver function tests be performed at least monthly and hematocrit be checked every 3 months for these patients. There is concern that the endothelin antagonists as a class may be capable of causing testicular atrophy and male infertility. Younger males who may consider conceiving should be counseled regarding this possibility prior to taking these drugs.

Selective ETA Receptor Antagonists. Sitaxsentan and ambrisentan are the two commercially available selective ET_A receptor antagonists. In patients with PAH who were in NYHA functional class II, III or IV, sitaxsentan improved exercise capacity as assessed by the 6-mile walk test and improved functional class after 12 weeks of treatment.[227] The incidence of liver abnormalities was more favorable for the 100-mg dose group (0%) compared with placebo (3%) and the 300-mg group (10%). The Sitaxsentan to Relieve Impaired Exercise-2 study again demonstrated that the 100-mg dose of sitaxsentan improved exercise capacity as assessed by the 6-mile walk test and improved functional class compared with placebo. Although a 50-mg dose of sitaxsentan had a lower incidence of liver enzyme abnormalities, it was not different from the placebo group.[228] In a double-blind study, ambrisentan was evaluated at four dosages (1, 2.5, 5, or 10 mg) once daily for 12 weeks. Results of the 6-mile walk test improved over baseline with ambrisentan.[229] Two phase III clinical trials of ambrisentan in persons with PAH have been completed. These trials randomly assigned 202 and 192 patients with PAH, respectively, to placebo and ambrisentan. Doses of 5 and 10 mg of ambrisentan were compared with placebo in the Ambrisentan in Pulmonary Arterial Hypertension, Randomized, Double-blind, Efficacy Study (ARIES), and doses of 2.5 and 5 mg of ambrisentan were compared with placebo in ARIES-2.[230] After 12 weeks, improvements were noted in the primary end point of the 6-mile walk test in both the studies. Ambrisentan was approved by the FDA in 2007 for patients with PAH with functional class II and III symptoms. As a class, endothelin receptor antagonists have a potential for liver injury and teratogenicity. Monthly monitoring of liver function tests, a monthly pregnancy test in women of childbearing potential, and a periodic hemoglobin measurement are required. Precautions regarding contraception and testicular atrophy are similar to those for bosentan.

Nitric Oxide. The acute responsiveness to iNO seems to predict the subset of patients who might be responsive to oral CCBs and thus is a relatively safe and easy test to perform during cardiac catheterization.[231] Experience with long-term use of iNO in children with PAH is limited. Inhaled NO, however, is expensive and requires a fairly sophisticated delivery and monitoring system. Nonetheless, iNO dilates the pulmonary circulation while avoiding unwanted and dangerous systemic vasodilation and is economical and extremely effective in the management of PH in critically ill patients in intensive care units.[232] Inhaled NO has been used to assess the vasodilator capacity of the pulmonary vascular bed in children with CHD and elevated PVR.[184,233] Low-dose iNO (2 to 20 ppm) has been effective in the management of postoperative PH following corrective surgery in infants with CHD.[234] NO at higher doses (20 to 80 ppm) produced selective pulmonary vasodilatation in children with CHD and pulmonary hypertension.[235] Hemodynamic benefit with NO has been shown in newborns with total anomalous pulmonary venous connection and congenital mitral stenosis and in postoperative patients with preexisting left-to-right shunts and other lesions.[236] It can be used to help discriminate anatomic obstruction to pulmonary blood flow from pulmonary vasoconstriction, and it may be used in the treatment or prevention of pulmonary hypertensive crisis after cardiopulmonary bypass in neonates.[236,237] A trial of iNO may diminish the need for ECMO in patients with cardiopulmonary failure following cardiac surgery.[238,239] In children with PH and CHD, both iNO and aerosolized iloprost were equally effective in selectively lowering PVR.[217]

Phosphodiesterase Inhibitors

Type 5 phosphodiesterase (PDE-5) is primarily responsible for degradation of cGMP to inactive metabolite GMP. PDE-5 appears to be particularly abundant in pulmonary vessels.

One way of augmenting the concentration of cGMP in pulmonary vessels is by inhibiting the activity of PDE-5. PDE-5 inhibitors such as sildenafil and tadalafil might therefore be expected to prolong the vasodilating effects of cGMP. Sildenafil is a potent and selective inhibitor of cGMP-specific PDE-5[240] and has been shown to cause selective pulmonary vasodilatation in an ovine model of acute pulmonary hypertension.[241] Several agents that inhibit PDE-5 are shown to augment the response to NO.[242-245] Dipyridamole, a nonselective PDE-5 inhibitor, in combination with iNO, augments the decrease in PVR index and blunts the severity of acute hypoxic pulmonary vasoconstriction in children with PH.[246] When administered alone in children with PH, dipyridamole reduces the PVR index primarily through an increase in cardiac index.[246] In the Sildenafil Use in Pulmonary Arterial Hypertension study, 278 patients with PAH were randomly assigned to either placebo or sildenafil (20, 40, or 80 mg) orally 3 times daily for 12 weeks.[247] Results of the 6-mile walk test increased from baseline in all sildenafil groups. In all sildenafil groups, mean PAP was reduced and functional class improved. The incidence of clinical worsening did not differ significantly between the patients treated with sildenafil versus placebo. Long-term data in 222 patients (available for the 80-mg group) completing 1 year of treatment with sildenafil monotherapy showed sustained improvement from baseline at 1 year in the 6-mile walk test. The FDA-approved dose of sildenafil in patients with PAH is 20 mg administered three times daily for adults. Adverse effects include headache, flushing, dyspepsia, and epistaxis. The question of whether higher doses might confer additional hemodynamic benefit has generated considerable debate, and such doses continue to be studied in clinical trials. Another long-acting PDE-5 inhibitor, tadalafil, is currently undergoing clinical study. Like sildenafil, tadalafil has been approved by the FDA for erectile dysfunction. However, it continues to be investigated in patients with PAH.

Combination Therapy

Combining two agents may be clinically useful. As previously noted, agents that inhibit degradation of cGMP (PDE-5 inhibitors) may act synergistically with iNO. Similarly inhibiting PDE-3, a principal metabolizer of cAMP, might be expected to augment the response to PGI_2. Inhaled milrinone, either alone or in combination with inhaled PGI_2, selectively dilated the pulmonary vasculature without systemic effects in cardiac surgical patients with PH.[248] The goal of combination therapy is to maximize efficacy and to minimize toxicity. The safety and efficacy of combination therapy in persons with PAH is a subject of active investigation. In one recent study, inhaled Iloprost has been studied in patients who remained symptomatic (NYHA functional class III or IV) while undergoing stable bosentan therapy for at least 3 months.[249] After 12 weeks, the primary efficacy measure, a postinhalation 6-mile walk test, improved significantly in the Iloprost group compared with the placebo group. Improvements in mean PAP, functional class, and clinical worsening also were found. More recently sildenafil or placebo was evaluated in 267 patients with PAH who remained symptomatic while receiving a stable dose of epoprostenol for at least 3 months.[250] Patients treated with sildenafil experienced a placebo-adjusted improvement in the 6-mile walk test, mean PAP, and time to clinical worsening.

Pulmonary Thromboendarterectomy

Patients with suspected PAH should undergo evaluation for CTEPH. The screening tool of choice is the perfusion scanning. If indicative of CTEPH, pulmonary angiography should be performed. Patients are considered to be candidates for pulmonary thromboendarterectomy if they have surgically accessible disease and present an acceptable surgical risk. The surgery must be performed at a center experienced in performing this procedure with excellent technical skills and support systems in place.

Atrial Septostomy

Despite advances in medical treatment for PAH, many patients experience progressive functional decline, largely because of worsening right heart failure. Fortunately, it is uncommon to see patients in the pediatric age group in end-stage PAH compared with adults. In these patients, interventional and surgical options, including atrial septostomy and lung or combined heart and lung transplantation, should be considered. In patients with symptomatic cor-pulmonale secondary to pulmonary vascular disease, atrial septostomy can improve symptoms and may serve as a palliative bridge to heart and/or lung transplantation.[251,252] Several case series have reported hemodynamic and clinical improvement following atrial septostomy.[251,252] Improved cardiac output appears to be the principal hemodynamic benefit. Improvements in NYHA functional class and the 6-mile walk test also have been reported.[253] The success rates for bridging patients to transplantation, with septostomy, ranges from 30% to 40%.[251,252] The procedural mortality rate is high, however, with an estimate of 15% based on published series. Currently, atrial septostomy is recommended for patients with severe PAH and intractable right heart failure despite maximal medical therapy, including optimized PAH-specific agents and inotropes. The goals of the procedure are palliation and restoration and maintenance of clinical stability until a transplant can be performed.

Lung and Combined Heart/Lung Transplantation

Before PGI_2 became available as the long-term therapy, lung transplantation was the only option for survival for patients with severe PH. Single-lung, double-lung, and heart-lung transplantation have all been advocated as the operation of choice in persons with PPH. Transplantation is offered after maximal therapeutic effort with vasodilators and oxygen has been attempted and when the estimated 2-year survival is less than 50%.[254] Most centers now perform bilateral lung or heart-bilateral lung transplantation for persons with PPH. Intravenous PGI_2 has been used as a bridge to stabilize the patient until transplantation is accomplished. Of the 70 lung transplants performed in 1997, PH accounted for 7% of infants and 18% of older children requiring transplantation.[255] Survival rates have improved considerably in the 1990s, suggesting both technical improvements and earlier referral for transplantation. Recent data from the International Society for Heart and Lung Transplantation (January 1998 to December 2001) indicate an overall survival following lung transplant of 70% to 80% at 1 year and 50% at 3 years in children younger than17 years. Survival in all patients with PPH following lung transplant was 72% at 1 year and 58% at 3 years. In a single-center study, survival following heart-lung

transplant in patients with PPH was 72% at 1 year, 67% at 2 years, and 42% at 5 years.[256] Because outcomes for infants listed for lung or heart/lung transplantation is similar to that of children, very young age should not be considered a contraindication to lung or heart/lung transplantation.[257] Earlier diagnosis and listing may decrease pretransplant mortality.[257] Even though the early outcome following lung transplantation has improved considerably, long-term complications, including infections, bronchiolitis obliterans, and complications of immunosupression remain significant problems.[258] Aggressive medical therapy combined with early recognition of lung transplant candidates will improve quality of life and overall survival of these children.

Prognosis and Survival in Pulmonary Arterial Hypertension

Most of the studies have been focusing on short time end points, such as 12 weeks' duration or the 6-mile walk test, and long-term follow-up guidelines for these patients is lacking. Figure 48-14 summarizes the treatment algorithm of PAH with an emphasis on initial diagnosis and initial management of these patients from the expert consensus document for PH.[133] Although therapies to manage PAH are evolving rapidly, long-term experience with epoprostenol has suggested the importance of early follow-up, because patients who remain in NYHA functional class III or IV despite therapy have poor outcomes and should be considered for a lung transplant.[259]

Some of the earlier studies found that NYHA functional class, 6-mile walk, and hemodynamic variables were all related to prognosis and survival. All of these parameters were studied as primary end points in many prospective trials. The National Institutes of Health cohort study showed that among 194 patients who received a diagnosis of idiopathic PAH, the risk of death was higher among patients in NYHA functional class III or IV than among those in functional class I or II. Median survival among patients presenting with NYHA functional class I or II symptoms was nearly 6 years versus 2.5 years for functional class III and 6 months for functional class IV symptoms.[260] Other studies have confirmed the importance of functional class as a prognostic variable, even during treatment.[261] Patients who improved to functional class I or II with epoprostenol had a better prognosis than did patients who remained in functional class III or IV.[261]

In the pivotal epoprostenol idiopathic PAH trial, performance in the 6-mile walk test was found to be an independent predictor of survival, leading to use of this test as the primary end point in many trials.[262] All large published evaluations implicate hemodynamics as an important predictor of survival.[259,261] In the National Institutes of Health registry, three hemodynamic variables that were associated with an increased risk of death included increased mean PAP (>55 mm Hg), increased right atrial pressure (>12 mm Hg), and decreased cardiac index (<2.0 L/min/m^2).[260] Similarly, responders to vasodilator testing have an excellent prognosis with up to a 95% survival at 5 years.[192] In a recent single-center study of 65 children with PAH, the 5-, 10- and 15-year survival rates were 96%, 92%, and 65%, respectively, and no significant correlation between outcome and immediate response to the vasodilators was found.[263]

While echocardiography has been a pivotal screening test, studies evaluating the prognostic value of echocardiography have been limited to relatively small series. The presence of any degree of pericardial effusion has been proven to be a consistent predictor of mortality.[264] More recently, tricuspid annular plane systolic excursion on echocardiography has been shown to be a robust measure of RV function and a powerful predictor of patient survival among those with PH.[265] Tricuspid annular plane systolic excursion of less than 1.8 identifies patients with more advanced RV dysfunction in patients with PH. In addition, these patients had reduced survival over a median follow-up of 19 months. Cardiac MRI

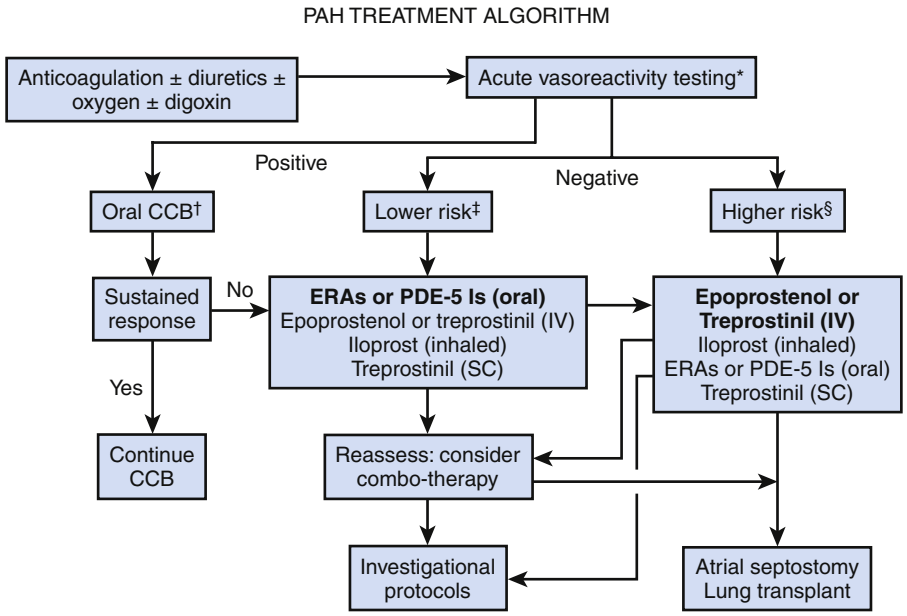

Figure 48–14. Treatment algorithm for pulmonary arterial hypertension. *(From McLaughlin VV, et al: Expert Consensus Document on Pulmonary Hypertension, J Am Coll Cardiol 53(17):1573-1619, 2009; adapted with permission from Elsevier.)*

accurately assesses size and function of the RV with a high degree of reproducibility. RV function is an important prognostic indicator in persons with PAH, and MRI of poor RV function was found to be an independent predictor of mortality and treatment failure.[189] Cardiac MRI holds promise as a noninvasive tool to assess for evidence of RV response and remodeling with treatment. Brain natriuretic peptide and NT-proBNP appear to be significantly elevated and are independent predictors of poor prognosis.[266]

Assessing safety and efficacy of therapy in young pediatric patients is problematic, and even in older children assessment of exercise capacity is difficult. In addition, because of the biologic variability and the progressive nature of the disease in children, making longer-term observations regarding therapy is problematic. All of these factors make clinical investigations in children more difficult, but the potential rewards for having a significant impact on overall quality of life as well as long-term survival far outweigh the hurdles in developing newer management options for children.

Mechanical Ventilation and Respiratory Care

Shekhar T. Venkataraman

PEARLS

- Modern pediatric respiratory care requires a major institutional commitment in resource allocation for the state-of-the-art management of the patient undergoing mechanical ventilation.
- A team approach among the physician, the nurse, the respiratory therapist, and the family is required, in which the role and responsibilities of each of the team members is clearly defined and respected.
- Everyone is equally important for the care of the patient undergoing mechanical ventilation. Physician's medical expertise is of no value in the absence of appropriate nursing care and respiratory therapy.
- As new technologies are developed, every team member must become familiar with them so that they can be applied safely and effectively.
- Family involvement is crucial to provide emotional and psychological support to the child.

Vesalius, in 1555, was one of the first to suggest that artificial respiration in humans is possible by blowing air through a tube of reed or cane positioned in the trachea.[1] Positive pressure ventilation was first used in conjunction with general anesthesia in the 1920s.[2] Outside the operating room environment, mechanical ventilation during the 1920s was provided by negative pressure methods.[3] The utility of prolonged artificial respiration was first proven in the management of polio victims, where it was primarily used to maintain breathing until patients could recover their muscle strength.[4] Since then, tremendous advances have been made not only in the design and sophistication of mechanical ventilators, but also in the application of artificial respiration in its varied modes for a variety of illnesses and indications. This chapter will review the following: (1) applied physiology of breathing, (2) a conceptual framework for the design and function of mechanical ventilators, (3) a modern classification to understand the modes of mechanical ventilation, (4) practice parameters for mechanical ventilator support based on the pathophysiology, (5) philosophy and the practice of weaning, (6) the theory and practice of adjunctive respiratory care, (7) the theory and practice of high frequency ventilation, and (8) home respiratory care. The topic of noninvasive mechanical ventilation is covered elsewhere (Chapter 50).

Applied Respiratory Physiology

Lung Volumes and Capacities

Air gets in, air gets out; oxygen is taken up, carbon dioxide is eliminated; this is the essence of breathing, spontaneous or otherwise. Tidal volume is the volume of gas that is moved in and out of the lungs per breath. The normal tidal volume is 6 to 8 mL/kg, regardless of age. Total lung capacity (TLC) is the volume of gas present in the lung with maximal inflation. The normal range for TLC is 60 to 80 mL/kg. Vital capacity is the volume of gas that can be maximally expired from TLC. The normal vital capacity is about 30 to 40 mL/kg in infants and 45 to 55 mL/kg in adults. Functional residual capacity (FRC) is the volume of gas that is present in the lung at the end of expiration. FRC results from the balance between forces that favor alveolar collapse and maintain alveolar inflation. The normal FRC is about 30 mL/kg. Residual volume is the volume of gas present in the lung at the end of a maximal expiratory effort and cannot be expelled from the lung. Closing capacity (CC) refers to the volume of gas present in the lung at which small conducting airways begin to collapse. When FRC exceeds CC, the small airways and the alveoli remain open because the lung volume remains above CC. On the other hand, when CC exceeds FRC, the small airways and alveoli tend to collapse. In children older than 6 years, FRC exceeds CC. In infants and in children younger than 6 years, CC exceeds FRC. This explains the propensity for atelectasis in infants and young children.

Physiology of Inflation and Deflation

Thoracic structures impede lung inflation. Therefore a certain amount of force is required to overcome this impedance. One of the major determinants of impedance to lung inflation is elasticity of the lung and chest wall. Compliance, a measure of elasticity, is defined as the change in volume per unit change in transmural pressure. Lung compliance is defined as the change in lung volume for a unit change in transalveolar pressure (alveolar pressure minus the pleural pressure). Chest compliance is the change in thoracic cage volume produced by a unit change in transthoracic pressure (ambient pressure minus the pleural pressure). Specific lung compliance refers to

Box 49–1 Factors Associated with Decreased Total Respiratory Compliance

Decreased Lung Compliance
Surfactant deficiency or alteration
Respiratory distress of the newborn
Adult respiratory distress syndrome
Interstitial inflammation
Diffuse pneumonitis
Fibrosis
Pulmonary edema
Alveolar edema
Interstitial edema
Hyperinflation
Airway obstruction-both upper and lower
Excessive CPAP/PEEP or auto-PEEP
Atelectasis

Decreased Chest Compliance
Restrictive pleural disease
Pleural collection of air or fluid
Fibrosis
Increased intercostal muscle tone
Upper motor neuron disease
Drugs
Restrictive chest diseases
Deformations: kyphosis, scoliosis, or both
Ankylosis
Restrictive bandages

Diaphragmatic Restriction
Abdominal distension
Abdominal binding
Increased abdominal pressure: peritoneal dialysis, post-laparotomy, etc.

CPAP-PEEP, Continuous positive airway pressure-pulmonary end-expiratory pressure.

lung compliance that is normalized to the lung volume or body weight and is similar in children and adults. Disease processes that result in an abnormal lung or chest wall compliance are given in Box 49-1. The second major determinant of impedance to lung inflation is airway resistance. Airway resistance is defined as the change in transpulmonary pressure (proximal airway pressure minus the alveolar pressure) required to produce a unit flow of gas through the airways of the lung. In the infant, the airway resistance is equally distributed between the upper and lower airways. With increasing age, most of the airway resistance resides in the upper airways. Two additional factors impede inflation. One is inertia of the respiratory gas, or inertance.[5] The other is the frictional resistance to deformation of the lungs, thoracic cage, and abdominal contents.[5] Frictional resistance is also known as the *nonelastic viscous resistance*. Therefore, taking into consideration all the forces that impede lung inflation, the total pressure (Ptp) required to inflate the lung can be mathematically expressed as follow,s termed the *equation of motion*:

$$P_{tp} = P_{Compliance} + P_{resistance} + P_{Inertance} + P_{Frictional\ resistance}$$

where $P_{Compliance}$ is the pressure required to overcome the compliance of the respiratory system, $P_{resistance}$ is the pressure required to overcome the resistance of the airways, $P_{Inertance}$ is the pressure required to overcome inertance, and $P_{Frictional\ resistance}$ is the pressure required to overcome the frictional or tissue resistance to deformation of the lungs, thoracic cage, and abdominal contents.

$$P_{Compliance} = Volume / Compliance \text{ or } Volume \times Elastance$$

where *Elastance* is the reciprocal of compliance.

$$I.\ P_{resistance} + P_{Frictional\ resistance} = Total\ respiratory\ resistance \times Flow$$

Normally, $P_{Inertance} + P_{Frictional\ resistance}$ is negligible. In certain pathologic conditions, such as pulmonary edema, interstitial lung disease, and pulmonary fibrosis, frictional resistance may be increased. Therefore with the effect of inertance neglected, a simplified equation of motion can be expressed as follows:

$$Ptp = (Volume / Compliance) + (Total\ Resistance \times Flow)$$
$$\text{or } (Volume \times Elastance) + (Total\ Resistance \times Flow)$$

It takes a finite amount of time to inflate the lung with a given volume of gas. This factor is directly proportional to the compliance and the resistance. Time constant is the product of compliance and resistance, and it defines the time taken to cause a given change in lung volume with a constant distending pressure. The rate of inflation and deflation of the lung is normally exponential; one time constant is the time taken to cause a 63% change in volume, and three time constants is the time taken to cause a 95% change in volume.[5] Normal expiration is passive because of the elastic recoil of the lung. Elastic recoil of the lung is attributable to alveolar surface tension and tissue elasticity. Surface tension is greatest at high lung volumes, and lowest at FRC. Elastic recoil of the lung provides most of the force required to expel the gas from the lungs. Again, the time taken to expel a certain tidal volume depends on the time constant of the respiratory system. Because inspiratory and expiratory resistances are different, inspiratory and expiratory time constants may be different.

Work of Breathing

During normal tidal breathing, the work of breathing is performed entirely by the inspiratory muscles (Figure 49-1), and almost all of the work is performed during inspiration. Nearly half of the work of breathing during inspiration is dissipated as heat to overcome frictional resistance to deformation.[5] The remaining inspiratory work is stored as potential energy that is used to perform the expiratory work. Increased airway resistance and decreased chest and lung compliances would require a greater Ptp to inflate the lung to the same lung volume. This imposes a greater workload on the respiratory muscles and increases the oxygen cost of breathing. When the oxygen supply/demand balance to the respiratory muscles is perturbed, respiratory failure may ensue because of muscle fatigue.

Determinants of Gas Exchange

The determinants of systemic arterial oxygenation are inspired oxygen concentration and tension, lung volume, cardiac output, ventilation/perfusion (V/Q) matching, and the magnitude of venous admixture or intrapulmonary shunting. Lung volumes are increased during inspiration and fall during expiration. During expiration, the presence of alveolar surfactant prevents alveolar collapse. A critical opening pressure is required to maintain both the patency of the terminal airways

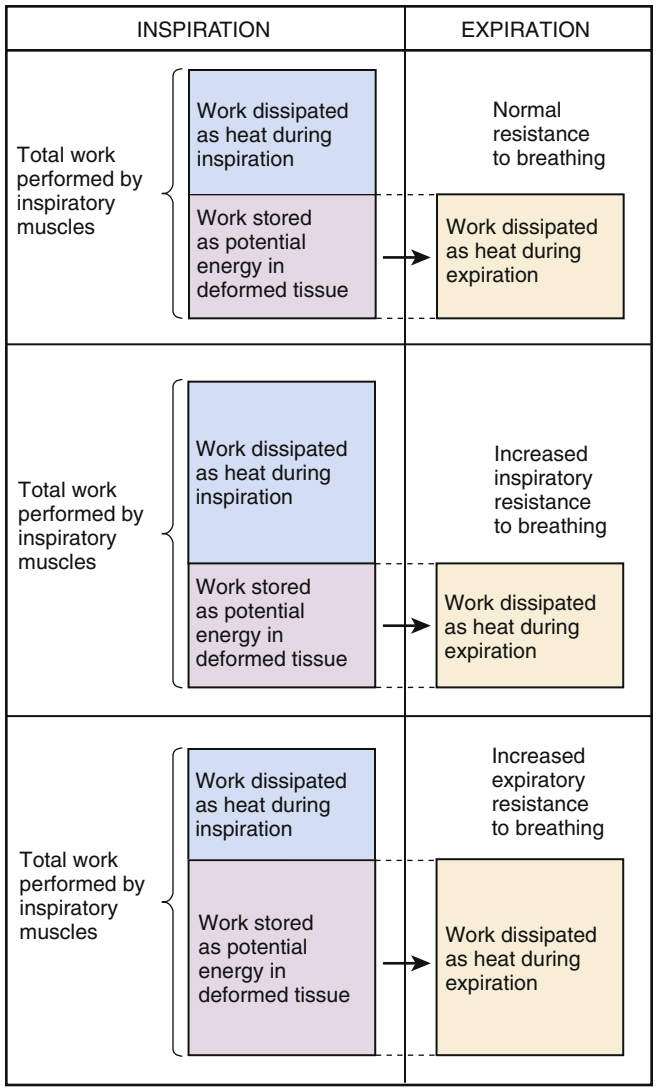

Figure 49–1. Work of breathing of respiratory muscles. The area in each box represents the amount of work performed. The left side shows the total amount of work performed with normal resistance, and increased inspiratory and expiratory resistances to breathing. *(From Nunn JF: Applied respiratory physiology, ed 3, London, 1987, Butterworth.)*

and alveolar volume. When the airway pressure is below the critical opening pressure, the terminal airway closes and the alveoli collapse because of continued absorption of gases into the bloodstream. Surfactant deficiency, loss, or alteration promotes alveolar collapse and increases the critical opening pressure. In parenchymal lung disease, which is characterized by an increased critical closing pressure, alveoli collapse during expiration if the airway pressures cannot be maintained above the critical opening pressure. Alveolar collapse leads to inadequate oxygenation from increased intrapulmonary shunting resulting from V/Q mismatch.

Inadequate ventilation results from a minute alveolar ventilation that is insufficient to meet the metabolic production of carbon dioxide. $Paco_2$ reflects the balance between metabolic production of carbon dioxide and its elimination. Failure of carbon dioxide elimination usually results from hypoventilation due to decreased central drive, lower airway obstruction, parenchymal disease, and muscle weakness (Box 49-2). Increased metabolic production of carbon dioxide usually results from hypermetabolic states and excessive caloric intake, especially high carbohydrate alimentation.

Box 49–2 Causes of Ventilatory Pump Failure

Decreased Respiratory Muscle Capacity

Decreased respiratory center output (CNS disorders)
Phrenic nerve injury
Decreased muscle strength or endurance
Malnutrition
Prolonged neuromuscular blockade
Muscle fatigue
Electrolyte abnormalities

Increased Respiratory Muscle Load

Increased work of breathing
Hyperinflation
Lower airway obstruction
Decreased respiratory system compliance
Increased ventilatory requirements
Increased carbon dioxide production (e.g., excessive carbohydrate intake)
Increased dead space
Hypercatabolic states (e.g., sepsis)

Indications for Mechanical Ventilation

Respiratory Failure

The primary indication for institution of assisted ventilation is respiratory failure. Apnea or respiratory arrest is an extreme form of respiratory failure and an absolute indication for mechanical ventilation. Respiratory failure is generally defined as the presence of (a) inadequate oxygenation, (b) inadequate ventilation, or (c) both. *Inadequate oxygenation*, objectively, is defined as partial pressure of arterial oxygen (Pao_2) less than 60 torr or an arterial hemoglobin oxygen saturation of less tha 90% in room air. Oxygenation can also be expressed as the ratio of PaO_2 to fractional concentration of oxygen in inspired gas (Fio_2). *Inadequate oxygenation* can also be defined as a Pao_2/Fio_2 ratio of less than 300. Other indexes include an alveolar/arterial oxygen gradient of more than 300 torr with an Fio_2 of 1.0 and a calculated or measured intrapulmonary shunt fraction greater than 15%. Inadequate oxygenation due to intrapulmonary shunting can be overcome with the addition of increased inspired oxygen concentration, provided the magnitude of the shunt is less than 15% (Figure 49-2). Intrapulmonary shunt can be decreased by with the reexpansion of collapsed alveoli or with the decrease of the fraction of pulmonary blood flow going to the collapsed alveolar segments. *Inadequate ventilation* is defined as $Paco_2$ greater than 45 torr with an arterial pH of less than 7.35 in the absence of chronic hypercapnia. Impending respiratory failure, characterized by rapidly rising $Paco_2$, progressive respiratory distress, $Paco_2$ out of proportion to the respiratory effort, or fatigue of respiratory muscles, is a relative indication for mechanical ventilation. Intubation and institution of mechanical ventilation in impending respiratory failure are likely to be more controlled than when full-blown respiratory failure develops. Therefore in critically ill children, establishing mechanical ventilation before respiratory failure develops is preferable. Chronic respiratory failure is defined as requirement for mechanical ventilation for more than

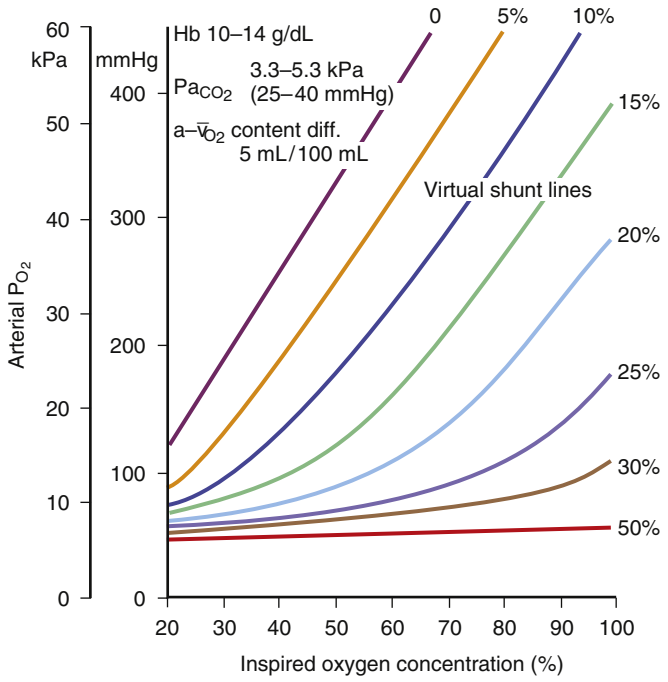

Figure 49–2. Iso-shunt diagram. This shows the relationship among the magnitude of intrapulmonary shunt, the inspired oxygen concentration, and the arterial oxygen tension for a hypothetical patient. *(From Nunn JF: Applied respiratory physiology, ed 3, London, 1987, Butterworth.)*

28 days. Children with chronic lung disease often fail to grow despite adequate caloric intake. In these patients, mechanical ventilation may decrease the work of breathing enough to allow the child to grow.

Cardiovascular Dysfunction

Moderate to severe cardiovascular dysfunction is another major indication for mechanical ventilation. The cardiovascular and respiratory systems must act in concert to maintain adequate gas exchange and thereby meet the metabolic demands of the whole body. Therefore the two systems cannot be functionally divorced from each other (until death do these part, unless one is undergoing extracorporeal membrane oxygenation [ECMO]). Cardiovascular dysfunction results in decreased respiratory reserve, in increased respiratory work, and may ultimately result in respiratory failure. Positive pressure ventilation decreases lactic acid production by respiratory muscles during circulatory shock, and withdrawal of ventilatory support results in a marked increase in cardiac work.[6,7] Therefore mechanical ventilation not only may decrease the work of breathing under these circumstances but also decrease the oxygen demand of the heart.

Neurologic and Neuromuscular Disorders

Acute neurologic disorders may require mechanical ventilation for many reasons. First, neurologic disorders may result in decreased ventilatory drive and therefore result in acute hypercapnia. Second, loss of airway protective reflexes may require an artificial airway for maintaining airway integrity and for providing an access for suctioning pooled secretions. Third, mechanical ventilation may be instituted to deliberately cause hyperventilation in disorders associated with intracranial hypertension to produce hypocapnia and respiratory alkalosis. Fourth, certain acute neuromuscular disorders such as Guillain-Barré syndrome, transverse myelitis, botulism, and drugs may result in decreased ventilatory effort because of muscle weakness and may result in hypoventilation and hypercarbia. Mechanical ventilation is usually instituted under these circumstances until the patient recovers from the primary disorder. Mechanical ventilation is also instituted for various chronic neuromuscular disorders such as muscular dystrophy and for permanent neurologic disorders such as spinal cord transection for prolonged home ventilator support.

Design and Functional Characteristics of Mechanical Positive-Pressure Ventilators

A detailed review of the physical characteristics and functional design of ventilators is beyond the scope of this chapter, and the reader is referred to several excellent reviews on this subject.[8-13] In 1991, Chatburn proposed a new system for understanding the design of mechanical ventilators.[10] A Consensus Conference on the Essentials of Mechanical Ventilators was held in Cancun, Mexico, in February 1992 and the proceedings published in the September issue of the *Respiratory Care Journal*. The goals of the conference were to (1) provide a standard nomenclature, (2) identify essential support features, (3) identify essential heat and humidity requirements, (4) identify essential monitoring/alarm features, and (5) identify what constitutes an order for mechanical ventilation. There are four key reviews that have increased our understanding of a standard nomenclature to classify mechanical ventilators and modes of ventilation.[10a-13] The scheme to classify mechanical ventilators was based on features of input power, control scheme, and the output variables (Box 49-3). Subsequent modifications to include newer modes of ventilation are described elsewhere.[11-13] The following is a brief summary that incorporates some of the elements of Chatburn's classification.

Ventilator as a Machine

The concept is a simple one—*a ventilator is simply a machine that performs external work*. This requires energy to be applied to the device which is then altered, transmitted, and directed in a predetermined manner to perform the work of breathing. This work can either replace the patient's work of breathing completely or partially or augment a patient's breathing efforts. Therefore a ventilator is a mechanical device that is used to move gas into the lungs by increasing P_{tp}. Positive pressure ventilators create P_{tp} by raising the airway pressure (P_{aw}) above the intrapleural pressure (P_{pl}), whereas negative pressure ventilators create P_{tp} by decreasing P_{pl} below P_{aw}. All ventilators include an input power, a drive system, a control system, a cycling mechanism, and a system to provide positive end-expiratory pressure (PEEP).[8-13] The accessories include a heated humidifier and an oxygen blender. The input power provides the energy to operate the ventilator and is usually electric or pneumatic. The drive system provides the force required to generate a gas flow. For gas flow to be provided, a pressure gradient needs to be created between the ventilator and the lungs. This is most commonly accomplished with compressed gases at high pressures from wall outlets or cylinders or a small

compressor designed to be used with individual ventilators. Alternatively, some ventilators have a built-in compressor such as a piston and cylinder (e.g., Emerson IMV), a diaphragm (e.g., Engtrom Erica), a system of bellows (Siemens Servo 900C), or a rotating vane (Bear 2). When a ventilator depends on an external source of compressed gases to power the ventilator, it acts mainly as a control system and will not function if the external source fails. On the other hand, a ventilator that has an internal compressor does not need an external source of gas to inflate the lung. The pressure generated within the ventilator can be thought of as the driving pressure that forces the gas into the lungs through the conducting system involving the ventilator circuit and the patient's airways. During mechanical ventilation, for a single breath, P_{tp} may be generated either by the ventilator or a spontaneous breath or a combination of both. Therefore the equation of motion can be reexpressed as:

$$P_{tp} = P_{mus} + P_{vent} = (\text{Volume} \times \text{Elastance}) + (\text{Total Resistance} \times \text{Flow})$$

where P_{mus} is the pressure exerted by the respiratory muscles and P_{vent} is the pressure exerted by the ventilator. Compliance and resistance are assumed to remain constant during lung inflation and are called parameters. Pressure, volume, and flow in the respiratory system change with time and are therefore referred to as variables. Figure 49-3 shows the classification scheme that is based on the equation of motion.

A ventilator can also be viewed as a form of mechanical controller that "controls" either pressure (in a pressure generator) or flow (in a flow generator). A pressure generator is a ventilator that generates a fixed pattern of pressure within the ventilator and at the mouth regardless of the lung conditions, leaving the flow waveform free to vary. This occurs when the generated pressure is low (generally between 20 and 50 cm H_2O), which results in a high initial flow rate that decays to zero as the alveolar pressure approaches the generated pressure. The generated pressure can be constant, nonconstant, increasing, or decreasing. The Hand-E-Vent (Ohio Medical Products), Bird Asthmatik (Bird Corporation), the Bennett PR-1, and the Bennett PR-2 ventilators are examples of pressure generators. A flow generator is a ventilator that generates a high driving pressure (3 to 50 psig corresponding to 200 to 3500 cm H_2O) and controls the inspiratory flow of gas into the patient by interposing a high series resistance system between

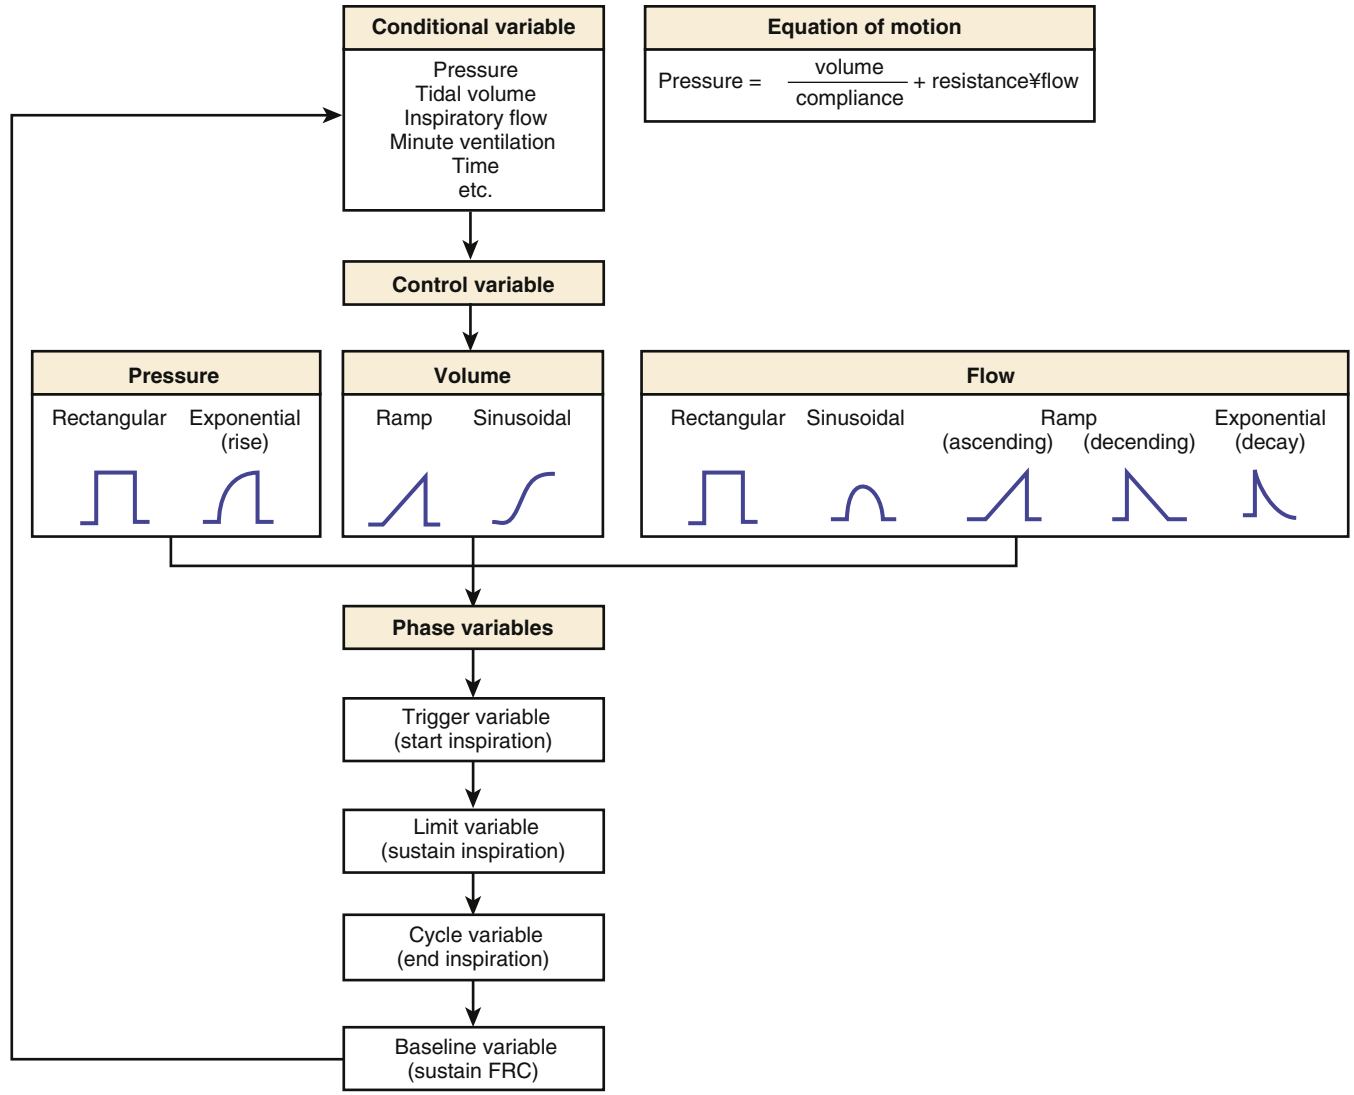

Figure 49–3. Chatburn classification system based on a mathematical model known as the equation of motion for the respiratory system. This model indicates that during inspiration the ventilator is able to directly control one and only one variable at a time (e.g., pressure, volume, flow). Some common waveforms provided by current ventilators are shown for each control variable. Pressure, volume, flow, and time are also used as phase variables that determine the parameters of each ventilatory cycle (e.g., trigger sensitivity, peak inspiratory flow rate or pressure, inspiratory time, baseline pressure). *(From Chatburn RL:* Classification of mechanical ventilators, respiratory care equipment, *Philadelphia, 1995, JB Lippincott.)*

the generated pressure and the patient. The flow generated may be constant, nonconstant, increasing, or decreasing.

The pattern of gas flow from the ventilator to the patient depends on the driving mechanism and the driving pressure in the ventilator. Four distinct flow patterns can be recognized: (1) a constant flow, (2) a decelerating flow, (3) an accelerating flow, and (4) a sinusoidal or sine-wave flow (Figures 49-4 to 49-6). A constant inspiratory flow is generated when the driving pressure is very high (e.g., 50 psig) relative to the airway pressure. The drive mechanism is usually a high-pressure gas system (compressed air or oxygen at 10 to 50 psig). The driving force may exceed 1000 cm H_2O and is severalfold higher than the typical proximal airway pressure that is required to inflate the lungs. An adjustable resistance controls the pressure and the flow to the proximal airway. The airway pressure and lung volume increase linearly until inspiration is terminated. Bird Mark 7 and Monaghan 225/SIMV are examples of high pressure drive systems with constant inspiratory flows. Constant flow can also be generated by a linear-driven piston, which moves at a constant rate of speed during inspiration (e.g., Bourns LS 104-150 Infant Ventilator). A decelerating inspiratory flow is created when the driving pressure is relatively low (<60 cm H_2O). In this case, a pressure-reducing valve controls the driving pressure to the desired level. As the airway pressure and lung volume increase during inspiration, the pressure gradient between the drive mechanism and the proximal airway decreases. Consequently, as inspiration continues, the inspiratory flow from the ventilator decreases and finally stops at the end of inspiration. The Bennett PR-1 and PR-2 are examples of low-pressure drive systems that produce decelerating inspiratory flows. A sine-wave or sinusoidal inspiratory flow is created when the drive mechanism is a rotary driven piston. As the rotary wheel turns, the piston is moved to and fro in the cylinder in an accelerating and then a decelerating fashion. The inspiratory flow produced also has a similar profile. Emerson 3-PV and 3-MV ventilators are examples of rotary piston devices. The notion that one specific flow pattern is more beneficial than

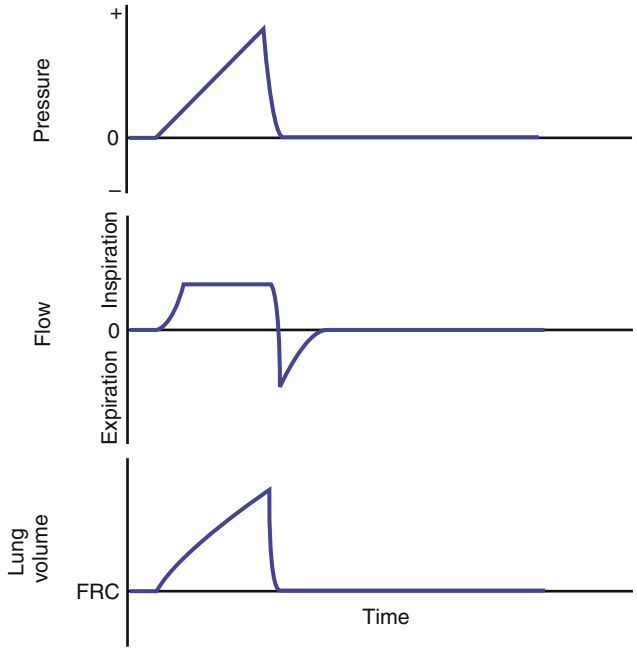

Figure 49–4. Constant inspiratory flow. The flow quickly reaches a plateau and remains constant throughout the inspiratory phase. The airway pressure and lung volume increases relatively linearly. *(From Kirby RR, Smith RA, Desautels DA:* Mechanical ventilation, *New York, 1985, Churchill Livingstone.)*

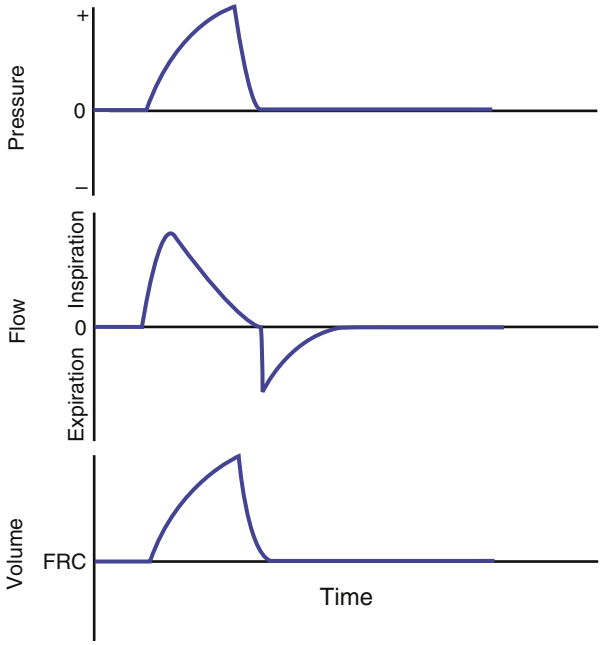

Figure 49–5. Decelerating inspiratory flow. Inspiratory flow is maximal early in inspiration and gradually falls to zero at the end of inspiration. the others is controversial. A detailed description of this topic is beyond the scope of this chapter, and the reader is referred to several excellent reviews.[8-13] Ventilators can also be classified as a single-circuit or a double-circuit device. A single-circuit device refers to a ventilator in which the gases go directly from the drive mechanism to the patient (e.g., Emerson-PV

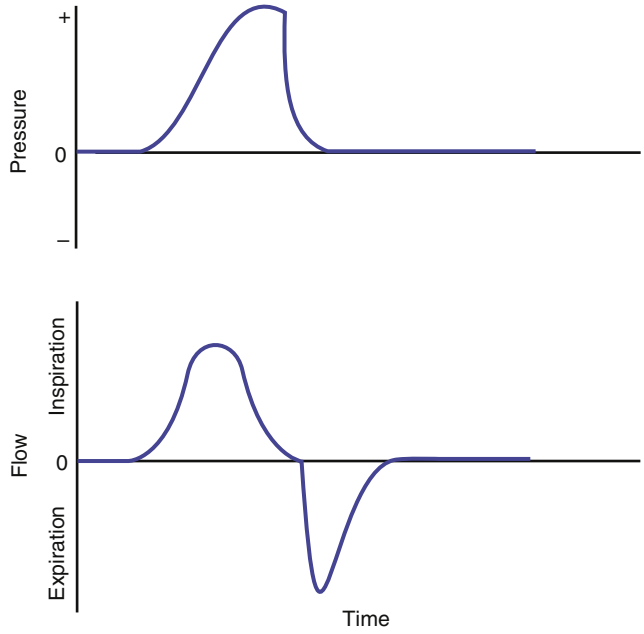

Figure 49–6. Sinusoidal, or sine-wave, inspiratory flow. Inspiratory flow increases gradually and then falls gradually to zero. The airway pressure and lung volume increase in an S-shaped fashion. *(From Kirby RR, Smith RA, Desautels DA:* Mechanical ventilation, *New York, 1985, Churchill Livingstone.)*

and 3-MV models, Bird Mark series, and the Siemens Elema 900 series ventilators). On the other hand, a double-circuit device refers to a system in which the drive mechanism is used to compress another system that then delivers the tidal volume (e.g., Engstrom 150 and 300 series, Bennett MA-1, and Monaghan225/SIMV ventilators).

All ventilators are equipped with mechanisms to provide four basic functions: (1) inflate the lungs, (2) terminate lung inflation, (3) allow lungs to empty, and (4) start lung inflation.[10,11] The ventilator performs these functions through four phases: (1) the inspiratory phase, (2) the changeover from the inspiratory to the expiratory phase, (3) the expiratory phase, and (4) the changeover from the expiratory phase to the inspiratory phase. The criteria for determining the phase variables during a mechanical breath are shown in Figure 49-7. The inspiratory phase is started when a variable measured in the circuit or at the airway reaches a preset value. This variable can be pressure, volume, flow, or time. This is called the trigger variable. Pressure- or flow-triggering requires a patient effort. On the other hand, time-triggered breaths do not require a patient effort but can be synchronized to the patient's efforts. During inspiration, a tidal breath is delivered to the lung. The volume of the tidal breath delivered to the patient depends on several factors: (1) the P_{tp} generated, (2) the compliance and resistance of the ventilator circuit, (3) the impedance to inflation of the patient's lungs, (4) leaks in the circuit, (5) leaks around the endotracheal tube, and (6) limitation or regulation of inspiratory phase variables (pressure, flow, or volume). Limitation or regulation of the inspiratory pressure, volume, or flow does not terminate inspiration. Modern ventilators such as the Siemens Servo 300 can control more than one phase variable during inspiration. Termination of inspiration depends on the cycling mechanism. Cycling refers to the mechanism by which inspiration is terminated and expiration is initiated. All ventilators require

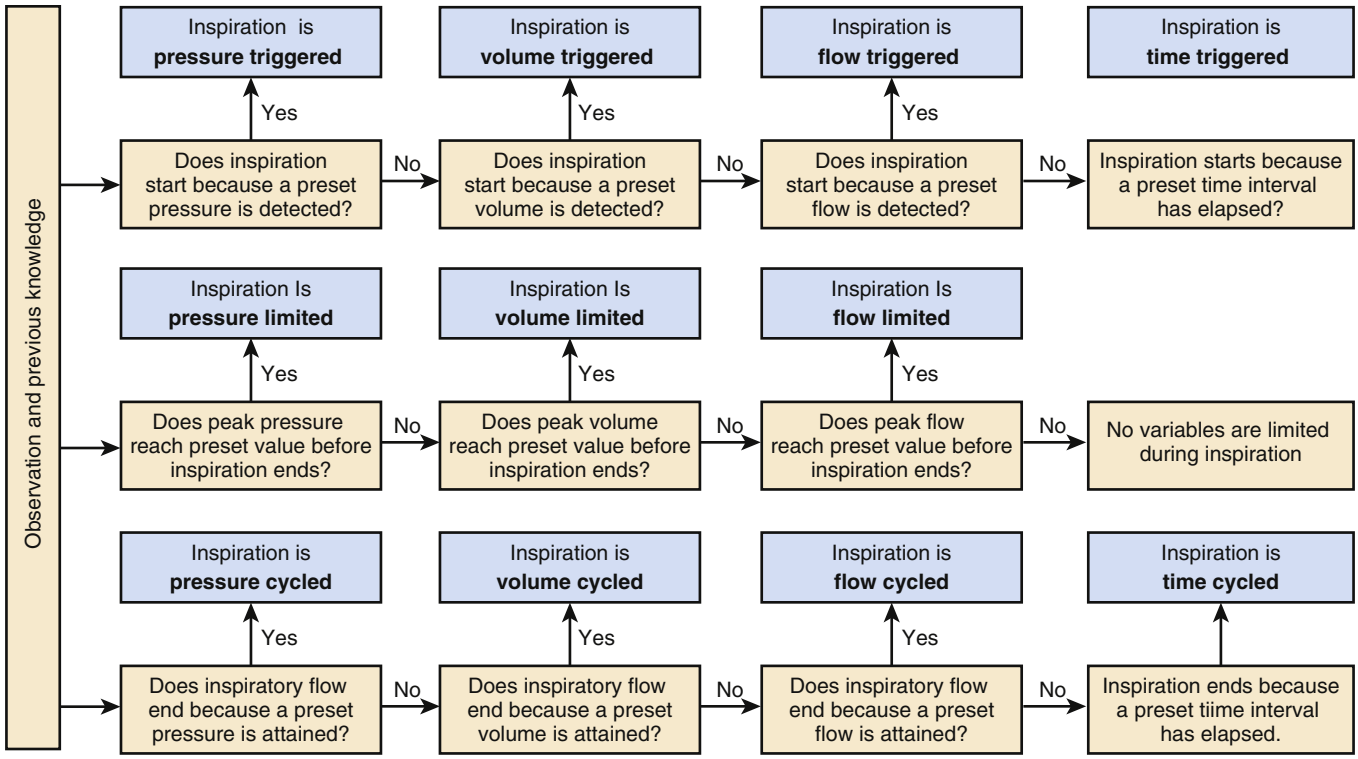

Figure 49–7. Criteria for determining phase variables during a ventilator-assisted breath. *(From Chatburn RL:* Classification of mechanical ventilators, *respiratory care equipment, Philadelphia, 1995, JB Lippincott.)*

a trigger mechanism to cycle. The trigger for cycling may be a predetermined time (time cycling), a predetermined pressure (pressure cycling), a predetermined volume (volume cycling), or a predetermined flow (flow cycling). Most conventional ventilators used in infants and children today are time-cycled or volume-cycled ventilators.

Modes of Ventilation

Mode of ventilation can be defined as the manner in which a ventilator achieves the objectives of mechanical ventilation.[12] In 2007, Chatburn proposed an update which simplified the nomenclature so that all modes of ventilation can be adequately described.[13] Box 49-4 describes the classification scheme from that review.[13] A breath refers to the occurrence of a positive airflow into the lungs (inspiration) and a negative airflow out of the lungs (expiration), which results in ventilation of the lungs. The positive and negative airflow are relative to a baseline. As described previously, all breaths have four important components. They are inspiratory trigger, phase of inspiration, termination of inspiration and the start of expiration (otherwise called *cycling*), and the phase of expiration.

There are two types of breaths: spontaneous and mandatory. A breath where the patient determines both the inspiratory timing and cycling is defined as a spontaneous breath (i.e., when the initiation and termination of a breath is under the control of the patient's breathing efforts). A spontaneous breath is both patient triggered and patient cycled. A spontaneous breath may be either unassisted or assisted. An unassisted spontaneous breath refers to a breath where the patient determines both the timing and size of the breath. T-piece breathing or breaths during continuous positive airway pressure (CPAP) are examples of unassisted spontaneous breathing. The size of the breath is determined solely by the effort of the patient with no additional help from the ventilator. An assisted spontaneous breath refers to a breath where the ventilator does some of the inspiratory work indicated by an increase in airway pressure above the baseline (i.e., a spontaneous breath with an inspiratory pressure that is greater than the expiratory pressure is referred to as an assisted mechanical breath). For an assisted breath, the patient must initiate a breath, and then the ventilator is triggered to provide a positive pressure breath. The trigger can be either pressure or flow. With an assisted spontaneous breath, the patient determines the timing but the ventilator contributes to the size of the breath. Pressure-supported breaths are examples of assisted spontaneous breaths. Mandatory breaths refer to those breaths that are not spontaneous. A mandatory breath may be initiated by the ventilator with a preset frequency or minute ventilation, or it can be initiated by the patient. Mandatory breaths can be triggered by either the machine or the patient. With a mandatory breath, the termination of the breath is under the control of the ventilator. A mandatory breath is always cycled by a preset time, pressure, or volume and is not under the control of the patient. Whether the mandatory breath is initiated by the ventilator or by the patient, the characteristics of the breath (changes in flow, pressure, and volume) and the inspiratory time of the breath are the same.

There are eight possible breathing patterns based on three possible control variables (volume, pressure, and dual control) and three breath sequences.[12,13] These are shown in Table 49-1. Continuous spontaneous ventilation (CSV) refers to a breath sequence in which all the breaths are spontaneous. Continuous mandatory ventilation (CMV) refers to a breath sequence in which all the breaths are mandatory breaths. During CMV, spontaneous breaths are not

Modified from Chatburn RL, Primiano FP Jr: A new system for understanding modes of mechanical ventilation, *Respir Care* 46:604–621, 2001; and Chatburn RL: Classification of ventilator modes: update and proposal for implementation, *Respir Care* 52:301–323, 2007.

permitted or do not occur between mandatory breaths. If the patient is breathing spontaneously during CMV, each spontaneous breath may trigger a mandatory breath. Assist-control refers to a mode of ventilation when a patient receives a combination of ventilator-initiated and patient-initiated mandatory breaths. The total number of mechanical breaths will be the sum of the preset frequency of ventilator breaths and the number of patient-triggered breaths. For example, if the preset frequency is 15 breaths/min and the patient triggers an additional 15 breaths/min, the total number of mandatory breaths will be 30 breaths/min. Mandatory breaths may be superimposed on spontaneous breaths (such as during high frequency) or vice versa (such as during airway pressure release ventilation). Intermittent mandatory ventilation (IMV) refers to a breath sequence where breaths are either mandatory or spontaneous. Volume control CSV is not possible because the definition of a spontaneous breath would conflict with the definition of volume control. When all minute ventilation is provided by the ventilator, it is referred to as total ventilatory support. When some of the minute ventilation is provided by spontaneous breathing and the rest by the ventilator, it is referred to as partial ventilatory support. Total ventilatory support is provided when the patient does not take any spontaneous efforts because of a primary disease process (e.g., quadriplegia, muscle disease), pharmacologic therapy (e.g., induced neuromuscular blockade), or suppression of spontaneous breathing efforts (e.g., hyperventilation). Total ventilatory support is provided entirely by CMV. On the other hand, partial ventilatory support can be provided by CMV, AMV, or a combination of both.

Mandatory Mechanical Ventilation

During inspiration, the control variable is pressure (pressure control), volume (volume control), flow (flow control), time (time control), or dual control. The two most common forms of controlled mandatory mechanical ventilation modes that are used in infants and children are pressure-regulated and volume-regulated mandatory modes of ventilation. Figure 49-8 shows pressure-time curves for some of the mandatory modes of ventilation.

Volume-Regulated Mandatory Breaths

Volume-regulated ventilation can be delivered either by volume-cycled breath, where inspiration is terminated after a preset volume is delivered and inspiratory time is allowed to vary, or by volume-regulated time-cycled breaths, where the cycling mechanism is preset time and the tidal volume delivered is regulated by adjusting the inspiratory flow rate. In volume-regulated ventilation, the tidal volume is delivered throughout inspiration. The peak inspiratory pressure (PIP) is variable and depends on the flow rate, the total resistance, and the total compliance of the ventilator circuit and the patient's lungs. Changes in resistance or compliance will be reflected by an increase in PIP, and the ventilator can be set to alarm at a pressure limit that is generally set 5 to 10 cm above the PIP.

Most modern ventilators deliver the preset tidal volumes reliably, but the tidal volumes delivered to the patient on a breath-to-breath basis may not always be constant. The tidal volume delivered by the ventilator is distributed between the ventilator circuit, the airways, and the patient's lungs. The compliances and resistances of the ventilator circuit, the endotracheal or tracheostomy tube, and the patient independently and together affect the distribution of tidal volume delivered by the ventilator. A decrease in the compliance or an increase in the resistance of the ventilator circuit will affect the actual tidal volume delivered to the patient. The ventilator circuit includes an internal volume and the external tubing.

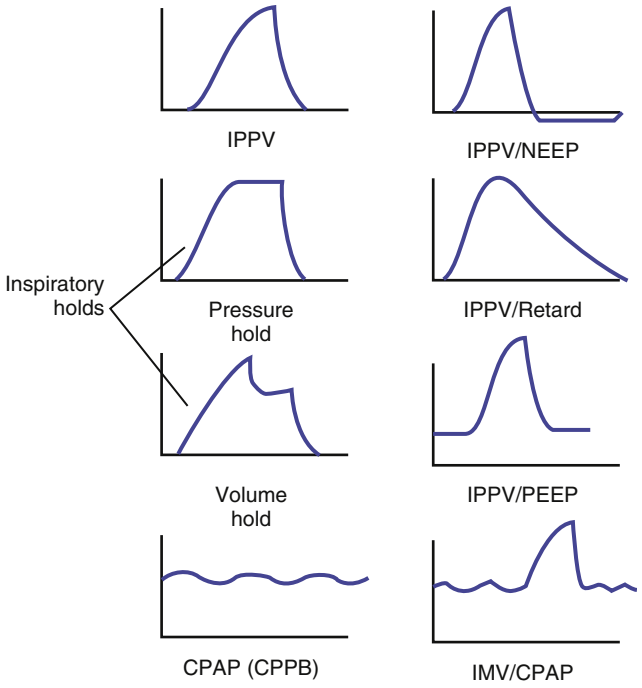

Figure 49–8. Pressure-time curves of some of the mandatory modes of ventilation. *(From Kirby RR, Smith RA, Desautels DA:* Mechanical ventilation, *New York, 1985, Churchill Livingstone.)*

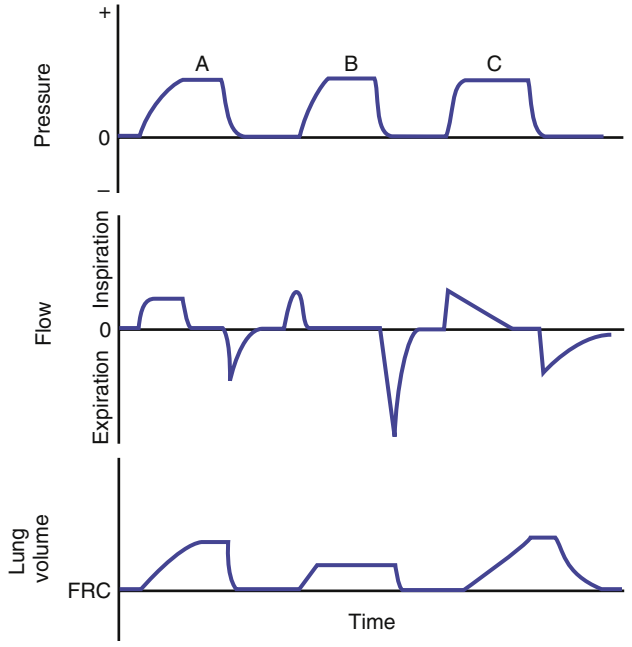

Figure 49–9. Pressure-control ventilation. Inspiratory flow pattern is constant. Airway pressure and lung volume rise relatively linearly. The airway pressure reaches a preset pressure limit and does not change throughout inspiration. Lung volume follows the time course of the pressure curve with a slight lag. **A,** Normal lung. **B,** Lung with decreased compliance. **C,** Lung with increased resistance. With decreased compliance the tidal volume delivered is decreased. With increased resistance, it takes longer to deliver the tidal volume. *(From Kirby RR, Smith RA, Desautels DA:* Mechanical ventilation, *New York, 1985, Churchill Livingstone.)*

The actual tidal volume or the effective tidal volume (VT_{eff}) delivered to the patient can be approximated by the following formula:

$$VT_{eff} = VT_{del} - VT_{circuit}$$

where VT_{del} is tidal volume delivered by the ventilator and $VT_{circuit}$ is the volume of gas that is distributed to the ventilator circuit. VT_{del} is equal to the inspired tidal volume, when there is no leak in the total respiratory system. When there is a leak in the system, however, such as with the use of uncuffed endotracheal tubes, then VT_{del} is less than the inspired tidal volume. $VT_{circuit}$ can be estimated by the following formula:

$$VT_{circuit} = C_{vent} \times (PIP - PEEP)$$

where C_{vent} is the compliance of the ventilator circuit. An increase in resistance or compliance of the ventilator circuit (including the endotracheal tube) or the patient's airways or lungs will increase the time constant to inflation. If the inspiratory time is less than five times the time constant of the whole respiratory system, which includes the ventilator circuit and the patient's airways, then the VT_{del} will be less than the preset tidal volume. During inspiration, after the tidal volume is delivered, an inspiratory hold will maintain inspiratory pressure and prolong the duration of inspiration (see Figure 49-8). During exhalation, expiratory flow curves depend on the type of expiratory resistance or PEEP valve in the system.

Pressure-Regulated Mandatory Breaths

Pressure-regulated ventilation can be either pressure-cycled or pressure-limited time-cycled ventilation. In pressure-cycled ventilators, inspiration is terminated when a preset pressure limit is reached. In this mode of ventilation, the inspiratory time may vary depending on the changes in resistance and compliance of the total respiratory system. This mode of ventilation is not widely used these days except for intermittent positive-pressure breathing treatments. Pressure-limited, time-cycled ventilation is most commonly used in the neonate with respiratory distress syndrome and in children with acute respiratory distress syndrome (ARDS). In this mode, inspiratory and expiratory times are constant, and the PIP reaches a preset limit quickly early in inspiration and is then maintained at that level during the rest of the inspiratory phase. Usually a high flow rate is used (4 to 10 L/kg/min). The tidal volume delivered depends on the compliance and resistance of the ventilator circuit and the patient's lungs. Pressure-controlled ventilation results in higher mean airway pressure for the same amount of minute ventilation. Figure 49-9 shows the time course of changes in airway pressure, inspiratory flow, and lung volume with normal lungs, lungs with decreased compliance and with increased resistance. As shown in Figure 49-9, with PIP remaining the same, lung volume delivered is affected by changes in lung compliance and airways resistance. Factors that would increase mean airway pressure during pressure-controlled ventilation are shown in Figure 49-10.

Continuous Flow Versus Demand Flow

Some ventilators that can provide pressure-regulated ventilation have both inspiratory and expiratory valves. Once PIP is reached, both inspiratory and expiratory valves close and the lung is held in inflation until the end of inspiration. For use in infants, ventilators were modified to provide continuous flow throughout the respiratory cycle.[14] A continuous flow device refers to a ventilator in which the flow of respiratory gas occurs throughout the respiratory cycle. Most infant ventilators are continuous flow devices (e.g., Infant Star, Baby Bird). In most continuous flow infant ventilators, inspiratory

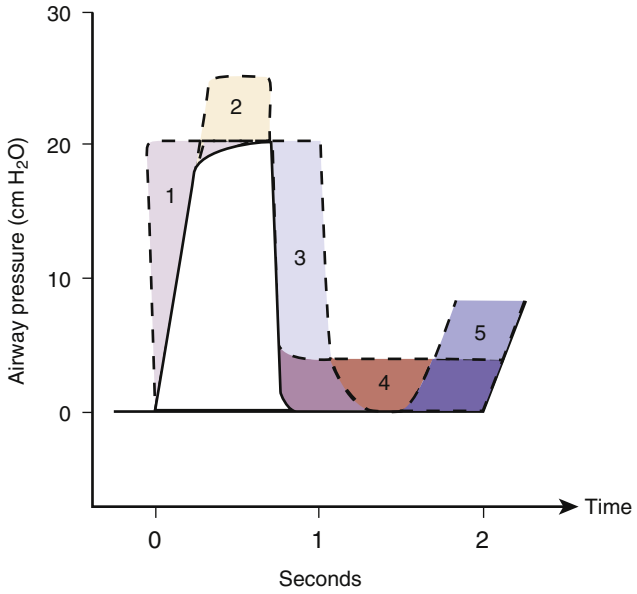

Figure 49–10. Factors that increase mean airway pressure during pressure controlled ventilation: (1) increased inspiratory flow rate, (2) increased preset pressure limit, (3) increased inspiratory time, (4) increased PEEP, and (5) increased ventilator rate. Note that with each maneuver, the area under the curve increases. Area under the curve represents mean airway pressure. *(From Goldsmith JP, Karotkin EH, editors:* Assisted ventilation of the neonate, *Philadelphia, 1988, WB Saunders.)*

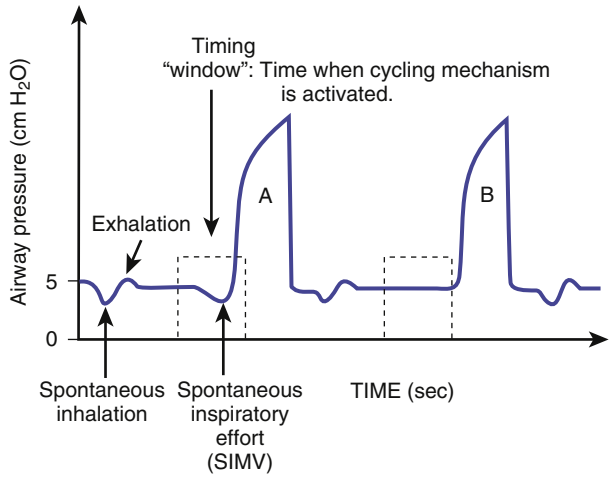

Figure 49–11. Synchronized intermittent mandatory ventilation (SIMV). At set intervals, the ventilator's timing circuit becomes activated and a timing "window" appears (*shaded area*). If the patient initiates a breath in the timing window, then the ventilator will deliver a mandatory breath. If no spontaneous effort occurs, then the ventilator will deliver a mandatory breath a fixed time after the timing window. *(From Kirby RR, Smith RA, Desautels DA:* Mechanical ventilation, *New York, 1985, Churchill Livingstone.)*

valves are lacking, and the cycling is controlled by the exhalation valve. Closure of the exhalation valve begins inspiration, and the flow of gas going through the circuit is diverted to the patient. If the inspiratory flow rate is low (1 to 3 L/kg) and if the PIP is not limited, the tidal volume delivered by the patient can be calculated from the inspiratory flow rate and the inspiratory time. This would result in a time-cycled, volume-regulated breath. For pressure-control ventilation, the flow rates used are usually higher (4 to 10 L/kg). Once the preset PIP is reached, the excess flow is vented through a pressure relief valve, and the lungs are maintained in inflation throughout the rest of inspiration. During exhalation, there is continuous flow of gas, allowing the patient to breathe from the circuit rather than open a demand valve. A demand flow ventilator refers to a ventilator that allows inspiratory flow of gas to the patient between ventilator breaths through a demand valve that is opened by the patient's inspiratory efforts. Work of breathing is higher with a demand flow ventilator compared with a continuous flow device because of the effort required to open the demand valve.

Intermittent Mandatory Ventilation

Intermittent mandatory ventilation (IMV) refers to a pattern of controlled ventilation in which spontaneous breathing is permitted. Between mandatory machine breaths, the patient can breathe spontaneously and the required gas flow is delivered through either a continuous flow or a demand system. The concept of IMV where spontaneous breathing occurred with a preset mechanical ventilator rate was first developed by Kirby et al.[14] in 1971 with the use of a continuous flow circuit in the management of respiratory distress syndrome of the neonate. IMV was first described by Downs et al.[15] in 1973 to describe a mode of ventilation that allowed the patient to breathe spontaneously with a preset ventilator rate. The spontaneous breaths are not assisted by a ventilator breath. Therefore the tidal volumes generated by the spontaneous breaths depend on the patient's effort alone and not on the ventilator support. The total ventilatory support time and duration of weaning were significantly reduced in infants using IMV compared with CMV.[16,17] Two systems are currently available to deliver IMV: one uses continuous flow, and the other uses a demand valve. Ventilators such as the InfantStar incorporate a continuous flow circuit that can be adjusted to the inspiratory flow demand of the patient. The ideal flow rate would result in minimal pressure swings associated with spontaneous inspiration and expiration. Most modern ventilators incorporate a demand valve that needs to be opened to satisfy the inspiratory flow requirements of the patient. This increases the inspiratory work of breathing. This can be minimized by the application of a small amount of pressure support. When IMV is synchronized to the patient's inspiratory efforts, it is referred to as synchronized IMV (SIMV) (Figure 49-11). The ventilator accomplishes this by creating a timing window just before the next mandatory breath is scheduled to be delivered. If the patient takes a spontaneous breath in this timing window and the ventilator senses this breath on the basis of the trigger sensitivity, then the mandatory breath is synchronized with the patient's effort. Each time a synchronized breath is delivered, the machine recomputes the time required to deliver the next mandatory breath. In SIMV, the total number of mandatory breaths will only be equal to the preset frequency of mandatory breaths. SIMV breaths can be both volume regulated or pressure limited.

Continuous Positive Airway Pressure/ Positive End-Expiratory Pressure

CPAP refers to the maintenance of positive airway pressure throughout the respiratory cycle with no positive pressure breaths being delivered to the patient. PEEP refers to the maintenance of positive airway pressure above atmospheric pressure at the airway opening at end expiration.[18]

CPAP/PEEP can be applied by a variety of devices. These include (1) an underwater column, (2) a water-weighted diaphragm, (3) a Venturi valve, (4) a spring-loaded valve, (5) a pressurized exhalation valve, (6) a magnetic valve, and (7) a fixed or adjustable orifice. Devices that retard expiratory flows (e.g., Venturi valve, fixed or adjustable orifice) tend to produce higher mean airway pressure than those that do not retard expiratory flow rates.

CPAP may be provided by several means:

1. Endotracheal CPAP[9,19]: This is the most reliable method of applying CPAP. The advantages of endotracheal CPAP are precise control of airway pressure and Fio_2; access to the airway for tracheobronchial toilet; maintenance of enteral feeding through a nasogastric tube; and, if necessary, immediate institution of mechanical ventilation. The disadvantages are those associated with those of endotracheal intubation and the long-term presence of an artificial airway.
2. Nasal CPAP: Specially designed nasal prongs,[20] a single cannula or a shortened uncuffed endotracheal tube inserted into the nasopharynx, and nasal masks,[21] provide a means of applying CPAP. Because of the location in the nasopharynx, there will be a loss of pressure in the hypopharynx so that the actual CPAP delivered to the trachea may vary. This technique is easy to apply and can be instituted by less-skilled personnel. This technique is most useful in infants who are obligatory nose breathers. Mouth breathing reduces the efficiency of this technique considerably. Nasal prongs are more prone to obstruction with thick secretions and require proper humidification and frequent suctioning. Nasal prongs have also been reported to increase the work of breathing.[22]
3. Face mask CPAP: A tight-fitting mask is placed on the face covering the nose and the mouth. CPAP is provided with the application of positive airway pressure to the mask. This technique is only useful in patients who are alert and cooperative, without a tendency for nausea and vomiting. A tight-fitting mask may produce pressure lesions on the face if applied too tight. Gastric distention with vomiting and aspiration are potential problems.

The primary effect of CPAP/PEEP is an increase in end-expiratory lung volume due to the increased P_{tp}. In lung diseases characterized by increased closing volume and decreased FRC, alveoli are unstable and tend to collapse. Recruitment of collapsed alveoli requires a P_{tp} greater than that required to sustain inflation once the alveoli are open. An increase in FRC above the closing volume restores this balance, prevents alveolar collapse, and maintains alveolar stability (Figure 49-12). This reduces the magnitude of V/Q mismatching because of improved distribution of alveolar ventilation.[23,24] Airway closure and alveolar collapse can be prevented if the level of CPAP/PEEP is above the critical opening pressure. In lung disease with nonuniform or heterogeneous parenchymal involvement, CPAP/PEEP may hyperinflate normal lung segments, and this hyperinflation results in redistribution of blood toward the diseased segments, increasing intrapulmonary shunt on one hand and increasing alveolar dead space on the other (Figure 49-13).

Selection of Parameters for Mandatory Breaths

The first parameter is the tidal volume. A practical approach to determining an adequate tidal volume is to evaluate the desired degree of chest expansion during manual ventilation and to reproduce that when the patient is connected to the

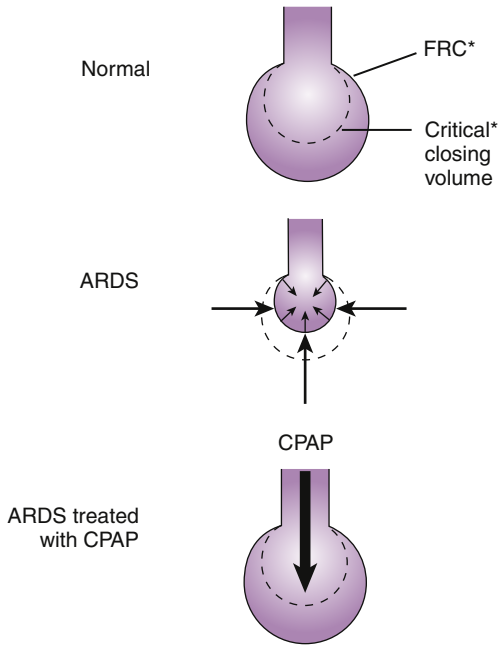

Figure 49–12. Effect of CPAP on FRC. **A**, In normal lungs, FRC is greater than critical closing volume. **B,** In ARDS, FRC is less than critical closing volume. CPAP restores FRC to be greater than critical closing volume and prevents alveolar collapse. *(From Kirby RR, Smith RA, Desautels DA:* Mechanical ventilation, *New York, 1985, Churchill Livingstone.)*

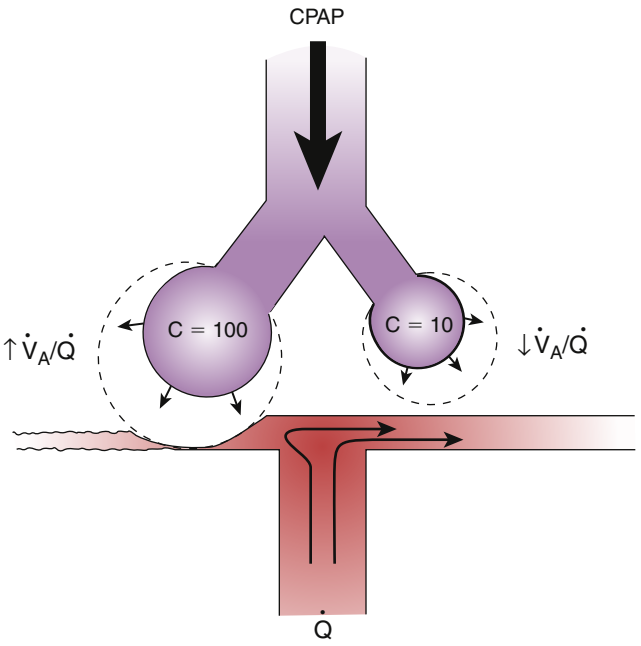

Figure 49–13. Effect of CPAP on nonhomogenous lung disease. CPAP increases FRC in the lung segment with decreased alveolar ventilation-perfusion ratio (*VA/Q*) and decreases shunt reaction. CPAP overdistends lung segments with high VA/Q and redistributes blood toward the segments with low VA/Q increasing the amount of shunt. The net effect depends on the balance between the two. *(From Kirby RR, Smith RA, Desautels DA:* Mechanical ventilation, *New York, 1985, Churchill Livingstone.)*

ventilator. A desirable VT_{eff} for most patients is 8 to 10 mL/kg. Patients with normal lung compliance may require a preset tidal volume of 12 to 15 mL/kg to produce a VT_{eff} of 8 to 10 mL/kg. Ideally, the end-inspiratory alveolar pressure should be less than 30 cm of H_2O. The end-inspiratory alveolar pressure can be measured using an inspiratory hold maneuver. With an inspiratory hold, inspiratory flow is stopped, both inspiratory and expiratory valves are closed and the proximal airway pressure equilibrates with the alveolar pressure. The end-inspiratory hold pressure is called the *pause pressure, plateau pressure*, or simply *end-inspiratory airway pressure*. A large VT_{eff}, especially those that results in an end-inspiratory airway pressure greater than 40 cm of H_2O should be avoided. During mechanical ventilation, end-inspiratory alveolar pressure can be estimated through the measurement of the end-inspiratory airway pressure with an end-inspiratory hold maneuver.

Ventilator rate is the next parameter to be selected. The initial rate selected depends on the age of the patient and the ventilatory requirements of the patient and may subsequently be adjusted according to the $PaCO_2$. The initial ventilator rate for a newborn infant usually ranges from 25 to 30 breaths per minute; for a 1 year old, between 20 and 25 breaths/min; and for an adolescent, from 15 to 20 breaths/min. The inspiratory time is selected to provide an inspiratory/expiratory time (I/E) ratio of at least 1:2 in most patients. Inspiratory time can be set either as a percentage of the total respiratory cycle or as a fixed time in seconds depending on the ventilator. Inspiratory time must be selected to allow sufficient time for all lung segments to be inflated. In heterogenous lung disease with varying regional time constants, a short inspiratory time may not be sufficient to inflate all lung segments and may contribute to underventilation and underinflation. Similarly, sufficient expiratory time must be provided for all lung segments to empty. If inspiration starts before the lung has completely emptied, this will result in air trapping and inadvertent positive end-expiratory pressure. The I/E ratio can be adjusted according to the pathophysiological cause of the lung disease. In infants with bronchiolitis and in children with asthma, the expiratory time may have to be lengthened to avoid air-trapping.

PEEP is the next parameter to be selected. The level of PEEP will depend on the clinical circumstance. PEEP increases mean Paw during both volume-controlled and pressure-controlled ventilation, which results in a higher mean lung volume. The goals of PEEP are (1) increasing end-expiratory lung volume above closing volume to prevent alveolar collapse, (2) maintaining stability of alveolar segments, (3) improving oxygenation, and (4) reducing work of breathing. The optimum PEEP is the level at which there is an acceptable balance between the desired goals and undesired adverse effects. The desired goals are (1) reduction in inspired oxygen concentration to "nontoxic" levels (usually ≤50%); (2) maintenance of PaO_2 or SaO_2 (arterial oxygen saturation) of more than 60 mm Hg or more than 90%, respectively; (3) improvement of lung compliance; and (4) maximal oxygen delivery.[25-27] Arbitrary limits cannot be placed on the level of PEEP or mean airway pressure that will be required to maintain adequate gas exchange. When the level of PEEP is high, peak inspiratory pressure may be limited to prevent it from reaching dangerous levels that contribute to air leaks and barotrauma.

Fio_2 is the next parameter to be selected. Fio_2 is adjusted to maintain an adequate PaO_2. High concentration of oxygen can produce lung injury and should be avoided. The exact threshold of inspired oxygen that increases the risk of lung injury is not clear. An Fio_2 less than 0.5 is generally considered safe. In patients with parenchymal lung disease with significant intrapulmonary shunting, the major determinant of oxygenation is lung volume, which is a function of the mean airway pressure. With a shunt fraction of more than 20%, oxygenation may not be substantially improved by higher concentrations of oxygen.

Assisted Mechanical Ventilation

As defined previously, all assisted ventilation requires the patient to trigger the ventilator to provide a breath. With assisted ventilation, every breath that reaches a trigger threshold will result in a mechanical breath that is predetermined. There are two forms of assisted ventilation. The first kind of assisted breath is one where a mandatory breath is triggered by the patient's effort. In this form of assisted breath, the breath is patient-triggered but machine cycled. The second kind of assisted breath is one where the breath is both patient-triggered and patient-cycled. The second kind of assisted breath is also classified as *pressure control continuous spontaneous ventilation* (PC-CSV) (see Table 49-1). There are various ways to assist spontaneous breaths with a PC-CSV breathing pattern. They include (1) pressure support: spontaneous breaths assisted with setpoint control; 2) volume assist: spontaneous breaths assisted with adaptive pressure control; (3) automatic tube compensation: spontaneous breaths assisted with servo control; (4) proportional assist ventilation: spontaneous breaths assisted with servo control; and (5) SmartCare: spontaneous breaths assisted with knowledge-based control.[12,13] Following is a description of the most common mode of assisted ventilation that is used today.

Pressure-Support Ventilation

Pressure-support ventilation (PSV) is a form of assisted ventilation in which the ventilator assists the patient's own spontaneous effort with a mechanical breath with a preset pressure limit. Figure 49-14 shows the important components of a pressure support breath. As with any form of support that is designed to respond to the patient's effort, the inspiratory pressure assist of PSV requires a signal to trigger the demand valve to initiate flow.[28] The patient's spontaneous breath creates a negative pressure (pressure triggering) or a change in flow through the circuit (flow triggering), which triggers the ventilator to deliver a breath. With initiation, the machine delivers high inspiratory flow to achieve a peak airway pressure level that is selected by the operator.[29-31] The pressure-limit stays constant as long as the patient's inspiratory effort is maintained with a variable gas flow rate from the ventilator.[30,31] As inspiration continues, the inspiratory flow rate decreases. A threshold reduction in the flow rate is a signal for the termination of the inspiratory assist, with the opening of an expiratory valve, after which passive exhalation occurs.[29-31] The termination signal can be a predetermined percentage of the peak inspiratory flow (10% or 25%) or a fixed flow (usually 5 L/min).[32-34] Many ventilators also incorporate backup flow termination criteria, such as the duration of inspiration greater than 5 seconds or an increase in the airway pressure above the set pressure support level (e.g., when a patient attempts to cough). In summary, PSV is patient triggered,

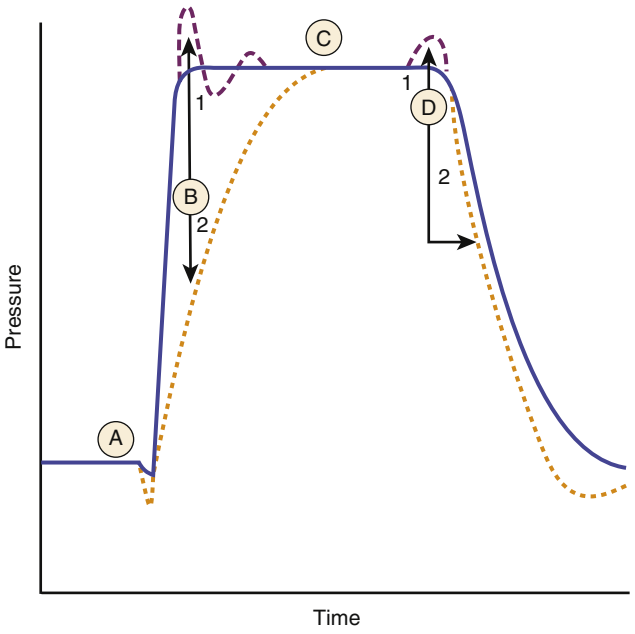

Figure 49–14. Components of a pressure-support breath. *Point A* is the patient's effort indicated by a negative deflection. When the ventilator senses this trigger (change in pressure or flow), it will deliver flow to reach the desired pressure-support level (*point B*) as rapidly as possible. Ventilator-delivered flow is then servo-adjusted to patient demand to maintain this pressure plateau (*point C*). Inspiration is terminated when a minimal flow criterion is reached (*point D*) and airway pressure returns to baseline. *(From MacIntyre NR: Pressure support ventilation. Mechanical ventilation and assisted respiration. In Grenvik A, Downs J, Rasanen J, et al, editors:* Contemporary management in critical care, *New York, 1991, Churchill Livingstone.)*

pressure limited, and flow cycled. PSV is entirely dependent on the patient's effort; if the patient becomes apneic, the ventilator will not provide any mechanical breath.

Other Modes of Ventilation

Airway Pressure Release Ventilation

Airway pressure release ventilation (APRV) is a method of mechanical ventilation introduced by Stock and Downs.[35,36] It was based on the premise that most patients with acute lung injury (ALI) or adult respiratory distress syndrome (ARDS) required positive pressure support to maintain an adequate lung volume and required minimal, if any, ventilatory assistance.[35,36] These authors theorized that if a sufficiently high level of CPAP were provided with a high gas flow rate, it would maintain an adequate lung volume and oxygenation while ventilatory needs would be met entirely by spontaneous breathing. If ventilatory assistance were to be required, CPAP level could be abruptly reduced for a short period of time and this could be repeated several times in a minute to enhance ventilation. So, the original circuit included a CPAP device and a mechanism to release airway pressure periodically to some desired low pressure. Simplistically, this can be thought of as pressure-limited, time-cycled ventilation, in which the preset pressure limit is equal to the level of CPAP required and the PEEP is usually ambient pressure or a selected lower airway pressure, with reversal of I/E ratio. Spontaneous breathing occurs at both levels of airway pressure. In the original description, the gas flow through the circuit was continuous and allowed unrestricted spontaneous breathing. It was recommended that the flow rate be kept slightly above the peak inspiratory flow rate of a spontaneous breath. Minute ventilation occurs with both spontaneous breaths and the periodic inflation and deflation that occur with the two levels of airway pressure. Gas exchange can occur throughout the respiratory cycle. Several studies with acute respiratory failure have shown that APRV results in improvement in gas exchange with much lower airway pressures.[35,37-39] Lower peak airway pressures are the consistent major advantage of ARPV. Because airway pressures are lower, APRV results in less adverse cardiovascular effects than IMV, when both are added to CPAP.[37,39] Some of the modern ventilators have incorporated features that allow spontaneous breathing through a demand-flow system during both the inspiratory and expiratory phases of a pressure-controlled, time-cycled breath. These are called by different names such as *biphasic positive airway pressure* and *intermittent mandatory pressure-release ventilation*. These different modes have been classified under the acronym APRV. Some ventilators incorporate pressure-support to be provided for the spontaneous breaths during these modes. It is clear that the patient-ventilator interactions are clearly different between the original APRV circuit and the modern APRV systems. Generally, demand-flow systems increase the trigger work of breathing and therefore are not necessarily unrestricted, especially in infants and children. At the present time, not enough information is available in infants and children.

Mandatory Minute Volume Ventilation

Mandatory minute volume ventilation (MMV) was first introduced by Hewlett et al.[40] in 1977. In this mode, the patient is guaranteed a preset delivered minute ventilation. If the spontaneous minute ventilation exceeds the preset value, then the ventilator reduces the rate to zero and does not deliver a mechanical breath. If there is no spontaneous minute ventilation, then the ventilator will deliver sufficient breaths to match the preset minute ventilation. If the spontaneous minute ventilation is insufficient to match the preset value, then the ventilator will provide the remainder of the minute ventilation. Different mechanisms are used by manufacturers to achieve this goal. In the Ohmeda CPU1 ventilator, the preset minute ventilation is compared with the patient's total minute ventilation (spontaneous and mechanical) every 24 cycles and then adjusted. In the Engstrom Erica ventilator, it is done on a breath-by-breath basis. Currently, there is not much experience with MMV in pediatric patients. The indications of MMV are in patients after abdominal surgery, especially with complications; patients who are recovering from respiratory muscle paralysis (e.g., Guillain-Barré syndrome, myositis, myasthenia gravis); and patients who have widely fluctuating respiratory drive (encephalopathy).

Dual Control Modes

Dual Control Within a Breath. These modes allow the ventilator to deliver a pressure-controlled breath or switch from a pressure-controlled breath to a volume-controlled breath within the breath. This is shown in Figure 49-15. This mode is referred to as VAPS (Bird 8400ST and Tbird, Bird Corp., Palm Springs, Calif.) and pressure augmentation (PA) (Bear 1000). Both of these techniques can operate during

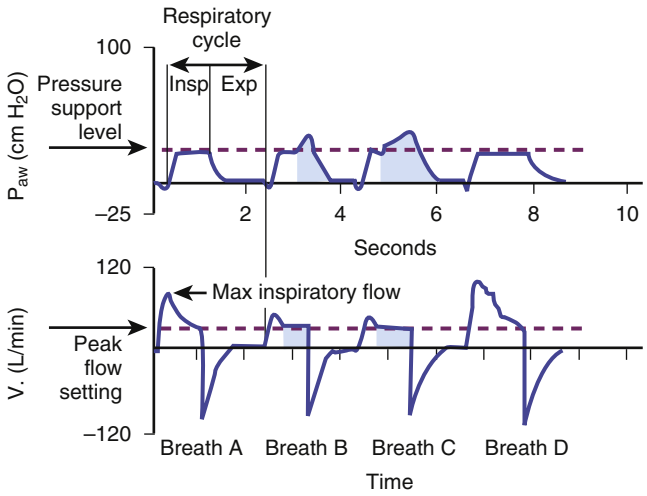

Figure 49–15. Pressure and flow waveforms illustrating VAPS. *(From Branson RD, MacIntyre NR: Dual-control modes of mechanical ventilation,* Respir Care *41:294–305, 1996.)*

mandatory breaths (pressure limited, time cycled) or pressure-supported breaths. During VAPS and PA, the clinician must set the respiratory frequency, peak flow, PEEP, inspired oxygen concentration, trigger sensitivity, and minimum desired tidal volume. During VAPS or PA, the ventilator's inspiratory flow waveform is constant (square). Additionally, the pressure support setting must be set. During pressure support, VAPS and PA can be considered a safety net that always supplies a minimum tidal volume. A VAPS or PA breath may be initiated by the patient or time triggered. After the breath is triggered, the ventilator attempts to reach the pressure support setting as quickly as possible. This portion of the breath is the pressure control portion and is associated with a rapid variable flow, which may reduce the work of breathing. As this pressure level is reached, the ventilator's microprocessor determines the volume that has been delivered from the machine (note: this is not exhaled tidal volume), compares this measurement with the desired tidal volume, and determines whether the minimum desired tidal volume will be reached. If the ventilator determines that the ultimate delivered tidal volume will be equivalent to the set tidal volume, the breath is delivered as a pressure support breath. If the ventilator determines that the ultimate delivered tidal volume will be less than the set tidal volume, then the breath changes from a pressure-limited to a volume-limited breath. At that point, inspiratory flow remains constant and the ventilator increases the inspiratory time until the desired volume has been delivered. Inspiratory pressure will increase above the set pressure support setting. Setting the high-pressure alarm remains important during VAPS. If pressure increases abruptly, the high-pressure alarm setting is reached, and the breath is pressure cycled (see Figure 49-15). VAPS breath can allow the patient a tidal volume larger than the set volume.

Mandatory Dual-Control Breath-to-Breath Modes. Dual-control breath-to-breath mode with mandatory pressure-limited time-cycled breaths is referred to as pressure-regulated volume control (PRVC) (with Siemens 300), adaptive pressure ventilation (APV) (with Hamilton Galileo), autoflow (Evita 4), or variable pressure control (Venturi), depending on the manufacturer. In this form of pressure-limited, time-cycled ventilation, delivered tidal volume is used as a feedback control for continuously adjusting the pressure limit. All breaths in these modes are time or patient triggered, pressure limited, and time cycled. One difference between devices is that the Siemens 300 only allows PRVC in the CMV mode. The newer Servo-i ventilator and the other ventilators allow dual control breath to breath with CMV or SIMV. During SIMV, the mandatory breaths are the dual control breaths. PRVC is selected on the mode selector switch, and the desired tidal volume is set. A "test breath" is delivered, and total system compliance is calculated. The next three breaths are delivered at a pressure limit that is 75% of that necessary to achieve the desired tidal volume on the basis of the compliance calculation. The ensuing breaths increase or decrease the pressure limit at less than 3 cm H_2O per breath in an attempt to deliver the desired tidal volume. The pressure limit fluctuates between 0 cm H_2O above the PEEP level and 5 cm H_2O below the upper-pressure alarm setting. The ventilator sounds an alarm if the tidal volume and maximum pressure limit settings are incompatible. With changes in lung compliance and resistance, the delivered tidal volume may not be equivalent to the set tidal volume. If the delivered tidal volume is less than the set tidal volume, the pressure-limit is increased to achieve the set tidal volume until the pressure limit is equal to a level 5 cm H_2O below the upper pressure limit alarm. The upper pressure-limit alarm must be adjusted with this in mind. It should be set to the maximum allowable pressure plus 5 cm of H_2O. When the delivered tidal volume is larger than the set tidal volume, then the ventilator will lower the pressure limit to achieve the set tidal volume. There is no lower limit for the reduction in the pressure-limit level. This mode of ventilation appears to be most beneficial when there are rapid changes in lung compliance (such as after surfactant administration).[41-43] Clinically controlled trials are required to evaluate the benefits of PRVC ventilation in acute lung disease, in ventilation of healthy lungs (i.e., in patients undergoing neurosurgical procedures), and during weaning from the ventilator.

Assisted Dual-Control Breath-to-Breath Mode. Dual-control breath to breath in the pressure support mode is simply closed-loop pressure support ventilation, with tidal volume as the input variable. It is referred to as volume support (Siemens 300) and variable pressure support (Venturi). All breaths are patient triggered, pressure limited, and flow cycled. Volume support is selected with the mode selector switch, and the desired tidal volume is set. The ventilator initiates volume support by delivering a "test breath" with a peak pressure of 5 cm H_2O when a patient effort is sensed. The delivered tidal volume is measured, and total system compliance is calculated. The subsequent three breaths are delivered at a peak inspiratory pressure of 75% of the pressure calculated to deliver the minimum tidal volume. Each subsequent breath uses the previous calculation of system compliance to manipulate peak pressure to achieve the desired tidal volume. From breath to breath, the maximum pressure change is less than 3 cm H_2O and can range from 0 cm H_2O above PEEP to 5 cm H_2O below the high-pressure alarm setting. The primary cycling mechanism is flow cycling of the pressure-supported breath. Similar to the PRVC mode previously described, the pressure-support level is adjusted to maintain the set tidal volume with changes in compliance and resistance. In addition to the

volume-support settings, a mandatory ventilator frequency must be set. This frequency is set according to the age of the patient; the frequency for ages younger than 6 months is 16 to 20 breaths per minute; for 6 months to 2 years, 14 to 18 breaths/min; for 2 to 5 years, 12 to 16 breaths/min; and for older than 5 years, 10 to 16 breaths/min. A secondary cycling mechanism is activated if inspiratory time exceeds 80% of the set total cycle time. There is also a relationship between the set ventilator frequency and tidal volume. The minute ventilation calculated by the set tidal volume and the backup ventilator rate gives the minimum minute ventilation that needs to be achieved. If the patient is breathing at a frequency faster than the set ventilator rate, then the only adjustment that is made by the ventilator is to manipulate the pressure-support level to achieve the desired tidal volume. The total minute ventilation in this instance will be larger than the minimum level that needs to be achieved. When the patient's breathing rate is less than the set frequency, then the total minute ventilation will decrease to a level below the set minimum level. Then, the tidal volume target is automatically increased by raising the pressure-support level up to a maximum of 150% of the initial set value. If the tidal volume has to be increased beyond the 150% of the initial set value or the minute ventilation cannot be maintained at the set minimum level, then the ventilator will alarm and switch to the PRVC mode to ensure that at least the set minimum minute ventilation is delivered.

AutoMode

AutoMode combines mandatory and assisted dual-control breath-to-breath modes. The patient's effort or lack of breathing effort determines whether the breaths are flow cycled or time cycled. AutoMode is available on the Siemens 300A ventilator. Simplistically, AutoMode can be thought of as the combination of volume support and PRVC in a single mode. When the patient is breathing spontaneously, then the patient is in volume-support mode. If the patient becomes apneic or is paralyzed, the ventilator provides PRVC. The apneic threshold setting is 12 seconds for adults, 8 seconds for children, and 5 seconds for neonates. The change from PRVC to volume support or from volume support to PRVC is accomplished at equivalent peak pressures.

Automatic Tube Compensation

Automatic tube compensation (ATC) is a technique of overcoming the imposed work of breathing caused by artificial airways available in the Evita 4 ventilator. It accomplishes this by using the known resistive characteristics of the artificial airways. ATC is essentially pressure support in which the ventilator adjusts the pressure support to compensate for the imposed work of breathing by the artificial airways and the flow demand of the patient. The equation for calculating tracheal pressure (P_{trach}) is $P_{trach} = P_{aw} - (K \times V^2)$, where P_{aw} is airway pressure, V is flow, and K is the tube coefficient describing the nonlinear pressure/flow curve of the ETT.

To select the level of ATC required, the operator needs to input type of tube, endotracheal or tracheostomy, and the percentage of compensation desired (10% to 100%). Most of the interest in ATC revolves around eliminating the imposed work of breathing during inspiration. Under static in vitro conditions, pressure support can eliminate the endotracheal resistance, but in vivo, where the inspiratory flow demands of the patient are changing, a single level of pressure support is unlikely to be effective. Moreover, there are no in vivo measurements of the minimal pressure support needed to overcome the endotracheal tube resistance. During periods of tachypnea, the level of pressure support no longer eliminates work imposed by the endotracheal tube. Additionally, the resistance of the endotracheal tube creates a condition early in the breath in which ventilator flow is high, tracheal pressure remains low, and undercompensation for imposed work occurs.[44] Late in the breath, when pressure begins to equilibrate during the pressure plateau, pressure support tends to overcompensate, prolong inspiration, and exacerbate overinflation.[44] During expiration, however, there is also a flow-dependent pressure decrease across the tube. ATC also compensates for this flow-resistive component and may reduce expiratory resistance and unintentional hyperinflation. During expiration, the calculated tracheal pressure is greater than airway pressure.

Proportional Assist Ventilation

Proportional assist ventilation (PAV) is a mode of mechanical ventilation that is based on the equation of motion. The design of PAV allows the ventilator to change the pressure output (pressure control) to always perform work proportionally to patient effort. PAV is simply PSV in which the level of pressure support is adjusted as a multiple of the sum of the volume and flow signals. The ventilator tries to maintain a constant percentage of work performed by the patient per breath irrespective of the volume of the breath or the inspiratory flow of the breath. Currently, there are major issues of interface and accurate breath-to-breath measurement of elastance and resistance and the need to take into account the confounding effects of endotracheal tube resistance, level of auto-PEEP, and the problem of nonlinearity of elastance and resistance.

High-Frequency Ventilation

Definitions

High-frequency ventilation (HFV) refers to diverse modes of ventilation characterized in general by supraphysiologic ventilatory frequencies (>60 cycles/min) and low tidal volumes (less than or equal to physiologic dead space during conventional ventilation). Four distinct methods of HFV are recognized: high-frequency positive pressure ventilation (HFPPV), high-frequency jet ventilation (HFJV), high-frequency oscillatory ventilation (HFOV), and high-frequency chest wall oscillation (HFCWO).

1. **HFPPV** was first described by Oberg and Sjostrand[45] in 1969 and refers to ventilation at a frequency of 60 to 100 cycles/min with a tidal volume of 3 to 4 mL/kg using a ventilator with a small internal dead space, low internal compliance, and minimal compression of gases within the ventilator. HFPPV was initially instituted by insufflation through a catheter positioned within the endotracheal tube, with expiration occurring through an expiratory valve connected to the outer orifice. Since 1973, a pneumatic valve, based on the Coanda or wall effect, was developed in which the gas mixture was intermittently delivered through a sidearm branching off the main channel of the pneumatic valve connector (Figure 49-16). This main channel remains open for insertion of a bronchoscope or a laryngoscope.

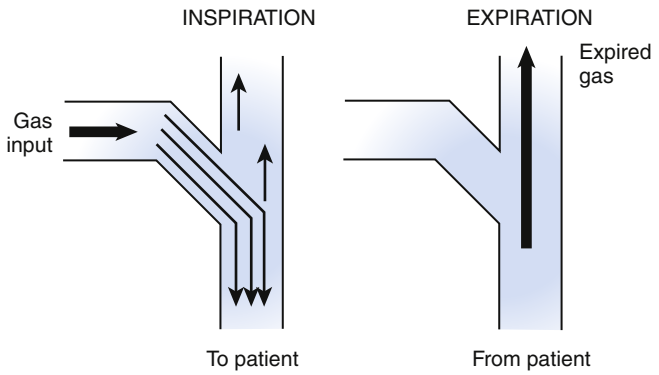

Figure 49–16. High-frequency positive-pressure ventilator. The inspiratory limb is angled so that the inspiratory gas can be directed to the patient. During inspiration, some gas escapes through the expiratory limb, preventing entrainment. During expiration, the gas flows out into the expiratory limb. *(From Shoemaker WC, Ayres S, Grenvik A, et al editors:* The textbook of critical care, *Philadelphia,1989, WB Saunders.)*

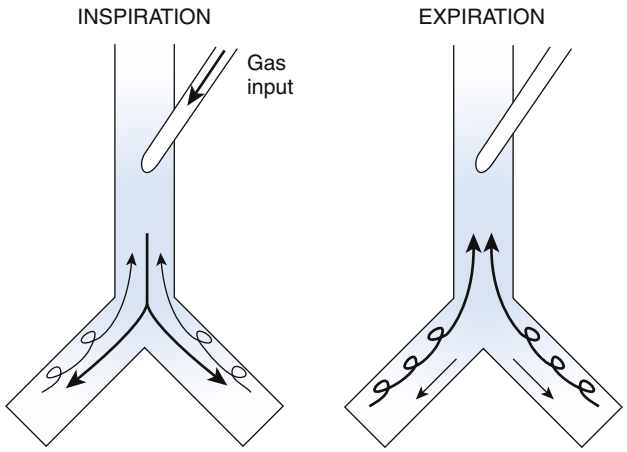

Figure 49–17. High-frequency jet ventilator. Gas is introduced into the trachea at a high pressure through a small catheter. *Arrows* represent coaxial and turbulent flow patterns. *(From Shoemaker WC, Ayres S, Grenvik A, et al editors:* The textbook of critical care, *Philadelphia, 1989, WB Saunders.)*

2. **HFJV,** which was first described by Sanders[46] in 1967 to assist bronchoscopy, refers to delivery of inspiratory gases through a jet injector at a high velocity into the trachea at a rate of 100 to 400 cycles/min (Figure 49-17). Tidal volumes delivered are usually 3 to 5 mL/kg.
3. **HFOV** was first described by Lunkenheimer[47] in 1972 and refers to ventilation at frequencies of 900 to 3600 cycles/min, with an alternating positive and negative pressure in the airway. This oscillatory flow may be produced by a piston pump or a diaphragm with tidal volumes of 1 to 3 mL/kg (Figure 49-18).
4. **HFCWO** was first described by Zidulka et al.[48] in 1983 and refers to a method of ventilation in which a rigid harness surrounds the chest and is oscillated at a frequency of 180 to 600 cycles/min; minute ventilation is controlled with adjustment of the inflation pressure and frequency. A variant of HFCWO is high-frequency body surface oscillation (HFBSO), in which the body is encased in an air-tight tank.

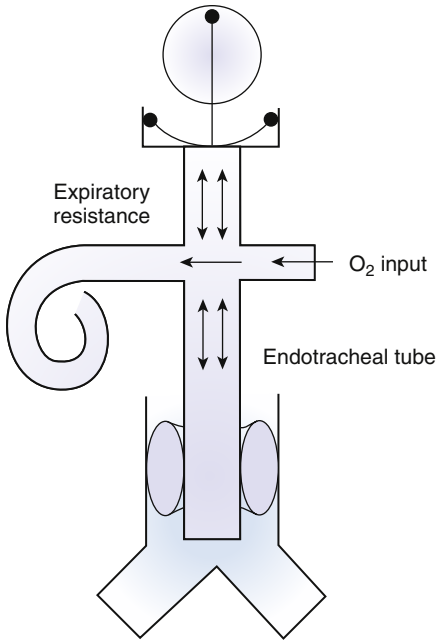

Figure 49–18. High-frequency oscillation system. Uses a reciprocating pump (*top*) to oscillate a column of gas that is a mixture of inspired and expired gases. Excess gas is vented through the overflow side port (*left*). *(From Shoemaker WC, Ayres S, Grenvik A, et al editors:* The textbook of critical care, *Philadelphia, 1989, WB Saunders.)*

Only HFPPV, HFJV, and HFOV have been extensively used clinically.

Mechanism of Gas Flow in High-Frequency Ventilation in the Normal Lung

The exact mechanism of gas transport in HFV is currently not clear. It is possible that each mode of ventilation may have differing mechanisms of gas flow from the proximal airway to the alveoli. If gas flow to the lungs is increased more than 200 times the minute volume of oxygen demand, the lung parenchyma can be made to oscillate.[49,50] At ventilatory frequencies less than 7 Hz, regional alveolar ventilation depends on segmental compliance and airway resistance. At a ventilatory frequency greater than 7 Hz, a frequency-dependent excitation of the lung parenchyma and airway conduits occurs,[51] and at frequencies greater than 10 Hz, ventilation becomes independent of regional compliance. When the gas in the airways is oscillated at high frequency, the airways begin to undergo spatial oscillation inside the chest. These oscillations are composed of periodic changes in length and width, movements of curved or angular bronchi, and wave motions in the bronchi. When the frequency of oscillation approaches the natural resonant frequency of the lung structures, the oscillations of the airways, and the lung parenchyma are amplified. These result in shaking and squeezing of the neighboring parenchyma, resulting in intraparenchymal and interparenchymal gas mixing.[52] Other mechanisms involved in gas transport during HFV include accelerated axial dispersion, increased collateral flow through pores of Kohn, intersegmental gas mixing or Pendelluft phenomenon, Taylor dispersion, asymmetric gas flow profiles, and gas mixing within the airway from the nonlinear pressure-diameter relationship of the bronchi.

Parameters to Be Selected

High-Frequency Jet Ventilation

The main controls in HFJV are the driving pressure inspiratory time, and rate. The driving pressure is usually initiated at a desired mean airway pressure and adjusted according to the level of lung expansion and gas exchange. Inspiratory time is usually kept to a minimum at 20%. A higher inspiratory time may be used but may result in air-trapping. The rate can be adjusted up to 600 breaths per minute depending on the jet ventilator used. PEEP is applied through a separate bias flow circuit with continuous flow. Fio_2 delivered to the patient is adjusted through regulation of the inspired oxygen concentration of the bias flow circuit. In certain circumstances, conventional ventilation can be combined with HFJV. Here, conventional ventilation provides "sigh breaths" of approximately 10 to 12 mL/kg to prevent atelectasis and maintain lung volumes during HFJV. The size of each breath increases with a higher driving pressure, increased inspiratory time, and a decreased frequency. Because there is entrainment of gas with HFJV, it is difficult to predict the effect of ventilator parameters on minute ventilation. Ventilation is most effective when the jet catheter is close to the carina. The main concerns with HFJV are airway injury and air-trapping. Airway injury can be minimized with placement of the tip of the catheter sufficiently proximal in the endotracheal tube and without close placement close to the carina. Air-trapping can be avoided with the minimal inspiratory time and the lowest driving pressure.[53]

High-Frequency Oscillatory Ventilation

Currently, the HFOV systems available in North America are the Viasys Critical Care 3100A and 3100B ventilators. The main difference between the two ventilators is the age range each of them supports. The 3100A is designed to support HFOV in neonates and small children. The 3100B is designed to support older children and adults weighing more than 35 kg. Input power for both the ventilators requires two pneumatic gas sources and one electrical source. The first pneumatic connection through a blender determines the Fio_2 delivered to the patients. The second pneumatic connection is for cooling the oscillator. The drive mechanism is a square-wave driver which has an electric linear motor and a piston. The stroke of the piston (both positive and negative) determines the amplitude. The position of the piston determines the mean airway pressure of the circuit.

The main controls in HFOV are mean airway pressure, oscillatory pressure amplitude, bias flow, frequency, and inspiratory time. With piston-driven oscillators, piston-centering is an additional control mechanism. Mean airway pressure determines the mean lung volume of the lung. Oscillatory amplitude is the total change in pressure around the mean airway pressure produced by forward and backward displacement of the piston. The pressures developed in the patients' airways are considerably dampened because of the impedance of the endotracheal tube. Similarly, the pressure profile is further dampened in the distal airways because of the impedance of the proximal airways. If the oscillatory frequency approaches the natural resonant frequency of the lung and airways, then there may be amplification of the pressure waves. The oscillatory amplitude determines the volume displacement with each stroke of the piston. If the volume of gas displaced is less than the dead space of the airways and lungs, then there is little chest displacement. If sufficient chest displacement is seen with each stroke, then the volume of gas displaced tends to be larger than the physiologic dead space and results in some direct alveolar ventilation. Frequency is the next parameter that can be controlled and is usually in the range of 5 to 10 Hz. For a given amplitude, a lower frequency will result in less attenuation of pressures along the airways and improve gas exchange. Inspiratory time is generally controlled at 33% of the total cycle time. In certain circumstances, a lower inspiratory time may be used. Bias flow is a continuous flow of fresh humidified gas and allows replenishing oxygen and removing carbon dioxide from the circuit. Determinants of oxygenation during HFOV are mean airway pressure and Fio_2. Minute ventilation during HFOV is directly proportional to the frequency and the square of the tidal volume. Tidal volume is determined by the amplitude and the duration of each stroke. With increased frequency, the time for each stroke is reduced, decreasing the tidal volume. When the ventilatory frequency is decreased, this increases the time for each stroke and thereby increases the tidal volume. The primary determinant of ventilation is oscillatory amplitude. Decreasing the frequency to reduce attenuation and increasing the inspiratory time are less effective strategies to improve carbon dioxide elimination.

High-Frequency Percussive Ventilation

High-frequency percussive ventilation (HFPV), a newer mode introduced during the past 20 years, combines the beneficial effects of HFV with conventional ventilatory support.[54-56] HFPV has been described as an exceptionally versatile form of HFV that delivers subphysiologic tidal volumes at rapid rates (up to 500 breaths/min) using the volume-diffusive respirator.[54-56] It has been shown to provide the same or improved oxygenation and ventilation at lower peak, mean, and end-expiratory pressures when compared with conventional ventilation.[54-56]

The high-frequency percussive ventilator (Percussionaire, Bird Technologies, Sandpoint, Idaho) is a pneumatically powered, time-cycled, and pressure-limited ventilator with inspiratory and expiratory oscillation. The ventilator is connected to a high pressure flow generator, fed by an air-oxygen blender. Two inspiratory circuits come off the ventilator—one a high-pressure and the other a low-pressure circuit. The low-pressure circuit is connected to the humidifier and a nebulizer system. The humidifier and nebulization system provides a gas mixture that is appropriately heated and fully humidified. The high-pressure circuit is a low compliant tubing. Both the circuits attach to a system called the Phasitron, which is a sliding Venturi that acts as both an inspiratory and expiratory valve. The phasitron is driven by a high-pressure gas supply at a high-frequency rate of 200 to 900 beats/min superimposed on a conventional I/E pressure-controlled cycle that is set at a desired rate. From the Phasitron, there are two branches—one is the inspiratory limb that attaches to the endotracheal tube and the other an expiratory limb. The Phasitron consists of a hollow cylinder in which there is a spring-controlled piston which is driven by the high-pressure circuit. There are two safety valves, one inspiratory and one expiratory that regulate the pressure delivered to the airway. There are seven control variables: (1) peak inspiratory pressure,

(2) positive end-expiratory pressure, (3) continuous positive airway pressure, (4) inspiratory time, (5) expiratory time, (6) percussive frequency, and (7) rate. The tidal volume delivery is a product of the PIP setting and subtidal volumes produced by the oscillatory function. During inspiration, lung volumes are progressively increased in a controlled, stepwise fashion by repetitively diminishing subtidal volume deliveries until an oscillatory plateau is entered and maintained.[4] At the end of inspiration, the lung is allowed to empty passively until the preset expiratory baseline is reached. Gas exchange has been noted to be as good, if not better, than CV at lower airway pressures. The endotracheal tube cuff should be left partially deflated to allow for a continuous air leak through the trachea.

Clinical Uses of High-Frequency Ventilation

The principal theoretical advantage for the use of HFV lies in the ability to ventilate effectively at low airway pressures. The most common use of HFV is in the operating room for use in airway operations; in laryngoscopies; in bronchoscopies; and in emergency airway management, in which airway movement has to be reduced to a minimum.[53] HFV has been used to manage neonates with idiopathic respiratory distress syndrome with the goal of decreasing the incidence of pulmonary barotrauma. Initial studies showed improvement in gas exchange with lower airway pressures, provided periodic sigh maneuvers were performed.[57-60] HFV has been also been shown to support adequate gas exchange with severe pulmonary interstitial emphysema (PIE) in neonates.[61,62] The initial enthusiasm for HFOV as a method for reducing pulmonary barotrauma in premature neonates with idiopathic respiratory distress syndrome requiring mechanical ventilation has been tempered by a recent multicenter trial in which HFOV did not prove to be superior to conventional mechanical ventilation.[63] One area of relatively proven benefit of HFV is in the management of bronchopleural fistulae. HFJV has proven useful in the management of bronchopleural fistula, with consistent improvement in arterial blood gas, when conventional ventilation had previously failed.[64] Recent studies have suggested a role for HFV in children after cardiac surgery and with ARDS.[65-70] HFJV has been shown to improve cardiac function after a Fontan procedure.[65] HFJV and HFOV have been shown to improve oxygenation and ventilation compared with conventional ventilation in children with respiratory failure.[67-70]

The most common approach to HFOV in infants and children is as a rescue therapy when conventional mechanical ventilation proves to be insufficient to recruit the lungs and maintain adequate gas exchange. There are many reported strategies with the use of HFV: (1) "high lung volume strategy," which requires HFV to be provided at a mean airway pressure that is at least 3 to 5 cm higher than with conventional ventilation; (2) combined HFV and conventional ventilation (usually used with HFJV), in which conventional tidal breaths are interposed during HFV usually at a rate of 5 to 8 breaths/min; or (3) application of HFV at the same mean airway pressure as conventional ventilation. The high lung volume strategy seems to be the most promising one at least for HFOV. When transitioning the patient to HFOV from conventional ventilation, the mean airway pressure on HFOV is set to 3 to 6 cm H_2O above the mean airway pressure on conventional ventilation. It is important to recruit the lung before placing the patient on HFOV. Amplitude is set by adjusting the Power control while observing for adequacy of chest wall vibrations. The goal for oxygenation is to employ a mean airway pressure that will allow reduction of Fio_2 to at least 0.6 while maintaining an arterial oxygen saturation of at least 90%. This may require titrating the mean airway pressure from the initial setting. Adequacy of lung recruitment is usually verified by ensuring that both hemidiaphragms are displaced to the level of the ninth posterior rib on a chest radiograph. After an appropriate degree of lung inflation as well as patency of the endotracheal tube are verified, ventilation needs to be addressed. Arterial $Paco_2$ can be maintained at the desired level by changing the amplitude or frequency. Ventilation is increased by an increase in amplitude and a decrease in frequency. It is also important to deflate the cuff of the endotracheal tube, if a cuffed tube is used. Adjusting the bias flow can also aid in ventilation but is seldom done in routine clinical practice.

Case series in neonates with respiratory failure showed that HFPV can result in improvement in oxygenation and ventilation with a reduction in Fio_2 and PEEP requirements.[71-73] One other purported advantage to HFPV is the mobilization of secretions. This has generated much interest from the burn community, particularly for the treatment of children and adults with inhalation injury.[74-80] Two prospective, randomized trials of HFPV have been reported in the pediatric burn population. Compared with the conventional ventilation, HFPV resulted in similar ventilation and improved oxygenation at significantly lower peak inspiratory pressures. Pneumonia and mortality rates were lower in the high frequency group.[75,76]

Approach to Mechanical Ventilation Based on Underlying Pathophysiology

Primary Respiratory Muscle Failure ("Respiratory Pump Failure")

The primary difficulty in these disorders is inadequate ventilation due to weakness of the respiratory muscles (pump failure). Tidal volumes and ventilatory rates are set to provide normal minute ventilation to maintain normocarbia. Complete control of ventilation may result in disuse muscle atrophy and complicate weaning from mechanical ventilation; therefore spontaneous breathing should be encouraged as much as possible. Assisted ventilation is a useful mode of ventilation in these disorders because the trigger sensitivity can be adjusted to encourage spontaneous breathing on the one hand and prevent muscle fatigue on the other. Fio_2 is usually kept to a minimum because these disorders are not associated with inadequate oxygenation. In chronic hypoventilation, hypercarbia is often acceptable, provided the arterial pH is within the normal range. PEEP is usually set at a relatively low level (3 to 5 cm H_2O).

Disorders with Airway Obstruction

Provision of an artificial airway relieves respiratory distress because of upper airway obstruction (e.g., epiglottitis, croup). Respiratory failure from lower airway obstruction poses a

special problem during mechanical ventilation. Depression of cardiac output and hypotension may occur during intubation because of the institution of positive airway pressure to already hyperinflated lungs. This causes further impedance to venous return and increased pulmonary vascular resistance. Volume-controlled ventilation is the preferred mode of ventilation. Inspiratory-expiratory ratio should be at least 1:2. The expiratory time required depends on the severity of the lower airway obstruction. If the expiratory time is inadequate to empty the lung, "auto-PEEP" or "inadvertent PEEP" will result. Inadvertent PEEP results in air-trapping and hyperinflation with its attendant complications. The level of PEEP selected for patients with lower airway obstruction is controversial. There are two schools of thought: "low PEEP" and "high PEEP." Low PEEP advocates usually apply a PEEP of 3 to 5 cm H_2O because of the concern for pulmonary barotrauma from air-trapping and alveolar hyperinflation. In lower airway disease, air-trapping often results in an end-expiratory alveolar pressure that is higher than the proximal airway pressure because of incomplete emptying of the alveoli. This results in "auto-PEEP" or "inadvertent PEEP." End-expiratory lung volume and therefore the level of alveolar inflation will not be affected by the level of proximal set PEEP as long as it is less than the amount of auto-PEEP. In adults with severe asthma, high levels of PEEP, which is closer to the level of auto-PEEP, have been shown to decrease the magnitude of air-trapping and work of breathing without significant complications.[81-83] In children with tracheomalacia or bronchomalacia, PEEP decreases the airway resistance by distending the airways and preventing dynamic compression during expiration. The use of low levels of PEEP compared with high levels has been described previously.

Parenchymal Lung Disease

ARDS, idiopathic respiratory distress syndrome, and interstitial pneumonias are examples of parenchymal lung disorders that are characterized by a reduction in FRC, an increase in closing volume higher than FRC, and diffuse subsegmental atelectasis. These diseases are characterized primarily by inadequate oxygenation because of V/Q mismatching and intrapulmonary shunting. Therapy should be directed toward maintaining lung volumes higher than closing volume throughout the respiratory cycle, increasing FRC higher than closing volume, and reducing V/Q mismatching and intrapulmonary shunting. The most effective method of achieving these goals is with an increase of mean lung volume, which is usually obtained with an increase of the mean airway pressure. During spontaneous breathing without any ventilatory assistance, CPAP is the most reliable method to increase lung volume. CPAP is effective in improving oxygenation in idiopathic respiratory distress syndrome[14] and ARDS.[84,85] During positive-pressure breathing, the level of PEEP required to maintain adequate oxygenation primarily depends on the severity of the underlying lung disease. The degree of intrapulmonary shunting, ventilation-perfusion mismatching, alveolar edema, alveolar collapse, and decreased compliance is directly proportional to the severity of lung disease. As the severity of lung disease increases, the airway pressures required to maintain adequate gas exchange also increase. Therefore arbitrary limits cannot be placed on the level of PEEP or mean airway pressure that will be necessary to maintain adequate gas exchange. Tidal volumes should be limited to 6 to 8 mL/kg. Studies in adults, including the ARDSNetwork study, have demonstrated that using high tidal volumes of 12 ml/kg is detrimental to patient outcome.[86,87] When high levels of PEEP are used, PIP may reach levels that contribute to pulmonary air leak and barotrauma. Attempts to decrease PIP with the reduction of tidal volume will result in decreased mean airway pressure, mean lung volume, and decreased minute ventilation. With a high airway pressure maintained throughout inspiration, pressure-control ventilation may provide higher mean airway pressure and maintain a higher mean lung volume compared with volume-control ventilation. A general rule of thumb is to consider switching to pressure-limited time-cycled ventilation when PEEP requirement is more than 10 cm H_2O. For hyperinflation to be avoided, the end-inspiratory pause pressure should not exceed 35 cm H_2O. Hypercapnia may be permitted under these circumstances provided arterial pH is adequate (permissive hypercapnia). It has been recommended that the optimal PEEP should be set above the critical closing or critical opening pressure of the airways. This can be deduced by the lower inflection point generated with static pressure-volume loops (Figure 49-19). As the lung is inflated from zero end-expiratory pressure, in many lungs there is an abrupt change in compliance as denoted by the "lower inflection point." It is generally thought that this is the critical opening pressure of the airways above which the alveoli and airways remain open. As the lung is further inflated in increments, the pressure-volume slope increases and then abruptly changes direction as noted in Figure 49-19 as the "upper inflection point." It is generally thought that the upper inflection point reflects overdistension of the alveoli. The general recommendation is to keep the PEEP level above the lower inflection point and to keep the end-inspiratory pause pressure below the upper inflection point. Currently, bedside use of static pressure-volume loops to set PEEP is not a standard practice in infants and

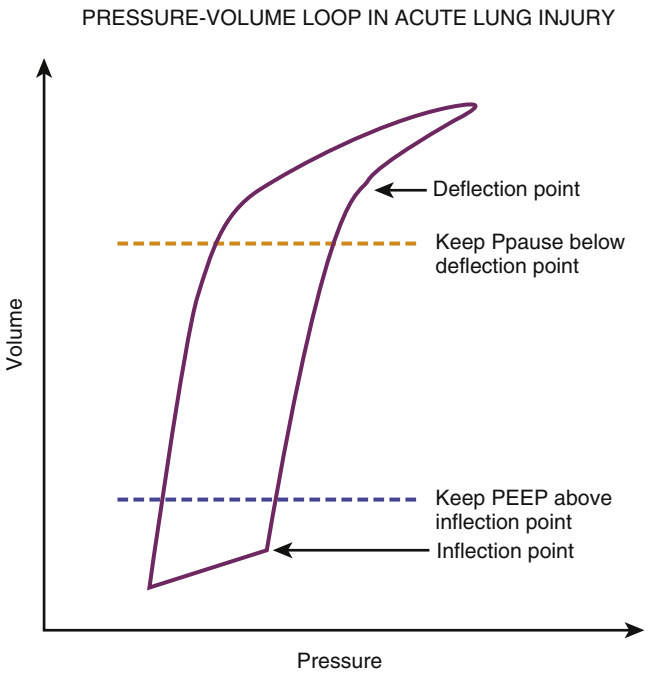

Figure 49–19. Optimal PEEP and peak alveolar pressure setting in ALI/ARDS on the basis of static pressure-volume loop. The goal is to keep the PEEP level above the lower inflection point and to keep the end-inspiratory pause pressure below the upper inflection point.

children. Therefore the level of PEEP should be set by titrating the level of PEEP and selecting the level by the maximal level of improvement in oxygenation compliance seen without affecting systemic hemodynamics. The repeated collapse and reopening of the lung units at low lung volume have been shown to contribute to ventilation-induced lung injury.[88-91] A strategy combining recruitment maneuvers, low-tidal volume, and higher PEEP has been shown to decrease the incidence of barotrauma or volutrauma.[88-91]

Alveolar Recruitment and Derecruitment

Alveolar recruitment with maintenance of lung volume by preventing derecruitment during mechanical ventilation is a goal in ventilating the lungs of patients with ALI and ARDS. The benefits of optimal lung recruitment and prevention of derecruitment are (1) a reduction in the intrapulmonary shunt fraction and venous admixture resulting in an improvement in arterial oxygenation; (2) improvement in lung compliance; and (3) prevention of repeated alveolar collapse and reopening, which may ameliorate or prevent ventilator-induced lung injury. The primary determinants of alveolar recruitment and derecruitment are transpulmonary pressure and PEEP both of which increase mean airway pressure. Mean lung volume depends on mean alveolar pressure. Mean airway pressure has been shown to be an excellent marker of mean alveolar pressure.[93] Increasing mean airway pressure will improve oxygenation if there is alveolar recruitment. Several techniques of alveolar recruitment have been described in the literature. These include manual inflation to high airway pressures, the increase of PEEP in a stepwise manner, application of a sign maneuver, the use of pressure-limited time-cycled ventilation with a high peak inspiratory pressure, and the combination of titrated levels of PEEP with increased inflation pressures. Ventilatory sighs are effective in recruiting alveoli in ARDS.[94] They are effective, however, only from an optimal level of PEEP that does not result in derecruitment. At optimal PEEP, a sigh maneuver increases end-expiratory lung volume and improves oxygenation.[95] Gattinoni et al.[96,97] showed and quantified alveolar recruitment induced by PEEP and showed that the primary role of tidal volume inflation was to open the lung and the primary role of PEEP was to avoid derecruitment. Not all patients have recruitable lungs. In some patients, the lungs may be maximally recruited and any further increase in airway pressures may either cause no change in lung mechanics or gas exchange or result in a deterioration of lung mechanics and gas exchange due to overdistension.[98] The low tidal volume and moderate PEEP approach used in the ARDSNetwork study has been shown to result in derecruitment in many patients. Richard et al. showed that increasing PEEP or performing periodic recruitment techniques counteracted the derecruitment in these patients.[99] Periodic high levels of PEEP, high inflation plateau pressures, or both have shown to be beneficial in improving lung mechanics and oxygenation, through alveolar recruitment.[100-102]

Prone Positioning

Prone positioning has been proposed as a means to improve gas exchange in patients with ARDS with severe hypoxemia. Oxygenation improves in most adult patients with ALI/ARDS when they are placed prone.[103-107] A large, multicenter trial of prone positioning for almost 7 hours per day did not show improvement in mortality rates in patients with ALI/ARDS; however, a post hoc analysis suggested improvement in those patients with the most severe hypoxemia.[106] A recent multicenter trial of prone positioning for almost 20 hours a day also suggested improvement in this patient subgroup that did not reach statistical significance.[108] Bruno et al.[109] reported the short-term effects of 1 to 2 hours of prone positioning in children with respiratory failure. They found that only 28% of the patients had a significant improvement in oxygenation.[109] Curley et al., in a preliminary single-center study in children with ALI/ARDS, showed that oxygenation improved with prone positioning in 84% of patients without any critical incident.[110] Relvas et al.[111] also reported a retrospective study on the effects of prone positioning in children with ARDS and showed that the improvement in oxygenation was much more sustained if the duration of prone positioning was between 18 and 24 hours than when the duration of prone positioning was between 6 and 10 hours. A recent multicenter study on prone positioning in children with ALI/ARDS showed that patient recruitment within 48 hours of meeting acute lung injury criteria, prone positioning for 20 hours per day for a maximum of 7 days did not show any differences in the number of ventilator-free days between the two groups. There were no differences in the secondary endpoints, including proportion alive and ventilator-free on day 28, mortality from all causes, the time to recovery of lung injury, organ failure–free days, and cognitive impairment or overall functional health at hospital discharge.[112]

Although some patients benefit by an improvement in oxygenation, there are no data on its efficacy in improving patient outcome. Although the magnitude of the response varies widely from marginal to dramatic, there is no adequate model predicting where a particular patient with ARDS will fall in the spectrum. Furthermore, patients' response times vary from immediate to several hours. As a result, little is known about the optimal time period to maintain the prone position. Some patients respond to a return to a supine position after a trial of prone positioning by reverting to their original oxygenation, others have a reduction in oxygenation that is better than the original supine value, and some patients show an improvement. Prone positioning may have potentially life-threatening complications, including accidental dislodgement of the endotracheal tube and central venous catheters. Marcano et al. reported that prone positioning resulted in cephalad movement of the endotracheal tube within the trachea in children with ARDS ranging from 10% to 57% of their thoracic tracheal length.[113] Their study also suggested that if the tip of the endotracheal tube is not deeper than one third of the thoracic tracheal length before prone positioning, it might slide into the cervical trachea as a result of prone positioning.[113]

Unilateral Lung Disease or Severely Differential Lung Disease

Unilateral or asymmetric lung disease in infants and children poses special problems during mechanical ventilation. Some of these patients may have severe intrapulmonary shunts leading to hypoxemia requiring mechanical ventilation. Because of regional differences in compliance and resistance, the time constants for inflation and deflation may vary widely between

lung segments. During conventional ventilation, tidal volume delivered tends to preferentially inflate the more compliant lung and underventilate the stiffer, more affected lung. This may result in overinflation of the relatively "normal" lung and cause redistribution of pulmonary blood flow away from the hyperinflated lung, thus exaggerating the ventilation-perfusion mismatching. Such overinflation may contribute to further barotrauma. In such circumstances, with unilateral or asymmetrical lung disease, simultaneous independent lung ventilation (SILV) may allow each lung to be ventilated according to its needs without affecting the opposite lung. Currently, independent lung ventilation (ILV) can be generally indicated in the treatment of unilateral lung disease, such as unilateral atelectasis or consolidation, emphysema, pneumonia, pneumothorax, and bronchopulmonary fistula, and postoperative care, ILV can be used for lung reexpansion after thoracic surgery, for correction of V/Q mismatch in the lung remaining dependent during surgery, and for the treatment of pulmonary complications arising during anesthesia and surgery (e.g., pneumothorax or aspiration syndrome).[67-73] A new possible indication for ILV can be the selective administration of drugs to one lung, such as antibiotics or surfactant. SILV requires a bilumen tube with one tube being the longer "bronchial" tube and the other shorter "tracheal" tube. Usually, the bronchial tube is advanced into the right main stem bronchus so that both lungs can be ventilated separately. In adults, SILV has been shown to be useful in the treatment of unilateral lung disease.[114-117] In infants and children, SILV has been limited because of the lack of a suitable bilumen tube. Marraro[118] reviewed their experience with SILV in infants and children younger than 1 year with a bilumen tube developed in their department, but it is currently available through Portex Ltd. (Mythe, Kent, UK). The indications included bronchopneumonia with unilateral prevalence, unilateral pneumonia, lobar atelectasis, and diaphragmatic hernia. Nine of 41 patients treated with SILV had rapid improvement in lung disease, whereas the other 32 recovered more slowly. No major complications were attributed to SILV. In newborns and infants, it is possible to provide ILV with a double-lumen endotracheal tube manufactured by Portex as special equipment. In children older than 6 to 8 years, selective bronchial intubation is possible using a cuffed double-lumen tube similar to that used in adults (26- to 28-Fr Bronchocath Mallinckrodt, Broncho-port Rusch). The Marraro Paediatric Endobronchial Bilumen Tube, produced by SIMS-Portex, may be used in neonates and children age 2 to 3 years.[119] It is uncuffed to maximize the internal diameter of the tube and has no carinal hook; this minimizes tracheal trauma.[118-120] ILV requires two ventilators that permit the application of different modes of ventilation and different PEEP levels for each lung. Synchronization of the beginning of the inspiratory phase and the inspiratory time can avoid mediastinal shifts that impede venous return and reduce cardiac output.[118-120]

Heart Failure

The goals in respiratory management in congestive heart failure are prevention and relief of alveolar collapse from alveolar and interstitial edema from pulmonary vascular congestion, as well as decreased oxygen demand on the heart with a reduction in the work of breathing. CPAP/PEEP will provide relief of atelectasis. Hyperinflation should be avoided because it may increase pulmonary vascular resistance and increase right ventricular afterload. The oxygen cost of breathing can be reduced with a decrease in the work of breathing. This can be provided by a judicious combination of controlled ventilation and sedation. By unloading the respiratory muscles, mechanical ventilation can also reduce the work of breathing. In extreme cases, muscle relaxation by neuromuscular blockers may provide additional reduction in oxygen cost of breathing. As a general principle, the greater the inotropic support a heart needs, the greater should be the respiratory support provided. Tidal volumes should be generally maintained on the lower range (8 to 12 mL/kg). In adults with congestive heart failure, positive intrathoracic pressure has been shown to improve cardiac output.[121,122] This effect has been attributed to decreased left ventricular afterload provided by positive airway pressure.

Postoperative Management After Repair of Congenital Heart Disease

After open heart surgery, many infants and children require mechanical ventilation during the postoperative period. The duration of requirement of mechanical ventilation depends on several factors such as age of the patient, complexity of the cardiac lesion, complexity of the operative procedure, duration of bypass, duration of circulatory arrest, and postoperative cardiopulmonary status. Prolonged intubation and mechanical ventilation are more likely in children younger than 1 year of age, with more complex heart lesions, prolonged bypass and prolonged circulatory arrest times, and postoperative respiratory failure and hemodynamic instability. In the immediate postoperative period, patients should be supported with controlled mechanical ventilation until hemodynamic functions improve. Adequate PEEP should be applied to prevent and relieve atelectasis. Initially, the ventilator rate should be appropriate for the age. As the hemodynamic function improves, the rate can be weaned, as dictated by the clinical status. The choice of ventilatory parameters depends on the goals for each patient. In patients with pulmonary hypertension or pulmonary vascular disease, hyperventilation to provide respiratory alkalosis will decrease pulmonary vascular resistance and right ventricular afterload. In patients with marginal cardiac output, high airway pressures are to be avoided. In patients who have undergone a Fontan procedure, early extubation is desirable, and if that is not possible, then spontaneous ventilation should be encouraged. Because these patients are totally dependent on venous return for their cardiac output, airway pressures must be kept at a minimum. High intrathoracic pressure may not only impede venous return, but also decrease pulmonary blood flow from increased pulmonary vascular resistance.

Diseases with Abdominal Distention

The presence of abdominal distention poses a special problem. Positive intraabdominal pressure tends to elevate the diaphragm, decrease Ptp alveolar lung volumes in the lung bases. For normal lung volumes to be maintained, a greater Ptp has to be generated. This increases the airway pressures during positive pressure ventilation and increases work of breathing during spontaneous breathing. During positive pressure ventilation, a higher Ptp may cause hyperinflation of the apical regions while restoring normal volumes in the bases. Therapy

should be directed primarily toward reducing the intraabdominal pressure.

Neurologic and Neuromuscular Diseases

Hyperventilation with respiratory alkalosis is an effective method of reducing intracranial pressure. High intrathoracic pressure may impede venous return from the brain by increasing central venous pressures; therefore high levels of PEEP are to be avoided. The goals of respiratory support in patients with acute neuromuscular diseases that are self-limiting are (1) provision of respiratory assistance to maintain adequate minute ventilation and (2) avoidance of disuse muscle atrophy from mechanical ventilation. Spontaneous breathing must be encouraged as much as possible. Neuromuscular blockade must be avoided.

Patient-Ventilator Asynchrony

When the patient is capable of spontaneous breathing or allowed to breathe spontaneously, monitoring and titrating mechanical ventilation to either minimize or eliminate patient-ventilator asynchrony are important. One of the primary goals of mechanical ventilation is to reduce the patient's work of breathing. This can be achieved only if the patient's respiratory muscles and the ventilator act in a coordinated manner. The patient should not be attempting to inspire when the ventilator is in the expiratory phase and should not be attempting to exhale when the ventilator is attempting to deliver a breath. Patient-ventilator asynchrony is defined as a mismatch between the inspiratory times of the patient and the ventilator. Asynchrony can occur during assisted ventilation, assist-control as well as synchronized intermittent mandatory ventilatory ventilation.

The types of asynchronies are as follows:

1. Ineffective triggering: Ineffective triggering refers to the failure of a patient's effort to trigger a ventilator breath. This may be due to muscle weakness which results in an effort that is below the trigger threshold, increased load on the muscles at the start of inspiration such as induced by intrinsic PEEP, or due to too high a trigger threshold. Ineffective triggering can be detected as a pressure drop in the airway with a flow decrease but not followed by a ventilator breath. Ineffective triggering can be resolved by setting the trigger sensitivity low enough to capture the patient's efforts but not result in auto-triggering (see the following section).
2. Auto-triggering: Auto-triggering refers to a ventilator breath that occurs in the absence of an inspiratory effort by the patient. Auto-triggering is usually generated by leaks in the ventilator circuit. It can be triggered by cardiogenic oscillations and other sources that cause a change in airway pressure or flow in the absence of an inspiratory effort.
3. Double triggering: Double triggering refers to the occurrence of a two consecutive ventilator breaths that are separated by a very short or absent expiratory period. This can occur when the ventilator inspiratory time is too short and the ventilator demand is high. It can also occur with condensation in the circuit.
4. Delayed triggering: Delayed triggering refers to the delay in the start of the ventilator breath after the patient's effort has been detected. This is usually intrinsic to the trigger-sensitivity and electronic response of the ventilator circuit.
5. Delayed cycling: Delayed cycling refers to the prolongation of the ventilatory inspiration breath beyond the start of the patient's expiration. This can occur during pressure-support ventilation and can induce adverse effects such as increasing hyperinflation and intrinsic PEEP due to a shortened expiratory time.
6. Premature cycling: Premature cycling refers to the ventilator terminating inspiration while the patient is still continuing to have inspiratory efforts. This most commonly occurs in the presence of a leak in the ventilator circuit or around the endotracheal tube. When the ventilator phase (inspiration or expiration) is not synchronized completely with the phase of the spontaneous breath, it is referred to as asynchrony. When the ventilator phase is only partially not synchronized with the spontaneous breath, it is referred to as dyssynchrony. The interplay between the respiratory pump and the ventilator can occur either within one breath or on a breath-to-breath basis.

Ideally, ventilator breaths should be synchronized with spontaneous breaths. Asynchrony between mechanical ventilation and spontaneous breathing is common, especially in small infants. The most common form of asynchrony is active exhalation during a ventilator-delivered inspiratory breath. This has several detrimental effects. These are increased expiratory work of breathing, decreased overall minute ventilation with hypercarbia, patient discomfort, and increased risk for air leak.[123,124] Patients exhibiting asynchrony during mechanical ventilation have shown improved oxygenation and ventilation after neuromuscular blockade.[125,126]

Use of Neuromuscular Blockade

Neuromuscular blockers are often used as adjunctive therapy to mechanical ventilation. Although spontaneous breathing is to be encouraged as much as possible, respiratory muscle paralysis becomes necessary at times as an aid to mechanical ventilation. The indications for the use of neuromuscular blocking agents during mechanical ventilation are (1) asynchrony between the patient and the ventilator; (2) use in controlled ventilation; (3) a decrease in oxygen demand of skeletal muscles, especially in patients with hemodynamic instability; and (4) prevention of coughing, especially in patients with intracranial hypertension. Neuromuscular blockade is also used in patients when ventilation is to be controlled so that the appropriate minute ventilation is delivered. Paralysis of respiratory muscles may also be required in patients after congenital heart surgery to reduce the oxygen demand on the heart. Prolonged neuromuscular blockade is to be avoided because it tends to promote muscle atrophy. This, in turn, will prolong weaning from mechanical ventilation.

Special Techniques of Respiratory Support

Altering Inspired Oxygen and Carbon Dioxide Concentration

A low alveolar oxygen tension increases pulmonary vascular resistance (hypoxic pulmonary vasoconstriction), and a high alveolar oxygen tension decreases pulmonary vascular

resistance.[127] With certain types of congenital heart disease such as hypoplastic left heart syndrome, it is critical to control pulmonary blood flow and prevent pulmonary overflooding. One approach is to decrease the Fio_2 to less than 0.21 with a blending of room air with nitrogen. The exact Fio_2 delivered must be monitored to avoid administering excessively low inspired oxygen. The other approach, especially in patients undergoing mechanical ventilation, both preoperatively and postoperatively, is to increase the inspired carbon dioxide concentration ($Fico_2$).[128] Increased $Fico_2$ also increases pulmonary vascular resistance. During mechanical ventilation, increased $Fico_2$ allows one to hyperventilate and prevent atelectasis without producing hypocarbia. One of the difficulties with a boost in $Fico_2$ is increased spontaneous ventilatory drive from an increased $Paco_2$. This increases the work of breathing and with marginal cardiac reserve may impose undue strain on the heart. Therefore in spontaneously breathing patients, neuromuscular blockade and total ventilatory support may be necessary with increased $FIco_2$ to avoid an increased workload on the heart.

Helium-Oxygen Mixture

Helium-oxygen mixture has much lower density compared with oxygen-nitrogen mixture and offers a reduced resistance to breathing. This property has been used in the successful treatment of upper airway obstruction after extubation in children, upper airway obstruction from laryngotracheobronchitis and postextubation subglottic edema in infants and children.[129] Helium is usually administered in at least 30% to 40% oxygen through a tight-fitting face mask. Use of an Oxyhood is not indicated because helium tends to separate and layer at the top of the Oxyhood with the patient breathing very little helium. Recently, helium-oxygen mixture has been shown to improve gas exchange in neonates with respiratory distress syndrome.[130] Oxygenation should be monitored during administration of helium-oxygen mixture to avoid hypoxia, especially in neonates.[131] In adults, helium-oxygen mixture has also been used in the management of severe lower airway obstruction in asthma. Because ventilator transducers are calibrated with an air-oxygen mixture, the true volumes delivered tend to be different from preset values. Therefore when helium-oxygen mixture is administered through the ventilator, direct volume measurements are necessary to ensure that the appropriate VT_{eff} is being delivered.

Inhaled Nitric Oxide

Inhaled nitric oxide produces selective pulmonary vasodilation. Indications for inhaled nitric oxide include diaphragmatic hernia, pulmonary hypertension after repair of congenital heart disease, primary pulmonary hypertension, and isolated right heart failure. In babies with severe hypoxemia and pulmonary hypertension, inhaled nitric oxide rapidly increases arterial oxygen tension without causing systemic hypotension.[132-135] Randomized controlled studies showed that nitric oxide inhalation safely improves arterial oxygen levels and decreases the need for ECMO therapy.[132-135] Oxygenation improves in approximately 50% of infants receiving nitric oxide. In addition, Kinsella and Abman[136] showed that high-frequency ventilation seems to augment the response to inhaled nitric oxide probably by better recruitment of alveoli. In children with ALI/ARDS, Ream et al.[137] showed an improvement in oxygenation in more than two thirds of the patients. Researchers of a randomized controlled trial of inhaled nitric oxide in children with acute hypoxemic respiratory failure have also reported an improvement in oxygenation.[138] Results from several adult studies, however, showed that several participants failed to show any improvement.[139-142] In these multicenter studies in children and adults, there were no differences in ventilator-free days and no effect on mortality between treatment groups. Not all patients respond to inhaled nitric oxide. It seems prudent to test whether a patient will respond to inhaled nitric oxide. At Children's Hospital of Pittsburgh, a 2-hour trial of inhaled nitric oxide with 20 to 40 ppm is administered to infants and children with ALI/ARDS with hypoxemic respiratory failure. A good response is defined as improvement in Pao_2/Fio_2 ratio of greater than 100%. A partial response is defined as an improvement in Pao_2/Fio_2 ratio between 50% and 100%. If the response is less than 50%, the patient is considered a nonresponder. Inhaled nitric oxide is then continued in only those patients who show a partial or good response. Nitric oxide binds to hemoglobin to produce methemoglobin. Therefore methemoglobin levels should be monitored during administration of nitric oxide. In addition, nitric oxide combines with oxygen to form nitrogen dioxide. Nitrogen dioxide is known to cause lung injury. Therefore the concentration of nitrogen dioxide should be monitored in the inspired gas to keep it below 1 to 2 ppm.

Adverse Effects of Mechanical Ventilation

Yin-Yang of Mechanical Ventilation

Mechanical ventilation has profound effects on various organ systems; some are beneficial and others have adverse effects. The beneficial and adverse effects can occur simultaneously; the net effect of mechanical ventilation results from the interaction of useful and deleterious effects. The beneficial effects in the lung are related to improvements in pulmonary mechanics and gas exchange. Adverse effects of positive pressure ventilation are related to (1) consequences of positive intrathoracic pressure, and (2) injury to the airway. Some of the important adverse effects of mechanical ventilation are shown in Box 49-5.

Airway Injury from Mechanical Ventilation

The presence of an endotracheal tube traversing the upper airway can be associated with significant airway injury. Oropharyngeal and nasopharyngeal injuries are rare. Ulceration of the ala nasi from pressure necrosis may occur following prolonged nasotracheal intubation, particularly if the skin perfusion of the ala nasi is compromised by very tight taping. Similar ulceration may occur at the angles of the mouth from tight taping of orotracheal tubes.[143,144] Palatal grooves and traumatic cleft palate can occur in infants.[145] Laryngeal injury may extend from minor swelling to ulceration of the mucosa of the vocal cords and aryepiglottic folds. Similarly, injuries in the subglottic region may extend from minor swelling to major ulceration. Healing of the severe injuries may lead to scarring, granuloma formation with airway obstruction,

Decreased cerebral venous drainage

which may be partial or complete. The majority of the subglottic tracheal lesions is due compression of the tracheal mucosa by the endotracheal tube. High-pressure cuffs, cardiovascular instability, upper respiratory tract infection, duration of intubation, and head and neck movement all increase the risk of tracheal injury. Airway injury can also result from suction catheters.[146] Necrotizing tracheobronchitis is a severe form of airway injury seen in patients on mechanical ventilation which is characterized by extensive ulceration and mucosal damage. The sequelae of tracheal injuries include tracheal stenosis, tracheomalacia, tracheoesophageal fistula, tracheoinnominate artery fistula.

Injury to the airway can be prevented by attention to several details. The endotracheal tube should be of the proper size, with a gas leak around it at less than 20 cm H_2O positive pressure. Excessive pressure on the skin should be avoided while taping of the endotracheal tube. Excessive patient movement should be prevented by adequate sedation and restraints. Endotracheal tube cuffs should be inflated with pressures less than 20 cm H_2O. Suctioning should be gentle, preferably with a catheter with multiple side holes. Suction catheters should not be routinely advanced beyond the tip of the endotracheal tube.

Effects on the Lung

Adverse effects of mechanical ventilation on the lung are due to the following factors: (1) high airway pressures, (2) overdistension of the alveoli, 93) altered mucociliary clearance, (4) lung water clearance, and (5) oxygen toxicity. The adverse effects of positive pressure ventilation may be manifested as (1) parenchymal injury, (2) altered ventilation-perfusion relationship leading to impaired gas exchange, and (3) increased risk for infection. Increased airway pressure may cause hyperinflation of the alveoli and predispose to alveolar rupture. Hyperinflation may increase alveolar dead space, impair cardiac filling, and compress alveolar vessels. *Pulmonary barotrauma* is a loose term that encompasses many entities of parenchymal injury. Alveolar rupture from overdistended alveoli is the most common manifestation of pulmonary barotrauma. Air leak may occur from the lung into the pleura (pneumothorax), the interstitium (pulmonary interstitial emphysema), the mediastinum (pneumomediastinum), the pericardium (pneumopericardium), the peritoneal cavity (pneumoperitoneum), and the subcutaneous tissue (subcutaneous emphysema). Even though the term implies high airway pressures as the main mechanism of parenchymal injury, pulmonary barotrauma is often multifactorial.[147-150] The physiologic consequences of extra-alveolar air may range from no adverse effect to life-threatening cardiorespiratory compromise. A pneumothorax may be small and inconsequential or may be large and under tension. Tension pneumothorax would need immediate evacuation of the pleural air. Pulmonary interstitial emphysema may decrease lung compliance and increase pulmonary vascular resistance.[151] Pneumomediastinum requires careful observation. The natural tendency of pneumomediastinum is to track along fascial planes either cephalad to produce subcutaneous emphysema or caudad to produce pneumoperitoneum or pneumoretroperitoneum. Pneumomediastinum rarely requires evacuation. Pneumopericardium can range from minimal inconsequential amount of air to life-threatening cardiac tamponade. Cardiovascular compromise is an indication for immediate evacuation of pericardial air.

A special form of pulmonary air leak is a bronchopleural fistula, where a fistulous track develops between the bronchus and the pleural space. This results in an almost continuous flow of air from the airway into the pleural space. The fistula flow is wasted ventilation and may result in hypercarbia. Attempts to increase minute ventilation by increasing tidal volume will only serve to increase the fistula flow by increasing the pressure gradient across the fistula. If attempts to decrease airway pressures with conventional ventilation are not possible without compromising gas exchange, a trial of high-frequency ventilation may be tried.

Barotrauma can be minimized by avoiding factors that predispose to pulmonary air leakage. The principal factors that can be controlled are airway pressures and lung volumes. As long as acceptable gas exchange is maintained, every effort must be made to reduce airway pressures to a minimum. Hyperinflation must be avoided. When the lung disease is severe, deliberate hypercarbia may be tolerated provided the arterial pH is normal. Inspired oxygen concentration should be maintained at nontoxic levels (usually <50%).

Effects on the Circulatory System

The cardiovascular effects of positive intrathoracic pressure are complex and depend on the underlying lung disease, uniformity of lung disease, transmission of airway pressure to the pleural space, lung volume, etc. Cournand et al.[169] were one of the first to demonstrate that positive pressure ventilation decreased cardiac output. Positive intrathoracic pressure decreases impedes right ventricular filling by decreasing the pressure gradient to venous return.[152-154] Positive airway pressure also increases pulmonary vascular resistance provided, the airway pressure exceeds left atrial or critical

closing pressure.[155] Positive intrathoracic pressure has also been shown to decrease left ventricular afterload.[121,122] The net effect is a combination of all the effects mentioned above and the reflex cardiovascular adjustments that accompany these changes. Positive-pressure breathing also decreases urine output, decreased hepatic, portal venous, and mesenteric perfusion.[156-160] Many of these effects can be offset by volume loading.

Respiratory Care During Mechanical Ventilation

Pulmonary Hygiene

The fundamental goals of pulmonary hygiene are clearance of secretions and prevention and relief of atelectasis. The most effective method of clearing secretions is a combination of changing body position and vigorous coughing by the patient.[161] When the patient is unable to cough effectively, it is common practice to resort to chest physiotherapy and active suctioning of the trachea. Suctioning the trachea usually requires disconnecting the patient from the ventilator, passage of a suction catheter into the endotracheal tube, and application of suction to the catheter while the catheter is withdrawn from the endotracheal tube. In patients with marginal oxygenation, suctioning may result in hypoxia; arrhythmias; hemodynamic instability; and, in rare instances, cardiac arrest.[162-164] This can be prevented by prior hyperoxygenation. Suctioning may also result in cardiac arrhythmias. Chest physiotherapy refers to a variety of respiratory maneuvers performed to aid in the clearance of airway secretions and promoting lung expansion. These are (1) postural drainage, (2) chest percussion and chest vibration, and (3) deep breathing exercises. The efficacy of chest physiotherapy in patients who have undergone intubation is unclear. In adults, some studies have shown a benefit when all the components of the chest physiotherapy regimen are performed.[165] In children with cystic fibrosis, no additional benefit was provided by chest physiotherapy maneuvers when compared with spontaneous coughing.[166] Recently, several devices have been proposed as an adjunct to the standard chest physiotherapy. They include an intrapulmonary percussive ventilator (IPV); a mechanical insufflator-exsufflator (CoughAssist); the FLUTTER mucous clearance device and Acapella devices; intermittent positive pressure breathing (IPPB); mechanical percussors; and the ABI Vest, formerly known as the ThAIRapy Vest. The IPV is used in mechanized chest physical therapy; the IPV device delivers high-flow jets of air to the airways by a pneumatic flow interrupter at a rate of 100 to 300 cycles/min through a mouthpiece. The patient controls variables such as inspiratory time, peak pressure, and delivery rates. Initial studies showed that in children with cystic fibrosis, IPV was as effective as standard aerosol and chest physiotherapy.[167,168] IPV was recently reported to improve atelectasis in children, compared with conventional chest physiotherapy.[169] A more recent study suggests that IPV may be more beneficial in secretion clearance in children with cystic fibrosis.[170] The mechanical insufflator-exsufflator (CoughAssist) is a portable electric device that uses a blower and a valve to alternately apply a positive and then a negative pressure to a patient's airway to assist the patient in clearing retained bronchopulmonary secretions. This device attempts to simulate a cough. Air is delivered to and from the patient through a breathing circuit incorporating a flexible tube; a bacterial filter; and a facemask, a mouthpiece, or an adapter to a tracheostomy or endotracheal tube. Miske et al.[171] reported that in children with neuromuscular disease and impaired cough, the use of a mechanical insufflator-exsufflator was safe, well tolerated, and effective in preventing pulmonary complications. The FLUTTER mucous clearance device and Acapella device are small handheld devices that provide positive expiratory pressure (PEP). Exhaling through the device creates oscillations, or "flutter," in pressures in the airway resulting in loosening of mucus. Other PEP devices are used with a small volume nebulizer and function in conjunction with medication delivery. A recent Cochrane review concluded that there was no clear evidence that PEP was a more or less effective intervention overall than other forms of physiotherapy, and there was limited evidence that PEP was preferred by participants compared with other techniques.[172] IPPB devices use pressure to passively fill the lungs when a breath is initiated. An incorporated manometer and mechanical valves serve to terminate the flow of inspired air when a predetermined pressure is reached on inhalation. IPPB breathing circuits are designed to nebulize inhaled medication. Most IPPB devices are powered by compressed air and are not suitable for home use. Mechanical percussors are typically electrical devices used in lieu of a caretaker's hands for chest percussion or vibration. Conventional chest physiotherapy is both labor intensive and time consuming. A high-frequency chest wall vibrating/oscillating device is currently available (the ABI Vest). Arens et al.[173] showed that in hospitalized patients with cystic fibrosis, high-frequency chest compression with the vest conventional chest physiotherapy was equally safe and effective when used during acute pulmonary exacerbations.

Humidification Systems

During spontaneous breathing, inspired air is warmed and almost completely humidified as it passes through the upper airways.[174] The use of an endotracheal or a tracheostomy tube bypasses the natural warming and humidifying functions of the upper airway. The mucosal surface below the artificial airway must then provide both humidification and heat to the inspired air. This may adversely affect mucociliary clearance.[174,175] If the inspired gases are not warmed to the body temperature, insensible water loss in the lung is increased. All gases used in respiratory therapy are dry with no moisture. Therefore these gases must have moisture added to them during delivery to the patients. When a gas is warmed, its relative humidity decreases.

Humidifiers can be classified into those that provide only humidity and those that provide both heat and humidity. There are several types of nonheated simple humidifiers. The simplest in design is the pass-over or blow-by humidifier. The second type is the bubble humidifier, probably the most common device used in respiratory therapy. In this device, the gas is directed below the surface of the water and allowed to bubble to the surface. A jet humidifier produces an aerosol; humidity is provided by evaporation of the aerosol particles. An underwater jet humidifier uses a combination of jet and bubble humidification principles. In the clinical setting, the amount of humidity provided by the simple humidifiers is about the same. Although the more efficient humidifiers increase humidification, they also tend to cool the inspired air.

Therefore the absolute humidity delivered tends to be similar among the simple humidifiers. Relative humidity of 100% at room temperature is less than 40% relative humidity at body temperature. When inspired gases are humidified with one of these devices, the balance of the moisture is provided by the airway mucosa. Therefore when the upper airway is bypassed by the presence of an artificial airway, then the inspired gases must be additionally heated to provide 100% humidity at body temperature. The factors that determine the efficiency of humidifying devices depend on (1) time of contact with the gas and water, (2) temperature of both the gas and water, and (3) the surface area of contact of the gas/water interface. The efficiency of humidification increases as the time of contact increases and as the surface area of contact increases. Increasing the temperature of the inspired gas before delivery decreases the humidity that needs to be provided by the airway mucosa and adds to patient comfort. Heated humidifiers use the same principle as the simple humidifiers and have in addition a heating element. The relative humidity with these systems can be as high as 100%. The heating system can be servo-controlled to adjust the heat according to the relative humidity.

Aerosol Therapy

Aerosolized drug administration is often used in the treatment of infants and children with respiratory diseases including reversible lower airway obstruction, pneumonias due to Pneumocystis carinii and respiratory syncytial virus, and hyaline membrane disease. Common drugs used as aerosol agents include β_2 agonists, atropine, ipratropium bromide, cromolyn sodium, antiviral agents, corticosteroids, antibiotics, surfactant, pentamidine, and mucolytics. A drug aerosol increases the therapeutic index of the drug by delivering it directly to the site of action with minimal side effects. The factors that affect deposition of aerosol particles are gravity, viscosity of the gas, kinetic activity of the particles, particle inertia, physical nature of the particle, temperature and humidity of the aerosol, and the ventilatory pattern. Compared with that in adults, deposition of aerosolized particles in infants and children is poor because of factors such as a small airway caliber, greater airway resistance, high respiratory rate with a short inspiratory time, increased chest wall compliance, ineffective coordination effort, and inconsistent breathholding maneuvers. Despite poor aerosol deposition, a clinical response to inhaled medications can often be seen. The dose and the delivery method should be individualized to each patient to ensure a good clinical response.

Nebulizers are devices that generate aerosols. Particle size has to be at least 1 to 5 μm for deposition in the distal airways. Currently, four types of delivery systems are available for clinical use that generate medication aerosols. These are the jet nebulizers (small-volume and large-volume nebulizer), ultrasonic nebulizers, metered-dose inhalers, and dry-powder inhalers. A jet nebulizer uses the Bernoulli principle to create an aerosol. The size of the particle depends on the jet flow rate and the size of the capillary tube. Baffles placed in the path of the aerosols tend to remove larger particles, allowing delivery of smaller particles to the patient. A pneumatic nebulizer is a device that creates the aerosol using the same principle as the jet nebulizer, but the aerosol particles are carried to the patient by a main gas flow. A pneumatic nebulizer may be a mainstream nebulizer in which the aerosol is generated in the path of the main gas flow or a sidestream nebulizer in which the aerosol is generated in a separate chamber and carried passively into the path of the main gas flow. The ultrasonic nebulizer uses a piezoelectric crystal that produces a highly concentrated output of aerosol particles and has been used primarily for cough and sputum production or bronchoprovocational challenges. Ultrasonic nebulizers have not been routinely used for drug delivery in infants and children. With the replacement of the saline solution with medication; however, the highly concentrated output from the ultrasonic nebulizer may perform better than a small-volume nebulizer in accomplishing greater deposition of medications in children. The metered-dose inhaler uses a pressurized canister that dispenses a single bolus of aerosolized medication. Such inhalers are convenient, cost effective, and versatile, and generally have an effective deposition rate of 10% to 15%. The canister is activated into the spacer and the medication remains suspended in the chamber until the patient inhales. A dry-powder inhaler delivers a large bolus of medication during a single inspiration maneuver and produces therapeutic effects similar to a metered-dose inhaler and an aerosol nebulizer. The dry-powder medication, released from a capsule and deposited into a small canister, is delivered to the lungs during inspiration. The inspired flow rate causes a turbulent state within the canister, and the powder is directed toward the respiratory tract.

Aerosolized medications are often delivered through mechanical ventilators for the treatment of bronchospasm. Aerosol delivery is inefficient when delivered through a ventilator. The endotracheal tube is the most significant barrier to effective delivery. The smaller the inner diameter of the tube, the less efficient is aerosol delivery. The nebulizer is most effective when it is synchronized to fill the inspiratory limb of the circuit with aerosolized particles during the exhalation phase of ventilation, thereby improving the delivery of medication during the subsequent inspiration. The inspiratory portion of the circuit serves as a spacer chamber, similar to the spacer used for metered dose inhalers. Some current ventilators offer a synchronized nebulization capability, in which a portion of the preset inspiratory gas is diverted to power the nebulizer. The effects of added volume delivered to the inspiratory limb should be taken into account and minimized with the addition of a pressure relief valve to the circuit. Metered-dose inhalers can be equally effective as nebulizers during mechanical ventilation.

Weaning from Mechanical Ventilation

Weaning from mechanical ventilation is defined as liberation from mechanical ventilation while spontaneous breathing is allowed to assume the responsibility for effective gas exchange. Weaning can be considered a success when a patient can maintain effective gas exchange, with complete spontaneous breathing and without any mechanical assistance. Weaning can be considered a failure when spontaneous efforts are incapable of sustaining effective gas exchange without mechanical ventilator support. Extubation is defined as the removal of an endotracheal tube. The timing of extubation should coincide with an assessment that the patient is capable of maintaining effective gas exchange without any mechanical ventilator support. Avoiding both premature extubation and unnecessary prolongation of mechanical ventilation is important.

When the indications that were met for provision of mechanical ventilation are no longer present, then the patient can be weaned from mechanical ventilation. Weaning should start when (1) the underlying disease process is improving; (2) gas exchange is adequate; (3) no conditions exist that impose an undue burden on the respiratory muscles, such as cardiac insufficiency, severe hyperinflation, severe malnutrition, and multiple organ system failure; and (4) the patient is capable of sustaining spontaneous ventilation as ventilator support is decreased without expending an excessive amount of energy. It is the patient who dictates the initiation of the weaning process and the pace of the weaning process. Patients cannot be arbitrarily forced to wean. Improvement of the underlying disease process can be assessed with measurement of indices of gas exchange, pulmonary mechanics, ventilation perfusion relationships, and radiographic findings. The patient's ability to take over the responsibility from the ventilator depends on several factors: (1) respiratory muscle strength, (2) stability of the cardiovascular system, (3) work of breathing, (4) general nutritional status of the patient, and (5) the presence or absence of an underlying hypercatabolic state (e.g., sepsis). Weaning cannot be accomplished unless all of these factors are optimal. The pathophysiologic determinants of weaning outcome include the following: (1) adequacy of pulmonary gas exchange; (2) respiratory drive; (3) respiratory muscle performance and capacity; (4) respiratory muscle load; (5) amount of dead-space ventilation; and (6) work of breathing and ventilatory requirements. Box 49-6 shows the specific parameters to be met before initiating weaning. There are currently two approaches to weaning. One is the "traditional" method of slowly reducing the ventilator support, including inspired oxygen concentration, to a minimal acceptable level and then assessing the patient's readiness to extubate. The other is the "modern" concept of assessing the patient's readiness to extubate as soon as the patient meets criteria to initiate weaning.

Traditional Method of Weaning

In the traditional method, the exact sequence of the weaning process will be dictated by the clinical circumstance. At each step of weaning, the patient must demonstrate an ability to sustain effectiveness of breathing. Minute ventilation is reduced primarily with a decrease in the ventilator rate.

Box 49–6 Criteria to Meet Before Initiating Weaning

1. Alert mental status
2. Good cough and gag reflexes
3. Core temperature below 38.5° C
4. Spontaneous respiratory effort
5. pH 7.32–7.47
6. PaO_2 >60 mm Hg or pulse oximetry reading <95%
7. Fio_2 ≤0.50
8. PEEP ≤7 cm H_2O
9. $PaCO_2$ <50 mm Hg
10. No further need for vasoactive agents
11. No clinical need for increased ventilator support in the past 24 hours
12. No planned operative procedures requiring heavy sedation in the next 12 hours

Mean airway pressure is then reduced to a minimum with a decrease in CPAP/PEEP. Most children are currently weaned with SIMV or IMV alone, with SIMV and added pressure support, or with pressure support alone. Despite earlier indications that weaning with IMV was useful,[176,177] current studies do not advocate weaning with IMV in adults.[178,179] In infants, provision of a continuous flow device has been shown to decrease work of breathing and aid in weaning.[14] PSV has been advocated as a weaning mode because it can result in better synchrony between the patient and the ventilator than IMV, volume-assisted ventilation, or pressure control ventilation.[180-183] Pressure support will allow ventilatory muscle loads to be returned gradually during the weaning process.[180-183] Because each breath is assisted, it alters the pressure-volume relationship of the respiratory muscles in such a way as to improve its efficiency.[180-183] The parameters that can be manipulated to titrate the muscle loading are the magnitude of the trigger threshold and the preset pressure limit. PEEP is provided to maintain FRC and prevent alveolar collapse. The amount of pressure support to be provided depends on the clinical circumstance. PSVmax, or the maximum pressure support needed to reduce the respiratory work to zero, requires a pressure limit that delivers a VT_{eff} of about 10 to 12 mL/kg. PSVmax is not necessary at the start of weaning. The level of pressure support that should be selected should allow for spontaneous respiration without undue exertion and still result in normal minute ventilation. No strict criteria can be established; they have to be applied and titrated on an individual basis. Weaning of PSV is accomplished with a decremental reduction of the pressure limit. Similar to that previously mentioned in the weaning guidelines, with each wean, the effect of weaning on muscle loading has to be evaluated clinically. An increase in respiratory rate is an early indication of increasing muscle load. Retractions and use of accessory muscles would indicate a more severe muscle load. If respiratory rate increases during the weaning process, the level of pressure support should be increased until there is reduction in the respiratory rate. A relative contraindication to the use of PSV is a high baseline spontaneous respiratory rate. There is a finite lag time involved from the initiation of a breath to the sensing of this effort and from the sensing to the delivery of a mechanical breath. In infants breathing at a relatively fast rate (>50 breaths/min), this lag time may be too long, and this may result in asynchrony between the patient and the ventilator.

"Modern" Method of Weaning

The premise underlying the modern method is that not all patients require a prolonged weaning process. Esteban et al.[178] showed that 76.2% of patients successfully underwent a 2-hour trial of spontaneous breathing, and 89.4% of them immediately underwent extubation. In a recently completed randomized, controlled trial of weaning modes in children, 42% of the patients initially tested with a minimal pressure-support trial passed the test and underwent extubation.[184] These studies validate the modern method of weaning patients from mechanical ventilation. If patients meet the criteria for weaning as outlined in Box 49-7, they can be subjected to a Readiness to Extubate Trial (RET) to test their ability to breathe spontaneously and maintain gas exchange. If the RET is successful, then the patient is ready to be extubated. If the patient fails an RET, there are two choices, either

continuation of invasive mechanical ventilation or extubation to noninvasive ventilation. If invasive mechanical ventilation in continued, then the RET can be repeated in 24 hours. The level of invasive mechanical ventilator support should keep the patient comfortable with no increased work of breathing.

Box 49–7 Criteria for Terminating a Readiness to Extubate Trial

1. Inability to maintain gas exchange
   - Pulse oximeter saturations <95% with 40% inspired oxygen
   - Needing >50% inspired oxygen to maintain oxygen saturations >95%
2. Inability to maintain effective ventilation
   - Measured exhaled tidal volume <5 mL/kg
   - An increase in $PaCO_2$ >50 mm Hg or an increase of >10 mm Hg
   - Respiratory acidosis with pH <7.3
3. Increased work of breathing
   - Respiratory rate outside of the acceptable range for age:
     <6 months: 20–60 breaths/min
     6 months to 2 years: 15–45 breaths/min
     2–5 years: 15–40 breaths/min
     >5 years: 10–35 breaths/min
   - Use of accessory respiratory muscles
   - Intercostals/suprasternal/supraclavicular retractions
   - A paradoxic breathing pattern
4. Other signs of distress
   - Diaphoresis
   - Anxiety
   - Heart rate >90th percentile for a given age
   - Change in mental status (agitation or somnolence)
   - Systolic blood pressure <third percentile for a given age

If a patient has any of these signs at any time during the breathing trial, the trial should be terminated and mechanical ventilation should be reinstituted.

If the decision is to extubate to noninvasive positive pressure support, then it would be prudent to test the patient on a level of pressure support that is necessary to maintain gas exchange and decrease the work of breathing. The criteria for terminating an RET are shown in Box 49-7.

Readiness to Extubate Trial

Currently, there are three methods of RETs: (1) T-piece trials, (2) CPAP trials, and (3) minimal pressure-support trials.[178,179,184-187] In T-piece trials, the patient is removed from the ventilator but does not undergo extubation. Humidified supplemental oxygen is provided to the airway without any positive pressure support through a T-piece (Figure 49-20). In this system, a corrugated tubing from the nebulizer/humidifier attaches to one end of the T-piece, and an extension of corrugated tubing attaches to the other end of the T-piece. The flow rate should be adjusted to produce a constant mist coming from the extension piece on the T-tube both during inspiration and expiration so that the patient's minute ventilation is matched by the device. Roughly, this corresponds to at least about three times the minute ventilation of the patient.

The RET can also be conducted without removing the patient from the ventilator with a low level (e.g., 5 cm H_2O) of CPAP or with a low level of PSV. Randolph et al.[184] described a minimal pressure support technique in which the level of pressure support was adjusted for the endotracheal tube size (3 to 3.5 mm = pressure support of 10 cm H_2O; 4 to 4.5 mm = pressure support of 8 cm H_2O; >5 mm = pressure support of 6 cm H_2O). On the other hand, in a study comparing minimal pressure support with T-piece trials, Farias et al.[185-187] used a pressure support of 10 cm H_2O for all patients. The duration of the trial can range from 30 minutes to 2 hours. The proponents of a "minimal pressure support" approach to the RET speculate

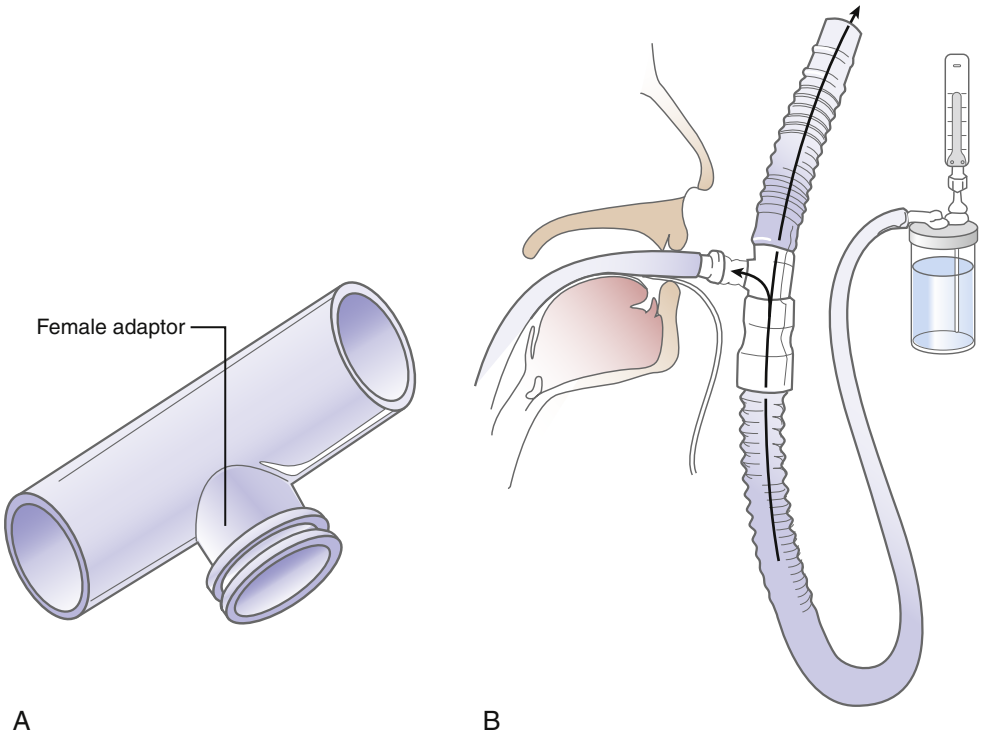

Figure 49–20. T-piece circuit. *(From Kofke WA: Postoperative respiratory care techniques. Part III. Weaning from mechanical ventilation and oxygen therapy,* Curr Rev RACN *13:161, 1992.)*

that this overcomes the resistance to breathing through the artificial airway. Ishaaya et al.[188] showed that minimal pressure support based on in vitro studies overestimated the amount of support required to overcome the resistance of the endotracheal tube and ventilator circuitry. There are no measurements in vivo validating this concept in children. In one study of adults, the authors reported a similar resistance to breathing through the upper airway after extubation as that with the endotracheal tube in place.[189] Resistance through the artificial airway is affected by many factors, including the inspiratory flow of the patient, the inner diameter of the tube, the use of either an endotracheal or a tracheostomy tube, and the presence of secretions in the tube. In children, Farias et al.[186] recently compared two methods of RET, one with pressure support of 10 cm H_2O and the other with a T-piece circuit. The extubation failure was not different between the two groups.[186]

Physicians are reluctant to subject infants and young children to a trial of complete spontaneous breathing with either CPAP or a T-piece circuit because of concern about the work of breathing imposed by the endotracheal tube and the breathing circuit. Proponents of this paradigm routinely extubate patients after a "minimal pressure support" RET. Willis et al.[190] showed, very elegantly, that the work of breathing associated with T-piece breathing was similar to that with complete spontaneous breathing after extubation. In fact, this study showed that the work of breathing with all the support modes including minimal pressure support mode was considerably less than that after extubation. Taken together, these studies suggest that with support modes the patient is receiving a substantial amount of assisted ventilation. Therefore an RET performed with a support mode may not truly represent complete spontaneous breathing and any evaluation made may overestimate the ability of children to breathe spontaneously when they are extubated. The studies by Farias et al.[185-187] have shown that RETs with a T-piece circuit are well tolerated by children. These should serve to dispel the myth that infants and children cannot be subjected to a T-piece trial before extubation. Despite these theoretical concerns, Farias et al. showed that patients extubated using either T-piece or pressure-support trials had similar rates of reintubation.[186] There is another school of thought that infants and children need not be subjected to a RET before extubation. Proponents of this practice routinely extubate infants and children from a "low" level of ventilator support. Studies in children, however, have shown that when the fraction of minute ventilation provided by the ventilator is more than 30%, the risk of extubation failure is increased.[191,192] It is preferable that the ability to breathe effectively be determined with complete spontaneous breathing without ventilator support. An important dictum to remember is that "the test for extubation readiness is not extubation."[193]

Extubation

When RET is successful, the patient can undergo extubation and be liberated from mechanical ventilation. The patient must be awake, be alert, and have airway protective reflexes. The patient must be breathing effectively, without undue exertion. Adequate gas exchange with a relatively low Fio_2 must be established. A stable cardiovascular system must be established. Metabolic, nutritional, and electrolyte balance must be ensured. Airway pressures must be reduced to a minimum.

Table 49–2 Threshold Values for Low- and High-Risk of Reintubation for Bedside Parameters of Respiratory Function

Respiratory Parameter	Low Risk (≤10%)	High Risk (≥25%)
Spontaneous tidal volume (mL/kg)	>6.5	<3.5
Fraction of inspired oxygen	<0.3	>0.4
Mean airway pressure (cm H_2O)	<5	>8.5
Peak inspiratory pressure (cm H_2O)	<25	>30
Dynamic compliance (mL/kg/cm H_2O)	>0.9	<0.4
Fraction of the total minute ventilation provided by the ventilator (%)	<20	>30
Mean inspiratory flow (mL/kg/sec)	>14	<8

Respiratory parameters were measured just before extubation. Risk of reintubation is percent of patients who were reintubated within 48 hours of extubation.

Extubation failure can be predicted using simple measures of respiratory function such as inspiratory drive, lung mechanics, gas exchange, and level of ventilator support before extubation.[191,192] A low risk is defined as an extubation failure rate of less than 10%, and a high risk of failure is defined as an extubation failure rate of at least 25%.[191,192] Table 49-2 lists the threshold values for the respiratory parameters with identified low- and high-risk values.[191,192] Additional parameters that may be useful in determining eligibility for extubation are an intrapulmonary shunt fraction less than 15% (requires pulmonary artery catheterization), a physiologic dead space less than 40%,[194] a vital capacity of at least 15 mL/kg, and a maximum negative inspiratory force of at least 30 cm H_2O.

Weaning Problems

Farias et al.[185-187] distinguish between two types of failure: trial failure and extubation failure. Trial failure is defined as a failure to sustain effective gas exchange and breathing during an RET of spontaneous breathing while the patient is still intubated. Extubation failure is defined as the requirement for reintubation within 48 hours after extubation. Some patients take longer than others to wean. Factors that prolong the weaning process are (1) slow resolution of the underlying disease process, (2) ventilatory pump failure, and (3) psychological factors. In many instances, weaning is delayed because of the slow resolution of the underlying disease process. Ventilatory pump failure can be due to increased respiratory workload, decreased respiratory muscle capacity, or a combination of both. Decreased ventilatory drive may result from respiratory center dysfunction caused by sedative agents; neurologic disease, particularly if it affects the brainstem; sleep deprivation; and metabolic alkalosis. Phrenic nerve injury usually results as a complication of birth trauma or operative procedures involving the heart and other thoracic structures.[195-197] This may result in either paresis or paralysis of one or both hemidiaphragms. When muscle weakness is present, weaning should generally be slow, allowing sufficient time for regaining muscle strength and endurance. Muscle training through an incremental increase in muscle work can be achieved by a gradual increase in the trigger threshold for assisted ventilation. Ventilatory requirements can be reduced with a decrease in carbon dioxide production

with a reduction in excess caloric intake. Muscle loading may occur during IMV because of patient asynchrony. Asynchrony between the patient's breathing and the mechanical breaths may occur during both phases of the respiratory cycle. When the patient exhales while the ventilator delivers a mechanical breath, the airway pressures will be higher and the mechanical breath is wasted. This increases the work of breathing during exhalation. Prolonged asynchrony may result in muscle fatigue and may contribute to prolonged weaning. Considering nonrespiratory factors that may affect extubation failure is important. In a study by Khamiees et al.,[199] although all patients passed an RET, poor cough strength and endotracheal secretions were synergistic in predicting extubation failure.

Tracheostomy and Weaning

Most airway resistance resides in the upper airways. The presence of an endotracheal tube markedly increases the airway resistance (Figure 49-21) and contributes to the work of breathing. Tracheostomy may aid in the weaning by several mechanisms. First, it reduces airway resistance by bypassing the upper airway. This reduces the work of breathing. Second, it increases patient comfort and allows better interaction between the patient and the caretakers, especially the parents. Third, it increases nursing comfort. Tracheostomy is not without risk. The procedure and complications of tracheostomy are described in detail elsewhere. Immediate complications are those related to bleeding, those related to pulmonary air leak, and those associated with anesthesia. Long-term complications include infections of the trachea and the lung, granuloma formation with subglottic stenosis from scarring, erosion of the trachea, and bleeding from erosion into a major thoracic vessel (e.g., innominate artery).

Home Respiratory Care

Chronic respiratory failure is defined as the requirement for mechanical ventilation for longer than a month. Because of improved medical care and technology, the prevalence of children surviving with chronic respiratory failure is increasing. In 1984, the Ad Hoc Task Force on Home Care of Critically Ill Infants stated that "the goal of a home care program for infants, children, or adolescents with chronic conditions is the provision of comprehensive, cost-effective health care within a nurturing home environment that maximizes the capabilities of the individual and minimizes the effects of disabilities."[200] Respiratory care requirements in these children may range from supplemental oxygen to long-term mechanical ventilation. Long-term care in a tertiary care center is expensive and can alternatively be provided in a specialized chronic care rehabilitation center or at home. In 1986, the American College of Chest Physicians published guidelines for the management of ventilator-dependent patients in the home and at alternate community sites.[201] Since the late 1970s and early 1980s, home care has been shown to be as safe as hospital care for infants with tracheostomies and infants and children requiring long-term mechanical ventilation.[202-208] The diagnoses included neuromuscular disease, spinal cord trauma, and respiratory failure from chronic cardiorespiratory disease.[183-189] Home care is psychosocially more acceptable to the families, less

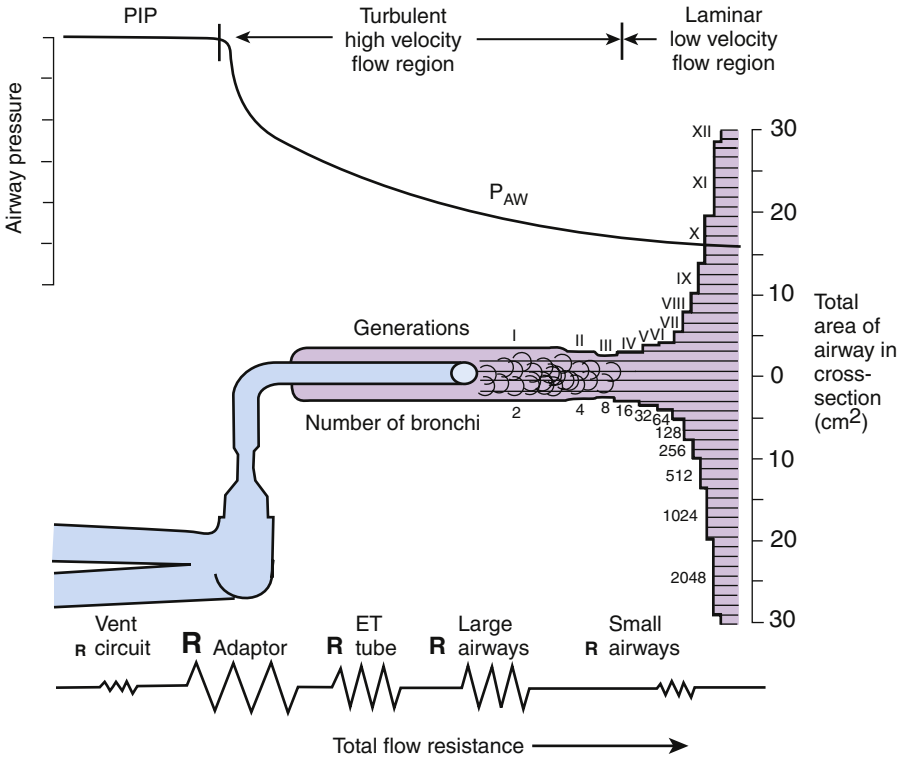

Figure 49–21. Representation of resistances and pressure drop across the entire respiratory system in an intubated patient. Approximately 60% to 80% of the total airway resistance in a spontaneously breathing patient resides within the first few generations of bronchi. Addition of an endotracheal tube and the ventilator circuit increases the resistance to breathing. *(From Goldsmith JP, Karotkin EH editors:* Assisted ventilation of the neonate, *Philadelphia, 1988, WB Saunders.)*

expensive, and may provide a better quality of life for respiratory technology-dependent children.[209,210]

Indications for Home Respiratory Care

The goals of long-term home respiratory care include (1) provision of comprehensive, cost-effective respiratory care, (2) enhancement of quality of life, (3) reduction of morbidity, and (4) wherever possible, extend life. The major indication for home respiratory care is chronic respiratory failure. This may occur in children with parenchymal or airway disease or in children with normal lungs. In children with normal lungs, respiratory failure is usually the result of central or peripheral nervous system dysfunction, neuromuscular disorders, or chest wall abnormalities. Patients who require home respiratory care generally fall under the following categories: (1) patients whose underlying disease is most likely to recover and therefore would need respiratory care during the recovery phase such as infants with bronchopulmonary dysplasia and children recovering from adult respiratory distress syndrome, (2) patients whose underlying disease is irreversible but not progressive such as patients with spinal cord injury, and (3) patients whose underlying disease is irreversible and progressive such as patients with muscular dystrophy. The approach to home care planning will be different depending on the natural course of the underlying disease.

Logistics of Home Care

Home care requires a team approach with interaction between several health care personnel (e.g., a primary physician, home care nurses, respiratory therapists, social workers, and sometimes the State Health Agency) and the family and the patient (Box 49-8). First, the patient must be ready for home care.[208,210,211] In some patients, a stable tracheostomy with a mature stoma is essential. Inspired oxygen requirement should not be greater than 35%. Pao_2 should be greater than 60 to 70 torr with a $Paco_2$ less than 60 torr with a normal arterial pH at relatively low ventilator settings. The family must demonstrate not only a desire to provide home care, but also a minimal ability to provide various aspects of home care. Health care personnel must be available in the local community to assist the family in providing care. The home must have adequate facilities to maintain and run all necessary equipment and supplies. Contingency plans must be made for emergencies. The location of the home has major implications for home care. The home must be easily accessible by standard transportation. A home care provider should be available on a 24-hour basis to respond to emergencies. The home must have adequate space to accommodate all the caretakers and the required equipment. Discharge planning must be thorough and take into account all the factors listed in Table 49-2. A detailed description of the various respiratory care equipment used for home care is beyond the scope of this chapter and the reader is referred elsewhere.[212,213] A thorough knowledge of the limitations of various devices is essential for the respiratory care personnel coordinating home care. Parents who are motivated to providing home care for their children are willing to take on the cumbersome responsibility of carrying all the necessary equipment from place to place just to have the benefit of having the child at home.

Noninvasive Ventilation: Concepts and Practice

Shekhar T. Venkataraman

PEARLS

- Noninvasive ventilation can be used for both short-term and long-term indications depending on whether respiratory failure is acute or chronic.
- Not all patients are suitable candidates for noninvasive ventilation. Careful selection of patients is important for noninvasive ventilation to be successful.
- Equipment needs are different when noninvasive ventilation is provided in the hospital versus home.
- A properly fitting interface is crucial to the success of noninvasive ventilation.
- Family involvement is essential for success when long-term noninvasive mechanical ventilation is provided at home.

Conventional mechanical ventilation provided by endotracheal intubation or tracheostomy is a life-saving technique for the management of patients with respiratory failure. Endotracheal intubation and tracheostomy are associated with complications including injury to the airway and nosocomial infections. In addition, mechanical ventilation of children by endotracheal intubation often requires use of sedatives with attendant side effects and complications. *Noninvasive ventilation* (NIV) refers to a technique of respiratory support that is provided without an artificial airway in the trachea. NIV can be provided using either positive or negative-pressure ventilators. Positive pressure NIV is provided by an interface that increases the proximal airway pressure, whereas negative pressure NIV is provided by creating a negative pressure around the chest wall. In both instances, the transpulmonary pressure is raised causing airflow into the lungs. This review will describe the various noninvasive ventilatory techniques available, published reports on their efficacy, their advantages and disadvantages, and future directions. Throughout most of this chapter, NIV will refer to positive pressure noninvasive ventilation. Negative-pressure ventilation is described at the end of the chapter.

Historical Perspective

Dalziel, in 1832, reported the use of a bellows-operated box with a seal around the neck or shoulders to provide artificial respiration to a drowned seaman.[1] In 1867, Woillez designed the first workable noninvasive negative-pressure ventilator, which was operated manually.[2] Doe, in 1989 described a box used for resuscitating newborns.[3] Drinker developed the first tank ventilator in 1928 that was subsequently used with great clinical value in patients with poliomyelitis.[4] Negative-pressure ventilation was introduced for use with neonates in the 1960s.[5,6] In 1953, Lassen reported that positive-pressure ventilation administered using an endotracheal tube or a tracheostomy was more successful that negative-pressure ventilation in treating patients with poliomyelitis.[7] Major technologic advances in the design of positive-pressure ventilators led to the marked decrease in negative-pressure ventilation. Noninvasive positive-pressure ventilation by facemask was first used by Barach et al.[8] for the treatment of hypoxemic respiratory failure secondary to acute pulmonary edema. Gregory et al.,[9] in 1971, reported that constant positive airway pressure (CPAP) through nasal prongs was effective in improving oxygenation in neonates with hyaline membrane disease. Vidyasagar and Chernick showed that constant negative pressure applied about the chest and abdomen was as effective as CPAP in improving oxygenation in neonates with hyaline membrane disease.[10] Despite these early reports, noninvasive ventilation did not become popular until more recently. There is a renewed interest in noninvasive ventilation coinciding with technologic advances in the manufacture and design of noninvasive ventilators. NIV through a mask for neuromuscular disorders was pioneered in the 1980s by Rideau et al.[11] and subsequently by Bach et al.[12]

Indications

The indications for the use of NIV can be categorized into short-term and long-term NIV. Short-term NIV is indicated where positive pressure support is needed acutely in a hospital setting in acute care or critical care areas for conditions that are reversible within a few days. Long-term NIV is indicated in conditions where respiratory failure is likely to be chronic or progressive.

Short-Term Noninvasive Ventilation

The indications for use of NIV in acute care and critical care situations are given in Box 50-1. The selection guidelines are given in Box 50-2. The first step is to determine whether a

Box 50–1 Indications for Short-Term NIV

Acute hypoxemic respiratory failure
- Acute lung injury
- Acute cardiogenic pulmonary edema
- Pneumonia

Acute lower airway disease
- Acute asthma

Avoiding intubation
- Immunocompromised patients
- Restrictive chest diseases
- Neuromuscular disorders
- Postoperative respiratory failure
- Patients with orders not to intubate
- Postextubation respiratory failure

Facilitate weaning and extubation

Box 50–2 Selection Guidelines for Short-Term NIV

1. Potentially reversible condition
2. Need for *moderate* ventilatory assistance

Moderate to severe increase in work of breathing
- Tachypnea
- Retractions
- Paradoxical breathing
- Accessory muscle use

Gas exchange criteria
- Ventilatory failure ($Paco_2$ >45 mm Hg with a pH <7.35)
- Oxygenation failure (Pao_2/Fio_2 ratio <300)

3. No contraindications to NIV

Respiratory or cardiac arrest
Unstable (hypotension, shock)
Poor airway protective reflexes
Recent upper airway and esophageal surgery
Excessive secretions
Uncooperative
Agitation
Untreated pneumothorax
Inability for a good mask fit
Rapidly progressive neuromuscular weakness (e.g., Guillain-Barré syndrome)

patient has a reversible cause of respiratory failure. The second step is to determine whether the patient needs positive pressure support to maintain gas exchange. Before attempting NIV in acute respiratory failure, the clinician must answer the following questions:

1. Does the patient have any contraindications to the use of NIV (see Box 50-2)?
2. Does the patient need to be promptly intubated?

If the answers to both questions are no, then the patient can be considered for NIV. Additional questions that the clinician needs to consider are the following:

1. Does the patient only need increased positive airway pressure to recruit the lung to improve oxygenation?
2. Does the patient need additional ventilatory assistance based on the clinical signs and symptoms or gas exchange derangements?

If the patient only needs increased airway pressure to recruit atelectatic lung and to maintain lung volumes, then the patient can be placed on noninvasive CPAP through an appropriate interface. If the patient needs ventilatory assistance, the patient is a candidate for NIV.

Figure 50-1 shows the algorithm to be followed for initiation of NIV in acute respiratory failure. If NIV is used in acute situations, there should be a determination within 1 to 3 hours whether the patient has improved. Signs of success and failure are given in Box 50-3. A good response to NIV is indicated by: (1) reduction in respiratory rate, (2) reduction in work of breathing, (3) reduction in dyspnea, (4) improvement in pH, (5) improvement in oxygenation, and (6) reduction in $Paco_2$. Additionally, there may be hemodynamic effects such as a reduction in heart rate, improved blood pressures, and perfusion. Generally, for short-term use, NIV is used continuously until the patient improves or fails NIV. The goals of short-term NIV are given in Box 50-4.

Adult Studies on the Short-Term Use of Noninvasive Ventilation

Adult studies have shown that NIV can be used in hypoxemic respiratory failure (Pao_2/fraction of inspired oxygen [Fio_2] ratio <300) with bilateral parenchymal disease to prevent endotracheal intubation. Ferrer et al. showed that NIV reduced the intubation rate from 52% to 25% with a reduction in intensive care unit (ICU) mortality rate from 39% to 18%.[13] But, this finding must be tempered by studies that show that NIV may not reduce the need for endotracheal intubation.[14,15] CPAP, not strictly a form of ventilatory assistance, was described by Barach et al.[8] for the treatment of acute cardiogenic pulmonary edema. Since then, several studies have demonstrated that both CPAP and NIV can decrease the rate of intubation, improve work of breathing and improve gas exchange.[16-18] In adults with acute exacerbations of chronic obstructive pulmonary disease, NIV has been shown to improve both short-term and long-term outcomes.[19-21] It is reasonable to expect a similar response to acute asthma because many of the pathophysiologic features are similar. Uncontrolled studies and one randomized controlled study showed improvement in patients having an acute asthma attack.[22-24] It is desirable to reduce the probability of nosocomial infections in immunocompromised patients. Therefore, it is appealing to apply NIV to avoid endotracheal intubation in these patients. Adult studies have shown that NIV can reduce the rate of intubation and may improve short term mortality.[25-27]

Adult studies have shown that respiratory insufficiency that develops postoperatively in patients can be successfully treated with NIV. NIV reduces the rate of intubation and is more effective than CPAP or chest physiotherapy.[28,29] In patients after lung resection surgery, NIV reduced the rate of intubation and mortality compared with conventional therapy.[30] Children with restrictive chest diseases who develop respiratory failure after surgery such as spinal fusion are good candidates for NIV if they develop postoperative respiratory failure provided they do not have any other contraindications.

Endotracheal intubation and invasive mechanical ventilation are associated with complications including ventilator-associated pneumonia, ventilator-induced lung injury, and airway trauma. To minimize these complications, it is desirable to extubate the patient as quickly as possible. Generally, extubation coincides with the end of weaning (i.e., the patient is not placed on any form of positive pressure support

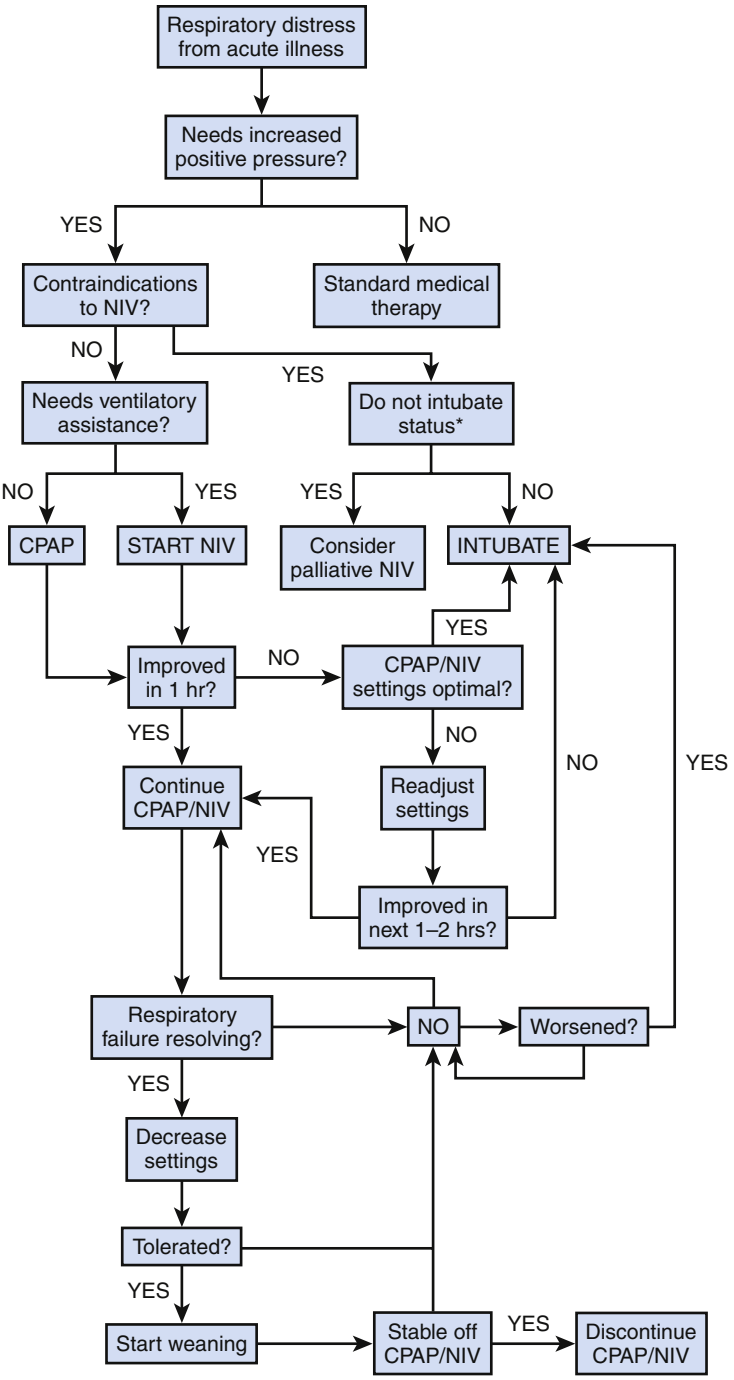

Figure 50–1. Algorithm for initiation and weaning of short-term continuous positive airway pressure and NIV.

postextubation). In some patients, who take a long time to wean, but require fairly low ventilatory assistance, it is possible to extubate them to NIV. Theoretically, it would reduce the incidence of complications associated with endotracheal intubation and invasive mechanical ventilation. Udwadia et al. were among the first to test this paradigm in 22 adult patients who were successfully stabilized on NIV after extubation.[31] Three adult studies have demonstrated that the use of NIV resulted in a reduction in the duration of mechanical ventilation, a reduction in the incidence of nosocomial pneumonia, and a reduction in the duration of hospital stay.[32-34] Similar pediatric studies are lacking. NIV to facilitate extubation should be carried out only if the patient meets the following criteria: (1) is awake and alert, (2) has intact bulbar function with a preserved cough reflex, (3) has minimal airway secretion, (4) is able to breathe spontaneously, (5) has stable hemodynamic status, (6) does not have gastric distension, and (7) has a requirement for 40% or less supplemental oxygen. Recently, some adult studies have examined the use of NIV for postextubation respiratory failure (i.e., respiratory failure that develops after extubation on complete spontaneous breathing). The rationale for the use of NIV in this circumstance is the avoidance of endotracheal intubation. In at least one study in adults, this approach was shown to increase the time from

Box 50–3 Signs of Success and Failure Within 1–2 Hours of Application of NIV for Short-Term NIV

Signs of Success

Reduction in respiratory rate to a range that is normal for age
Absence of retractions
Absence of paradoxical breathing
Improvement in gas exchange
- Improved pH
- Improved Pao_2/Flo_2
- Reduction in $Paco_2$

Signs of Failure

Signs of work of breathing
Gas exchange
Hemodynamic instability
Signs of respiratory fatigue
Change in mental status
Increased agitation

Box 50–4 Goals of NIV

Short-Term NIV

Relieve respiratory distress
Decrease work of breathing
Improve gas exchange
Avoid intubation

Long-Term NIV

Ameliorate symptoms
Improve gas exchange
Improve quality of life
Improve sleep duration and quality
Improve survival

respiratory failure to intubation with an increase in mortality rate.[35] It is difficult to extrapolate from adult studies to pediatrics. It is possible that some children may benefit from the institution of NIV for postextubation respiratory failure.

Pediatric and Neonatal Studies

In 1981, Sullivan et al.[36] first demonstrated that nasal CPAP was effective in reversing obstructive sleep apnea in four adults and one teenager. Guilleminault et al.,[37] in 1986, reported that nasal CPAP reversed or reduced obstructive sleep apnea in some children. There were problems related to poor cooperation from parents and difficulty in preventing leaks around the nasal mask. Since the first report, several studies have shown that nasal CPAP was effective in obstructive sleep apnea in infants and children.[37-42] In 1995, Guilleminault et al.[43] reported that nasal CPAP was successful in 70 of 72 infants with sleep-disordered breathing. In many instances, it provided an interim solution while allowing the patient to grow and postponing surgery.

Patients in a fairly wide age range appear to tolerate NIV therapy in the acute setting, provided they are adequately monitored and sedated. In 1993, Akingbola et al.[44] published a case report describing effective NPPV therapy in two pediatric patients with acute respiratory distress. Since that time, NIV has been applied to pediatric patients with a variety of respiratory disorders associated with acute hypoxemic respiratory failure, including pneumonia, pulmonary edema, postoperative respiratory decompensation in sleep apnea syndrome, status asthmaticus, spinal muscular atrophy, and end-stage cystic fibrosis.[45-51]

Padman et al.[52] published a preliminary report on 15 patients ages 4 to 21 years who had respiratory failure because of cystic fibrosis (four patients) and neuromuscular disease (11 patients). In 14 patients, the placement of an artificial airway was avoided. They observed significant improvement in hospital days, respiratory rate, heart rate, serum bicarbonate, arterial carbon dioxide, dyspnea, activity tolerance, and quality of sleep. In 1995, Fortenberry et al. reported a retrospective study on the efficacy and complications of biphasic positive airway pressure (Bi-PAP) in 28 children with acute hypoxemic respiratory insufficiency.[47] Bi-PAP significantly decreased respiratory rate and improved both oxygenation and ventilation. The use of Bi-PAP decreased hospitalization rate and increased patient comfort. Only three of 28 patients required intubation or reintubation. Padman et al. conducted a prospective study in 34 patients with impending failure all of whom required airway or oxygenation/ventilation support and required admission to the pediatric ICU.[50] A decrease in respiratory rate, heart rate, and dyspnea score, and an improvement in oxygenation were noted in more than 90% of patients studied. The frequency of intubation in these patients was only 8%. Birnkrant et al.[51] reported their experience with Bi-PAP in six patients with spinal muscular atrophy and three patients with other causes of respiratory failure. This uncontrolled study showed that in these patients noninvasive positive-pressure ventilation facilitated extubation. Teague et al.[53] reported that NIV treatment acutely improved oxygenation and reduced cardiorespiratory distress in 19 of 26 patients. This group of "NIV responders" had significantly shorter lengths of stay in both the ICU and hospital. However, the seven nonresponders required endotracheal intubation as respiratory distress progressed despite sedation. Teague et al.[53] also showed that NIV improves gas exchange in children with upper airway obstruction In a prospective, randomized, controlled trial of NIV in children with acute respiratory failure, Yan et al.[54] showed that NIV improved hypoxemia and the signs and symptoms of acute respiratory failure and reduced the rate of endotracheal intubation. Thill et al.,[55] in a randomized, crossover study in children with lower airway obstruction, showed that NIV decreased signs of work of breathing such as respiratory rate, accessory muscle use, and dyspnea as compared with standard therapy with no serious associated morbidity. Pancera et al.[56] recently published their experience with NIV in immunocompromised pediatric patients. NIV as the first-line therapy was compared to invasive mechanical ventilation. Seventy-five percent of the patients treated with NIV did not require endotracheal intubation showing that NIV is a viable first-line therapy for respiratory failure in immunocompromised patients for preventing endotracheal intubation.[56] More recently, NIV has been suggested as an alternative to endotracheal intubation for the perioperative management of scoliosis correction in patients with muscular dystrophy.[57]

Interfaces

A properly fitting facial appliance is essential for the optimal application of NIV. There are currently several devices in use: (1) oral-nasal mask, (2) nasal mask, (3) total face mask,

(4) Adam's circuit, (5) head hood, (6) nasal prongs, and (7) mouthpieces. A correctly sized interface minimizes leaks, improves effectiveness of positive pressure support, and improves comfort.

Oral-Nasal Masks

This is the most common interface used to provide NIV. The ideal face-mask should (1) be made of a clear material to allow visual inspection, (2) conform to the contours of the patient's face, (3) be easily moldable from its factory shape, (4) be soft and not apply excess pressure on the skin of the face, and (5) maintain its deformed shape (has "memory") when it is removed. The mask should extend from the bridge of the nose to just below the lower lip. The mask is secured using an anchoring system that goes around the head.

Nasal Masks

A nasal mask rests between the bridge of the nose and above the upper lip. As a rule, the smaller the mask, the better the fit. Patients who are unable to keep their mouth closed may use chin straps to close the mouth.

Total Face Mask

This mask covers the whole face including the eyes. The advantage of a total face mask is that it does not have to conform to the shape of the face and therefore does not have to be molded to fit every patient. The disadvantage is that it has an increased deadspace and therefore, there may be difficulty in eliminating CO_2.

Adam's Circuit

This device uses a "nasal pillow" that attaches to a manifold that is placed over the top of the head. Some patients prefer this to the nasal mask. "Nasal pillows" are available in various sizes.

Head Hood

Also called a *helmet,* the head hood has been used successfully in a number of European ICUs. It appears best suited for application of CPAP. Dead space is a major concern and therefore should be reserved for patients in the ICU.

Equipment

A detailed description of the devices available for NIV at home is beyond the scope of this chapter and the reader is referred to several excellent reviews.[58,59] This discussion focuses on the characteristics of positive-pressure ventilators that can be used for providing NIV. Negative-pressure ventilators are discussed elsewhere in the chapter. The ventilators that are used for NIV can be classified into three categories: (1) conventional ICU ventilators with a double limb circuit without leak compensation, (2) devices with a single limb circuit with leak compensation, and (3) devices that combine the above two categories to include both leak compensation and having a double-limb circuit. Category 1 devices can only be used in the hospital. Category 2 and 3 devices can be used both in the hospital and at home. The examples of these devices would be any of the conventional ICU ventilators that can provide pressure support with positive end-expiratory pressure (category 1), Respironics Bi-PAP (category 2), and the Pulmometrics LTV ventilator (category 3). The performances of these ventilators vary widely in delivered tidal volumes, air-leak compensation, response to simulated effort, inspiratory trigger, expiratory cycling, rebreathing, response to high ventilatory demands, and patient-ventilator synchrony.[60] Category 1 or ICU ventilators operate with high-pressure gas sources with an oxygen blending system. Category 2 and 3 devices can operate without a high-pressure gas source. Bilevel ventilators do not have a blender; therefore the delivered Fio_2 is unpredictable depending on the oxygen flow rate, ventilator settings, amount of leak, site of oxygen enrichment, and the type of exhalation port.[61]

Optimizing Patient-Ventilator Interaction

Optimal patient-ventilator interaction requires that the ventilator be able to detect the patient's inspiratory efforts as quickly as possible and terminate inspiration (expiratory cycling) as close to the beginning of the patient's expiration as possible. Inspiratory trigger function differs significantly among the ventilators.[62-64] Factors affecting the inspiratory trigger function include trigger response to the inspiratory flow, leak-induced auto-triggering, and pressure-time and flow-time waveform heterogeneity.[62-64] Strategies to optimize expiratory cycling include setting a suitable threshold for the inspiratory time and adjusting the expiratory cycling flow threshold. Patients with obstructive lung disease tend to do better with high inspiratory flow, whereas patients with neuromuscular disease seem to do better with low inspiratory flows.[65] An adjustable backup rate is available in most modern ventilators used for NIV. This is particularly useful when sedation is used to improve patient compliance with NIV. Leaks around the interface reduce its effectiveness. Some amount of leak around the interface is expected with NIV. Complete elimination of air leak is not desirable because it comes at the expense of a very tight-fitting mask that may lead to patient discomfort and skin breakdown. Ventilators differ in their capacity to compensate for leaks. One of the drawbacks of a large airleak is auto-triggering. Humidification is important to prevent mucosal drying. Humidification can be provided using a heated humidifier, HME, or a pass-over humidifier.

Ventilator Settings

With CPAP, the pressure level is selected based on clinical need. There should be relief of symptoms within 1 to 2 hours of application of CPAP. With short-term NIV, two strategies have been employed. One approach is to start with a high inspiratory pressure (about 20 to 25 cm H_2O). The goal of such an approach is rapid relief of symptoms. If successful, a lower level that also is tolerated is selected. This approach is called the *high-low approach*. The other approach starts with a lower inspiratory pressure (about 8 to 10 cm H_2O) and gradually increased to produce relief of symptoms. The aim of this approach is to maximize patient comfort and tolerance. This is called the *low-high approach*. Within the first 1 to 3 hours, subsequent adjustments may be necessary depending on the

patient response. Expiratory pressure is used routinely during short-term NIV. Maximal FIo_2 with bilevel ventilators is usually about 45% to 50%. If a higher FIo_2 is required, and endotracheal intubation is not indicated, then an ICU-type ventilator may be used.

Complications and Concerns During Short-Term Noninvasive Ventilation

Aerophagia and gastric distension can occur with NIV. The higher the pressure used, the greater the chance of gastric distension. Regurgitation of gastric contents and aspiration into the lungs are major concerns with the use of an oronasal total face mask and a helmet. Close monitoring is needed to prevent aspiration. A nasogastric tube to keep the stomach decompressed is necessary in these acutely ill patients. Pressure sores related to the masks are the other major concern. It should be possible to pass one or two fingers between the headgear and the face. Care should be taken to avoid fitting the interface too tightly. A spacer with soft padding can reduce the incidence of pressure sores on the face.

Circuit and Carbon Dioxide Rebreathing

Single limb circuits that are employed with bilevel ventilators can result in significant CO_2 rebreathing. All single-limb circuits have an exhalation port that is placed close to the patient interface through which exhaled gas will escape. If the exhaled gas flow exceeds the rate of escape through the exhalation port, exhaled air is rebreathed with the next inspiration. This results in significant CO_2 rebreathing and can cause hypercarbia. Rebreathing also depends on the level of expiratory positive airway pressure (EPAP), the location of the exhalation port, and the design of the exhalation port. Earlier devices had significant CO_2 rebreathing of the exhaled air, especially if the expiratory positive airway pressure levels were set too low. In the newer designs, this problem has been reduced. The closer the exhalation port to the patient interface, the less the rebreathing of CO_2. In fact, if the exhalation port is located in the mask itself, it results in the lowest amount of CO_2 rebreathing. Dual-limb circuits eliminate the risk of rebreathing.

Long-Term Noninvasive Ventilation

Long-term NIV is indicated in conditions that result in chronic respiratory failure. This can be either progressive or nonprogressive. Generally, long-term NIV is intermittent with periods off NIV. The most common form of long-term NIV is nocturnal NIV with off-periods during the daytime. The goals of long-term NIV are given in Box 50-4. The indications for long-term NIV are given in Box 50-5.

Physiologic Effects and Outcomes of Long-Term Noninvasive Ventilation

Intermittent NIV consistently improves daytime gas exchange.[66,67] Patients with neuromuscular and chest wall disorders often have sleep-related disturbances.[68] NIV ameliorates hypoventilation, intermittent sleep apneas, and other sleep-disordered breathing.[69] In children with neuromuscular disorder, symptoms of daytime sleepiness, headache, and sleep quality improved after initiation of NIV.[70] Hospitalization rates and health care costs decreased. Quality of life remained stable after NIV, despite disease progression.[70] NIV, applied appropriately, improves the quality of life with restrictive thoracic disorders.[71] Children with spinal muscular atrophy (types 1 and 2) often develop thoracoabdominal asynchrony, especially during sleep. NIV improved sleep breathing parameters and thoracoabdominal coordination during sleep in spinal muscular atrophy Types 1 and 2.[72] Long-term NIV combined with mechanically assisted coughing has also been shown to increase survival in patients with Duchenne muscular dystrophy.[73]

Box 50–5 Indications for Long-Term NIV

Restrictive thoracic diseases
- Chest wall deformity—kyphoscoliosis

Slowly progressive neurologic disorders
- Postpolio syndrome
- Muscular dystrophies
- Spinal muscular atrophy

Nonprogressive chronic respiratory failure
- High spinal cord injury

Ventilator Settings

As with short-term NIV, the ventilator settings must relieve patient symptoms. The approach that is generally recommended for long-term NIV is the low-high approach with gradual increase in support. A backup rate sufficiently high to control breathing nocturnally can rest the respiratory muscles and prevent apnea, especially in patients with neuromuscular disease. NIV can be provided both intermittently and continuously. There has been an increase in the continuous use of NIV, especially in patients with neuromuscular disorders. This has resulted in prolonging survival in these patients.

Monitoring of Patients with Long-Term Noninvasive Ventilation

Monitoring patients who are on long-term NIV requires an assessment of their respiratory function. Pulse oximeters are useful in detecting hypoxemia especially during sleep. End-tidal CO_2 monitors are only used in the clinic or hospital. Treatment of sleep-disordered breathing improves the quality of life and may prolong survival. Polysomnography may be required to document sleep disorders but is more expensive than nocturnal pulse oximetry. If a patient has bulbar weakness or severe obesity, there may be obstruction of the upper airway or obstructive sleep apnea in addition to sleep hypoventilation. Both problems may be treated with nocturnal ventilation.

Negative-Pressure Ventilation

Design and Modes of Negative-Pressure Ventilators

All negative-pressure ventilators have a chamber in which subatmospheric pressure is generated and a pump which generates this pressure. The chamber may cover only the chest and

the upper abdomen (cuirass) or all of the extracranial portions of the body (tank respirator, isolette, or a body suit). The tank respirator has both the chamber and the pump in one unit. In all other cases the two units are separate. The cuirass can be prefabricated or custom designed to fit the contours of the chest. Custom-designed cuirasses are especially useful in patients with skeletal or spinal deformities. All body suits fit over a hard shell similar to the cuirass placed over the chest and the upper abdomen. Most negative pressure pumps in use today are pressure cycled. Some volume-cycled pumps have been used but their use has been limited because the pump cannot compensate for the variable amounts of air leak. Additionally, some ventilators provide an inspiratory assist mode. At the present time, there are four modes of negative pressure application: (1) cyclical negative pressure, (2) negative/positive pressure, (3) continuous negative extrathoracic pressure (CNEP), and (4) negative pressure/CNEP. *Cyclical negative-pressure ventilation* refers to a mode where the ventilator generates the preset subatmospheric pressure during inspiration while expiration is passive. Negative/positive-pressure ventilation refers to a mode which is a combination of negative pressure during inspiration with positive pressure during expiration. *CNEP* refers to a mode in which a constant subatmospheric pressure is provided throughout the respiratory cycle and the patient breathes spontaneously. Negative pressure/CNEP refers to a mode where negative pressure inspiratory cycles are superimposed on CNEP.

Clinical Applications

Box 50-6 shows the indications, advantages, disadvantages, contraindications, and clinical side effects of negative-pressure ventilation. In 1965, Stahlman et al.[74] first reported on the use of a tank respirator to treat neonates with respiratory distress syndrome. Vidyasagar and Chernick,[10] in 1971, were the first to show that CNEP improved oxygenation in neonatal respiratory distress syndrome. In the 1970s, several controlled and uncontrolled studies showed that negative-pressure ventilation was effective in the management of neonatal respiratory syndrome.[75-77] However, the utility of this technique was limited because of problems such as upper airway obstruction, difficulties in achieving access to patients, difficulties in achieving an adequate seal, sores from the neck seal, and inability to maintain an adequate neutral thermal environment. Negative-pressure ventilation has been reintroduced in the treatment of neonatal respiratory distress syndrome. A recent randomized control study showed that application of CNEP was associated with fewer intubations and decreased the total duration of oxygen therapy.[78] However, CNEP was associated with a slightly higher (not statistically significant) mortality rate, cranial ultrasound abnormalities, and pneumothoraces. Further studies are warranted to assess the utility and safety of negative-pressure ventilation in neonatal respiratory distress syndrome.

Respiratory Dysfunction and Failure

During the polio epidemics in the 1930s and 1940s, negative-pressure tank ventilators reduced mortality in patients with spinal polio.[79-81] There has been a resurgent interest in negative-pressure ventilation in patients with neuromuscular diseases and skeletal deformities. In adults with kyphoscoliosis and neuromuscular disorders with chronic hypoventilation, intermittent use of negative-pressure ventilation, mostly nocturnal, decreased or reversed day time symptoms of hypoventilation and gas exchange abnormalities.[82,83] These studies show that negative-pressure ventilation is useful in acute or chronic respiratory failure associated with skeletal or neuromuscular

Box 50–6 Indications, Advantages, Disadvantages, and Contraindications of Negative Pressure Ventilation

Indications

1. Parenchymal lung disease
   - Respiratory distress of the newborn
   - Interstitial pneumonias
   - Acute respiratory distress syndrome
   - Acute pulmonary edema
2. Respiratory pump failure
   - Poliomyelitis
   - Neuromuscular diseases
   - Skeletal deformities
   - Persistent flail chest deformity
3. Cardiovascular disorders
   - After Fontan-type operations
   - Repair of total cavopulmonary connection
   - Tetralogy of Fallot
   - Phrenic nerve palsy after pediatric cardiac surgery

Advantages

1. Avoids intubation or tracheostomy
2. Preserves physiologic functions such as speech, cough, swallowing, and feeding
3. Allows fiberoptic bronchoscopy to be performed without disconnection from the ventilator
4. Promotes venous return by creating negative intrathoracic pressure.

Disadvantages

1. Noisy
2. Access to patient is difficult
3. Tank ventilators produce abdominal pooling of blood resulting in hypotension (tank shock)
4. Regulation of inspiratory-expiratory ratio is difficult (more recent ventilators such as the Hayek negative-pressure ventilator allows for regulation of inspiratory/expiratory ratio and application of negative end-expiratory pressure)
5. Difficult to sterilize
6. Lack of protection of the upper airway, especially in unconscious patients or those with bulbar dysfunction
7. Upper airway obstruction can be minimized with an oral airway
8. Difficulty in achieving an adequate seal
9. Discomfort

Contraindications

1. Gastrointestinal bleeding
2. Rib fracture
3. Recent abdominal surgery
4. Uncooperative patients
5. Sleep apnea syndrome
6. Neurologic disorders with bulbar syndrome

Clinical Side Effects

1. Tiredness
2. Musculoskeletal pain or tightness
3. Esophagitis
4. Rib fractures and pneumothorax
5. Impaired sleep quality
6. Poor compliance

disorders. Isolated case reports in adults have been published about using CNEP in adult respiratory distress syndrome and in persistent flail chest deformity.[84-87] CNEP has been used to assist ventilation in children with diffuse alveolar disease and progressive respiratory failure.[88-90] In 1975, Sanyal et al.[89] published a case series of five children with progressive respiratory failure from *Pneumocystis carinii* pneumonitis. Three patients improved with CNP and survived, whereas the other two continued to worsen and died. Sanyal et al.,[90] in 1977, published a larger series where CNEP was used to assist ventilation in 14 children who had progressive respiratory insufficiency caused by diffuse bilateral alveolar disease. Within 6 hours after therapy was started, oxygenation improved. The improvement was sustained and within 24 hours permitted a decrease in fractional concentration inspired oxygen. There was a concomitant decrease in intrapulmonary right-to-left shunt and a decrease in respiratory rate. Four of the 14 patients developed pneumothorax that was successfully decompressed. Ten patients survived. These observations establish CNEP therapy as an effective means of improving arterial oxygenation in spontaneously breathing older children, avoiding endotracheal intubation and prolonged use of muscle relaxants and sedatives.

Cardiovascular Disorders

Raine et al.[91] in 1992 published a pilot study in 10 children with respiratory failure and found the CNEP, introduced either in conjunction with intermittent positive-pressure ventilation or alone, did not produce large changes in cardiac output. In patients with Fontan-type operations, pulmonary blood flow and cardiac output increases with spontaneous inspiration and positive-pressure ventilation decreases antegrade pulmonary blood flow and may increase pulmonary valvular incompetence in patients with restrictive right heart physiology after repair of tetralogy of Fallot.[92] In children after repair of total cavopulmonary connection and tetralogy of Fallot and after Fontan-type procedures, negative-pressure ventilation provided using a Hayek external high-frequency oscillator improved cardiac output by 42% to 46% almost entirely by an increase in stroke volume with improvement in mixed venous oxygen saturation.[93] Systemic and pulmonary vascular resistances decreased significantly as well. A similar finding was observed in children after transcatheter occlusion of an asymptomatic patent ductus arteriosus and after open heart surgery.[94] Raine et al.[95] in 1992 reported in an uncontrolled study that negative-pressure ventilation using either CNEP or intermittent negative-pressure ventilation was a viable alternative to positive-pressure ventilation in patients with phrenic nerve palsy after pediatric cardiac surgery, reduced the need for diaphragmatic plication, and facilitated weaning from positive-pressure ventilation. These studies show that negative-pressure ventilation is a useful technique in selected patients after cardiac surgery where positive-pressure ventilation is not desirable or results in unwanted hemodynamic effects.

Summary

NIV is a viable alternative to invasive mechanical ventilation in selected children. NIV can be used both to meet short-term and long-term needs. Selection of patients is crucial to ensure success with NIV.

Ventilator-Induced Lung Injury

Jean-Damien Ricard, Didier Dreyfuss, Alexandre T. Rotta, and Georges Saumon

PEARLS

- Although essential to the support of patients with respiratory failure, mechanical ventilation can be associated with the development of pulmonary tissue injury, termed ventilator-induced lung injury (VILI).
- The concept of VILI has been elegantly tested in the research laboratory in both normal and diseased lungs, where the individual contribution of various factors, such as tidal volume, positive end-expiratory pressure, and overall state of lung distension can be determined. Lung volume at the end of inspiration (i.e., the overall degree of lung distension) probably is the main determinant of VILI severity.
- One must take the magnitude of the loss of aerated lung volume and alterations in lung mechanics into account to assess the risk of VILI.
- Experimental and clinical data support the idea that reasoned tidal volume reduction designed to prevent volutrauma can be advantageous in the management of these patients.

Mechanical ventilation is essential to life support of patients with respiratory failure. Several potential drawbacks to mechanical ventilation were identified early in its history.[1] More recent experimental studies have showed that certain ventilation modalities may produce subtle tissue damage similar to that seen in early acute respiratory distress syndrome (ARDS) and termed ventilator-induced lung injury (VILI). This issue has recently received much attention in the clinical field.[2,3] The purpose of this chapter is to describe pathophysiological events leading to VILI and to place these observations into a clinical perspective of ventilatory management of patients with ARDS.

Evidence for Ventilator-Induced Lung Injury

Ventilation of Intact Lungs

High Lung Volume Ventilator-Induced Lung Injury

Webb and Tierney[4] found that pulmonary edema rapidly developed in rats subjected to 45 cm H_2O peak airway pressure ventilation, whereas it did not develop in rats undergoing ventilation for a longer time with 14 cm H_2O peak airway pressure. Edema severity and rate of development increased with peak airway pressure magnitude. It was later confirmed that such a ventilation modality produces endothelial and epithelial cell damage and lung capillary permeability changes that result in nonhydrostatic pulmonary edema.[5] This edema formation is now generally believed to be the hallmark of VILI.

The respective roles of increased airway pressure and increased lung volume in this injury were clarified when mechanical ventilation at high and low tidal volume (V_T) were compared at identical (45 cm H_2O) peak airway pressures.[6] The injury was found only in rats subjected to high V_T and not in those undergoing ventilation at high airway pressure in which lung distention was limited by thoracoabdominal strapping (Figure 51-1).[6] Furthermore, in animals undergoing ventilation at high V_T by negative external distending pressure, pulmonary edema still developed, confirming that excessive airway pressure is not the causal factor of this type of injury.[6] This VILI that depends mostly on end-inspiratory volume has been called volutrauma.[7,8] The alveolar pressure corresponding to end-inspiratory volume is the "plateau" airway pressure (measured at no-flow), and its clinical importance has been emphasized in a Consensus Conference on mechanical ventilation.[9] Several investigators reached the same conclusions in other species using different protocols.[10-12]

Taken together, these experimental studies have shown that large tidal volumes are more critical than high intrathoracic pressures in the genesis of ventilator-induced lung edema in intact animals.

Low Lung Volume Ventilator-Induced Lung Injury

Unlike volutrauma, ventilation at low lung volumes does not seem to injure healthy lungs. Intact animals tolerate mechanical ventilation with physiologic V_T and low levels of positive end-expiratory pressure (PEEP) for prolonged periods of time without any apparent damage. Taskar and colleagues[13] have shown that the repetitive collapse and reopening of terminal units during 1 hour of mechanical ventilation does not result in appreciable lung damage, although it does alter gas exchange and reduce compliance, as does spontaneous (low V_T) ventilation under deep anesthesia.

Ventilation of Damaged Lungs

High-Volume Lung Injury

Several investigators have evaluated the effect of overdistension on damaged lungs. These studies consistently demonstrated the increased susceptibility of diseased lungs to the detrimental effects of some modalities of mechanical ventilation.

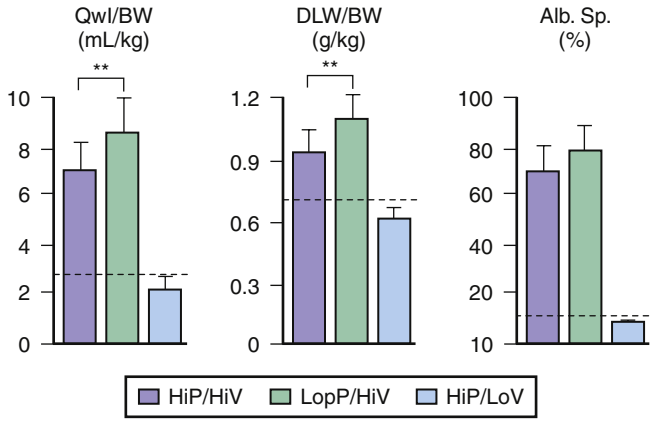

Figure 51–1. Comparisons of the effects of high-pressure–high-volume ventilation *(HiP-HiV)* with those of negative inspiratory airway pressure high tidal volume ventilation (iron lung ventilation, *LoP-HiV)* and of high-pressure–low-volume ventilation (thoracoabdominal strapping, *HiP-LoV). Dotted lines* represent the upper 95% confidence limit for control values. See Figure 51-3 for details on edema indices. Permeability edema occurred in both groups receiving high tidal volume ventilation. Animals undergoing ventilation with a high peak pressure and a normal tidal volume had no edema. *BW,* Body weight; *DLW,* dry lung weight; *Qwl,* extravascular lung water. *(From Dreyfuss D, Soler P, Basset G et al: High inflation pressure pulmonary edema. Respective effects of high airway pressure, high tidal volume, and positive end-expiratory pressure,* Am Rev Respir Dis *137:1159-1164, 1988.)*

The first studies were performed on isolated lungs. Bowton and Kong[14] showed that isolated perfused rabbit lungs injured by oleic acid gained significantly more weight when ventilated with 18 mL/kg V_T than with 6 mL/kg V_T. Hernandez and colleagues[15] compared the effects of oleic acid alone, mechanical ventilation alone, and their combination on lung capillary filtration coefficient and wet-to-dry weight ratio (which reflects lung protein accumulation) in young rabbits. Filtration coefficient and wet-to-dry weight were not significantly affected by low doses of oleic acid or by mechanical ventilation at a peak inspiratory pressure of 25 cm H_2O for 15 minutes. However, the filtration coefficient increased significantly when oleic acid injury was followed by mechanical ventilation at these pressures. Wet-to-dry weight ratio was also significantly higher than in lungs subjected to oleic acid injury or ventilation alone. The same team also showed that inactivating surfactant with dioctyl-succinate aggravates the filtration coefficient increase produced by ventilating isolated blood-perfused rabbit lungs at 30 to 45 cm H_2O peak pressure.[16] Whereas light microscope examination showed only minor abnormalities (minimal hemorrhage and vascular congestion) in the lungs of animals subjected to ventilation or surfactant inactivation alone, their combination caused severe damage (edema and flooding, hyaline membranes, and extensive alveolar hemorrhage).

These results suggested that ventilation at high volume and pressure might favor VILI in abnormal isolated lungs and that it might occur at lower airway pressure than in the normal lung. Whether this could also occur in lungs in situ was investigated by comparing the effects of different modalities of mechanical ventilation in rats with α-naphthylthiourea (ANTU)-injured lungs[17] (Figure 51-2). ANTU infusion alone caused moderate permeability pulmonary edema. Mechanical ventilation alone resulted in a permeability edema of severity related to magnitude of V_T. It was thus possible to calculate the theoretical amount

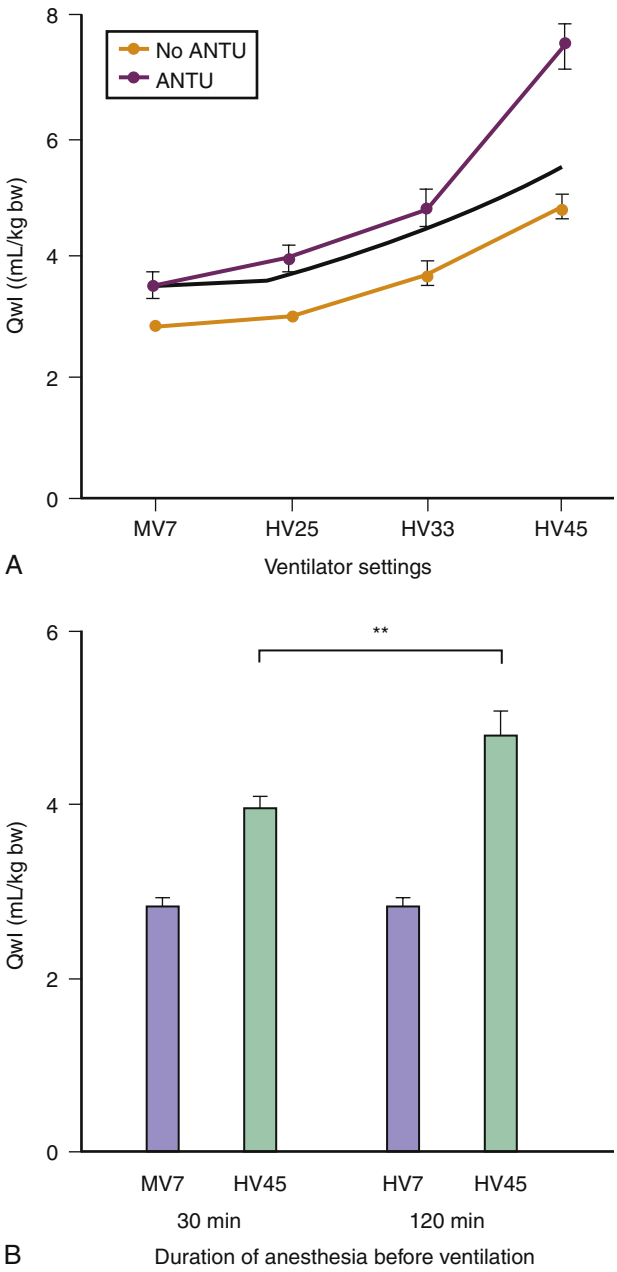

Figure 51–2. Interaction between previous lung alterations and mechanical ventilation on pulmonary edema. **A,** Effect of previous toxic lung injury. Extravascular lung water *(Qwl)* after mechanical ventilation in normal rats *(orange circles)* and in rats with mild lung injury produced by α-naphthylthiourea (ANTU) *(purple circles).* Tidal volume (V_T) varied from 7 to 45 mL/kg body weight *(bw). Black line* represents the Qwl value expected for the aggravating effect of ANTU on ventilation edema assuming additivity. ANTU did not potentiate the effect of ventilation with V_T up to 33 mL/kg bw. In contrast, ventilation at 45 mL/kg bw V_T resulted in an increase in edema that greatly exceeded additivity, indicating synergy between the two insults. **B,** Effect of lung functional alteration by prolonged anesthesia. Intact rats were anesthetized and breathed spontaneously for 30 or 120 minutes prior to mechanical ventilation with 7 mL/kg bw *(open bars)* or 45 mL/kg bw *(shaded bars)* V_T in intact rats. Qwl of animals that underwent ventilation with a high V_T was significantly higher than in those that underwent ventilation with a normal V_T. Qwl was not affected by the duration of anesthesia in animals that underwent ventilation with a normal V_T. In contrast, 120 minutes of anesthesia before high V_T ventilation resulted in a larger increase in Qwl than did 30 minutes of anesthesia. $^{**}P < .01$. *(From Dreyfuss D, Soler P, Saumon GL: Mechanical ventilation-induced pulmonary edema. Interaction with previous lung alterations,* Am J Respir Crit Care Med *151:1568-1575, 1995.)*

of edema that would result from ventilating ANTU-diseased lungs with a given V_T by summing up the separate effect of mechanical ventilation and ANTU. However, lungs of animals injured by ANTU had more edema than predicted when they underwent ventilation with a high V_T (45 mL/kg body weight), indicating that the two insults acted in synergy. Even slight lung alterations, such as those produced by spontaneous ventilation during prolonged anesthesia (which inactivates surfactant and promotes focal atelectasis[18,19]), are sufficient to exacerbate the harmful effects of high-volume ventilation.[17] The extent to which lung mechanical properties are altered prior to ventilation is a key factor in this synergy. The amount of pulmonary edema produced by high-volume mechanical ventilation in animals given ANTU, or after prolonged anesthesia, was inversely proportional to respiratory system compliance measured at the very beginning of high-volume mechanical ventilation.[17] Thus the more severe the lung abnormalities were before ventilation, the more severe was the VILI.

The reason for this synergy requires clarification. The presence of zones of alveolar edema in animals given this harmful ventilation was the most evident difference from those that underwent ventilation with lower, less harmful V_T.[17] Because alveolar flooding reduced the number of alveoli available for ventilation, they were more prone to overinflation, more vulnerable, and at greater risk of alveolar flooding. This in turn would further reduce aerated lung volume and result in positive feedback. The same reasoning applies to prolonged anesthesia, during which aerated lung volume was probably gradually reduced by atelectasis.[17] Both flooding and atelectasis decrease lung compliance by a "baby lung" effect, a reduction in the volume of lung available for ventilation. It is not surprising that the lower the compliance before ventilation, the more severe were the lung alterations induced by high-volume ventilation.[17] Thus uneven distribution of ventilation during acute lung injury[20] favors regional overinflation and injury. To substantiate this phenomenon, rats underwent ventilation with V_T of up to 33 mL/kg after alveolar flooding by instillation of saline solution into the trachea. Flooding with saline solution did not significantly affect microvascular permeability when V_T was low. As expected, capillary permeability alterations were more important in animals that experienced alveolar flooding than in intact animals that underwent ventilation at high V_T. Correlations also were found between end-inspiratory (plateau) airway pressure, the pressure at the "lower inflection point" on the pressure-volume (PV) curve, and the capillary permeability changes found in animals that experienced alveolar flooding and underwent ventilation with at high V_T (Figure 51-3).[21] Thus the changes in capillary permeability caused by lung overinflation are more severe in poorly recruitable (and less compliant) lungs.

Low-Volume Lung Injury

An increase in trapped-gas volume during pulmonary edema and acute lung injury probably occurs because of airway closure and is worsened by impaired surfactant function.[22] Under such conditions, the slope of the inspiratory limb of the respiratory system PV curve often displays a sharp increase at low lung volume. This change reflects the sudden and massive opening of units previously excluded from ventilation and has been termed the "lower inflection point." This phenomenon often has a dramatic effect on arterial oxygenation, because

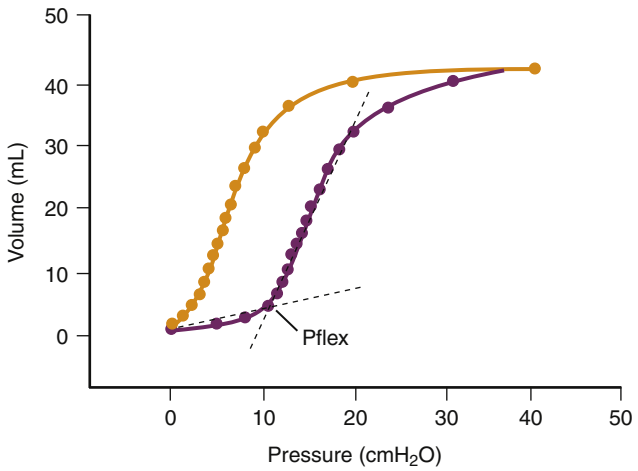

Figure 51–3. Static volume-pressure relationship for the total respiratory system of a surfactant-depleted juvenile rabbit. *Pflex* indicates the lower inflexion point.

setting PEEP above the pressure at this inflection point often decreases shunt and increases PaO_2.[23-26]

The possibility that pulmonary dysfunction may be aggravated if this inflection point lies within the V_T has been a recent focus of attention. Experimental evidence for this possibility initially was provided by studies comparing conventional mechanical ventilation with high-frequency oscillatory ventilation in premature or surfactant-depleted lungs. Studies performed on such lungs ventilated at various levels of PEEP suggest that repeated closure and reopening of terminal units can cause lung injury.[27-29] Argiras and colleagues[27] and Sandhar and associates[28] studied this issue in rabbits with surfactant-depleted lungs. During volume-controlled ventilation, peak inspiratory pressure was initially 15 mm Hg but increased to 25 mm Hg 5 hours later because lung compliance fell. PEEP was then adjusted to be either above (8 to 12 mm Hg) or below (1 to 2 mm Hg) the lower inflection point of the inspiratory limb of the PV curve. Mortality rates in the two groups were identical, but arterial PaO_2 was better preserved and less hyaline membrane formation occurred in the high-PEEP group.[27,28] This lessening of pathologic alterations was observed even when inspiratory/expiratory time ratios were adjusted so that mean airway pressures were the same in the low-PEEP and high-PEEP groups.[28] Muscedere and colleagues[30] reported similar results in isolated, unperfused rabbit lungs lavaged with saline solution and ventilated with a low (5 to 6 mL/kg) V_T and with a PEEP set below or above the inflection point. However, Sohma and colleagues[29] did not find this injury in vivo in rabbits whose lungs had been injured with hydrochloric acid.[29]

It often is argued that the lower inflection point on the PV curve reflects the recruitment of collapsed zones that are found predominantly in dependent areas[31,32] and that this recruitment persists during further lung expansion. Recently Martynowicz and coworkers[33] have questioned the existence of the repetitive collapse-reexpansion phenomenon during tidal ventilation and have reevaluated the significance of the lower inflection point on the PV curve. They studied the regional expansion of oleic acid–injured lungs using the parenchymal marker technique in dogs. They found that the gravitational distribution of volume at functional residual capacity was not

affected and not associated with a decreased parenchymal volume of the dependent regions. In addition, they found that the between-region asynchrony of tidal expansion was not influenced by oleic acid injury. Their findings therefore did not support the hypothesis that a more important gravitational gradient during VILI produces atelectasis by compression of the dependent lung, cyclic recruitment and collapse, and ultimately shear stress injury.[33] They propose that the displacement of air-liquid interfaces along the tracheobronchial tree causes the lower inflection point on the PV curve and conclude that this knee on the curve reflects the mechanics of partially fluid-filled alveoli with constant surface tension and not the abrupt opening of airways or atelectatic parenchyma.[34] It therefore remains unsettled whether injury caused by the repetitive reopening of collapsed terminal units and the protective effect of PEEP is restricted to the peculiar situation of surfactant depletion by bronchoalveolar lavage. In the clinical arena, the recent negative results of the ALVEOLI trial[35] and the two other more recent randomized controlled trials[36,37] cast doubt on the clinical existence of repetitive opening and closing lung injury.[38]

Roles of Tidal Volume, Positive End-Expiratory Pressure, and Overall Lung Distention

The influence of PEEP on acute lung injury (and more specifically on ventilator-induced pulmonary edema) must be studied in the context of the level of V_T. Indeed, PEEP increases functional residual capacity (FRC) and recruits the lung but also increases end-inspiratory volume when V_T is kept constant, thus possibly favoring overinflation. PEEP application also may depress hemodynamics and affect lung fluid balance. Therefore close analysis of the numerous studies that have been done to clarify the relationships between PEEP, oxygenation, and extravascular lung water accumulation during hydrostatic or permeability type edema must take into account the experimental approach used, that is, intact animals or isolated lungs (for which lung water content will differ), and whether or not V_T is reduced (thus increasing or not increasing end-inspiratory lung volume).

Effects of Positive End-Expiratory Pressure When Tidal Volume Is Kept Constant

Application of PEEP may result in lung overinflation if it is followed by a significant change in FRC because of the increase in end-inspiratory volume. Overinflation will affect preferentially the more distensible areas that receive the bulk of ventilation, which may explain the lack of reduction or even the worsening of edema reported following PEEP application in most experiments.[39] PEEP does not affect the severity of hydrostatic[40] or permeability[40,41] edema in intact animals, although it improves oxygenation[40] because of the recruitment of flooded alveoli (Figure 51-4). In isolated ventilated-perfused lungs, PEEP rather aggravates edema fluid accumulation[42] (Figure 51-5). Thus when V_T is left unchanged, increasing FRC with PEEP affects edema differently in isolated lungs or in intact animals. In the latter, the lack of effect of PEEP depends on the balance between PEEP-induced increase in end-inspiratory lung volume, which decreases interstitial pressure and increases filtration pressure in extra-alveolar vessels, and the hemodynamic depression due to elevated intrathoracic pressure that, in the opposite, decreases filtration pressure. In contrast, preservation of perfusion rate in isolated-perfused lungs favors edema formation.[42]

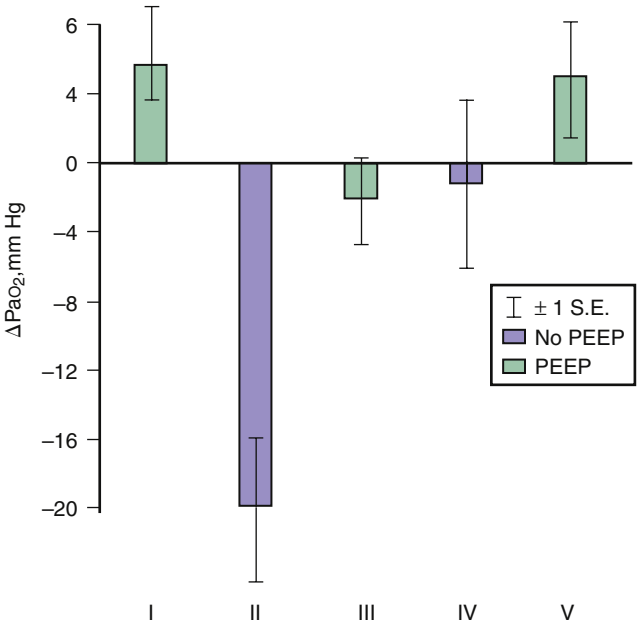

Figure 51–4. Change in arterial oxygen tension (ΔPaO_2, mm Hg) during 1-hour period between the initial and final measurements for groups I (control), II, and III (severe hydrostatic pulmonary edema, without and with positive end-expiratory pressure [PEEP], respectively), and IV and V (moderate pulmonary edema, without and with PEEP, respectively). The difference between ΔPaO_2 for groups II and III is significant ($P < .01$). *(From Hopewell PC, Murray JF: Effects of continuous positive-pressure ventilation in experimental pulmonary edema,* J Appl Physiol *40:568-574, 1976.)*

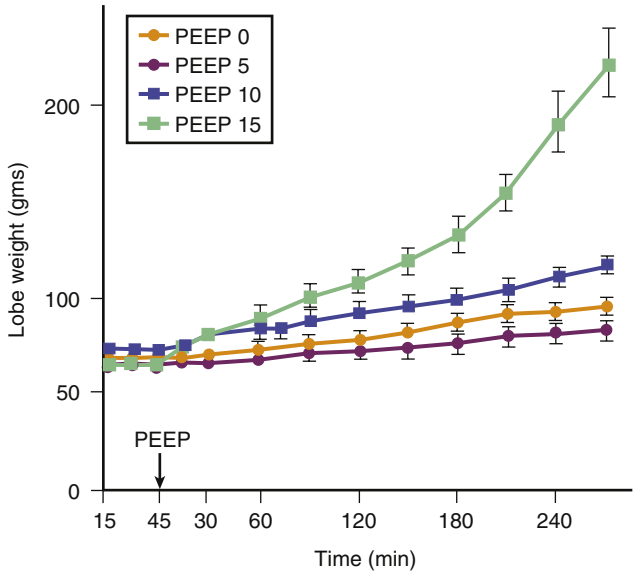

Figure 51–5. Effect of three levels of positive end-expiratory pressure (PEEP) on water accumulation in hydrochloric acid–injured ventilated-perfused dog pulmonary lobes. The highest PEEP resulted in a further increase in pulmonary edema. *(From Toung T, Saharia P, Permutt S, et al: Aspiration pneumonia: beneficial and harmful effects of positive end-expiratory pressure,* Surgery *82:279-283, 1977.)*

Effects of Positive End-Expiratory Pressure when Tidal Volume Is Reduced

Edema is less severe during high-volume ventilation (even though FRC is increased by PEEP) when end-inspiratory lung volume is kept constant by decreasing V_T (Figure 51-6). Webb and Tierney[4] showed that less edema developed during ventilation with 45 cm H_2O peak airway pressure when 10 cm H_2O PEEP was applied. The authors attributed this beneficial effect of PEEP to the preservation of surfactant activity. It was later shown that, although PEEP decreased the amount of edema, it did not prevent alteration of capillary permeability.[6] However, animals undergoing ventilation with PEEP had no alveolar damage in contrast with those that underwent ventilation without PEEP. The only cellular alterations found in animals that underwent ventilation with PEEP consisted of capillary endothelial blebs.[6] No satisfactory explanation has been found for this preservation of the epithelial layer. It may be that PEEP prevented fluid movement in terminal units, thereby decreasing shear stress at this level. Similar observations have been made by other investigators in intact animals[43,44] and in isolated perfused canine lobes.[45] The hemodynamic alterations induced by PEEP probably play an important role in lessening the severity of edema. Application of PEEP produces an increase in mean intrathoracic pressure that adversely affects cardiac output.[46,47] For example, in rats subjected to high peak airway pressure and 10 cm H_2O PEEP, edema was more severe when the hemodynamic alterations induced by PEEP were corrected with dopamine infusion.[48] The amount of extravascular lung water was correlated with systemic blood pressure, suggesting that restoration of cardiac output increased filtration pressure and was responsible for aggravation of edema. The reduction of edema and of the severity of cellular damage by PEEP during ventilation-induced pulmonary edema may be linked to reduced tissue stress by decreasing volume-pressure excursion, movement of foam in distal airways, preservation of surfactant activity, and a decrease in capillary filtration.

Importance of Overall Lung Distention

Lung volume at the end of inspiration (i.e., the overall degree of lung distention) is probably the main determinant of the severity of VILI. Pulmonary edema developed in rats that underwent ventilation with a low V_T and 15 cm H_2O PEEP, whereas it did not develop in rats that underwent ventilation with the same V_T but with 10 cm H_2O PEEP.[48] Similarly, doubling this V_T in the presence of 10 cm H_2O PEEP produced pulmonary edema, whereas it did not produce pulmonary edema in animals that underwent ventilation without PEEP. Thus the safety of a given V_T depends on how much FRC is increased.

In conclusion, permeability edema and VILI occur when a threshold degree of lung overinflation is reached. This situation can occur when V_T is increased from a given level of end-expiratory pressure. In contrast, when PEEP is increased at constant end-inspiratory pressure, it slows the development of edema and diminishes the severity of tissue injury but does not prevent altered microvascular permeability.[6,48] Finally, when the application of PEEP increases the end-inspiratory (plateau) pressure, it increases the risk of edema formation.[48]

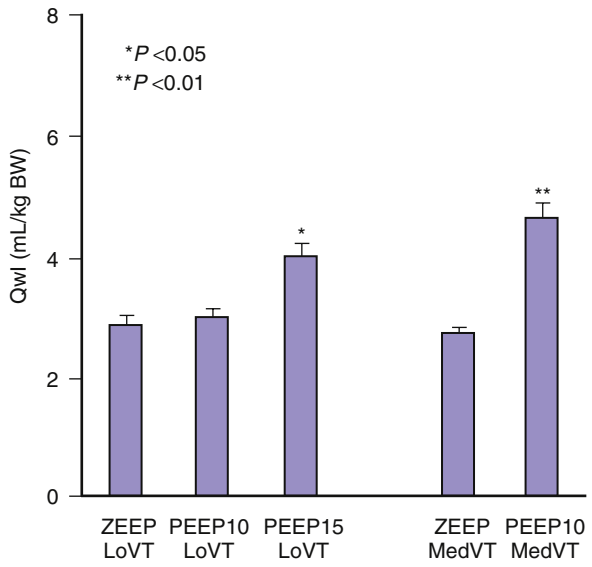

Figure 51–6. Effect of increasing positive end-expiratory pressure (PEEP) from 0 to 15 cmH_2O during ventilation with two different tidal volume (V_T) values (7 mL/kg body weight *[BW]*: LoV_T and 14 mL/kg BW: $MedV_T$). Pulmonary edema (as evaluated by increases in extravascular lung water [Qwl]) occurred when PEEP was increased. PEEP required to produce edema varied with V_T: 15 cmH_2O PEEP during ventilation with low V_T and 10 cmH_2O PEEP during ventilation with moderately increased V_T. $*P < .05$; $**P < .01$ vs. zero end-expiratory pressure (ZEEP) and the same V_T. *(From Dreyfuss D, Saumon G: Role of tidal volume, FRC, and end-inspiratory volume in the development of pulmonary edema following mechanical ventilation,* Am Rev Respir Dis *148:1194-1203, 1993.)*

Possible Mechanisms of Ventilator-Induced Lung Injury

It is now clear that ventilation-induced pulmonary edema is essentially the result of severe changes in the permeability of the alveolar-capillary barrier. Small increases in filtration pressure may combine with altered permeability to aggravate edema.

Ventilation may damage lungs by two different mechanisms, and the severity of damage depends on both intensity and duration of the insult. A rapidly occurring and severe permeability pulmonary edema may be produced in small animals as a consequence of acute lung stretch. This edema does not appear to require the involvement of inflammatory cells or secretion of mediators and can occur within a few minutes. Edema develops more slowly in larger animals for the same plateau pressure, rendering the situation more complex. A low lung volume injury may contribute its own effects to high end-inspiratory volume damage. Further, ventilation without PEEP may reduce aerated lung volume and gradually worsen mechanical nonuniformity. This lung inhomogeneity will in turn promote overinflation of the more compliant and probably healthier zones, leading to positive feedback aggravation. In addition, when lung lesions develop slowly, inflammatory pathways have enough time to be activated and may participate in tissue injury (Figure 51-7).

Mechanisms of Increased Vascular Transmural Pressure

Increased fluid filtration may occur at both extraalveolar[49,50] and alveolar[51-53] sites during mechanical ventilation. Increased transmural pressure in extraalveolar vessels results from the increase in lung volume, and the decrease in

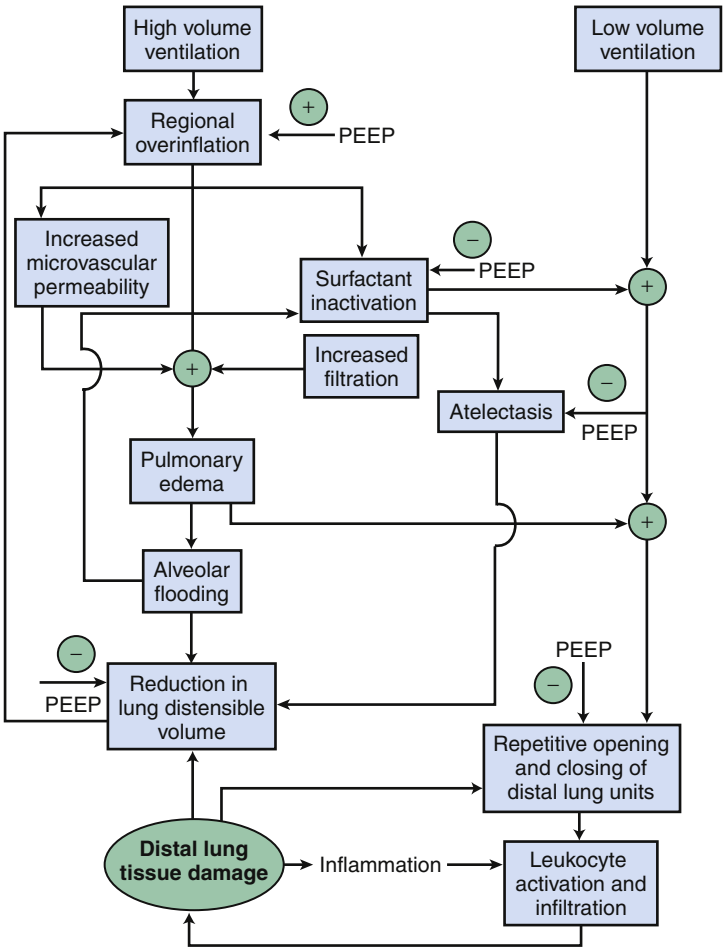

Figure 51–7. Flow diagram summarizing the contributors to mechanical ventilation–induced lung injury. Positive end-expiratory pressure (PEEP) generally opposes injury or edema formation *(minus sign)* except when it contributes to overinflation *(plus sign). (From Dreyfuss D, Saumon G: Ventilator-induced lung injury: lessons from experimental studies,* Am J Respir Crit Care Med *157:294-323, 1998.)*

perivascular interstitial pressure is the consequence of lung stretch.[46,54,55] Increased filtration across alveolar microvessels also may be promoted by the surfactant inactivation[4,53] that accompanies ventilation at high V_T or because of the presence of plasma proteins (such as fibrinogen and albumin) in airspaces.

Mechanisms of Altered Permeability

While capillary permeability alterations are obvious and may be severe during ventilator-induced edema, the underlying mechanisms are not fully understood and may vary according to the extent and duration of lung overdistension.

Effects of Surfactant Inactivation

In addition to its effects on fluid filtration, surfactant inactivation and elevated alveolar surface tension may increase alveolar epithelial permeability to small solutes. Surfactant inactivation by detergent aerosolization increases diethylenetriaminepentaacetic acid (DTPA) clearance in rabbits[56] and dogs.[57] This effect has been ascribed to the ventilation inhomogeneities and regional overexpansion that result from uneven inactivation of surfactant and maldistribution of lung mechanical properties rather than to the elimination of peculiar barrier properties of surfactant.[57] The effects of surfactant inactivation and large V_T ventilation on alveolocapillary permeability (as assessed by pulmonary DTPA clearance) are additive.[58] Endothelial permeability may be altered because the increased surface tension due to surfactant inactivation augments radial traction on pulmonary microvessels.[53]

Participation of Inflammatory Cells and Mediators

Role of Inflammatory Cells. The endothelial cell disruption observed during overinflation edema in small animals may allow direct contact between polymorphonuclear cells and the basement membrane. This contact may promote leukocyte sequestration. A striking feature of the VILI that occurs after several hours is the infiltration of inflammatory cells into the interstitial and alveolar spaces. In one of the earliest studies on this subject, Woo and Hedley-White[59] observed that overinflation produced edema in open-chest dogs and that leukocytes accumulated in the vasculature and macrophages in the alveoli. Further studies have confirmed these results[60] and have shown that high transpulmonary pressure increased the transit time of leukocytes in the lungs of rabbits.[61] Conversely, when animals are depleted in neutrophils, high-volume pulmonary edema is less severe than in nondepleted animals.[62] Protracted ventilation in small mammals also recruits leukocytes in lungs that may contribute to VILI.[63]

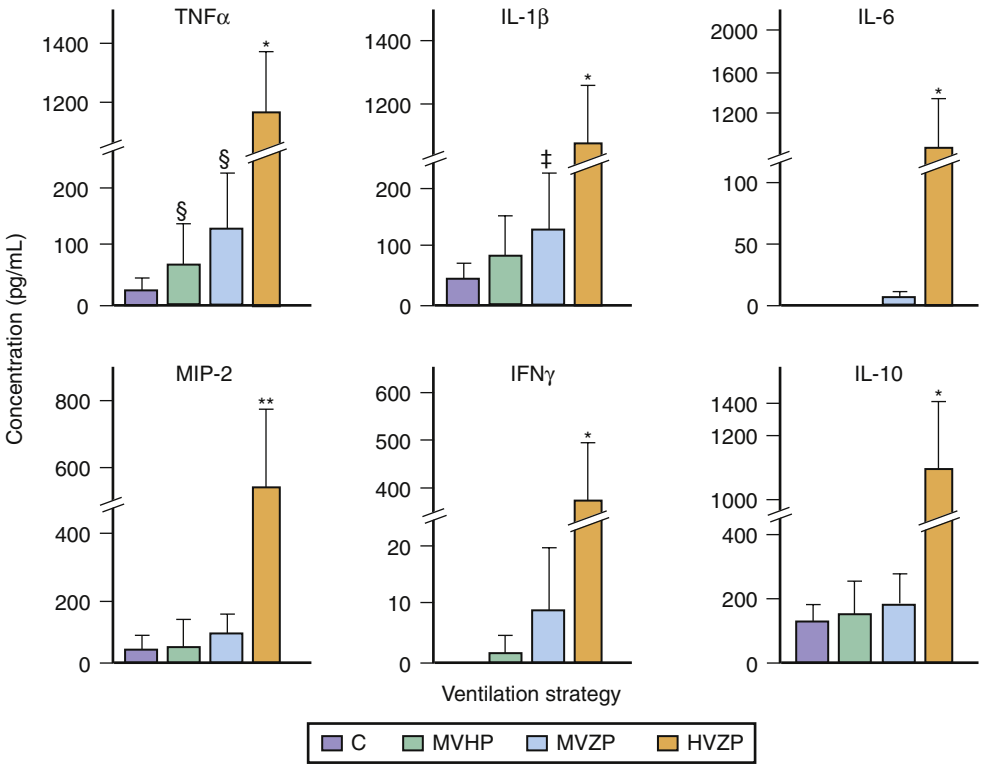

Figure 51–8. Effect of different ventilatory strategies on cytokine concentrations in lung lavage of isolated unperfused rat lungs. Four ventilator settings were used: controls (*C,* normal tidal volume [V_T]), moderate V_T + high positive end-expiratory pressure (PEEP) *(MVHP),* moderate V_T + zero PEEP *(MVZP),* and high V_T + zero PEEP *(HVZP)* resulting in the same end-inspiratory distension as MVHP. Major increases in cytokine concentrations were observed with HVZP. *IFN,* Interferon; *IL,* interleukin; *MIP,* macrophage inflammatory protein; *TNF,* tumor necrosis factor. *(From Tremblay L, Valenza F, Ribeiro SP et al: Injurious ventilatory strategies increase cytokines and c-fos m-RNA expression in an isolated rat lung model,* J Clin Invest *99:944-952, 1997.)*

Role of Inflammatory Mediators. The role of inflammatory cytokines in the course of VILI has been the subject of recent studies and is a matter of debate.[64,65] Tremblay and colleagues[66] examined the effects of different ventilatory strategies on the level of several cytokines in bronchoalveolar lavage fluid of isolated rat lungs ventilated with different end-expiratory pressures and V_T. High V_T ventilation (40 mL/kg) with zero end-expiratory pressure resulted in considerable increases in tumor necrosis factor (TNF)-α, interleukin (IL)-1β and IL-6, and macrophage inflammatory protein (MIP)-2 (Figure 51-8). Unfortunately, results from this study have not been replicated by another group using the same ex vivo lung model (Figure 51-9).[67] It is worth noting that stretching in vitro human alveolar macrophages[68] or A549 epithelial cells[69] led to no TNF-α release but to release of IL-8. In vivo studies of intact animals show that high-volume mechanical ventilation that produces a very severe pulmonary edema does not induce the release of TNF-α.[67,70] Studies on TNF-α messenger ribonucleic acid (mRNA) also yield conflicting results. Takata and coworkers[71] showed large increases in TNF-α mRNA in the intraalveolar cells of surfactant-depleted rabbits after 1 hour of conventional mechanical ventilation with peak inspiratory and end-expiratory pressures of 28 and 5 cm H_2O (resulting in a mean airway pressure of 13 cm H_2O), whereas Imanaka and colleagues[71a] showed no increase in lung tissue TNF-α mRNA of rats that underwent ventilation at high pressure (45 cm H_2O of peak inspiratory pressure[71]).

The only mediator that is constantly found in the different experimental studies is MIP-2 (or IL-8, pending on the

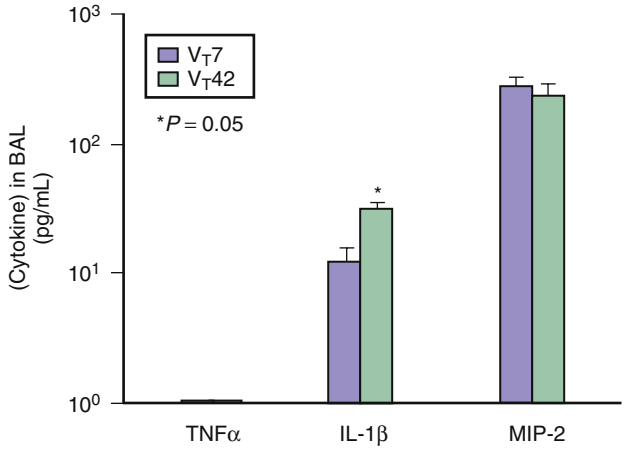

Figure 51–9. Effect of different ventilatory strategies on cytokine concentrations in lung lavage. Tumor necrosis factor (TNF)-α, interleukin (IL)-1β, and macrophage inflammatory protein (MIP)-2 concentrations in bronchoalveolar lavage fluid (BALF) of rats ventilated for 2 hours with 7 mL/kg tidal volume (V_T) and 3 cm H_2O positive end-expiratory pressure (PEEP) (V_T7) and 42 mL/kg V_T and PEEP (V_T42). TNF-α was undetectable whatever the ventilation strategy. IL-1β and MIP-2 were found in small amounts. IL-1β was slightly higher (*P = .05) in BALF of rats ventilated with the larger V_T. (Note that 100 signifies a value below the detection threshold). *(From Ricard J-D, Dreyfuss D, Saumon G: Production of inflammatory cytokines in ventilator-induced lung injury: a reappraisal,* Am J Respir Crit Care Med *163:1176-1180, 2001.)*

experimental model). The presence of this neutrophil chemoattractant mediator in lungs subjected to high-volume ventilation is in agreement with the well-documented recruitment of neutrophils that occurs after long-term ventilation.[59,72-74] In vivo inhibition of MIP-2 ligand interactions led to a marked reduction in neutrophil sequestration and lung injury in mice subjected to high-volume ventilation for 6 hours.[63]

In addition to increasing the amount of cytokines in the lung, it has been suspected that overinflation during mechanical ventilation may promote the release of cytokines[75,76] or bacteria[77,78] into the blood, thus giving a causative role for mechanical ventilation in multiorgan dysfunction.[79,80] However, this hypothesis remains to be proven.[81]

New Insights in Ventilator-Induced Lung Injury

Cellular Response to Mechanical Strain

Interest is growing in the cellular response to mechanical strain, and related issues recently have been reviewed.[82] Parker and colleagues[83] studied the different signal transduction pathways that may be involved in the microvascular permeability increases observed during experimental VILI. They found that gadolinium (which blocks stretch-activated nonselective cation channels) annulled the increases in vascular permeability induced by high airway pressure.[84] The authors concluded that stretch-activated cation channels might initiate the increase in permeability induced by mechanical ventilation through increases in intracellular Ca^{2+} concentration. To further explore the involvement of this pathway, the same team showed that Ca^{2+}/calmodulin–myosin light chain kinase inhibitors significantly attenuate the vascular permeability increase induced by high-pressure mechanical ventilation in an isolated perfused rat model.[85] High-volume ventilation of isolated rat lungs leads to the release of reactive nitrogen species.[86] Nitric oxide participates in the control of endothelial permeability, and nitric oxide overproduction results in increases in endothelial permeability and blebs at the ultrastructural level very similar to those observed after periods of high-volume ventilation.[87]

Taken together, these results suggest that the increase in microvascular permeability may not simply be a passive physical phenomenon (a "stress failure"[88,89]) but may at least in part be the result of biochemical reactions. Maintenance of plasma membrane integrity is essential in response to mechanical stress. Recently Vlahakis and colleagues reported a heretofore-undescribed response of alveolar epithelial cells to deformation.[90] They labeled membrane lipids to study deformation-induced lipid trafficking and observed cell responses to deforming forces by laser confocal microscopy. A 25% stretch deformation resulted in lipid transport to the plasma membrane that ensured cell integrity and increased its surface area. This lipid trafficking occurred in all cells, in contrast with plasma breaks that were seen in only a small percentage of cells. The authors concluded that deformation-induced lipid trafficking serves in part to repair plasma breaks and that this could be viewed as a cytoprotective mechanism against plasma membrane stress failure seen during VILI.[6,89] Other investigators have focused on the relative importance of deformation frequency, duration, and amplitude in stress-induced cell injury.[91] Interestingly, authors found that limiting the deformation amplitude resulted in significant reductions in cell death at identical peak deformations (Figure 51-10). From these results, an analogy

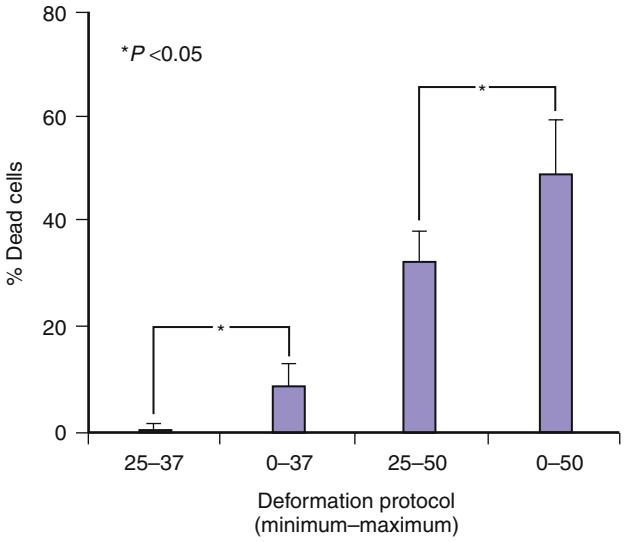

Figure 51–10. Relative importance of deformation magnitude and amplitude. Deformations were applied for 60 minutes at 15 cpm. Data are given as mean ± SD. Reducing the amplitude to 12% ΔSA or 25% ΔSA significantly reduced cell death when maximum deformation was held at 37% ΔSA or 50% ΔSA, respectively. *$P < .05$. *(From Tschumperlin DJ, Oswari J, Margulies SS: Deformation-induced injury of alveolar epithelial cells. Effect of frequency, duration, and amplitude,* Am J Respir Crit Care Med *162:357-362, 2000.)*

can be drawn with experiments that showed a decrease in lung injury when V_T was reduced with a constant PEEP level, thus reducing end-inspiratory lung volume.[48]

Influence of Carbon Dioxide Tension on Ventilator-Induced Lung Injury

Deleterious effects of hypocapnia have been extensively reviewed.[92] However, it is important to note that, in addition to detrimental effects of hypocapnia[93] and hypercapnia[94] on ischemia-reperfusion lung injury, experimental studies suggest that hypercapnia may protect from the acute increase in capillary permeability caused by overinflation[86] and from inflammation during VILI.[95]

Strategies to Reduce Ventilator-Induced Lung Injury: Use of the Pressure-Volume Curve

The ARDS network trial[2] has undisputedly shown that reducing V_T from 12 mL/kg to 6 mL/kg resulted in a 22% reduction in mortality rate (Figure 51-11). By protocol, the same reduction of V_T was applied to all patients allocated to the low V_T group. However, it has repeatedly been shown that pressures and the volumes considered safe for some patients with ARDS may cause lung overdistension in others.[31,32,96,97] Conversely, arbitrary settings may result in an unnecessary reduction in V_T, which a recent meta-analysis has suggested as being potentially harmful.[3]

It has been suggested that information from the inspiratory PV curve of the respiratory system could be used to tailor ventilator settings. For instance, the presence of an opening pressure (lower inflection point) could be used to adjust the PEEP.[23-25] It has been proposed that the V_T be adjusted according to PV curve analysis by limiting end-inspiratory pressures to the pressure at which a decrease in slope is seen at high

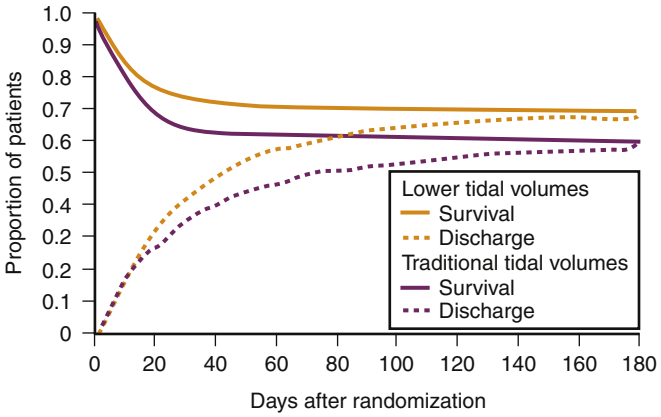

Figure 51–11. Probability of survival and of being discharged home and breathing without assistance during the first 180 days after randomization in patients with acute lung injury and acute respiratory distress syndrome. *(From The Acute Respiratory Distress Syndrome Network: Ventilation with lower tidal volumes as compared with traditional tidal volumes for acute lung injury and the acute respiratory distress syndrome,* N Engl J Med *342:1301-1308, 2000.)*

pressure/volume (the upper inflection point [UIP]).[96,97,100] The UIP often seen in patients with ARDS has been ascribed to overinflation[96,97] or to the end of recruitment[101,102] during lung expansion. However, whether ventilator settings that would result in pressure/volume excursions above the UIP are deleterious remains unsettled and has never been assessed experimentally. The impact of pulmonary edema and the resulting decrease in ventilatable lung volume on the inspiratory limb of the respiratory system PV curve has not yet been evaluated. A better understanding of its significance is required before the UIP can be used to set V_T in patients. A recent experimental study[103] found that the reduction in ventilatable lung volume (the baby lung effect) not only decreases the compliance of the lung[31,104] but also affects the position of the UIP. It also was noted that the development of edema altered the PV curve by causing distal airway obstruction and that individual characteristics of the PV curve reflected the susceptibility of the lungs to the deleterious effects of high-volume ventilation. The authors found that the higher the compliance and the volume of the UIP were before ventilation, the less severe edema there was after overinflation. Taken together, these results suggest that the position of the UIP is a marker of ventilatable lung volume and is both influenced by and predictive of the development of edema during mechanical ventilation. Because the UIP is less influenced by ventilatory mechanics than is respiratory system compliance, it may be of greater clinical value.

Imaging Ventilator-Induced Lung Injury

Alveolar epithelial and pulmonary microvascular permeability to proteins was evaluated using a two-way protein flux scintigraphic study in rats during lung inflation.[105] Two tracers were used, ^{99m}Tc-albumin (in the alveolar instillate) and ^{111}In-transferrin (in the blood). Alveolar epithelial permeability was estimated from the rate at which ^{99m}Tc-albumin left the lungs. Microvascular permeability was simultaneously estimated measuring the accumulation of ^{111}In-transferrin in the lungs. Increasing lung tissue stretch by ventilation at high airway pressure immediately increased microvascular but also alveolar epithelial permeability to proteins. The same end-inspiratory pressure threshold (between 20 and 25 cmH_2O) was observed for epithelial and endothelial permeability changes.[103] In a subsequent study,[104] the same authors instilled a ^{99m}Tc-labeled albumin solution in a distal airway to produce a zone of alveolar flooding. The instillation protocol produced a zone of alveolar flooding that stayed localized during conventional mechanical ventilation or spontaneous breathing. High-volume ventilation dispersed alveolar liquid in the lungs. This dispersion was prevented by PEEP even when VT was the same and thus the end-inspiratory pressure was higher. High-volume ventilation resulted in the leakage of instilled ^{99m}Tc-albumin from the lungs. This increase in alveolar albumin permeability was reduced by PEEP.[104] Finally, the effect of two routes of administration (intratracheal and intraperitoneal) of terbutaline on VILI was evaluated.[105] High-volume ventilation resulted in immediate leakage of ^{99m}Tc-albumin from alveolar spaces and increased pulmonary uptake of systemic ^{111}Intransferrin. Terbutaline in the instilled solution and PEEP lessened alveolar ^{99m}Tc-albumin leakage and pulmonary ^{111}In-transferrin uptake due to high-volume ventilation, whereas terbutaline given intra-peritoneally only lessened ^{111}In-transferrin uptake. Terbutaline in the instilled solution also lessened the increase in lung wet-to-dry weight ratio due to high-volume ventilation.[105] Taken together, these results indicate that simple noninvasive imaging techniques can be used to noninvasively study the changes in lung microvascular and alveolar permeability to proteins in vivo and the movement of fluids in the lungs during mechanical ventilation. Continuously and simultaneously monitoring such variables might be of great interest in experimental research on VILI because it allows the assessment of physiologic or pharmacologic interventions.

Conclusion and Clinical Applications

The experimental concept of VILI is undeniably relevant to clinical practice.[2] High-volume injury contributes to mortality of patients with ARDS and may be reduced by decreasing V_T and plateau pressure. On the other hand, the concept of low lung volume injury that should benefit from high levels of PEEP has not received the same convincing clinical confirmation, given the negative survival data from three randomized controlled trials comparing two levels of PEEP.[35-37] Thus the ideal ventilatory strategy has yet to be determined. For the time being and until further evidence is obtained, one may put forward the following conclusions:

- Drastic V_T reduction may not be justified for every patient with ARDS.
- Reasoned V_T reduction designed to avoid volutrauma may be guided by mechanical lung properties provided by respiratory system PV curves to avoid excessive or insufficient V_T reduction.
- Although use of PEEP remains the cornerstone of management of hypoxemia during ARDS, to date, generalized use of high levels of PEEP is not justified.
- Ventilatory management of ARDS is not yet deeply supported by evidence, but basic physiologic principles remain helpful to clinicians.[38,65,106,107]

Chapter 52

Acute Respiratory Distress Syndrome in Children

Stéphane Dauger, Philippe Durand, Etienne Javouey, and Jean-Christophe Mercier

PEARLS

- The incidence of acute lung injury and acute respiratory distress syndrome is quite low in children.
- Insults leading to acute lung injury and acute respiratory distress syndrome are similar to those observed in adults, that is, direct lung injury including pneumonia, gastric content aspiration, lung contusion, hydrocarbon ingestion, smoke inhalation, and sickle cell disease; or indirect injury including near-drowning, multiple emergent transfusions, and sepsis.
- Endothelial and epithelial injury is critical to diffuse alveolar damage and pulmonary edema.
- Acute lung injury resolution may be hastened by strategies that activate apical ENaC type channels and basal Na^+/K^+-ATPase channels, including β-adrenergic agents.
- Ventilator-induced lung injury is now known to play a major role in the outcome, Ventilator strategies using both limited tidal volume (V_T) less than 6 to 8 mL/kg and inspiratory plauteau pressure less than 25 to 30 cm H_2O with permissive hypercarbia, and sufficient levels of positive end-expiratory pressure to decrease inspired fraction of oxygen are widely used.
- No adjunct therapies including high-frequency oscillatory ventilation, prone positioning, surfactant replacement, and inhaled nitric oxide therapy have demonstrated significant benefits. Despite a lack of conclusive trials, extracorporeal life support is used in some centers as a last resort.
- Noninvasive ventilation may be valuable in the management of respiratory failure in immunocompromised children, given the high mortality observed when tracheal intubation and mechanical ventilation are required.
- Although no conclusive data have emerged from appropriately designed trials, there is some evidence to suggest that steroids used at the late fibrosing stage of acute respiratory distress syndrome may be of benefit.

The acute respiratory distress syndrome is a common and devastating clinical syndrome of acute lung injury that affects both medical and surgical patients. In 1967, Ashbaugh et al. described 12 adults with the acute onset of tachypnea and cyanosis refractory to oxygen therapy, diffuse infiltrates on the chest x-ray, and decreased lung compliance.[1] Initially called the "adult" respiratory distress syndrome, this entity has now been coined the "acute" respiratory distress syndrome (ARDS), since it does also occur in children[2-5] and in newborns.[6] However, ARDS is rare in children, and its incidence is estimated to be from 1% to 5% of the children hospitalized in the PICU.[7-10]

Because the initial definition lacked specific diagnostic criteria, there was controversy over the incidence and natural history of the syndrome. Some investigators attempted to exclude cardiogenic causes of pulmonary edema by requiring a "normal" pulmonary capillary wedge pressure, and specified values range from 12 mm Hg or less,[11] to less than 18 mm Hg.[12] In 1988, an expanded definition was proposed that quantified the respiratory impairment through a four-point lung-injury scoring system that was based on the degree of infiltration evident on the chest radiograph, the ratio of the partial pressure of arterial oxygen to the fraction of inspired oxygen (PaO_2/FiO_2), the level of positive end-expiratory pressure (PEEP), and the decrease in the static lung compliance.[13] Mild-to-moderate acute lung injury (ALI) was defined by a lung injury score less than 2.5, and severe lung injury (ARDS) by a score higher than 2.5. Although the lung injury scoring system has been widely used to quantify the severity of lung injury in clinical trials, it cannot be used to predict the outcome during the first 24 to 72 hours after the onset of ARDS. In contrast, when used at 4 to 7 days after the onset of the syndrome, scores greater than 2.5 may be predictive of a complicated course and the need for prolonged mechanical ventilation.

Furthermore, the direct (e.g., aspiration, fat embolism, drug ingestion, toxic gas inhalation, infectious pneumonia) or indirect (e.g., sepsis, acute pancreatitis, multiple blood transfusions, disseminated intravascular coagulation) cause of the acute lung injury was thought to influence the outcome, as well as the presence or absence of nonpulmonary organ dysfunction. However, the former concept was later challenged.[14]

In 1994, the American-European Consensus Conference Committee proposed a new definition (Table 52-1).[15] The consensus definition had two advantages. Firstly, it recognized that the severity of clinical lung injury varies: patients with less severe hypoxemia (as defined by PaO_2/FiO_2 ratio ≥200 and ≤300) were considered to have ALI, and those with more

Table 52–1 The American-European Consensus Conference Definitions of ALI and ARDS

Criteria	Timing	PaO_2/FiO_2	Chest Radiograph	Pulmonary Wedge Pressure
ALI	Acute onset	≤300	Bilateral infiltrates	≤18 mm Hg or the absence of clinical evidence of left atrial hypertension
ARDS	Acute onset	≤200*	Bilateral infiltrates	≤18 mm Hg or the absence of clinical evidence of left atrial hypertension

Many authors now advocate reevaluating the PaO_2/FiO_2 ratio after 1 day of optimized care, after 30 minutes of FiO_2 = 1.0, and with PEEP = 5 cm H_2O.

severe hypoxemia (as defined by PaO_2/FiO_2 ratio <200) were considered to have ARDS. Earlier recognition of patients with ALI was supposed to facilitate earlier enrollment of patients in clinical trials. Secondly, the definition was simple to apply in the clinical setting, where measurement of static compliance had been largely abandoned. However, the new definition did not take into account other important factors that influence the outcome,[16] such as the optimization of ventilation including PEEP level,[17,18] a significant improvement in blood gas exchange within the first 24 hours,[19] the underlying cause, and whether other organ systems were affected.[20] Nevertheless, the widespread acceptance of both the 1988 lung injury scoring system and the 1994 consensus definition has improved the standardization of clinical research and trials.[21] Using the 1994 definition, the radiographic diagnosis of ARDS showed a large interobserver variability in adults[22] and in children.[23] Also, diffuse alveolar damage with the involvement of the four lung quadrants is seen in less than half of the patients, and is not well-correlated to defined histological changes.[24] Thus the evaluation of PaO_2/FiO_2 or SpO_2/FiO_2 ratios[25] on the second day of optimized care has been introduced in order to better identify different degrees of lung injury of divergent outcome.[26]

Pathogenesis

Endothelial and Epithelial Injury

The alveolar-capillary barrier is formed of two separate cellular linear barriers, the vascular endothelium and the alveolar epithelium.[27] The acute phase of ALI and ARDS is characterized by the influx of protein-rich edema fluid into the air spaces as a consequence of increased permeability of the alveolar-capillary barrier.[28] The importance of endothelial injury and increased vascular permeability to the formation of pulmonary edema that characterizes the early phase of ARDS has been well established.

The critical role of epithelial injury to both the development of and recovery from ARDS has been more recently recognized.[29] The loss of epithelial integrity has numerous consequences. First, the diffuse alveolar damage contributes to alveolar flooding. Second, epithelial injury disrupts normal epithelial fluid transport, and impedes the removal of edema fluid from the alveolar space. Alveolar fluid clearance has been found to be impaired in the majority of patients with ALI and ARDS.[30] Third, alveolar type II cell injury impedes surfactant production and turnover, contributing to the characteristic surfactant abnormalities.[31] Finally, the inflammatory cascade is activated with the release of numerous mediators. Activated macrophages secrete proinflammatory cytokines including tumor necrosis factor-α (TNF-α), and interleukins (IL-1, IL-6, IL-8) that act locally to stimulate chemotaxis and activate neutrophils.[32] Neutrophils adhere to the injured capillary endothelium and marginate through the interstitium into the airspace. Neutrophils can, in turn, release oxidants, proteases, leukotrienes, and many other proinflammatory molecules (Figure 52-1).[33]

Role of Cytokines

A complex network of cytokines and other proinflammatory compounds is thought to initiate and amplify the inflammatory response in ALI and ARDS.[34] The regulation of cytokine production may be influenced by extrapulmonary factors including microbial products, lipopolysaccharide endotoxins, and macrophage inhibitory factor, which has been found in high concentrations in the bronchoalveolar lavage fluid of patients with this syndrome.[35]

Not only the production of proinflammatory cytokines is important, but also the balance between the proinflammatory and antiinflammatory mediators.[36] Several endogenous inhibitors of proinflammatory cytokines have been described, including soluble tumor necrosis factor receptor, interleukin-1 receptor antagonist, and antiinflammatory cytokines such as interleukin-10 and -11. The critical role of cytokines in acute lung injury and ventilator-induced lung injury has been, however, recently challenged.[37]

Role of Ventilator-Induced Lung Injury

While high fractions of inspired oxygen have long been considered potentially toxic to the lung, experimental evidence has recently accumulated that high volumes and pressures can injure the lung, causing increased permeability edema in the uninjured lung,[38] and enhanced edema in the injured lung.[39] Initial theories focused on capillary stress failure due to alveolar distension.[40] More recently, alveolar distension associated with the repeated collapse and reopening of alveoli was shown to initiate a cascade of proinflammatory cytokines.[41] As most patients with acute lung injury who die do so from multisystem organ failure, it has been postulated that ventilator-induced lung injury plays a key role in determining the negative clinical outcome of patients exposed to mechanical ventilation.[42] The term *cellular biotrauma* has been coined to describe the process by which mechanical stress produced by mechanical ventilation leads to the upregulation of an inflammatory response.[43] Thus cells are required to sense mechanical forces and activate opposite intracellular signaling pathways: (1) able to release growth factors and surfactant when forces are physiologic (e.g., fetal or postnatal lung breathing), and (2) proinflammatory cytokines when forces are pathologic (e.g., barotrauma or volutrauma due to either excessive inspiratory positive pressures

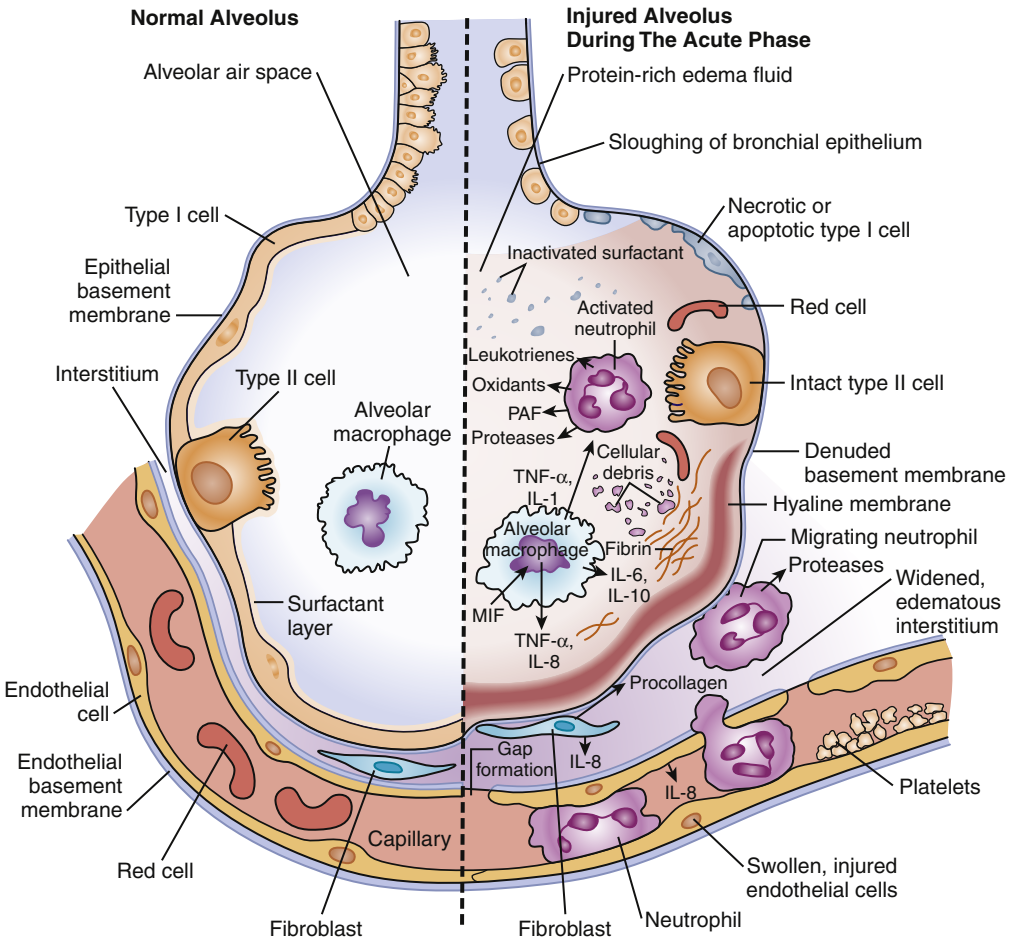

Figure 52–1. The normal alveolus (*left side*) and the injured alveolus in the acute phase of acute lung injury and the acute respiratory distress syndrome. In the acute phase of the syndrome (*right side*), there is sloughing of both the bronchial and alveolar epithelial cells, with the formation of protein-rich hyaline membranes on the denuded basement membrane. Neutrophils are shown adhering to the injured capillary endothelium and marginating through the interstitium into the air space, which is filled with protein-rich edema fluid. In the air space, an alveolar macrophage is secreting cytokines, interleukin-1, 6, 8, and 10, (IL-1, 6, 8, and 10) and tumor necrosis factor a (*TNF-a*), which act locally to stimulate chemotaxis and activate neutrophils. Macrophages also secrete other cytokines, including interleukin-1, 6, and 10. Interleukin-1 can also stimulate the production of extracellular matrix by fibroblasts. Neutrophils can release oxidants, proteases, leukotrienes, and other proinflammatory molecules, such as platelet-activating factor (*PAF*). A number of antiinflammatory mediators are also present in the alveolar milieu, including interleukin-1–receptor antagonist, soluble tumor necrosis factor receptor, autoantibodies against interleukin-8, and cytokines such as interleukin-10 and 11 (not shown). The influx of protein-rich edema fluid into the alveolus has led to the inactivation of surfactant. *MIF,* Macrophage inhibitory factor. *(Modified from Ware LB, Matthay MA:* N Engl J Med *342:1334-1349, 2000, with permission of the publisher.)*

or tidal volumes).[44] Multiple other pathways can perpetuate or inhibit lung injury. Abnormalities of the coagulation system along with impaired fibrinolysis leads to alveolar fibrin formation,[45] and occlusion of small pulmonary vessels by platelet-fibrin thrombi contributes to pulmonary vascular remodeling and pulmonary hypertension.[46-48] Abnormalities in the production, composition, and function of the surfactant contribute also to alveolar collapse and gas exchange anomalies.[49]

Resolution of Lung Injury

Prognosis appears dependent on resolution of the pathologic processes. Alveolar edema is resolved by the active transport of sodium and perhaps chloride from the distal air spaces into the lung interstitium (Fig. 52-2).[50,51] Apical ENaC type channels and basal Na^+,K^+ ATPase channels appeared to be highly regulated by beta-adrenergic agents, whereas amiloride-sensitive sodium transport is modulated by basal nitric oxide.[52] Water follows passively through transcellular water channels, the aquaporins, located primarily on type I cells.[53] Lung fluid clearance is impaired in the majority of patients with ALI and ARDS, but maximal alveolar fluid clearance has been found to be associated with significantly lower mortality and a shorter duration of mechanical ventilation.[54] The removal of insoluble protein is also particularly important, since hyaline membranes provide a framework for the growth of fibrous tissue.[55] Insoluble protein appear to be removed by endocytosis and transcytosis, by alveolar epithelial cells, and by phagocytosis by macrophages.[56] Type II cells proliferate to cover the denuded basement membrane and then differentiate into type I cells, restoring the normal alveolar architecture and the fluid-transport function of the alveolar epithelium. This proliferation is controlled by epithelial growth factors, including keratinocyte and hepatocyte growth factors.[57] New blood vessels are formed mostly as a result of

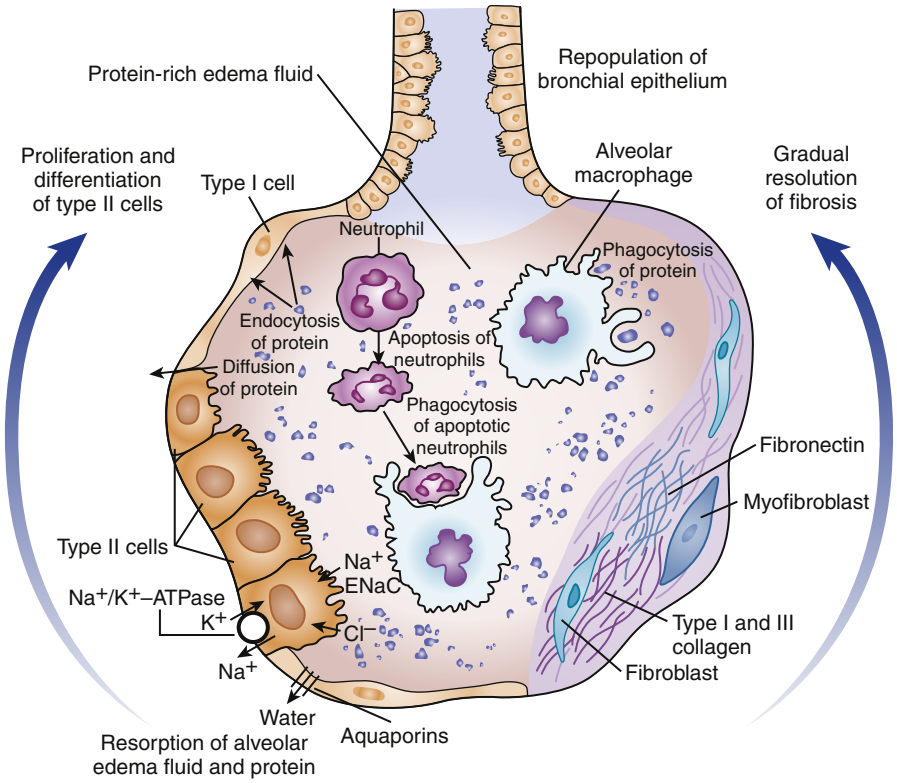

Figure 52–2. Mechanisms important in the resolution of acute lung injury and the acute respiratory distress syndrome. On the left side of the alveolus, the alveolar epithelium is being repopulated by the proliferation and differentiation of alveolar type II cells. Resorption of alveolar edema fluid is shown at the base of the alveolus, with sodium and chloride being transported through the apical membrane of type II cells. Sodium is taken up by the epithelial sodium channel (*ENaC*) and through the basolateral membrane of type II cells by the sodium pump (Na^+/K^+*-ATPase*). The relevant pathways for chloride transport are unclear. Water is shown moving through water channels, the aquaporins, located primarily on type I cells. Some water may also cross by a paracellular route. Soluble protein is probably cleared primarily by paracellular diffusion and secondarily by endocytosis by alveolar epithelial cells. Macrophages remove insoluble protein and apoptotic neutrophils by phagocytosis. On the right side of the alveolus, the gradual remodeling and resolution of intraalveolar and interstitial granulation tissue and fibrosis are shown. *(Modified from Ware LB, Matthay MA:* N Engl J Med *342:1334-1349, 2000, with permission of the publisher.)*

the vascular endothelium growth factor, and contribute to the normalization of the blood gas exchange.[58] Potential application of mesenchymal stem cells in acute lung injury has been explored in various in vivo models.[59]

Fibrosing Lung Injury

After the initial phase of acute lung injury and the acute respiratory distress syndrome, progression to fibrotic lung injury usually occur by 5 to 10 days after the onset of the disorder. The alveolar space becomes filled with fibroblasts and procollagen III peptide, of which the early appearance in the alveolar space has been associated with an increased risk of death.[60] The finding of marked fibrosing alveolitis on lung biopsy (or autopsy) correlates with an increased risk of death.[61] The mechanisms underlying the resolution of the inflammatory-cell infiltrates and fibrosis are unclear. Apoptosis is thought to play a major role for the clearance of neutrophils from the injured lung, as high concentrations of the markers of apoptosis have been shown in the bronchoalveolar lavage fluid taken from patients with the acute respiratory distress syndrome.[62,63] Antiinflammatory cytokines and proteases are also likely to play a major role. Mechanisms of repair and remodeling in acute lung injury have been recently reviewed.[64] It has become apparent that the process of fibrosing alveolitis begins early in the course of ARDS.[65] Determinants of persistent injury and abnormal repair and remodeling may be profoundly affected by both environmental and genetic factors. Recently, Chang et al.[66] performed proteomic and computational analyses on bronchoalveolar lavage fluid in patients with ARDS to identify proteins enriched and interactions that might be important for pathogenesis of lung injury, but no clear profile has emerged yet.

Clinical Features

Incidence and Etiology

The incidence of acute lung injury and acute respiratory distress syndrome is from 1% to 5% of pediatric intensive care admissions.[67-72] However, ARDS nowadays appears to be a relatively rare disease in children, perhaps because of more strict definitions or changing diagnostic criteria over the years. Within a 6-month period in nine large pediatric intensive care units across North America, 1096 (17.1%) of a total of 6403 admissions required mechanical ventilator support for a minimum of 24 hours. Of these, 701 (64%) met other criteria than primary respiratory failure for requiring mechanical support, including 13.5% upper airway obstruction, 11.5% cyanotic congenital heart disease, 9.7% life support restriction, and 5.5% chronically ventilated. In the 395 children who were eligible for respiratory failure studies, 62.4% had an acute primary diagnosis

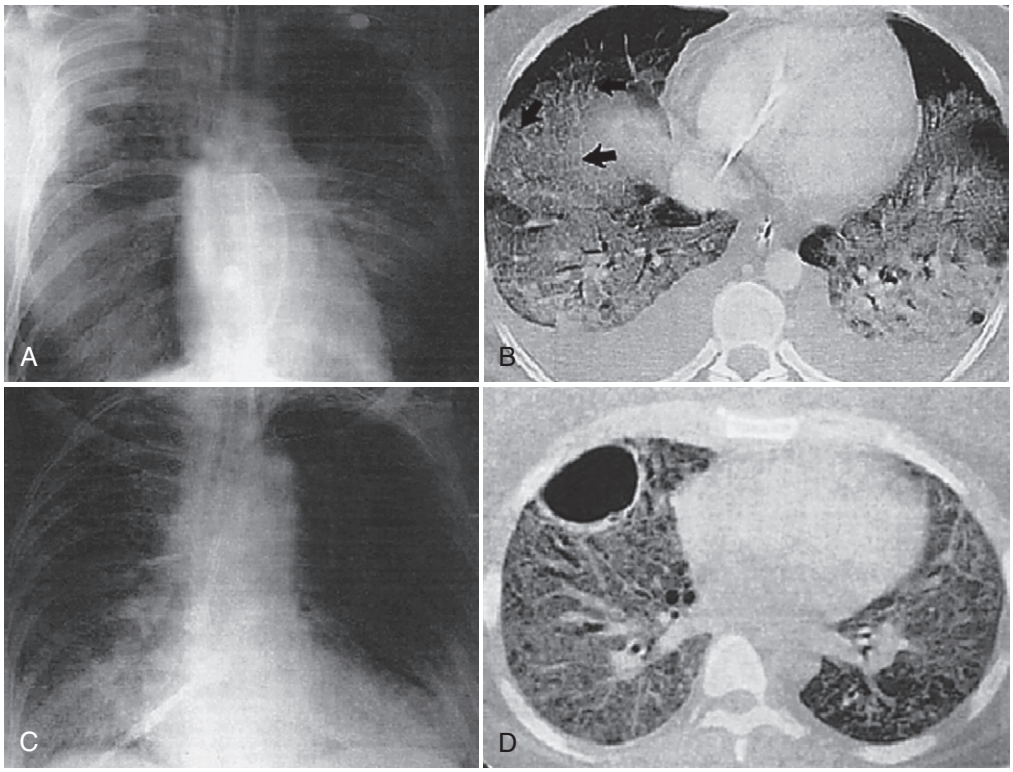

Figure 52–3. Radiograph and computed tomographic (CT) findings in the acute exudative phase (Panels **A** and **C**) and the fibrosing-alveolitis phase (Panels **B** and **D**) of acute lung injury and the acute respiratory distress syndrome. The *arrow* indicates thickened interlobular septa, consistent with pulmonary edema. *(From Goodman LR:* Radiol Clin North Am *34:33-46, 1996.)*

of pulmonary disease, 14.2% neurological disease, and 8.9% cardiac disease. Chronic underlying conditions were present in 43.2% of the patients. The most common acute diagnosis was bronchiolitis in infants (43.6%), and pneumonia in children 1 year old and older (24.5%). ARDS was identified in only 9 (5.7%) and 14 (9.7%) of the children with primary lung disease younger than 1 year and older than 1 year, respectively. Thus ARDS actually occurred in 23 children out of 6403 admissions, for a true incidence of 0.36%.[73,74]

Insults causing ALI or ARDS may either directly or indirectly injure the lung. Causes of direct lung injury include pneumonia, gastric contents aspiration, lung contusion, hydrocarbon ingestion, smoke inhalation, and sickle cell disease. Near-drowning, multiple emergent transfusions, and sepsis lead to ALI as part of multiorgan failure. Sepsis is the more common and lethal predisposing condition associated with ARDS, whether it is related to community-acquired infection (e.g., severe meningococcal shock), nosocomial infection (e.g., ventilator-associated pneumonia),[75] or serious underlying conditions (e.g., immunocompromised states).[76]

Clinical Course

The clinical course of ALI and ARDS parallels the histopathological abnormalities. Clinical changes that first occur are tachypnea, dyspnea, agitation, and hypoxemia. These findings usually develop rapidly during a period of hours, but can evolve over 1 to 5 days.[77] As the lung become edematous and consolidated, tachypnea and hypoxemia are caused by progressive restrictive lung disease and respiratory muscle fatigue. Chest radiographs show diffuse bilateral alveolar opacities, sometimes accompanied by small pleural effusion (Figure 52-3). However, CT scans reveal juxtaposition of abnormal dense lung regions and more functional lucent regions. Dense lung regions often develop in the dependent regions of the lung, reflecting collapse of the edematous lung with secondary atelectasis, whereas aerated regions usually prevail in nondependent areas.[78] Lung function measurements show a reduced functional residual capacity. Total lung compliance is reduced, but compliance of the small regions of functional lung is normal. Hypoxemia results from intrapulmonary shunting and the regions with low ventilation-perfusion relationships. These regions can be recruited in response to PEEP, thereby improving oxygenation.[79]

During the fibroproliferative phase, lung compliance is reduced by progressive lung fibrosis, and the effects of PEEP on oxygenation are less impressive. Lung parenchyma becomes better aerated despite accentuated interstitial markings indicative of fibrosis. At this stage, carbon dioxide retention is not uncommon. The requirement for mechanical ventilation may be prolonged for weeks, and clinical recovery usually requires a few months in children.[80] Although pediatric survivors of acute hypoxemic respiratory failure perceive no limitation in lifestyle, significant abnormalities in lung function, including bronchoreactivity, have been found.[81] Likewise, adult survivors of ARDS have persistent functional disability 1 year after discharge from the intensive care unit. Most patients have extrapulmonary conditions, with muscle wasting and weakness being most prominent.[82]

Oxygenation and Ventilator Strategy

Most patients with ALI and ARDS require supplemental oxygen and mechanical ventilation. These interventions can, however, themselves produce lung injury and worsen the acute respiratory distress syndrome.

Cellular toxicity of oxygen has been well established in both animals and human beings.[83] However, high levels of oxygen appear to be surprisingly well-tolerated in patients with acute respiratory failure, even for several days.[84] The reasons for this phenomenon are unclear. Antioxidant defense mechanisms have been found to be more efficient in primates than in rats.[85] Furthermore, prior lung exposure to endotoxin or cytokines (i.e., tolerance phenomenon) has been shown to protect animals exposed to 100% oxygen for several days, as compared to naive animals, who died rapidly.[86]

Ventilator-induced lung injury has recently been the subject of intensive experimental and human research (see Chapter 51). Traditionally, mechanical ventilation was delivered in an effort to normalize arterial blood gases. Tidal volumes of 10 to 15 mL/kg of body weight were used to normalize $PaCO_2$ values. After numerous experimental studies clearly demonstrated that excessive tidal volume traumatized lung structures, particularly when functioning lung volume is reduced to an aerated "baby lung" surrounded by extensive consolidated areas,[87] an international conference addressed factors likely responsible for ventilator-induced lung injury.[88] Several clinical trials evaluated lower ventilator settings as a means to minimize ventilator-induced lung injury and pulmonary fibrosis, even at the expense of normal blood-gas exchange, with little success apart from one preliminary study.[89-92] The culmination of this research, the ARDS Network trial, ultimately reported convincing improved clinical outcomes with a lung-protection ventilator strategy, compared with standard treatment for ARDS, in 861 adults.[93] The study group received 4 to 6 mL/kg of predicted body weight tidal volume and positive plateau pressure of less than 30 cm H_2O, compared with an 11 to 12 mL/kg tidal volume and positive plateau pressure of less than 50 cm H_2O in the control group. PEEP was adjusted to minimize FiO_2 but maintain oxygen saturation between 88% and 95%. $PaCO_2$ values were allowed to rise, but pH was maintained higher than 7.15. Adult patients receiving a lung protection strategy had a significantly reduced mortality rate (31% vs. 40%), fewer hospital days with extrapulmonary organ failure, and increased ventilator-free days (55% vs. 66%) over the first 28 hospital days compared with the control group). However, the marked improvement in the significant outcomes was later criticized when it appeared that the control group may have received higher than normal tidal volume on purpose.[94] Indeed, the lack of difference in significant outcomes observed in all previous trials but one may have been related to the relatively limited tidal volume (~10 mL/kg) used in the control group. A fierce debate ensued and was summarized in two successive commentaries.[95,96] Nevertheless, this paradigm is now also applied in children.[97]

PEEP maximizes alveolar recruitment, improves oxygenation insufficiency, and minimizes the need for oxygen supplementation, thereby minimizing iatrogenic oxygen toxicity. Early use of PEEP does not prevent the development or progression of ARDS.[98] In animal models of ALI, tidal volumes delivered without PEEP increase the shear stress between interfacing normal and injured regions, creating neutrophilic inflammation and cytokine release similar to ARDS.[99] However, PEEP can also overdistend the normal lung and compromise hemodynamic function (Figure 52-4).[100] Intensivists have therefore searched for the "best" PEEP, which maximizes lung compliance and oxygenation efficiency yet minimizes overdistension and reduced cardiac output.[101] For years, the issue of how to set up optimal PEEP remained controversial, when recently a new trial of the ARDS Network demonstrated that in patients with ALI and ARDS who received a tidal volume of 6 mL/kg of predicted body weight and an end-inspiratory plateau-pressure limit of 30 cm H_2O, clinical outcomes were similar whether lower (8.3 ± 3.2 cm H_2O) or higher (13.2 ± 3.5 cm H_2O) PEEP was used throughout days 1 to 4.[102] Two other trials of higher PEEP in adult patients receiving lung-protective ventilation failed to demonstrate a mortality difference but were safe and showed benefits that advocates will find reassuring.[103,104] Practical guidelines for ventilator settings in ALI or ARDS are provided in Table 52-2.[105]

Prone positioning is another way to recruit atelectatic dependent zones of the lung. Several mechanisms have been proposed to account for this effect, including an increase in end-expiratory lung volume, better ventilation/perfusion matching, and regional changes in ventilation associated with alterations in chest wall mechanics.[106] Prone positioning was shown to improve overall oxygenation in most patients including children with acute respiratory failure.[107,108] However, although it improved oxygenation, prone positioning did not improve survival in a multicenter randomized trial, in either adult or pediatric patients with ALI or ARDS.[109,110] Since then, three meta-analyses reached remarkably similar conclusions: that there was neither an observed effect on mortality nor on duration of mechanical ventilation.[111-113]

Permissive Hypercapnia

Permissive hypercapnia is a well accepted consequence of lung protection strategies of ventilator support. Goals of management are to allow gradual increase in $PaCO_2$, that is, no more than 5 mm Hg increase per hour, and to avoid acute severe acidosis.[114] $PaCO_2$ values of 65 to 85 mm Hg are well tolerated in most patients, although additional sedation may be necessary to reduce air hunger and dyspnea. Permissive hypercapnia is contraindicated in children with suspected increased intracranial pressure and in those with sickle cell disease.

High-frequency oscillatory ventilation (HFOV) reflects the extreme form of reduced tidal volume delivery, providing 1 to 2 mL/kg inspiratory volumes at frequencies of 5 to 15 Hz. Amplitudes of oscillation are set to minimize hypercapnia (HFOV is often very efficient in normalizing hypercapnia), whereas mean airway pressure is set to maximize lung inflation and oxygen efficiency. In a prospective, randomized, crossover study involving 70 children with diffuse alveolar disease and/or airleak syndrome, children receiving HFOV alone had better survival (94% vs. 60%), fewer days with supplemental oxygen, and chronic lung disease less often (11% vs. 30%) compared with the control group.[115] Fifty-eight percent of children who did not respond to conventional ventilation crossed over to HFOV and survived, whereas 18% of those crossing over to conventional ventilation because of persistent respiratory failure survived. Parallel to the emerging consensus that ventilator-induced lung injury was preventable, the

use of high-frequency oscillatory ventilators has significantly increased in severe pediatric respiratory failure. Recently, a multicenter randomized trial compared HFOV to conventional ventilation in 148 adults with ARDS. Although an early but not sustained improvement in PaO_2/FiO_2 ratio was observed in the HFOV group, no other significant differences were seen in oxygenation failure, ventilation failure, barotraumatism, and survival at day 30.[116]

Adjunct Therapies

Adjunct therapies aim at improving lung function and minimizing the risks of ventilator support.

Surfactant replacement therapy aims to reinflate a collapsed area of the lung, improve compliance, and reduce intrapulmonary shunting, thereby leading to reductions in morbidity and mortality. Surfactant not only is decreased in quantity but also is functionally abnormal in patients with ARDS.[117] Thus, on the basis of the similarities with neonatal respiratory distress syndrome, several anecdotal case reports, and then phase II trials, were encouraging. However, a multicenter randomized trial of 725 adult patients with sepsis-induced ARDS who received continuous aerosolization of a synthetic surfactant (Exosurf, GlaxoSmithKline, London, UK) for up to 5 days showed no significant effect on 30-day survival, length of stay in the intensive care unit, duration of mechanical ventilation, or physiologic function.[118] The lack of effect was attributed perhaps to the low level alveolar deposition and an absence of surfactant protein. Natural surfactant was therefore tested in a limited number of children with severe ARDS, and led to sustained improvement in the oxygenation in the subgroup of children without pneumonia and with PaO_2/FiO_2 ratio higher than 65.[119] Recently, in two international combined randomized double-blind trials involving 448 adult patients with ARDS from various causes, up to four intratracheal doses of a recombinant surfactant protein C–based surfactant given within a period of 24 hours failed to improve survival.[120] However, patients who received surfactant had a greater improvement in gas exchange during the 24-hour treatment period than patients who received standard therapy alone, suggesting the potential benefit of a longer treatment course.

Fluid management and hemodynamic support[121] are critical in the management of ALI and ARDS both of which are associated with sepsis.[122] Assessment of vascular volume status is not easy,[123] and its management is particularly difficult when large amounts of fluid must be administered to treat septic shock at the same time that capillary leak promotes accumulation of extravascular lung water. Although there was no effect on 28-day mortality, a low-fluid regimen significantly decreased the overall duration of mechanical ventilation in adult patients.[124] Fluid-refractory shock clearly affects the outcome of ARDS, since the need for vasopressors was found to be associated with increased mortality in adult patients with ARDS.[125,126] Both pulmonary hypertension associated with ARDS, and excessive airway pressures may significantly increase right ventricular afterload.[127] Despite their inherent shortcomings, transthoracic or transesophageal echocardiography are probably the most useful techniques to assess cardiac function in patients mechanically ventilated for ARDS.[128] Right ventricular dysfunction may be improved by cautiously decreasing PEEP, or limiting inadvertent PEEP by reducing the respiratory rate and adjusting the inspiratory: expiratory ratio. Persistent cor pulmonale should lead one to consider the use of specific pulmonary vasodilators such as inhaled nitric oxide and/or systemic vasopressors such as norepinephrine, since right ventricular function critically depends on right coronary perfusion pressure.[129]
