The principle of electroneutrality requires that positive and negative charged molecules in the serum must balance. The presence of toxins in the blood that cause a metabolic acidosis also frequently increase the gap between the total measured versus theoretical anions by the direct addition of organic acid anions, the indirect generation of such anions, or (rarely) the reduction of cations in the serum. The anion gap calculation is derived as follows: Anion gap = $Na^+ - (Cl^- + HCO_3^-)$, where all components are expressed in milliequivalents per liter. The "normal" anionic gap ranges from 3 to 16 mEq/L in older children and adults. Hypoalbuminemia or diluted blood both can cause misleadingly low anion gaps. The presence of elevated concentrations of unmeasured anions (e.g., as a result of dehydration or treatment with sodium salts of citrate, lactate, or acetate) or conditions associated with a decrease in unmeasured cations (e.g., as a result of hypomagnesemia, hypocalcemia, hypokalemia) can lead to an elevated anion gap. Table 105-9 lists toxins associated with changes in the total serum anions.

Table 105–9 Anion Gap Changes Associated with Specific Toxin Exposures

Elevated Anion Gap	Depressed Anion Gap
Methanol	Bromide
Paraldehyde, phenformin	Lithium
Iron, isoniazid	
Ethylene glycol, ethanol	
Salicylate, strychnine	

Many agents that cause seizures (e.g., isoniazid, organochlorine pesticides, theophylline, tricyclic antidepressants) or excessive muscular activity and hyperthermia (e.g., cocaine, amphetamines, phencyclidine, neuroleptic malignant syndrome, serotonin syndrome) may predispose the patient to rhabdomyolysis and subsequent myoglobin-induced acute renal failure. The overdose patient who is agitated or delirious and is held in physical restraints for long periods of time and the overdose comatose patient who has muscle necrosis from dependency position injury are at high risk for rhabdomyolysis. Laboratory parameters that may be useful in serial monitoring in such circumstances include serum lactic acid, creatine phosphokinase, aldolase, and myoglobin levels and urinary sediment, urine output, and urinary myoglobin levels. Alternatively, a urine dipstick that is positive for blood and negative for red blood cells contains either hemoglobin or myoglobin.

Frequently other baseline laboratory evaluations are included in the initial evaluation of the patient. Depending on the agent involved and the clinical course, the following tests often are clinically useful in the evaluation of the poisoned patient: arterial blood gases (acid-base assessment), blood count, platelet count, leukocyte differential, blood clotting parameters, electrocardiogram, electroencephalogram, liver function tests, renal function tests, serum electrolytes and blood glucose, and urinalysis including urine pH.

Additional Investigations

Radiographic Studies

Radiographs can be helpful in locating swallowed foreign bodies having toxic potential. Patients who have ingested disc batteries should undergo serial chest and abdominal radiography to ensure that the battery has cleared the esophagus and is continuing to move along the gastrointestinal tract.

Drug smugglers who have swallowed quantities of heroin or cocaine-filled balloons, condoms, or other containers can be diagnosed as a "body packer" by radiographic examination.[11] Chest and abdominal x-ray films may be of value in locating pills, tablets, or, in some cases of childhood lead poisoning, lead-containing paint chips or plaster. Sometimes agglutinated masses of pills (bezoars) can be detected in this manner or even highlighted by the use of small amounts of radiopaque contrast material. Box 105-4 lists some drugs and chemicals that may be visualized on x-ray films.

Diagnostic Trials

For a few suspected toxins, administration of an antidote not only initiates therapy but also assists in the diagnosis of the agent involved. Table 105-10 lists some of the diagnostic trials that may be appropriate in the pediatric ICU setting. For example, flumazenil, a specific benzodiazepine antagonist, can be used as a diagnostic agent administered to the comatose patient. At an intravenous dose of 1 to 2 mg, adults show a rapid improvement in consciousness (analogous to naloxone's effectiveness in reversing narcotic-induced CNS depression) after overdose involving a variety of benzodiazepines. Caution must be exercised; if a second, seizure-causing agent such as a tricyclic antidepressant has also been coingested, then the reversal of the benzodiazepine's anticonvulsant effects may inadvertently unmask seizures in the victim. Physostigmine can be of benefit in pediatric patients who have ingested Jimsonweed seeds (*Datura stramonium*) or other pure anticholinergic agents; however, caution is dictated in unknown poisonings where cardiac conduction toxicity is a consideration, since physostigmine itself can cause severe cardiac toxicity, bradycardia, and asystole.[12]

Summary

More than 2 million poisonings, with about 50% occurring in children younger than 6 years, are reported to poison centers in the United States annually. Intensive care physicians face some of their greatest diagnostic challenges when confronted with patients who are admitted to the hospital with a baffling constellation of symptoms and signs and whose differential diagnosis includes poisoning. A careful medical history explores the intersection of underlying patient factors, likely toxic agents, and conducive environmental circumstances within the context of a time line of evolving symptoms. The history alone will often clarify the clinical picture and suggest to the clinician potential drugs or toxins that might be responsible for the patient's illness. Physical findings attendant to a comprehensive examination of the patient, with a focus on vital signs and those organ systems typically affected by toxic injury, such as the skin, gastrointestinal, cardiovascular, pulmonary, and neurological systems, may confirm the clinician's suspicions. Knowledge of common toxidromes can help the intensive care physician to focus his or her thinking as to which poison or pharmacological category of toxic agents may be responsible. Repeated physical examinations and monitoring over time are essential to determining additional management needs and judging more accurately the patient's prognosis and likely medical outcome. The nearest regional poison control center has 24-hour availability of medical toxicology expertise. Toxicologists can assist the intensivist with timely and state-of-the-art, specialist-level consultation in the diagnosis and management of individual patients. For a few suspected toxins, diagnostic studies can be helpful in the assessment of the severity of toxicity and in the prediction of a patient's expected hospital course and outcome. While broad toxic screens are rarely helpful, qualitative or quantitative blood or urine levels of some specific drugs or chemicals can be invaluable in the assessment of the poisoned patient. The investigation of anion or osmolar gaps, derangements in blood gases or electrolytes, electrocardiographic abnormalities caused by cardiotoxic agents, and/or special imaging studies will often be indicated

Table 105–10 Useful Diagnostic Trials

Agent Detected	Agent Administered	Technique	Positive Results
Anticholinergic agents (pure)	Physostigmine	0.02 mg/kg slow IV (maximum 0.5 mg)	Improved consciousness
Benzodiazepines	Flumazenil	0.2-0.3 mg/kg IV (maximum 3 mg)	Improved consciousness
Iron	Deferoxamine	40 mg/kg IM (maximum 2 g)	"Vin rose" urine color
Opiates	Naloxone hydrochloride	0.03 mg/kg (up to 4 mg)	Improved consciousness
Organophosphate	Atropine	0.1 mg/kg	Mydriasis, less secretions
Phenothiazine (dystonia)	Diphenhydramine	1–2 mg/kg IV (maximum 25 mg)	Resolution
Phenothiazine (NMS)	Dantrolene	1–3 mg/kg IV	Resolution
Insulin reaction	Dextrose	1 g/kg IV	Improved consciousness
Isoniazid	Pyridoxine	5 g IV	Seizures abate; improved consciousness

NMS, Neuroleptic malignant syndrome.

in critically ill patients. The administration of an antidote in selected cases may not only initiate therapy but also assist in the diagnosis of the poison involved, since an improvement in a patient's clinical status soon after receipt of the antidote may confirm the clinician's tentative diagnosis.

Toxidromes and Their Treatment

Ashley N. Webb and Prashant Joshi

PEARLS

- When given for a benzodiazepine overdose, flumazenil may precipitate acute withdrawal in the patient who habitually uses benzodiazepines or may unmask seizures caused by a coingested substance.
- Although rare, pulmonary edema may be a serious complication of reversal of opioids with naloxone.
- β-Adrenergic antagonists, when used to lower blood pressure in a sympathomimetic overdose, may lead to unopposed α-receptor stimulation and therefore paradoxic worsening of hypertension.
- Physostigmine should be reserved for severe, life-threatening manifestations of anticholinergic toxicity because of the risk of asystole or seizures. It is absolutely contraindicated in the reversal of the anticholinergic toxidrome produced by tricyclic antidepressant ingestion.
- Pulse oximetry is unreliable in methemoglobinemia and may show falsely increased or falsely decreased values depending on the methemoglobin concentration.
- Methylene blue should not be administered to individuals with known glucose-6-phosphate dehydrogenase deficiency because they lack adequate concentrations of reduced nicotinamide adenine dinucleotide phosphate to produce reductase activity and because methylene blue can trigger hemolysis or methemoglobinemia in those individuals.
- The skin is a distinguishing factor between sympathomimetic (pale, cool, and diaphoretic) and anticholinergic (flushed, warm, and dry) toxidromes.
- The toxic differential diagnosis of hyperthermia should include malignant hyperthermia, serotonin syndrome, neuroleptic malignant syndrome, sympathomimetic poisoning, and anticholinergic poisoning.
- An elevated osmolar gap suggests ingestion of a toxic alcohol, whereas a normal result does not exclude it. Levels in the blood are the gold standard for diagnosis and prognosis.
- Succinylcholine is generally contraindicated in cholinesterase inhibitor toxicity, and its duration of effect will be significantly prolonged.
- Nitrites should be used with extreme caution in patients with cyanide poisoning and concomitant carbon monoxide poisoning because of the risk of further decreasing oxygen-carrying capacity.
- Total iron-binding capacity may be falsely elevated in patients with acute iron overdose and is not a reliable marker in iron toxicity.
- In the United States, the local Regional Poison Center may be reached by calling 800-222-1222.

Every year almost 2.5 million human exposures to toxic substances are reported to poison centers in the United States.[1] Of these, approximately 60% involve children younger than 12 years, and this age group accounts for approximately 4% of the reported fatalities. Although 75% of calls are managed without referral to a health care facility, of the 25% of patients who are seen in a health care facility, one in eight is admitted to a critical care unit.

In most cases of poisoning, the agents involved are known, or at least circumstantial evidence points to a specific toxin or toxins. However, even in cases in which the toxic exposure is unknown or the clinical presentation is inconsistent with the history, the intensivise care physician can find physical and analytical clues of the inciting agent and provide targeted therapy. The term *toxidrome,* a contraction of *toxic syndrome,* refers to a constellation of signs associated with certain substances or groups of substances. Several toxidromes have been described; although their expression may not be complete in every case, they can provide valuable information to guide investigation and treatment. A list of toxidromes appears in Chapter 105.

The patient should be examined carefully and thoroughly, paying particular attention to vital signs, mental status, pupil size and reactivity, skin characteristics (color, temperature, moisture), and bowel sounds. Other important aspects of the physical examination include muscle tone, respiratory effort, presence of tremor, and characteristics of the mucous membranes. Laboratory investigations may help narrow the differential diagnosis and determine the need for additional examination while guiding therapy. However, diagnostic laboratory tests should be reviewed with caution. Some assays may further cloud the clinical picture because of false-positive results from cross-reactivity and may lead to an inaccurate diagnosis, inappropriate therapy, or withholding of a specific antidote.[2] Utility of a specific test should be based on its probability of indicating or guiding therapy and prognosis of end-organ toxicity.

This chapter addresses some common presentations of toxic ingestions and their treatment. For more in-depth information, the reader is referred to several comprehensive textbooks of medical toxicology.

Opiates

The classic triad of respiratory depression, coma, and miosis is seen with both naturally occurring opiates and synthetic opioids. Additional features include bradycardia, hypotension,

and decreased gastrointestinal (GI) motility. A similar clinical picture may be encountered with ingestion of clonidine, other imidazoline derivatives found in over-the-counter eye drops or nasal sprays, or tizanidine, all of which are centrally acting α_2-adrenergic agonists that decrease sympathetic tone.[3-5] Not all patients exposed to an opiate present with the classic toxidrome. Respiration becomes shallow with increasing central nervous system (CNS) depression, so hypercarbia may occur before overt respiratory depression.[6-9] In addition, several opiates and opioids, including morphine, meperidine, pentazocine, diphenoxylate/atropine, and propoxyphene, may result in mid-position or mydriatic pupils either from their pharmacologic activity or from brain anoxia.[3,10,11]

Effects on respiration are likely a result of action at the μ-receptors. Analgesic effect is exerted through action at both μ- and κ-receptors.[6] Several opioids have been designed to function as agonist-antagonists. In general, they provide spinal analgesia through agonist effects at the κ-receptors and simultaneously antagonize μ-receptors. This allows them to provide pain relief at higher doses while reaching a ceiling effect on respiratory depression.[7] However, in overdose, receptor selectivity may be lost, and decreased respiratory drive can occur with these medications.

Naloxone is an opiate receptor antagonist that reverses the toxic effects of opioids. A starting dose of 0.1 mg/kg intravenously is recommended to prevent the need for artificial ventilation in life-threatening opiate-induced respiratory depression. If no intravenous access is available, it can be administered subcutaneously, intramuscularly, or via endotracheal tube. However, the intramuscular route exhibits variable pharmacokinetics with an unpredictable duration of action and may therefore allow recurrent sedation after a period during which the patient is thought to be free of further toxicity. Naloxone may precipitate acute withdrawal in opioid-dependent individuals; in such patients a lower starting dose, titrated upward to effect, may be warranted. Because of the different receptor affinities of each opioid, some individuals may not respond to lower doses of naloxone. The titration should proceed upward to 10 mg, at which point if no response has been illicited, naloxone should be discontinued and an etiology other than opioids should be considered for the cause of respiratory depression.[12] In patients with apnea, artificial ventilation should be promptly provided before the administration of naloxone. Because the duration of action of naloxone is shorter than that of most opioids, repeated doses or a continuous intravenous infusion may be necessary. The accepted infusion rate is two thirds of the initial reversal dose per hour.[12]

Reversal of opioid toxicity has been associated with pulmonary edema, although this has also been described in the setting of opiate toxicity itself.[13-16] Naloxone has been reported anecdotally to reverse clonidine overdose, although failure of naloxone to reverse clonidine has also been described.[17] Naloxone administration has occasionally been associated with significant hypertension.[18,19] This is usually short lived and does not require treatment. If hypertension persists, treatment should consist of a short-acting antihypertensive such as nitroprusside so that the drug and its effects can be quickly stopped. This will prevent the development of hypotension as the hypertensive crisis resolves.

Nalmefene is a newer, long-acting opiate receptor antagonist. It is available as a parenteral product with a potency equivalent to naloxone on a milligram-per-milligram basis but with a duration of action nearly five times longer.[20-22] Its half-life can range from 2 to 8 hours. Before it is administered, a test dose of naloxone should be used to exclude the possibility of acute withdrawal. In at least one prospective, controlled trial, it offered no advantage over naloxone.[21] It has a similar side effect profile, including cases of short-lived noncardiogenic pulmonary edema, and may provide false security in a patient who has ingested a long-acting opioid in which symptoms may recur after the antagonist has worn off.

Sympathomimetic Agents

Symptoms and signs of sympathetic excess may be seen with a number of therapeutic and illicit agents that either mimic endogenous excitatory neurotransmitters or act on receptors to increase their release.[23] Drugs that produce the sympathomimetic toxidrome are listed in Box 106-1. Any or all of the manifestations in Box 106-2 may be observed depending on the agent involved. Agents with predominantly β-adrenergic activity are more likely to produce tachycardia and hypotension from peripheral vasodilation compared with agents with predominantly α-adrenergic effects that may produce severe hypertension with reflex bradycardia. Hyperthermia, rhabdomyolysis, and myoglobinuria may result from increased metabolic activity. Additional morbidity, including ischemic or hemorrhagic stroke, have been documented. With cocaine use, for example, cases of myocardial ischemia and infarction have been reported[23,24] Thrombolytics should not be used unless the patient has confirmed myocardial infarction and is at low risk for intracranial bleeding.[25] The methylxanthines, caffeine and theophylline, are not sympathomimetics per se, but they may produce many of the same clinical features as a result of their β-adrenergic activity and effect on adenosine receptors.[26-28] Patients with acute overdose of methylxanthines may initially present with severe GI symptoms and quickly progress to hypotension, tachydysrhythmias, and status epilepticus.[27,29,30] Designer amphetamines, such as methylenedioxyamphetamine (MDMA) and its derivatives, additionally cause a release of serotonin and may precipitate hallucinations in addition to the sympathomimetic effects listed above. These patients are at risk for seizures, dysrhythmias, hyperthermia, rhabdomyolysis, the syndrome of inappropriate secretion of antidiuretic hormone resulting in hyponatramia, and disseminated intravascular coagulation.[28,31]

Benzodiazepines are the first-line agent to reduce CNS catecholamine release, thereby eliminating severe hypertension, tachycardia, agitation, and muscle overactivity. Large doses may be required. Caution should be exercised when adrenergic antagonists are used to treat tachycardia and hypertension; β-adrenergic antagonist use may result in unopposed α-adrenergic receptor stimulation and cause a paradoxic worsening of hypertension. Although labetalol is a β-antagonist with weak α-blocking activity, it has not been shown to be effective in this scenario. Concomitant administration of a vasodilator in refractory hypertension is recommended.[23,24,32] Agents such as cocaine may deplete norepinephrine, leading to cardiovascular collapse. Therefore short-acting agents are the only advisable treatment for hypertension if benzodiazepines administration has failed. Seizures should also be managed with benzodiazepines. In patients refractory to this therapy, a barbituate such as phenobarbital should be considered.

Decreased bowel sounds

Phenytoin does not play a role in seizures resulting from toxicity and, in the case of methylxanthines, may actually worsen patient outcome by lowering the seizure threshold.[28] Confirmation by urinary drug screening is of little use in the emergency setting. While a positive test result for cocaine is likely confirmatory for its use, a positive result for amphetamines is not. Several medications cross-react to produce a false-positive amphetamine presence, including buproprion[2] and pseudoephedrine.[23]

Anticholinergic Agents

The anticholinergic toxidrome, more appropriately referred to as an *antimuscarinic toxidrome,* is produced by a number of agents that possess antimuscarinic properties as their primary effect or as a side effect. Examples of such toxins are provided in Box 106-3. Muscarinic receptors are located in the CNS, in the target organs of the parasympathetic nervous system (PNS), and in the sweat glands (sympathetic nervous system).[33] The syndrome may have features that are similar to those of the sympathomimetic toxidrome (Box 106-4). Examination of the skin usually provides clues to differentiate between the two; the patient will be dry in this scenario versus increased diaphoresis with sympathomimetic toxicity. Hypertension and tachycardia are typically less severe than when seen with sympathomimetics. Also, the dilated pupils in the anticholinergic syndrome are nonreactive because there is associated cycloplegia.[33,34]

Because sweating is inhibited in intoxicated patients, treatment of agitation is important to prevent hyperthermia. Benzodiazepines are the drug of choice. Physostigmine is a cholinesterase inhibitor that may be used to reverse the central and peripheral manifestations of anticholinergic toxicity.[33] Because of case reports of convulsions[35] or asystole[36] associated with administration of physostigmine, it should not be used to treat the anticholinergic manifestations of tricyclic antidepressant overdose. Diphenhydramine overdose can present with anticholinergic toxicity and also manifest electrocardiographic (ECG) changes, including sodium channel blockade. Therefore the use of physostigmine to reverse toxicity in this patient population should be approached with caution. In general, physostigmine has a short duration of action compared with the anticholinergic agent ingested; because of its severe side effects, it has fallen out of favor as an antidote for most previously indicated ingestions.

Cholinergic Agents

Cholinergic agents are best divided into the following three categories: muscarinic agents, nicotinic agents, and cholinesterase inhibitors. The muscarinic agents act in the CNS, at postganglionic parasympathetic nerve endings, and in the sweat glands. Nicotinic agents act in the CNS, in the autonomic ganglia (both sympathetic and parasympathetic), and at the neuromuscular junction. Cholinesterase inhibitors increase the available acetylcholine in the cholinergic synapse and present with a combination of symptoms that result from action at both the nicotinic and muscarinic receptors.[37,38] Agents with cholinergic activity are listed in Box 106-5. Signs and symptoms of cholinergic excess are listed in Box 106-6.

Direct-acting muscarinic agents produce typical features of excessive parasympathetic activity. Nicotine produces salivation, nausea, and vomiting.[37,38] Hypotension, bradycardia,

and respiratory depression can be preceded by tachycardia, hypertension, and tachypnea. Central features include initial stimulation followed by seizures, lethargy, and coma. Neuromuscular blockade may occur. Management of nicotine poisoning, which can be severe, is entirely supportive.[39-41] Children are at increased risk of nicotine poisoning from ingestion of cigarettes or chewing tobacco as well as from exposure to smoking cessation products, including gums, lozenges, patches, and inhalers.

Cholinesterase inhibitors, such as organophosphate pesticides and nerve agents, produce a mixed picture of toxicity. Parasympathetic manifestations tend to dominate the autonomic component of toxicity. Organophosphates bind to and inactivate acetylcholinesterase, preventing the normal termination of cholinergic stimulation at the postsynaptic receptors. The end result is excessive nicotinic and muscarinic activity in the PNS and CNS. At the neuromuscular junction, the result is depolarizing neuromuscular blockade. Over time the enzyme becomes phosphorylated, a process referred to as *aging*. Not all organophosphorous agents age at the same rate. Some nerve agents may age in as quickly as a few minutes, whereas some pesticides can take as long as 72 hours to permanently inactivate the cholinesteraseses.[42] Cholinesterase activity is only restored by synthesis of a new enzyme.[38] Carbamates bind reversibly to acetylcholinesterase, and the enzyme/chemical complex undergoes spontaneous hydrolysis, generally restoring cholinesterase function within hours. Carbamates do not penetrate the CNS well, so central manifestations are less severe. Because these agents cause bronchorrhea, bronchospasm, decreased respiratory drive, and paralysis of the muscles involved in breathing, death results from respiratory failure. The order of appearance of signs and symptoms depends on the route of administration. With dermal exposure, the first manifestation may be local hyperhidrosis, followed by systemic manifestations once the agent is absorbed through the skin. Inhalational exposure results in initial upper airway manifestations and respiratory distress. Ingestion presents with drooling and vomiting as the earliest expression of toxicity.

Treatment of cholinergic toxicity involves atropine to reverse the muscarinic effects, an oxime to reverse neuromuscular blockade, and benzodiazepines to treat seizures. Extremely large doses of atropine may be necessary, and the end point of therapy is the drying of secretions, not heart rate or pupil size. Organophosphate-poisoned patients may manifest tachycardia as a result of their exposure, and atropine is not contraindicated in these patients. Tachycardia during therapy is limited and not life-threatening.[42,43] Depending on the agent involved, repeated doses or a constant infusion may be necessary. Pralidoxime is the oxime available and indicated for organophosphate poisoning in North America. It works by preventing aging of the cholinesterase and reactivating the enzyme. Pralidoxime is generally not indicated in carbamate overdose because of the reversible binding of toxin to acetylcholinesterase, which limits the duration of toxicity.[38] Pralidoxime does not readily cross the blood-brain barrier, and benzodiazepines should initially be provided for the prevention of seizures.[43] Cholinesterase levels can be obtained in poisoned patients and may confirm exposure and indicate the severity of toxicity. However, they are usually not available in real time and should not be used to guide therapy because this will likely delay treatment of the severely poisoned patient.

Methemoglobinemia

Methemoglobinemia results from the oxidization of iron in hemoglobin from the ferrous (2+) form to the ferric (3+) form. It results in the inability to carry oxygen; by shifting the oxygen saturation curve to the left, it decreases off-loading of any bound oxygen at the tissues.[44] Methemoglobinemia is associated with drugs and toxins that cause oxidative stress (Box 106-7). Clinically, the patient appears cyanotic, and the cyanosis does not respond to the administration of oxygen. The blood may have a chocolate color, and exposure of the blood sample to oxygen does not restore a normal appearance. The diagnosis is confirmed by multiple-wavelength co-oximetry. Standard pulse oximetry, which uses only two wavelengths of

Phenazopyridine
Prilocaine
Sulfonamides

light, cannot reliably be used to assess the degree of methemoglobinemia. However, newer models of pulse oximeters that use several different wavelengths of light may be used to measure methemoglobin levels. Standard pulse oximetry may overestimate or underestimate true oxygen saturation depending on the methemoglobin level.[45,46] In a patient with cyanosis and a normal partial pressure of oxygen, methemoglobinemia should be suspected.

The body produces a small amount of methemoglobin (typically <1%). Under normal physiologic conditions, this is reduced by a methemoglobin reductase dependent on reduced nicotinamide adenine dinucleotide (NADPH). Additional reduction can occurr through a minor pathway requiring the presence of reduced NADPH. Because a large oxidative stress overwhelms the reducing capacity of these pathways, the result is clinically apparent methemoglobinemia.

Patients may appear blue with methemoglobin concentrations as low as 15 g/L, treatment may not be required. The appearance of cyanosis depends on the total methemoglobin present. Although anemic patients have less hemoglobin to convert to methemoglobin, this is usually a larger percent of their functioning hemoglobin. So, although they may not manifest cyanosis, they are less tolerant of methemoglobin at a lower percentage and are more likely to express symptoms of hypoxia.[44] Therapy should be provided according to the signs of hypoxia and not the methemoglobin level or the presence of cyanosis. If required, treatment begins with the administration of 100% oxygen (to maximize oxygen-carrying capacity with the certainty that unaffected hemoglobin is fully saturated), followed by intravenous methylene blue at a dose of 1 mg/kg. Methylene blue facilitates the reduction of the oxydized heme iron of methemoglobin to its normal state by NADPH-dependent methemoglobin reductase. Response is rapid and occurs within 30 minutes. Depending on the toxin involved, in the case of dapsone, recrudescent methemoglobinemia may be seen and may require repeated doses of methylene blue. The total (cumulative) dose should not exceed 7 mg/kg because methylene blue can itself be an oxidizing agent, cause additional methemoglobinemia, and potentially lead to hemolysis. Methylene blue may be ineffective in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency, in whom it may increase the risk of hemolysis or methemoglobinemia. In general, the patient can safely be treated with two doses of methylene blue; if no response is elicited, G6PD deficiency should be suspected. G6PD testing, however, should not be conducted until several months after resolution of the methemoglobinemia. When done concommittantly with the insult, patients will have a false-positive result for the deficiency. In nonresponding patients who are severely ill, exchange transfusion should be considered. Although hyperbaric oxygen increases the percent of oxgen-saturated blood, this is likely not beneficial for treatment of methemoglobinemia because no functioning hemoglobin has been added and patients will return to their previous state when removed from the chamber.[44,47]

Hyperthermia

Several distinct hyperthermia syndromes may result from xenobiotics. In addition to the following syndromes described, the sympathomimetic and anticholinergic syndromes may also cause hyperpyrexia and are detailed separately. Distinction of malignant hyperthermia, serotonin syndrome, and neuroleptic malignant syndrome are provided in Table 106-1. While differences exist, there is also potential for overlap, and diagnosis may be difficult when there is no previous patient history available.

Malignant Hyperthermia

Malignant hyperthermia is a genetically determined condition that is triggered by exposure to depolarizing neuromuscular blocking agents (succinylcholine) or inhalational anesthetic agents. It is a life-threatening condition that results from dysfunction of the ryanodine receptors. This elevates the intracellular calcium in somatic muscle cells, resulting in rigidity and muscle damage. This syndrome requires prompt intervention with aggressive cooling and treatment with dantrolene, which allows muscle relaxation through blockade of calcium release from the sarcoplasmic reticulum.[48] Malignant hyperthermia is discussed in more detail in Chapter 124.

Serotonin Syndrome

Serotonin syndrome is a constellation of features resulting from excessive serotonergic activity in the CNS. It is most commonly associated with therapeutic regimens that include two or more drugs that increase CNS serotonin transmission, often by different mechanisms (Box 106-8). Serotonin syndrome has also been described with single agents in overdose, with the most commonly mentioned being clomipramine, a potent tricyclic antidepressant. Hallmark features include altered mental status, excessive muscle activity, and autonomic instability. Diagnostic criteria have been suggested by Sternbach.[49] This diagnosis requires history of exposure to a serotonergic agent(s) and the presence of three of the following: mental status change, agitation, myoclonus, hyperreflexia, diaphoresis, shivering, tremor, diarrhea, incoordination, and/or fever. A distinguishing feature from the other hyperthermic syndromes is the presence of rigidity and hyperreflexia more pronounced in the lower limbs than in the upper limbs and the rigidity described more as "clasp knife" than "lead pipe."[48,50] Symptoms typically start within hours of exposure to the offending agent and resolve within 24 hours, providing a quick-on, quick-off effect. Most cases are mild and self-limiting; however, patients with severe toxicity may develop extreme hyperthermia and rhabdomyolysis with renal failure and cardiovascular collapse. Treatment is supportive: withdrawal of all serotonergic agents, benzodiazepines for muscle overactivity,

Table 106–1 Differences Between Drug-Induced Hyperthermia Syndromes

Syndrome	Causative Agent	Timing of Onset	Treatment
Malignant hyperthermia	Depolarizing neuromuscular blockers or Inhalational anesthetics	Minutes	Dantrolene
Serotonin syndrome	Coadministration of two or more serotonergic agents	Hours	Supportive care, cyproheptadine
NMS	Antipsychotic drugs	Days	Supportive care, bromocriptine

Monoamine oxidase inhibitors
Selective serotonin reuptake inhibitors
Trazodone
TCAs
Venlafaxine

and aggressive cooling. Cyproheptadine, a serotonin blocker, has been proposed for the treatment of serotonin syndrome. Doses range from 16 to 32 mg in divided doses up to four times daily. Although it might be considered to prevent further progression of the syndrome early in its course, its utility has not been established.[51-53] In cases of severe hyperthermia, cyproheptadine will do little to prevent further symptoms and should be abandoned for more aggressive therapy with cooling and paralysis with a nondepolarizing paralytic.

Neuroleptic Malignant Syndrome

Neuroleptic malignant syndrome (NMS) is a constellation of features triggered by exposure to neuroleptic drugs (phenothiazines, butyrophenones, atypical antipsychotics). It is most commonly associated with initiation of therapy or with a dose escalation; it can also be triggered by the addition of a serotoninergic agent to an established antidopaminergic agent or the withdrawal of dopaminergic agents used to treat Parkinson disease.[54,58] The onset is insidious, occurring over several days. The diagnosis requires exposure to a neuroleptic drug, fever, muscular rigidity, and at least two of the following: mental status change, mutism, tachycardia, labile blood pressure, diaphoresis, dysphagia, tremor, incontinence, leukocytosis, or elevated creatine kinase level.[55] Muscle rigidity in this syndrome is often described as "lead pipe" and greater in the upper extremities than in the lower extremities. Distinguishing NMS from lethal catatonia may be difficult. NMS is thought to represent the extreme end of the spectrum of extrapyramidal (antidopaminergic) side effects of these medications. Unlike its milder counterparts, however, it is unresponsive to centrally acting anticholinergic agents; therefore diphenhydramine or benztropine have no role in the treatment of this syndrome. The recommended treatment is supportive, including sedation, neuromuscular blockade with a nondepolarizing paralytic, and active cooling if required. Hyperthermia does not respond to antipyretics. Myoglobinuria and renal failure may complicate the course. Bromocriptine, a dopamine receptor agonist, and dantrolene have been advocated in the treatment of NMS, but their value is debated.[56] Because it is a syndrome that results from CNS activation, dantrolene's action at the muscle end plate is likely not effective, and its nonselective activity on skeletal muscle could theoretically weaken the diaphragm and increase respiratory dysfunction.[57]

Box 106–9 Agents that Cause Anion Gap Metabolic Acidosis

Isoniazid
Metformin
Methanol
Paraldehyde
Phenformin
Salicylates

Metabolic Acidosis with Increased Anion Gap

Metabolic acidosis is a laboratory toxidrome that presents a substantial differential diagnosis. Common nontoxicologic causes of this disorder in children include diabetic ketoacidosis, uremia, lactic acidosis, and inborn errors of metabolism. The agents most commonly associated with metabolic acidosis are listed in Box 106-9 (also see Chapter 68). In addition, any agent causing shock will increase lactate and cause metabolic acidosis with an increased anion gap. Note that although metabolic acidosis from toxic agents is generally associated with an increase in the anion gap, nonanion gap acidosis may be seen with the therapeutic use of carbonic anhydrase inhibitors such as acetazolamide or topiramate, or with toxins that cause renal tubulopathy with chronic use such as toluene (an agent seen commonly with inhalant abuse).

Methanol and Ethylene Glycol

Methanol and ethylene glycol are toxic alcohols found in various automotive antifreeze products and as chemical reagents. Ethylene glycol has a sweet taste that may be masked by the

addition of bittering agents to many antifreeze products. Ethylene glycol–containing radiator antifreeze products contain fluorescein, and examination of the urine under a Wood's lamp has been advocated to screen for ingestion.[59] In one study, even in the absence of ingestions, urinary fluorescence was shown in most hospitalized pediatric patients[60]; in addition, several types of hospital tubing and plastic containers may provide their own fluorescence under a Wood's lamp, calling into question the usefulness of this simple test.

Both compounds produce CNS depression, with intoxication seen more substantially with ethylene glycol than with methanol. Beyond that, they have little toxic effect in their parent form. Both substances are metabolized by alcohol dehydrogenase to highly toxic metabolites. The end product of methanol metabolism is formic acid, which causes severe metabolic acidosis and retinal toxicity described as "snowstorm blindness." Ethylene glycol is converted to a number of intermediate toxic products and ultimately to oxalate. This conversion results in severe metabolic acidosis, renal failure, and hypocalcemia through binding of oxylate to calcium to form crystals.[61]

Ingestions greater than 0.5 mL/kg of either agent are potentially toxic, and ingestions of more than 1 mL/kg are potentially fatal. Because both substances are osmotically active, they will increase serum osmolality and therefore raise the osmolar gap, the difference between calculated serum osmolarity and actual osmolality as determined by freezing point depression. Caution should be exercised in interpreting this gap. Because the normal range is −8 to +12, significant levels of toxic alcohols may be present with a "normal" osmolar gap. In short, an elevated gap suggests toxic alcohol poisoning, but a normal result does not exclude it.[62] As the parent compound is metabolized and the anion gap increases from the development of acid metabolites, the osmolar gap will fall and therefore may be normal in patients presenting with symptoms of toxicity. Measured levels of ethylene glycol and methanol are the gold standard for diagnosis and treatment guidance. Hemodialysis is indicated in severely toxic patients, even when the parent compound is no longer detectable, to eliminate toxic metabolites and correct metabolic abnormalities.

Once the diagnosis of toxic alcohol poisoning is made and life-sustaining measures have been undertaken, initial therapy is targeted at blocking alcohol dehydrogenase to limit further generation of toxic metabolites. This may be achieved either with ethanol or with fomepizole. Ethanol infusion is difficult to titrate; requires frequent measurements; and carries the risks of inebriation, CNS depression, hypoglycemia, and hypotension. Fomepizole, a drug with known kinetics and approval by the Food and Drug Administration (FDA) for the treatment of toxic alcohol poisoning, is the agent of choice. A loading dose of 15 mg/kg followed by 10 mg/kg every 12 hours is sufficient. The dose must be increased to 15 mg/kg after 48 hours because of induction of its own metabolism. In addition, the dosing regimen requires adjustment during hemodilayisis to maintain suffucient concentrations to continue to block alcohol dehydrogenase because fomepizole is itself dialyzable.[63] Once alcohol dehydrogenase is blocked, the parent alcohol is excreted through the kidneys with a half-life of 19.7 hours for ethylene glycol[64] and 54 hours for methanol.[63] Hemodialysis is recommended in the presence of high levels of methanol or ethylene glycol, in the presence of significant acidosis or electrolyte disturbance, or if there is renal or visual impairment.

Table 106–2 Half-Life of COHb

Oxygen Concentration	Half-Life
21% (room air)	4–5 hours
100% (mask or endotracheal)	60–90 minutes
100% (hyperbaric molecular oxygen)	20–30 minutes

Carbon Monoxide

Carbon monoxide (CO) is the product of incomplete combustion of carbonaceous fuels. These include natural gas, fuel oil, gasoline, propane, and charcoal. CO causes tissue hypoxia through several mechanisms: it binds with high affinity to oxygen-binding sites of hemoglobin; it binds to myoglobin and disrupts the transfer of oxygen from erythrocytes to mitochondria; it binds to mitochondrial cytochrome oxidase; and it interferes with electron transport and adenosine triphosphate production. CO also displaces nitric oxide from platelets, leading to increased generation of the free radical peroxynitrite. Standard pulse oximetry is unreliable at detecting CO poisoning and overestimates arterial oxygen saturation. The diagnosis is made with multiple-wavelength co-oximetry on a blood sample. Additional CO levels are not required with appropriate oxygen therapy because they will reliably decrease with time. An exception to this rule occurs in the case of inhalation of methylene chloride, found in degreasers and furniture strippers. Its metabolism leads to endogenous production of CO. In this case, serial levels should be obtained, watching for a downward trend during treatment.

Correlation between symptoms and carboxyhemoglobin (COHb) level is poor, but a level should be obtained to confirm the diagnosis. At low levels of CO, symptoms are nonspecific and include fatigue, malaise, nausea, and headache. Higher concentrations lead to impaired cognition and finally coma. CO poisoning may also cause hypotension and syncope, explained in part by the effect of CO on nitric oxide. CO poisoning is also associated with delayed or persistent neurologic sequelae, particularly in patients who lose consciousness or demonstrate syncope.

Treatment consists of accelerating the removal of CO from hemoglobin by providing as much oxygen as possible. The half-life of COHb under various oxygen concentrations is provided in Table 106-2. Hyperbaric oxygen (HBO), the administration of oxygen at supra-atmospheric pressure, has been advocated in the treatment of severe CO poisoning.[65] In addition to increasing the rate of resolution of COHb, it accelerates the removal of CO from cytochrome oxidase. However, because most CO has been eliminated from the blood by the time the patient is placed in the chamber, the benefits are likley seen from the reduction of leukocyte adhesion to endothelium.[66] It is through this last mechanism that HBO is proposed to decrease the incidence of delayed neurologic sequelae, although two randomized trials have led to conflicting results.[65,67] There are no clinical trials of HBO in children. Although its use remains controversial, it is recommended in children who have a history of loss of consciousness or syncope or who have persistent neurologic findings on examination despite treatment with simple oxygen. A thorough neurologic exam should evaluate the patient for persistant ataxia when attempting to walk as well as other cerebellar signs. Adverse reactions to HBO therapy include

claustrophobia, barotrauma (pneumothorax, tympanic membrane rupture), and oxygen toxicity (seizures).[67] It is recommended that if the patient is to undergo HBO treatment, it should be completed within 24 hours of exposure. Patients who have had a cardiac arrest are not considered candidates for HBO.[65] Fetal hemoglobin has a higher affinity for CO than does adult hemoglobin. As a result, neonates may have higher COHb levels than older children with the same exposure. Although the fetus may serve as an additional compartment, or "sink," for CO, exhibiting higher CO levels, no data on pregnancy and HBO therapy are available.

Cyanide

Cyanide is a highly toxic compound that may produce poisoning from a variety of sources. It is widely used as a reagent in industry. A number of plants, including the seeds of several edible fruits (e.g., apples, cherries, peaches, pears), contain cyanogenic glycosides that may be converted to cyanide in the GI tract. The unapproved substance Laetrile, sometimes used to treat cancer, is synthesized from amygdalin, a cyanogenic glycoside. Fires, particularly those in which certain plastics or fabrics are combusted, can generate hydrogen cyanide (HCN). Finally, iatrogenic cyanide poisoning results from administration of nitroprusside, which is metabolized to cyanide and can cause toxicity at high doses, after prolonged therapy without coadministration of sodium thiosulfate, or in the presence of renal failure.[68,69]

Cyanide produces toxicity rapidly, especially through inhalation of HCN. Cyanide salts (sodium cyanide [NaCN], potassium cyanide [KCN]), when ingested, are converted to HCN in the presence of gastric acid and then absorbed. Cyanide binds to heme iron in the cytochrome complex IV of the electron transport chain (cytochrome C oxidase), resulting in inhibition of oxidative phosphorylation. Consequently, the patient is unable to use oxygen to produce adenosine triphosphate, and the result is energy failure. Signs and symptoms are nonspecific and reflect tissue hypoxia. However, a symptomatic patient with a lactate level of 10 mmol/L or more is highly suspect for cyanide toxicity.[70] Death may occur within minutes. Venous oxygen levels are elevated from the impairment of oxygen use at the cellular level. However, because of this, patients do not appear cyanotic.

Treatment of cyanide poisoning involves immediate life support measures followed by administration of an antidote. The traditional three-antidote kit contains inhaled amyl nitrite, intravenous sodium nitrite, and intravenous sodium thiosulfate. Amyl nitrite is only used if intravenous access is unavailable. Nitrites are therapeutic by inducing methemoglobinemia. Although the mechanism of action of nitrites in cyanide poisoning is incompletely understood, it is postulated that methemoglobin has a higher affinity for cyanide than cytochrome oxidase and therefore removes cyanide from the affected cytochromes. Nitrites are potent vasodilators and can cause significant hypotension that may be avoided by slow administration. However, the most significant vasodilation occurs in the most hypoxic tissues, and therefore this effect may provide additional therapuetic benefits. Excessive methemoglobinemia is a potential risk. The initial dose in pediatric patients is 0.2 mL/kg of a 3% solution. The dose should be decreased in the presence of anemia. Nitrites should not immediately be administered to fire victims, who may have significant CO poisoning. The induction of methemoglobin in these individuals may reduce oxygen-carrying capacity below critical levels. The third antidote, sodium thiosulfate, reacts with cyanide in the presence of the mitochondrial enzyme rhodanese to produce the nontoxic thiocyanate that is then excreted in the urine. Although part of a three-antidote kit, sodium thiosulfate may be used without nitrites and can be administred early in patients with significant CO levels because it will not affect hemoglobin. It, too, can cause hypotension if administered rapidly. Additional side effects may include nausea and vomiting; however, it has a minimal adverse effect profile. Hydroxocobalamin (HCO) is an alternative antidote that has been used to treat fire victims in France for several years; it is now available in the United States.[71,72] It is a cobalt-containing molecule that allows cyanide to replace a hydroxyl group to produce cyanocobalamin (vitamin B_{12}), which is then excreted in the urine.This antidote, although effective, may be limited by its adverse affects, interference with laboratory assays, and expense. Patients may experience hypertension after administration. Both their skin and body fluids will exhibit a reddish hue as a result of the red color of cyanocobalamin. This discoloration interferes with several important assays that may be needed for patient monitoring because many of the analyses performed in the lab are colorimetric. Patients have also reported severe acne 1 to 2 weeks after administration.[72] Pediatric administration consists of a 70 mg/kg dose administered over 30 minutes (IV push is acceptable in severe toxicity). A second dose may be administered if necessary over a total administration time of 6 to 8 hours. The onset of action of HCO is more immediate than sodium thiosulfate, which may take up to 20 minutes to exert its effect. However, because HCO must be reconstituted slowly over 20 minutes and still requires intravenous access, its administration time limits its onset of action and therefore likely provides no benefit over thiosulfate in this respect. It is suspected that the two medications will work synergystically but should be administered in separate lines. To date there are no comparative trials to show that hydroxocobalamin alone is superior to the traditional three-antidote kit.

Iron

Iron is available alone and in combination with other vitamins. Several salts have different proportions of elemental iron. Iron toxicity is often divided into several phases. The first phase occurs early, usually within 30 minutes, and consists of GI manifestations of vomiting and diarrhea, which may include both hematemesis and hematochezia. Fluid and electrolyte losses may be severe during this period, and aggressive resuscitation may be necessary. The second phase, the so-called *latent period,* is a quiescent phase in which the initial GI symptoms have ceased but the patient continues to feel unwell. This is not truly a quiescent phase because the patient may remain tachycardic, and an anion gap metabolic acidosis develops. The third phase, which begins after 12 hours, is characterized by cardiovascular collapse and shock; the fourth phase is liver failure. The corrosive effect of iron on the GI tract may also lead to the development of scarring or stricture after recovery from acute toxicity.[73] Doses higher than 20 mg/kg of elemental iron reliably produce GI irritation, although systemic toxicity is generally not seen with doses less than 60 mg/kg. Absence of a prodromal GI phase within 4 hours of ingestion generally precludes the development of serious systemic iron toxicity.[74]

Iron is not effectively adsorbed to activated charcoal, and lavage of the stomach or whole-bowel irrigation can be considered if iron tablets are suspected to have remained in the GI tract. Plain radiographs of the abdomen may help visualize the location of pills and guide decontamination decisions, although not all forms of iron can be visualized. Multivitamins, children's preparations, and liquid preparations will not be visible on radiographs. Serum iron levels should be determined within 6 hours of ingestion; after that time, significant redistribution to tissues may have occurred. Total iron-binding capacity, used in the evaluation of chronic iron overload, may be falsely elevated in acute iron ingestion and should not be used in treatment decisions.

Chelation with deferoxamine is indicated for serum levels higher than 500 μg/dL or for signs of circulatory failure.[75] The initial dose is 15 mg/kg/h intravenously. If the patient remains symptomatic beyond 24 hours, the deferoxamine dose should be decreased or temporarily discontinued because prolonged use beyond this time is associated with the development of acute respiratory distress syndrome.[76] Interestingly, children's multivitamin preparations do not produce toxicity at the same iron content as adult preparations, and very few children have ever experienced toxicity with large ingestions.[73] Prenatal vitamins, on the other hand, except those containing iron carbonyl, have led to extreme toxicity even in minor ingestions.

Isoniazid

Isoniazid (INH), a relative of pyridoxine and nicotinic acid, is a hydrazine used in the treatment of tuberculosis. It has a complex set of metabolic actions on several enzyme systems but produces its acute toxicity primarily by interfering with pyridoxine metabolism. INH both inhibits pyridoxine phosphokinase, which is required to activate pyridoxine by conversion to pyridoxal-5-phosphate, and reacts with pyridoxal-5-phosphate to form an inactive metabolite that interferes with and prevents the conversion of glutamate to γ-aminobutyric acid (GABA). After the acute ingestion of a large quantity of INH, early GI symptoms and drowsiness are followed by seizures, coma, and metabolic acidosis. The seizures result from the depletion of GABA and are difficult to control with usual anticonvulsant therapy. The acidosis results from lactate and is produced by seizure activity and possible interference by INH in the conversion of lactate to pyruvate. Treatment of INH poisoning is with pyridoxine, which should be administered in a dose equal to the ingested dose of INH (by weight). If the dose ingested is unknown, 5 g is a reasonable empiric starting dose. INH is effectively removed by hemodialysis, although the efficacy of pyridoxine should obviate its need in most cases. Benzodiazepines may work synergistically with pyridoxine; phenobarbital may also be considered in refractory cases.

Ingestion of mushrooms from the group of hydrazine-containing mushrooms, including *Gyrometra* spp., produces a toxicity identical to INH through its interefence with pyridoxal-5-phosphate and depletion of GABA. This mushroom toxicity is treated with an empiric starting dose of 5 g of pyridoxine in the same manner as above.

Salicylates

There are several forms of salicylate, the most common of which is acetylsalicylic acid (ASA), or aspirin. The most potent form is wintergreen oil, which is made up of 98% methylsalicylate. Other forms include bismuth subsalicylate, sodium salicylate, and magnesium salicylate. Doses up to 100 mg/kg are likely to produce only minimal toxicity, whereas doses above 300 mg/kg may have serious consequences, including death.

Early signs of salicylate toxicity include an increase in minute ventilation (primary respiratory alkalosis), tinnitus, nausea, and vomiting. Salicylates also produce metabolic acidosis through several mechanisms including uncoupling of oxidative phosphorylation and inhibition of the tricarboxylic acid cycle. Mixed-picture respiratory alkalosis and metabolic acidosis from an ingestion are nearly pathognomonic for salicylate intoxication and warrant obtaining a salicylate level for evaluation. Uncoupling of oxidative phosphorylation may also lead to hyperpyrexia. Cerebral edema and pulmonary edema are rare but potentially fatal complications of salicylate poisoning and are more common with chronic toxicity than with acute poisoning. Levels greater than 35 mg/dL produce minor symptoms; significant toxicity and acidosis start to manifest at approximately 45 mg/dL in acute ingestion. Patients with chronic ingestion or exposure may show more severe symptoms at much lower levels (approximately 30 mg/dL).

Enhancement of the elimination of salicylates may be achieved through alkalinization of the urine. This is accomplished by administration of an infusion of sodium bicarbonate. The urine pH should be frequently monitored (every void in patients without a catheter) and the bicarbonate infusion rate adjusted accordingly to target a urine pH above 7.5. The goal is to maintain a normal urine output and not to perform forced diuresis. Serum pH should be periodically monitored to avoid serious alkalemia. In addition, serial potassium and magnesium levels should be obtained and maintained in the normal range. As the body tries to retain potassium, it will exchange it for protons in the urine, and obtaining an alkaline urine will be nearly impossible. Potassium can be added to the alkalinizing fluid and/or provided as a separate infusion. Patients should also be monitored for glucose. A bolus of dextrose may be warranted[77] even if serum glucose levels are normal in salicylate ingestion with depressed sensorium. In a patient with significant CNS alteration and/or salicylate levels greater than 70 mg/dL, hemodialysis is an effective method for salicylate clearance. As levels approach the therapeutic range, the free fraction of salicylate declines and the efficiency of dialysis is diminished. Its use should be considered for very high serum levels; in the presence of renal impairment, volume overload, or pulmonary edema; and in the case of severe electrolyte or acid-base abnormalities.

Bradycardia, Hypotension, and Cardiac Conduction Abnormality

The most important cardiovascular agents that cause bradycardia and hypotension are calcium channel antagonists, β-adrenergic antagonists, and digoxin. All these agents may result in severe toxicity that requires specific therapy.

Calcium Channel Antagonists

Calcium channel blockers exert their action on L-type calcium channels in the heart and vascular smooth muscle. Blockade of calcium channels in the heart results in negative inotropic,

chronotropic, and dromotropic effects. Blockade of calcium channels in arteriolar smooth muscle causes vasodilation. Dihydropyridine calcium channel antagonists (e.g., nifedipine, amlodipine, felodipine, nicardipine) act primarily on the vascular smooth muscle. Verapamil, in addition to vasodilatory effects, also has potent cardiac calcium channel–blocking activity and may cause bradycardia, heart block, and myocardial depression. Diltiazem has similar effects to verapamil but is a less potent inhibitor of cardiac calcium channels. Calcium channel blockers also impair the release of insulin in overdose and may cause significant hyperglycemia.

Treatment depends on the agent involved and the severity of toxicity. Except in extremely large ingestions, dihydropyridines produce hypotension and reflex tachycardia. These patients may respond to volume expansion alone. Intravenous calcium and vasopressors are indicated if the hypotension remains refractory to intravenous fluids. Verapamil and diltiazem overdose is further complicated by pump failure. These patients may benefit from inotropes such as dobutamine. Glucagon, which acts at a receptor other than the β-receptor, increases cyclic adenosine monophosphate (cAMP) and has been reported to reverse refractory hypotension in calcium channel overdose. The reported dose is 0.15 mg/kg intravenous bolus followed by an infusion of 0.05 to 0.1 mg/kg/hr.[78] Phosphodiesterase inhibitors (amrinone, milrinone) may provide some efficacy by preventing the destruction of cAMP. However, animal data have not shown these to be of benefit over glucagon.[79,80]

High-dose insulin/euglycemia therapy has shown efficacy in several successful animal models as well as in several case reports and case series to reverse cardiogenic shock associated with calcium channel antagonist overdose.[81,82] The recommended dose is from 0.5 to 1 unit/kg of insulin as a bolus, followed by an infusion titrated to efficacy. Given the risks of hypoglycemia and its profound deleterious effects, serum glucose concentration should be monitored hourly. Patients with overdose of calcium channel antagonists are not usually responsive to transcutaneous pacing because of an inability to capture. If capture is achieved, the patient should be paced at a low rate, near 60, to attempt to maximize filling of the ventircules. However, most patients exhibit a decreased contractility that, even with pacing, prevents achievement of significant cardiac output. Patients who are unresponsive to medical management should be considered for a left ventricular assist device or extracorporeal life support (see Chapters 27 and 53, respectively).

β-Adrenergic Antagonists

β-Adrenergic antagonists comprise a fairly extensive list of therapeutic agents that are largely distinguished from each other by their selectivity (or lack thereof) for the β_1 receptor. Atenolol, metoprolol, esmolol, and acebutolol are β_1-selective agents, whereas agents such as propranolol, nadolol, and pindolol act both at β_1 and β_2 receptors. Propranolol is unique in that it is highly lipophilic and has sodium channel–blocking activity. Labetalol, in addition to β-blocking activity, possesses α-receptor–blocking activity. β_1 Receptors are largely found in the heart, and agonism causes positive inotropic and chronotropic effects. β_2 Receptors are found in the airway smooth muscle, where they cause bronchodilation; in the small blood vessels, where they cause vasodilation; and in several other organs, where they have a number of effects that are not important in the context of poisoning.

Acute overdose of β-adrenergic antagonists results in bradycardia, hypotension, and conduction delay. Toxicity is generally much lower than with calcium channel antagonists such as verapamil and diltiazem. Bronchospasm may occur in susceptible individuals. Propranolol, by virtue of its sodium channel–blocking activity, causes QRS widening, exaggerated negative inotropy, chronotropy, and conduction delay. Patients are also risk for coma and seizures because of the drug's ability to cross into the CNS. Labetalol may cause vasodilation in addition to β-receptor blockade. Hypoglycemia may also be seen with drugs in this class and has been reported in children with usual dosing of propranolol.[83,84]

Treatment beyond monitoring is not necessary if the only manifestation is asymptomatic bradycardia. Patients with bradycardia and hypotension may respond to atropine, although they are expected to have decreased vagal tone to start with. β-Agonists have variable effects in the presence of β-adrenertgic blockade. In theory, mixed agonists could worsen hypotension by causing β_2 receptor–mediated vasodilation. The phosphodiesterase inhibitors amrinone and milrinone have a theoretical benefit of improving contractility by blocking the breakdown of cAMP but have not been shown to be more effective than glucagon.[79,80] Glucagon acts by a nonadrenergic receptor to increase intracellular cAMP and improve cardiac contractility. The recommended dose is the same as that previously described for calcium channel blockers. Patients who do not respond to these measures, such as patients with calcium channel blocker overdose, should be considered for extracorporeal life support. Seizures should be treated with benzodiazepines as first-line therapy, and bronchospasm may respond to anticholinergic agents if inhaled β_2-agonists fail to overcome the β-blockade.

Digoxin

Digoxin and related digitalis glycosides are used in the management of cardiac failure and tachydysrhythmias. Digoxin blocks the sodium-potassium adenosine triphosphatase (Na/K-ATPase) and ultimately leads to increased intracellular calcium concentration and improved contractility. It also increases vagal tone and causes sinoatrial (SA) and atrioventricular (AV) nodal depression. In overdose, sympathetic tone is increased and may lead to increased automaticity.

Overdose of digoxin presents with nausea, vomiting, lethargy or confusion, and cardiac dysrhythmias. Although virtually every rhythm has been described in digoxin toxicity, bidirectional ventricular tachycardia and atrial tachycardia with AV block are characteristic. Blockade of Na/K-ATPase causes hyperkalemia, and levels greater than 5.5 mEq/L have been associated with a significant mortality rate.[85] The diagnosis is confirmed with measurement of the serum digoxin level. Because of a long distribution phase, the serum level may not accurately reflect tissue levels until at least 6 hours after ingestion.

Sinus bradycardia or heart block may respond to atropine alone. More serious arrhythmias are an indication for treatment with digoxin-specific Fab fragments (e.g. Digibind, DigiFab). Drugs that further depress the SA or AV node should be avoided. Hyperkalemia resolves with Fab fragment therapy because it restores function of the Na-K pump.

Because digoxin causes intracellular hypercalcemia, calcium is best avoided because it could theoretically increase toxicity.[86] Fab fragment therapy in children is indicated with known digoxin ingestion (strong history of ingestion of at least 0.1 mg/kg or digoxin level greater than 5 ng/mL) and signs and symptoms of digoxin toxicity (rapidly progressing signs and symptoms of digoxin toxicity or potentially life-threatening arrhythmias or serum potassium level greater than 6 mEq/L).[87]

A clinical picture similar to digoxin poisoning may be seen with the ingestion of certain cardiac glycoside-containing plants such as oleander. Oleander poisoning may cause a false-positive result on digoxin immunoassay and may respond to Fab fragment therapy.[88] An antidote dose cannot be calculated from the level obtained because of the differences between digoxin and the cardiac glycoside found in the ingested plant. Therefore an empiric dose of 10 to 20 vials is recommended in both pediatric patients and adults.

Acetaminophen (Paracetamol)

Although it does not cause a toxidrome per se, acetaminophen is the most commonly ingested drug in intentional overdose. It may cause fulminant hepatic failure leading to admission to the pediatric intensive care unit. Major routes of elimination of acetaminophen are through conjugation or sulfation and then excretion in the urine. A minor pathway is via CYP2E1 to produce *N*-acetyl-p-benzoquinone-imine (NAPQI), a toxic metabolite capable of binding to hepatocytes and causing cell death. With therapeutic doses of acetaminophen, NAPQI is rapidly detoxified by glutathione. In overdose, larger amounts are formed and may overwhelm the available glutathione stores, resulting in a centrilobular hepatic necrosis.

Patients may initially present with nausea and vomiting, but often they have no symptoms or signs. Initial metabolic acidosis may occur with extremely large ingestions. Transaminases begin to be elevate at approximately 24 hours after ingestion and peak between 48 and 72 hours. Patients either progress to fulminant hepatic failure or recover completely (see Chapter 88). Treatment with *N*-acetylcysteine (NAC) reduces the incidence of hepatotoxicity when administered in a timely fashion after overdose. NAC acts through several mechanisms, including enhancing the synthesis of glutathione and as a possible free radical scavenger.[88] It is most efficacious when administered within 10 hours of ingestion but has shown benefit when administered to patients presenting after this window of time.[88] In one study, intravenous NAC decreased the risk of death from acetaminophen-induced fulminant hepatic failure even in patients who presented with already established hepatic encephalopathy.[89] Decision to treat an acute ingestion is based on plotting a single acetaminophen blood level at least 4 hours after ingestion on the Rumack-Matthew nomogram (Figure 106-1). After 24 hours, the nomogram is of no benefit. An acetaminophen level should be measured and liver function analysed to assess the patient's risk for development of toxicity or potential prognosis. In addition, the nomogram has not been validated in chronic ingestion or multiple, staggered ingestions. In these cases, the nomogram should not be relied on for an assessment of toxicity. A poison control center should be consulted for specific treatment advice in those scenarios.

Tricyclic Antidepressants

Tricyclic antidepressants (TCAs) are a group of drugs with potentially serious toxicity that are used in the treatment of psychiatric disorders, enuresis, and pain syndromes. Although

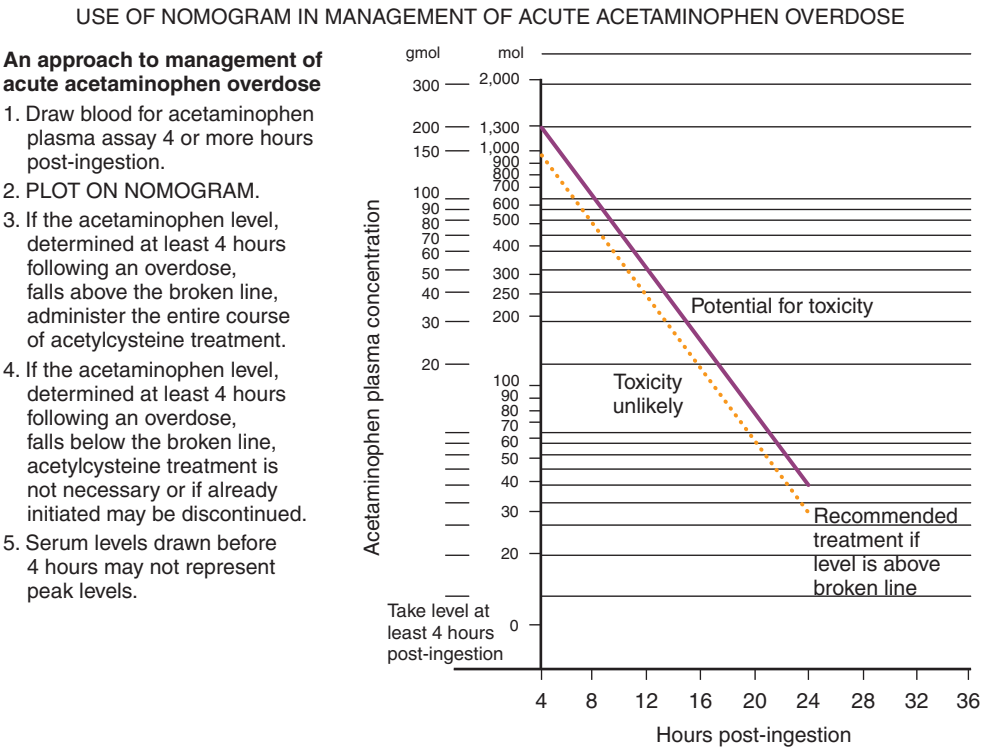

Figure 106–1. Use of a nomogram in the management of acute acetaminophen overdose.

in the treatment of depression they have largely been supplanted as first-line agents by less toxic compounds, they still represent a significant cause of morbidity and death.

TCAs have multiple mechanisms of toxicity and produce a wide spectrum of clinical effects. Their anticholinergic properties may produce the anticholinergic toxidrome (se Box 106-4). α-Adrenergic inhibition may cause sedation and hypotension. Blockade of cardiac sodium channels causes decreased myocardial contractility and is seen on the ECG as widening of the QRS complex. QRS widening correlates with the development of seizures (QRS >100 ms) and arrhythmias (QRS >160 ms).[90] Potassium channel blockade leads to a prolonged QT interval. Seizures, which tend to be single and short lived, occur and may be attributable to a combination of TCA effects on GABA and on reuptake of biogenic amines in the CNS. This constellation of anticholinergic syndrome, seizures, hypotension, and widening of the QRS complex should create a high index of suspicion for TCA overdose. A similar picture may be seen with type Ia antiarrhythmics.

Severe toxicity tends to occur early in the course of TCA poisoning. Patients who do not manifest QRS widening, conduction abnormalities on ECG, altered mental status, seizures, or hypotension within the first 6 hours can be classified as low risk and no longer need PICU monitoring.[91] Anticholinergic manifestations should be treated supportively only. Seizures, if prolonged, should be treated with benzodiazepines. If benzodiazepines have been coingested by the patient, then flumazenil, a benzodiazepine receptor antagonist, should not be administered because it may unmask TCA-induced seizures. Widening of the QRS complex (>100 ms in adults) or ventricular arrhythmias should be treated with sodium bicarbonate to produce alkalinization of the serum. Bicarbonate should be given in boluses of 1 to 2 mEq/kg until ECG improvement is seen (narrowing of the QRS). Recurrence of QRS widening may be treated in the same manner. Alternatively, a bicarbonate infusion can be started after the initial bolus to maintain alkalemia (with monitoring to prevent overalkalinization [i.e., pH >7.55]). If continuous infusion of bicarbonate is performed, it may be stopped and the ECG monitored after approximately 6 hours of normal ECG tracings. Although drug levels are available for monitoring these medications in therapy, they serve no purpose in acute toxicity, and studies have shown that ECG findings are superior predictors of toxicity on this scenario.

Bites and Stings

Sean P. Bush

PEARLS

- Snakebite-related injury and death are reduced most by rapid transport, intensive care, and the administration of antivenin.
- Measures not recommended for snakebite first aid are incision, suction, tourniquets, electric shock, ice directly on wound, alcohol, or folk therapies.
- Antivenins can induce immediate anaphylactic (type I hypersensitivity) or anaphylactoid reactions, which can be rapidly life threatening. Airway swelling, wheezing, shock, and urticaria characterize these reactions. Anaphylactic and anaphylactoid reactions are treated with antihistamines, histamine (H_2) blockers, epinephrine, steroids, and ventilatory/circulatory support as needed.
- All children with snake envenomations should be admitted to the hospital. Serious effects can be delayed and can recur even after treatment with antivenin.
- Typically, a widow spider bite site has a "target" appearance. There may be a central reddened, indurated area around fang puncture site(s) surrounded by an area of blanching and an outer halo of redness. The findings around the bite wound may be subtle.
- Any bee, wasp, or ant can cause toxic, even fatal, complications when they attack en masse. Sting removal after a honeybee sting should be done as quickly as possible, regardless of the method of removal.

The general principles of envenomation medicine are similar around the world, although the availability of resources varies widely. A comprehensive discussion of all available antivenins is beyond the scope of this text.[1] On the basis of my experience and in consideration of space constraints, the scope of this textbook, and its audience, the chapter focuses on United States antivenins. Readers are encouraged to become familiar with the prescribing information for the antivenin(s) available in their area(s) of practice for the envenomations they may encounter.

Snakebites

Snakebite is a particularly challenging clinical problem because of the wide variety of toxic effects. Children with snakebites may have little more than a fang puncture mark, or they may have multisystem failure and death.[2,3] Part of this is due to the extreme variability of snake venom, even within the same species.[4] Snake venom contains multiple enzymes, proteins, and peptides that can damage local tissues and have serious systemic effects. Unfortunately, it is difficult to predict at the time of the bite which patients will have relatively mild symptoms and which will have a rapidly progressive and potentially fatal envenomation syndrome.

Snakebite envenomation syndromes can be loosely associated with snake family. Viperidae includes old-world vipers and pit vipers (collectively referred to as viperids). Most snakebites in the United States are inflicted by pit vipers, which include rattlesnakes, cottonmouths (also known as water moccasins), and copperheads.[5] All pit vipers have a triangular head, elliptical pupils, and a heat-sensing pit between the eye and nostril (Figure 107-1).[6] The pit organ has thermal receptors that can detect temperature differences of 68° C at 1.5 m in predatory interactions and 108° C at 1 m in defensive contexts (A. Krochman, personal communication, January 17, 2005). The family Elapidae ("elapids") includes cobras, coral snakes, kraits, and mambas.[7] Their venom effects can be as diverse as the species that make up this family of snakes. Cobras are showy, hooded, high-profile snakes that inhabit Africa and southern Asia (Figure 107-2). The coral snakes of the Americas and kraits of Asia and India are often small, shy, colorfully banded snakes (Figure 107-3). Mambas in Africa are long, lean, and very fast. Australian elapids can be large and nondescript. Sea snakes possess some of the world's most toxic snake venom, although few bites occur mostly because of the marine distribution and nonaggressive temperament of these snakes. Most snakes from the Colubridae family ("colubrids") are considered harmless, although several species possess venom and some have primitively specialized teeth to facilitate venom delivery. Some, such as the boomslang in Africa, are considered dangerous to humans, and antivenin is produced.

Epidemiology

It is often stated that children are more severely affected by snakebite than adults.[8] Indeed some preliminary data suggest that smaller patients have increased severity. There is not much in terms of evidence, however, to support the assertion that outcomes for children are worse than adults. For example, of the more than 100,000 exposures and two dozen deaths

Figure 107–1. Copperhead (*Agkistrodon contortrix*). *(Photo Courtesy Sean Bush, MD.)*

Figure 107–2. Red spitting cobra (*Naja pallida*). *(Photo Courtesy Mike Cardwell.)*

described by the American Association of Poison Control Centers (AAPCC) since its first report in 1983, only a relatively small percentage of the deaths are described in pediatric patients.[9] In some respects, children are no different than adults when it comes to snakebite. For instance, antivenin dosing is not based on the patient's weight,[10,11] yet there are a few concerns specific to pediatric patients. For example, because young children may not be able to give a good description of the snake or circumstances, it may be unclear whether a venomous snake has bitten them.

Pathophysiology

Although viper and pit viper venom composition varies from snake to snake, components can lead to capillary leak, abnormal clotting, inefficient muscle movement, or neurotoxicity. Capillary leak and abnormal clotting can lead to tachycardia, hypotension, or even hemorrhagic shock. Neurotoxicity or inefficient muscle movement can lead to respiratory difficulty or distress.[12] Meanwhile, proteolytic enzymes, predominant in viper and pit viper venoms, digest tissue. The longer enzymatic components of venom have time to work, the more tissue gets damaged. Thus "time is tissue."[13] The sooner that antivenin can be started, the sooner that irreversible injury can be prevented.[14] After tissue is injured by way of digestion, however, antivenin will not reverse the damage; it will have to heal over time.[15] Myotoxicity and rhabdomyolysis can ensue.

Envenomation by most elapids is notable for severe neurological dysfunction, such as cranial nerve abnormalities, paralysis, and respiratory arrest. Some elapids, however, such as spitting and monocellate cobras, can also cause local necrosis. Most do not induce coagulopathy. Other symptoms and signs may include swelling, lethargy, vomiting, chest pain, and shock. Some cobras and cobralike species can "spit" venom toward the face of an antagonist, which can result in eye pain and visual impairment. Sea snake envenomation can cause profound neurotoxicity and myotoxicity, but generally does not induce coagulopathy or result in serious local injury. Sea snakes are found in waters around Southeast Asia and Australia. Additionally, some individuals may experience anaphylactic or anaphylactoid reactions to venom.[16,17] Finally, some responses can be attributed to anxiety, although this should be a diagnosis of exclusion.[6]

Clinical Presentation

Immediately after a snakebite, the only apparent manifestation may be fang puncture wounds. If a patient is seen soon after a snakebite, an envenomation syndrome might not have developed yet. The onset of symptoms and signs can occur rapidly or it may be insidious. Generally the more severe an envenomation, the more rapidly it progresses; however, even a

Figure 107–4. Southern Pacific rattlesnake (*Crotalus helleri*) bite wounds. *(Photo Courtesy Sean Bush, MD.)*

Figure 107–5. Ptosis after Mohave rattlesnake (*Crotalus scutulatus*) envenomation. *(Photo Courtesy Sean Bush, MD.)*

slowly progressing envenomation can lead to severe sequelae. If a patient is seen very late, the envenomation could have already run its course, and antivenin will not be as effective.[14]

Snakebites by pit vipers and vipers cause pain around the bite site as tissues distort with swelling. There may or may not be associated taste changes. Difficulty breathing can follow many types of venomous snakebites and can progress to respiratory distress or failure in some cases. Patients may experience nausea, vomiting or diarrhea, and venom-induced coagulopathies (often associated with viper and pit viper envenomation) can lead to hematemesis, hematochezia, or both. Certain snakebites, such as those inflicted by most elapids and some populations of rattlesnakes, can also be associated with neurological symptoms, such as motor weakness or paresthesias. Syncope or lethargy can result from severe or prolonged hypotension.[6] Vital signs may reflect tachycardia, hypotension or hypertension, tachypnea, or hypoventilation. On physical examination, there may be one, two, or more fang puncture wounds, or none may be discernible. There is usually tenderness and swelling surrounding the bite site, which expands as the venom spreads locally. Other local signs can include erythema, ecchymosis, and bullae after viperid envenomation (Figure 107-4). Systemic evidence of viperid envenomation may manifest in many ways. There may be abnormal bleeding, such as prolonged bleeding from fang puncture wounds or intravenous (IV) start sites. Patients may have epistaxis or gingival bleeding. Serious and potentially life-threatening bleeding may manifest via the gastrointestinal tract or within the cranium. In extremely rare instances, snakebite can also cause hypercoagulability, which can lead to infarcts. Additionally, there may be neurological signs, such as ptosis (Figure 107-5), and muscle fasciculations or "myokymia."[6]

Diagnostic Studies

Initial laboratory tests after pit viper or viper envenomation should include a complete blood count (CBC), prothrombin time (PT), partial thromboplastin time (PTT), international normalized ratio (INR), fibrinogen, and a type and screen. Venom-induced coagulopathy is common after many types of viperid envenomations and is most typically characterized by thrombocytopenia and hypofibrinogenemia. Even if coagulation values are normal on presentation, they may need to be rechecked depending on the clinical scenario. Venom-induced coagulopathies can develop late, recur, or persist. If initial laboratory findings are abnormal, more frequent monitoring may be necessary depending on how severely abnormal they are and how they respond to treatment. If the findings are abnormal, repeating the CBC, PT, PTT, INR, and fibrinogen tests 1 hour after completion of an infusion of antivenin may be helpful to monitor treatment efficacy. When laboratory values are rechecked, in addition to the initial laboratory panel, additional blood should be sent for creatine kinase (CK), electrolytes, blood urea nitrogen, and creatinine clearance. All snakebite can result in rhabdomyolysis, which usually responds to aggressive fluid hydration, but can require dialysis if myoglobinuric renal failure develops. In certain regions, such as Australia, venom detection kits (e.g., enzyme-linked immunosorbent assays) may be available to help identify species and guide specific antivenin selection. Other diagnostic studies may be indicated on the basis of a patient's medical history or special circumstances.[6]

Pitfalls

It is possible that a snakebite might be mistaken for a puncture wound from another cause (e.g., from a plant thorn), if the patient is seen very early, if the envenomation is mild, or if there are difficulties obtaining a reliable history. If there is any question about whether a patient has been bitten by a venomous snake, an observation period and diagnostic studies may help clarify the diagnosis. Snakebites usually progress if significant envenomation has occurred. Certain signs (e.g., ecchymosis), symptoms (e.g., local paresthesias), and laboratory data (e.g., thrombocytopenia, hypofibrinogenemia), if affected, are fairly consistent with viperid envenomation. If a bite by an elapid is suspected, envenomation should be assumed until proven otherwise after adequate observation and evaluation.

Prehospital Care

The factors that most reduce snakebite-related injury and death in the United States are rapid transport, intensive care, and the administration of antivenin.[18] All patients with

snakebites should be transported to the hospital as expeditiously and safely as possible, preferably through a 911 call (where available). The following measures are not recommended for first aid: incision, suction, tourniquets, electric shock, ice directly on wound, alcohol, or folk therapies.[19-21] Insufficient evidence exists for splinting or positioning (e.g., above or below the level of the heart). Therefore the extremity should initially be maintained in a neutral position of comfort. The Australian technique of pressure immobilization resulted in significantly longer survival, but higher intracompartmental pressures after artificial, intramuscular (IM) western diamondback rattlesnake envenomation in a pig model.[22] This technique involves immediately wrapping the entire extremity that was bitten starting at the bite site and proceeding proximally with an elastic Ace wrap or crepe bandage as tightly as one would wrap for a sprain, then splinting and immobilizing the extremity. Although pressure immobilization is not recommended widely, certain scenarios may warrant its use. It is generally not recommended for most viper bites or for bites by spitting cobras, but it is recommended for most types of Australian fauna, cape cobras, kraits, coral snakes, mambas, and sea snakes. Once pressure immobilization is placed, it should not be removed until preparations are made to manage acute toxicity and/or immediate hypersensitivity because of a potential bolus effect after its removal. Although it is difficult to predict snakebite severity at the time of the bite, certain factors may reflect increased likelihood of a more severe envenomation: large snake size, dangerous snake species, small patient size, prolonged fang contact, previous snakebites (treated or not) or exposures to snakes, or delays to medical care.

Emergency and Critical Care

All emergency personnel should be able to distinguish a venomous from a nonvenomous snake if it occurs naturally in their region of practice. If there is uncertainty about whether a particular snake is venomous, consider taking photographs of the snake from a safe distance of at least 6 feet away using a digital or Polaroid camera. These images can be seen immediately and may help make clinical decisions. Although it may be helpful to identify the species of snake,[15,23] transporting it (alive or dead) is discouraged because of inherent dangers with capturing it. On scene, snakes should only be moved or contained if absolutely necessary. A snake hook or long shovel may be helpful to move the snake into a large, empty trash canister where it can be recovered by professionals, such as an animal control agent.

Airway support, advanced pediatric life support protocol, or both should be provided as needed. Severe respiratory difficulty may require intubation and mechanical ventilation. Check vitals frequently, provide oxygen, and place monitors (cardiac, blood pressure, and pulse oximetry). Start two IV lines. Central venous or intraosseous access may need to be obtained. It may be appropriate to avoid placing a central line in a noncompressible site (e.g., internal jugular) after viperid envenomation because of the risk of bleeding from venom-induced coagulopathy. A normal saline fluid bolus of 20 mL/kg should be administered. If there is evidence of shock, give a second fluid bolus. Because viperid envenomation can induce coagulopathy and bleeding, transfusion may be required after treatment with two fluid boluses. Give packed red blood cells of 10 mL/kg for acute, life-threatening blood loss or anemia. Persistent hypotension may require the administration of vasopressors and inotropic agents. Urine output may be used as a measure of adequate hydration and to check for the occurrence of rhabdomyolysis. The patient should take nothing by mouth until it has been determined that the patient will not need airway control and mechanical ventilation.

After pit viper or viper envenomation, remove rings, other constricting jewelry, and clothing in anticipation of severe swelling. The expanding area of swelling and tenderness can be used to follow the progression of viperid envenomations. Tenderness is more sensitive than swelling for detecting progression. Also, it is preferable to follow the advancing edge of tenderness or swelling than to follow serial measurements of circumference. Palpate until the edge of advancing tenderness is found. Mark this leading edge with a permanent marker and write the time alongside. Repeat this often enough to gauge progression. This may mean checking every 15 to 20 minutes initially. Once antivenin is started, it should still be followed every 1 to 2 hours.

All hospitals should stock at least enough antivenin to treat one patient. This should be arranged ahead of time if possible, although sometimes there are antivenin shortages and other resource challenges. Presently only one agent is commercially available in the United States for treatment of pit viper envenomation: Crotalidae Polyvalent Immune Fab (Ovine), which goes by the trade name CroFab (Protherics Inc., Nashville, Tenn.).[24] Antivenin Crotalidae Polyvalent is no longer produced. Several manufacturers produce antivenin for bites in Africa (e.g., South African Vaccine Producers), Asia, Europe, and Australia (e.g., Commonwealth Serum Laboratories [CSL]), and the Americas (e.g., Instituto Bioclon in Mexico, Instituto Clodomiro Picado in Costa Rica, and the Butantan Institute in Brazil). A polyvalent sea snake antivenin (CSL) is the drug of choice for sea snake envenomation, but tiger snake antivenin may have adequate efficacy if sea snake antivenin is not available. Information on antivenin should be researched ahead of time, and practitioners should be familiar with sources and administration techniques for the antivenins available for envenomations they may encounter. Each antivenin has varying specificity, efficacy, and safety. Some antivenins developed for one species may have some efficacy against other closely related species. If an exotic envenomation is encountered in the United States, calling the AAPCC or consulting the Antivenom Index may help locate antivenin. Many zoos stock antivenins for the exotic species they keep. If antivenin is unavailable, a patient with an elapid or sea snake envenomation may need his or her airway secured and ventilatory support provided for days or even weeks. Meanwhile, hypotension should be treated with IV fluids and then vasopressors. Edrophonium may temporarily improve weakened muscles of respiration after elapid envenomation while awaiting antivenin.

There are various suggested methods to determine the need for antivenin in your patient. Many grading scales are available, but it is better to treat a patient based on envenomation progression or potential. Grading scales should not be used for elapid or sea snake envenomations. Antivenin should be given promptly for best results, although it may have benefit for days to weeks after an envenomation. Anytime antivenin is given, allergic reactions should be anticipated. It may be helpful to know whether the patient has allergies or previous

exposures to papain, papaya or animal serums, or other agents used to make antivenin. Obtain informed consent when possible. Many of the principles of antivenin administration are similar. The technique for administering CroFab is outlined as an example. A starting dose of CroFab is 4 to 6 vials,[25] which is the same for children as it is in adults. Each vial is reconstituted with 10 ml of sterile water. It can take anywhere from about 10 to 30 minutes to go into solution. It is best to swirl or roll the vials between the hands rather than to shake them. After each vial goes into solution, it should be further diluted into a total volume of 250 mL of normal saline. No skin test is recommended for CroFab, although manufacturers of many other types of antivenin recommend skin testing. With CroFab, the infusion is started slowly, at a rate of 1 mL/min for the first 10 minutes. While the infusion is started, a physician skilled in resuscitation should be at bedside. Difficult airway equipment, epinephrine, diphenhydramine and a histamine (H_2) blocker (e.g., cimetidine) should be immediately available. If the infusion is tolerated for the first 10 minutes without evidence of an adverse reaction, the rate should be increased to complete thee total volume of 250 mL/hour. If there is a problem at any time, stop the infusion, treat the adverse reaction accordingly, and reassess the need to continue antivenin treatment. A physician should be nearby at all times during the remainder of the infusions. Repeat four- to six-vial increments until initial control is achieved. Initial control is defined as the arrest or significant slowing of progression of any and all components of the envenomation syndrome (i.e., minimal to no further advancement of swelling, improvement of systemic effects, and improving coagulopathy). Assess at up to 1 hour after each dose. After initial control is achieved, a maintenance dose of two vials of CroFab every 6 hours for three doses is recommended in the prescribing information, although maintenance dosing has been shown not to reduce recurrence phenomena.[26] Read the package insert for additional details.[25] For pharmacokinetic reasons that are not entirely understood, recurrence phenomena are associated with antivenins.[27-29] Local recurrence is the return of new progressive swelling after initial control. That is, the leading edge of tenderness or swelling begins to advance again. An additional two vials of CroFab should be given as soon as progressive swelling recurs, and more antivenin may be necessary to regain control, although experience has shown that local effects may continue to progress despite additional antivenin. Patients with rattlesnake bites commonly have thrombocytopenia and hypofibrinogenemia, which can resolve with CroFab and then recur (coagulopathy recurrence). Indications for an additional two vials of CroFab are serious abnormal bleeding, fibrinogen less than 50 μg/mL, platelet count less than 25,000 mm^3, INR greater than 3, multicomponent coagulopathy, worsening trend in patient with prior severe coagulopathy, high-risk behavior for trauma, or comorbid conditions that increase bleeding risk. Coagulopathy can recur as late as 2 weeks or more after treatment.

It is necessary to transfuse if antivenin does not correct coagulopathy or if there is an imminent risk of serious bleeding. Transfusion of the appropriate blood product is generally recommended for life-threatening bleeding, platelets less than 20,000 mm^3 and refractory to antivenin, or hemoglobin less than 7 g/dL. Additionally, fresh frozen plasma, platelets, or both may be required to treat venom-induced coagulopathy if antivenin does not promptly resolve. Consider computed tomography of the brain if the patient has a severe headache or an altered level of consciousness with a severe coagulopathy. Ocular exposure to venom necessitates prompt and copious irrigation and an ophthalmologist's evaluation.

Provide pain relief (e.g., fentanyl 1 μg/kg/dose IV/IM, may repeat at 30- to 60-minute intervals or morphine sulfate, in increments of 0.02 mg/kg up to 0.1 to 0.2 mg/kg IV, titrated to relief of pain while maintaining a respiratory rate and blood pressure that is appropriate for age). Nonsteroidal antiinflammatory drugs (NSAIDs) are contraindicated for approximately 2 weeks after viper and pit viper envenomation because they can contribute to venom-induced coagulopathy and bleeding.

Prophylactic antibiotics are unnecessary. Empiric antibiotic therapy should only be started if an infection develops and once aerobic and anaerobic wound cultures have been obtained. If an abscess occurs, it should be drained in standard fashion. An infected snakebite should prompt a further examination of the wounds for potential retained teeth or fangs.[5]

Envenomations by vipers and pit vipers are remarkable for the amount of swelling they can produce. With prompt and adequate antivenin treatment, fasciotomy or digit dermotomy is rarely indicated, even after severe viperid envenomation.[30-33] Fasciotomy, however, may be indicated if measured compartment pressures remain persistently and severely elevated despite adequate antivenin. Antivenin has been shown to limit the decrease in perfusion pressure associated with compartment syndrome.[34] Compartment syndrome may manifest subjectively, with complaints of increasing pain, and objectively, with tenderness on passive muscle stretch, a rock hard feel to the compartment, or a diminished capillary refill. True compartment syndrome, however, is rare after snakebites, even in patients with severe swelling. It may be difficult to distinguish compartment syndrome from the effects of envenomation. Similar to compartment syndrome, viperid envenomation may cause a bluish discoloration of the skin or pallor (because of subcutaneous bruising), severe swelling, paresthesias, and pain. If effects are only caused by envenomation and the patient does not have compartment syndrome, capillary refill should be normal and compartmental pressures should not be elevated. If compartment pressures are elevated, Gold et al.[31] recommend limb elevation, along with IV mannitol (1 to 2 mg/kg) administration and an additional four to six vials of CroFab over 1 hour. Consultation with a surgeon (e.g., general, orthopedic, or hand) should be initiated concurrently. Compartment pressures should be measured before surgical intervention.

Therapeutic Complications

Antivenins can induce immediate anaphylactic (type I hypersensitivity) or anaphylactoid reactions, which can be rapidly life-threatening. Airway swelling, wheezing, shock, and urticaria characterize these reactions. Anaphylactic and anaphylactoid reactions are treated with antihistamines, H_2 blockers, epinephrine, steroids, and ventilatory/circulatory support as needed.

Antivenins can also cause serum sickness, a delayed (type III hypersensitivity) reaction characterized by fever, urticaria, lymphadenopathy, and polyarthralgias days to weeks after treatment. Although serum sickness can be an uncomfortable experience, it is usually benign and self-limited, and the patient is treated on an outpatient basis with antihistamines

and steroids. Also, adverse reactions are much less common after treatment with Fab-based antivenins than they are with whole immunoglobulin formulations.[14] All commercially available antivenins in the United States use mercury, in the form of thimerosal, as a preservative, which in high doses can cause nerve and kidney toxicities in small children.[25]

Resources

The AAPCC can assist in the management of envenomations. Poison control may be contacted at 800-222-1222.

Disposition

It is prudent to admit all children with snake envenomations to the hospital. Serious effects can be delayed and can recur even after treatment with antivenin. Therefore close observation with monitoring, frequent measurements of swelling/tenderness, and neurological checks for at least 24 hours are recommended. This degree of monitoring may require transfer and admission to a pediatric intensive care unit (PICU). On discharge, the patient should return immediately for further swelling or severe pain. Additionally, the patient should return immediately for any abnormal bleeding or bruising, dark tarry stools, petechiae, or severe headache. Also, patients should be given wound care instructions and told to return for signs of wound infection. Signs of serum sickness should be outlined, and the patient should return or follow up if these signs show up anytime in the few weeks after treatment with antivenin. The patient should be told not to take NSAIDs for 2 weeks after a pit viper or viper bite. Instead, acetaminophen with or without a combined opiate analgesic should be prescribed. The patient should not engage in contact sports or schedule any elective surgery or dental work for 2 weeks after viperid bites. Recommend that the patient drink plenty of liquids and advise that the patient return if decreased urination or cola-colored urine is noticed. Some patients may need referral to a physical therapist. Blisters, blebs, and bullae should be left in place but may need debridement along with necrotic tissue after several days, so surgical referral as appropriate is suggested.[30] Skin grafting is sometimes necessary. If the patient was bitten on the foot or leg, crutches and crutch training should be provided. The patient should be encouraged, however, to bear weight and mobilize the extremity as tolerated. In some cases, a next-day wound check may be appropriate. Otherwise, the patient should return or follow up in a few days.[28] At that time, laboratory tests may need to be repeated, depending on the clinical scenario. Retreat with antivenin as needed.

Prognosis

Most patients recover fully after snakebite. Viperid envenomation results, however, in tissue loss, deformity, or loss of function in a clinically significant percentage of patients.[8,35]

Preventative measures should be explained to parents and children. Teach children to leave snakes alone. They should never touch, handle, or try to kill venomous snakes. Many people are bitten when they are intentionally interacting with the snake. Even after a snake is believed to be dead, fangs still can inject venom. Snakes that were presumed dead have bitten many people and delivered serious, even fatal, envenomations. Additionally, a snake can strike faster and farther than one might think—about half its body length. Children should stay at least two giant steps away from snakes. If a child finds a snake, he or she should tell an adult. Additionally, tell children not to reach or step into places that they cannot see. Wearing boots and jeans may prevent some (but not all) snakebites.

Future Directions

Modifications of the antivenin molecule or formulations may reduce recurrence phenomena, and this is being investigated. Several antivenins are being developed by Instituto Bioclon for use in the United States and other parts of the world.

Widow Spider Bites

Widow spiders belong to the genus Latrodectus and are represented in the United States by the black widows (Figure 107-6), the brown widow, and the red-legged widow.[36] The redback spider is endemic to Australia. Other species, such as the kara kurt and black button spider, are found in other parts of the world, including Europe, South America, and South Africa. The adult female black widow spider is approximately 2 cm in length and shiny black with a red-orange hourglass or spot on the ventral abdomen. The male is much smaller, brown, and much less commonly implicated in human envenoming. Juvenile females are also brown with yellow and white markings but have the general body shape of the adult. Males and juveniles have a pale hourglass shape, similar to adult females. Webs are irregular; low lying; and commonly seen in garages, barns, outhouses, and foliage. Other widow spiders around the world are generally black but may have red spots, such as the kara kurt, or a dorsal red stripe, such as the redback spider. The brown widow is brown with red and yellow markings. Similar species include the false black widow or cupboard spider, *Steatoda* spp., which can produce symptoms that are similar in character but milder in intensity than widow spiders.

Figure 107–6. Black widow spider (*Latrodectus hesperus*). *(Photo Courtesy Sean Bush, MD.)*

Epidemiology

No deaths caused by widow spider envenomation have been reported to the AAPCC since its first annual report in 1983. A few recent deaths have been reported, however, after a black widow spider bite in Greece, Mexico, and the United States.[37,38]

Pathophysiology

The envenomation syndrome caused by the various species of widow spiders around the world is similar.[39,40] The predominant clinical effects after widow spider envenomation are neurological and autonomic.

Clinical Presentation

Typically, the bite site has a "target" appearance. There may be a central reddened, indurated area around fang puncture site(s) surrounded by an area of blanching and an outer halo of redness (Figure 107-7). The findings around the bite wound may be subtle, and the wound does not become necrotic. The predominant symptoms frequently involve painful muscle cramping. If a person is bitten on the lower extremity, pain usually progresses from the foot, up the leg, and into the back and abdomen. If a person is bitten on the upper extremity, pain usually progresses from the hand, up the arm, and into the chest and abdomen. Abdominal pain may be so severe as to mimic an acute abdomen, with tenderness and rigidity.[41] Diaphoresis locally around the bite site is distinctive for widow spider envenomation, although diaphoresis may be diffuse and profuse or it may manifest in unusual patterns remote from the bite site. Local piloerection is sometimes seen. Patients may exhibit "Latrodectus facies" (Figure 107-8), which is characterized by spasm of facial muscles; edematous eyelids; and lacrimation, which may be mistaken for an allergic reaction. Other common symptoms and signs include high blood pressure, rapid heart rate, nausea, vomiting, headache, and anxiety. In a typical progression, symptoms onset within an hour, reach maximum intensity by about 12 hours, and can last for days to weeks. Unusual presentations have been described after widow spider envenomation including pulmonary edema, myocarditis, and priapism.[37,42] It has been suggested that there may be increased danger to pediatric patients with widow spider bites and that this population may require more aggressive treatment and hospitalization, although this assertion has been challenged.[43] Little evidence supports either assertion. A recent and well-documented fatality from widow spider envenomation involved a healthy 19-year-old woman. Other recent reports involved adults as well.

Diagnostic Studies

Rhabdomyolysis has been reported after widow spider envenomation,[42] so a total CK test should be performed if severe envenomation develops. If the patient has respiratory difficulty, a chest radiograph should be obtained. Electrocardiography or echocardiography may detect that rare case of venom-induced myocarditis in a critically ill patient. Otherwise, diagnostic tests are not particularly helpful. If the diagnosis is uncertain, evaluation should be aimed at uncovering other causes such as appendicitis.

Pitfalls

Misdiagnosing an acute abdomen in a patient with a widow spider envenomation could lead to unnecessary surgery.

Emergency and Critical Care

There are two basic treatment options. Widow spider envenomation can be managed with antivenin or a combination of pain medications and sedatives. There are risks and benefits associated with each. Management with an opioid analgesic, such as fentanyl 1 μg/kg/dose IV/IM, may repeat at 30- to 60-minute intervals or morphine in increments of 0.02 mg/kg up to 0.1 to 0.2 mg/kg IV/IM, and a benzodiazepine such as lorazepam 0.01 to 0.03 mg/kg IV is generally considered safe. This treatment option, however, is purely palliative, and symptoms may persist for days or even weeks. The pain and discomfort associated with widow spider envenomation can be severe. In contrast, antivenin is remarkably effective. Unfortunately it can be associated with severe side effects and death.[44] Because death is so rare after widow spider envenomation, some would argue that the treatment is more dangerous than the bite itself. Historically, IV calcium was recommended, although it has now been found to be ineffective.[44]

Figure 107–8. Latrodectus facies. *(Photo Courtesy Sean Bush, MD.)*

Several antivenins have been manufactured including Black Widow Spider Antivenin (equine) in the United States, Australia Redback Spider Antivenom, and South Africa spider antivenin (button spider).[1] Indications for antivenin use and routes of administration vary around the world. According to the package insert of Black Widow Spider Antivenin, one vial should be reconstituted in 2.5 mL of the sterile diluent supplied. It is further diluted into a volume of 50 mL saline and administered IV over 15 minutes. Patients usually experience dramatic relief within an hour of treatment with one vial, although sometimes two and rarely three vials are necessary. It may be effective days, weeks, or possibly even longer after the envenomation.[45] The risk of allergy to antivenin must be weighed against the benefit of relieving prolonged discomfort, avoiding hospitalization, and preventing complications. Although most widow spider envenomations can be managed with opioid analgesics and benzodiazepines, antivenin may be indicated for patients who have severe envenomations with pain refractory to these measures. Antivenin should be given if there is an imminent risk of a severe complication of envenomation. Factors that could increase the risk of antivenin include allergy or previous exposure to horse serum or a medical history of reactive airways.[46] Antibiotics are not indicated for widow spider envenomation. Also, update tetanus prophylaxis as appropriate.

Therapeutic Complications

Serious, even fatal, adverse reactions have been documented after treatment with black widow spider antivenin. Anaphylactic and anaphylactoid reactions to antivenin can occur and may even be more life threatening than the envenomation itself. Skin testing, with the intradermal injection of 0.02 mL of the test material supplied and the observation for an urticarial wheal in 10 minutes, variably predicts immediate hypersensitivity to antivenin and may influence the decision regarding its administration. Premedication with antihistamines (H_1 and H_2 blockers) may reduce the likelihood that an acute allergic reaction will occur. Serum sickness, characterized by fever, urticaria, lymphadenopathy, and polyarthralgias, can occur days to weeks after treatment and is treated with antihistamines and steroids.

Resources

The AAPCC may be helpful with management of widow spider envenomations and can be contacted at (800) 222-1222.

Disposition

Because it so effectively resolves symptoms, antivenin has been shown to decrease the need for hospitalization after widow spider envenomation. Admission to the hospital and possibly the PICU is prudent for severely symptomatic children, those with intractable pain and contraindications to antivenin, those with unusual complications of envenomation, and those who have anaphylaxis to antivenin. Patients who experience relief with opioid analgesics, benzodiazepines, or antivenin may be discharged. On discharge, signs of serum sickness should be outlined, and the patient should return or follow up if these signs show up anytime in the few weeks after treatment with antivenin.

Prognosis

The envenomation syndrome usually resolves completely, with or without treatment, and does not leave the patient with long-term sequelae. Death is rare.

Prevention

Spider bites may be prevented by eliminating the spider's food and habitat; by shaking sheets, shoes, and clothing before donning; by keeping the child's bed away from the wall; and by brushing spiders off rather than crushing them.

Future Directions

Safer antivenins are being developed and investigated.

Hymenoptera Stings (Bees, Wasps, and Ants)

Stings by bees, wasps, and ants are less of a toxicological concern than they are an allergic one. Details on treatment of anaphylaxis are covered elsewhere in this text. The focus of this section will be mass envenomation. Any bee, wasp, or ant can cause toxic, even fatal, complications when they attack in large numbers. Bee behavior, however, can vary, even within the same species. European honeybees tend to be docile and will tolerate approach of their hive to some degree, but can become provoked. Africanized honeybees (*Apis mellifera scutellata*) are much more aggressive and will defend their hive much more proactively. Africanized honeybees were imported to South America in the 1950s to boost honey production, and they have steadily extended their range northward into the southwestern United States. The primary difference between Africanized and European honeybees is their behavior in that Africanized honeybees behave much more aggressively. The effect of an individual stinging event is similar. Subtle wing morphological differences and DNA testing can also distinguish the bees.

If a person is swarmed by bees or wasps, the best thing for the person to do is create barriers between himself or herself and the bees. For example, getting behind a door will evade many bees and getting behind another door will evade many more. Older children may be able to outrun bees, which fly at approximately 4 mph and may pursue up to 150 yards. Younger children, however, may be unable to run fast or far enough. Attempting to submerge oneself or another person in water is not recommended because Africanized honeybees will wait until the person surfaces to continue delivering stings. This can result in multiple stings to the airway. A lethal dose of honeybee stings is estimated at 500 to 1200, but serious envenomation can result from as few as 50 stings (or even fewer after certain species of wasp stings). Sting removal should be done as quickly as possible, regardless of the method of removal. Even a delay of a second or two (to find a knife or credit card) results in a higher dose of venom injected. Contrary to conventional advice, it has been shown that grasping the stinger does not increase the venom dose.

Clinical complications can include hemolysis, coagulopathy, rhabdomyolysis, and liver dysfunction. Delayed toxic reactions have been documented, and so 24-hour hospitalization is recommended for pediatric and older patients, as well as patients

with underlying medical problems or abnormal laboratory test results within a 6-hour observation period and those with 50 or more stings.[47] Laboratory analysis should be aimed at uncovering the aforementioned clinical complications. Treatment involves IV fluids, intensive care, and possibly dialysis and transfusion as needed. For sensitive individuals, venom immunotherapy in children leads to a significantly lower risk of systemic reaction to stings even decades later.[48]

If an Africanized honeybee hive is suspected, local vector control authorities should be contacted. Avoiding perfume and brightly colored clothes may prevent some stings. Similar to African honeybees, fire ants (Solenopsis invicta) are extending their range in the southeastern United States and can cause serious (even fatal) complications after massive envenomation, particularly in infants and small children. These ants typically bite and sting.

Heat Injury

Ofer Yanay and Eli Gilad

PEARLS

- According to the Centers for Disease Control and Prevention, from 1979 to 1999, 6864 deaths were attributable to excessive heat exposure in the United States. During this period, more people died of extreme heat than as a result of hurricanes, lightning, tornadoes, floods, and earthquakes combined.
- With an increased occurrence of heat waves, even in temperate areas, the risk of heat-related illness is rapidly increasing.
- After the onset of heat stroke, the inflammatory response may continue despite adequate control of body temperature. Inflammation, coagulopathy, and progression to multiple organ failure may ensue. New approaches for modulation of the inflammatory response may play a role in treatment of heat-related injury in the future.
- Thorough knowledge and understanding of these disorders may prevent the progression from heat stress to heat stroke.
- Maintaining organ perfusion and rapid cooling are the major treatment goals for patients with heat stroke.
- The central nervous system is particularly vulnerable to heat, with the cerebellum being most susceptible. Pyramidal dysfunction, dysphagia, mental changes, quadriparesis, extrapyramidal syndrome, and neuropathy have all been described.
- Neurologic dysfunction is a cardinal feature of heat stroke. Brain dysfunction is usually severe but may be subtle, manifesting only as inappropriate behavior or impaired judgment; more often, however, patients have delirium or coma.

The interest in heat-related illnesses has grown enormously, largely because of global warming and an increased frequency of heat waves.[1,2] According to the Centers for Disease Control and Prevention, from 1999 to 2003, excessive heat exposure caused 3442 deaths in the United States.[3] During this period, more people died of extreme heat than as a result of hurricanes, lightning, tornadoes, floods, and earthquakes. Among the pediatric population, neonates and infants are at highest risk, mainly because of poorly developed thermoregulatory mechanisms and total dependence on caregivers to provide adequate protection from excessive heat. Children with mental illness and chronic diseases are at high risk. Adolescents are also at increased risk mostly due to poor judgment or intoxication.

Over the past decade, the understanding of cellular and molecular responses to heat stress has improved dramatically. This is a multiorgan injury resulting from a complex interplay between the cytotoxic effect of the heat and the inflammatory and coagulation responses of the host.[4] Despite progress in the understanding of the pathophysiology of heat injury, treatment remains supportive, with emphasis on immediate cooling. Prevention and education are still the best tools available in the hands of healthcare providers to minimize heat-related morbidity and death. This chapter covers the epidemiology, pathophysiology, clinical manifestations, and treatment of nonexertional heat-related illness in the pediatric population.

Definitions

There are several heat-related illnesses that may take the form of heat syncope, heat cramps, heat exhaustion, or heat stroke. The following are key terms used in this chapter:

1. *Heat syncope* (fainting) is a mild form of heat illness, which results from physical exertion in a hot environment. In an effort to increase heat loss, the skin blood vessels dilate to such an extent that blood flow to the brain is reduced. This reduction results in symptoms of lightheadedness, dizziness, headache, increased pulse rate, restlessness, nausea, vomiting, and possibly even a brief loss of consciousness. Inadequate fluid replacement, which leads to dehydration, contributes significantly to the problem.
2. *Heat cramps* are painful sustained muscle contractions, most often in the legs or abdominal wall, primarily due to inadequate circulation, dehydration, hyponatremia, and muscle fatigue. Body temperature is usually normal.[5,6]
3. *Heat exhaustion* is a mild-to-moderate illness due to water or salt depletion (excessive sweat) resulting from exposure to high environmental heat or strenuous physical exercise. The patient may have a headache, intense thirst, muscle weakness, dizziness, fainting, nausea, and visual disturbances. Core temperature may be normal or elevated, but is less than 40° C. Postural hypotension may occur.

4. *Heat stroke* is a life-threatening emergency that occurs when core temperature exceeds 40° C and the patient is in hypovolemic shock and has central nervous system abnormalities such as delirium, convulsions, or coma. Exposure to environmental heat (classic heat stroke) or strenuous physical exercise (exertional heat stroke) can cause heat stroke. Alternatively it can be defined as a form of hyperthermia associated with a systemic inflammatory response leading to a syndrome of multiorgan dysfunction in which encephalopathy predominates.[4]
5. *Exertional heat stroke* develops in a previously healthy patient in the setting of a recreational or occupational exercise. It results from heat production by muscular work, which exceeds the body's ability to dissipate it.
6. *Classic heat stroke* develops in the setting of high ambient temperature. The term nonexertional heat stroke has also been used to describe classic high ambient temperature heat stroke.
7. *Heat index* is a measure of the effect of combined elements (e.g., heat and humidity) on the body.
8. *Wet-bulb temperature* is a standard created to reflect the combined influence of temperature and humidity.
9. *Wet-bulb globe temperature* (WBGT) is an index of heat stress that reflects the combined influence of temperature, humidity, and solar radiation.
10. *A heat wave* is three or more consecutive days of air temperatures greater than or equal to 90° F (≥32.2° C).
11. *Heat-related death,* according to the definition by the National Association of Medical Examiners (NAME), includes exposure to high ambient temperature either causing the death or substantially contributing to it; cases in which the body temperature at the time of collapse was greater than or equal to 105.8° F (≥40.6° C); and a history of exposure to high ambient temperature and the reasonable exclusion of other causes of hyperthermia.[7] Because death rates from other causes (e.g., cardiovascular and respiratory disease) increase during heat waves, deaths classified as caused by hyperthermia represent only a portion of heat-related death.

Epidemiology

Excessive heat is the second largest contributor to death by natural events in the United States.[8] In the period from 1999 to 2003, an annual average of 688 deaths in the United States was attributable to "excessive heat exposure." Persons aged 15 years and younger accounted for 7% of deaths within the group of deaths caused by weather conditions.[9] During heat waves, there is a significant increase in the heat-related death rate. For example, in 1980, a year with a record heat wave, the death rate was more than three times higher than that for any other year during the 19-year period of 1979 to 1997.[10] Data on heat-related death are imprecise because this condition is underdiagnosed, its definition varies,[4] and many cases of patients with near-fatal heat stroke who survive the acute hospitalization have a high 1-year death rate.[11] In Saudi Arabia, where the temperature is extremely hot, the incidence of heat stroke varies seasonally, from 22 to 250 cases per 100,000 population.[12] Heat-related illness is reported from subtropical and cold parts of the world as well. In Taiwan, a subtropical country without any history of heat waves, a cluster of heat shock cases was reported during periods of sustained hotter-than-average temperatures.[13] In an observational study in which cold and hot areas in Europe were compared, it was shown that heat-related death started at higher temperatures in hot regions than in cold ones.[14] High ambient temperature and humidity, lack of acclimatization, unavailability of air conditioning, and vigorous physical activity[15] are major predisposing factors for heat-related illness. Within the pediatric population, children younger than 2 years are at higher risk, with specific factors like diarrheal disease, sweat gland dysfunction, child neglect, and underlying chronic or febrile illness contributing. Risk factors for adolescents include poor judgment that may lead to continuation of physical exertion despite warning symptoms. Alcohol and drug abuse and exposure to environmental toxins may put the adolescent at risk. Neuroleptic phenothiazines and tricyclic antidepressants, taken for medical indications; amphetamine and derivatives; marijuana and cocaine; or organophosphates, constituents of many pesticides, may all lead to heat-related illness.[16] Their effect may be due to impaired heat loss or increased heat production.[17] Lithium and fluoxetine (Prozac) may induce heat intolerance.[18]

Pathophysiology and Pathogenesis of Heat-Related Illnesses

Understanding the systemic and cellular pathophysiology of heat-related illnesses involves an appreciation of thermoregulation, physiologic alterations directly related to hyperthermia, acute phase response, and the production of heat shock proteins (HSPs). For normal enzymatic and cellular function, it is essential that body core temperature be maintained within a narrow range of about 37° C ± 0.5 to 0.9° C.[16,19] The thermoregulation system, controlled by the hypothalamus, receives input from thermosensitive receptors in the skin and body core, compares the data with a reference level (the "set point"), and responds to an elevation of 0.3° C[16,20] with activation of heat loss mechanisms.[4,16,21]

Heat dissipation occurs by means of four mechanisms: (1) conduction to the adjacent air and objects, (2) convection through air or liquid, (3) radiation of heat energy, and (4) evaporation. Once activated by the hypothalamus, the efferent heat response is both autonomic and behavioral. Blood delivery to the body surface is increased by sympathetic discharge causing cutaneous vasodilatation. Blood flow may increase eightfold to sixteenfold, up to 8 L/min.[22] Thermal sweating, in response to parasympathetic discharge, can produce approximately 1 L/h/m^2 of body surface of sweat. Evaporation of 1.7 mL of sweat will consume 1 kCal of heat energy; thus at maximal efficiency sweating can dissipate 588 kCal of energy per hour. Secondary to cutaneous vasodilatation and sweating, blood is shunted toward the periphery, and visceral perfusion is reduced, especially to the liver, kidneys, and intestines.[23] Rising core temperature will also lead to tachycardia, a high cardiac output state, and an increase in minute ventilation. When ambient temperature equals or exceeds body temperature, conduction, convection, and radiation cease to be effective. Losses of salt and water through sweating may lead to dehydration and salt depletion, resulting in impaired thermoregulation.[24] A combination of high ambient humidity and temperature creates a particularly dangerous situation. With ambient humidity of 90% to

95%, evaporation of sweat essentially stops, and if ambient temperature reaches body temperature, the body can no longer eliminate heat.

Acclimatization

Prolonged exposure to a hot environment results in adaptation and tolerance to higher temperature levels. Acclimatization to heat may take several weeks and involves multiple organs. Sweat glands develop increased capacity to secrete sweat, plasma volume is increased, and the renin-angiotensin-aldosterone axis is activated and leads to improved salt conservation. The adaptability of the cardiovascular system is probably the most important single determinant of one's ability to tolerate heat stress.[4,25] Even acclimatized people have definite limitations for heat tolerance. Once driven beyond a critical level, progression to a catastrophic condition may result.

Hyperthermia directly induces cellular injury. The severity of injury is cumulative, so exposure to a very high temperature for a brief period of time may cause similar injury to an exposure to a lower temperature for a longer period of time.[26] Once extreme temperatures of 49° to 50° C have been reached, full destruction and cell necrosis occur. At lower temperatures cell death is mainly due to apoptosis.[27]

Acute Phase Response

Heat stress initiates cellular acute phase responses aimed at protecting against injury and promoting tissue repair. A variety of cytokines are produced in response to heat stress. Cytokines mediate a wide range of cellular, systemic, and both proinflammatory and antiinflammatory acute phase protein productions. For example, interleukin-6 (IL-6) has a pivotal role in modulating synthesis of inflammatory cytokines, both locally and systemically.[4,28] IL-6 also stimulates production of antiinflammatory cytokines, which inhibit production of reactive oxygen species (ROS) and proteolytic enzyme release from activated leukocytes.[28,29] Plasma levels of both proinflammatory (tumor necrosis factor alpha [TNF-α], IL-1, and interferon-γ) and antiinflammatory cytokines (IL-6, IL-10, TNF receptors p55 and p75) are elevated in patients with heat stroke.[30-35] Soluble TNF, IL-2, and IL-6 receptors are also elevated in heat stroke.[36,37] It has been shown that the severity of symptoms during heat stroke correlates well with IL-1 and IL-6 levels.[30] Progression from heat stress to heat stroke depends on the time and extent of exposure to severe environmental conditions, but the acute phase response may continue after the patient is cooled. Onset of inflammation may be local with systemic progression,[4,35] involving endothelial cell activation, release of endothelial vasoactive factors,[38] endothelial cell injury, and microvascular thrombosis.[38-41] The gastrointestinal tract may also play a role in the exaggeration of the inflammatory response. Vascular congestion, hemorrhage, thrombosis, and massive loss of surface epithelium in the jejunum was observed in a baboon model of heat stroke.[42] These changes facilitate bacterial and endotoxin translocation which contributes significantly to inflammation and multiple organ dysfunction syndrome (MODS).[23,43-46] Evidence for this phenomenon exists in animal models, but much less in humans.[23,43,45-49] Alterations in the barrier function of the intestines may allow leakage of endotoxins that fuel the inflammatory response.

Part of the effect on endothelial cells involves activation of both the coagulation and the fibrinolytic systems.[40] Heat stress by itself is a procoagulation condition since it causes platelet clumping in small vessels. In addition, heat stress may mediate endotoxemia, elevated levels of proinflammatory cytokines, and macrophage activation (via factor VIIa), all of which are well known inducers of coagulation. Injured endothelium, (e.g., heat stroke) plays an important role in producing and releasing both procoagulant and anticoagulant substances (e.g., von Willebrand factor antigen [vWF-Ag], tissue plasminogen activator, and plasminogen activator inhibitor).[38,39] Circulating vWF-Ag, thrombomodulin, endothelin-1, nitric oxide (NO) metabolites, soluble E-selectin, and ICAM-1 (intercellular adhesion molecule 1) are elevated in heat-related illness, creating a clinical picture of disseminated intravascular coagulation (DIC).[38,50-52] The cooling of patients with heat stroke reverses only part of these coagulation abnormalities.[40] Another aspect of the cellular response to stress involves the heat shock response.

Nearly all cells will respond to heat stress with increased production of HSPs. Expression of HSP is controlled mainly at the gene transcription level. Increased intracellular HSP levels facilitate tolerance to heat stress with better cell survival.[53,54] In animal models, it has been shown that preconditioning with heat or chemical stress conferred significant protection against heat stroke-induced hyperthermia, hypotension, and brain injury.[55-57] These effects were mediated mainly by Hsp70 and Hsp72.[56] Blocking the production of HSP results in increased cellular sensitivity to even mild degrees of heat stress.[58] Conditions associated with low level of expression of HSP such as lack of acclimatization or certain genetic polymorphisms may make certain patients more vulnerable to heat stress or faster progression to heat stroke. There appears to be a preferential expression of different families of HSPs in different cell populations. There are also distinct post-injury time frames of induction for each family of HSP, emphasizing differences in cellular functional requirements for each family of HSP.[59] It was suggested that Hsp72 may be used as a semiquantitative diagnostic probe of heat stress.[60] In one human study, researchers found that levels of autoantibodies against Hsp71 in heat-induced diseases correlated well with the severity of illness.[61] Thus the individual response to heat stress depends on the direct thermal injury (including thermal cytotoxicity, cardiovascular failure, and hypoxia in the face of increased metabolic requirement) and the acute-phase response of the host. Genetic factors likely play a significant role in determining response to heat stress. This complex interplay between leukocytes, endothelial and epithelial cells, and a variety of systemic changes may lead to the most extreme form of heat-related illness, heat stroke. A similar sequence of events has been shown to occur in sepsis.[62] Recent studies, using a baboon model for heat stroke, provide more data on pathways of heat stroke-induced tissue injury and cell death. This model can be used to evaluate clinical changes and may be suitable to test immunomodulation therapies to improve outcome.[42,63]

Systemic Clinical Features

Involvement of multiple organs may be seen, to a certain degree, in heat syncope, heat cramps, and exhaustion. Heat stroke is a true systemic disorder. Per definition, core temperature must exceed 40° C, and the patient exhibits hypovolemic

shock and central nervous system abnormalities such as delirium, convulsions, or coma. The heat stroke-mediated systemic dysfunction was shown to be similar to exertional heat stroke in reported cases with adult patients.[11]

Central Nervous System

Neurologic dysfunction is a cardinal feature of heat stroke. Brain dysfunction is usually severe but may be subtle, manifesting only as inappropriate behavior or impaired judgment; more often, however, patients have delirium or coma.[21] Seizures may occur, especially during cooling. The central nervous system is particularly vulnerable to heat, the cerebellum being most susceptible.[64] Pyramidal dysfunction, dysphagia, mental changes, quadriparesis, extrapyramidal syndrome, and neuropathy have all been described.[21,65] No data regarding long-term neurologic outcome in children have been reported. In one adult series, 33% of the patients had moderate to severe impairment of neurologic function at discharge from the hospital.[11]

Pulmonary

The pulmonary system is not involved in early stages of heat-related illnesses. However, a high incidence (23% to 25%) of acute respiratory distress syndrome (ARDS) has been reported in adult patients with heat stroke.[66,67] Patients with ARDS have a poor prognosis, with up to a 75% mortality rate.[66] Lung involvement is part of the systemic response, as indicated by the fact that all patients who had ARDS also had coagulopathy and DIC.[66]

Cardiovascular

The cardiovascular system is usually compromised in heat-related illness. Hypotension and shock may result from dehydration, translocation of blood from central circulation to the periphery, or increased production of NO.[21] Usually, circulation is hyperdynamic in these patients, with tachycardia and high cardiac output.[68] Vasomotor tone may remain abnormally low, even after normal temperature and intravascular volume have been restored.[25] Electrocardiographic changes are common in patients with heat stroke, including rhythm disturbances, conduction defects, prolonged QT interval, and ST segment changes. These may subside with cooling or may require correction of potassium, magnesium, or calcium abnormalities.[69]

Renal

Elevated blood urea nitrogen and creatinine levels are seen even in mild heat-related disease such as heat cramps.[70] Moderate to severe renal insufficiency is common in classic heat stroke (up to 53% in one series[11]). Direct thermal injury, hypoperfusion (due to dehydration, cardiac failure, or both), rhabdomyolysis with myoglobinuria, release of vasoactive mediators, and DIC may all contribute to renal injury.[4,21,71,72]

Gastroenterologic

Involvement of the gastrointestinal system plays a significant role in the development of MODS in patients with heat stroke.[4,73] The importance of the gastrointestinal system in other forms of heat-related illnesses is not well studied. Jejunal injury may lead to mild to moderate diarrhea. The liver may be severely injured in heat stroke. This is a metabolically active organ and a major site of heat production in the body. During periods of hyperthermia, liver temperature is among the highest of any organ in the body, putting it at high risk for injury.[26] Abnormal liver function tests may be seen during heat-related illnesses. Elevation of aspartate aminotransferase (AST), alanine aminotransferase (ALT), γ-glutamyl transpeptidase (γ-GT), lactate dehydrogenase (LDH), and total bilirubin have been described.[11,21,70] Patients with heat stroke demonstrate a typical rise in AST and ALT levels within 30 minutes from onset, that peaks at 48 to 72 hours following injury, with return to normal values after 10 to 14 days.[26,74] Severe liver damage is more common in exertional heat stroke. Fulminant liver failure is rare and usually carries a grave prognosis even with liver transplantation.[75]

Metabolic

Early in the course of heat injury, the most common acid-base abnormality is a mixed non-anion gap metabolic acidosis and respiratory alkalosis. Hypokalemia resulting from the respiratory alkalosis, sweat losses, and renal wasting may change to hyperkalemia because of leak of cellular potassium. Several hours into the injury the clinical picture changes into a predominantly metabolic acidosis that is caused by sustained tissue injury.[11,21,76]

Hematologic

Thrombocytopenia, an elevated clotting time, and DIC are well documented in patients with heat stroke.[4,11,21,41] The pathophysiology of DIC in patients with heat stroke has been previously discussed. The rapid decline of hematocrit in the first 24 hours following heat stroke is a common feature. This is partially explained by rehydration, but is most probably multifactorial. The red blood cell (RBC) half-life is shortened after heat stroke. In addition, RBCs are more fragile following exposure to high temperatures, leading to early removal from the circulation.[26] Hypersegmented neutrophils may be observed in peripheral blood for the first few hours following the onset of heat stroke. The cause for theis phenomenon is unclear. These cells are thought to be undergoing changes associated with apoptosis.[26]

Infectious

In the early phase of heat stroke, blood culture findings are negative,[77] but within 24 hours from admission, one study demonstrated that up to 27% of patients had positive blood cultures and 25% had positive urine cultures.[11] The existing data come from adult series. The incidence of positive findings in blood or urine cultures in the pediatric population with heat stroke is unknown.

Treatment

The treatment of heat stroke starts at the scene with removing the patient from the circumstances that led to heat stroke in order to prevent any further increase in core temperature.

Rapid cooling and maintenance of organ system perfusion and function are the two major goals. Adherence to the basic resuscitative guidelines is required, with protection of the airway, management of breathing and monitoring for hypovolemia/shock, and appropriate fluid resuscitation. The most severely affected children have altered mental status, rising body temperature, and hypovolemic shock. After the airway is secured, the child with heat stroke should be moved to a cool environment; clothes should be removed; intravenous access should be obtained with one or two large-bore catheters; and a normal saline or lactated Ringer solution bolus of 20 mL/kg should be administered. Fluid resuscitation, besides ensuring organ perfusion, increases heat dissipation and lowers core temperature[24] by improving skin blood flow. Cooling should be started as early as possible with whatever method is available, and the patient should be transported to the nearest hospital appropriate for children. Decreasing body temperature below 38.9° C within 30 minutes of presentation has been shown to improve survival.[21]

A variety of cooling methods have been used to promote heat loss, and controversy continues regarding the best cooling technique. Cold/ice-water immersion was twice as rapid in reducing the core temperature as the evaporative spray method in patients with exertional heat stroke.[78] The mechanism for this rapid cooling relates to the high thermal gradient between skin and ice-water, leading to a faster heat loss by conductance as compared with evaporation.[79] Ice water is readily available, does not require special equipment, and is suitable for both classic and exertional heat stroke. While some authors regard ice water immersion to be the most efficient cooling method,[80] others claim there is no evidence to support the superiority of any cooling technique, especially in classic heat stroke.[81,82] Critics of immersion point out that it may complicate resuscitation efforts of the comatose child who requires endotracheal intubation, mechanical ventilation, and close observation. Also, it is uncomfortable to the conscious child and may cause shivering and cutaneous vasoconstriction, which is counterproductive. Sponging the patient with ice water while massaging the body and using a fan may overcome some of these disadvantages, yet other studies have shown that keeping the skin relatively warm while allowing evaporation and convection to dissipate body heat is the most rapid way to decrease core body temperature.[83,84] This can be done with special cooling units,[83,85] but the concept of keeping the patient "wet and windy" can be easily achieved with the application of tepid water to the skin while a fan is used to keep high air flow and to maintain cool ambient temperature.[86] Thus hospitals located in high-risk areas may consider buying special equipment, but most emergency departments and pediatric intensive care units (PICUs) may use this technique with readily available equipment.

Cooling blankets are widely used in the PICU setting. The effectiveness of this approach was evaluated only in patients with fever[87] and no data are available concerning heatstroke patients. Invasive cooling techniques including iced peritoneal lavage as well as bladder and gastric lavage have been suggested and investigated to some extent. Peritoneal lavage is difficult to perform and requires placement of a peritoneal catheter and trained personnel. Evidence for gastric lavage comes mostly from canine models and was found to have no advantage over evaporative cooling.[82] Recent reports of an intravascular cooling device to control body temperature found the system to be highly effective. However, as this was not evaluated on patients with heatstroke, it cannot be recommended at this point.[88,89] Antipyretics cannot be recommended since their effect has not been systematically studied in this group of patients.[82] In addition, these drugs lower body temperature by normalizing the elevated hypothalamic set point. In heat stroke, the elevated body temperature reflects failure of cooling mechanism rather than abnormal set point. Acetaminophen and salicylates should be avoided due to their potential to aggravate coagulopathy and hepatic injury.[81,82] Dantrolene, which has been used successfully in the treatment of malignant hyperthermia and neuroleptic malignant syndrome, has been administered in the treatment of heat stress. Some studies have claimed that it may be effective in the treatment of heat stroke,[90,91] whereas in others, including a double-blind randomized study,[92] it was shown to be ineffective.

Once a core body temperature of 38.9° C has been achieved, active cooling may be be stopped. This end point appears to be safe in terms of mortality. Unfortunately a safe end point for long-term morbidity (particularly neurologic outcome) has not yet been established.[81] All pediatric patients with heat stroke should be observed in the PICU, even if respiratory support is not required. Basic laboratory workup should include electrolytes (including sodium, potassium, magnesium, phosphate, and calcium), renal and liver function tests, complete blood count, and coagulation studies. Urine output should be followed closely, and a urine sample should be sent for myoglobin analysis. As previously mentioned, patients with heat stroke may continue to deteriorate even after body temperature is normalized because of the inflammatory response. There are no specific guidelines for treating patients with MODS that results from heat stroke.

Prevention is still the best treatment for heat-related illness. Whenever possible, people should acclimatize themselves to hot weather. Physical activity should be undertaken during cooler hours, and water intake should be increased. Children should never be left unattended in a closed car, especially during hot weather. Physicians' awareness and knowledge may promote diagnosis of early forms of heat-related illness, thus preventing progression to heat stroke. On a national level, a good weather forecasting system and air-conditioned shelters for vulnerable populations may decrease heat-related morbidity and death during heat waves.[93,94]

Accidental Hypothermia

Björn Gunnarsson and Christopher M.B. Heard

PEARLS

- Accidental hypothermia is a potentially lethal complication of exposure to cold. It can occur as a result of exposure to cold air, water immersion, or submersion (near-drowning).
- Risk factors include accidents, neglect, toxins, mental disorders, and violence.
- Information about the duration and severity of cold exposure, scene details, and any other associated injuries may help in the selection of the appropriate facility and rewarming methods.
- Many organ systems are affected by hypothermia including a marked depression of cerebral blood flow and oxygen use.
- Rescuers should initiate resuscitation on all patients with hypothermia unless the patient has a frozen chest or any other obvious nonsurvivable injury. The key of rescue in all individuals with hypothermia is prevention of further heat loss, careful transport, and rewarming. Avoiding excessive activity and abrupt movements of patients with hypothermia is important because this may precipitate cardiac dysrhythmias.
- Various techniques have been used for in-hospital resuscitation from deep hypothermia. Active external rewarming has been shown to be effective. However, extracorporeal rewarming of blood is the preferred method to resuscitate patients with severe hypothermia and cardiac arrest or cardiovascular instability.
- Prediction of patient outcome is difficult. The decision to terminate resuscitative efforts must be based on the unique circumstances of each case.

Humans have a high capacity to dissipate heat and a relative poor capacity to increase heat production. As such, humans rely heavily on environmental regulation in the form of clothing and warm shelter to maintain normal body temperature. Thermoregulation is controlled by the hypothalamus. Heat production increases with movement. Shivering increases the rate of heat production three to five times above resting levels, but at the cost of greatly increased oxygen consumption. There are four primary means of heat loss: (1) conduction, (2) convection, (3) radiation, and (4) evaporation. Changes in the environment can radically increase heat loss (e.g., cold-water immersion can increase conductive heat loss by a factor of 32).[1] Susceptibility to heat loss is greater in children than in adults because of a large surface area relative to body mass and less subcutaneous tissue, but severe accidental hypothermia is uncommonly encountered in most pediatric intensive care units. Neonates have a capacity for nonshivering thermogenesis, primarily by metabolism of brown fat; however, this is at the cost of greatly increased oxygen consumption. Neonates are therefore extremely sensitive to relatively minor deviations from neutral thermal environment.

There is no uniformity in the definition of hypothermia. The 2005 European Resuscitation Council Guidelines for Resuscitation classify a core temperature of 35° C to 32° C as mild hypothermia, 32° C to 30° C as moderate hypothermia, and less than 30° C as severe hypothermia.[2] Hypothermia is further classified as accidental or intentional (as in cardiopulmonary bypass) and primary or secondary. Primary accidental hypothermia is due to environmental exposure, with no underlying medical condition causing disruption of temperature regulation.

Pathophysiology

The body can compensate to a great degree for mild hypothermia. The hypothalamus sends signals that produce cutaneous vasoconstriction, increased muscle tone, and metabolic rate. When muscle tone reaches a certain level, shivering thermogenesis begins. The clinical manifestations depend on the severity, acuity, and duration of temperature reduction; the patient's age; premorbid conditions; and superimposed disease states. Each organ system may be affected by hypothermia.[3,4]

Central Nervous System

Central nervous system dysfunction is progressive. Cerebral oxygen consumption decreases in proportion to the reduction in metabolism. Cerebral blood flow decreases 6% to 7% for each 1° C decrease in temperature.[1] Mild hypothermia may be associated with confusion, dysarthria, and impaired judgment.[3-5] Deep tendon reflexes are depressed at core temperature lower than 32° C because of slowed peripheral nerve conduction. As body temperature drops, many patients no longer complain of cold. Shivering thermogenesis ceases at approximately 31° C. Pupillary responses decline and dilated unreactive pupils may be noted at temperatures lower than 30° C. Patients may experience hallucinations and sometimes paradoxically remove their clothes. The electroencephalogram (EEG) shows abnormal activity at temperatures less than 32° C, and at 20° C the EEG may appear consistent with brain death.[1]

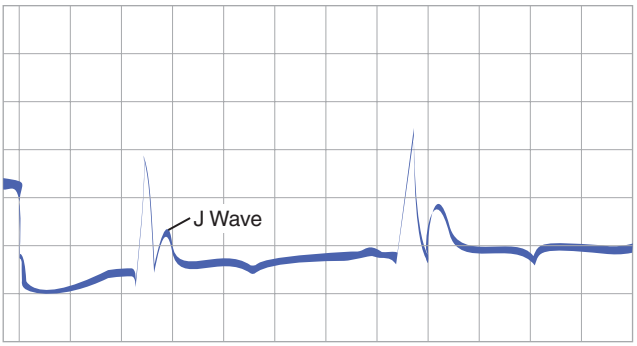

Figure 109–1. Characteristic J or Osborne wave of hypothermia closely follows the QRS. It may be mistaken for T wave with narrow QT interval if the true T wave is not appreciated. Slightly rounded peak distinguishes it from the R′ of bundle branch block. *(Data from Welton D, Mattox K, Miller R, et al: Treatment of profound hypothermia,* JAMA *240:2291, 1978.)*

Cardiovascular System

The initial cardiovascular responses are vasoconstriction, tachycardia, and increased cardiac output.[5] Further hypothermia results in decreased pacemaker and conduction velocity, causing bradycardia, heart block, and prolongation of PR, QRS, and QT intervals. Bradycardia becomes severe by 32° C. The myocardium becomes irritable and arrhythmias are common when core temperature reaches 30° C. The electrocardiogram may show characteristic J or Osborne wave following the QRS complex (Figure 109-1).[1,6-10] The presence of this wave is not pathognomonic for hypothermia and has no prognostic implications.[11] Myocardial contractility, systemic blood pressure, and cardiac output are often decreased dramatically in patients who have severe hypothermia. These changes may be persistent during rewarming.[12] Patients with hypothermia generally are volume contracted because of cold-induced diuresis.[1,5,13]

Respiratory System

Hypothermia affects tissue oxygenation through several complex physiologic mechanisms. Initially, the respiratory rate may be increased. As hypothermia worsens, the respiratory center becomes depressed and hypoventilation causes carbon dioxide retention, although the increase in carbon dioxide is blunted because of decreased production with increasing hypothermia. Respiratory arrest is a late occurrence. Suppression of cough and mucociliary reflexes leads to atelectasis and pneumonia.[5] Oxygen delivery to the tissues is further compromised through the shifting of the oxyhemoglobin dissociation curve to the left.[1] Blood gas analyzers warm blood to 37° C before analysis.[14] In patients with hypothermia, arterial blood gases show higher oxygen and carbon dioxide levels and a lower pH than a patient's actual values. The best approach to interpretation is to compare the uncorrected blood gas values with the normal values at 37° C (alpha-stat strategy).[15-17]

Renal System

Renal injury may occur either because of hypothermia or during the rewarming process.[18] The mechanisms involved in cold diuresis may include peripheral vasoconstriction and blunted response to antidiuretic hormone. Renal vasoconstriction and ischemia to the kidney may lead to oliguria and acute tubular necrosis in those with severe hypothermia.[5] Progressive hypokalemia develops during hypothermia, probably because of the shifting of potassium from extracellular to intracellular compartment, and significant hyperkalemia may develop during rewarming.[19-21] Metabolic and respiratory acidoses are not uncommon findings in patients who have moderate and severe hypothermia.[14] Hemodialysis has been required for renal failure and may also be of use as an active rewarming strategy.[22]

Coagulation

Hypothermia inhibits the intrinsic and extrinsic pathways in the clotting process. The degree of coagulopathy, however, is often underestimated because dynamic coagulation tests are generally performed at 37° C in the laboratory. Thrombocytopenia, from bone marrow suppression and splenic sequestration, and platelet dysfunction are common.[1,15]

Treatment

The key to rescue in all individuals with hypothermia is prevention of further heat loss, careful transport, and rewarming.[1] Wet clothes should be removed, and the individuals should be insulated and shielded from wind and cold. Paying special attention to the head and neck is important because radiant heat loss from those areas can be profound. Detecting signs of life in patients with deep hypothermia may be difficult, and the rescuer should therefore assess breathing and then pulse for 30 to 60 seconds to confirm respiratory arrest, cardiac arrest, or bradycardia. Chest compressions should be started immediately if the patient is pulseless with no detectable signs of circulation. Endotracheal intubation should be performed if the patient with hypothermia is unconscious or if ventilation is inadequate. Anecdotal reports of sudden cardiac death associated with tracheal intubation appear to be exaggerated, particularly if the patient is adequately preoxygenated and the procedure is performed in a gentle manner. If cervical spine injury is suspected, the neutral position must be maintained with manual cervical stabilization. Care should be taken not to overventilate the patient's lungs because this can increase ventricular irritability.[23] Rewarming by the administration of warmed humidified oxygen (42° C to 46° C) and warmed saline (43° C) should begin as soon as possible. Ringer's lactate solution is not recommended because a hypothermic liver cannot metabolize lactate. Defibrillation can be tried up to three times for ventricular tachycardia or fibrillation. If arrhythmia is resistant to three shocks in a patient with deep hypothermia, then further defibrillation attempts should be deferred until core temperature is increased. The hypothermic heart may also have a reduced response to cardioactive drugs and pacemaker stimulation.[1,2] Therefore the efficacy of drugs in severe hypothermia is limited and there is concern that medications can accumulate to toxic levels if they are administered repeatedly.[24-26]

No randomized controlled clinical trials in which rewarming methods are compared exist.[16] The rewarming of patients who are conscious and who have only mild or moderate hypothermia can be achieved with passive techniques (e.g., blankets, warm shelter). Management of severe hypothermia in the field is more controversial. Active external rewarming

with heat devices (e.g., forced air, radiant heat, warm bath, warm packs) requires careful monitoring and should therefore be used with caution. The concerns are core temperature afterdrop and rewarming shock.[1,4,15,16,27-29] The term *core temperature afterdrop* refers to a continued decrease in core temperature and associated clinical deterioration of a patient after rewarming has begun. Some researchers suggest that peripheral vasodilatation due to external rewarming leads to circulation of cold blood into the core of the body.[28] Simple equilibration of temperature between the periphery and the core is probably a far more important mechanism. Heat flows from the core to the periphery during cooling and the opposite is true during external rewarming. However, there is a delay in the reversal of temperature flow in deeper tissues and the core temperature may decrease for some time after rewarming has begun. It follows that the magnitude of core temperature afterdrop is greater if cooling is rapid because the temperature gradient between the surface and core is greater.[30] The hazard of afterdrop may be overrated. It is not uncommon, though, for patients with hypothermia to have "rewarming shock" or "postrescue collapse."[1,29,31,33] However, the underlying pathophysiologic condition behind this remains obscure and several mechanisms may contribute including myocardial dysfunction, decreased vascular tone, derangements of the microcirculation, and hypoxia or sudden changes in pH.[12,29,31] Depleted intravascular volume may also contribute to the development of shock, and most patients will benefit from volume expansion.[1,14] The patient should be kept horizontal to minimize hypotension and sympathetic discharge. Avoiding excessive activity and abrupt movements of patients with hypothermia is important because this may precipitate cardiac dysrhythmias.

Techniques that can be used for in-hospital rewarming of hemodynamically stable patients include continued active external rewarming, and active core rewarming with lavage of body cavities or warming of blood with extracorporal circulation. Active external rewarming can be effective, and there are several reports of successful use of active external rewarming or minimally invasive techniques in children with severe hypothermia and cardiac arrest.[33-41] Cardiopulmonary bypass should be considered in patients, even those without cardiac arrest, who suffer from severe hypothermia. It remains the preferred method to resuscitate patients with severe hypothermia and cardiac arrest or cardiovascular instability.[1,2,42-52] In most reports, partial bypass from femoral artery to femoral vein is described in adult patients. Full bypass with a median sternotomy may be preferable in small children.[44,53] Other methods of core rewarming that can be considered include peritoneal lavage with heated potassium-free dialysate, thoracic lavage, and the use of esophageal rewarming tubes.[54-57]

Outcome

Knowledge about outcome is mostly based on adult studies and isolated pediatric case reports. If rewarmed and resuscitated, patients with accidental hypothermia may recover neurologically intact after prolonged arrest. This was recently confirmed in a 16-year longitudinal review of profound hypothermia. In this series of 46 Swiss patients with deep hypothermia (temperature <28° C) and circulatory arrest, 32 underwent rewarming with cardiopulmonary bypass and 15 of those were long-term survivors, all with excellent functional outcome.[43] Recovery has occurred in an adult patient who sustained prolonged circulatory arrest with initial core temperature of 13.7° C, and there are many reports of successful resuscitation of children with severe hypothermia.[31,37-40,53,58]

If drowning precedes the hypothermia, successful resuscitation is rare. This has been confirmed in a recent series of 26 Norwegian patients, with hypothermia and circulatory failure or cardiac arrest, who were resuscitated with the use of extracorporeal circulation. Of those who probably had asphyxia before and during cooling, only 1 of 15 survived, compared with 7 of 11 patients who did not have asphyxia.[44] Most cases in the asphyxia group were pediatric drowning accidents. Authors from the same institution recently reported a remarkable story of a 48-year-old male who capsized his boat in a Norwegian fjord during the month of December. He was wearing a personal heart rate monitor/pulse watch which recorded his heart rate during the incident. The sea temperature was 3.5° C. He managed to keep his head out of water for some time, but then submersed and went into a cardiac arrest 38 minutes after the boat capsized. He had no signs of life when rescued from the sea 26 minutes later. Cardiopulmonary resuscitation was initiated 31 minutes after the onset of cardiac arrest and was continued for 90 minutes until cardiopulmonary bypass was established, at which time his heart was in asystole and the core body temperature 20.6° C. He made a full recovery.[59] There are also many reports of dramatic recovery after prolonged cold-water submersion of pediatric patients.[31,38,40,41,50,60,61] Cases of good outcome in near-drowning victims are generally associated with water temperatures at, or near, freezing and hypothermia on arrival to hospital. It is therefore reasonable to assume that good outcome in these cases must be associated with cerebral hypothermia.[16,59,60,62] Rapid cooling of the body because large surface area relative to body mass and little subcutaneous tissue may offer protection to pediatric patients. Furthermore, it is thought that rapid cooling of the brain may largely depend on repeated aspiration of cold water into the lungs.[29,50,62,63] Reviews from Finland and Canada, however, did not show a correlation between water temperature and age on outcome, so other factors must play a critical role.[60,64,65]

Severe coagulopathy, acidosis (venous pH ≤6.5), and hyperkalemia (>10 mmol/L) are among factors that have been associated with poor outcome.[46,66] These laboratory values may help identify those who had irreversible asphyxia before hypothermia commenced, but no chemical factor can predict with accuracy who will survive.[16,44,67] A good example of this is a 31-month-old girl who survived extreme hypothermia. Her rectal temperature on arrival to the hospital was 14.2° C, and her serum potassium level was 11.8 mmol/L.[53] Clinical judgment will have to be exercised, and it must be kept in mind that children with accidental hypothermia have tremendous potential for good outcome despite a catastrophic presentation. A reasonable approach, in most cases, is to resuscitate and warm the child aggressively until the core temperature reaches near normal. At that point, if no signs of life are present and the patient is not responding to aggressive life support measures, termination of resuscitation may be indicated.

VII Chapter 110

Drowning

Mary W. Lieh-Lai, Ajit A. Sarnaik, and Ashok P. Sarnaik

PEARLS

- As defined by the World Congress, drowning is a process of respiratory impairment from submersion or immersion in liquid. The definition implies that a drowning victim develops an air-liquid interface that prevents breathing air. All other terms such as *near-drowning* and *secondary drowning* should not to be used in standardized literature.
- Central nervous system injury is by far the most important cause of death and long-term functional impairment among drowning survivors.
- The outcome of drowning victims depends largely on the success of resuscitative measures at the scene of injury. Patients who are successfully resuscitated and who are conscious on arrival to a hospital have an excellent chance of intact survival. Monitoring of intracranial pressure in the management of drowning victims has not been shown to be useful.
- Pulmonary edema encountered in children after drowning is due to acute respiratory distress syndrome and not from fluid overload. It should be treated with positive end-expiratory pressure and not diuretics. Such children are often hypovolemic and may require isotonic fluid resuscitation.
- In an unexplained drowning episode or with a similar history in familial members, an underlying predisposing disorder such as long QT syndrome should be suspected.

Of all the clinical entities encountered in a pediatric intensive care unit, drowning accidents are among the most tragic. Within minutes, previously healthy children with hopeful futures die or are left severely incapacitated with no chance of meaningful cognition. The parents, once full of dreams for their youngsters, are suddenly beset with tremendous grief and guilt because in many instances the accident could have been prevented by simple measures.

Definitions

The definition of drowning events remains a source of confusion. In addition to *drowning*, various terms such as *near-drowning, suffocation by submersion in water, secondary drowning, immersion syndrome,* and *wet and dry drowning* have been used. The plethora of terms and the lack of a standard definition have made it difficult to analyze and compare studies and outcomes. In June 2002, the World Congress on Drowning was convened to develop a more standardized definition of drowning using the Utstein-style for uniform reporting of data, and to make recommendations regarding preventive measures and care. The Congress was initiated by the *Maatschappij tot Redding van Drenkelingen* (Dutch Organization to Rescue People from Drowning), an organization established in Amsterdam in 1767 to promote drowning awareness in the Netherlands.[1] The final recommendation of the Congress was to define *drowning* as the process of experiencing respiratory impairment from submersion/immersion in liquid. The definition implies that a drowning victim develops an air-liquid interface that prevents the breathing of air. All other terms such as *near-drowning* and *secondary drowning* were abandoned. Outcome is described according to death or survival with survivors further categorized according to neurologic function. Papa et al. performed a systematic review of definitions for drowning accidents in 2005 and identified at least 43 publications where various definitions of drowning were used (Table 110-1).[2] They concluded that there is a need to use a single, uniform definition of drowning and supported the one recommended by the Utstein Focus World Congress on Drowning.

Epidemiology

In 2005, the latest year for which statistics are available, drowning accounted for 30% of all deaths in children from 1 to 4 years of age.[3] Drowning is the second-leading cause of unintentional injury-related deaths in children age 1 to 14 years. Those younger than 5 years and males aged 15 to 19 years are the two groups most at risk. Males are four times more likely to die from unintentional drowning than females. Between 2000 and 2005, the mortality rate from drowning of African Americans of all ages was 1.3 times that of whites, and among children age 5 to 14 years, the rate was 3.2 times higher. Cultural and racial differences in access to swimming pools and emphasis on swimming skills may play a role in the difference in drowning rates. Children younger than 1 year most often drown in bathtubs, buckets, or toilets. Child abuse should be investigated in these situations.[4] As many as 35% of children between the ages of 10 to 18 months are able to climb into a bathtub.[5] Drowning in a bathtub should not therefore be considered as a priori evidence of child abuse. Others at risk for bathtub drowning are those with seizure disorders.[6] The residential swimming pool is the most common site for drowning in children younger than

Table 110–1 Categories and Terms Used to Describe Drowning

Terms	Explanation
SPECIFIC CATEGORIES	
Primary vs. secondary	"Secondary drowning" is delayed death from drowning from complications *or* death occurring in minutes to days after initial recovery.
Wet vs. dry/with aspiration vs. without aspiration	"Dry drowning" or "without aspiration" is laryngeal spasm with no or little aspiration of water *or* from respiratory obstruction and asphyxia from a liquid medium. "Wet drowning" or "with aspiration" indicates that aspiration of fluids has occurred.
Warm vs. cold water	"Cold water drowning" is drowning in an outside body of water during the autumn, winter, and early spring months with a patient core temperature of ≤32° C on arrival to the emergency department. Some use water temperature <20° C.
Salt vs. fresh water	Kind of water in which incident occurred.
Active vs. passive (or silent)	"Active" refers to a witnessed drowning event in which victim makes some motion. In "passive" drowning, the victim is found motionless.
Intentional vs. nonintentional	Describes cause.
Fatal vs. nonfatal	Describes outcome.
Submersion vs. immersion	"Submersion" suggests the head was submerged in water; "immersion" suggests the head was out of water.
With and without hospitalization	Whether victim was admitted to hospital.
SPECIFIC CIRCUMSTANCES	
Iceberg phenomenon	People who have been submerged but have subsequently not died from drowning.
Immersion frigida	Death from cooling in water.
Immersion syndrome/ immediate disappearance syndrome	Occurs when syncope is provoked by sudden contact with water at least less than 5° C, presumably from bradycardia, tachycardia, or arrhythmia.
Save	Rescue of victim from water by someone who perceived individual to be a potential victim of submersion injury.

From Papa L, Hoelle R, Idris A: Systematic review of definitions for drowning incidents, *Resuscitation* 65:255–264, 2005.

5 years, whereas older children and adults more frequently drown in canals, lakes, ponds, and oceans.[7] Drowning is highest during the summer months. Most children who drown were last seen inside the home, in the care of one or both parents, but left unsupervised for less than 5 minutes.[8]

Other important risk factors in drowning deaths include failure to wear a life jacket and alcohol use. In 2006, the U.S. Coast Guard reviewed reports of boating incidents. Of the 500 people who drowned, 9 of 10 were not wearing life jackets.[9] Alcohol use is involved in up to half of adolescent and adult deaths associated with water recreation.[10] Ethanol and other neurotropic agents can diminish manual dexterity, impair judgment, and increase risk-taking behavior. Recent alcohol consumption by supervising adults may also contribute to submersion accidents involving children.[11] Expert swimmers have also been known to drown during underwater swimming. The practice of hyperventilation to prolong the duration of underwater swimming is particularly hazardous in this regard because significant hypoxemia may result in loss of consciousness before hypercarbia stimulates respiration and alerts the swimmer of the urgent need to breathe.[12]

Review of the drowning literature suggests that the key to prevention includes careful supervision of children, and education of the public regarding drowning prevention and the hazards of drowning. Children playing near or in water should always be supervised by a responsible adult who is not distracted by any other activity. Alcohol should be avoided before or during swimming, boating, and while supervising children. A four-sided, self-closing, self-latching fence at least 4 feet high that completely separates the house and play area of the yard should be installed around household pools. Those who are in or around natural bodies of water should wear U.S. Coast Guard approved life jackets irrespective of distance to be travelled, size of boat, or swimming ability.[9]

Pathophysiologic Considerations

The sequence of events after submersion has been described by Karpovich[13] in an animal model. After the initial panic and violent struggle, automatic swimming movements are followed by breath-holding and swallowing of large amounts of water. Subsequently, water is aspirated into the lungs as a result of attempts to breathe. Convulsions and spasmodic efforts resulting from asphyxia precede death. The single most important and prognostically significant consequence of drowning is decreased oxygen delivery to the tissues. A number of clinical variables determine the magnitude of hypoxia and the subject's ability to withstand it. The pathophysiology of drowning is thus closely integrated with the genesis of hypoxemia and its effects on various organ functions. A working knowledge of these pathophysiologic principles and multiorgan involvement is extremely helpful in directing therapeutic strategies for optimum survival.

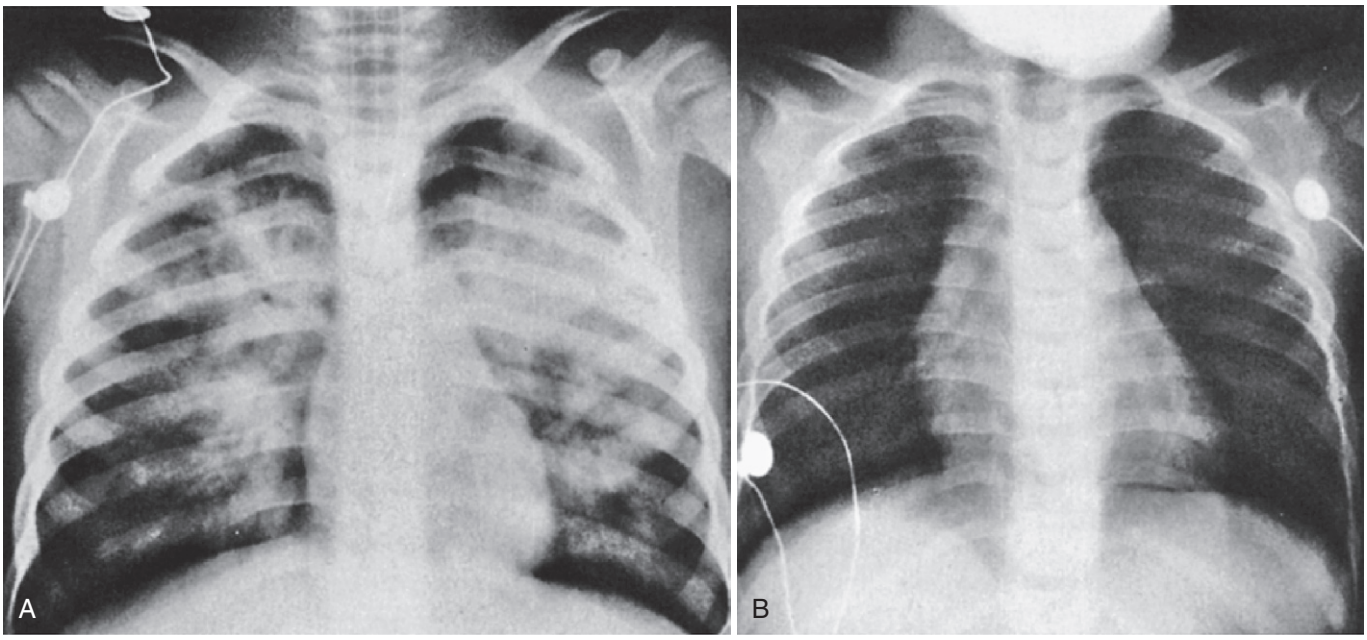

Figure 110–1. Drowning with and without aspiration. Radiographs show a patient with severe pulmonary edema (**A**), and another without significant fluid aspiration (**B**). *(From Ciullo JV, editor:* Clinics in sports medicine, *Philadelphia, 1986, WB Saunders.)*

Type of Aspirated Fluid

Although the differences between changes in electrolytes and blood volume after salt and fresh water aspiration have been emphasized in the past, they are of little clinical significance in patients who survive long enough to be transported to a medical facility.[14] Aspiration of more than 11 mL/kg of fluid is required for blood volume to be altered, and aspiration of more than 22 mL/kg is necessary before significant electrolyte changes occur.[15,16] Most drowning victims aspirate less than 3 to 4 mL/kg of fluid. Hypervolemia resulting from fresh water aspiration is rarely a problem. Most drowning victims are hypovolemic regardless of the type of aspiration because of excessive capillary permeability resulting from asphyxia and the loss of protein-rich fluid into the alveoli.

Pulmonary Effects

Functional residual capacity (FRC) is the only source of gas exchange at the pulmonary capillary level in the submerged state. Increased metabolic demands from struggling, breath-holding, a depletion of FRC from breathing efforts, and aspiration of fluid into the lungs all result in seriously compromised O_2 uptake and CO_2 elimination, with consequent hypoxia and hypercarbia. Between 10% and 15% of drowning victims have severe laryngospasm after submersion resulting in fatal asphyxiation without aspiration of water into their lungs (Figure 110-1). A combined respiratory and metabolic acidosis caused by hypercapnia and anaerobic metabolism is often encountered. Patients without significant fluid aspiration recover from asphyxia rapidly if they are successfully resuscitated before cardiac arrest or irreversible brain damage occurs. Aspiration of fluid, however, results in persistently abnormal gas exchange. Aspiration of a little as 1 to 3 mL/kg of fluid results in profound impairment of gas exchange.[16,17] Soon after the aspiration of fluid, there is an elevation of $Paco_2$ and a fall in Pao_2 as a result of airway obstruction, hypoventilation, and impaired gas exchange between alveoli and pulmonary capillary blood. With adequate resuscitation, normocapnia or even hypocapnia is usually achieved while hypoxemia persists, indicating a significant ventilation/perfusion mismatch and diffusion defect leading to intrapulmonary shunting and venous admixture.[18]

The surfactant system of the lung is affected differently in fresh water and seawater aspiration.[19] Freshwater aspiration results in marked disruption of the surfactant system of the lung resulting in alveolar instability and atelectasis. Seawater, because of its hypertonicity, draws water into the alveoli. Although the surfactant may be diluted by the presence of seawater in alveoli, its surface tension properties are not significantly altered. Zhu et al.[20] examined serum levels of pulmonary surfactant-associated protein and lung weights in 53 victims of fatal drowning. They showed significantly heavier lungs in those who drowned in seawater versus freshwater, suggesting an osmolar effect. Although they found no difference in serum surfactant-associated protein, intra-alveolar aggregates of pulmonary surfactant associated protein were noted more frequently in those who drowned in freshwater. This is likely related to the disruption of surfactant noted in freshwater drowning. Karch demonstrated marked changes in the pulmonary vasculature in rabbits within 30 minutes of aspiration of both freshwater and salt water.[21] Mitochondrial swelling and disruption of pulmonary vascular endothelial cells were consistently observed in these experiments. Clinically, pulmonary abnormalities are encountered in both fresh and sea water aspiration. These are consistent with pronounced injury to alveoli and pulmonary capillaries resulting in increased membrane permeability, exudation of proteinaceous material in alveoli, pulmonary edema, decreased lung compliance, and increased airway resistance. The extent of these abnormalities may not be manifested fully for several hours after the submersion episode and may be progressive in nature.

Acute respiratory distress syndrome (ARDS) is the hallmark of delayed pulmonary insufficiency resulting from aspiration

in drowning. This is characterized by progression of alveolar-capillary block, increased capillary permeability, and pulmonary edema. Reduced FRC and diffusion barrier resulting from accumulation of fluid and inflammatory cells in the alveoli and interstitium further accentuate hypoxemia. Aspiration of stomach contents and other debris such as sand, mud, and algae may also impair gas exchange. Bacterial pneumonia resulting from aspiration of contaminated water may further contribute to pulmonary insufficiency. A number of factors contribute to drowning-associated pneumonia. These include aspiration of vomitus or aspiration of contaminated material from water that may contain sewage. Water temperature plays a role, with warmer temperatures predisposing to a higher number of organisms. The chemical composition of the water such as pH, salt content, and presence of organic and inorganic substances influence bacterial growth as well. Organisms include aerobic gram-negative bacteria such as *Klebsiella* and *Pseudomonas*, and gram-positive bacteria, which include *Streptococcus pneumoniae* and *Staphylococcus aureus*. Fungi such as aspergillus have been reported to cause drowning-associated pneumonia as well. The diagnosis of pneumonia is based on clinical parameters such as fever, leukocytosis, respiratory cultures, and new infiltrates on chest radiographs.

Understanding the alterations in pulmonary mechanics is important in order to provide the necessary support in the least injurious fashion. The predominant respiratory manifestations of drowning are those of ARDS. Although pulmonary involvement is often bilateral and diffuse, there is considerable inhomogeneity, with some areas more affected than others. Overall, lung compliance is reduced, necessitating higher inflation pressures to maintain adequate tidal volume (Vt). Low Vt at low FRC leads to a vicious cycle of atelectasis, decreased compliance and further reduction in Vt. The critical opening pressure necessary to begin alveolar inflation is increased. Appropriate positive end-expiratory pressure (PEEP) needs to be administered to maintain the necessary FRC for adequate oxygenation and ventilation above the critical opening pressure. Airway resistance is relatively less affected or only minimally elevated unless there is airway obstruction from aspirated debris. Time constant, a product of compliance and resistance, reflects the time needed for pressure equilibration between the proximal airway and alveoli to occur. In ARDS, time constant is decreased allowing for quicker approximation of pressures at these sites during the inspiratory and expiratory phases of the mechanical ventilation. Relatively large tidal volume ventilation (10 to 12 mL/kg) is associated with greater ventilator-induced lung injury in ARDS, whereas smaller tidal volume ventilation (6 mL/kg) is associated with less volutrauma. Because of the changes in the time constant, prolongation of inspiratory time to improve oxygenation and increasing the respiratory rate for CO_2 elimination are often effective options during mechanical ventilation.

Cardiovascular Effects

Profound cardiovascular instability is often encountered after a severe submersion event thereby posing an immediate threat to survival after the initial rescue. The hypoxemia that occurs because of ventilation-perfusion mismatch can cause life-threatening dysrhythmias such as ventricular tachycardia, ventricular fibrillation, and asystole. The two determinants of oxygen delivery, namely cardiac output and arterial O_2 content, can be adversely affected by the submersion event. A decrease in Pao_2, if sufficiently severe, decreases oxygen saturation and therefore arterial O_2 content. This decrease in arterial O_2 content can cause a decrease in myocardial oxygen delivery, which contributes to worsening cardiac output and decreased myocardial perfusion pressure. Smooth muscle contraction banding in the media of major coronary arteries and local ventricular myocytes with focal myocardial necrosis have been described after a submersion episode.[22,23] Cytosolic calcium overload and oxygen-derived free radicals have also been implicated in the mechanism of myocardial injury after resuscitation after cardiac arrest.[24] Cardiogenic shock may result from hypoxic damage to the myocardium. Metabolic acidosis may further impair myocardial performance. Additionally, therapeutic application of PEEP causes decreased venous return, right and left ventricular preload, and right ventricular afterload while decreasing left ventricular afterload. Right ventricular afterload is also increased by structural pulmonary microvascular damage and humoral inflammatory mediators involved in ARDS. The right ventricle is anatomically designed to tolerate increased preload, but it is not as tolerant of high pressures and afterload as the left ventricle. If pulmonary hypertension is severe enough, it may lead to decreased left ventricular preload due to right ventricular failure. These factors, as well as the excessive capillary permeability of pulmonary and systemic capillaries, result in hypovolemia and decreased left ventricular filling pressures. These alterations of components of oxygen delivery; namely oxygen content, myocardial contractility, left and right ventricular afterload, and preload, can potentially result in an inadequate supply of oxygen to tissues to meet their metabolic demands.

Central Nervous System Effects

Hypoxia, if sufficiently prolonged, causes profound disturbances of central nervous system (CNS) function. The severity of brain injury depends on the magnitude and duration of hypoxia and cerebral hypoperfusion, as well as on mechanisms of secondary brain injury. Oxygen depletion and impaired neuronal metabolism result in loss of consciousness. However, even severe encephalopathy is reversible if the victim is promptly rescued and successfully resuscitated.

After restoration of adequate cerebral oxygen delivery after the initial hypoxia and/or hypoperfusion after drowning, there are several mechanisms of secondary brain injury at the tissue, synaptic, and cellular level. At the tissue level, increased intracranial pressure (ICP), and alterations in cerebral blood flow can adversely impact local tissue oxygen delivery. At the synaptic level, the excitotoxic neurotransmitter glutamate can cause an imbalance in the neuronal supply and demand. Intracellularly, accumulation of cytosolic calcium, neuronal energy failure associated with DNA damage and repair, the generation of oxygen derived free radicals, and activation of the triggers of apoptosis and necrosis can all contribute to secondary neuronal death.

There are several developmental factors that render the neurologic effects of pediatric cardiac arrest and hypoxia different than that of adults. Similar to other causes of pediatric asphyxia, such as foreign body airway obstruction, apnea, asthma, and suffocation, cardiac arrest encountered after drowning is preceded by a period of hypoxic perfusion. This leads to worse neurologic injury as opposed to a sudden

cardiac arrest, such as that induced by a dysrhythmia, which is the more common precipitating factor for adult cardiac arrest.[25,26] Approximately 13% of all children with cardiopulmonary arrest survive to hospital discharge, and only 9% if the arrest occurred outside the hospital.[27] Studies in humans and animals indicate that there are several developmental differences in excitotoxic pathways. In the neonatal period, there is increased vulnerability to NMDA receptor activation[28] and glutamate toxicity,[29] as well as heightened capability for apoptosis, which, albeit an important process of normal brain development, may render the immature brain vulnerable to neuronal loss after an insult.[30] In addition, a developmental difference exists in cerebral blood flow (CBF) after cardiac arrest. In adult models of cardiac arrest, global hyperemia is present for 15 to 30 minutes after return of spontaneous circulation followed by delayed hypoperfusion that persists for several hours. In an immature animal model of a brief asphyxial cardiac arrest, hyperemia is observed for 10 minutes after return of spontaneous circulation followed by restoration of baseline CBF, whereas prolonged cardiac arrest is followed by hypoperfusion and blood pressure-dependent CBF.[31]

Effects on Other Organ Systems

Multisystem failure resulting from prolonged ischemic-hypoxic state, sepsis, and therapeutic modalities used to manage these children may complicate the clinical course.[32] Renal and hepatic insufficiency, disseminated intravascular coagulation, gastrointestinal injury, and metabolic abnormalities are important management considerations. However, these complications rarely pose a threat to survival in an otherwise salvageable patient.

Submersion Hypothermia

Hypothermia has been shown in numerous animal and human studies to mitigate many of the processes involved in the development of secondary brain injury from both trauma and asphyxia. Positive effects of hypothermia include a decrease in cerebral metabolic rate, ICP, excitotoxic neurotransmission, cytotoxic edema, generation of deleterious oxygen-derived free radicals, and the cerebral hyperemia which can cause ischemia/reperfusion injury and further increase ICP. These effects of hypothermia are particularly germane to drowning injury, as astonishingly good outcomes have been reported in children submerged in ice water (< 5° C) for prolonged periods.[15,39] It appears that for submersion hypothermia to be protective, rapid cooling in ice water is necessary, as a lesser degree of hypothermia in warmer water does not offer cerebral protection.[40] Furthermore, intact survival is more an exception than a rule in patients with prolonged submersion, even in ice water. The young and the elderly are most susceptible to hypothermia. Infants lose heat rapidly when subjected to a hypothermic environment because of their relatively large surface area. Its protective effects notwithstanding, hypothermia by itself poses a direct threat to survival, due to its adverse effects on cardiac rhythm.

Mammalian Diving Reflex

A certain degree of protection against submersion hypoxia has been proposed to occur in the form of a response similar to the diving reflex observed in seals and other air-breathing diving mammals. The ability of these animals to remain submerged for periods up to 20 minutes is due to a remarkable redistribution of blood flow that occurs after diving underwater. While heart, brain, and lungs remain adequately perfused, blood flow to tissues resistant to hypoxia (i.e., gastrointestinal tract, skin, and muscle) is markedly reduced. Significant bradycardia occurs with a reduction in cardiac output. Such a response, albeit quantitatively less, is also observed in humans after total body immersion.[33] The mammalian diving reflex acts as an oxygen-conserving adaptation in response to submersion. It has been proposed that this reflex is most active in infancy and is potentiated by fear and low water temperature.[34] A combination of marked bradycardia and impalpable pulses resulting from vasoconstriction may make the victim appear dead at a time when mouth-to-mouth resuscitation could be life-saving.[33] Clinical studies involving children and adults have failed to demonstrate an efficient diving reflex in response to cold-water submersion.[35,36] Young children had a significantly decreased breath-hold duration and consequently a weaker dive response compared with older children and adults.[36] The role of the mammalian diving reflex in enabling children to withstand prolonged cold-water submersion thus remains controversial.

Preexisting Associated Conditions

An underlying etiologic mechanism should be explored depending upon the clinical scenario involving unexplained drowning. Children with seizure disorders are at greater risk for submersion accidents. Similarly an occurrence of vasovagal syncope or a hypoglycemic episode during swimming may be the underlying factor responsible for drowning. Occult cardiomyopathy or a cardiac arrhythmia should also be considered in an unexplained drowning event. An episode of drowning might be the first manifestation of long QT syndrome (LQTS). Ackerman et al. studied blood samples or archived autopsy tissue samples in 35 cases of autosomal dominant LQTS. Six of these patients had a personal history or extended family history of near-drowning. All of these patients were found to have LQTS mutations at *KVLQT1* whereas such an abnormality was found in only 3 of the remaining 29 patients who did not have a personal or family history of submersion episode.[37] Thus swimming appears to be a gene-specific (*KVLQT1)* arrhythmogenic trigger for LQTS. Diagnosis of inherited LQTS allows for identification of other family members with similar affliction. Yoshinaga et al. showed that face immersion in cold water results in abnormal lengthening of the QT interval in children identified with nonfamilial LQTS, and such children could potentially be at risk of a life-threatening arrhythmia during swimming.[38]

Management

Because the full extent of CNS injury cannot be adequately determined immediately after the rescue, all drowning victims should receive aggressive basic and advanced life support at the site of the accident and in the emergency department. The primary determinant of survival and maximal brain salvage is prompt and effective management of hypoxemia and acidosis. In this context, the management in the immediate postdrowning period is of paramount importance. The success or failure

of cardiopulmonary resuscitation (CPR) at the site of the accident often determines the outcome.[41,42] The issue of the duration of submersion in relation to the success of resuscitation is often raised. Although asphyxia for longer than 5 minutes frequently results in significant brain injury, this should not be a consideration in deciding whether or not to initiate on-site resuscitation. The emotional excitement surrounding the accident makes it impossible to accurately estimate the duration of hypoxia.

Management at the Scene

Ensuring the adequacy of the airway, breathing, and circulation is the goal of basic life support after the initial rescue. In cases of inadequate airway and cardiopulmonary status, CPR must be instituted immediately. The fundamentals of basic life support are the same after drowning as for any other situation requiring CPR; however, some practical aspects are worth considering. In the management of a drowning victim, the aim of resuscitation at the scene is to prevent irreversible tissue injury from prolonged hypoxia and ischemia. The victim should be removed from the water as soon as possible. Mouth-to-mouth breathing should be performed even while in the water if it can be accomplished. The stability of the cervical spine must be ensured, especially in drowning suspected to be related to diving. To this end, the preferred airway opening maneuver is anterior displacement of the jaw, rather than extension of the neck. Chest compressions should not be attempted in the water because it is ineffective and wastes valuable time.[43] Prolonged attempts to remove water from the lungs are futile and may hinder ongoing ventilatory support. Heimlich and Patrick[44] have recommended the use of subdiaphragmatic pressure in drowning victims to remove water from the airway. In addition to the fact that most drowning victims aspirate relatively small amounts of water, there is no evidence to suggest that the Heimlich maneuver can remove aspirated fresh water or pulmonary edema fluid.[42] On the other hand, such patients frequently swallow large amounts of water. Consequently, increased abdominal pressure may result in regurgitation of gastric contents into the oropharynx and aspiration into the tracheobronchial tree.[45] Any debris observed in the oropharynx should be removed before initiation of mouth-to-mouth breathing. Presence of airway obstruction caused by a foreign body should be suspected if effective chest expansion cannot be accomplished with appropriate ventilatory technique. A subdiaphragmatic thrust in such a situation would be indicated. As soon as the equipment becomes available, ventilation with 100% oxygen via bag-valve mask device should be initiated for patients who are not breathing adequately. Pressure used during resuscitation to inflate the lungs of submersion victims may have to be higher than anticipated because of reduced compliance of the edematous lungs. A PEEP valve should be used, if available. Overinflation should be avoided, however, because this can lead to pulmonary barotrauma, and overdistention of the stomach with regurgitation and aspiration of gastric contents. In patients who are too obtunded to maintain airway protection, exhibit hypoxia, or otherwise unable to maintain oxygenation despite bag-valve mask ventilation, endotracheal intubation should be performed. Noninvasive assessment of oxygenation and ventilation with the use of pulse oximetry, end-tidal CO_2, and transcutaneous O_2/CO_2 monitor provides valuable information especially during transport of such patients. Last, a common precipitating cause of drowning is cardiac dysrhythmia. In children, the most likely causes include myocarditis or familial long QT syndrome. Therefore, an automatic external defibrillator device, if available, should be applied to any patient who has not achieved adequate return of spontaneous circulation.

Emergency Department Evaluation and Stabilization

As with any form of accidental injury, other forms of associated trauma must be considered. Children who slip and fall into the pool may sustain external head injury such as abrasions, lacerations, and contusions. Occasionally, profuse bleeding from scalp lacerations may be sufficient to aggravate hypovolemic shock. Even in the absence of external signs of trauma, the possibility of intracranial lesions or bleeding should be entertained. In bathtub drowning, or in instances where child abuse is suspected, fractures and other evidence of previous injury should be looked for. In adolescent victims, drowning is frequently associated with illicit drug or alcohol use. When appropriate, urine and blood toxicology tests should be performed. Spinal injuries associated with drowning are not uncommon, especially with diving accidents involving young adults.[42]

The need for hospitalization should be determined by the severity of the drowning episode and clinical evaluation. All patients with a history of drowning should be observed in the emergency department for at least 4 to 6 hours. Those with insignificant history and normal physical examination may be safely treated as outpatients.[46] Patients with respiratory symptoms, decreased O_2 saturation indicated by pulse oximetry or blood gas determination, and altered sensorium should be hospitalized.

The extent of cerebral hypoxia can be quantified by Conn's criteria as category A (awake), category B (blunted consciousness), and category C (comatose). Category C is subclassified into C_1 (decorticate), C_2 (decerebrate), and C_3 (flaccid).[47] The Glasgow Coma Scale has also been proposed to estimate severity of neurologic dysfunction.[48] Both the Glasgow Coma Scale and Conn's classification are helpful in determining management and judging response to therapy and for prognostication.

Maintaining adequate airway, respirations, and peripheral perfusion with continued attention to oxygenation, ventilation, and cardiac performance should take priority. Electrocardiographic monitoring and arterial blood gas determination should be performed as soon as possible. Ventricular dysrhythmias, asystole, and hypotension may result from the asphyxial episode and are commonly encountered during the early resuscitation phase. The standard CPR techniques also apply to the drowned child. Patients with respiratory acidosis and hypoxemia, and those who are unconscious with significant respiratory distress or poor respiratory efforts, require endotracheal intubation and mechanical ventilation. Early use of PEEP is effective in reversing hypoxemia. Because pulmonary edema is not caused by hypervolemia in drowning, diuretics are not helpful and, in addition, may exacerbate the prevalent hypovolemia. Therefore pulmonary edema after near-drowning is best treated by mechanical ventilation with positive pressure breathing and PEEP rather than diuretics. Hypovolemia is commonly encountered in the early resuscitation phase. Isotonic crystalloids (20 mL/kg) or colloids

(10 mL/kg) infused over 15 to 20 minutes should be used for intravascular volume expansion. Additional volume expansion can be carried out based on clinical and hemodynamic status. Administration of large amounts of hypotonic fluid is contraindicated because such solutions are ineffective for intravascular volume expansion. Furthermore, the resultant decrease in serum osmolality may exacerbate cerebral edema. In the face of continued hypotension and/or impaired peripheral perfusion after appropriate intravascular volume expansion, inotropic support using dopamine or dobutamine may be necessary. Central venous pressure monitoring is extremely helpful for ongoing assessment and management of intravascular volume. Mild-to-moderate metabolic acidosis may resolve along with improvement of oxygenation and tissue perfusion. In more severe cases, sodium bicarbonate administration may be necessary based on blood gas values. Radiologic studies should include a chest radiograph to determine the presence or absence of pneumothorax or pneumomediastinum. Unless head injury is suspected, computed tomography scan of the head is usually not necessary because early findings are often normal even in the face of severe hypoxic damage.[49]

Severe bradycardia and intense vasoconstriction associated with marked hypothermia (<32° C) may make drowning victims appear dead. However, resuscitative efforts should be continued while normalizing body temperature. Treatment of hypothermia is discussed elsewhere in the textbook.

Management in the Intensive Care Unit

Continued attention to oxygenation and ventilation status and cardiac performance is essential. Pulse oximetry is readily available and provides a good indication of oxygen saturation and may especially be useful in continuous monitoring of patients who may develop ARDS. However, because of the nature of the oxygen-hemoglobin dissociation curve, pulse oximetry does not accurately reflect changes in Pao_2 greater than 70 mm Hg. Arterial and central venous pressure monitoring are necessary in most patients who require intensive care. A useful parameter to monitor is mixed venous oxygen saturation. Provided arterial oxygen content and oxygen consumption remain constant, venous oxygen saturation is a useful indicator of changes in cardiac output.

The need for endotracheal intubation and different ventilatory strategies should be determined on an individual basis and by clinical judgment. Respiratory acidosis, Pao_2 less than 60 mm Hg with an FIo_2 greater than 0.5, clinical signs of impending respiratory fatigue, and depressed level of consciousness are the most common indications for mechanical ventilation. Early use of PEEP and supplemental oxygen are extremely effective in reversing hypoxemia. The goal of mechanical ventilation is to provide adequate gas exchange to ensure tissue viability while minimizing the inevitable ventilator-associated injury from oxygen, barotrauma, volutrauma, and ineffective tracheobronchial toilet. Ventilatory strategy should take into account the major alterations in pulmonary mechanics. As noted earlier, most children who drown have decreased FRC, compliance, and time constant along with increased critical opening pressure. Salutary effects of PEEP are from maintaining alveolar stability, alveolar recruitment and increasing FRC. It stabilizes the relatively softer chest wall of a child thus minimizing chest wall recoil and further decrease in FRC. PEEP also displaces intra-alveolar water into interstitial and perilymphatic spaces resulting in decreased venous admixture and improved compliance. On the other hand excessive amounts of PEEP can result in decreased venous return and cardiac output, pulmonary overdistension and decreased compliance, and barotrauma. Maintenance of normovolemia is an important consideration in patients receiving PEEP.

It is now recognized that in patients with acute lung injury and ARDS, ventilation with lower tidal volumes (6 mL/kg) results in improved survival compared to those ventilated with a larger tidal volume (12 mL/kg).[50] There are various ventilatory strategies that may be used to minimize barotrauma in a patient with ARDS while maintaining adequate gas exchange. The underlying principle is to recruit lung volume by application of optimum PEEP to maintain FRC above the critical opening pressure and ventilate with a tidal volume approximating 6 to 7 mL/kg. Both pressure controlled and volume controlled strategies can be used using this principle. The authors recommend pressure controlled ventilation with a relatively low peak airway pressure and prolonged inspiratory time while still allowing adequate time for complete exhalation. Alternatively, the pressure-regulated, volume-control mode can also be used to deliver a preset tidal volume with the minimum possible inflating pressure. The level of PEEP can be optimized by gradual increments depending on its effects on the Pao_2/FIo_2 ratio and cardiovascular function. The ability of modern ventilators to display exhaled tidal volume and graphic displays of flow, pressure and volume waveforms has enabled the clinician to adjust mechanical ventilatory support according to individual alterations in pulmonary mechanics. Optimal PEEP as evidenced by improvement in dynamic compliance can be determined by measuring exhaled tidal volume at varying levels of PEEP. When PEEP exceeds critical opening pressure or the lower inflection point on the pressure/volume curve, dynamic compliance improves. Ventilatory rate, inspiratory/expiratory times, and peak airway pressures can also be adjusted according to their effects on dynamic compliance, and by ascertaining the return of expiratory flow to baseline. In patients without CNS injury and intracranial hypertension, the technique of permissive hypercapnia can be used to minimize barotrauma in a patient with ARDS. This involves using lower inflation pressures or tidal volume and accepting higher levels of PCO_2 as long as pH remains near normal.

High-frequency ventilation is another strategy that can be used in the management of hypoxic respiratory failure. This mode of ventilation uses a relatively high mean airway pressure while minimizing excessive fluctuations in pressures during the respiratory cycle. High-frequency ventilation is a safe and effective modality in the treatment of severe acute respiratory failure that is unresponsive to conventional mechanical ventilation.[51,52] Although extracorporeal life support (ECLS) has been used for rewarming in patients with severe hypothermia following drowning in cold water, the routine use of ECLS for the treatment of ARDS associated with drowning is less clear. The presumed benefit of ECLS is the avoidance of barotrauma and oxygen toxicity in patients who do not improve despite maximum ventilatory support. However, the risks of carotid artery ligation for the purposes of ECLS cannulation in patients who may have suffered hypoxic-ischemic CNS injury are unknown.

Recent studies have shown the benefits of the administration of exogenous surfactant in children with ARDS.[53]

Evidence indicates disruption of surfactant, particularly in those children who drown in freshwater. Exogenous surfactant administration may be a reasonable therapeutic modality in children who develop ARDS after drowning, and who have persistent pulmonary insufficiency in spite of aggressive respiratory support including high-frequency ventilation. While there are no randomized controlled trials examining the benefits of surfactant administration in patients with ARDS following drowning, there are case reports that describe improvement in oxygenation following instillation of exogenous surfactant.[54,55]

Secondary bacterial infection resulting from aspiration or as a complication of endotracheal intubation and mechanical ventilation is sometimes observed. There is no evidence to suggest that "prophylactic" antibiotics help prevent drowning-associated pneumonia.[56] However, fulminant *Staphylococcus pneumoniae* bacterial sepsis and pneumonia have been described shortly after a severe submersion injury. It is therefore reasonable to institute empiric antibiotic therapy in patients with severe cardiopulmonary deterioration especially when this occurs after a period of stability.[57] The use of corticosteroids for aspiration pneumonia is probably of no benefit.[58]

After the patient is successfully resuscitated, the severity of encephalopathy is the main determinant of mortality and morbidity from drowning. With improved techniques of cardiopulmonary support, delayed deaths resulting from pulmonary insufficiency are becoming less frequent. CNS injury is by far the most important cause of death and long-term functional impairment among the immediate survivors of drowning accidents. Measures for cerebral protection after drowning have been used by several investigators.[34,47] The emphasis of such modalities is on managing cerebral edema, controlling intracranial hypertension, and decreasing cerebral metabolic requirements with the use of fluid restriction, diuretics, hypothermia, corticosteroids, and barbiturates. However, studies have failed to demonstrate beneficial effects of such therapy in improving the outcome of hypoxic encephalopathy associated with drowning.[59] Furthermore, a significant increase in infections and pulmonary insufficiency was observed in association with therapeutic hypothermia in this setting. Pentobarbital has the theoretical advantage of decreasing cerebral oxygen demand. However, induction of pentobarbital coma, although effective in controlling intracranial hypertension, has not improved the neurologic outcome of comatose children following hypoxic-ischemic brain injury.[59-61] The role of cerebral edema and intracranial hypertension in potentiating CNS injury in otherwise salvageable children is questionable in this setting. The authors' experience suggests that significant intracranial hypertension is not commonly encountered in the early post-immersion period, whereas late, uncontrollable intracranial hypertension carries an unfavorable prognosis.[62] Additionally, satisfactory control of intracranial hypertension has not been shown to result in improved outcome.[59,60,62] It appears that the occurrence of cerebral edema and intracranial hypertension 2 to 3 days after a submersion accident is a reflection of the early hypoxic injury rather than a manifestation of a reversible process. Late, persistent intracranial hypertension associated with a comatose state is of ominous significance and is almost always associated with an unfavorable outcome.[62]

Currently, the routine use of ICP monitoring in children with hypoxic-ischemic encephalopathy after drowning is not recommended. The emphasis of management of a comatose child in the immediate post-drowning period should be on maintaining adequate oxygenation/ventilation, oxygen delivery with avoidance of hypotonic fluid and fluid overload. Pathophysiologic changes from asphyxia, as well as various therapies aimed at cerebral salvage such as barbiturates and osmotic diuresis may adversely affect myocardial performance.[63] Cardiovascular support with maintenance of intravascular volume and the use of inotropic agents is often necessary to maintain optimum organ perfusion in patients who have suffered a significant hypoxic-ischemic insult.

The neuroprotective properties of therapeutic hypothermia that have been extensively demonstrated in laboratory studies suggest potential merits as a therapy in some children, including victims of drowning. A randomized controlled trial of therapeutic hypothermia has shown benefits in neonatal hypoxic-ischemic encephalopathy,[64] and such therapy is currently being studied in older children. Much of the interest in the clinical application of therapeutic hypothermia originated in the treatment of submersion injury. In the late 1970s, Conn showed improvement in neurologic outcome in children who were victims of submersion injury, using "HYPER" therapy that included hypothermia, hyperventilation, neuromuscular blockade, barbiturates, and dehydration.[34] However, subsequent studies in pediatric drowning injury showed that not only did hypothermia not improve outcome, it increased infectious complications.[59,65] It is possible that studies designed with a different depth and/or duration of hypothermia, or rewarming procedure may yield different results. Although hypothermia has been shown to decrease ICP in trauma, rebound intracranial hypertension can occur during rewarming.[66,67] Thus, in cases of cold water drowning, although the patient should be actively warmed to prevent arrhythmias and secondary infections, once a core body temperature of 30° C is achieved, warming should be slower and more passive to prevent increases in cerebral blood flow and ICP, ischemia/reperfusion injury, and fever from overaggressive rewarming. However, given the lack of positive randomized controlled trials in pediatric asphyxial arrest or in submersion injury, hypothermia cannot be strongly recommended as a therapy at this time.

Prognosis

The outcome of drowning victims depends largely on the success of resuscitative measures at the scene of injury. Patients who are successfully resuscitated and who are conscious on arrival at the hospital have an excellent chance of intact survival.[41,68,69] With improved ventilatory techniques and aggressive management, pulmonary injury can be successfully managed in most patients. However, some groups have suggested that the neurologic prognosis is very poor if the patient arrives comatose in the emergency department, whether or not they receive aggressive "brain resuscitation" (i.e., goal-directed therapy for optimization of cerebral perfusion pressure).[70] Variables such as age, length of submersion, serum pH, and body temperature, although previously thought to influence outcome,[71] have not been shown to be reliable prognostic indicators.[61] In addition, our experience suggests that the absence of cognitive function 72 hours after the hypoxic episode is strongly associated with either death or survival in a persistent vegetative state.[62] The need for continued CPR at the hospital, CPR greater than 25 minutes,

fixed and dilated pupils, seizures, flaccidity, Glasgow Coma Scale of 5 or less, and decreased cerebral blood flow are of poor prognostic significance in the absence of hypothermia. Severe hypothermia has been shown to influence the outcome favorably even after prolonged submersion; however, not all hypothermic submersion victims are fortunate to escape serious neurologic damage. A database review of 267 cases of serious pediatric submersion events in Massachusetts from 1994 to 2000 showed better outcome in younger age groups, females, and Hispanic children, and worse outcomes in African-American children.[72] These data likely reflect differences in time to first responder arrival, and suggest that prevention strategies should take into account differences in age, gender, and ethnicity.

Burn and Inhalation Injuries

Kevin R. Kasten, Amy T. Makley, and Richard J. Kagan

PEARLS

- The accurate estimation of the extent and depth of burn injury is crucial for appropriate resuscitation and maintenance of adequate urine output and hemodynamics.
- Early endotracheal intubation of pediatric burn patients with suspected inhalation injury is essential to reduce morbidity and mortality.
- Enteral nutrition via oral intake or post–pyloric feeding tube early postburn is recommended.

Burns account for approximately 2 million injuries annually in the United States alone,[1] of which 500,000 seek medical treatment and 100,000 require hospitalization.[2] Approximately 50% of burns occur in the pediatric population,[3] with children younger than 5 years representing 17% of reported burn cases.[2] Infants and children are a unique patient population that demonstrate increased susceptibility to death.[4] Not only do young children have limited physiologic reserves, but their patterns of injury are very different from adults. Although thermal burns secondary to scald or flame are by far the most common etiologies in children and adults, injuries from chemical and electrical burns may be devastating and require early recognition and treatment. Pediatric burn diagnosis and management is complex and requires the expertise of a multidisciplinary team.

With appropriate resuscitation and nutritional support, prompt recognition and management of inhalational injury, and early surgical treatment, mortality rates can be minimized.[5] This has been noted in tertiary care institutions, such as the Shriners Hospitals for Children, which focus on the treatment of pediatric burns. It is no coincidence that more than 60% of burns in the United States are admitted to one of 125 hospitals with specialized burn centers.[2] These centers are staffed by experienced burn and plastic surgeons working with a cadre of anesthesiologists, burn nurses, pharmacists, respiratory therapists, occupational and physical therapists, and social workers to produce optimal outcomes for pediatric patients. Although care in this specialized setting is not required for most pediatric burns, an understanding of burn pathophysiology and the principles of burn management will aid in the care of these patients by all clinicians.

Types of Burn Injuries

Scald Burns

Infants and toddlers younger than 5 years have a higher incidence of scald burns compared with older children.[6,7] In recent series, scald injuries accounted for the majority of pediatric burn admissions both globally and in the United States.[8-10] Accidental hot liquid spills account for many of these injuries and a thorough history should include the type and consistency of the causative liquid. Compared with water and thin liquids, oil and thick soups have a higher heat capacity and are more viscous. This may translate into longer contact and higher temperatures causing greater skin and soft-tissue damage.[11] In general, water heated to a temperature of 140° C will cause a deep burn after 3 seconds of contact; water heated to 160° C will cause the same burn after 1 second of contact.[12] Current preventive strategies to minimize accidental scald burn injuries include educational campaigns and legislation to mandate maximum water heater settings of 140° C, both with mixed results.[13,14] Scald burns are more likely to be associated with child abuse than other types of burn injuries.[15] Classic scald patterns consistent with child abuse include glovelike or stockinglike burns to the hands or feet, and/or symmetric burns to the buttocks, legs, or perineum. Concomitant injuries including fractures and retinal hemorrhages, as well as delays in seeking treatment or inconsistencies in the patient history, should trigger concern. These scenarios must prompt a full evaluation by social services with referral to appropriate state or government agencies regardless of the depth or extent of burn.

Thermal Burns

Thermal injury secondary to flame or contact with hot objects remains prevalent in pediatric burn injuries.[16] They account for approximately 50% of all burn admissions. Injuries from contact or flame are the most common cause of burn injury in children older than 5 years.[17] Up to 90% of injuries are minor and can be managed on an outpatient basis with good outcomes.[18] In larger burns, however, mortality is greatly influenced by the size of the burn, the age of the patient, and the presence or absence of concomitant inhalation injury.[5,18] The extent of soft tissue injury is greatly dependent on the duration of exposure and the presence and type of clothing material, all of which should be investigated during the initial evaluation.

Electrical Burns

Electrical burns remain a rare but devastating type of injury, accounting for 2% to 3% of pediatric burns.[19] The majority of injuries involve electrical cords and outlets, with a rare minority from lightening. Most homes in the United States use alternating current (AC), which although more efficient than direct current (DC), is more dangerous.[20] Injuries caused by AC have the potential for increased tissue damage from tetanic contractions caused by cyclic flow of electricity.[19] In addition, the "let go" threshold, the maximum current a person can grasp and "let go," is lower for children than adults.[19] Children are more susceptible to electrical injuries from their propensity to chew on cords or insert objects into outlets. Wet or moist skin, including the mucous membranes around the mouth, has negligible resistance, and these injuries often result in considerable soft tissue trauma. Nerves, blood vessels, and muscles exhibit the least resistance, as compared to bone, fat, and tendons.[19] The clinician should be aware that lack of overt skin damage may mask more significant underlying soft-tissue damage.

Chemical Burns

Chemical burns represent a unique group of injuries, the most common of which are caused by strong bases contained in common household products. Alkali drain cleaners composed of sodium hydroxide cause significant tissue injury from interaction with cutaneous lipids. Initial treatment of chemical burns includes copious irrigation with tepid water for more than 15 minutes. The severity of injury is determined not only by the type and concentration of the chemical, but the duration of exposure.[21] Appropriate treatment of chemical burns never involves neutralization of the acid or base as the resultant exothermic reaction worsens tissue injury. Hydrofluoric acid burns represent a distinct clinical scenario. In addition to being a corrosive agent, fluoride causes a severe, deep liquefaction necrosis.[22] Copious irrigation will attenuate the initial chemical burn, but neutralization with calcium or magnesium is occasionally necessary to halt further necrosis. Current treatment recommendations include topical calcium and close monitoring of serum calcium levels with supplementation as necessary.[22]

Depth and Extent of the Burn Injury

Normal Anatomy

The skin serves a thermoregulatory role, along with providing protection against fluid loss, mechanical damage, and infection. Divided into two distinct layers, the epidermis consists of keratinocytes, melanocytes, and Langerhans cells, all with barrier function. The dermis consists of structural proteins and cells responsible for tensile strength.[23] Additional appendages including blood vessels, hair follicles, and sweat glands are rooted in the dermis and are responsible for the regeneration of epidermal cells after superficial injury.[18] Assessment of burn depth is vital as deeper burns destroy these dermal appendages. Without skin grafting, the wounds heal from the margins of injury resulting in delayed healing, wound infection, and debilitating scars and contractures.

Superficial Burns

Traditionally, burn depth has been categorized as either first, second, third, or fourth degree. Although these terms are commonly used, division of burn depth and severity guided by the need for surgical treatment may be more clinically relevant. First-degree, or superficial, burns are characterized by erythematous changes, lack of blistering, and significant pain. Damage is isolated to part of the epidermis only, sparing the dermis and dermal structures. These burns blanch easily on examination and heal within 2 to 3 days after the damaged epidermis desquamates. This level of injury is exemplified by sun overexposure. Scarring is rare given the superficial depth.[18]

Superficial Partial-Thickness Burns

Superficial partial-thickness burn wounds differ from first-degree burns in that the entire epidermis and superficial dermis are injured in the former. These burns typically form fluid-containing blisters at the dermal-epidermal junction. After debridement, the underlying dermis is erythematous, wet-appearing, painful, and blanches with pressure. As the deeper dermis is left undamaged, wounds heal within 2 weeks without the need for skin grafting, typically without hypertrophic scarring.[18]

Deep Partial-Thickness Burns

Both superficial and deep partial-thickness burns have traditionally been classified as second-degree burns. The two categories merit distinction as deep partial-thickness burns behave clinically similar to third-degree burns. Deep partial-thickness burns blister, but as tissue damage extends deep into the dermis, the blister base may appear to have a mottled pink and white appearance. The blood vessels of the dermis are partially damaged, giving rise to variance in discoloration of the wound base. These wounds do not easily blanch and are less painful than superficial burns due to nerve injury. Treatment of these wounds customarily requires excision and grafting. Some burn surgeons advocate initial monitoring for up to 14 days to allow for demarcation. Arguments in favor of this approach cite the need for fewer operations and less extensive grafting. Rarely, these wounds will heal without surgical intervention, but remain at risk for developing hypertrophic burn scars and/or contractures.[18]

Full-Thickness Burns

Full-thickness burns are synonymous with third-degree injuries. These wounds are defined by complete involvement of all skin layers and require definitive surgical management. On examination, these wounds are white, cherry red, brown, or black in color, and do not blanch with pressure. The burned areas are dry and often leathery compared to normal skin. Wounds are typically insensate because of superficial nerve injury. Fourth-degree burns are full-thickness injuries involving the underlying subcutaneous fat, muscle, and tendons. These injuries are more commonly associated with limb loss and/or need for extensive reconstruction in addition to grafting.[18]

Zones of Injury

Burn wounds continue to evolve for days after the initial injury and the subsequent inflammatory process may last for several months.[24] The wound is divided into zones of injury: the zone of coagulation, the zone of stasis, and the zone of hyperemia. The zone of coagulation is easily identified, as it comprises the necrotic tissues closest to the injury site. The zone of hyperemia consists of normal, uninjured skin with a physiologic increase of blood flow in response to local tissue injury. The zone of stasis is located between the zones of coagulation and hyperemia, representing an area of ongoing injury.[23] Poor perfusion of this zone can result in the progression of initially viable tissue in this area to further necrosis and deeper wounds. Current research is looking at new methods to salvage these zones of intermediate injury.[25]

Estimating the Extent of the Burn

An accurate assessment of both the extent and depth of the burn is necessary to guide initial therapy and minimize morbidity and mortality. Total body surface area (TBSA) involvement of the burned area is an independent risk factor that correlates with length of hospital stay and mortality in pediatric burn injuries[5]; however, the extent of burn injuries may be overestimated up to 75% by the initial care provider.[26] This results in over-resuscitation with resultant devastating complications, inappropriate transfer to burn centers, and poor use of limited resources.[27] Newer methods are being researched to improve the calculation of burn surface area using computerized imaging, two- and three-dimensional graphics, and body contour reproductions.[28]

Current methods of calculating combined second- and and third-degree burn size in adults include burn diagrams, the "rule of nines," and a general estimate that the palm and fingers of one hand account for 1% of the normal body surface area.[29] Palaski and Tennison developed the rule of nines, a rough estimation of adult body surface area divided into multiples of 9%.[30] This calculation rarely underestimates TBSA, but often overestimates it, especially in children.[30] Body surface area is distributed differently in children and infants due to proportionally larger heads and smaller extremities. This supports the need for age-specific surface area charts such as the Lund Browder diagram to better estimate the extent of burn in children (Figure 111-1).

Early Management of Burn Injuries

After removing or extinguishing the source, burns should be washed with tepid water.[31] Chemical burns should be flushed copiously to remove the inciting agent and prevent further tissue damage. Ice or iced water has been shown in animal studies to increase tissue damage and mortality, and should not be used given the added risk of hypothermia in patients with more extensive burns.[32,33] Approximately 10% of all burn patients present with additional traumatic injuries and the primary caregiver should not be distracted by obvious external burn injury when performing a rapid trauma evaluation.[18] Patients with severe burn shock or trauma are at risk for loss of airway due to altered mental status or supraglottic obstruction from edema formation.[34] Signs of potential inhalation injury include facial burns, singed nasal hairs, carbonaceous sputum, hypoxia, and history of entrapment in an enclosed space. Individually, these symptoms carry a high false-positive rate for inhalation injury, but merit temporary treatment with supplemental oxygen until a definitive diagnosis is made. Evaluation of circulation includes intravenous access and resuscitation in pediatric burns greater than 10% TBSA because these injuries are characterized by a systemic inflammatory response that may lead to hemodynamic lability.[24,35] Electrical injuries require specific evaluation given the propensity for compartment syndromes and multiorgan system involvement. Cardiac dysrhythmias and direct muscle necrosis can develop with high voltage electrical burns, requiring intervention or prolonged cardiac monitoring.[19] Seizures and spinal cord transections are possible, as well as respiratory arrest secondary to injury of the brainstem or tetany of the respiratory musculature.[19]

After a complete primary and secondary survey, attention should turn to evaluation and management of the burn injury. Using appropriate tools such as the Lund Browder chart, the depth and extent of burn should be assessed and used to guide further care. Approximately 60% to 70% of burns seen in emergency departments involve less than 10% TBSA.[36] The majority of these burns can safely be treated with minor debridement, oral hydration, topical wound care, and outpatient follow-up. Those patients requiring supplemental nutrition or hydration, or who fail outpatient treatment, may need continued care in an inpatient setting. In adults with more than 20% TBSA involvement, in infants with more than 10% TBSA involvement, or if there is a suspicion for inhalation injury, inpatient treatment with intravenous resuscitation and potential transfer to a burn center should be considered.

Transfer to Burn Centers

The optimal treatment and management of large or complicated burn injuries is in a high volume center by a multidisciplinary team including burn surgeons and nurses, physical and occupational therapists, dieticians, psychiatrists, respiratory therapists and social service support staff.[18,37] Current American Burn Association guidelines recommend the transfer of patients with severe injuries or those meetings specific criteria to dedicated burn centers (Box 111-1). Before transfer, wounds should be covered with clean, dry material or nonadherent gauze.[3] The use of wet dressings should be avoided to prevent development of hypothermia and subsequent complications in patients with large burn wounds.[37] Tetanus prophylaxis should be administered along with appropriate pain control before transport. In patients with extensive burns, a Foley catheter should be inserted to help guide fluid management.

Burn Resuscitation

In children with more than 10% TBSA involvement, adequate intravenous access should be obtained via peripheral or central routes. In burns less than 20% TBSA with no associated comorbidities or injuries, resuscitation via peripheral access can be performed. Delayed initiation of resuscitation has been shown to increase mortality following severe burn injury in children.[5] Infusion of a balanced crystalloid solution should be started as soon as intravenous access is obtained, with the

Figure 111–1. Shriners Hospitals for Children diagram used for estimation of burn depth and extent in the acute pediatric burn patient.

Box 111–1 American Burn Association Criteria for Burn Center Referral

- Partial and full-thickness burns >10% TBSA in patients <10 years or >50 years
- Partial and full-thickness burns >20% TBSA in patients in other age groups
- Partial and full-thickness burns involving face, hands, feet, genitalia, perineum, or major joints
- Electrical burns
- Chemical burns
- Inhalation injury
- Burn injury in patients with preexisting medical disorders that could complicate management, prolong recovery, or increase mortality rate
- Any burn with concomitant trauma in which the burn injury poses the greatest risk
- Burn injury in children admitted to hospitals without qualified personnel or equipment for pediatric care
- Burn injury in patients requiring special social, emotional, or rehabilitative support, including child abuse cases

infusion rate titrated after full assessment of burn injury. Initial resuscitation guidelines have historically followed one of two formulas, the Parkland or modified Brooke. These formulas serve only as guidelines. Resuscitation must be tailored to each individual patient with the goal of restoring and maintaining perfusion without inducing fluid overload.

The Parkland formula was developed in the 1970s by Baxter and Shires, arising out of 30% to 50% TBSA flame burn experiments in dogs. They found that resuscitating with a higher volume in the first 8 hours improved cardiac output, which could be maintained over the next 16 hours with lower fluid rates. Based on these studies, recommendations for resuscitation of large burns using the Parkland formula were extrapolated.[38] This formula recommends the total administration of 4 mL/kg/%TBSA burn over the first 24 hours postinjury. One half of this volume is administered during the first 8 hours with the remaining volume delivered during the next 16 hours.

While the Parkland formula is the most widely used resuscitation formula, it is closely followed by the modified Brooke formula. Based on work done at the Brooke Army

Burn Center, Pruitt et al. altered the original Brooke formula, which recommended 1.5 mL/kg/%TBSA burn of crystalloid and 0.5 mL/kg/%TBSA burn of colloid. This group demonstrated that a lower volume of fluid could achieve the same endpoints of resuscitation as the Parkland formula.[38] The modified Brooke formula calls for 2 mL/kg/%TBSA burn of balanced salt solution over the first 24 hours after injury and no colloids. Although both formulas call for the titration of fluid rates; in a comparative analysis, the Parkland formula more often resulted in overresuscitation, proving to be an independent risk factor for mortality.[39] A separate comparative study found no clinical differences in outcomes between patients resuscitated using these two formulas.[40]

Consensus fluid resuscitation by standardized formula has not been reached.[38] In children, resuscitation strategies should include the administration of estimated basal fluid requirements in addition to the replacement of extensive fluid losses secondary to burn injury. At our institution the child's basal fluid requirements (1500 mL/m^2 body surface area or 2000 mL/m^2 body surface area for children younger than 2 years) are added to the resuscitation calculated using the Parkland formula (Figure 111-2). All formulas rely on the accurate assessment of extent and depth of burn in order to provide appropriate resuscitation. Fluid requirements should be titrated for clinical endpoints including urine output of 0.5 to 1 mL/kg/hr in children[39] and restoration of appropriate hemodynamic parameters.[38] To avoid the complications of inadequate or excessive resuscitation, current research is being performed to examine the utility and efficacy of closed-loop autonomous resuscitation.[41]

Colloid Resuscitation

The timing and use of colloid in burn resuscitation is controversial. Historically, initial resuscitation formulas called for its use in the first 24 hours after injury as an adjunct to crystalloid.[38] In pediatric patients with extensive burn injury, colloid replacement is sometimes necessary due to rapid serum protein decrease resulting in crystalloid resuscitation failure.[42] Patients who receive colloid as part of their resuscitation require less crystalloid and total fluid compared to those receiving crystalloid only.[43] However, recent evidence has shown that colloid resuscitation provides no long-term benefits, does not affect mortality, and is more expensive compared to crystalloid solutions.[44] The theoretical reduction in complications and mortality with colloid use has not been demonstrated in human trials.

Complications of Resuscitation

Inadequate resuscitation may result in poor perfusion to both vital organs and the evolving zone of stasis. This leads to necrosis of previously viable tissue and progression of superficial burns to deeper injuries requiring grafting.[25] The complications of over-resuscitation are similarly of great concern. Recent review of the literature has shown that a significant proportion of burn injuries are being resuscitated with fluid volumes in excess of that calculated by the Parkland formula due to use of fluid resuscitation algorithms based on bolus therapy (i.e., Pediatric Advanced Life Support).[45] The volume infused should be continuously titrated to avoid both over-resuscitation and underresuscitation[42] with little to no role for fluid bolus therapy during initial burn management.

Risks for the development of compartment syndrome in the extremities, torso, or abdomen have been linked to the presence of deep, full-thickness circumferential burns, as well as the volume of fluid infused during resuscitation. Severe burn injury results in a systemic inflammatory response leading to microcirculatory leak, vasodilatation, and decreased cardiac output and contractility.[46] With tissue edema, reperfusion injury following resuscitation, and external compression from circumferential burns, compartment syndromes may develop, most commonly within the first 24 to 48 hours. Excessive fluid resuscitation increases the incidence of compartment syndrome and leads to

RESUSCITATION CALCULATIONS

I. RESUSCITATION

A. Calculated resuscitation and basal requirement (less than 2 yrs. — 2000 mL/m^2)

1. (4 mL _____ kg _____ % burn) + (1500 mL _____ m^2) = mL/24 hours
   (_____) + (_____) = _____ mL/24 hours

B. Resuscitation fluid per 8 hours

1. 1st 8 hours _____ mL, _____ mL/hr.
2. 2nd 8 hours _____ mL, _____ mL/hr.
3. 3rd 8 hours _____ mL, _____ mL/hr.

II. MAINTENANCE FLUIDS

A. Basal fluid requirement — 1500 mL/m^2 (less than 2 yrs. — 2000 mL/m^2)

1. Total body surface area _____ m^2
2. 24 hours _____ mL
3. Hourly _____ mL/hr.

B. Evaporative water loss

1. Adults — (25 + % burn) m^2 = mL/hr.
   Children — (35 + % burn) m^2 = mL/hr.
2. Calculated evaporative water loss
   a. (_____ + _____ % burn) _____ m^2 = _____ mL/hr;_____ mL/24 hours

C. Total maintenance fluids — Basal requirement and evaporative water loss

1. 24 hours _____ mL
2. Hourly _____ mL

additional complications.[47] Clinical suspicion of compartment syndrome is supported by findings of delayed capillary refill, cyanosis, paresthesias, and diminished pulses. It is imperative to make the diagnosis before the loss of pulses as this indicates long-standing compartment syndrome with a higher likelihood of muscle necrosis and nerve damage. Compartment pressures can be measured using an 18 gauge needle connected to an arterial pressure transducer with placement under the eschar into subcutaneous or subfascial tissue. A pressure greater than 30 mm Hg is considered diagnostic, mandating decompression through escharotomy and/or fasciotomy. Escharotomies are performed at the bedside under sedation with electrocautery utilized to incise the full length of eschar down to subcutaneous fat. Bulging of muscle and surrounding tissues demonstrates adequate decompression. Fasciotomies are generally performed in the operating room under general anesthesia. All extremity compartments must be opened with evaluation of muscle for signs of necrosis. Escharotomies and fasciotomies should only be performed by experienced practitioners due to increased morbidity from incorrectly executed procedures.[48]

Abdominal hypertension with subsequent compartment syndrome significantly decreases perfusion to vital organs including the small and large bowel, liver, and kidneys, thereby contributing to the development of multisystem organ failure.[38] Patients will often present clinically with abdominal distention and decreased urine output. In addition, decreased pulmonary compliance secondary to elevated abdominal pressures can compound respiratory challenges. The incidence of intraabdominal hypertension in patients with extensive burns is approximately 70%, with up to 20% of those identified requiring decompressive laparotomy.[46] Preventive measures to avoid abdominal compartment syndrome include appropriate titration of resuscitation fluid, as well as early recognition of abdominal hypertension through serial bladder pressure evaluations.[49] Timely decompressive laparotomy should be performed at the onset of increased compartment pressures to avoid significantly increased morbidity and mortality related to fluid loss with an open abdomen. In small children, percutaneous drainage using peritoneal dialysis catheters may be an effective alternative to laparotomy provided that the increased intraabdominal pressure is related to fluid accumulation and not organ edema.

The development of pulmonary complications including acute lung injury, pulmonary edema, and acute respiratory distress syndrome (ARDS) has been attributed to excessive fluid resuscitation.[50] In the absence of inhalation injury, the systemic inflammation seen after severe burn injury results in third spacing of fluids and the accumulation of interstitial edema in the lungs. The treatment of this immune response remains challenging. Alternative resuscitation strategies including the use of colloid and hypertonic saline as adjuncts to crystalloids are continually being investigated with mixed results.[51,52] In several series, the presence of inhalation injury results in increased resuscitation fluid requirements and is predictive of the development of respiratory failure and increased mortality.[5,18,44,53]

Inhalational Injury

The diagnosis of inhalation injury in burn patients is important as a clear link exists between inhalation injury and mortality,[54-56] with the presence of inhalation injury being the single most important risk factor for mortality.[5,56-61]

Pathophysiology of Inhalation Injury

Inhalation injury involves exposure of the upper airway to heated dry air or steam. The lower airway, consisting of the tracheobronchial tree and lung parenchyma, is rarely injured by heated dry air because of reflexive vocal cord closure and evaporative cooling capacity.[12,62] Direct thermal injury manifests similar to cutaneous thermal injury with a resultant inflammatory response and edema. Histamine release, signaled by increasing complement at the site of injury, produces reactive oxygen and nitrogen species after formation of xanthine oxidase. These reactive species increase vascular permeability leading to extrusion of fluid and increased tissue edema. Prolonged extrusion of proteinaceous exudate and associated tissue edema may result in the formation of airway casts and obstruction, similar to mucous plugging.[63] Smoke and inhaled toxins pose a particular risk to both upper and lower airways. Toxins such as ammonia, sulfur oxides, pyrolysates and chlorine gas, form strong alkalis and acids upon contact with moist mucosal walls.[64] Fat-soluble agents such as aromatics activate alveolar macrophages and may initiate direct cellular damage[65] resulting in hyperemia of the airway, which can be visible shortly after injury. If inhalants induce an inflammatory response in the pulmonary parenchyma, surfactant synthesis may be disrupted with further worsening of lung compliance.[66] Loss of ciliary action in the respiratory mucosa can lead to increased pulmonary infections, ultimately resulting in irreparable damage to the respiratory tree.[58]

Carbon monoxide (CO) and cyanide are key components of inhalation injury in the acute burn patient. During fires, incomplete oxidation of hydrocarbons leads to formation of CO. CO is an odorless, colorless gas well known for its rapid uptake in the lungs and deleterious effects including tachypnea, hypoxia, altered mental status, coma, and death.[67] Clinical signs stem from an increased affinity of CO to bind hemoglobin, resulting in carboxyhemoglobin formation and as well as left shift of the oxygen-hemoglobin dissociation curve that impairs oxygen delivery at the tissue level. Relative tissue hypoxia ensues with subsequent metabolic acidosis. Hydrogen cyanide, a colorless gas with an odor described as being similar to bitter almonds, is produced by combustion of carbon and nitrogen-containing substances (i.e., wool, cotton). Cyanide inhibits oxidative phosphorylation via reversible inhibition of cytochrome C oxidase.[68] Similar to CO poisoning, cyanide poisoning produces relative tissue anoxia and metabolic acidosis.

Diagnosis of Inhalation Injury

The diagnosis of inhalation injury begins with a focused history and physical examination. The mechanism of injury provides a strong indication of the risk in the pediatric burn patient. Closed-space burns involving steam, combustibles, hot gases, or explosions should alert the treating physician to possible airway injury. Inhalation injury may occur without evidence of cutaneous burns. Acute pulmonary insufficiency may manifest in the first 36 hours, pulmonary edema between 48 to 96 hours, finally culminating in bronchopneumonia 3 to 10 days postburn. The physical exam should include inspection for soot in the oropharynx, carbonaceous sputum, singed nasal or facial hairs, and burns involving the face or neck. Signs of respiratory distress including wheezing, stridor, tachypnea

or hoarseness, along with altered mental status, agitation, anxiety or obtundation are indicative of inhalation injury. Many pediatric patients with inhalation injury will develop progressive respiratory failure, tachypnea, hypoxia, and cyanosis after resuscitation, even when appearing normal upon initial presentation. To compound matters, noninvasive monitoring of pulse oximetry in burn patients can be misleading. For this reason, laboratory and invasive studies are pertinent to diagnosis. Initial laboratory studies should include arterial blood gas (ABG) analysis and measurement of carboxyhemoglobin. A PaO_2/FiO_2 ratio less than 300 on completion of resuscitation is indicative of significant inhalation injury,[69] along with possible early evidence of acute lung injury. Albeit controversial, this ratio has been proposed as an indicator of poor outcome in burn patients.[70-73] ABG values may suggest a diagnosis with demonstration of either respiratory or metabolic acidosis, but are often misleading, especially if values are within normal limits. Carboxyhemoglobin values should be correlated with time from injury and oxygen therapy provided in the interim. The half life of CO is 240 to 320 minutes, decreasing to 40 to 80 minutes with 100% normobaric oxygen.[74] If suspected, blood cyanide levels should be also drawn.[75]

Chest radiographs and computed tomography scans are insensitive for the diagnosis due to a relatively normal lung and airway appearance early in the clinical course.[76,77] Repeat studies over time may demonstrate development of pulmonary edema or ARDS. Xenon-133 scanning may demonstrate trapping or delayed excretion of the isotope within injured lungs.[78] This technique is limited by availability of technology and technical expertise, and is oftentimes used as a confirmatory test where other methods have yielded inconclusive results.[69] Fiberoptic bronchoscopy is the gold standard for the diagnosis of inhalation injury. Direct visualization of the supraglottic and infraglottic airway allows quantification of hyperemia, exudate, mucosal sloughing, edema and presence of carbonaceous material. In a study spanning a 10-year period, 71% of pediatric patients with inhalation injury were diagnosed using bronchoscopy versus 25% by history/clinical exam alone and 4% by carboxyhemoglobin levels.[56] In some cases, fiberoptic bronchoscopy can be therapeutic with removal of excessive exudate, plugs or casts followed by placement of an endotracheal tube.[79]

Management of Inhalation Injury

Inhalation injuries can quickly progress to obstruction, hypoxia and death, so timely endotracheal intubation is required. In pediatric patients, small sized airways, the inability to perform bronchoscopy, and an increased likelihood of adverse events necessitate early endotracheal intubation. When endotracheal intubation is not indicated, nasopharyngeal airways should be considered. Oxygen therapy at an FIo_2 of 1.0 should be initiated immediately to treat increased carboxyhemoglobin levels and provide maximal oxygen delivery to peripheral tissues. Duration of oxygen therapy depends on patient condition and can be quantified by documenting return of carboxyhemoglobin levels to below 10% and normalization of acidosis.[80] Continuous pulse oximetry is used after carboxyhemoglobin levels have normalized.

Following endotracheal intubation, the acute burn patient with inhalation injury may benefit from either a volumetric diffusive respiratory (VDR) mode or an airway pressure release ventilation (APRV) mode of ventilation. The choice of mode is dictated by patient condition, clinician and staff familiarity, and treatments required (i.e., repeat bronchoscopy, inhalation agents). The use of high-frequency oscillatory ventilation may complicate treatment in the patient with inhalation injury due to inability to provide inhaled agents at proper doses or to perform regular bronchoscopy.[81] The VDR (Figure 111-3) provides ventilation and oxygenation with a decreased mean airway pressure, reducing the risk of barotrauma. The mechanism involves high-frequency ventilation with progressive accumulation of subtidal breaths and passive exhalation once a set airway pressure is met,[82] allowing for gas exchange through more recruited alveoli. The amplitude of subtidal breaths correlates with peak inspiratory pressure and the frequency of subtidal breaths is adjusted to maximize oxygenation. By altering the I/E ratio, a diffusive (lower I/E) or percussive (higher I/E) flow wave is created. In a small prospective study of pediatric burn patients, Rodeberg et al. demonstrated increased Pao_2, increased Pao_2/FIo_2 ratio, and decreased mean airway pressure, all without affecting hemodynamic function.[82,83] Long term, this mode has been shown to decrease pneumonia and mortality compared to individuals treated with conventional modes of ventilation.[84-86] APRV (Figure 111-4), in its most simple form, is a reverse I/E method of ventilation with two levels of PEEP support. High PEEP is continuous during a prolonged inspiratory time, providing for adequate oxygenation and recruitment of closed alveoli. Low PEEP is exerted during expiration and facilitates ventilation while maintaining recruitment of alveoli. The benefit to patients is reduced barotrauma, improved oxygenation and ventilation due to improved V/Q matching, and decreased sedation and paralysis requirements because of patient comfort. Unlike the VDR, there is no percussive component involved; however, the external movement of secretions may occur through another mechanism.[87] While data exist supporting the use of APRV over conventional modes of ventilation in surgical intensive care and trauma patients, randomized control trials have not been completed in burn patients.

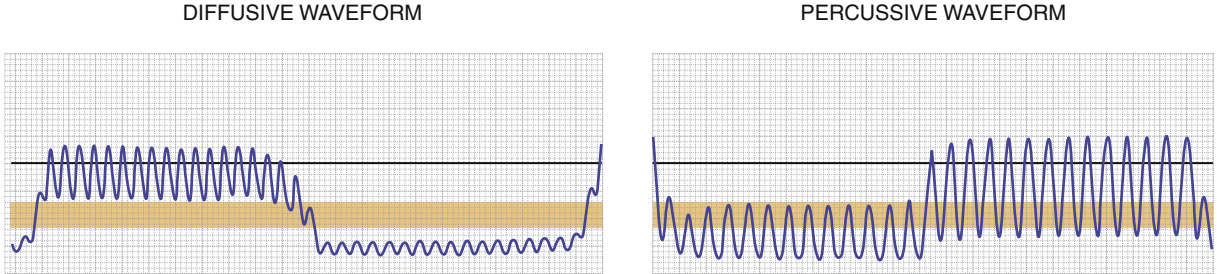

Figure 111–3. Volumetric diffusive respiratory ventilation pressure-time tracings. Percussive and diffusive waveforms from a pediatric burn patient volumetric diffusive respiratory ventilator at Shriners Hospital for Children–Cincinnati.

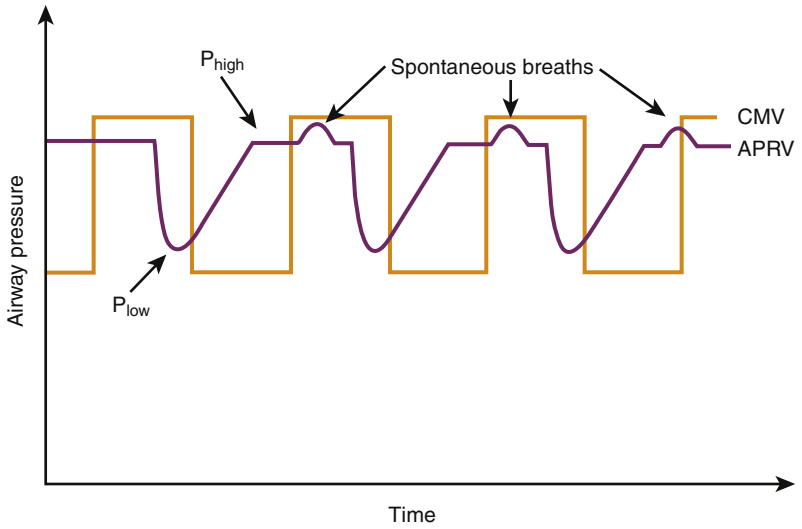

Figure 111–4. Airway pressure release ventilation and controlled mechanical ventilation pressure-time tracing. *(Modified from Fan E, Stewart TE: New modalities of mechanical ventilation: high frequency oscillatory ventilation and airway pressure release ventilation,* Clin Chest Med *27:615-625, 2006.)*

Venovenous extracorporeal oxygenation (ECMO), or extracorporeal life support (ECLS), is more commonly used in the nonburned neonate with respiratory failure. However, its use is documented in burn patients refractory to conventional ventilation strategies. Kane et al. found that nonsurvivors had greater peak and mean airway pressures prior to onset of ECLS,[88] but scattered reports throughout the literature document minimal success using this method in patients with inhalation injury when survival is used as the endpoint.[89-91] Although the technical limitations involving education, staffing and equipment preclude widespread use of this strategy, it remains an option for clinicians.

Appropriately trained respiratory therapists are invaluable in the management of burn patients and are a mainstay in specialized burn care units. Together with ventilatory management, other adjunctive therapies such as aggressive pulmonary toilet, nitric oxide, nebulized heparin, *N*-acetylcysteine, and/or bronchodilators may be used. Inhaled nitric oxide is an ultra short-acting vasodilator used in the treatment of pulmonary hypertension that works by increasing cyclic guanine monophosphate in smooth muscle.[92] Limited studies in burn patients have demonstrated variable improvement in Pao_2/FIo_2 ratios and improved survival in those patients who respond to treatment.[93] If a response is not demonstrated between doses of 5 and 20 ppm of nitric oxide within 60 minutes of treatment onset, the patient is unlikely to respond and therapy should be discontinued due to futility and cost.[93] Inhalation injury has been shown to result in fibrin deposition within the airways, solidifying and leading to obstruction (hence the need for aggressive pulmonary toilet).[94,95] Nebulized heparin and tissue plasminogen activation have demonstrated potential efficacy in both animal and human studies through breakdown of fibrin deposition with maintenance of alveolar structure and reduced airway obstruction.[95] The mechanisms by which aerosolized heparin exerts a beneficial effect in inhalation injury are as yet undetermined, but may be related to breakdown of fibrin casts and reduction in the inflammatory response from neutrophil migration into the airways.[96] *N*-acetylcysteine was noted to decrease leukocyte number in bronchoalveolar lavage and MPO in rat lung tissue, supporting the conclusion that *N*-acetylcysteine may ameliorate tissue damage after inhalation injury.[97] Although survival benefit has not clearly been demonstrated with use in ARDS and acute lung injury (ALI),[98] evidence exists for attenuation of lung inflammation.[99] β-Adrenergic agonists are widely used in treatment of lung conditions including asthma and ARDS/ALI. The aerosolized delivery of specific β_2-adrenergic agonists produces preferential effects including bronchodilation, attenuation of lung inflammation and potentially increased fluid clearance with limited systemic cardiac activation.[100] One retrospective review of burn children showed increased Pao_2/FIo_2 ratios, improved compliance and pH during treatment with continuous albuterol therapy.[100] Well-designed clinical trials are needed to further elucidate those adjunctive therapies most likely to improve morbidity and mortality in pediatric inhalation injury patients.

Perhaps most controversial in the management of inhalation injury is the use of corticosteroids. Although clearly beneficial for many chronic pulmonary diseases including asthma, benefits in acute pulmonary inflammation related to inhalation injury and ARDS have not been definitively demonstrated.[101-103] Corticosteroid therapy has been shown to increase mortality (from 13% to 53%) and complication rates (from 31% to 82%) in at least one study.[80] However, more recently Meduri et al.[104] demonstrated the potential utility of methylprednisolone given for 28 total days with fewer days on ventilator, a shorter ICU stay, fewer infections and increased survival. Until larger prospective studies are completed, corticosteroids for inhalation injury should be used with caution.

Nutritional Support in Burn Patients

Nutritional support of the pediatric burn patient is important for prevention of malnutrition, adequate wound healing, and moderation of the pro-inflammatory response induced by a hypermetabolic state. For the burn patient, a multitude of protocols exist for determining patient caloric requirements, onset of feeding, and choice of vitamin supplementation.

Box 111–2 Mayes Equations to Calculate Energy Requirement After a Burn

Mayes equation for a 5- to 10-year-old burn patient with injury <50% TBSA:

$$818 + 37.4\ (\text{weight in kilograms}) + 9.3 \times \%\ \text{TBSA burn}$$

Mayes equation for a 5.5-year-old patient with a 45% TBSA scald burn weighing 20 kg:

$$818 + 37.4\ (20\ \text{kg}) + 9.3 \times 45\ \%\ \text{TBSA scald}$$

$$818 + 748 + 481.5 = 2047.5\ \text{calories/day}$$

Burns induce a hypermetabolic state that may persist for up to 12 months after injury.[105,106] Although exact mechanisms remain unclear, levels of epinephrine and norepinephrine are known to be greatly amplified following a large burn with subsequent increases in stress hormones. Theories suggest the bulk of metabolic disturbances occur secondary to inflammation stimulating the hypothalamus with resultant increases in the temperature set point and production of catecholamines.[107] Pediatric patients are more susceptible to adverse changes in carbohydrate, lipid and amino acid metabolism, made worse by the propensity of children to lose more body heat via a thinner dermis. The systemic response to burn includes increased oxygen consumption, increased protein catabolism, increased lipolysis, culminating in decreased lean body mass, poor wound healing, and worsened host defense if appropriate nutrition is not maintained.

Calculating Nutritional Requirements

It is commonly assumed that hypermetabolism is directly related to burn size, but more than likely it is related to stress hormones as described previously.[107] In pediatric patients, plotting of weekly weights on an appropriate growth curve aids in estimating caloric requirements. Numerous equations have been developed to estimate the energy requirements of pediatric burn patients, although no single standard currently exists.[108-120] At our institution, we use the Mayes equation, which takes age, weight, and % TBSA burn into account (Box 111-2). Most formulas overestimate caloric requirements compared with indirect calorimetry, long considered the gold standard for calculating resting energy expenditure (REE). Indirect calorimetry is the preferred method to adjust nutritional support.[69] Total energy requirements can be estimated as 120% to 130% of REE.[69] Respiratory quotient, the measurement of VCO_2/VO_2 from indirect calorimetry, has proven unreliable in evaluating the nutritional status of burn patients with regards to under or overfeeding.[121] In children, carbohydrates should account for 60% to 70% of energy requirements while fats should account for 15% to 20%. Protein requirements vary from 2.5 to 4 g/kg/day.

The implications of correctly computing resting energy expenditure and caloric requirements involve prevention of overfeeding or underfeeding burn patients. Overfeeding results from excessive carbohydrate or fat intake, both of which are detrimental to the critically ill burn patient. Carbon dioxide production is increased following excessive carbohydrate consumption with subsequent respiratory abnormalities that interfere with pulmonary function and weaning from mechanical ventilation.[122,123] Excessive carbohydrates also lead to increased fat stores, hepatic dysfunction, hyperglycemia, dehydration via osmotic diuresis, and poor wound healing.[69,107,123] Although burns promote augmented protein catabolism, too much protein does not help offset catabolism, but may actually increase it.[123] Although some studies have demonstrated improved survival and reduced hospital stay with underfeeding of nonburned critically ill patients,[123] the bulk of burn literature supports early feeding to prevent malnutrition. Early feeding also promotes wound healing, mediation of inflammation, suppression of the hypermetabolic response, and reduction of sepsis-related morbidity and mortality.[124]

Monitoring Nutritional Status

A multitude of blood tests have been advocated together with indirect calorimetry for monitoring of nutritional status. Visceral proteins have proven better as prognostic markers than as indicators of protein status in acute burns.[120] Albumin is a poor surrogate for nutritional status as serum concentrations are known to fall as a result of burn. Albumin replacement below certain levels maintains no scientific basis as it does not stimulate production of endogenous albumin, nor has replacement been shown to have any clinical benefits regarding pulmonary function, wound healing, gastrointestinal function or mortality.[107] Prealbumin is advocated for long term monitoring of patient nutrition as it is a distinct marker for protein synthesis. It has a relatively short half-life, allowing the clinician a more sensitive marker for patient nutritional support. An absolute value lower than 15 mg/dL is consistent with malnutrition, but the physician must take into account the organ function of individual patients in interpreting prealbumin levels in pediatric patients. Static measurements of serum concentrations of nutritional markers such as transferrin, carotene, iron, and calcium are likely unreliable indicators of nutritional status in burn patients.[125]

A known aspect of the hypercatabolic response in burn injury involves an increased and sustained release of acute phase reactants from the liver, resulting in an exaggerated release of pro-inflammatory mediators that may contribute to multiple organ dysfunction.[126-128] Hyperglycemia occurs in most burn patients regardless of injury severity because of increased rate of glucose production and impaired tissue glucose extraction.[129,130] Insulin may serve dual functions in burn patients, both in its anabolic effects and ability to lower hyperglycemia. Jeschke et al. have demonstrated modulation of the inflammatory response with tight glucose control using insulin through mediation of hepatocyte apoptosis, which allows for improved hepatic function.[126]

Enteral Support

Enteral feeding is a mainstay of nutritional support in pediatric burn patients and is considered the ideal route for caloric and nutrient supplementation. Studies have shown enteral support helps maintain intestinal integrity following burn injury. Maintenance of gut integrity, in which glutamine plays a role,[131,132] is hypothesized to reduce the risk of bacterial translocation that may contribute to burn sepsis, while also

allowing for the appropriate absorption of nutrients required for wound healing.[131] The role of specialty amino acids, proteins and fatty acids present in commercial tube feed preparations for pediatric burn patients is controversial, as studies have both shown improvement in end point outcomes[133] and no effect on outcomes.[134] If the patient's caloric intake by mouth will be inadequate at 5 to 7 days after injury, the clinician should place a feeding tube. At our institution, nasoduodenal feeding tubes are routinely placed under fluoroscopic guidance to reduce the risk of perforation or incorrect positioning. After pyloric placement is confirmed, enteral feeds are then initiated at low rates, customarily 10 to 20 mL/hr. The speed at which tube feedings are increased is multifactorial. Working closely with a dietician will aid in starting the correct tube feed at the appropriate concentration and rapidly achieving the goal rate. The dietician is also invaluable in adjusting enteral supplementation based on clinical parameters and indirect calorimetry.

Although many clinicians anecdotally feel early enteral feeding is beneficial, some have questioned this practice in light of data suggesting lack of benefit and a possible increase in complications. In nonburn animal models and adult patients, calorie restriction has been demonstrated to be potentially beneficial.[123] Studies demonstrating reversal of hypermetabolism and hypercatabolism in burn animals have not been replicated in humans. Possible reasons for this include inability to realistically start "early" enteral feeding (i.e., within 1 to 2 hours of burn), or that the body's response to burn injury causes cellular changes in humans which are not present in the current animal burn models.[124] Mediation of inflammation from early enteral feeding has also been difficult to demonstrate in burn patients, contrary to animal experiments.[124] Studies evaluating improvement in clinical measures such as decreased length of stay, decreased incidence of infection and decreased mortality have also not conclusively been shown[120] when compared to later onset of enteral feeding (>72 hours). The risk of adverse events from technical errors in tube placement, aspiration, and intestinal necrosis must also be taken into account. In a prospective, randomized trial, Gottschlich et al.[124] found that four of five patients who developed an abdominal catastrophe from intestinal necrosis were in the early feeding arm of the study. Interestingly, intestinal necrosis has been shown to not always correlate with vasopressor support. This may be due to increased hypotensive episodes during early burn resuscitation, altered gut blood flow during burn shock, and increased blood flow requirement in the intestine when being fed.[124] Despite some of these concerns regarding early enteral feeding, initiation upon patient stabilization is considered standard of care in the pediatric burn patient.

Parenteral Support

Parenteral nutrition (PN) is considered a mainstay of therapy for many critically ill patients. In burn patients, central venous PN is reserved for individuals unable to tolerate enteral feedings from severe diarrhea or an organic gastrointestinal problem. Complication rates increase when burn patients are placed on PN because of line infections. Peripheral parenteral nutrition (PPN) is not an option because lack of adequate calorie delivery and high risk of peripheral access damage from PPN extravasation.

Vitamin and Anabolic Steroid Supplementation

Although supplementation is poorly understood in children, guidelines and dosages from the National Advisory Group/American Medical Association are customarily followed. Fat-soluble vitamins are more slowly depleted and less apt to be replaced compared to water-soluble vitamins such as B and C. The exceptions for fat-soluble vitamin replacement are vitamins A and D. Vitamin A has been shown to aid wound healing following burn injury.[135] Replacement of vitamin D, together with calcium supplementation, is required for adequate bone formation in children. Vitamin C plays a vital role in collagen synthesis and wound healing, necessitating its supplementation. There are some reports of replacing trace elements, often done when TPN support is given to critically ill patients. Interestingly, wound exudates were found to be the primary site of loss for trace elements,[136] suggesting burn patients may require replacement more than other critically ill patients. The trace element zinc is involved with wound healing and some reports suggest decreased zinc levels in septic patients are associated with subsequent adverse events.[69] For these reasons, zinc supplementation is often included as part of enteral nutrition. More studies are needed to determine the role of trace element supplementation in pediatric burn patients.

Because of hypercatabolism in burns, lean body mass is lost even with adequate nutritional support. Negative nitrogen balance is often seen during the first 1 to 2 weeks after burn.[120] To combat this, studies have demonstrated the effectiveness of anabolic agents such as oxandrolone in restoration of lost lean body mass and improved wound healing.[69] These results are controversial with regards to impact on the course of burn disease,[120] so anabolic steroids such as oxandrolone are not universally used in the management of pediatric burn patients.

Wound Care

Burn wounds will "evolve" over time based on factors ranging from mechanism of injury to fluid resuscitation, sometimes requiring 10 to 14 days for complete demarcation. It is not uncommon for previously diagnosed superficial partial burn wounds to demarcate as full thickness burns many days following the initial presentation. If the burn wound is improperly managed and allowed to desiccate or become infected it will convert to a deeper wound requiring definitive surgical management. Cleansing and debridement of the wound is absolutely essential for proper diagnosis of size and depth. This is accomplished with mild soap and water, or in the specialized burn center, chlorhexidine/normal saline washes may be used. Pain should be effectively controlled to allow for complete debridement of all necrotic tissue. Although there exists some controversy regarding the treatment of blisters, most burn experts recommend debridement of all blisters unless smaller than 0.5 cm or in a difficult to manage area. This reduces the risk of bacterial colonization or infection that will delay appropriate wound healing.

Burn wounds become colonized in the first few hours with gram-positive bacteria such as *Staphylococcus aureus* and *epidermidis,* and are predominantly colonized with gut flora such as *Pseudomonas aeruginosa, Enterobacter cloacae,* and *Escherichia coli* by 5 days. Health care workers involved with

the cleansing and debridement of burn wounds must be vigilant in hand washing and maintenance of a clean environment around the wound for prevention of cross-contamination in these immunocompromised patients. Culture swabs of all wound beds should be obtained on arrival and on a scheduled basis to monitor for changes in colonization. Quantitative cultures of burn wound invasion are best obtained by tissue biopsy, either in the operating room or at bedside. Bacterial colonization of burn wounds does not require systemic antibiotics, but should be managed with early debridement, appropriate topical and/or biologic dressings, and scheduled dressing changes. After cleansing and debridement, topical antimicrobial therapy is initiated even if early excision and grafting will be performed. Topical therapy is not intended to sterilize the burn wound, but to control colonization. Agents are applied twice daily after repeat cleansing and debridement. Upon placement of topical agent, several layers of gauze and sterile dressings are used for coverage with a resultant decrease in evaporative water losses and metabolic rate.[137] The choice of topical agent depends on the depth and extent of the wound being treated. Minor burns, including superficial and small superficial partial burns, can be managed with any triple antibiotic ointment, biologic dressing or silver-coated dressing. Superficial burns can also be treated with moisturizing creams such as Eucerin or aloe. Superficial partial-thickness burns to the face are treated in a similar fashion. Nonadherent gauze or petroleum gauze can be placed over tribiotic topical agents to provide a comfortable, protective environment that promotes epithelialization. Perhaps the most commonly used topical agents are silver sulfadiazine (Silvadene), mafenide acetate (Sulfamylon), and silver nitrate. Silvadene has been used in burns for decades and continues to demonstrate effective control of burn wound colonization against a continually widening spectrum of bacteria. It is easy and painless to apply, a benefit for both in- and outpatient treatment. Drawbacks include minimal eschar penetration and complications related to leukopenia and red blood cell hemolysis.[138] Mafenide acetate cream (Sulfamylon) is also easy to apply, but is rather painful in superficial partial burns. Eschar penetration is greatest using this agent, making it the topical of choice in burns where eschar will not be excised immediately. Its antimicrobial activity includes control of *Pseudomonas aeruginosa*, a common colonizing bacterium in pediatric burn patients. Sulfamylon is a carbonic anhydrase inhibitor so complications related to metabolic acidosis may occur. Although the above two agents are used most often in care of pediatric burns, silver nitrate 0.5% solution has fallen out of favor due electrolyte abnormalities and poor tissue penetration.

The use of topical antimicrobials has been called into question because of the need for frequent dressing changes resulting in traumatized epithelialization and delayed wound healing. Silvadene in particular has been shown to delay wound healing due to direct toxic effect on keratinocytes.[139,140] Newer agents such as hydrocolloid, hydrogel and polyurethane film dressings provide effective humidity and control of exudate, but are lacking in antimicrobial coverage. Silver-impregnated dressings such as Acticoat, Mepitel, and Mepilex provide combined antimicrobial coverage, adequate humidity for the wound, and decreased trauma to healing wounds with less frequent dressing changes. Biosynthetic substitutes such as Biobrane are marketed as epidermal substitutes that allow for faster reepithelialization.[141] These agents are useful for very superficial partial burns seen early in a burn center before bacterial colonization has taken place.

The previously described topical therapies are used in the outpatient pediatric burn setting. Inpatients, while often treated with similar therapies, are also managed with surgical excision and placement of xenograft, allograft, autograft or cultured epithelial autografts (CEA). Placement of skin substitutes and replacements requires adequate wound bed excision and preparation. Use of these materials on eschar or an improperly prepared wound bed will lead to graft loss and prolongation of definitive therapy. Although no consensus exists on the timing of burn wound excision, most experienced burn surgeons advocate early wound excision within the first 1 to 5 days after thermal injury to attenuate the inflammatory response of burn and reduce the risk of sepsis.[142-145] At our institution, a staged approach is often taken for more extensive injuries whereby the wound is excised and controlled on day one with subsequent donor site harvest and grafting on day two. The benefits of this approach include shorter operations, tighter temperature control and ability to perform sheet grafting through improved hemostasis. Prior to wound excision an operative plan is made dictating prophylactic antibiotic coverage, units of blood on hold, and type of wound coverage agent to be used.

Xenograft (pig skin) is a less expensive alternative to allograft (cadaver skin) for coverage of superficial partial burn wounds. It is incapable of engraftment and best used for temporary coverage, providing effective protection that allows for re-epithelialization. Allograft has revolutionized burn care by providing effective, medium term coverage for patients requiring excision without available autograft. Although burn patients demonstrate altered immunocompetence, allograft is typically rejected within 2 to 3 weeks after placement. Similar to xenograft, allograft placed in an infected or highly colonized wound will not engraft, necessitating re-excision and repeat placement. Autograft provides definitive coverage of deep partial and full thickness burns. Donor site selection depends on available areas and extent of burn to be covered. Autograft can be applied as sheet (85% of donor site provides coverage), or mesh 1:1 (110% coverage) and up to 4 or 6:1. Using large mesh grafts more than 2:1 is becoming uncommon even in treatment of large burns because of improved local wound management techniques and availability of synthetic skin substitutes. Cultured epidermal autografts are derived from the pediatric burn patient's own cells and were first successfully used in the 1980s.[146,147] However, these thin grafts are fragile, difficult to work with, take 2 to 3 weeks to grow and usually result in hypertrophic scarring and unstable epithelium. For these reasons, CEAs are considered only for burns involving greater than 85% TBSA. For the past two decades, our institutions has made use of a cultured skin substitute consisting of autologous keratinocytes and fibroblasts grown on a collagen-based scaffold.[148,149] Compared to CEA, there are fewer complications related to placement and healing postoperatively, as well as less hypertrophic scarring and improved aesthetic results. When compared to coverage provided only by autografting, cultured skin substitute allows for reduced autograft harvesting in coverage of burns more than 50% TBSA.[150]

VII Chapter 112

Evaluation, Stabilization, and Initial Management After Multiple Trauma

Steven Elliott and Randall S. Burd

PEARLS

- The primary survey, as defined by Advanced Trauma Life Support, is a prioritized evaluation and management protocol focused on identifying and treating the most life-threatening injuries first.
- Injured children who present to the emergency department can be divided into three categories with respect to initial airway management: those with a patent airway requiring no manipulation, those who have undergone interventions in the field or at another hospital to establish a patent airway, and those who will need intervention to establish a patent airway. The first group is the most common.
- The most effective, objective, and rapid steps in evaluating breathing and adequate ventilation are auscultation of the chest, application of a pulse oximeter for measurement of oxygen saturation, and assessment of respiratory rate.
- The greater physiologic reserve of children makes early identification of cardiovascular compromise more difficult in this group than in adults. Assessment and management of circulatory status in the primary survey is focused on early identification and treatment rather than defining the specific etiology of the shock state.
- Of the three main components of the Glasgow Coma Scale, the motor score has been shown to be the best predictor of outcome after injury.

Trauma is the leading cause of death and acquired disability in children and adolescents, resulting in more deaths in children than all other causes combined.[1,2] Because children with severe injuries can rapidly deteriorate, resources for rapidly identifying and treating injuries are needed immediately on arrival at the receiving hospital. The initial evaluation of injured children in the emergency department ("trauma resuscitation") has two main goals: (1) identify and immediately treat potentially life-threatening injuries, and (2) determine disposition after the trauma resuscitation based on known or suspected injuries. The trauma team must stabilize the child, determine the extent of the injury, and develop an initial treatment plan for the child's hospitalization.

Advanced Trauma Life Support (ATLS) is a protocol developed to standardize the initial evaluation and management of injured patients and avoid omission of potentially lifesaving interventions. The ATLS training program was initiated by an orthopedic surgeon in 1978 in response to suboptimal care that he and his family received in a rural hospital after an airplane crash in a Nebraska cornfield. After 30 years of refinement, ATLS serves as the standard for initial management of injured patients and is now taught to providers around the world.[2] The impact of ATLS on reducing morbidity and mortality after injury has been affirmed in several studies.[3,4] ATLS training is mainly focused on treating the injured adult, but includes modules that emphasis the anatomic, physiologic, and psychological features that make management of the injured child unique.

The first phase of ATLS is the *primary survey* and is a rapid evaluation for identifying life-threatening injuries. The steps include evaluation and treatment of airway injuries (A, *airway*) followed by evaluation of respiratory dynamics (B, *breathing*), evaluation of the patient's hemodynamic status (C, *circulation*), followed by a neurologic assessment (D, *disability*). The final phase of the primary survey (E, *exposure*) is removing the patient's clothing to identify concealed injures and to ensure that the patient is protected from environmental heat loss. The primary survey is then followed by the secondary survey—a detailed head-to-toe evaluation that identifies other injuries. The steps within the primary survey are repeated as needed if the patient's status changes and to monitor treatments given. The initial evaluation and treatment period can usually be accomplished within the first 20 to 60 minutes after arrival to the emergency department. The patient's disposition from the emergency department depends on the type of injuries and the need for treatment and may range from admission to an inpatient or intensive care unit to transport directly to the operating room, transfer to a higher level facility, or discharge.

The initial management of injured adults has been the domain of trauma surgeons; however, the jurisdiction of care for the injured child is not as well defined at many centers. Frequently, pediatricians have an active role in the initial

management and treatment of injured children.[5] While formal ATLS training is not needed for most pediatric providers, this training should be mandatory for those actively involved in the initial evaluation of injured children. At the least, a working knowledge of the evaluation and management steps of ATLS is needed for pediatricians and pediatric specialists who encounter injured patients in an acute care setting. The goal of this chapter is to provide a focused introduction to the initial resuscitation of injured children. This chapter does not serve as a replacement for ATLS training but will instead highlight aspects of the resuscitation that are unique to injured children or may not be emphasized in the ATLS curriculum.

Prehospital Care and Trauma Team Activation

Initial field care, appropriate triage and rapid transport are all aspects of prehospital care that can have an important impact on the outcome in pediatric trauma. Cities and regions have developed trauma systems that coordinate these aspects of care by creating networks of prehospital and hospital providers. The most severely injured children are triaged to the centers within each trauma system that have the personnel, facilities, and equipment to manage these patients. Equally important, minimally injured patients can be directed to nontrauma hospitals to avoid burdening pediatric trauma centers with these patients. Field triage is based on several components including physiological criteria, anatomic injury, mechanism of injury, and underlying medical conditions. Triage criteria have been designed to minimize inappropriate transport of severely injured patients to non-trauma hospitals (undertriage) but achieve this goal at the cost of directing some patients to trauma centers who are only minimally injured (overtriage). Because of the limited time and resources available for evaluation in the prehospital setting, overtriage is an unavoidable aspect of current trauma systems. Injured children who have met criteria for transport to high-level trauma centers by current criteria may be minimally injured and require no specific interventions before discharge from the emergency department. A key aspect of the initial management of the injured child in the emergency department is effectively continuing the care started in the field while avoiding unneeded care for those with minimal injuries.

One approach that has been used in many centers to address the problem of overtriage is the use of a tiered team response in the emergency department.[6] Based on prehospital criteria, patients who are identified as being most at risk for severe injury are met by a full team upon arrival, including a trauma surgeon, emergency department physicians, critical care physicians, anesthesiologists, nurses, and radiology technicians. Patients with a lower likelihood of severe injury are initially met by a smaller team with the option of summoning a larger team if the initial evaluation suggests a severe injury. Centers that have used this approach for team activation have significantly reduced the expenditure of resources on minimally injured patients without any impact on the care received for more severely injured patients.[7]

Trauma Resuscitation

Similar to medical codes, trauma resuscitations are among the most resource-intensive and time-pressured events in any hospital. The severity of the patient's injuries, the number of team members required, and the number of simultaneous evaluation and management steps needed contribute to the complexity of the environment. To manage the complexity of trauma resuscitation, a systematic team-based and process-focused approach is needed to rapidly identify and treat life-threatening injuries and minimize team errors.

Designating a specific room and team for trauma resuscitations helps ensure needed resources are immediately available. A single location ensures that supplies (e.g., emergency airway kits, chest tube and thoracotomy trays, and central or intraosseous vascular access kits) are available and that team members know to gather at a specific site. Physicians, nurses, radiography technicians, respiratory therapists, and other hospital personnel needed for trauma resuscitation are identified in advance as trauma team members and assemble and assume their roles in the resuscitation area upon arrival of the injured child (Figure 112-1). These seemingly simple preparations ensure that the arriving patient has the maximal resources available at the receiving hospital.

Before arrival to the hospital, prehospital providers transmit information to hospital providers about the mechanism of injury, the status of the patient, and initial treatments given. This information can alert the team to prepare specific equipment or resources or to summon other essential personnel. Before the patient arrives, it is good practice for the team to review prehospital information to ensure all team members are aware of the patient's status and anticipated needs. A "time out" or quiet period facilitates this information transfer. Upon arrival to the emergency department, an additional and final exchange of information between the prehospital providers and the trauma team occurs. Essential elements that should be obtained in this report include details about the injury event, vital signs obtained at the scene and during transport, pertinent physical findings, and the initial treatments administered and response to these treatments.[8] Allowing the prehospital providers to give their report before starting the patient evaluation or even transferring the patient to the emergency department gurney improves information exchange and prevents repetitive questions later in the resuscitation. Obtaining a record of the prehospital event completes the formal information exchange between prehospital and in-hospital providers. These records can contain critical information for early in-hospital management but often are not immediately obtained because prehospital providers are moving on to their next assignment and the trauma team is focused on direct care of the patient.

The Primary Survey

Overview

The primary survey, as defined by ATLS, is a prioritized evaluation and management protocol focused on identifying and treating the most life-threatening injuries first. This approach is different from the traditional initial evaluation in a patient where an extensive history and physical exam is performed before diagnosis and treatment. The steps of the primary survey are taught in the ATLS course as a sequence followed by one provider with one nurse assistant. In actual practice, most centers have a team of providers rather than only two, allowing the evaluation and management steps to proceed forward even if one step leads to a delay. For example, a relatively more time-consuming step such as placing an intravenous catheter

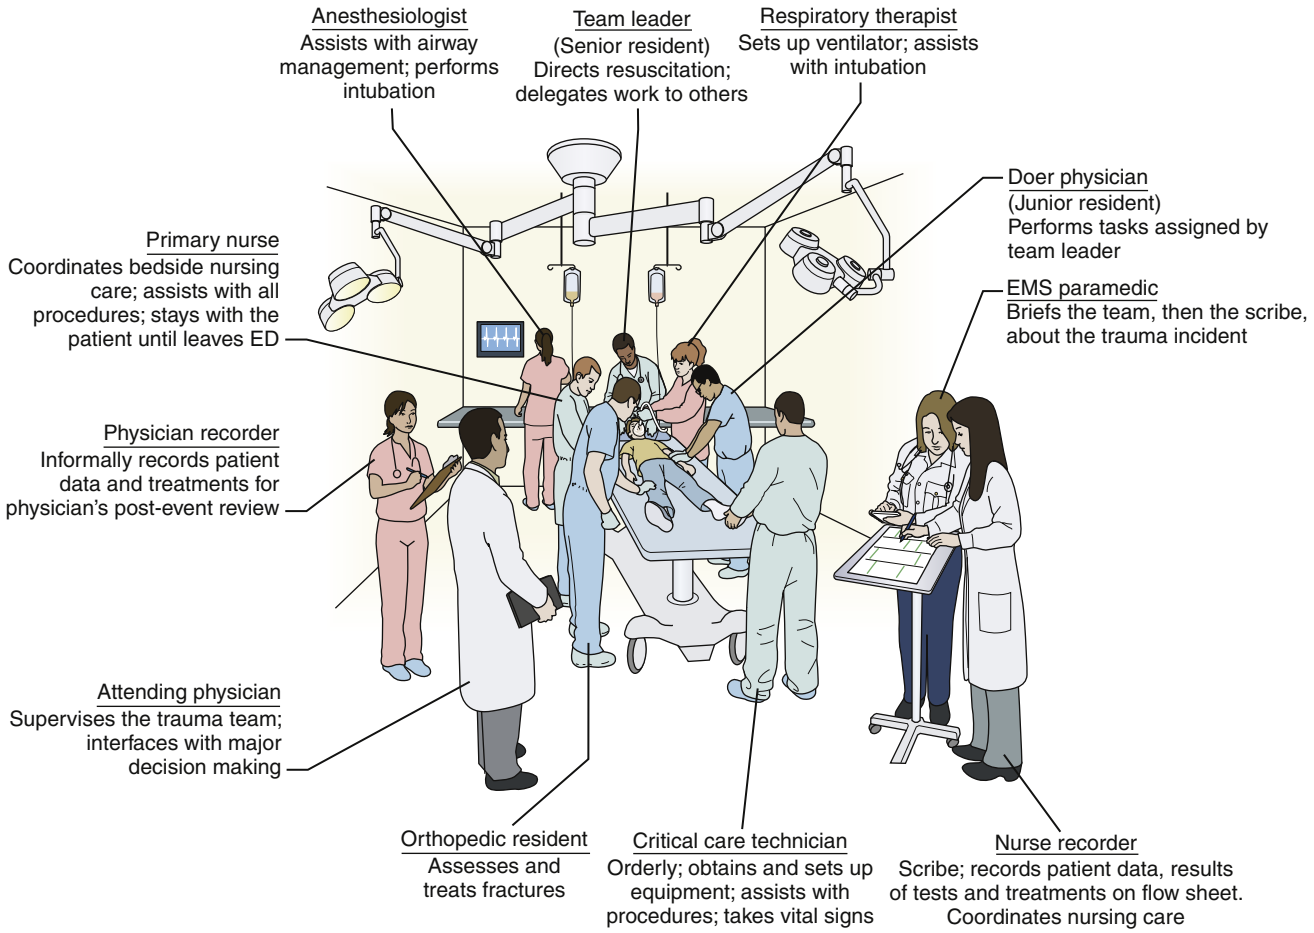

Figure 112–1. The trauma room and team. *(From Sacrevic A, et al:* Quantifying adaptation parameters for information support of trauma teams. *CHI 2008 Proceedings.)*

can be performed by one team member while others move on to subsequent steps in the primary survey. The typical model used at many trauma centers is to have a single provider on the team perform and report the components of the primary survey, supported by other team members as it is conducted. A designated team leader stands at the foot of the bed, receives information reported by the team and provides higher level direction of the conduct of the resuscitation. While the steps of the primary survey provide the framework for the initial assessment, new information may be obtained in later phases, or a patient's status may change, requiring iterative performance of each step. It is often a challenge to ensure the team retains its focus on the underlying prioritization scheme of the primary survey and does not omit or minimize steps in this process (Figure 112-2).[2] When resuscitations are evaluated, compliance with ATLS protocols is often low, mandating continued training and retraining to ensure the well-established benefits of this protocol are realized.[9]

Establish an Airway with Cervical Spine Stabilization (A)

Establishment of a patent airway with cervical spine stabilization is the first step of the primary survey. All patients should immediately receive oxygen as the evaluation is begun. After oxygen is placed, evaluation of the airway can proceed. Injured children who present to the emergency department can be placed into three categories with respect to initial airway management: (1) those with a patent airway requiring no manipulation, (2) those who have undergone intervention in the field or at another hospital to establish a patent airway, and (3) those who will need an intervention to establish a patent airway. Most children evaluated by the trauma team are in the first group. For these patients, evaluation should include several simple steps including asking the patient's name, inspection for craniofacial injuries, assessment for voice changes, and listening for obvious stridor. These steps can be performed easily and rapidly in most children. A simple statement that "the airway is patent" will communicate to the team these confirmatory steps have been accomplished. Because most injured children will not require any specific airway management, omission of elements of the airway assessment are common in pediatric trauma resuscitation. In a study of pediatric trauma resuscitations analyzed by video review, the most common omission in airway evaluation was not providing supplemental oxygen (omitted in 67% of resuscitations). Fewer than one quarter of resuscitations included a complete assessment of the airway along with assessment of 'breathing,' the second component of the primary survey.[10] Although the patency of the airway may seem "obvious" in many patients, subtle and early signs of pending airway compromise will be missed if a formal airway evaluation is not completed (Table 112-1).

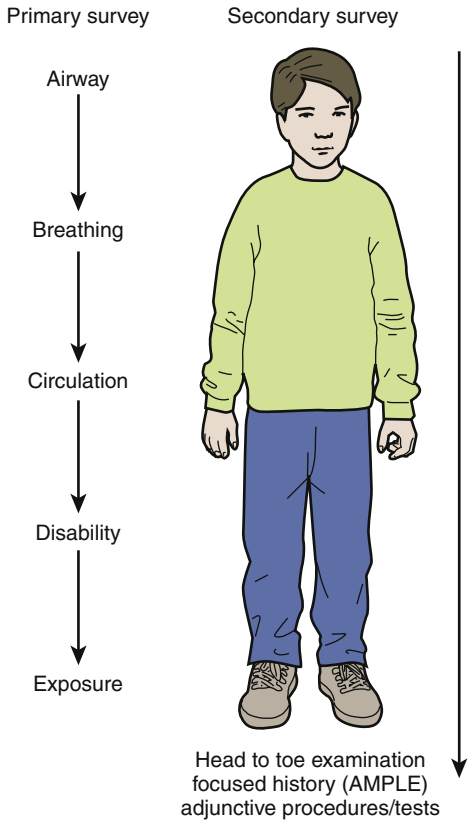

Figure 112–2. Schematic of initial trauma resuscitation.

The second category is children with an airway already established in the field or other hospital, usually by endotracheal intubation. Airway interventions performed prior to a patient's arrival should not be interpreted as an adequate airway and additional steps should be performed to assess airway patency, especially in light of the relative tenuous nature of pediatric airways placed under emergency situations.[11] The key steps to evaluating an endotracheal tube placed outside the emergency department are assessing the appropriateness of tube size, evaluating tube depth, assessing adequacy of ventilation by auscultation and inspection of the chest, measurement of end tidal CO_2, and confirmation of tube position with a chest radiograph. The appropriate tube size can be evaluated using age-specific formulas and charts or by comparing the tube with the child's fifth (little) finger. Deep placement of an endotracheal tube in a prehospital setting is common especially among younger children. Most prehospital providers have more experience with intubating adults, leading to a tendency toward deeper tube placement. In addition, the shorter airway of children increases the likelihood that an endotracheal tube will migrate from the proper position during transport. An easy rule for rapidly assessing tube depth is that the length of the tube at the teeth should be three times the tube size. Age-specific formulas for evaluating endotracheal tube depth are available and are more easily used by providers with greater experience in management of airways. Assessment that the endotracheal tube is an adequate airway should include steps that are more formally part of the breathing (B) phase of the primary survey, including assessment of ventilation by auscultation and inspection and measurement of end tidal CO_2. Because of a shorter airway and relatively less margin for movement of an endotracheal tube in younger child, correct endotracheal tube position cannot be reliably confirmed by auscultation of bilateral breath sounds alone.[12] Final confirmation of endotracheal tube position requires obtaining a chest radiograph. In most cases, the chest radiograph should be deferred until later in the resuscitation because simpler and more rapid evaluations can be performed to verify tube position that do not interrupt the conduct of the primary survey. However, a chest radiograph should be performed in the emergency department before transport to other areas of the hospital to avoid the need for airway management in less optimal hospital settings.

The final category of injured children undergoing airway evaluation is those who present with airway compromise requiring intervention. Because this category of injured children is least common, clearly defined personnel and procedures are needed to prepare the team to efficiently and safely establish an airway. Indications for endotracheal intubation in pediatric trauma include apnea, inability to maintain a patent airway by other means, need to protect the lower airway

Table 112–1 Missed Components of the Primary and Secondary Survey in Pediatric Trauma Resuscitation: Management Errors Among All Patients (N = 90)

Errors Identified	N (%)
AIRWAY AND BREATHING	
Delay in oxygen therapy	60 (67)
Chest not auscultated	40 (44)
Oxygen saturation not measured	33 (37)
Neck not adequately examined	71 (79)
CERVICAL SPINE	
No head stabilization on transfer	18 (20)
CIRCULATION	
Inappropriate intravenous access	18 (20)
Pulse not assessed	37 (41)
Central capillary refill not assessed	59 (66)
Blood pressure not measured	28 (31)
Fluid bolus not warmed	33 (89)
DISABILITY	
Pupils	22 (25)
Posture	22 (25)
SECONDARY SURVEY	
Perineum not examined	41 (45)
Head not examined	13 (15)
Ears not examined	16 (18)
Mouth not examined	41 (45)
Back not examined	13 (15)
Chest not examined	3 (3)
Abdomen not examined	2 (2)

Modified from Oakley E, Stocker S, Staubli G, et al: Using video recording to identify management errors in pediatric trauma resuscitation, *Pediatrics* 117: 658-664, 2006.

from aspiration of blood or vomitus, impending or potential compromise of the airway, presence of a closed head injury (Glasgow Coma Scale [GCS] score ≤8), and inability to maintain adequate oxygenation with face-mask oxygen supplementation.[2] An altered level of consciousness, usually due to an intracranial injury, is the most commonly observed reason for emergency airway intervention in the acutely injured child. Although a neurologic assessment is performed later in the primary survey, early recognition of children requiring a formal airway because of an altered level of consciousness is essential. The AVPU scale (***a***wake, responds to ***v***erbal stimuli, responds to ***p***ainful stimuli, and ***u***nresponsive) is one model for assessing consciousness that has been found to correlate with the GCS scale and which may be useful for identifying children who are at risk for a compromised airway because of an altered level of consciousness.[13] Patients with an AVPU score of "P" or "U" can be anticipated to have a GCS score of 8 or 3, respectively, and should receive early airway intervention.[14]

Once the trauma team has confirmed the need to establish an airway, the least invasive method for achieving this goal should be chosen. A chin lift and jaw thrust may be sufficient for initially opening the airway in some patients and are simple and rapid steps that can facilitate bag mask ventilation. However, in the presence of a suspected cervical spine injury, only a jaw thrust should be used. Because these maneuvers are not sufficient for long-term airway management, further interventions are usually needed to establish a definitive airway. Small children on a flat spine board may have a partially occluded airway because their proportionately large head forces the neck into a kyphotic position, resulting in upper airway obstruction. Simple manipulation of the young child's head to maintain the plane of the face with the plane of the spine board can improve airway patency, particularly among infants.

When a more definitive airway is needed, the preferred method for establishing an airway in pediatric trauma is orotracheal intubation. A rapid-sequence technique is preferred for most injured children, because intubation is made easier by eliminating protective airway reflexes and safer by preventing aspiration and decreasing physiological stress that can lead to increased intracranial pressure in children with severe head injuries.[15] During intubation, steps should be taken to account for the short length and narrow diameter of the trachea and the narrowing of the trachea at the cricoid ring, including choosing an appropriately sized tube and confirming tube position. While it can be a good option in other settings, nasotracheal intubation is usually not performed for injured children because this technique is more difficult due to the acute angle of the posterior pharynx of the child. Nasotracheal intubation has not been recommended in patients with facial trauma, cerebrospinal fluid leaks, or suggestions of basilar skull fractures, because these injuries suggest the possibility of a disruption between the cranial vault and nasopharynx.[16,17] Laryngeal mask airway (LMA) is also an option for emergency airway management in situations in which endotracheal intubation cannot be accomplished.[17-19] However, as the LMA does not protect against aspiration and cannot be used effectively to provide positive pressure ventilation in patients with altered respiratory compliance or resistance, it should be used only as a rescue technique if the patient cannot be intubated.[20]

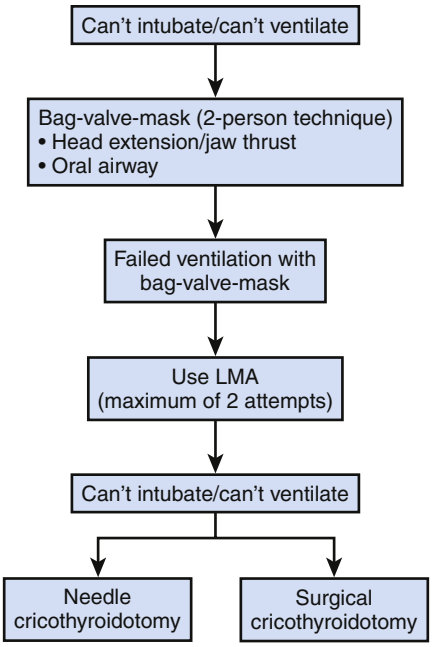

Figure 112–3. Flow chart for "can't intubate/can't ventilate" airway emergencies. *(Modified from Henderson JJ, Popat MT, Latto IP, et al: Difficult Airway Society guidelines for management of the unanticipated difficult intubation,* Anaesthesia *59:675-694, 2004.)*

Fewer than 1% of all adult patients who require an emergency airway in the emergency department require a surgical airway.[21] The percentage of children requiring an emergency airway after injury is likely to be even smaller. Among injured children with a comprised airway, endotracheal intubation may not be possible because of significant craniofacial injuries, massive bleeding from the nasopharynx or oropharynx, or preexisting anatomical features such as a short neck, micrognathia, or small mouth that make intubation more difficult. In this "cannot intubate/cannot ventilate" subset, a systematic approach is needed to rapidly secure a patent airway (Figure 112-3).[20]

If bag-mask ventilation is successful, the team has time to find alternative routes of securing an airway. Examples include attempting fiberoptic intubation or bringing a more experienced physician to the trauma bay to assist with establishing an airway. If bag-mask ventilation is not successful, an appropriate invasive procedure may be required. Among injured children, appropriate options include surgical or needle cricothyrotomy, depending on the child's size. Among children with a larger airway whose cricothyroid membrane is easily palpated, a surgical cricothyrotomy is preferred.[2] If small neck size or other anatomic features preclude the safe placement of a cricothyrotomy, a needle cricothyrotomy with needle jet insufflation of oxygen into the airway is the recommended approach. Surgical cricothyrotomy should be performed by members of the team with experience with this technique. This procedure has four main steps: (1) identification of the cricothyroid membrane, (2) making an incision through the skin and cricothyroid membrane, (3) stabilization of the larynx with a tracheal hook at the inferior aspect of the ostomy, and (4) placement of a tube in the trachea.[22] Training in this technique is now included as part of the ATLS course.

Although controversy surrounds whether needle cricothyrotomy should be used at all in pediatric patients, it is still

advocated by some authorities as a rescue technique in specific clinical scenarios. Needle cricothyrotomy can be performed using commercially available kits. When one is not available, the procedure can be carried out by inserting a large bore (12 to 18 gauge) angiocatheter in a caudal direction at a 30- to 45-degree angle through the cricothyroid membrane. During needle advancement, constant negative pressure is applied to the plunger of the syringe to aspirate air and confirm its endotracheal position.[23] After confirmation of endotracheal placement, the syringe and stylet are removed and the cannula is connected to an oxygen source. Among larger children and adolescents, the cannula should be connected to an unregulated oxygen supply of 50 psi, because ventilation cannot be adequately provided using an ambu bag.[24] While pediatric evidence is limited, a flow of 25 to 35 psi from a standard regulator set at 10 to 12 L/min for most children has been recommended. Another approach that can be used is based on flow rates and estimated tidal volumes (TV): 10 to 25 psi with TV of 340 to 625 mL for children 8 years and older; 5 to 10 psi with TV of 240 to 340 mL for children 5 to 8 years old; and 5 psi with TV of 100 mL for patients who are 5 years and younger.[23] Standard intravenous tubing can be connected to the cannula and a Y connector placed between the intravenous tubing and the oxygen tubing. Intermittent occlusion for 1 second and release of the Y-connector for 4 to 5 seconds provides some passive ventilation. A needle cricothyrotomy is a highly tenuous airway and should be carefully secured after placement and converted to a more stable airway as soon as possible. This approach is only sufficient for 30 to 45 minutes because of the progressive respiratory acidosis that results from underventilation.[2] Because surgical airway management is rarely performed in pediatric patients, centers that manage injured children should have the equipment and adequately trained personnel for performing these procedures when needed.

Cervical spine stabilization should be viewed as part of the "A" step and is included as part of airway management in ATLS. In contrast to intubation in other hospital settings such as the intensive care unit, intubation in the trauma bay should proceed with the assumption that a cervical spine injury is present until this type of injury has been formally ruled out. This step is needed in patients with any mechanism of injury that can be associated with cervical spine trauma. Many injured children present to the emergency department with a cervical collar that was placed in the field because of the mechanism of injury. The initial evaluation of the airway should be immediately followed or simultaneously performed with an assessment of the proper size and fitting of the cervical collar or placement of a cervical collar when one is not present. When endotracheal intubation is required, in-line cervical spine stabilization should be used. A member of the team holds the neck on each side with his or her hands and forearms maintaining the stability of the spine during airway manipulation. Despite the importance of this step, neck inspection and palpation while maintaining C-spine precautions and head stabilization during transfer to the trauma gurney are steps omitted in 80% and 20% of trauma resuscitation performed for injured children, respectively.[10]

Breathing (B)

Establishment of a patent airway is an important initial step but is not sufficient to ensure adequate oxygen delivery. The breathing (B) step of the primary survey is the immediate assessment of ventilation and performance of measures to establish adequate ventilation if it is compromised. The three most effective, objective, and rapid steps in evaluating ventilation are auscultation of the chest, application of a pulse oximeter for measuring oxygen saturation, and assessment of respiratory rate. Because patients are supine during the primary survey, auscultation is limited to sites on the anterior and lateral chest. Auscultation should be performed in both these areas to obtain the most accurate evaluation of ventilation. Localizing abnormal ausculatory findings to a specific region of the chest can be more difficult in younger children because of smaller chest size and the usual supine position of the injured patient during the primary survey. However, in most children, auscultation can be used to identify significant compromise in ventilation requiring lifesaving intervention. These steps can be supplemented by a subjective evaluation of the adequacy and symmetry of chest wall movement and an evaluation for evidence of chest wall trauma. Because of the pliability of the chest wall of younger children, significant chest injury may be present even in the absence of any chest wall deformity.

A main focus of the B phase of the primary survey is on identifying four specific thoracic injuries that can significantly impair ventilation and that require immediate treatment: (1) tension pneumothorax, (2) open pneumothorax, (3) flail chest with pulmonary contusion, and (4) massive hemothorax. The diagnosis of a tension pneumothorax should be made on clinical criteria, including tracheal deviation, unilateral absence of breath sounds, neck vein distention, tachycardia, hypotension, and respiratory distress. Delaying treatment to obtain a confirmatory chest radiograph should be avoided because of the time delay associated with processing, and interpreting this study. When the clinical diagnosis of a tension pneumothorax is made, the chest should immediately be decompressed by placing a 14 to 18 gauge, 5-cm needle into the second intercostal space at the midclavicular line. The needle should be sufficiently long to penetrate the chest wall and enter the pleural space. A minimum length of 5 cm is recommended in older children and adults, but shorter needles may suffice in infants and younger children.[2] Proper intrathoracic placement of the needle can be partly confirmed by an audible rush of air when entering the chest. Because needle decompression will convert a tension pneumothorax into a simple pneumothorax, a chest tube will be needed regardless of the response to needle decompression. Advanced prehospital providers are often trained in needle decompression of the chest in the field. If a child arrives after needle decompression, tube thoracostomy placement is also needed for definitive treatment.

An open pneumothorax or "sucking chest wound" occurs when the size of a chest wall injury approaches two thirds the area of the tracheal lumen, causing a preferential pull of air into the pleural space and out of the wound. This injury can lead to mediastinal shift, decreased venous return, and eventual cardiopulmonary collapse. Open pneumothorax is rare in children and is usually the result of a penetrating injury. Airflow through the wound will be audible or can be visualized by bubbling of blood at the wound. A rectangular petroleum jelly/gauze dressing that is occlusive on three sides beyond the wound edge will produce a one-way valve effect that will allow air to escape on expiration but inhibit air from entering the thoracic cavity on inspiration.[25]

Flail chest occurs when a segment of the chest wall has lost continuity with the movement of the thoracic cage, occurring

when two or more ribs are fractured in two or more positions. The pediatric thoracic cage is more compliant than adults and rib fractures are not always present when parenchymal injuries exist. When occurring in infants and young children, rib fractures suggest a significant amount of blunt force to the chest and the possibility of an underlying pulmonary injury. Because fractured ribs can lead to direct lung injury, the presence of a flail chest segment should raise the suspension of a pneumothorax and hemothorax. Due to compromised ventilatory function and underlying pulmonary injury, management of flail chest is focused on providing temporary ventilatory support until the injury heals. Intubation may be immediately needed in the emergency department when ventilation is significantly compromised by this injury.

Significant bleeding may occur with thoracic trauma from intercostal vessels, internal mammary vessels, lung parenchyma, or cardiopulmonary vessels, leading to massive hemothorax. Children with this injury will present with decreased breath sounds and dullness to percussion on the affected side. Eliciting the finding of dullness to percussion can be difficult in a noisy trauma resuscitation area but is a diagnostic feature that can be used to distinguish this injury from a pneumothorax. While the diagnosis is optimally made with a chest radiograph, the team should proceed with immediate chest tube placement if clinical evidence suggests the presence of a large amount of intrathoracic blood. When a massive hemothorax is present, fluid resuscitation or blood transfusion will often be needed. After chest tube placement, the amount of blood initially obtained and the rate of continued bleeding from the tube should be evaluated. A definitive thoracotomy for controlling bleeding from the chest wall, lung, or heart may be indicated if the initial volume exceeds 20% to 25% of estimated blood volume, bleeding continues at a rate exceeding 2 to 4 mL/kg/hr, the rate of bleeding is increasing, or the pleural space cannot be drained of blood and clots. The latter three criteria may be observed after the child is initially stabilized and has been admitted to the hospital.

About 75% of traumatic chest injuries can be treated expectantly or with placement of a chest tube and volume resuscitation.[26] While placement of a chest tube in an injured child is similar to placement in other settings, additional steps should be considered in the injured child. When placing a chest tube for trauma, the tube should be directed posteriorly to allow for adequate drainage of blood in a supine patient. A sufficiently large tube should be selected to allow drainage of blood and fluid without becoming clogged with blood clot. The fifth intercostal space in the anterior midaxillary line is ideal in most patients to prevent placement of the tube through the diaphragm or abdomen but allows sufficient length in the chest for drainage and avoiding later dislodgement. While it is often taught that the lung should be palpated with a gloved digit before tube placement, this verification step may be difficult to perform in infants and small children with smaller intercostal spaces. Confirmation of tube placement in the pleural space can be confirmed in infants and smaller children by the egress of air or blood after placement. Proper tube placement in the thoracic cavity can also be evaluated by observing air condensation on the internal surface of the tube and movement of fluid in the water-seal chamber in time with the patient's respirations when connected to a pressure regulated collection device. When palpating the lung in larger children, the use of double gloves will avoid cross contamination of the patient and the person placing the chest tube that may result from glove tears from broken ribs when palpating a track through the chest wall. A chest radiograph should be performed to verify placement of the tube before leaving the resuscitation area.

Circulation (C)

The "C" step of the primary survey is the assessment, recognition, and management of shock. Because of greater physiological reserve, early identification of cardiovascular compromise can be more difficult in children than adults (Table 112-2). Assessment and management of circulatory status in the primary survey is focused on early identification and treatment rather than defining the specific etiology of the shock state. Determining the site of internal hemorrhage and defining the specific type of shock state are steps that are deferred until after the primary survey. Objective assessment of circulation is done by measuring heart rate and blood pressure, and assessing pulses and capillary refill. In addition to cardiovascular compromise, tachycardia after injury can indicate pain, fear, or other psychological stress. Tachycardia therefore cannot be used as the sole criteria for diagnosing cardiovascular compromise and needs to be combined with other clinical criteria before treatment is initiated. A manual blood pressure measurement should be obtained, using the appropriate size cuff, upon arrival to the resuscitation area. Periodic reassessment of blood pressure should continue throughout the resuscitation to verify the child's hemodynamic status. Palpation of central and peripheral pulses is a rapid method for

Table 112–2 Systemic Response to Blood Loss in Pediatric Patients

System	Mild Blood Volume Loss (<30%)	Moderate Blood Volume Loss (30%–45%)	Severe Blood Volume Loss (>45%)
Cardiovascular	Increased heart rate, weak peripheral pulses	Low normal blood pressure, narrowed pulse pressure, tachycardia, absent peripheral pulses, weak central pulses	Hypotension, tachycardia then bradycardia
Central nervous system	Anxious, irritable, confused	Lethargic, dulled response to pain	Comatose
Skin	Cool, mottled, prolonged capillary refill	Cyanotic; markedly prolonged cap refill	Pale, cold
Urinary output	Minimal	Minimal	None

Data from Committee on Trauma, American College of Surgeons: *Advanced trauma life support for doctors, student course manual,* ed 7, Chicago, 2004, American College of Surgeons.

detecting hypotension and often can be accomplished before a cuff blood pressure is obtained. Because pulses are most likely to be lost in progressive hypotension in the wrist or feet followed by the groin followed by the neck, palpation for pulses in each of these areas can provide a crude estimate of the level of hypotension. Assessment of peripheral perfusion can also include an estimate of capillary refill in addition to a visual evaluation of skin perfusion. Because these latter assessments are more subjective, these should be used only in conjunction with more objective measurements in directing treatment. While assessment of circulatory status is essential to the initial evaluation of an injured child, these steps are often omitted or delayed until later in the resuscitation. During video review of pediatric trauma resuscitations, blood pressure was not measured in 31% of patients, pulses not assessed in 41%, and central capillary refill not assessed in 66% during the initial evaluation.[10]

The two main interventions for managing cardiovascular compromise during the primary survey are controlling external hemorrhage and administration of fluid. Active hemorrhage is easy to recognize and can usually be treated by direct manual pressure or the application of compression bandages. Scalp lacerations are a common source of external bleeding in injured children and the blood loss from this site should not be underestimated. A full evaluation for external hemorrhage, however, is only complete after the child has been exposed completely later in the primary survey.

Administration of fluids requires the establishment of intravenous access. In pediatric trauma, the preferred order of sites depends on the child's age and the urgency of establishing intravenous access. If a percutaneous peripheral intravenous line cannot be established, intraosseous access, percutaneous central venous access, or cutdown on a vein should be considered. Intraosseous access is achieved by placing a needle into the marrow cavity of a long bone in an uninjured extremity. This procedure is rapid, requires minimal training, and is the preferred alternate method of vascular access in infants and younger children. The availability of new equipment and techniques has expanded the use of intraosseous infusions to older children and even adults. Percutaneous placement of a central venous catheter can be pursued as alternate access in older children when equipment for intraosseous access in older patients is not available or when ossification of the long bones precludes placement of an intraosseous needle. Femoral placement of a central line in the injured child has advantages over placement in a jugular or subclavian vein position because it can be performed in most patients without interfering with ongoing assessment and management of other components of the primary survey. However, the femoral route is not recommended if there is a concern of the potential for intra-abdominal injuries. Despite the importance of establishing intravenous access in the injured child for fluid resuscitation and administration of medications, vascular access was not performed or inadequate access was obtained in 20% of recorded pediatric resuscitations.[10]

The goal of fluid resuscitation is to rapidly replace intravascular volume, initially with warmed crystalloid solution and then moving to blood products based on the child's response to crystalloid boluses (Figure 112-4). When cardiovascular compromise is detected, an initial bolus of 20 mL/kg of warmed isotonic crystalloid fluid (lactated Ringer's solution or normal saline) should be administered. Given that it

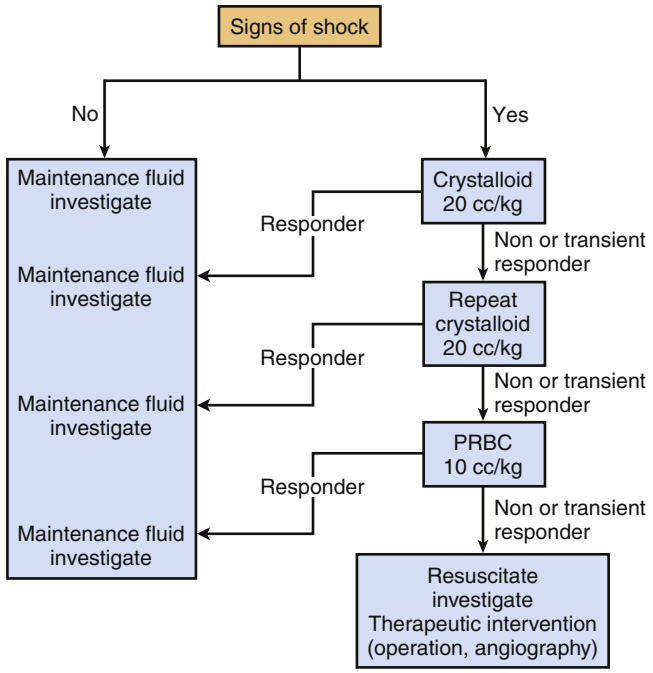

Figure 112–4. Algorithm for pediatric fluid resuscitation.

is relatively hypotonic, Ringer's solution is not recommended for fluid resuscitation in patients with evidence of traumatic brain injury. Fluid administration should not be delayed by slow-rate drip infusion, but instead should be administered as a bolus using a hand-pump device, a syringe, or a pressure bag to ensure that the effect of the bolus and assessment of need for additional fluid proceeds rapidly. If a second bolus of crystalloid is needed, preparations for the potential administration of blood products should begin. If the child responds to fluid administration, intravenous fluid is continued at a maintenance rate as further investigations concerning the need for fluid are performed. If there continues to be no response or transient response to crystalloid, blood administration should be considered. During the primary survey, cross-matched, type-specific blood is often not yet available, and O-negative blood should be administered. Blood should be administered in boluses of 10 mL/kg. The four sites of hemorrhage that can lead to major blood loss after injury include external sites (e.g., scalp laceration), intrathoracic injury, intraabdominal injury, and pelvic or multiple long-bone (usually femur) fractures. While external bleeding can be easily detected, bleeding in other sites is evaluated after the primary survey has been completed.

Disability (D)

The primary survey continues with a neurologic assessment of the child, the disability (D) component of the primary survey. This assessment includes two main components, calculating the GCS and assessment of pupillary responses (Figure 112-5). More extensive neurologic evaluation should be deferred to the secondary survey to avoid slowing the primary survey. As with airway assessment, a formal evaluation of GCS is often omitted when it is "obvious" that no neurologic injury is present. This practice should be avoided because subtle changes may be missed with only a cursory assessment. In addition,

INFANTS	CHILDREN	ADULTS
Best eye opening 4 – Spontaneous 3 – Opens to verbal stimulus 2 – Opens to painful stimulus 1 – No response	**Best eye opening** 4 – Spontaneous 3 – Opens to verbal stimulus 2 – Opens to painful stimulus 1 – No response	**Best eye opening** 4 – Spontaneous 3 – Opens to verbal stimulus 2 – Opens to painful stimulus 1 – No response

Figure 112–5. Components of the GCS at different ages.

establishment of a baseline GCS may have prognostic value among children with an evolving intracranial injury. To account for variations in response related to age, the GCS should be calculated using age-specific criteria. Among the three main components of the GCS, the motor score has been shown to be the best predictor of outcome after injury.[27] Particular attention should be paid to ensure that this component is accurately assessed and recorded. Pupillary assessment includes an evaluation of pupil size and response to light and can easily and rapidly be assessed, reported, and recorded. Findings from the neurologic assessment are used to plan additional evaluation and management steps, including the need for endotracheal intubation, the requirements of additional imaging, and the final disposition after leaving the emergency department. Despite the importance of obtaining a GCS and assessing pupils, these steps were both omitted in 20% of observed pediatric trauma resuscitations.

Exposure (E)

The final step in the primary survey is exposure of the patient, the "E" component of the primary survey. In this phase, clothing is removed to visually inspect all body regions to minimize the chance of missing an obvious injury. A team-coordinated log roll of the child, maintaining cervical spine stabilization, can be used to assess the back and spine for external injury. When rolled on their side, patients are in an ideal position for assessing the spinal column for deformities and tenderness and for undergoing a rectal examination if indicated. While not all of these steps are formally part of the primary survey, the additional time required for them is minimal, leading to the inclusion of these steps as part of exposure in many centers. Immediately after exposing the injured child, the child should be covered again with warm blankets to minimize heat loss. Infants and younger children are particularly vulnerable to heat loss because of a relatively large surface area in relation to body volume. Other measures for warming or maintaining an injured child's temperature include warming the room and the use of overhead warmers or a Bair hugger. The patient's temperature should be obtained at this point, a step that is frequently omitted in the initial evaluation of the injured child.

The Secondary Survey

After completion of the primary survey, the secondary survey is then performed. This includes a medical and event history, a more complete physical examination, and additional adjunct interventions. The secondary survey is less structured than the primary survey and its components and sequence can be modified to reflect patient needs, provider preferences, and institutional practices. The secondary survey should not be performed until the components of the primary survey have been completed and interventions needed to address issues identified in the primary survey have been implemented. It is a common pitfall to move to components of the secondary survey or to mix components of the secondary survey during performance of the primary survey. This practice should be discouraged so as to avoid losing focus on the primary survey and the life-threatening injuries that it is designed to identify. During the secondary survey, attention should be intermittently refocused on vital signs and other monitoring steps of the primary survey. When changes are observed, the primary survey evaluation and treatment steps should be reinitiated to ensure that potentially life-threatening injuries are addressed.

In contrast to a typical history performed during evaluations in other settings, the history performed in the secondary survey is more focused and follows rather than precedes the performance of the physical examination. It is common practice to obtain this information while simultaneously performing the physical examination components of the secondary survey. The most important history elements to obtain are those that most directly impact injured patients and the evaluation and treatments needed for them. The acronym AMPLE is useful for remembering these key elements (***a***llergies,

medications, ***p***ast medical history, ***l***ast meal, and the ***e***nvironment and events related to the injury). Parents or other caregivers are often the best source of this information.

The physical examination contains elements similar to those performed in other settings but should be modified to include steps that identify common and important injuries. Examination of the entire scalp should be performed to identifying lacerations, contusions, or evidence of fractures. Posterior scalp lacerations can easily be missed because of hair or the position of the cervical collar. Massive facial injuries can produce significant facial edema making the eye examination difficult. Because facial swelling most often worsens with time, it is important to obtain an initial eye examination while the patient is in the emergency department. Fractures to the maxillofacial bones including nondisplaced fractures of the nasal bone, zygomatic arch, and orbital rim can be difficult to detect on physical examination and often require radiographic imaging. Examination of the chest in pediatric trauma can be misleading because severe intrathoracic injury may be present without evidence of obvious skeletal trauma. Abdominal injuries should be aggressively sought in children who have sustained a significant blunt injury to the torso. Repeated examinations are often needed to evaluate for the presence or absence of abdominal tenderness in the anxious child after injury.[28]

Examination of the perineum, rectum, and vagina should be focused on detecting direct trauma as well as for detecting evidence of a pelvic fracture. Digital rectal examination may often be omitted in children with no other signs of injury but should be included if the child sustained significant blunt trauma, has other findings suggesting a pelvic fracture, or has neurologic findings suggesting a spinal cord injury. While the rectal examination in adult trauma is used in part to detect the presence of a high-riding prostate that suggests a pelvic fracture, this physical examination finding is rarely detectable among infants and younger children. Any evidence of pain, swelling, or limitation of movement may suggest an underlying fracture and usually warrants radiographic evaluation. The secondary survey should include a more complete neurologic assessment than was performed in the primary survey as well as a formal assessment of sensory and motor functions.

While the secondary survey can be performed in a free-form fashion, a systematic strategy is needed to avoid missing key components of this evaluation. In reviews of pediatric trauma resuscitations, components of the secondary survey that are often omitted include examination of the mouth, ears, back, and perineum. As in the primary survey, findings in the secondary survey should be communicated to the team. The trauma team leader should address the need for tetanus administration (depending on child's vaccine requirements) and antibiotic administration (e.g., for open orthopedic fractures) during the secondary survey.

Missed injuries do occur in trauma resuscitations, which may lead to preventable morbidity during the patient's hospital stay. About 4% of injured children will have an injury missed in the primary and secondary survey. The risk of a missed injury is higher in children with more severe injuries, including those transported by air, those who undergo endotracheal intubation in the emergency department, those with a low admission GCS, and those with an injury severity score greater than 15.[29] Missed injuries have been shown to be reduced with the implementation of a designated pediatric trauma response team, supporting a focused and stepwise approach to the initial evaluation of the injured children.[30] Critical care providers should be alert to the possibility of missed injuries in patients admitted to their unit and not rely on the emergency department evaluation for detecting all injuries.

Diagnostic Assessment

The secondary survey is supplemented by diagnostic testing that focuses on identifying and treating injuries not found in the primary survey. Performance of a standard set of tests is discouraged to avoid unnecessary discomfort, exposure to radiation from excessive imaging, and cost. Injured children may be overtriaged to the resuscitation area and require no additional testing after the primary and secondary survey has been completed. Observation in the emergency department before discharge and close outpatient follow-up is an appropriate option for children identified as low-risk for injury.

Laboratory Studies

Routine laboratory evaluations in pediatric trauma have been shown to be of little value in the management of injured children.[31,32] Among children injured from a significant blunt mechanism, a focused screening set of laboratory studies to identify occult intraabdominal or retroperitoneal injury and hemorrhage has been shown to be sufficient. Based on the current literature, a screening panel that includes aspartate aminotransferase (AST) and alanine aminotransferase (ALT), urinalysis, and hemoglobin will effectively screen for most intraabdominal injuries.[33] The ALT, AST, and urinalysis are screening tests to determine the need for an abdominal CT scan and can be omitted if other clinical indications suggest the need for abdominal imaging. Threshold values of greater than 100 U/L for AST and ALT and more than 5 red blood cells/hpf suggest the presence of an intraabdominal injury and suggest the need for abdominal imaging.

Among children with major head injuries, penetrating trauma, multiple extremity fractures, and significant mechanisms of injury, this panel of laboratory studies may be expanded to include coagulation studies, electrolytes, and blood for cross-matching. Coagulation studies in pediatric trauma are most often abnormal in the presence of severe traumatic brain injury. If obtained early after injury, electrolyte studies are most often normal and serve only as a baseline for a patient who will require aggressive management of severe head injuries or aggressive resuscitation. Blood should be obtained for cross-matching if significant fluid resuscitation has been required, the child has a preexisting condition causing a predisposition to bleeding, has a major head injury, or will undergo a surgical procedure with a potential for a blood loss. Early after injury, pancreatic enzymes do not need to be obtained as a screen for pancreatic injury because of the low diagnostic yield of these studies.[34] Screening tests for alcohol or drug use may be appropriate in older children and adolescent patients.

Radiographic Imaging

Radiographs may be needed to rule out specific injuries or to evaluate known injuries. Imaging in the resuscitation area is often performed with a portable system or with a built-in

system within the trauma room to avoid moving the child. The three most common radiographs obtained are cervical spine, chest, and pelvic radiographs. While these studies are commonly referred to as a *trauma series* and ordered as a set, the performance of all three is often not necessary. The need for each radiograph should be evaluated based on the mechanism of injury and patient symptoms and examination.[35]

A cervical spine injury should be suspected in any child sustaining a significant head injury or injured by a major blunt mechanism. Although cervical spine injuries are rare, these injuries can be devastating and can have worse outcomes when adequate spine precautions are not taken early after injury. A systematic and efficient approach using both clinical and diagnostic modalities is needed to ensure that a cervical spine injury is not present. Implementation of standards for cervical spine assessment and clearance have been shown to decrease the time for cervical spine clearance.[36] Each institution should develop an institution-specific protocol for managing the initial and subsequent imaging of the cervical spine to avoid either incomplete evaluations or excessive imaging. Criteria for cervical spine imaging include midline cervical tenderness, altered level of consciousness, evidence of intoxication, neurologic abnormalities potentially attributable to a spine injury, and presence of a distracting injury precluding a reliable clinical assessment.[37] The cervical spine evaluation in nonverbal children is particularly difficult to asssess. A recent study of this subgroup identified GCS less than 14, GCS eye component of 1, an injury sustained in a motor vehicle crash, and age less than 2 years as important variables associated with the presence of a cervical spine injury.[38]

A cervical spine series consists of a cross-table lateral, an anterior-posterior view, and an open-mouth view to assess the dens process of C1. With adequate films, a three-view series has a high sensitivity (89%) and a negative predictive value of 99.9%.[39] Among these views, the lateral cervical spine film is most useful and has been adopted as the initial screening film at many institutions.[40] If an injury is noted on screening cervical spine imaging, a cervical spine CT or MRI may be needed to further evaluate the injury. If either the clinical or radiographic findings cannot be used to safely rule out a cervical spine injury in the resuscitation area, the child should remain in a cervical spine collar and be evaluated later for the need for further imaging.

Chest radiographs can be often be omitted for children without physical examination findings or symptoms suggesting a thoracic injury.[35] This study, however, should be obtained for children who are injured by a major blunt mechanism such as a high-speed motor vehicle crash or those who have sustained other significant torso injuries. Pelvic radiographs can be safely omitted among children who are awake, alert, and have no physical examination findings or proximity injuries (e.g., a proximal femur fracture) to suggest a pelvic injury. Radiographs of the extremities or other areas may also be needed in the resuscitation area depending on the findings of the primary and secondary survey.

Computed tomography is a powerful and accurate diagnostic tool and has become an integral component of the evaluation of injured patients. Although CT scans can be essential in the evaluation of many children, excessive use is discouraged because of the higher radiation exposure associated with CT scans, rare but important complications such as contrast reactions, and added costs. CT scans are a growing source of medical radiation exposure in children and may contribute to the occurrence of radiation-related malignancy, particularly when performed among younger children.[41]

The two most common body regions imaged with a CT scan in pediatric trauma are the head and abdomen. A noncontrast head CT is performed to assess for closed head injuries and fractures that may require additional treatment such as a depressed skull fracture. The most common indication for a head CT scan after pediatric injury is a history of loss of consciousness or altered mental status. A head CT scan may also be needed for preverbal children whose injury was not observed or those who have received endotracheal intubation or are sedated as they cannot reliably be assessed for a potential head injury.[42-44] A large multicenter trial derived and validated predictive rules to identify children at very low risk of clinically important traumatic brain injury after blunt trauma where a head CT scan may be unnecessary. These prediction rules had a sensitivity of 100% in children less than or equal to 2 years old and 96.8% in children older than 2; negative predictive value was 100% for all ages (Figure 112-6).[45]

Recent emphasis on developing approaches to reduce the need for screening abdominal CT scans in pediatric trauma continues to evolve. Abdominal imaging is indicated when an injury is suggested by physical examination findings such as major abdominal ecchymoses or abdominal tenderness. Among children who sustain a significant blunt injury but do not have physical examination findings suggesting an abdominal injury, the yield of screening abdominal CT scans is low. Screening laboratory tests, however, can be used to reduce unneeded imaging for these children. A multicenter trial is underway that will define the specific studies and study parameters that are optimal for directing abdominal imaging.

While focused abdominal sonogram for trauma (FAST) has been widely adopted as a diagnostic tool for adult trauma patients, its value in pediatric trauma is less certain. FAST is focused on identifying fluid in four areas, the presence of which is suggestive of hemopericardium or intraabdominal injury: the pericardial sac, hepatorenal fossa, splenorenal fossa, and pouch of Douglas. Current evidence suggests that the role of FAST for evaluating children after blunt abdominal injury is limited. When used in children, FAST has only modest sensitivity (80%) for the detection of hemoperitoneum, and a negative ultrasound has questionable utility as the only test to exclude an intra-abdominal injury.[46] Recent studies have suggested that FAST may be combined with screening laboratory studies to increase sensitivity, specificity, positive predictive value, and negative predictive value.[47] The utility of FAST in the assessment of pediatric trauma still needs to be defined.

Emergency Department Thoracotomy

Emergency department thoracotomy can be a lifesaving intervention among some children presenting in extremis after injury. This procedure, however, should be used very selectively, because its effectiveness has been shown to be limited to specific patient subsets, including those who have received a brief period of cardiopulmonary resuscitation after sustaining a blunt injury or witnessed penetrating injury. Patients who sustain a penetrating injury are more likely to benefit from an emergency department thoracotomy, because the higher potential for identifying injuries that can be treated after a thoracotomy has been performed. Data defining the role of

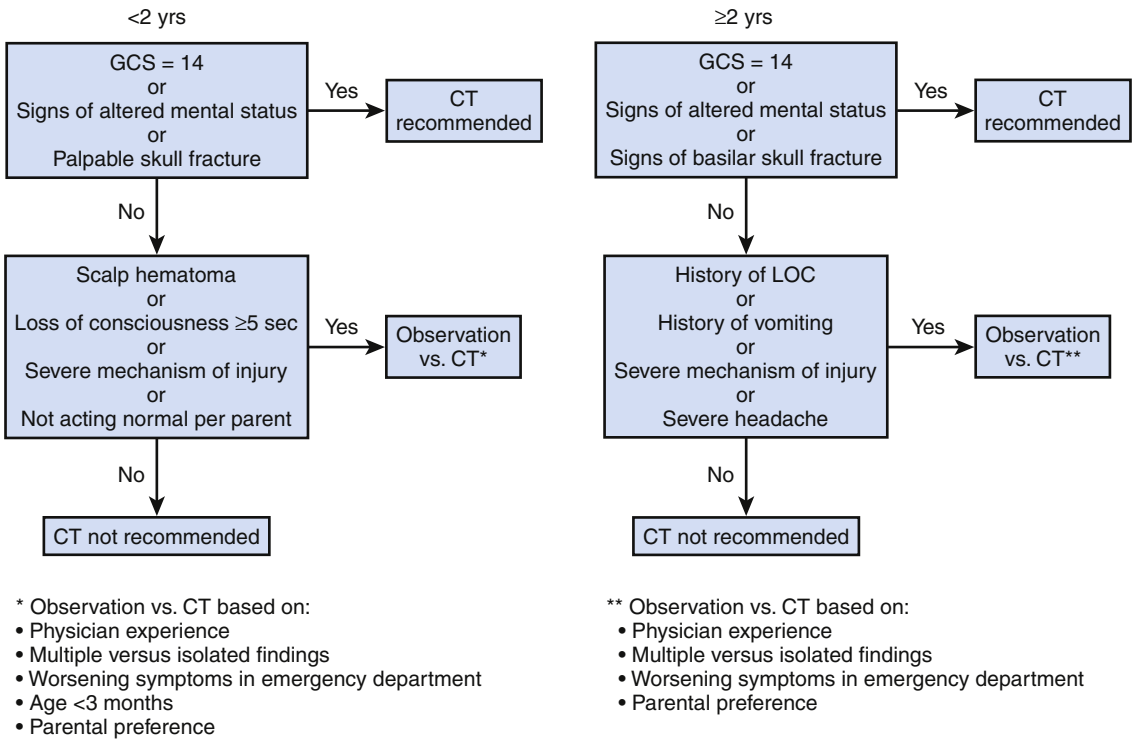

Figure 112–6. Algorithm for head CT using predictive rules. *(Modified from Kupperman N, Holmes JF, Dayan PS, et al: Identification of children at very low risk of clinically-important brain injuries after head trauma: a prospective cohort study,* Lancet *374:1160-1170, 2009.)*

emergency department thoracotomy in children are limited to small patient series and dated retrospective reviews. Available evidence suggests that this procedure should be reserved for pediatric patients who present with detectable vital signs and deteriorate despite maximal resuscitation.[48-51] Each institution should establish guidelines for the use of emergency department thoracotomy to aid in decision-making when this rare procedure needs to be performed.

Emergency department thoracotomy should only be performed by a surgeon with appropriate training in this technique. A left anterolateral thoracotomy incision is made extending from left of the sternum in the fifth intercostal space to the table. A large incision is needed to aid visualization and therapeutic interventions. This incision may be extended across to the right side of the chest if needed. The next step is to control hemorrhage by digital compression, suture control, or clamping of bleeding blood vessels. A pericardiotomy is performed using a longitudinal incision to evacuate blood and inspect the heart for injuries. Open cardiac massage can be performed if needed. Cross-clamping the descending aorta will stop blood loss below the diaphragm and allow cardiac filling to achieve cardiac and brain perfusion. The pulmonary hilum can be clamped or manually compressed to control bleeding from the lung and pulmonary vessels.

Stabilization and Definitive Care

Following the initial resuscitation, a plan for the next step in care is defined. Children can be discharged from the emergency department if no injuries requiring inpatient observation or management are identified and there is a low suspicion of injury based on the clinical evaluation and mechanism of injury. Other children may require inpatient admission to either the general hospital ward or intensive care unit depending on the injuries identified. Some children may have injuries that require immediate operative repair and need to be moved directly to the operating room. Transfer to a higher level of care facility after evaluation and stabilization may be needed if injuries are identified that cannot be treated at the receiving hospital. The period from the time of injury until a definitive emergency department disposition is an active period of medical decision-making in the care of all injured patients.

Conclusions

Pediatric trauma care requires an efficient team-based approach from prehospital care until the time of discharge. Within current trauma systems, patient care is optimized for efficiency and outcomes when each team member has a defined role and effective communication is established within the team. By understanding the prioritized sequence of ATLS, rapid recognition and treatment of life-threatening injuries will occur efficiently within the team and greatly improve the outcome of these injured patients. Pediatric critical care providers will continue to take an active role in the management of the most severely injured pediatric trauma patients. Pediatric critical care physicians proficient in emergent procedures and knowledgeable of resuscitative measures in trauma care will augment the multidisciplinary approach to pediatric trauma care.

VII Chapter 113

Child Abuse and Neglect

Paula M. Mazur, James J. Woytash, and Lynn J. Hernan

PEARLS

- Accidental trauma differs from nonaccidental trauma in presentation, workup, treatment, and outcome. In child abuse, the history of trauma is withheld or falsified, and if the presenting symptoms are vague and nonspecific, the diagnosis and treatment of injuries may be delayed. This contributes to the increased death and long-term morbidity seen in abused children.
- Abusive head trauma is the most common nonaccidental injury seen in the pediatric intensive care unit. It is the most common cause of death in abused children. Abusive head trauma is more likely to be fatal and more likely to cause long-term morbidity in survivors than accidental head trauma.
- The infant brain is more vulnerable to injury, especially to shaking (shaken baby syndrome [SBS]). The infant's neck muscles are underdeveloped and the head is proportionately larger than that of the adult. Large cerebrospinal fluid spaces in the infant allow greater movement of the brain within the skull. The infant brain has greater water content and increased deformability. Neurons and axons are less protected because of incomplete myelinization. Increased cerebral vasoreactivity predisposes the infant brain to cerebral edema.
- Accidental head trauma generates translational forces that result in focal damage. Nonaccidental trauma (e.g., shaking) generates rotational forces from rapid acceleration/deceleration of the head. Rotational forces tear cerebral bridging veins (creating subdural hematoma) and axons (creating diffuse axonal injury).
- Signs of SBS include subdural hemorrhage, retinal hemorrhage, and skeletal injury. A small number of cases will have all three signs. The presence of subdural hemorrhage and retinal hemorrhage, alone or in combination, in the appropriate clinical setting, are suggestive of SBS.
- Posterior rib fractures, metaphyseal fractures, and spinous process fractures are highly specific for abuse because their proposed mechanisms of injury are unlikely to occur accidentally.
- Abdominal trauma is the second leading cause of fatal child abuse, with death rates approaching 40% to 50%. Inflicted abdominal injury is often occult, presenting without obvious signs or symptoms; thus recognition is delayed. Treatment may be delayed because of a delay in seeking medical attention or a failure to consider nonaccidental injury in the differential diagnosis.
- Two types of forces are generated in inflicted abdominal trauma. Compression forces crush viscera against the anterior spine, and this crush causes burst injuries of the solid viscera and perforation of air-filled viscera. Deceleration forces cause shear injuries at the site of fixed, ligamentous attachments, with tears and hematoma formation at the ligamentous attachments of the liver and small bowel. Children with inflicted abdominal injury often have concomitant injuries suggestive of child abuse (bruises, head trauma, long-bone and skull fractures).
- Abusive thermal burns are of uniform thickness and closely replicate the shape of the inflicting object. Accidental thermal burns have varying degrees of thickness and irregular shapes. Abusive scald burns have an immersion pattern with a burn that is circumferential, is of uniform depth with a well-defined edge, and spares body creases. Accidental scald burns have more random patterns, vary in depth, have poorly defined edges, and do not spare body creases.
- All cases of suspected child abuse must be reported to child protective services and law enforcement. All cases of fatal child abuse must be referred to the medical examiner. Detailed, legible medical documentation and good communication between the treating physician and the medical examiner are essential to secure evidence needed for successful prosecution of the case.

Only a small percentage of physically abused children require hospitalization in the pediatric intensive care unit (PICU), but these children have been shown to have higher morbidity and death rates than critically injured victims of accidental trauma.[1,2] The types of injuries that result from nonaccidental injury, coupled with delays in diagnosis and management, account for the worse outcome in abuse victims. Diagnosis and management of life-threatening injury is often delayed because the history of preceding trauma is not provided, or is so vague or the trauma is depicted as so minor that the physician is led away from a possible traumatic cause for the patient's condition. The "golden hour" allotted for successful trauma resuscitation is spent considering an infectious, neurologic, or metabolic cause for the child's illness. In addition, there can be considerable delay in seeking medical care. Several hours to days may elapse between time of injury and time of presentation to a medical facility.

Head trauma is the most common type of inflicted injury seen in the PICU, followed by abdominal trauma, burns, and thoracic trauma. Child abuse victims should be approached

like trauma patients. They may have occult multiple-organ injury. The discovery of one injury demands a thorough evaluation for additional trauma. A meticulous investigation for injury has obvious medical utility, but it also becomes an essential part of the forensic investigation that ensues once a report of suspected child abuse is filed with child protective services and law enforcement.

Recognition of Child Abuse

History of Injury

The history of an injury must account for the type and severity of injury that is seen on physical examination. Suspicion of abuse should arise when any of the following occur:

1. The caretaker is unable to explain the injuries or gives a mechanism of injury that does not match the degree of injury seen. For example, a minor fall would not explain the presence of life-threatening cerebral edema.
2. The timing of the injury does not fit with the time of presentation (e.g., a critical head injury cannot be attributed to a fall that occurred 1 week before presentation).
3. The child's developmental stage does not fit the history (e.g., rolling off a changing table should raise suspicion if the child is younger than 4 months).
4. The history of injury changes over time or from caretaker to caretaker. A careful review of all histories documented in the medical record may reveal discrepancies.

Patterns of Injury

Inflicted injury may be differentiated from accidental injury by its appearance, location, and distribution on the body (Table 113-1).

Bruising

Inflicted bruises are often bilateral, widely distributed, and located on soft tissue areas of the body that are unlikely to make surface contact during a fall. They may take the shape of the inflicting object (e.g., fingers, a hand print, linear whip marks from a belt, loop marks from a folded belt or cord). They are frequently found on the posterior trunk, buttocks, and the posterior side of the extremities because the victim would naturally be trying to run away from the perpetrator. Bruise color is not a reliable indicator of the time an injury occurred. Bruises resolve and therefore change color at different rates depending on their location and the force with which they were inflicted.[1] Nevertheless, documenting bruise color is important, particularly with the presence of bruises of markedly different colors at the same time, suggesting that the child may have been abused on more than one occasion. A simple gingerbread-man drawing of the child's body, marked with the locations of all the child's injuries, is a concise descriptive tool that will quickly jar a physician's memory before any legal proceeding.

Early photographic documentation of the child's injuries is essential. Thirty-five mm photography has been the standard for documentation, but digital cameras, both still and video, are replacing 35 mm photography. Polaroid photographs have been used in court, but they are inferior to 35 mm and digital photographs in both clarity and durability. Every effort should be made to obtain the best photographs; 35 mm photographs taken by a medical or law enforcement photographer are ideal. If a professional photographer is unavailable or if the attempt to obtain a professional is unsuccessful, any staff member familiar with the use of the camera should take photographs for the medical record.

Burns

Numerous researchers have attempted to describe the profile of an abused burned child and to characterize inflicted burns. In general, the child is often from a single-parent family of lower socioeconomic status on which previous suspicions of child abuse or neglect may have been filed. Compared with accidental burns, abuse burns are more extensive in degree and distribution, and often require management in a PICU.[2,3] Inflicted burns are of two types. Thermal injuries involve forced contact with a hot object, and scald injuries involve contact with a hot liquid, usually water. Abusive thermal burns are of uniform thickness and closely replicate the shape of the inflicting object. For example, an inflicted cigarette burn is approximately 8 mm round and uniform in depth. Accidental thermal burns have varying degrees of thickness and irregular shapes. If a child accidentally brushes against a hot cigarette, the burn will be more linear and of varying depth along its length.[1]

Abusive scald burns have an immersion pattern. Part of the child's body, usually the buttocks or limbs, are forcefully immersed and held in hot water. The resulting burn is circumferential and of uniform depth with a well-defined edge called a tide mark. Body creases are spared (withdrawal sign) during inflicted scald injury because the child pulls and folds his arms and legs inward to avoid immersion in the hot water. Accidental scald burns have more random patterns, vary in depth, have poorly defined edges, and do not spare body creases.[2]

Ideally, photograph documentation should be done before the initial burn dressing. Additional photographs taken 24 to 48 hours later, when the burn has fully evolved in depth and distribution, can also be valuable during litigation.

Fractures

Many of the characteristics used to recognize inflicted bruises and burns can be applied to fractures. The mechanism of injury described by the caretaker must remain consistent, be compatible with the child's developmental stage, and must account for enough force to break the child's bone. Inflicted fractures can be bilateral fractures of the same age or multiple fractures in different stages of healing. In his textbook *Diagnostic Imaging of Child Abuse,* Kleinman[4] divides fractures according to their degree of specificity for inflicted injury. Posterior rib fractures, metaphyseal fractures, and spinous process fractures are highly specific for abuse because

Table 113–1 Patterns of Injury

Accidental	Nonaccidental
Unilateral	Bilateral/symmetrical
Isolated injury	Multiple injuries
Amorphous shape	Well-defined shape
Prominent bone areas	Soft tissue areas
Posterior aspect of body	Anterior aspect of body
One age of injury	Multiple ages of injury

their proposed mechanisms of injury are unlikely to occur accidentally. Scapula and sternum fractures are highly specific for abuse if the caretaker's history does not account for a tremendous amount of force having been applied to these bones. Fractures of low specificity for abuse are fractures commonly seen after bumps and falls (e.g., clavicle fractures, linear skull fractures, long-bone fractures in ambulatory toddlers). Between high and low specificity for abusive trauma are acute, bilateral fractures, multiple fractures of different ages, widened (diastatic) or depressed skull fractures, and long-bone shaft fractures occurring in the young, nonambulatory infant.

It was long held that spiral fractures were highly suggestive of abuse because their spiral configuration implied that a forceful twisting motion had been applied along the length of the bone. Dalton et al.[5] looked at femur fractures in children younger than 3 years, dividing the fractures into three types (oblique, transverse, spiral), and into three age categories (0 to 1 year, 1 to 2 years, 2 to 3 years). Their results showed that the incidence of spiral fractures increased significantly with increasing age, whereas the incidence of abuse was highest in the youngest age group regardless of fracture type. Spiral fractures can occur accidentally in vigorous, ambulatory toddlers. The age of the child holds more significance than fracture type when the possibility of inflicted injury is considered.[5,6]

Posterior rib fractures and metaphyseal fractures are frequently seen in shaken or battered infants. Posterior rib fractures occur when the child's chest is compressed. This compression causes the rib to rock back over its articulation with the transverse vertebral process. The transverse process acts as a fulcrum for the rib, and a fracture occurs on the rib's pleural surface. Although this fracture has been seen in pediatric patients with major, high-speed trauma, it does not occur accidentally in healthy children during mild to moderate thoracic trauma. Cardiopulmonary resuscitation (CPR) has not been shown to cause posterior rib fractures. A detailed discussion of posterior rib fractures can be found in Kleinman's textbook, *Diagnostic Imaging of Child Abuse*.[4] Acute rib fractures are difficult to see on a plain film. They may only first be visible 2 to 3 weeks after injury, when a callus has formed around the fracture site. Therefore finding a callused fracture on x-ray film is discovering trauma that occurred at least 2 to 3 weeks before the radiograph.[4]

The periosteum of a pediatric long bone is loosely attached to its cortex. Any violent pull, tear, or twist on the shaft of a child's long bone displaces the periosteum. The results are subperiosteal hemorrhage and periosteal elevation that can be seen on x-ray film. Conversely, the periosteum is tightly attached at its point of origin, the metaphyseal plate. The metaphyseal plate, which is the most newly laid-down bone above the growth plate, has delicate trabeculations. Violent forces applied to the midshaft periosteum are transferred to its point of origin, the metaphyseal plate, and an avulsion fracture occurs through the delicate trabeculae. Depending on the angle at which the radiograph is taken, a metaphyseal avulsion fracture can appear as a thin line through the metaphysis, as "corners" broken off the edges of the long bone, or as a "bucket handle" attached to the end of the long bone. Like posterior rib fractures, metaphyseal fractures are pathognomonic for abuse. These corner fractures or bucket handle fractures are occult. There is no deformity or swelling, and they are not obviously tender to palpation. Like posterior rib fractures, metaphyseal fractures are usually found on a radiograph obtained for other reasons or on a skeletal survey done during the medical investigation of a suspected abuse case. Spinous process fractures are the remaining type of fractures listed under "high specificity" in Kleinman's text. They are thought to occur during infant shaking, when the spine is in hyperflexion, causing sudden stress on the posterior spinous ligament as it articulates with the posterior spinous processes.[4]

Skull fractures are the second most common fracture seen in abused children, but skull fractures are also commonly seen in accidental head trauma. A skull fracture is suspicious for abuse when there is no significant trauma to account for the fracture. An unexplained skull fracture obligates the physician to look for additional injuries that are pathognomonic for abuse. For example, a skeletal survey may reveal occult posterior rib or metaphyseal fractures. A noncontrast computed tomographic (CT) scan may reveal bilateral subdural hematomas, which are not commonly associated with accidental skull fractures.

The guidelines for dating fractures are broad. In general, periosteal elevation can occur acutely, within hours to days after injury. Callus formation is seen approximately 2 weeks after injury. Loss of the fracture line begins to occur 3 weeks after the injury, and remodeling of the fracture occurs anywhere from 3 months to a year after injury, depending on the child's age. Infants will heal and remodel faster than older children. Skull fractures and metaphyseal fractures are difficult to date because they do not show the same periosteal reactions that healing ribs and long bones do.[4] However, a diastatic skull fracture, which is a linear skull fracture greater than 3 mm wide, is not an acute injury. It takes time for a skull fracture to separate more than 3 mm.

Skeletal Survey

Finding one suggestive injury on a child necessitates a radiological evaluation of the entire skeleton. Skeletal survey is the most common screening tool used in child abuse investigation. Two views of every bone in the body, radiographed with orthopedic technique, is the gold standard. "Body grams" or "baby grams," in which the entire infant's skeleton is pictured on one x-ray plate, are unacceptable. We have been able to obtain adequate surveys at the bedside when the patient has been too unstable to move from the critical care area to the radiology department. We have also obtained postmortem skeletal surveys before transferring the child's body to the medical examiner (ME), because the quality of our surveys far surpasses radiographs performed in the morgue and therefore may serve to focus the ME on particular areas of the skeleton during autopsy.

The younger the child, the higher the yield of a skeletal survey. Because smaller children are easier to lift, shake, throw, or pull, it is possible to generate the forces required to create the classic abuse fractures previously discussed. In general, skeletal surveys have the highest yield in children younger than 2 years and are obtained in children up to age 5 years, after which the yield becomes low.[1]

Because fractures pathognomonic for abuse, such as posterior rib fractures or metaphyseal fractures, are difficult to see on initial radiographs, it is strongly recommended that a second skeletal survey be obtained approximately 2 weeks after the initial survey. The later survey may reveal callus formation of healing fractures that were not visible on the initial skeletal survey.

Occult fractures can be detected by bone scan, but bone scan is not specific for fracture. The radioactive isotope used in bone scan will also enhance areas of infection, neoplasm, and growth. Therefore positive bone scans cannot be used as evidence of injury in court. A positive scan serves to focus attention on a particular area of the skeleton in need of closer study, but the area of injury must always be verified by subsequent plain film. Bone scans are most useful in detecting occult rib fractures. They are not as useful in verifying metaphyseal fractures because the metaphysis lies next to an area of vigorous bone growth, and growth areas are normally enhanced in pediatric scans.[4]

Abusive Head Trauma

Abusive head trauma (AHT) is the most common form of child abuse seen in the PICU and is the number one cause of death in child abuse victims overall. Roughly 50% of all trauma in children younger than 1 year is head trauma. The median age of abusive head trauma victims is 2 to 4 months. When Bruce and Zimmerman[7] looked at a population of children younger than 2 years with head trauma, they found that 90% of the head injuries were accidental, and 10% were attributed to abuse. Eighty percent of the deaths from head trauma, however, occurred in the smaller percentage of abused children. Outcome studies comparing children surviving accidental and nonaccidental head trauma show significantly higher morbidity rates in the nonaccidental victims. Clearly abusive head injury differs vastly from accidental head injury.

Characteristics of the Infant Brain and Cervical Spine

The infant brain is more vulnerable to injury than the adult brain for several reasons. The neck muscles inadequately support the infant's head, which is relatively large compared with the rest of the body. Consequently, the head is put through a broad range of random motions during a traumatic event like shaking. The cerebrospinal fluid (CSF) spaces are large. These spaces allow greater movement of the brain within the skull, and the brain has greater water content, thereby increasing deformability. Open sutures increase skull flexibility so that an infant's skull can be pushed inward causing cortical damage without fracturing. Incomplete myelinization leaves neurons and their axons less protected, and increased cerebral vasoreactivity at the site of injured neurons predisposes the brain to cerebral edema.[8,9] The infant upper cervical spinal cord is predisposed to injury because of the increased ligament elasticity, poorly supportive paraspinal muscles, incompletely ossified vertebrae with flattened, horizontal facet joints, and increased cord mobility within the cervical canal. In addition, the large infant head causes traction injury to the upper cervical cord during acceleration-deceleration. These factors combined require that the infant with suspected AHT be immobilized in a cervical collar until the cervical spine can be thoroughly evaluated for injury.

Mechanisms of Head Injury

Accidental head trauma, such as a fall from height, generates translational forces, which are applied directly to the site of impact resulting in focal damage to the cerebral cortex. We may see a focal contusion, a coup-contre-coup injury, or an epidural hematoma. Nonaccidental trauma (e.g., shaking) generates rotational force as a consequence of rapid acceleration/deceleration movements of the head. Rotational force distorts both gross and microscopic cortical structure.[15] The tearing of cerebral bridging veins creates subdural hematoma. Axons that are torn at the microscopic level result in neuron death and global cerebral injury.[16] Although subdural hematomas are a hallmark of shaken baby syndrome (SBS), they are rarely life-threatening lesions. The increased morbidity and mortality associated with AHT is attributed to brain injury at the cellular level. This cellular injury has been called diffuse axonal injury (DAI) or traumatic axonal injury (TAI). Furthermore, increased vasoreactivity at the site of damaged axons causes a rapid onset of diffuse cerebral edema, which increases intracranial pressure (ICP) and compromises blood flow to vital areas of the brain. Therefore the child is placed at risk for seizures, respiratory compromise, herniation, and death. Within hours of a shaking injury, a CT scan will begin to show a "black brain" with diffuse edema and a loss of gray-white matter differentiation.[8]

Neuroimaging of Abusive Head Trauma

CT imaging is the universally accepted screening tool for suspected AHT. It is readily available, does not require sedation, and easily identifies subdural hemorrhage. CT scan does not reliably date a central nervous system (CNS) bleed. An acute subdural hematoma may contain both clotted and unclotted blood, each of which has different attenuation on CT. This falsely gives the impression that an acute bleed has occurred within a preexisting or chronic hemorrhage. Magnetic resonance imaging (MRI) is not readily available and requires sedation, but it is a better tool for identifying subarachnoid hemorrhage, petechial hemorrhage, infarction, hypoxic-ischemic encephalopathy, and axonal injury. Subtle evidence of AHT and its consequent secondary brain injury are more easily seen on MRI. In addition, MRI is a more useful forensic tool than CT scan during a child abuse investigation. Hemoglobin degradation within a CNS bleed occurs in a predictable sequence and can be roughly timed. Each hemoglobin degradation product has a unique appearance on T1- and T2-weighted images, and an experienced neuroradiologist may be able to narrow down the time of CNS injury. MRI should ultimately be used in all forensic child abuse investigations. Forensic interpretation of MRI findings should only be done by an experienced neuroradiologist. Ultrasound is not a useful screening tool for AHT.[10]

Retinal Hemorrhages

It is widely hypothesized that the eye is subjected to the same acceleration/deceleration forces that the brain endures. Retinal vessels, coursing through the 11 layers of retina, will randomly tear, forming hemorrhages of multiple shapes (e.g., dots, blots, flame hemorrhages). Hemorrhage shape is determined by the cell orientation in the particular retinal layer where tearing occurs. Intraretinal hemorrhages of multiple shapes in various retinal layers are a classic finding in shaken baby syndrome.[11] Controversy still surrounds the mechanism of retinal hemorrhage formation and there have been

scattered reports of scant retinal hemorrhage found after CPR, or in the face of increased ICP (Terson syndrome) or increased thoracic pressure (Purtscher retinopathy). These retinal hemorrhages, however, differ in appearance from the classic retinal hemorrhages of SBS.[11,12] Approximately 30% of healthy neonates will have retinal hemorrhages at birth, but these rapidly resolve by the third or fourth week of life. The retinal hemorrhages of SBS extend into the periphery of the retina, which can only be fully viewed by indirect ophthalmoscopy. The standard for investigation of SBS requires an indirect ophthalmoscopy evaluation by an ophthalmologist and photodocumentation of the retinal hemorrhages using a retinal camera.

Shaken Baby Syndrome

The diagnosis of SBS is made in the presence of a constellation of signs (i.e., subdural hemorrhage, retinal hemorrhage, skeletal injury). The mechanisms of injury proposed to cause subdural hematoma and retinal hemorrhage have been previously discussed. Posterior rib fractures occur when the infant's chest is compressed during shaking. Metaphyseal fractures are thought to occur as the legs and arms are flailed back and forth. Only a small percentage of cases will have all three signs of SBS (subdural hematomas, retinal hemorrhages, and skeletal injury). More than half the cases will show both subdural hematoma and retinal hemorrhage, but the presence of subdural hemorrhage or retinal hemorrhage alone still suggests the diagnosis of SBS.[13]

A proposed sequence of events in SBS would be as follows: The frustrated caretaker impulsively attempts to stop the infant's crying by violently shaking the infant. The infant immediately loses consciousness and becomes apneic, at which time the caretaker impacts the infant down onto the mattress or floor and leaves the child to recover on its own. The cerebral damage and ensuing edema lead to increased ICP, ischemia, seizures, and further respiratory compromise.[1] Eventually medical care is sought for the child. The clinical history is vague, although there is usually some history of altered mental status. The child has nonspecific symptoms such as lethargy, poor feeding, and irritability, or may have had a seizurelike episode. The differential diagnosis includes sepsis, meningitis, new-onset seizure, or a metabolic disorder. These children commonly have no external evidence of trauma. Trauma may only become part of the differential when a CT scan done for other purposes reveals intracranial hemorrhage or when a bloody spinal tap fails to clear. Bloody taps that fail to clear should be spun down within 2 hours to look for xanthochromic CSF, which is indicative of a preexisting intracranial hemorrhage. CSF that has a clear supernatant suggests the presence of blood for less than 2 hours, supporting a diagnosis of bloody tap. For early diagnosis and management of a potentially lethal injury to be facilitated, trauma must always be included in the differential when a young child is seen with altered mental status, seizures, or apnea. Jenny et al.[14] reviewed 174 children with abusive head injury who were seen at the Denver Children's Hospital over a 5-year period and found that, in 31% of these children, the diagnosis of abusive head trauma was missed on first presentation for medical evaluation. The most frequent misdiagnoses made were gastroenteritis, followed by accidental head injury, sepsis, increasing head size, otitis media, and seizure disorder. Examiners were most likely to make the correct diagnosis if one of the following was present: severe respiratory symptoms, seizures, facial or scalp injuries, or single-parent household. Cases were often missed in the youngest patients, white infants, infants with less severe symptoms, and two-parent households.[14]

Inflicted Abdominal and Thoracic Trauma

Abdominal Trauma

After head injury, abdominal trauma is the second leading cause of fatal child abuse. Death rates approach 40% to 50%.[17] Cooper et al.[15] reviewed 10,000 pediatric patients with trauma who were admitted between 1972 and 1986, identifying approximately 4400 victims of inflicted injury. Of these, only 22, or 0.5%, had abdominal trauma, but the death rate for this small subgroup was 45%. Several factors probably contribute to these high death rates. Inflicted abdominal injury is often occult, presenting without obvious signs or symptoms; this delays recognition. There is usually a delay between time of inflicted injury and time of presentation to a medical facility. Parents may not bring the child to medical attention until the secondary effects of severe abdominal trauma, namely, hemorrhagic shock and peritonitis, manifest. Health care personnel further delay treatment by failing to consider nonaccidental injury in the differential diagnosis. In the study by Cooper et al.[15] the mean time of delay between time of injury and time of presentation for medical care was 13 hours. Of significance, all the children with inflicted abdominal injury in the study by Cooper et al.[15] had concomitant injuries commonly seen in child abuse. Ninety-five percent had soft tissue injuries, 45% had head trauma, and 27% and 18% had long-bone fractures and skull fractures, respectively. Half of the families had been previously reported to child protective services for suspected abuse or neglect. The most recent abdominal injuries seemed to represent an escalation of abuse in the home. Therefore, any suggestive injury should prompt physicians to look for occult abdominal trauma and to contact child protective services for investigation of the child's social situation.

Children with nonaccidental abdominal trauma tend to be older (>1 year) than children with abusive head trauma. Because they are larger and ambulatory, they are more difficult to grab, lift, and shake, but they are still vulnerable to physical blows. Inflicted abdominal trauma is blunt force applied to the abdominal wall, usually a punch, kick, or blow to the midepigastrium. Two types of force are generated. Compression forces crush viscera against the anterior spine, and deceleration forces cause shear injuries at the site of fixed, ligamentous attachments. We may find burst injuries of the solid viscera, perforation of the hollow, air-filled viscera, or tears and hematoma formation at the ligamentous attachments of the liver and small bowel.[15] The spectrum of inflicted abdominal injuries varies from that seen in accidental abdominal injury because the force of an inflicted blow is concentrated in the midepigastrium. Most inflicted injury will involve the small bowel (duodenal hematoma), liver lacerations, and pancreatic injury. A wider array of injury is seen in accident victims, involving kidneys, spleen, liver, and, to a much lesser extent, small bowel and pancreas.[16,17] Pancreatitis is rare in childhood, and trauma is the primary cause. Unless there is a history of significant injury to the epigastrium, nonaccidental injury must be strongly considered when pancreatitis is found

in young children. Given the occult nature of nonaccidental abdominal trauma, CT scan of the abdomen is the evaluation of choice when intraabdominal trauma is being ruled out in child abuse victims.[4]

Child abuse consultants often screen for occult abdominal injury using hepatic transaminases. Lindberg et al.[18] recently conducted a multicentered prospective observational study of children less than 60 months of age who were referred to a child abuse consultant for a physical abuse evaluation. Of the 1676 patients recruited to the study, 1276 were screened with hepatic transaminases (76%). Fifty-four (3.2%) of the 1276 screened patients were found to have abdominal injury on CT. The authors concluded that 3.2% percent does not justify routine screening for abdominal injury using CT. Of the 54 patients with verified abdominal injury, 14 (26%) had no clinical signs of abdominal injury and the decision to screen the child with CT was influenced by the child's hepatic transaminases. The authors used a threshold of 80 IU/L for either alanine aminotransferase or aspartate aminotransferase, which is a lower threshold than has been used by previous authors studying the same question. Using a threshold of 80 IU/L, the sensitivity and specificity of hepatic transaminases as a screening tool for occult abdominal trauma was 77% and 82%, respectively.[18]

Thoracic Trauma

Beyond the pathognomonic rib fractures of child abuse, extensive thoracic trauma is rarely seen. A child's thoracic cage is so plastic and deformable, however, that, even in the absence of rib fractures, a child abuse victim could sustain compromising pulmonary injuries, namely, pneumothoraces, hemothoraces, or pulmonary contusions. As with abdominal trauma, the physician's index of suspicion must remain high to avoid delayed management of a life-threatening thoracic injury. The reader is referred to subsequent chapters of this text for detailed discussion of pediatric thoracic trauma.

Sexual Abuse

Physically abused children may also be sexually abused. When a patient is examined for evidence of physical trauma, a careful genital examination is warranted. Any evidence of old or new genital trauma must be documented with photographs. Genital trauma is usually subtle, difficult to recognize, and difficult to photograph. When possible, consult a physician who specializes in sexual abuse and who may be able to perform a noninvasive colposcopic examination of the external genitalia. The best photo documentation of genital injury is obtained with a colposcope. Of great significance, using colposcopy to videotape and photodocument a child's forensic exam eliminates the need for repeat examinations on the already traumatized sexual assault victim. If acute genital trauma is suspected or identified, a "rape kit" or forensic collection of evidence must be performed, and the police must be involved early. The forensic evidence becomes legal documentation of the sexual assault, and a chain of evidence must be carefully maintained between the hospital and the forensic laboratory. All cultures must be collected in culture medium or broth. DNA probes for gonorrhea and chlamydia cannot be used as evidence in court. Ideally, evidence collection should occur before any washing of the genitalia, including before the skin prep for insertion of a Foley catheter. Speculum and bimanual examination of sexually abused children is not warranted unless there is concern about internal lacerations in need of surgical repair. To avoid the need for repeat examinations, a sexual abuse expert or pediatric gynecologist should perform this examination with the patient under anesthesia.[1]

Box 113–1 Protocol for Medical Investigation of Child Abuse

Physical examination for skin and genital trauma
Photography of all injury
Skeletal survey for children <5 years
Bone scan (if skeletal survey results are negative)
CT head scan for children <3 years
Ophthalmology consultation to rule out retinal hemorrhage
Abdominal trauma laboratory values
Serum amylase/lipase
Liver enzymes
Urine analysis
CT abdomen scan
All nonverbal children
Positive findings from abdominal examination
Abnormal laboratory results
MRI of the head if AHT is identified on CT or is strongly suspected despite equivocal CT findings

Protocol for the Medical Investigation of Child Abuse

To ensure complete and objective evidence collection during the medical investigation of child abuse, we have established an investigative protocol for our institution that is based on the current medical literature. This protocol has worked well across all pediatric subspecialty services in our institution and has provided consistency when communication occurs with law enforcement, legal services, child protective services, and our community pediatricians (Box 113-1).

Fatal Child Abuse

Fatal child abuse is not merely a phenomenon of the twentieth century. There have been reports of fatal child abuse throughout history. Caligula's daughter died of inflicted head trauma in AD 41. The French literature records the fatal whipping of a 4-year-old girl in the 1850s. In 1860, Professor Ambroise Tardieu published a paper describing fatal physical and sexual abuse inflicted on infants and children by parents. Tardieu's account listed thermal burns, fingernail imprints, contusions due to pinching, intracranial hemorrhages, and other injuries similar to those seen today. Likewise, these parents and caretakers offered explanations for the injuries that were incompatible with the severity of injury, such as falls during play or by other minor accidents. Knight[19] concludes, in his historical review of child abuse, that fatal child abuse is nothing new.

Eighty percent of fatal child abuse is caused by head injury. Because many of these children undergo surgical intervention before their death, the forensic pathologist/ME is often faced with an autopsy in which the injuries have been altered by surgical procedures. An exact description of the injuries present before treatment is essential: for example, the extent (amount), location, and radiologic information (CT, MRI,

plain films) of all epidural, subdural, and subarachnoid hemorrhages. The chart must reference any biopsy specimens (usually blood clots) submitted to the pathology laboratory during surgical procedures. Documenting the extent and location of retinal hemorrhages may assist the forensic pathologist/ME during gross examination of the eyes. Although there are nontraumatic causes of retinal hemorrhage, CPR is not a common cause. The location and size (in inches/centimeters) and a brief description of any abrasions, lacerations, and contusions should be stated. With respect to contusions, the color on admission and on successive days should be recorded. Likewise, any skin breakdown following medical procedures, notably on the posterior scalp and neck, needs documentation.[20]

As previously stated, visceral trauma is the second leading cause of death in child abuse. Abdominal injuries include liver, spleen, intestinal, mesenteric, and renal contusions, lacerations, and rupture. There may be minimal external evidence of such catastrophic injuries. In the event that they are discovered during surgery, the amount of blood in the peritoneum and extent of organ damage should be carefully documented. Abdominal injuries resulting from CPR are extremely rare.[21]

Osseous Injury in Fatal Child Abuse

Fractures of bones in fatal child abuse are evidence. Documentation of the site of fracture (e.g., metaphyseal distal femur), type of fracture (e.g., transverse, spiral), and possible dating by x-ray analysis should be done on all cases. A head-to-toe approach with skeletal survey will aid the forensic pathologist/ME by locating injuries before the autopsy. During the autopsy, sections of these fractures are taken. Although some authorities consider histologic dating to be accurate, there are wide variations in the chronological healing of fractures. Only an approximate time frame can be assigned to a fracture.[22] Osseous injuries will also alert the staff to possible nontraumatic causes such as osteogenesis imperfecta.

Scene Investigation in Fatal Child Abuse

The scene is where the infant became unresponsive, became apneic, or sustained injuries that led to hospital admission. The scene typically belongs to and is secured by law enforcement officers, so the earlier they become involved, the more timely and accurate the scene investigation will be. Emergency medical service (EMS) providers or firefighters are often the first to arrive on the scene. Their narrative description of the immediate circumstances and surroundings is a crucial part of scene investigation. They are encouraged to describe the place and position in which the child was found; the type of bed and bedding the child was found in; the presence of body fluids (blood, vomit, urine, feces) at the scene; the tidiness of the environment; and the presence of drugs, medications, drug paraphernalia, or alcohol at the scene. They often record the initial reactions of caretakers, identify potential witnesses to the preceding events, and discover other vulnerable children within the household. Talking to EMS providers on their arrival with the critically injured child can provide a wealth of information leading to early suggestions of child abuse/neglect, timely medical interventions, and early law enforcement and child protective services involvement.

Witnessed by whom (or unwitnessed)
First responders to scene
Field interventions (CPR, intubation, drugs)
Description of victim as found
Description of environment
Scene diagram (supplied by law enforcement)
Interviews with parents, caretakers, witnesses
Cardiopulmonary resuscitation

Autopsy

The successful identification of tragic fatal child abuse cases depends on a team approach. Box 113-2 lists the minimal information desired by the forensic pathologist/ME before autopsy.[23] Clearly this list is best assembled as a collaborative effort of EMS, law enforcement, and physicians. Ideally, representatives of the pediatric team, law enforcement, and the district attorney's office would attend the autopsy examination. Although law enforcement attendance is routine in all fatal child abuse cases, numerous constraints interfere with pediatric presence at autopsy. Minimally, a phone conversation between the ME and the pediatric attending physician is strongly recommended.

Organ Procurement Organization and Fatal Child Abuse

The limited supply of organs for transplantation is well known. Although all age groups are represented, there is a lower organ donation percentage in the pediatric age group because this group has a lower relative death rate. Thus the use of organs from the pediatric age group is critical. When a child or infant sustains injuries leading to brain death, organ procurement is sought by organ procurement organizations (OPOs). Initially, some forensic pathologists/MEs may deny the use of organs on the basis that it may cause problems with judicial procedures.[24] This is not absolute. All three agencies must examine each individual case. The district attorney, forensic pathologist/ME, and the pediatrician must work with the OPO to see if organs not damaged by injury may be used in transplantation. If all parties are satisfied, then a representative of the ME's office (ideally the forensic pathologist/ME who will do the autopsy) should be present when the organs are retrieved for transplantation. The interacting groups are listed in Box 113-3.

Documentation and Testifying in Court

Testimony of medical personnel begins with thorough and legible documentation in the medical record. Complete, rather than brief, documentation is strongly recommended, because trials may be delayed for months to years. Handwritten notes will become a memory lifeline during testimony. One must document information objectively. Be specific about where information is coming from. When recording conversations with caretakers, place their exact words in italics and write "per conversation with…." Months to years later,

Box 113–3 Key Groups Needed for Tissue Procurement

Pediatrician representing family's request
OPO representative
ME office
District attorney's office

one will not remember exactly who was interviewed or who actually said what is written in the chart. Written words may be misconstrued as opinion, and defense attorneys frequently make this an issue when witnesses testify to confuse or discredit testimony.

Testifying on behalf of a child who has been abused or murdered is emotional. Stick to the facts and remain objective. Remember that medical personnel are not the judge in this case. Stay calm, particularly when being cross-examined by the defense attorney, and remember that medical personnel and their work are not on trial. There is no urgency in court. Take the time you need to formulate answers. Responses should be brief and limited to the questions asked, unless one is specifically told to elaborate further. If a question is not understood, ask that it be clarified before an answer is given. If a detail (e.g., a date, a time, a person's name) cannot be recalled, simply state so. One is allowed to refer to the medical records once they have been entered into medical evidence. If a witness does not think that he or she possesses the expertise to answer a question, then the witness should simply state so.

The more prepared one is, the less stressful the experience in court will be. It is the responsibility of medical personnel to review the medical records, laboratory reports, and radiological studies before trial. If the prosecuting attorney is properly preparing the case, the attorney will meet with each witness before testimony is given. This meeting gives both the attorney and the witness a chance to clarify specific issues that will be raised in court and to discuss the limits of the testimony. One may be asked to submit an updated curriculum vitae to establish credentials. If one is being called as a fact-finding witness, the court will not solicit opinions. During the trial, one may be qualified as an expert witness in his or her medical subspecialty. Then, one will be allowed to express opinions more freely.

If one is called to testify again regarding the same case or if a deposition was given before trial, then previously recorded statements should be reviewed so that testimony remains consistent. It serves to keep the witness from becoming uncomfortably entangled in unintended contradiction and legal rhetoric on the stand. Included in the following reference list are suggested readings that may be helpful in preparation trial.[25-27]

VII Chapter 114

Thoracic Injuries in Children

Mauricio A. Escobar Jr. and Michael G. Caty

PEARLS

- Thoracic injuries in children are uncommon but result in significant morbidity and mortality, mainly from the frequently associated head trauma and abdominal trauma.
- Most thoracic injuries in children result from blunt trauma.
- The most common manifestations of thoracic trauma in children are rib fractures, pneumothoraces, hemothoraces, and pulmonary contusions.
- Traumatic asphyxia and commotio cordis are more common in children than in adults.

Thoracic injuries in children are relatively uncommon, but result in disproportionate morbidity and mortality compared with other traumatic injuries, mainly because thoracic injuries often are associated with other life-threatening conditions and injuries. Children, unlike adults, undergo constant growth and change. Any consideration of the injured child must take into account several factors including age-related limitations in their ability to communicate and to understand their injuries, a limited ability to cooperate with care, and their potential for recovery, growth, and life-long productivity.[1] Children with significant thoracic injuries require intensive monitoring and hemodynamic and respiratory support. It is important to establish an accurate diagnosis. High-resolution imaging techniques such as helical computed tomography (CT) are indicated to detect intrathoracic lesions. This chapter discusses the epidemiology, diagnosis, and immediate approach to children with thoracic injuries and the current management of specific injuries to the thorax.

Epidemiology

The National Pediatric Trauma Registry (NPTR) was created in 1994 and has collected information from 94 trauma centers in the United States. From 1994 to 2001, 3721 patients with thoracic injuries were reported, which corresponds to 7.7% of all pediatric trauma.[2] Interestingly, isolated thoracic injuries accounted for only 0.7% of all pediatric trauma patients. Thoracic trauma occurs more frequently in males, with a male/female ratio of approximately 2:1. No differences in age distribution are noted. Blunt trauma is the most frequent cause of injury (92%). The incidence of penetrating chest injury in urban areas is increasing with the escalating use of firearms in society. However, penetrating injuries (gunshot wounds and stab wounds) currently account for only 8% of all thoracic injuries in the pediatric patient.[2]

An analysis of consecutive pediatric patients treated at a Level 1 trauma center found that the most common thoracic injuries were pulmonary contusion (48%), pneumothorax/hemothorax (39%), and rib fractures (32%).[3] Thoracic injuries most commonly present concomitantly with other injuries.[2-4] From 60% to 85% of children with thoracic injuries have significant injury to at least one other organ system, most notably the central nervous system (CNS), the abdominal cavity, or the musculoskeletal system.[3,4] The most common mechanisms of injury are motor vehicle-related accidents (40.7%), children as pedestrians struck by a motor vehicle (19.2%), bicycle accidents (6.6%), and falls (5.8%). Additionally, abuse accounts for 7% to 8% of blunt trauma in children.[5] The pediatric traumatologist must also be aware of other modes of blunt injury including skateboarding, skiing, snowboarding, sports injuries, fights, and suicide. The advent of "extreme sports" in geographically risky areas must also be kept in mind. Finally, the role of alcohol and drugs in injury must be addressed.[1]

The clinical importance of thoracic injuries is reflected in the greater severity of injury observed in children with thoracic injuries (Trauma Score [TS] 11, Injury Severity Scale [ISS] 27) compared with that seen in children without thoracic injuries (TS 15; ISS 7).[4] According to the NPTR, the overall mortality for trauma in the pediatric population is 3%. Thoracic injuries are present in 33% of fatal cases. The mortality rate for thoracic trauma is 12.2%. In patients with thoracic trauma, CNS injuries are the major cause of death (63.1%), followed by uncontrollable hemorrhage (13.5%).[2] The number and severity of associated injuries are important determining factors in the eventual outcome and survivability of the injury.[3-6] Stratification of mortality rates according to the number and type of associated injuries illustrates this point. In isolation, thoracic trauma in children carries a 5% mortality rate. Children with abdominal and thoracic injuries have a 20% mortality rate; children with chest and head injuries have a 35% mortality rate; and children with all three injuries have a 39% mortality rate.[4] Fortunately, immediately life-threatening chest injuries are infrequent; consequently, emergency thoracotomies in the operating room are required in only 3% to 6% of all

pediatric thoracic trauma.[7] Indications for emergency thoracotomy include victims of penetrating thoracic trauma who had signs of life at some point during the resuscitative efforts.[8] The indication for emergency thoracotomy in blunt trauma (witnessed cardiac arrest in the emergency department) is controversial.

Anatomic and Physiologic Considerations with Chest Injuries

The injured child is not a small injured adult. The thoracic organs in a child exhibit different physiologic characteristics than in an adult. Increased cartilage content and incomplete ossification of the ribs make the thoracic cage more compliant than that of an adult, permitting the anterior ribs to be compressed against the posterior ribs.[9] This compliance results in more kinetic energy being transmitted to intrathoracic organs without bony injury. Therefore pulmonary contusions without concomitant rib fractures are more common than in adults. Rib fractures and flail segments become more common as ossification occurs. The flail segment responds to changes in intrathoracic pressure rather than to the pull of respiratory muscles, resulting in retraction with inspiration and bulging with expiration. This paradoxical movement results in inefficient thoracic expansion and increased energy expenditure. Hypoventilation and subsequent atelectasis result from the associated pain.

The trachea is more compressible and narrower (narrowest at the level of the cricoid cartilage) early in life. Therefore children are susceptible to profound respiratory embarrassment from seemingly inconsequential insults (foreign body aspiration, etc.). A decreased functional residual capacity coupled with higher oxygen consumption per unit body mass leads to rapid development of hypoxemia in the traumatized child. This equalizes to adult values by age 8 to 10 years. Cardiac output in children is determined by heart rate and stroke volume. Contractility is largely fixed in early life. Children may compensate hemodynamically and maintain a normal blood pressure with up to a 40% blood loss. Additionally, the less complete fixation of the mediastinum in children allows more visceral shift, greater compromise of preload, and profound hypotension.[1]

Diagnosis and Immediate Management of Chest Injuries

The initial evaluation of the child with known or suspected thoracic trauma conforms to standard trauma protocols.[10] Life-threatening diagnoses should be sought in the unstable child at each step of the evaluation during the primary survey (Box 114-1). First, the patency of the airway is established. The inability to maintain an airway because of anatomical obstruction or depressed level of consciousness (Glasgow Coma Scale [GCS] ≤8) warrants endotracheal intubation. All patients with suspected cervical injuries should have manual in-line cervical stabilization maintained during intubation. If endotracheal intubation is not possible, an age-appropriate surgical cricothyroidotomy should be performed.

After the airway is secured, breathing is assessed. Both hemithoraces are observed for symmetrical motion and auscultation is performed to evaluate breath sounds. In the intubated patient the position of the endotracheal tube should be checked, looking for asymmetric chest expansion or decreased breath sounds, before any invasive procedures are performed. Arterial Pao_2 analysis and pulse oximetry are useful for assessing oxygenation whereas $Paco_2$ level and capnography, where available, are extremely helpful for assessing ventilation. Capnography is being used increasingly in the emergency care of critically ill infants and children. It not only documents the correct intratracheal position of the endotracheal tube, but may also help to guide ventilation during transport. The stable child with decreased breath sounds on one side should undergo immediate chest radiography. A chest tube should be placed if either a pneumothorax or hemothorax is demonstrated. In an unstable child, needle thoracentesis should be performed immediately on the side with decreased breath sounds (Figure 114-1).

Assessment of the circulation begins with recording the pulse rate and blood pressure. Observation of capillary refill provides an approximation of tissue perfusion. Appropriate intravenous access is established and fluid resuscitation is initiated. Cardiac tamponade should be suspected in the child with equal breath sounds and a normal chest x-ray film but hemodynamic instability. Pulsus paradoxus and jugular venous distension are inconsistent findings. Their absence should not be used to rule out the presence of cardiac tamponade.

Additional clues to the nature of injuries are obtained by observation and palpation. Specifically, looking at the patterns of abrasions and contusions may suggest the mechanism of injury and allow prediction of potential intrathoracic injuries. One example is the child with a sternal contusion, who should

Box 114–1 Acute Thoracic Conditions Requiring Immediate Correction

Cardiac tamponade

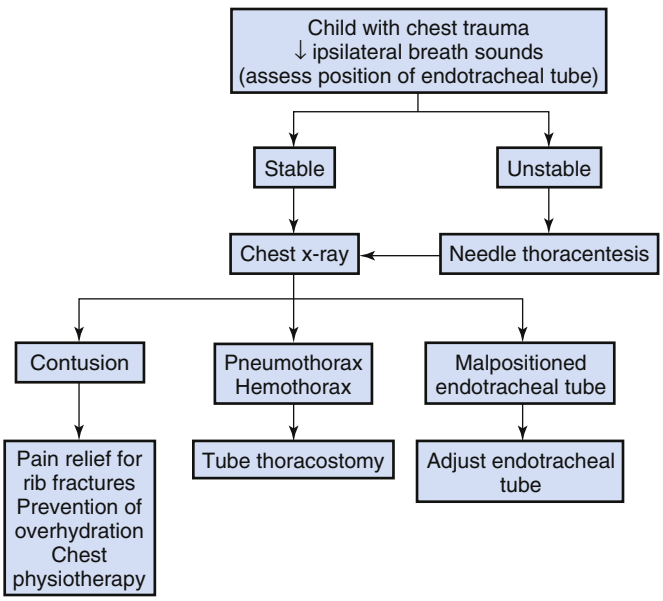

Figure 114–1. Management of the child with decreased breath sounds.

be assessed for a cardiac contusion. The thoracic cage should be palpated from under the arms to the abdomen in a sequential fashion, looking for rib tenderness and/or flail segments. Chest radiography completes the initial evaluation. The physician checks the x-ray film for evidence of pneumothorax, hemothorax, pulmonary contusion, and rib fractures. First and second rib fractures do not seem to be reliable indicators of aortic injury in children, but may be related to other significant vascular injuries (subclavian artery).[11-13] In general, approximately 60% of patients with a thoracic trauma diagnosis are admitted to the pediatric intensive care unit for further monitoring and management.[3,14]

Rib Fractures

Fractures of the bony thorax, specifically rib fractures, are more common than previously suspected.[3,6,15] In one large study, rib fractures were noted in 32% of all children with thoracic injuries.[4] However, in the context of all injured children admitted, rib fractures were infrequent and were observed in only 1.6% of injured children. Again, the pediatric experience stands in sharp contrast to the adult experience, in which rib fractures are frequently seen and are present in 33% of injured adult patients.[6] The importance of rib fractures as a marker of injury severity has been emphasized.[11] In one study, rib fractures were noted in only 1.6% of children admitted. However, the mortality rate of children with rib fractures was 42%, compared with a 2.1% mortality rate in children without rib fractures. When a head injury is associated, children with rib fractures have a disproportionately higher mortality rate of 71%. In addition, head injury and the number of ribs fractured correlate with risk of mortality in children.[14]

The mechanisms of injury resulting in rib fractures parallel those seen in other pediatric thoracic injuries, with the notable exception of the high incidence of intentional injury in younger children. Traffic injuries accounted for nearly 70% of all rib fractures, whereas child abuse accounted for 21%. The mean age of children with rib fractures is 4.7 years, and nearly 60% of children with rib fractures are 4 years or younger. It is noteworthy that child abuse accounts for nearly two thirds of rib fractures in children younger than 3 years.[14] The number of fractured ribs in both injured adults and children correlates directly with the severity of injury (assessed by the Revised Trauma Score [RTS] and the ISS), the likelihood of multisystem and intrathoracic injury, and higher mortality rates.[14,16] Presence of three or more rib fractures in a child reliably identifies him or her as having a significant likelihood of intrathoracic, as well as other organ involvement, and a significantly higher probability of dying.[6]

First and second rib fractures in children do not correlate with the presence of concomitant injury to the mediastinal great vessels and, in isolation, do not warrant aortography.[3,14,17] Additionally, neither posterior rib fractures nor scapular rib fractures were indicative of great vessel injury. However, first and second rib fractures are associated with pulmonary contusions, cervical spine injuries, and injuries to intrathoracic vessels and nerves.[13-19] Moreover, evidence suggests that the presence of thoracic spine fractures should heighten the suspicion of great vessel injury.[20] Lower rib fractures may be associated with liver and spleen injuries.[21]

The key to successful management of chest wall injuries is adequate pain control to promote effective air exchange and to facilitate pulmonary toilet.[6,22,23] The goal is to prevent atelectasis and pneumonia. Regional anesthetic techniques, such as epidural and intercostal nerve blockade, play an expanding role in pain control and are increasingly viewed as effective and safe adjuncts to traditional analgesia techniques.[22,23]

Flail segments result from multiple contiguous ribs with more than two points of fracture, fracture of the sternum and multiple costochondral junctions, or midaxillary fracture with fracture or dislocation of rib heads.[1,24] A 17-year review of 225 children treated for chest trauma revealed no incidences of flail chest.[24] These injuires are quite rare in children. For flail chest injury patients, an ISS greater than 23, the need for blood transfusions within the first 24 hours, and the presence or development of shock on admission are suggested as factors that predict the need for ventilatory assistance.[22] These assertions stem from an analysis of adult patients. Their validity in the treatment of children awaits further evaluation. Fortunately, the majority of children with fractured ribs do not require ventilatory assistance and have a good overall prognosis.[14]

Clavicle, Sternal, and Scapular Fractures

The medial physis of the clavicle does not typically close until 23 to 25 years of age.[25] Because of this, falls on the shoulder may lead to posterior sternoclavicular physeal fracture-dislocations in children. These injuries can be associated with dysphagia, dyspnea, and brachiocephalic compression.[26] The clinician must evaluate for esophageal and great vessel injuries in this population. Sternal fractures in children can occur from motor vehicle collisions, direct blows, or flexion-compression of the spine.[27-29] Although rare, these types of fractures may be associated with blunt cardiac injury.[30,31] All patients with sternal fractures or sternal bruising should be assessed for a cardiac contusion.

Scapular fractures are uncommon in children.[32] A significant amount of force is required to fracture the scapula. Scapular fractures are associated with rib fractures, pulmonary contusion, and head injury. Axillary artery or brachial plexus injury may also occur.[33]

Children with symptomatic chest wall injuries should have imaging performed to identify the fractures and associated intrathoracic injuries. Children with suspected posterior sternoclavicular fractures/dislocations, first rib fractures, and sternal fractures should be evaluated with CT imaging to evaluate the great vessels and intrathoracic organs.[34] Additionally, an electrocardiograph should be obtained in children with sternal fractures.[35] Any abnormal rhythm should lead to an echocardiogram and cardiac enzyme analysis to exclude blunt cardiac injury.[31]

Pulmonary Contusion

Pulmonary contusion rivals pneumothorax/hemothorax as the most common childhood thoracic injury. It is present in as many as 48% of children with thoracic injuries.[3,4] Pulmonary contusion is defined as nonanatomical areas of consolidation on chest radiograph or CT. Evidence suggestive of pulmonary contusion, such as external chest wall abrasions, tachypnea, and abnormal breath sounds, is frequently absent in children. Automobile crashes represent the most common mechanism

of injury. Pulmonary contusion is usually associated with other potentially more life-threatening conditions such as pneumothorax/hemothorax or other systemic injuries.[4,14,36-38]

Rib fractures are present in up to 32% of children with intrathoracic injuries.[4,14,36-38] Up to 40% of cases of pulmonary contusion and other intrathoracic lesions were not radiographically evident until 48 hours after injury.[36] Thus rib fractures are important markers of internal injuries because the radiographic manifestations of other intrathoracic injuries are often delayed. When pulmonary contusion is accompanied by rib fractures, serial chest radiographs should be performed during the initial 48 hours after injury to promptly identify other intrathoracic injuries.[36] Although most patients with pulmonary contusion are identified by sequentially obtained chest radiographs, CT imaging may be of greater value in demonstrating posttraumatic intrathoracic pathology in patients requiring endotracheal intubation and mechanical ventilation. For patients with an oxygenation index (Pao_2/Fio_2) less than 300, a CT scan may be helpful in defining the extent of pulmonary contusion and identifying those patients at higher risk for acute respiratory failure or those with unsuspected or incompletely treated hemothoraces or pneumothoraces.[39]

Management of pulmonary contusion centers on oxygen supplementation, judicious fluid management, pain control, adequate pulmonary toilet, and respiratory support. Many children with thoracic trauma exhibit wet lung, a syndrome characterized by a combination of pulmonary contusion, pneumonia, and atelectasis.[24,40] However, concern for wet lung should *not* compromise appropriate volume resuscitation during the initial evaluation. Corticosteroids are ineffective and probably harmful.[36] Prognosis for most children with pulmonary contusion is excellent, because the majority of these injuries are mild to moderate in severity, and children recover without the need for ventilatory support. For severe pulmonary contusions, differential lung ventilation may be valuable.[41-43] Early success of synchronized independent lung ventilation using a double-lumen endobronchial tube connected to two ventilators indicates a potentially lifesaving treatment option for the child with a significant pulmonary contusion.[37] Early institution of synchronized independent lung ventilation may increase survival in the severely injured patient with pulmonary contusion.[3,4,37,38,44] Extracorporeal life support measures may increase the risk of posttraumatic bleeding complications.[1] Approximately 20% of children with pulmonary contusion develop pneumonia, a risk factor for developing respiratory failure. Half of the children who develop respiratory insufficiency do so in the first few hours after injury.[40] Few develop true adult respiratory distress syndrome (Pao_2/Fio_2 <200), and death primarily related to the pulmonary contusion is rare in children.[40,45]

Traumatic Asphyxia

Traumatic asphyxia results from direct compression of the chest from crushing injury in conjunction with a deep inspiration and closed glottis. This results in a marked increased in intrathoracic pressure that is transmitted from the right atrium directly through the valveless superior and inferior vena cava, causing rupture of venules and capillaries of the face and head. A rapid increase in intracranial pressure may also occur.[44] Clinical manifestations include conjunctival hemorrhage, facial edema and cyanosis, ecchymotic or petechial hemorrhages of the chest and face, hemoptysis, epistaxis, hemotympanum, and exophthalmos.[46] Retina, vitreous body, or optic nerve hemorrhage may result in loss of vision. Associated neurologic symptoms include altered mental status, brachial plexus injuries, quadriplegia (without evidence of spinal cord injury), and coma.[47] Interestingly, while clinical manifestations of traumatic asphyxia can be quite dramatic, morbidity and mortality are generally due to associated injuries. For those children that survive the initial traumatic insult, the dramatic clinical manifestations usually resolve with no neurologic sequelae.

Pneumothorax/Hemothorax

Pneumothorax and hemothorax collectively represent the second most common intrathoracic injuries seen in children.[3,4,36] Together, they account for 39% to 50% of childhood intrathoracic injuries. Among all children who sustain thoracic trauma, approximately one third will develop a pneumothorax.[3,4] One third of the pneumothoraces occur in isolation.[3] The remainder will have associated intrathoracic and extrathoracic injuries. The majority (76%) of chest injuries resulting in pneumothorax or hemothorax require only a tube thoracostomy for successful management.[3,4,48] One of the most common mistakes in managing a significant hemothorax is placing a chest tube that is not large enough to adequately evacuate the blood (Table 114-1). Tube thoracostomy is best performed with the upper extremity fully abducted. This position elevates the ribs and widens the intercostal space, facilitating the placement of the chest tube, which may be both diagnostic and therapeutic. The chest tube is inserted more caudally and more posteriorly for a suspected hemothorax than for a pneumothorax. Ideally, the fifth intercostal space is used along the midaxillary line. At this level, there is little danger to the long thoracic nerve, and relatively little risk to the liver or spleen. More posterior placement of the tube can result in obstruction of the tube when the child lies in the supine position.

Because of the low arterial pressure in the pulmonary circulation, bleeding from tears in the lung parenchyma is slow and hemostasis occurs early after the lung is reexpanded. Prompt drainage of blood in the thorax is necessary for several reasons, including prevention of lung entrapment secondary to hemothorax organization, prevention of infection (empyema), and

Table 114–1 Chest Tube Sizes by Patient Weight

Age	Weight	Chest Tube Size
Newborn to 1 year	3–5 kg	10–12 Fr
≥1 year to 2 years	6–9 kg	12–16 Fr
3 years to 4 years	10–11 kg	16–20 Fr
	12–14 kg	20–22 Fr

	19–22 kg	24–28 Fr
8 years to 11 years	23–30 kg	28–32 Fr
≥12 years	>30 kg	32–42 Fr

Data from Bliss D, Silen M: Pediatric thoracic trauma, *Critic Care Med* 30(11): S409-S415, 2002.

accurate quantification of the amount of hemorrhage.[1] Exsanguinating hemorrhage usually involves intercostal, hilar, or mediastinal vessels. Thoracotomy is indicated when the initial thoracostomy tube output is greater than or equal to 20% to 30% of the blood volume, when the output is greater than 2 to 3 mL/kg/hr over the following 6 hours, or when significant rebleeding occurs.[49]

It is widely accepted that the erect chest radiograph with posteroanterior and lateral projections is highly accurate in demonstrating major intrathoracic pathology. However, with the overriding concern for possible cervical spine injury, chest radiographs during trauma resuscitation usually are taken with the child in the supine position. In that position, small and even modest collections of air may not be readily demonstrated. Although the portable chest x-ray film has a well-defined role during assessment of thoracic injuries, its limitations must be borne in mind.[48]

Whenever possible, standing anteroposterior and lateral chest x-ray images should be obtained as soon as the clinical condition allows. Some authorities, noting the lower sensitivity of chest radiographs, recommend that emergent chest CT scans be performed in stable patients with blunt high-energy torso trauma, cross-body injury patterns, or mechanisms of injury suggestive of chest trauma.[16,38,50] The focused assessment sonography for trauma (FAST) in the setting of thoracic trauma is useful for detecting fluid in the pleural cavity and has 95% sensitivity in detecting pneumothoraces compared with chest radiographs.[51] However, a recent meta-analysis evaluating FAST for abdominal injuries in children noted a sensitivity of 80% and specificity of 96%. When only the most methodologically stringent articles were used (six studies), the combined sensitivity of the FAST exam for identifying children with hemoperitoneum was 66%. Sensitivity for detection of all children with intra-abdominal injuries (including those without hemoperitoneum) was even lower at 50%.[52,53] The continued role of FAST in evaluating the child with thoracic injuries remains to be seen.

The increased mobility of the child's mediastinum places the pediatric patient at increased risk for the physiologic consequences of a tension pneumothorax, which may occur in 25% of children presenting with a pneumothorax.[3] However, as the mediastinum becomes more fixed, shifting is less likely. In older children and adolescents, tension physiology may be due to progressively less effective ventilation and oxygenation caused by increased intrathoracic pressure.[54] The traumatologist must also keep in mind other causes of hypoxemia and hypotension including cardiac tamponade, right mainstem position of the endotracheal tube (ETT), ETT obstruction, and gastric distension.[1] Fortunately, in the majority of cases, pneumothorax results from small disruptions of the lung parenchyma. These disruptions are associated with small to modest air leaks and are effectively treated with a tube thoracostomy.[4,11,55,56]

Tracheobronchial Injuries

Persistent air leaks suggest disruption of a major airway. If ventilatory support is necessary and if the size of the child's airway allows, a double-lumen tube can be used for selective management of the uninjured and injured lungs, thus minimizing the severity of the air leak and optimizing ventilation.[4,55-58] Single-lung intubation is an efficient alternative maneuver if double-lumen ventilation cannot be accomplished.

Severe tracheobronchial disruptions usually are seen after high-energy impact injuries, most frequently motor vehicle crashes. Consequently, these injuries in children likely have associated multisystem injuries that may require emergent treatment. Because of the increased compliance of the child's chest wall, tracheobronchial injury may occur without the suggestive chest wall injuries usually present in the adult patient with a similar mechanism of injury.

The most common presenting signs and symptoms are subcutaneous emphysema, dyspnea, sternal tenderness, and hemoptysis.[4,55-58] The typical radiographic findings are subcutaneous emphysema, pneumomediastinum, pneumothorax, air surrounding the bronchus, and an abnormal appearance of the endotracheal tube. These findings, in association with upper thoracic fractures, are highly suggestive of tracheobronchial disruption. An uncommon finding, but one that is nonetheless highly specific for tracheobronchial injury, is collapse of the lung toward the chest wall.[11,59] When the constellation of a likely mechanism of injury, a suggestive clinical picture, and radiographic findings are present, diagnostic bronchoscopy is a priority. In a stable patient, either flexible or rigid bronchoscopy should be performed to confirm the location and the extent of airway disruption. If possible, a flexible bronchoscope is passed through the ETT with the tube withdrawn enough to inspect the entire trachea. If size disparities between the ETT and the bronchoscope preclude passing the flexible bronchoscope through the ETT, the trachea should be examined with a ventilating (rigid) bronchoscope.

Tracheobronchial injuries range from irregular tears to complete transections. Major sternal injuries have been associated with partial or complete horizontal transections of the trachea. An associated esophageal laceration must be promptly recognized to avoid esophageal fistula and fatal mediastinitis. Esophagoscopy is mandatory in this setting. The site of the injury influences the choice of thoracotomy incision.[60] Injuries to the left main stem bronchus or parenchyma are managed best through a left thoracotomy. A right thoracotomy affords the best exposure for injuries to the right lateral or posterior aspect of the trachea or to the right bronchi or parenchyma. The anterior or left lateral aspect of the mediastinal trachea is best approached through a median sternotomy. Principles of bronchial surgery include conservative debridement of irregular ends; precise end-to-end approximation using interrupted, absorbable sutures; proportional placement of all sutures before tying; and layered coverage to provide an airtight seal and to prevent pleural-bronchial fistulas.[61] Primary reconstruction of the tracheobronchial tree should be performed as soon as possible to ensure the best results. Delayed operations have a high incidence of late scar formation, necessitating further operations.[57] Distal bronchial injuries are amenable to anatomic pulmonary resection.[1] Approximately one third of children with tracheobronchial injuries die, and 50% of these patients die within the first hour after injury.[9] Airway compromise is the primary cause of death. Long-term sequelae in patients with bronchial injuries may include bronchial stenosis, bronchopleural fistulas, or infection.

Rarely, pneumomediastinum without damage to the mediastinal organs is seen after blunt trauma to the torso.[62] The explanation offered for this phenomenon is that blunt trauma induces a sudden rise in intrapulmonary pressure, leading to passage of air from the perihilar alveoli into the mediastinum

along the peribronchial and perivascular spaces. Nevertheless, the clinical priority when pneumomediastinum is recognized on radiographic examination is to exclude, by whatever means deemed appropriate, the presence of aerodigestive tract injury. Video-assisted thoracoscopic surgery is suitable in cases of residual hemothorax, persistent air leaks, or posttraumatic empyema.[63,64]

Cardiac Injuries

Most cardiac injuries in children result from blunt trauma. These injuries have inconsistent manifestations, making diagnosis problematic. The incidence of trauma-related cardiac injuries in children is less than 3%.[50] For those who reach a hospital, cardiac injuries are discovered at autopsy in up to 15% of cases. Of these patients, 46% die at the scene of the accident; the rest die in the emergency department or later during hospitalization.[65] Myocardial contusion is by far the most common cardiac injury.[66] In a multicenter review, myocardial contusion represented 95% of the cardiac trauma in patients with a mean ISS of 27.[67] Cardiac contusion may resemble a myocardial infarction, with depressed myocardial function, or it may present as supraventricular and ventricular arrhythmias. Cardiac contusions in the pediatric population are more common than was previously appreciated.[15] Associated injuries include pulmonary contusions (50.5%) and rib fractures (23%). Cardiac contusion is more commonly diagnosed in the context of severe multiple system trauma rather than an isolated event.[67] Diagnosis of myocardial contusion depends on a high index of suspicion. Although the electrocardiogram (ECG) is generally accepted as a reliable screening tool,[35] its sensitivity in children has been questioned.[67]

Other studies of varying utility in identifying cardiac contusion are serum creatinine kinase and its isoenzymes, troponin, radionuclide angiography, and echocardiography.[68-75] Attempts to reliably identify patients at high risk for cardiac complications after blunt chest trauma have been challenging and have explored the predictive validity of a number of tests. One study identified an abnormal ECG and ISS greater than 10 as predictive of a myocardial contusion. However, this same study was unable to identify other factors predicting the development of complications of myocardial contusion.

Although a plethora of studies have addressed ways to diagnose myocardial contusion, it is important to recognize that, in most instances, cardiac contusion has limited clinical significance.[68-75] Indeed, the incidence of cardiac sequelae among patients with myocardial contusion is low.[71] Cardiac complications usually occur within 12 hours of injury and are forewarned by an abnormal ECG in most cases.[76] Patients with isolated chest wall contusions, a normal admission ECG, and normal rhythm 4 hours after injury rarely develop any cardiac-related complications during the course of their hospitalization.[72]

Other recognized trauma-related cardiac injuries are valvular dysfunction from papillary muscle or chordae tendineae rupture, cardiac rupture, pericardial effusion, and cardiac dysrhythmia.[15,66,72,76-85] Echocardiography is valuable for identifying pericardial effusions and global or segmental defects in heart wall motion. Conduction abnormalities noted on the admission ECG may be predictive of subsequent serious dysrhythmias, warranting close monitoring and possible treatment.[75] Echocardiography and isoenzyme levels, although frequently positive, do not predict cardiac-related morbidity. Ultimately there is no standard diagnostic test for the diagnosis of cardiac trauma in pediatric patients. Those who develop life-threatening complications can be identified in the emergency department setting using modalities readily available in most hospitals (e.g., 12-lead ECG) in most instances.[75] The mortality rate among patients with cardiac injury is 13%, mainly as a result of associated head or intra-abdominal injuries. Approximately 5% of survivors will have significant cardiac sequelae, most commonly valvular insufficiency and ventricular septal defects. Follow-up of children with cardiac injury should be ensured.[67]

Commotio Cordis

Commotio cordis is a unique phenomenon in pediatric trauma. It is defined as sudden cardiac arrest in the absence of apparent structural heart disease after a nonpenetrating chest injury.[86] It is characterized by the absence of pulmonary contusion, coronary artery abnormalities, structural anomalies, or conduction system pathology.[1] The rare occurrence of commotio cordis is largely explained by its mechanism, which requires the rare confluence of several determinants such as location of the blow directly over the heart and precise timing to the vulnerable phase of repolarization (just prior to T-wave peak).[86] These blunt, nonpenetrating chest blows, often innocent in appearance, cause virtually instantaneous sudden death, most commonly in young males. Ventricular tachyarrhythmias seem to be most associated. Sports-related commotio cordis deaths have triggered considerable interest in chest barriers to protect young sports participants from catastrophic precordial blows. However, many case reports have surfaced of commotio cordis even in the setting of protective gear.[86,87] Commotio cordis is a survivable phenomenon. The identification of ventricular tachyarrhythmias at the scene and in the emergency department resulted in shockable rhythms with survival due to the availability and use of an automated external defribillator.[86,88]

Aortic and Great Vessel Injuries

The overall mortality rate observed in children with aortic and great vessel injuries is 75%.[4] Of these children, approximately 85% die at the scene and 15% die after arrival to the hospital. Fatal hemorrhage in the 25% of patients who survive is avoided because the surrounding tissue contains the bleeding. However, left undiagnosed and untreated, 30% of those who arrive alive at the hospital will exsanguinate within 24 hours after admission.[89] Fortunately, these injuries are uncommon in children and are seen in only approximately 1% to 3% of injured children.[3,4] The most common and lethal of these injuries is traumatic aortic disruption, characteristically seen in the older adolescent population.[3,4] The well-recognized signs and symptoms associated with traumatic aortic rupture are midscapular back pain, unexplained hypotension, upper extremity hypertension, bilateral femoral pulse deficits, and large initial chest tube outputs.[90-92] Early recognition of these signs can prevent tragic delays in diagnosis. However, acute traumatic aortic rupture remains a highly lethal injury with no change in prognosis during the past two decades.[93]

The findings on chest radiographic examination include a widened mediastinum, deviation of the nasogastric tube or central venous lines, blurring of the aortic knob, abnormal paraspinous stripe, rightward tracheal deviation, or upward

shift of the left main stem bronchus.[90-92] Transverse mediastinal width and mediastinal width/chest width ratio on supine chest films have been suggested as useful tools for identifying the patient with possible traumatic aortic rupture.[14] However, their clinical usefulness is limited by considerable overlap between normal and abnormal measurements as is seen in infants with an enlarged thymus. This has prompted others to suggest that subjective assessment of anatomical mediastinal abnormality is more reliable in determining the need for aortography.[14]

The role of CT scan and angiography in ruling out a potential intrathoracic vascular injury remains debatable. Traditionally, invasive aortography has been considered the test of choice to rule out such injuries. Authors in favor of this technique find aortography more accurate and expeditious with high sensitivity (98%) in detecting aortic and major branch vessel injuries.[94-96] Both cut film arteriography and digital subtraction arteriography are used, with similar results and enhanced visualization.[97] On the other hand, helical CT scan is a noninvasive procedure that can be used as the initial diagnostic tool, with a sensitivity and negative predictive value of 100%, equivalent to that of aortography.[98] Helical CT scanning prevents unnecessary aortography, expedites patient care, and reduces costs. Some scanners are capable of performing CT aortography, which creates a three-dimensional reconstruction of the aorta. Using helical CT scan to exclude a mediastinal hematoma and to evaluate the cause of an abnormal aortic contour promotes more selective use of aortography.[98-100]

Another useful diagnostic tool is multiplane transesophageal echocardiography (TEE). In patients with severe blunt chest trauma, TEE and helical CT scan have similar diagnostic accuracy for identifying acute traumatic aortic injury. TEE also allows functional and anatomic assessment of the heart and identifies intimal or medial lesions of the thoracic aorta more readily.[101,102] Additional randomized studies comparing these techniques are required.

The issue of treatment priorities in patients with traumatic aortic rupture is evolving. The most common cause of death is hemorrhage, and 95% of these patients have associated injuries requiring surgery. The most common associated injuries requiring emergent treatment are serious closed-head injuries and intra-abdominal hemorrhage. The hemodynamically unstable patient with known intra-abdominal hemorrhage should undergo laparotomy before any other procedure. The hemodynamically stable patient with intra-abdominal hemorrhage should undergo aortography followed by laparotomy. Left hemothorax, pseudocoarctation, and/or supraclavicular hematoma can be found in patients at high risk for sudden free rupture and exsanguination. Patients demonstrating these characteristics may benefit from immediate thoracic exploration rather than waiting for aortography.[90] Repair of an aortic rupture using simple aortic cross-clamping alone is feasible in the majority of patients without increased mortality or spinal cord injury.[93] Although the traditional therapy for blunt traumatic rupture of the thoracic aorta is immediate repair, in some patients with concomitant head trauma, respiratory failure, cardiac dysfunction, or sepsis, this injury can be managed conservatively with selective delayed operative repair without increasing the risk for exsanguinating hemorrhage.[103] While experience with β-adrenergic antagonists in children with traumatic aortic injuries is limited, some authorities argue that the approach to pediatric traumatic rupture of the thoracic aorta should be identical to that in the adult.[104]

Finally, the advent of endovascular repair in adults makes this a tantalizing treatment modality in children. There have been case reports of endovascular aortic stent grafts being used in younger patients.[104] The known complications of stents include occlusion of the left main stem bronchus, erosions, perigraft leak, graft migration, limb ischemia, arch perforation, entrapment, infection, pseudoaneurysm, distal embolization, and femoral artery complications.[105] Long-term follow-up in these patients is mandatory to determine how the child's future growth affects outcome.

Other Miscellaneous Injuries

Significant injury from thoracic trauma may occur in less common sites in the thorax. Although infrequent, these injuries have equal capacity to result in morbidity and mortality. Among these injuries are diaphragmatic and esophageal rupture, posttraumatic lung cysts, and intercostal hernias. Diaphragmatic ruptures occur most commonly on the left side as a result of severe thoracoabdominal compression or by penetrating injury. The incidence in children is 4%.[106] A large diaphragmatic rupture can cause immediate respiratory compromise because of displacement of intra-abdominal viscera into the chest. However, most diaphragmatic injuries are initially asymptomatic and cause problems later because of incarcerated viscera. The key to diagnosis is a high index of suspicion for any abnormal chest radiograph. Radiographic findings that suggest diaphragmatic rupture include displacement of the nasogastric tube tip into the chest, abnormal gas patterns in the chest, and haziness of the diaphragm.[107] Herniated abdominal organs may be damaged when tube thoracostomy is performed in the hemithorax of an undiagnosed diaphragmatic injury. Most diaphragmatic injuries are best repaired through the abdomen. The lacerated diaphragm is repaired primarily and a chest tube is placed. If the injury results in loss of diaphragmatic tissue, a prosthetic patch may be necessary to close the defect.

Esophageal rupture rarely occurs after blunt trauma. It is more likely to occur after penetrating trauma. It should be suspected in the patient with pneumomediastinum or hydrothorax after thoracic trauma. Water-soluble esophagram and rigid esophagoscopy is indicated to make the diagnosis and identify the site of the injury. If the rupture is detected early, primary repair of the esophagus usually is possible. Broad-spectrum antibiotics, nasogastric decompression, and fluid resuscitation are indicated.

Lung cysts may present immediately after blunt thoracic trauma. They are thought to occur as a result of lung laceration. Although there are exceptions, most undergo slow resolution without surgical intervention. Injury to the intercostal muscles during blunt trauma may create an area of weakness, leading to an intercostal hernia. The weakness in the thoracic wall can be detected soon after injury or late in the course, up to 4 years after the initial injury. When detected, intercostal hernias should be closed with muscle or fascia from the adjacent thoracic cavity. A prosthetic mesh is required in some instances.[108,109]

Penetrating Trauma

Penetrating thoracic wounds are a challenge for the surgeon and often carry a high mortality rate. The vast majority of penetrating trauma occurs in patients older than 12 years, mainly in males. In a review of an urban Level 1 trauma center, 55%

of penetrating injuries resulted from stab wounds, while the remainder were caused by gunshot wounds. Isolated injuries were present in 69% of cases, whereas 31% incurred additional extrathoracic injuries.[110] Although most penetrating injuries are isolated, any chest injury at or below the nipple line anteriorly, or at or below the tip of the scapula posteriorly, is better classified as a thoracoabdominal injury. In children with penetrating injuries of this type, the presence of intra-abdominal injuries must be excluded. For a patient with an open chest wound, placement of an occlusive dressing (taped on three sides) may prevent development of an open pneumothorax.[111] Diagnostic aids include peritoneal lavage, triple-contrast CT scan, and laparoscopy. The last has been found to be effective in assessing disruption of the diaphragm in hemodynamically stable patients.[63] In patients with suspected penetrating cardiac injury, pericardial focused ultrasound has 100% sensitivity and 97% accuracy in detecting pericardial blood.[112]

Use of autotransfusion devices in children with significant hemothoraces may be beneficial. Patients with ISS of 25 or greater and blood pH of 7.3 or less at admission are more likely to require an operation. Additionally, these two parameters are good predictors for mortality in both gunshot wounds and stab wounds. The overall mortality rate for penetrating trauma is 17%, largely as a result of cardiac and intrathoracic great vessel injuries.[110] Almost all patients will require intensive monitoring after surgery.

Functional Outcome

Among all patients with pediatric thoracic trauma, more than 75% leave the hospital without serious disabilities, but approximately 15% will require some sort of rehabilitation. In terms of functional status, the assessment of the Functional Independence Measure for children older than 7 years has shown that 68% will achieve complete independence, 7% will require minimal to moderate assistance, and 7% will be completely unable to recuperate their abilities. Most of these limitations are related to extrathoracic injuries, especially intracranial sequelae.[2]

Summary

Thoracic injuries are a rare but potentially lethal subset of childhood injuries. Because they are so uncommon, the timely implementation of diagnostic and therapeutic measures may be less than satisfactory. The framework for successful management of pediatric chest injuries includes the widely held principles of establishing and managing the patient's airway, assessing breathing, and monitoring the adequacy of circulation. A detailed primary and secondary survey for the extent of thoracic and associated nonthoracic injuries is essential. Rapid resuscitation and institution of definitive therapy minimizes morbidity and mortality.

VII Chapter 115

Abdominal Trauma in Pediatric Critical Care

Christopher P. Coppola and James C. Gilbert

PEARLS

- In the initial resuscitation of trauma victims, the first priority remains the ABCs of ***a***irway, ***b***reathing, and ***c***irculation.
- When in doubt about the reliability of the airway, perform endotracheal intubation.
- The standard of care in treating hemodynamically stable children with hepatic or splenic injury is nonoperative observation.
- Patients who are hemodynamically stable may undergo further radiographic workup, whereas patients with evidence of an abdominal injury who remain clinically unstable after resuscitation with 40 mL/kg of fluid should be taken to the operating room for exploration.
- Splenic preservation is more important in younger children and is usually possible with nonoperative management or embolization.
- Vigilance and reexamination are necessary to detect a small bowel injury, which results in increases morbidity if missed for greater than 24 hours after trauma.

Trauma is the leading cause of morbidity and mortality in the pediatric age group. An estimated 1.5 million pediatric injuries occur each year, resulting in 500,000 hospitalizations and 20,000 deaths.[1] Thus trauma exceeds all other causes of death combined. Abdominal injuries are a marker of severe trauma, and evaluation of the child with an abdominal injury must include a thorough examination of the entire child. Failure to accurately assess the abdomen is the single most common error in the early treatment of the injured patient. Management of pediatric trauma requires a multidisciplinary approach with emergency department physicians, critical care specialists, anesthesiologists, and surgeons working as a multidisciplinary team to provide prompt stabilization, assessment, and treatment. Performing the primary and secondary survey, instituting fluid resuscitation, and arriving at a decision as to the most appropriate management plan are the principal goals of the trauma team leader.

The vast majority of abdominal injuries in children are preventable. Health care providers must work with the broader community to identify and alleviate causes of pediatric trauma. Education, public safety measures, and legislation will serve to prevent many cases of pediatric injury. Intentional abdominal trauma to children must be considered and, if suspected, must be reported to the appropriate agency. New developments in pediatric abdominal trauma include use of imaging modalities such as Focused Abdominal Sonography for Trauma (FAST) and embolization of solid organ injuries, which allows for increased utilization of nonoperative management. Laparoscopy can be applied in select scenarios. As part of disaster preparedness, clinicians providing trauma care for children should have an awareness of wartime and mass casualty injury management.

Mechanisms and Patterns of Injury

The severity and pattern of abdominal injury correlate with the mechanism of injury. Blunt injury accounts for 90% of abdominal trauma in children. The most common mechanisms are motor vehicle accidents, motor pedestrian accidents, falls from heights, bicycle accidents, and nonaccidental trauma. In pediatric blunt abdominal trauma, solid viscus organs such as the liver, spleen, and kidney are more frequently injured than hollow viscus organs. Children suffering lap belt injury, handlebar injury, or kicks may suffer small bowel perforation. Pedestrians struck by motor vehicles can have a pattern of head injury, splenic fracture, and left femur fracture (Waddell triad). In addition, urban violence and the high prevalence of firearms result in penetrating abdominal injuries in children. Although the mechanism of injury may correlate with the extent of injury, ongoing clinical assessment is a more sensitive indicator of the extent of blood loss and hemodynamic instability, and determines the resuscitation and management of the child with an abdominal injury.

Penetrating Abdominal Trauma

A national decrease in violent crime has reduced the incidence of penetrating trauma since the 1980s. Penetrating abdominal injuries are most commonly caused by firearm use or stabbings. In children, abdominal gunshot wounds result in more severe injuries than stab wounds because of the increased energy delivered by firearms, particularly shotguns and military rifles.[2] Significant intraperitoneal injuries are present in most children who sustain gunshot wounds, suggesting the

need for abdominal exploration in all gunshot victims. There is a controversial trend toward selective exploration of penetrating injuries in adults. For example, computed tomography has been successfully used to determine the use of selective laparotomy in penetrating torso trauma.[3] However, most trauma centers continue to perform mandatory laparotomy on all patients with gunshot wounds to the abdomen, although some nontherapeutic explorations will occur. Abdominal stab wounds that are found to penetrate the transversalis fascia on local wound exploration should undergo laparotomy or laparoscopy. Expectant observation of stab wounds in children should rarely be applied because the true extent of injury is not always appreciated on local exploration.

Recreational and Sports Injury

Specific recreational activities commonly practiced by children, such as bicycling, all-terrain vehicle (ATV) use, skiing, snowboarding, and horseback riding result in predictable injury patterns that guide evaluation. Snowboard injuries are increasing and include abdominal injuries in 25% of cases.[4] ATV crashes produce a particularly damaging pattern of injury as the ATV has the weight of a car and the lack of protection of a motorcycle. This results in a combination of an ejection and rollover mechanism of injury with the worst of both. The majority of deaths involve head and spine injuries. Lack of helmet use is associated with a higher mortality. ATV abdominal injuries include crush injuries to liver, spleen, and kidney. Child drivers are more susceptible to crash and it is alarming that child-sized ATVs are in production. Even where laws restrict ATV use by children, they are frequently injured and have a high rate of missed injuries.[5] Blunt impalement on a bicycle handlebar can result in a predictable pattern of injury to bowel, mesentery, or pancreas.

Wartime Trauma

It is unfortunate to note that children can also be victims of wartime trauma causing abdominal and other injuries. In contrast to wars of the past, modern warfare is often conducted in urban areas with a civilian population present and the frequent involvement of children. Additionally, medical infrastructure is disrupted in a war zone and many residents suffer malnutrition and infections which makes them more debilitated in the face of a new injury. Military high-energy rifles cause penetrating wounds in which the pressure wave of the projectile results in a cone of tissue destruction. In abdominal injuries, this necessitates wide debridement of soft tissues, and often a second-look laparotomy is required to detect evolving intestinal necrosis. It is common for children to suffer blast and fragmentation injuries from land mines, bombs, indirect fire weapons (rockets and mortars), improvised explosive devices, and suicide bombings.[6] Land mines and air-delivered cluster bomblets are particularly insidious because their interesting colors and shapes attract children's curiosity. Wounds include pressure wave blunt injury, shrapnel penetration, and burns. These injuries in children often require a damage-control laparotomy, wide debridement of soft tissues, temporary abdominal closure, and multiple operations. Vacuum-assisted wound dressings are particularly useful.[7] Wide-bore feeding tubes allow improvised feeds such as eggs, milk, honey, and grains. Long hospital stays are needed to ensure that the child can survive at home with little medical attention.

Evaluation and Resuscitation

Evaluation and resuscitation occur simultaneously when a child presents with an abdominal injury. The Advanced Trauma Life Support (ATLS) protocols developed by the American College of Surgeons should be used. The initial assessment, or primary survey, includes stabilization of the cervical spine while evaluating for airway patency, function of breathing, and adequacy of circulation (the ABCs). Prompt endotracheal intubation should occur in any patient in whom the stability of these functions is in doubt. Intravenous access in the small child can be particularly challenging, and skilled personnel should be employed. Pediatric Advanced Life Support (PALS) guidelines suggest utilizing an intraosseous line after three failed attempts to establish intravenous access or 90 seconds have expired and access has not been obtained. Basic neurologic function is assessed. The patient must be completely exposed for examination and then covered with blankets to maintain body temperature. Children are more susceptible to heat loss and dehydration because of their greater surface area/mass ratio.

Physical Examination

Abdominal examination includes observation of external signs, then palpation for tenderness, distension, or firmness. Children swallow a large amount of air when they cry and gastric distension may require nasogastric tube decompression. Upper quadrant ecchymosis, tenderness, and associated rib fractures suggest the presence of liver or spleen injury. Midabdominal ecchymosis from a seat belt suggests the possibility of a small bowel injury. Stability of the pelvis is assessed with lateral and axial manual compression of the pelvic ring. Extraperitoneal bladder ruptures may cause localized suprapubic tenderness, whereas an intraperitoneal bladder rupture may present as generalized abdominal distension.

Laboratory Tests

Laboratory examinations, including complete blood counts, serum chemistries, and urinalysis, should be obtained on all trauma patients. Additional studies, such as liver function tests and pancreatic enzymes, are indicated in certain injuries. Elevated transaminase levels suggest nonspecific parenchymal liver injury whereas elevated amylase and lipase levels suggest a pancreatic injury. A base deficit of greater than 6 meq/L is a strong indicator of intraabdominal injury in blunt trauma. Hematuria is associated with intra-abdominal injury and renal injury. Urinalysis demonstrating more than five red blood cells per high-power field combined with clinical assessment accurately predicts intra-abdominal injury. Hemoglobin concentrations as low as 7 g/dL are well tolerated in children after blunt abdominal injury, provided intravascular volume is repleted.

Radiographic Assessment

Prompt plain radiographs of the chest, lateral cervical spine, and pelvis should be obtained during the initial assessment. Patients who are hemodynamically stable may undergo

further radiographic workup, while patients with evidence of an abdominal injury who remain clinically unstable after resuscitation with 40 mL/kg of fluid should be taken to the operating room for exploration.

Computed Tomography

Computed tomography is the procedure of choice for definitive radiographic assessment after blunt abdominal trauma in children. Clinical impression remains the most sensitive indicator of the need for computed tomography. Computed tomography can be used to identify hepatic, splenic, intestinal, pancreatic, renal, and bladder injuries in children and can even detect intestinal and mesenteric injury with sensitivities of 94% and 96%, respectively.[8] Serial clinical assessments must be made before computed tomography. If the patient deteriorates, stabilization in the PICU or immediate operative intervention must be considered. Findings on computed tomography suggestive of intestinal injury are unexplained free fluid without solid visceral organ disruption, abnormal distribution of bowel loops, contrast extravasation, and contrast enhancement of intestinal wall.[9] The Organ Injury Scaling Committee of the American Association for the Surgery of Trauma has developed a grading system to estimate the extent of abdominal injury.[10,11] Short of operative exploration, computed tomography is the most accurate method used to grade the extent of injury.

Sonography

FAST is a rapid, noninvasive, and portable method to evaluate the abdomen. Various reports note that sonography for abdominal trauma has a sensitivity of 55% to 86% and a specificity of 95% to 98%.12-14 Sonography accurately identifies intraperitoneal free fluid, but it does not accurately identify the source of that fluid. Sonography is comparable to diagnostic peritoneal lavage (DPL) as a method for detecting free peritoneal fluid, but is less invasive. However, it does not supplant computed tomography in its ability to define the specific nature and extent of abdominal injury.

Additional Assessment Tools

Diagnostic Peritoneal Lavage

Refinement in the nonoperative management of pediatric abdominal trauma makes DPL unnecessary in stable patients, because the presence of free intraperitoneal blood is not an absolute indication for surgery in children. In addition, performing a DPL can be difficult in small children due to the decreased domain of the smaller abdomen. However, DPL is a useful triage tool for selectively applying laparotomy for blunt intestinal trauma in children. In one series, the cell count, amylase activity, and particulate matter in the DPL specimen were able to identify small bowel perforation with a sensitivity of 100%.[15]

Diagnostic Laparoscopy

Diagnostic video-assisted laparoscopic evaluation has been suggested as a safe and effective modality for evaluating the abdomen in the stable patient after penetrating trauma. Diaphragmatic injuries can be diagnosed and repaired laparoscopically.[16] Alternatively, thoracoscopy in hemodynamically stable penetrating-trauma patients can be used to avoid nontherapeutic laparotomy by ruling out penetration of the abdominal cavity and can identify thoracic and diaphragmatic injuries.

Management of Specific Abdominal Injuries

Children often demonstrate surprising hemodynamic stability in the face of significant hemorrhagic loss, until their capacity for compensatory vasoconstriction is surpassed. Although fluid resuscitation and blood transfusion is far and away the primary therapy, a select few children may require inotropic support after major trauma. Frequent serial abdominal examinations are performed to determine the need for surgical exploration for a missed hollow viscus injury. Operative intervention should not be delayed, because hypotension and decreased cerebral perfusion pressure worsen morbidity and mortality. Although abdominal compartment syndrome has a low reported incidence of 0.6% to 4.7% in critically injured children, it will only be detected through a high index of suspicion and frequent measurement.[17] In stable patients, early enteric feeding maintains immune function and shifts the patient to a more anabolic balance.

Nonoperative Management of Solid Organ Injuries

The standard of care in treating hemodynamically stable children with hepatic or splenic injury is nonoperative observation. Management of these injuries varies widely between adult and pediatric facilities, and splenectomy can be avoided if a child is taken to a facility that utilizes this nonoperative strategy. The American Pediatric Surgical Association Trauma Committee has proposed guidelines for care based on radiographic severity of injury (Table 115-1). Although this observation traditionally has taken place in the intensive care unit, evidence gathered to determine these recommendations suggests that observation on a patient ward is safe.[18]

Table 115–1 Proposed Guidelines for Resource Utilization in Children with Isolated Spleen or Liver Injury

CT Grade	I	II	III	IV
ICU stay (days)	None	None	None	1
Hospital stay (days)	2	3	4	5
Predischarge imaging	None	None	None	None
Postdischarge imaging	None	None	None	None
Activity restriction (weeks)*	3	4	5	6

*Return to full contact, competitive sports (e.g., football, wrestling, hockey, lacrosse, mountain climbing) should be at the discretion of the individual pediatric trauma surgeon. The proposed guidelines for return to unrestricted activity include "normal" age-appropriate activities.

Data from Stylianos S and the APSA Trauma Committee: Evidence-based guidelines for resource utilization in children with isolated spleen or liver injury, *J Pediatr Surg* 35:164–169, 2000.

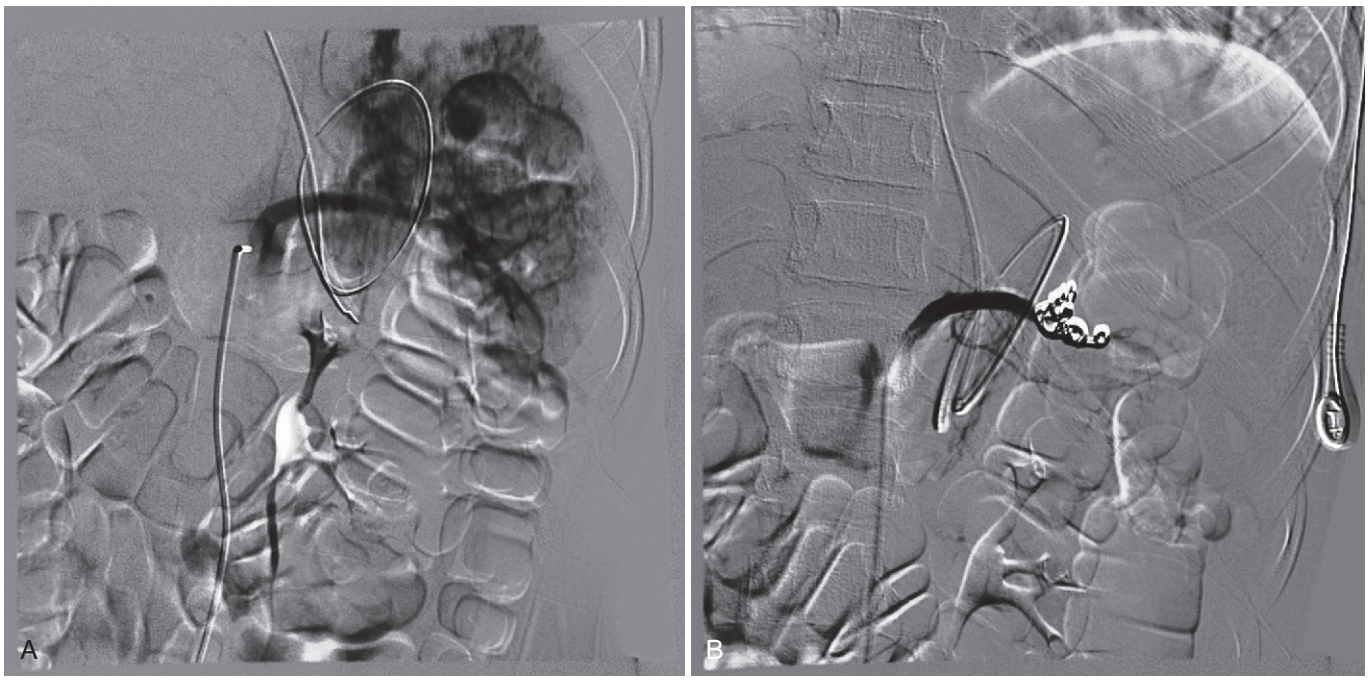

Figure 115–1. Nonselective splenic embolization. **A,** Angiography demonstrates splenic injury with active extravasation of blood. **B,** Postembolization image demonstrating coil in splenic artery and resolution of hemorrhage.

Embolization of Solid Organ Injuries

Computed tomography can identify active extravasation from splenic and hepatic injuries. Angiography is able to map out the specific site of hemorrhage and embolization coils can be used to selectively occlude the bleeding vessel. This therapy reduces the need for transfusion and can help avoid the need for a laparotomy. Nonselective embolization of the main splenic artery has also been shown to reduce bleeding (Figure 115-1). Angiography should be reserved for children with active extravasation who are still hemodynamically stable. Unstable patients with solid organ injury require laparotomy.

Injury to the Spleen

The spleen can extend below the costal margin in children and is the most commonly injured abdominal organ in blunt trauma. Treatment of splenic injury has evolved from routine splenectomy to a strategy of nonoperative management that is successful greater than 90% of the time.[19] Splenic injuries are most often caused by a direct blow to the left upper quadrant and manifest as localized tenderness, abrasion, or ecchymosis. Splenic injury is graded by computed tomography (Figures 115-2 and 115-3, Table 115-2). Operative intervention for splenic trauma usually results in splenectomy. For this reason, nonoperative management should be attempted in stable children, regardless of the severity of injury. If a stable child with a splenic injury requires laparotomy for injury to another organ, splenorrhaphy and autotransfusion increase splenic salvage, which reduces risk of infection.[20] Angiography and embolization of splenic vessels can control hemorrhage without laparotomy. At pediatric trauma centers, operating on a child with an isolated splenic injury is very rare. The indications for operative intervention are generally limited to persistent hypotension, greater than 50% blood volume replacement, or additional life-threatening abdominal injuries.

Figure 115–2. CT scan of a patient with a grade IV splenic laceration.

Nonoperative management generally consists of large-bore venous access for fluid resuscitation, a nasogastric tube for gastric decompression, intensive care unit monitoring, frequent hematocrit values, serial physical examinations, and bed rest. Recommendations from the American Pediatric Surgery Association Trauma Committee indicate only short periods of

Figure 115–3. CT scan of a patient with a grade IV splenic laceration demonstrating free fluid around the tip of the spleen.

observation are necessary.[18] This abbreviated observation of 1 day bed rest for Grade I and II injuries and 2 days of bed rest for higher grade injuries has been validated to be safe.[21]

Injury to the Liver

The liver, which also extends below the costal margin in children, is the second most commonly injured organ in blunt abdominal trauma. Liver injuries are associated with the highest mortality and may require surgical correction of injuries to the hepatic veins or vena cava. Liver injuries in stable patients can be managed nonoperatively. Ecchymosis, bruising, or abrasions over the right upper quadrant suggest significant injury. Liver injury is graded by appearance on computed tomography (see Table 115-2). However, the clinical course of the patient, not the appearance on computed tomography, should determine treatment (Figures 115-4 and 115-5). Elevated serum transaminase concentrations are associated with liver trauma and other intraabdominal injury.[22] The mortality associated with operative management of hepatic injuries is higher than in the nonoperative group. Late complications of liver injuries include bile peritonitis, abscess formation, hemorrhage, and hematobilia. Operative treatment is required for major hepatic trauma associated with hepatic vein or retrohepatic canal injuries. Often, definitive repair is not possible at the time of initial exploration, necessitating damage-control surgery with packing, stabilization, resuscitation, and repeat laparotomy. Select patients with ongoing bleeding from a hepatic injury can be stabilized with embolization of hepatic blood vessels.

Injury to the Small Bowel

Bowel injuries resulting from blunt trauma are relatively rare. However, a high index of suspicion must be maintained to avoid a delayed diagnosis, which is more common in children. The incidence of small bowel injury increases with increasing number of other organs injured.[23] The mechanisms of injury associated with blunt bowel trauma include motor vehicle/pedestrian accidents, handlebar injuries, lap belt injuries, and child abuse. Deceleration injuries in children restrained with a lap belt may occur as a constellation that includes intestinal injury, abdominal wall ecchymosis, and flexion-distraction injury (Chance fracture) to the lumbar spine (Figure 115-6). Intestinal injuries include bowel disruption, mesenteric avulsion, and bowel wall contusion. (Figure 115-7) Areas of the small bowel particularly prone to injury are the points of retroperitoneal fixation, such as the proximal jejunum at the ligament of Treitz or the terminal ileum near the junction with the cecum. A perforation may be present even without free air or significant spillage of succus on DPL. Delayed perforations may occur as a result of mesenteric disruptions and subsequent bowel necrosis. In some instances, a prolonged ileus that fails to resolve may be the only evidence of intestinal injury.

The mechanism of injury and abdominal wall ecchymosis can suggest the diagnosis of intestinal injury. Abdominal tenderness may be present on physical examination. Until spinal injuries are ruled out, a lateral decubitus film is preferred over an upright chest film for detection of free air. Findings on computed tomography consistent with small bowel injury are free air, contrast extravasation, focal bowel thickening, free fluid, and fat stranding or fluid in the mesentery.[24] Once diagnosed, bowel injuries are treated by laparotomy, exploration, and repair. Excision of injury and primary anastomosis to reestablish gastrointestinal continuity are usually possible. Morbidity and mortality are not increased if the delay in diagnosis is less than 24 hours.[15]

Injury to the Duodenum

Duodenal injuries are rare in children but occur more commonly than in adults. Children may have localized right upper quadrant tenderness, but the presentation may be subtle. The majority of duodenal injuries in children result in a duodenal hematoma without disruption of the lumen. When there is perforation, computed tomography demonstrates extraluminal gas or oral contrast extravasation in the right anterior pararenal space. Thickening of the duodenal wall is seen when a duodenal hematoma is present. Duodenal injuries are classified from grade I to V based on severity (see Table 115-2). The majority of pediatric duodenal injuries are grades I and II. Overall, mortality is 18% for patients with duodenal injuries. For grade I lesions, the mortality is 8%, with associated injuries as the usual cause of death.

A duodenal hematoma is treated with observation and parenteral hyperalimentation. Resolution generally occurs in 2 to 4 weeks. In some cases of duodenal hematoma, placement of a nasojejunal tube will allow enteral feeding distal to the point of obstruction. Repair of full-thickness duodenal injury may require duodenorrhaphy, pyloric exclusion, duodenoduodenostomy, duodenojejunostomy, pancreaticoduodenectomy, or simple drainage (Figure 115-8). The majority of injuries are treated with debridement and primary closure with drainage. Pyloric exclusion is recommended for complex duodenal injuries. Duodenostomy and regional drains are useful. In children, pancreaticoduodenectomy is rarely required to treat a duodenal injury.

Injury to the Pancreas

Injuries to the pancreas may require operative intervention depending on severity of injury and integrity of the pancreatic duct (see Table 115-2). Upper abdominal tenderness, elevated amylase level, edema of the gland, and unexplained fluid in the lesser sac on computed tomography suggest pancreatic

Table 115–2 Abdominal Organ Injury Computed Tomography Grading Scales*

Injury	Grade I	Grade II	Grade III	Grade IV	Grade V	Grade VI
Splenic hematoma	Subcapsular, <10% surface area	Subcapsular, 10%–50% surface; intraparenchymal, <5 cm diameter	Subcapsular, >50% surface or expanding; Intraparenchymal >5 cm or expanding; ruptured			
Splenic laceration	<1 cm depth	1–3 cm depth	>3 cm depth or involving vessel	Segmental vessel >25% devascularization	Shattered spleen	
Splenic vascular					Hilar injury 100% devascularization	
Hepatic hematoma	Subcapsular, <10% surface area	Subcapsular, 10%–50% surface; intraparenchymal, <10 cm diameter	Subcapsular, >50% surface or expanding; Intraparenchymal >10 cm or expanding; ruptured			
Hepatic laceration	Capsular tear, <1 cm depth	1–3 cm depth, <10 cm length	>3 cm depth	Disruption 25%–75% of lobe or 1–3 Couinaud segments in lobe	Disruption >75% lobe or >3 Couinaud segments in lobe	
Hepatic vascular					Injury to cava or hepatic vein	Avulsion
Duoenum hematoma	Single portion	>1 portion				
Duodenum laceration	Partial thickness	<50% circumference	50%–75% circumference second portion	>75% circumference second portion, ampulla, or common bile duct	Disruption duodenopancreatic complex	
Duodenal vascular					Devascularization of duodenum	
Pancreas hematoma	Minor contusion	Major contusion				
Pancreas laceration	Superficial	Major	Distal transaction or duct injury	Proximal transaction or ampulla injury	Massive disruption of head	
Kidney contusion	Hematuria					
Kidney hematoma	Subcapsular, nonexpanding	Confined to retroperitoneum				
Kidney laceration		<1 cm depth	>1 cm depth	Through cortex, medulla, and collecting system	Shattered kidney	
Kidney vascular					Avulsion	

*Add one grade for multiple injuries up to grade III.
From Moore EE, Cogbill TH, Malangoni MA, et al: Organ injury scaling, II: pancreas, duodenum, small bowel, colon, and rectum, *J Trauma* 30:1427-1429, 1990; and Moore EE, Shackford SR, Pachter HL, et al: Organ injury scaling: spleen, liver, and kidney, *J Trauma* 29:1664-1666, 1989.

injury. Handlebar injury, lap belt injury, direct blow to the abdomen, and motor vehicle crash are the most common mechanisms (Figure 115-9). When the gland is fractured, this generally occurs where it crosses the vertebral column (Figure 115-10). Pancreatic transection is best treated by early distal pancreatectomy and drainage. When the main pancreatic duct is intact, nonoperative treatment with an extended course of bowel rest and parenteral nutrition should be attempted. Devascularization of the pancreas and duodenum in blunt abdominal trauma is rare in children. When it does occur, laparotomy, pyloric exclusion, drainage, and repeated debridement with an open abdomen may be required. After pancreatic injury, pseudocysts may develop and require internal or external drainage after maturation. Operative drainage of a pseudocyst to the stomach or a roux-en-Y loop of intestine should be delayed for at least 6 weeks until the pseudocyst wall is mature. An infected pseudocyst with fevers may require urgent percutaneous drainage. Endoscopic retrograde cholangiopancreatography is useful to diagnose pancreatic duct disruption, and a pancreatic stent can be placed across the disrupted duct, which potentially prevents pseudocyst formation[25] (Figure 115-11).

Blunt Abdominal Aortic Injury

The majority of aortic injuries after blunt trauma are in the chest, with only 6% in the abdomen.[26] Pedestrians struck by a motor vehicle and unrestrained passengers are more likely to

have thoracic injuries, while passengers with lap belt injuries are more likely to injure the abdominal aorta.[27] Injury to the renal artery or mesenteric artery is more common than aortic injury.[28] Computed tomographic angiography is capable of definitive diagnosis; however, angiography may be required in some children. Aortic injuries include contusion, intimal dissection, and complete disruption. The most frequent site of disruption is at the inferior mesenteric artery or the renal arteries. Patients present with diminished or absent distal lower extremity pulses. Neurologic deficits may result from aortic compromise. Associated injuries are present in 65% of cases. When blunt abdominal aortic injury is recognized early, surgical intervention can dramatically lower mortality. A pseudoaneurysm can develop as a late complication. Major abdominal venous injuries resulting from blunt trauma are usually fatal.

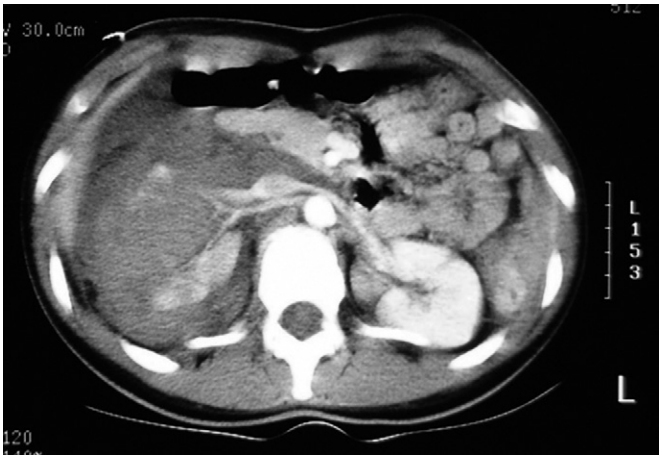

Figure 115–12. CT scan of patient with a grade IV renal laceration and vascular injury.

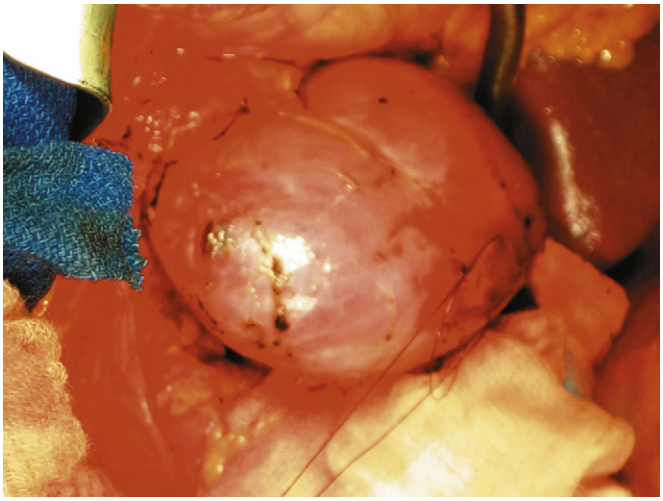

Figure 115–13. Repair of grade II renal laceration after penetrating trauma.

Renal Trauma

Renal injury rarely occurs as an isolated injury. Findings suggestive of renal injury include flank tenderness, flank or abdominal mass, or ecchymosis. Hematuria, either gross or microscopic, is the best indicator of serious renal injury. However, serious injury, especially renal pedicle injuries, may be present even without hematuria. In hemodynamically stable patients, computed tomography with intravenous contrast allows for a very accurate diagnosis of renal injury and function (Figure 115-12). Sonography also provides accurate diagnosis of extrarenal fluid collections.[29] Renal trauma can result in a hematoma, laceration, or vascular injury (see Table 115-2). Children who are hemodynamically stable may be safely managed nonoperatively. Angiography with embolization can control hemorrhage when contrast extravasation is seen on computed tomography.[30] Exploration is warranted in children who are hemodynamically unstable, have an expanding hematoma, or have an associated abdominal injury necessitating exploration. In unstable patients, nephrectomy is the safest choice; however, the surgeon must ensure that the contralateral kidney is present before proceeding. Renal repair or partial nephrectomy is possible in select cases (Figure 115-13). Isolated urinary extravasation

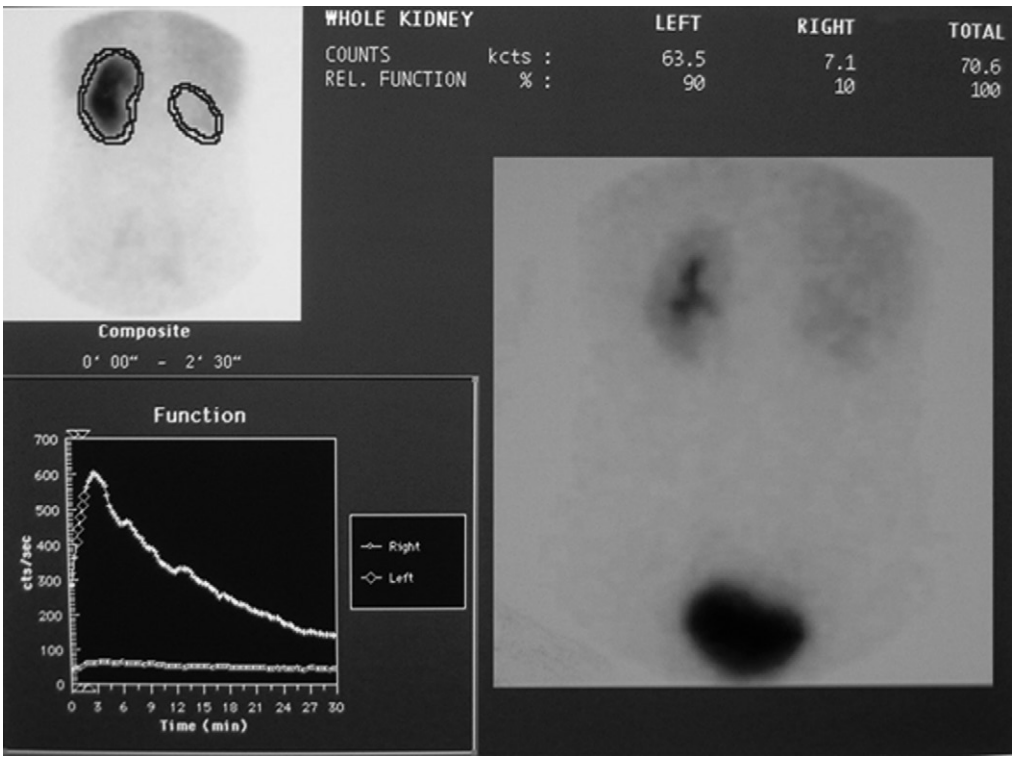

Figure 115–14. Renal scan of patient with grade IV renal laceration and vascular injury.

is not an indication for emergent exploration, but delayed operation or percutaneous drainage may be required for persistent extravasation or infection. If urinary extravasation is present, antibiotics should be administered. Patients with extravasation and devascularized segments on computed tomography have a higher incidence of delayed complications. Observation and bed rest usually result in excellent outcome, even with deep parenchymal lacerations associated with urinary extravasation. Patients with gross hematuria are kept on bed rest until the urine is grossly clear. Reevaluation is necessary for persistent hematuria, tenderness, or mass. All patients with renal injuries, regardless of severity, should be monitored for the delayed onset of hypertension. A captopril-furosemide DTPA (technetium-99m diethylenetriamine pentaacetic acid) renal scan is used to verify function after injury (Figure 115-14).

Renal pedicle injuries are rare and are suggested by lack of renal contrast enhancement on computed tomography. Renal angiography definitively establishes the diagnosis and directs operative management. Ureteral injuries require operative repair, but diagnosis of ureteropelvic junction disruption may be delayed because of a lack of clinical signs on presentation. Absence of contrast in the ureter indicates that ureteral stent placement will likely be necessary.[31]

Bladder Injuries

Bladder injuries are most often associated with blunt trauma. The bladder is predominantly intra-abdominal in children. Therefore, burst injuries are more common than in adults. Bladder rupture is associated with pelvic fractures. Clinical presentation of bladder rupture may be subtle, with only mild suprapubic tenderness. The severity of associated injuries may mask signs of a bladder injury. Hematuria is the most consistent finding. Recognizing the injury and identifying it as intraperitoneal or extraperitoneal are important. Cystography is best for establishing the diagnosis. Lack of extravasation on computed tomography does not exclude a bladder injury. Peritoneal fluid located in the lateral perivesical recess, superior to the bladder, and in the pouch of Douglas is suggestive of intraperitoneal bladder rupture. Extraperitoneal bladder rupture is noted by fluid extending superior and anterior to the level of the umbilicus and by fluid in the retrorectal presacral space. The distinction between intraperitoneal and extraperitoneal bladder rupture is important for treatment purposes. Controlled extraperitoneal ruptures are treated nonoperatively with urinary catheter drainage. Extensive extraperitoneal rupture and intraperitoneal injuries require operative intervention.

Pelvic Fractures

The most common mechanism resulting in pelvic fracture in children is a pedestrian struck by a motor vehicle. Single fractures of the pelvis are rarely associated with significant abdominal injury. Children with multiple fractures of the pelvis are at significant risk for abdominal injury even if hemodynamically stable (Table 115-3). Pelvic fractures are usually evident on the initial physical examination. Findings include abrasions, bruising, hemorrhage, instability, or swelling. Asymmetry of the bony structure, pain on palpation, or crepitus can be present. After recognition, attention should be directed toward stabilization and assessment of hemodynamic status. Pre-hospital providers may use inflatable pneumatic anti-shock garments, but they should be replaced with another method of stabilization after arrival

Table 115–3 Associated Injury by Location of Pelvic Fracture

Fracture site	Number (%)	Number with Abdominal Injury (%)	Number with Genitourinary Injury (%)
Unifocal	44 (81.5)	5 (11)	0
Pubic ramus	32 (59.3)	2 (6)	0
Iliac/pelvic rim	9 (16.7)	3 (33)	0
Sacrum	3 (5.60	0	0
Multiple	10 (18.5)	6 (60)	4 (40)
Total	54	11 (20)	4 (7.4)

to the hospital. An anteroposterior radiograph of the pelvis is obtained in the trauma bay to determine the anatomy of the fracture. Opening of the pelvic ring, associated with fracture at two points, should be stabilized with a sheet wrapped around the pelvis, a C-clamp, or an external fixator. Vertical shear injuries usually are not amenable to this treatment and will require operative reduction. Hemodynamically unstable patients should be aggressively resuscitated. Early angiography and embolization of bleeding vessels helps to stabilize patients and avoid the need for operative intervention. Hemodynamically stable patients should undergo computed tomography to evaluate for associated injuries. Special attention should be directed toward the rectum and urethra, which are especially susceptible to injury by bony fragments.

VII Chapter 116

Principles of Drug Disposition in the Critically Ill Child

Jeffrey L. Blumer

PEARLS

- Studies devoted to the disposition of drugs in critically ill patients and children are limited.
- Therapeutics is the branch of pharmacology concerned with the use of drugs for their therapeutic effects. It focuses on four fundamental questions that can serve as an outline for the clinician designing any pharmacotherapeutic plan: what drug, what dose, what route, and how long?
- Drug disposition is controlled by pharmacokinetics and pharmacodynamics. Pharmacokinetics is the discipline within clinical pharmacology that broadly describes the changes in the quantity of drug and/or drug metabolite in various body compartments over time. Whereas pharmacokinetics describes what the body does to the drug, pharmacodynamics encompasses the pharmacologic aspects that impact how the drug affects the body.
- Pharmacokinetic processes that influence drug disposition include absorption, distribution, metabolism, and excretion. Both ontogeny and critical illness may significantly impact any of these processes. Metabolism may be further affected by genetic differences in involved enzymes.
- Ontogeny and critical illness affect pharmacodynamics in infants and children, although formal study of these effects is limited.
- Pharmacotherapeutic strategies that can be used in the critically ill patient include the target concentration and target effect strategies. The target concentration strategy relies on concentration of drug in blood or plasma (usually) to guide therapy; this approach is best applied to drugs used chronically for signs or symptoms that manifest intermittently. The target effect strategy, the strategy most commonly used in the pediatric intensive care unit, relies upon an accepted clinical endpoint to determine drug dosing; clinical evidence of toxicity also impacts dosing. The latter strategy probably is the most reliable means by which to administer the "right amount" of drug to a highly variable patient population.

Pharmacology is the study of the interaction between chemical agents and biologic systems. When these chemical agents are used with the intent of palliating or curing disease, the agents are termed *drugs*. Perhaps nowhere is drug therapy more important than in critical care. In this setting, however, drug response often is difficult to predict. Physiologic aberrations and coincident pharmacologic and nonpharmacologic therapies may thwart intended drug effects. For the pediatric intensive care physician, pharmacotherapeutic decisions are further complicated by ontogenetic differences in drug processing and response. Finally, experience upon which to base pharmacotherapeutic expectations or prescription is sparse. Most drugs used in the intensive care setting have never been formally investigated in critically ill patients, let alone in children. As such, it is imperative that the pediatric intensive care physician have an understanding of the pharmacologic and related developmental constructs that influence drug response in patients.

The discipline of therapeutics provides a useful outline by which to design and monitor drug treatment. *Therapeutics* is the branch of pharmacology concerned with the use of drugs for their salubrious effects. It focuses on four fundamental questions pertaining to drug therapy as it relates to patient care: what drug, what dose, what route, and how long? The task of answering these important questions is facilitated by an understanding of the general pharmacologic principles that dictate drug response and the factors that lead to variation among patients.

Drug Disposition in Infants and Children

It should come as no surprise that controversy exists regarding drug dosing in pediatric patients. Over the years, a number of dosing rules been developed with the intent that drugs be safely administered to young children. All these rules depend on the standard adult dose with a scale-down factor based on body weight or age. However, distinct differences in pharmacokinetics and pharmacodynamics (Box 116-1) distinguish the pediatric patient from the adult patient. Critical illness may further alter pharmacokinetics and pharmacodynamics in children. These differences must be recognized before providing safe and effective dosing and during the initial selection of the drug itself.

Determinants of Effective Therapy

Effective therapy results when the drug(s) selected for a given condition has both favorable pharmacokinetic and favorable pharmacodynamic properties (see Box 116-1). Moreover,

administration to the patient must be individualized based on (1) a realistic clinical endpoint determined before administration; (2) sound knowledge of the quantitative aspects of the disposition of the drug selected; and (3) an understanding of the impact on the patient's illness of both the dosing regimen to be used and the anticipated therapeutic effect.

Pharmacokinetics

Pharmacokinetics is the discipline within clinical pharmacology that broadly describes the changes in the quantity of drug and/or drug metabolite in various body compartments over time. These changes can be described by four processes: absorption, distribution, metabolism, and excretion. Each of these processes can be affected by both development and disease. A clear understanding of pharmacokinetic processes and the factors affecting them will permit the clinician to design an effective treatment plan or to troubleshoot when an undesired response to treatment occurs. In other words, an understanding of basic pharmacokinetic principles will increase the likelihood that any treatment goal will be successfully accomplished with minimal adverse effects.

Drug Absorption

Absorption refers to the translocation of a drug from its site of administration into the bloodstream. When drugs are administered intravenously, as often occurs in the intensive care unit (ICU), the need for absorption is bypassed. When intravenous administration is not possible or convenient, several other routes of administration can be effectively used. Physicochemical properties of the drug and specific factors related to each route determine the rate and magnitude of absorption. Knowledge of these factors increases the likelihood that the clinician will be able to predict, if not control, this component of drug disposition.

Absorption of drugs from the gastrointestinal tract is affected by a number of factors (Box 116-2).[1,2] In general, enteral absorption depends on gastric emptying, intestinal surface area and motility, and hepatic first pass. Ontogeny and critical illness may significantly affect these and other patient factors (Figure 116-1 and Box 116-3).

Bioavailability (F) describes the fraction of a dose of drug that reaches the systemic circulation. Bioavailability of a single drug may vary significantly depending on the route of administration. By routes other than intravenous, absorption is a primary determinant of F. In enteral administration, an additional factor influences F. Excluding drugs primarily absorbed by the oral mucosa, drugs administered into the gastrointestinal tract may undergo metabolism by intestinal mucosal cells and/or metabolism and/or biliary excretion when they pass through the liver, before reaching the systemic circulation. This is known as the *first-pass effect*. With affected drugs, this phenomenon may significantly reduce F. This accounts for the fact that the enteral dose for many drugs is significantly greater than the intravenous dose. The susceptibility of a drug to hepatic first-pass metabolism may influence how the drug is administered; for example, nitroglycerin is given sublingually to circumvent a considerable first-pass effect in this drug.[3] Aside from the physicochemical nature of the drug itself, other factors may influence the extent of hepatic first-pass metabolism. Changes in hepatic blood flow may alter this action.[4] Age likely further influences the extent of hepatic first pass. As described later in the chapter, maturation of hepatic enzyme systems and transporters appears to occur postnatally.[7] Although the data dedicated to the ontogeny of metabolizing enzymes and transporters in the liver are limited, particularly as they relate to drug bioavailability, F probably decreases with age as these systems mature.[7]

Intramuscular Administration. The parenteral route of drug administration is important when a patient's disease state precludes oral therapy or when the bioavailability of an oral formulation is poor. The intravenous route for drug delivery is preferred over intramuscular (IM) injection. However, in children with poor intravenous access, IM injection is a viable and effective alternative for the administration of many drugs. Both physicochemical and physiologic factors affect the rate of drug absorption from the IM injection site.[8] Lipophilicity of a drug favors rapid diffusion into the capillaries; however, the drug must retain a degree of water solubility at physiologic pH to prevent precipitation at the injection site. For example, the sodium salt of phenytoin is principally an acid and thus is insoluble in the extracellular milieu of skeletal muscle. This explains the poor IM absorption of phenytoin. By contrast, phenobarbital and benzathine penicillin are well absorbed after IM administration. Both of these drugs are weak acids with pKa values close to physiologic pH and are therefore unlikely to precipitate in muscle under most physiologic conditions. By having knowledge of the physicochemical properties of a drug preparation, the clinician can predict, even control to some extent, how the drug is absorbed. While aqueous preparations will undergo rapid absorption, drugs in a solution of oil or other repository vehicles will be absorbed at a slower and more continuous rate.[9]

Another important factor that influences absorption of drug from an IM injection site is local blood flow, which may be compromised in patients with poor peripheral perfusion.[10] Rate and extent of absorption from an IM injection site also are influenced by the total surface area of muscle in contact with the injected solution, similar to the dependency of oral absorption on the total available absorptive area in the intestines.[8]

A final consideration in IM absorption is muscle activity, which may affect the rate of absorption and therefore affect the peak serum concentration. Sick, immobile infants and children or those chemically paralyzed may show reduced absorption rates after IM drug administration. Use of this route of administration in the ICU may be limited by actual or induced (anticoagulant therapy[9]) bleeding diatheses in some patients. A list of intramuscularly administered drugs used frequently in the pediatric intensive care unit (PICU) is provided in Box 116-4.

Subcutaneous Absorption. As with absorption of drugs from IM sites, absorption of subcutaneously administered drugs is influenced by local blood flow, as well as by proximal scarring or injury.[4] The pattern of absorption varies similarly to that following IM injection, depending on the physicochemical properties of the preparation. Frequently, drugs given by the subcutaneous route undergo slow and sustained absorption.[9] As such, the rate of absorption can be regulated by the drug formulation. For example, when drugs are administered in solid pellet form, absorption may occur over weeks to months.[9] Absorption can be slowed by the addition of a vasoconstrictor.[9] This route of administration is not appropriate for large volumes or for drugs that are irritating to tissues.

Percutaneous Absorption. Percutaneous absorption is inversely related to the thickness of the stratum corneum and directly related to skin hydration.[11] The stratum corneum is generally assumed, but not proven, to be thinner in children than in adults. The integument of the full-term neonate possesses intact barrier function.[12] This is not assured in the case of the premature infant.[6] Another important factor dictating percutaneous absorption is the surface area/body weight ratio, which is much larger in the full-term neonate than in an adult. Theoretically, if a newborn receives the same

percutaneous dose of a compound as an adult, the systemic availability per kilogram body weight is approximately 2.7 times greater in the neonate.

The percutaneous route of drug administration is taking on greater importance in the ICU setting. Historically, the most commonly used cutaneous preparation for systemic therapy is nitroglycerin.[13] More recently, advances in the technology associated with drug delivery systems have resulted in the common use of clonidine as a percutaneous preparation for treatment of hypertension and narcotic withdrawal. In addition, a number of narcotics exist as cutaneous preparations so that essentially "continuous infusions" of these drugs can be safely administered outside the ICU.[14] Finally, even drugs such as nitroglycerin ointment are finding potential new uses in the PICU, for example, treatment of the distal ischemia associated with purpuric injuries.

Rectal Absorption. Rectal administration of drugs is of potential therapeutic importance if a patient cannot take an agent orally and intravenous access for drug administration is impracticable. Because of the routes of the respective venous drainage systems, drugs administered into the superior aspect of the rectum are susceptible to hepatic first pass, whereas drugs administered lower into the rectum initially bypass the liver.[15] This may be an advantage for drugs such as lidocaine or propranolol that demonstrate a significant hepatic first-pass effect. The predominant mechanism for drug absorption from the rectum probably is similar to that observed in the upper gastrointestinal tract (i.e., passive diffusion). Theoretically, the physicochemical and host factors discussed earlier with respect to oral drug absorption also influence rectal drug absorption. In general, absorption from aqueous or alcoholic solutions is more rapid than from suppositories.

Lipophilic drugs with pK_a between 7 and 8, such as barbiturates and benzodiazepines, seem to be ideally suited for rectal administration because they exist mostly in unionized form and readily cross cell membranes. Rectal use of drugs such as thiopental and diazepam may be effective when intravenous access is a problem and rapid induction of anesthesia is desired or when a child is convulsing. Dulac et al.[16] showed that rectal administration of 0.25 to 0.5 mg/kg of a diazepam solution to children aged 2 weeks to 11 years produced serum concentrations comparable with those observed after intravenous administration. Additionally, peak serum concentrations occurred within minutes of administration. Potentially effective anticonvulsant serum concentrations were maintained for 1 to 3 hours in most of the study patients. Knudsen[17] demonstrated similar results in 20 children aged 1 to 2 years and further ascertained the clinical efficacy of rectal diazepam in preventing recurrent febrile seizures. In a similar fashion, Burckart et al.[18] reported rapid and effective sedation after rectal administration of thiopental suspension to 36 infants and children undergoing computed tomographic scanning.

Drug Distribution

Knowledge of drug distribution is important for selecting the appropriate drug and dose to be administered. Distribution of most drugs in the body is influenced by a variety of age-dependent factors, including protein binding, body compartment sizes, hemodynamic factors such as cardiac output and regional blood flow, and membrane permeability.[19,20] Any of these factors also can be altered by disease. This section briefly reviews the pharmacokinetic description of distribution and the effect of ontogeny and critical illness on several factors that determine drug distribution.

The primary pharmacokinetic parameter representative of drug distribution is the volume of distribution (V_d). V_d reflects the apparent space within the body available to contain drug and relates the amount of drug in the body to its concentration in a biologic fluid, usually blood or plasma.[9] V_d varies among drugs, based on the drug's extent of protein and tissue binding and its partition coefficient in fat.[9] Additionally, for any given drug, V_d varies among patients because of differences in protein stores or binding and body composition as a result of age or illness. For example, in neonates and infants, a relatively increased extracellular fluid volume, decreased protein binding, and increased brain and liver size all contribute to increased weight-normalized V_d for most drugs.[21] An understanding of the factors influencing V_d is of paramount importance to the clinician caring for critically ill children. V_d relates the administered dose of drug to its plasma or blood concentration, which determines therapeutic effects, both favorable and adverse. Alterations in V_d produce reciprocal changes in drug concentration.[21] Familiarity with the concept of V_d and the ontogenic and other factors influencing its variation will assist the intensive care physician in understanding why a standard drug dose might be inappropriate for a given patient.

Developmental Aspects of Protein Binding. Plasma protein binding of drugs depends on the concentration of binding proteins available, the affinity constant of the drug for the protein(s), the number of available binding sites, and the presence of pathophysiologic conditions or endogenous compounds that may alter drug-protein interaction.[22] The affinity of albumin for acidic drugs increases, as do total plasma protein levels, from birth to early infancy.[23] These values do not reach normal adult levels until age 10 to 12 months. In addition, although plasma albumin may reach adult levels shortly after birth, the neonatal albumin level in blood is directly proportional to gestational age, reflecting placental transport and fetal synthesis.[24] Binding of basic drugs by α_1-acid glycoprotein also is affected.[21,25] Studies in cord blood suggest that decreased levels of α_1-acid glycoprotein cause this decreased binding.[25] Some of the drugs that have exhibited decreased protein binding in the infant include diazepam, furosemide, propranolol, thiopental, phenytoin, and some antibiotics.[21] The comparative binding of some of these drugs in neonates and adults is given in Table 116-1. The impact of decreased binding of many of these drugs on efficacy has not been determined.[21] For drugs that are highly protein-bound and subject to therapeutic monitoring (e.g., phenytoin), however, any decrease in protein binding may result in a lower measured total drug concentration.[21] In such cases, monitoring of free drug concentration (if possible) will prove more clinically relevant.

Developmental Aspects of Fluid Compartment Sizes. Alterations in body water compartment sizes affect the volume of distribution of a drug. Age-dependent changes in the various fluid compartments (Table 116-2) were reviewed in detail by Cheek et al.[27] and Friis-Hansen.[28] Regardless of age, critical illness and related therapies may alter total body water and other fluid compartment volumes.

Table 116–1 Comparative Protein Binding of Some Representative Drugs

Drug	% Bound	
	Newborn	Adult
Acetaminophen	37	48
Ampicillin	10	18
Diazepam	84	99
Lidocaine	20	70
Morphine	46	66
Phenobarbital	32	51
Phenytoin	80	90
Propranolol	60	93
Theophylline	36	56

Data from Kurz H, Mauser-Ganshom A, Stickel HH: Differences in the binding of drugs to plasma proteins from newborn and adult man, *Eur J Clin Pharmacol* 11:463, 1977.

Table 116–2 Fluid Compartment Size as a Function of Age

Age	Total Body Water*	Extracellular Fluid*	Intracellular Fluid*
Fetus <3 mo	92	65	25
Term gestation	75	35-44	33
4–6 months	60	≈23	37
12 months		26-30	
Puberty	60	≈20	40
Adult	50-60	20	40

*As a percentage of body weight.

At 40 weeks of gestation, measurements of extracellular fluid volume have ranged from 350 to 440 mL/kg body weight. Cassady[29] demonstrated that the extracellular fluid volume of newborn infants correlated more closely with body weight than with gestational age. By age 1 year, extracellular fluid volume decreases to approximately 26% to 30% of body weight. After the first year, it decreases slowly and gradually approaches the adult value of 20% body weight by puberty. Intracellular fluid volume increases from 25% of body weight in the young fetus to 33% at birth to approximately 37% of body weight at age 4 months. Except for a sudden increase during early childhood, the intracellular fluid volume remains relatively constant thereafter, approximating 40% of body weight. The clinical relevance of this gradual reduction in the size of extracellular body water compartments with age cannot be overemphasized. To achieve comparable plasma and tissue concentrations of drugs distributing into extracellular fluid, higher doses per kilogram body weight must be given to infants and children than to adults.[30]

Developmental Aspects of Body Composition. The percentage of body weight composed of adipose tissue approximately doubles over the first year of life.[21] Additionally, the liver and brain account for a higher percentage of body weight in the neonate than in the adult.[6,21] All of these factors may lead to significant differences in weight-normalized V_d between infants and adults, depending on the drug. Differences in the amount of adipose tissue may alter clearance of some drugs.

Critical Illness and Drug Distribution. Because of impaired production or increased losses, respectively, conditions such as liver disease and nephrotic syndrome reduce circulating albumin concentrations, resulting in an increase in apparent V_d. Diseases that induce an acute phase reaction (e.g., malignancy, myocardial infarction, inflammatory bowel disease) may provoke increased binding of basic drugs because of increased levels of α_1-acid glycoprotein.[9] Additionally, accumulation of extravascular fluid collections (e.g., pleural effusions and ascites) results in the development of a reservoir for drugs that are distributed into the total body water.[31]

Drug Clearance

Clearance reflects the removal of drug from the body. Clearance occurs by two processes: biotransformation (i.e., metabolism) and excretion. Metabolism occurs primarily in the liver. Excretion is predominately facilitated by the kidney, although excretion also can occur via exhalation, saliva, sweat, or the gastrointestinal tract.[6,9] Redistribution of drug can contribute to total clearance if the reference compartment is blood or plasma, as is often the case.[4] When reflected in the blood or plasma, clearance quantitatively describes the volume of blood or plasma from which all drug is removed per unit of time.[4,6] Clearance is an important pharmacokinetic parameter to consider when the goal is maintenance of steady-state drug concentration, which correlates with therapeutic efficacy. Once steady state is achieved, clearance of the drug determines the quantity of drug that must be administered in order to maintain that concentration (i.e., Drug out = Drug in).[4,7] The clinically relevant pharmacokinetic concepts related to clearance are discussed later in this chapter. The ontogeny of systemic clearance mechanisms probably accounts for a significant portion of the difference in pharmacologic response between infants and adults.[7] These developmental factors also produce variability among pediatric patients. Critical illness may have an additional profound impact on clearance mechanisms.

Hepatic xenobiotic metabolism assumes an extremely important role in determining the pharmacokinetic and pharmacodynamic properties of many drugs. Clearance of a drug (Cl) by an individual organ depends on blood flow to the organ (Q) and the organ's extraction ratio (E) and can be described as follows[32]: $Cl = Q \times E$, where E is the ratio of the arteriovenous concentration difference divided by the arterial concentration (extraction) as expressed by $E = (C_a - C_v)/C_a$, where C_a and C_v are the arterial and venous concentrations, respectively. Organ clearance concepts are best described for the liver and kidneys. Hepatic clearance depends on hepatic blood flow, plasma free drug concentration, cellular uptake, hepatic metabolism, and biliary excretion. The hepatic clearance of a drug can be expressed by the following equation:

$$Cl_H = \frac{Q \times f_B \times Cl_{int}}{Q + (f_B \times Cl_{int})}$$

where Cl_H is hepatic clearance, Q is hepatic blood flow; f_B is fraction of free drug; and Cl_{int} is intrinsic clearance, which is a measure of hepatocellular metabolism. Drugs that are primarily cleared by the liver can be classified as flow limited or

capacity limited.[33] If a drug displays a high Cl_{int} and E, then doubling the Cl_{int} will have little effect on Cl_H, whereas a change in blood flow will produce a proportional change in Cl_H. In other words, for drugs that are highly extracted (>80%) and metabolized by the liver, Cl_H reflects the amount and rate of drug delivered to the liver.[34] The considerable declines in hepatic blood flow and oxygen delivery that occur immediately following birth do not appear to translate to significantly reduced clearance of flow-limited drug in the newborn compared with the adult.[7] Drugs with high extraction ratios are subjected to the first-pass effect when administered enterally.

Capacity-limited drugs display low extraction ratios (<20%) and a low intrinsic metabolic clearance. Therefore hepatic clearance depends on the degree of hepatic uptake and metabolism of the drug and is independent of hepatic blood flow. Capacity-limited drugs can be further subdivided into binding-sensitive and binding-insensitive drugs. Binding-sensitive drugs, such as clindamycin, have extraction ratios that approach the free drug concentration ($E = f_B$). Therefore factors that increase f_B, such as decreased protein binding, increase hepatic clearance. In contrast, other drugs may display extraction ratios that are much less than the free drug concentration. In these cases, an increase in f_B does not enhance extraction of the drug, and therefore the hepatic clearance is a function of the intrinsic clearance and is independent of protein binding. These drugs are referred to as binding-insensitive (e.g., chloramphenicol).

At every level, from the ontogenetic changes in hepatic blood and portal oxygen tension to the developmental alterations in protein binding and xenobiotic metabolizing enzyme activities, there is the potential for age to affect the processes associated with hepatic clearance. Very little investigative effort has been expended to elucidate these effects; however, some of the important available data are discussed further. For detailed reviews of this data, the reader is referred to articles by Alcorn and McNamara[7] and Leeder and Kearns.[35]

Biotransformation: Phase I Reactions. The biotransformation of endogenous and exogenous substances occurs primarily in the liver, although the adrenal gland, placenta, kidney, gut, and skin also are capable of metabolizing compounds. Once a drug enters the hepatocyte, it may be transformed by one or more enzymatic reactions. These pathways, or phase I reactions, include oxidation, reduction, hydrolysis, and hydroxylation.[36,37] In general, these reactions are responsible for transforming compounds into more polar, less lipid-soluble molecules that are more rapidly eliminated by the kidney, biliary system, or lung. However, parent compounds may be transformed into pharmacologically active intermediates, such as theophylline to caffeine, or into toxic metabolites, as occurs with oxidation of acetaminophen. In addition, pharmacologically inactive parent compounds (prodrugs) may be converted to active moieties, as occurs with hydrolysis of chloramphenicol succinate to chloramphenicol. The ontogeny of human enzyme systems differs dramatically from most animal species, especially for oxidation and glucuronidation pathways.[38] Therefore extrapolating data for enzyme system maturation from animals to humans is difficult. Of the enzyme systems capable of metabolizing drugs, the hepatic cytochrome P450 (CYP) mixed-function oxidase system has been studied in greatest detail. It is responsible for most of the phase I reactions catalyzed in the human liver.

Yaffe et al.[39] first demonstrated drug-oxidizing enzymes in the human fetal liver. During fetal life, these enzymes are present at 30% to 60% of adult activity in vitro.[40] Following birth, total CYP levels increase, approaching adult range by age 1 year.[7] Activity of all CYP enzymes is generally thought to be considerably lower in children, particularly neonates and infants, than in adults. In truth, the developmental aspects of expression and function vary among CYP enzyme families and isoforms. Although data delineating these variations are limited, particularly for specific families or isoforms, some insight into the ontogeny of select enzymes has been gleaned from immunochemical studies in hepatic microsomes and tissue, pharmacokinetic studies of known enzyme substrates, and studies evaluating the biotransformation of pharmacologic "probes" (e.g., carbamazepine in the case of CYP3A4). The ontogeny and the drugs affected by some of the important CYP isoforms are outlined in Table 116-3. A limited discussion of the most clinically relevant isoforms in pediatric patients follows.

CYP1A2. Cytochrome P450 1A2, the only CYP1A isoform found in human liver, is involved in the biotransformation of many drugs, including the methylxanthines.[35] Immunohistochemical studies have suggested that this protein is sparse, if present at all, in fetal liver.[41] These studies also demonstrate that levels of CYP1A2 do not appreciably increase until several weeks to months after birth, remaining below adult levels well into childhood. These findings are reflected in studies examining enzyme activity as assessed by biotransformation of theophylline. Nassif et al.[42] reported a significant correlation between a decreasing elimination half-life for enterally administered theophylline and increasing age. Decreased elimination was further suggested by a marked difference in dosage requirement, with patients younger than 4 months requiring approximately half the daily dose needed in patients age 8 to 13 months to maintain therapeutic levels. Tateishi et al.[43] evaluated biotransformation of intravenous theophylline, quantifying three metabolites (1-methyluric acid [IMU], 3-methylxanthine [3MX], and 1,3-dimethyluric acid [DMU]) in urine. The ratios of metabolites to theophylline in urine increased dramatically from the neonatal period to age 3 years, when they appeared to essentially plateau. However, a greater variation in these ratios was seen among patients older than 3 years. This study also established that the relative production of DMU, a product of reactions catalyzed by other CYP enzymes, including CYP2E1 and CYP3A4, was higher in the youngest patients compared with those older than 3 years. The relative production of the other two metabolites, which result from CYP1A2 activity alone, is similar between the groups. After age 1 year into early childhood, rates of theophylline clearance appear to exceed the rates in adults, prompting the need for an increased dose to maintain therapeutic levels.[35]

CYP2C9. The CYP2C family comprises a substantial portion (approximately 20%) of CYP enzymes in the adult liver and has comparable importance in the metabolism of drugs.[7] CYP2C9 is the principal isoform in this family. Enzyme protein is undetectable[44] to low[35,41] in fetal liver. In vitro studies in fetal hepatic microsomes suggest comparably low enzyme activity. Demethylation of diazepam, which is mediated by the CPY2C family, occurs at a level less than 5% that in adult microsomes.[44] On the other hand, hydroxylation of tolbutamide, which is catalyzed specifically by CYP2C9, is

Table 116–3 Ontogeny of Select Hepatic Enzymes

Enzyme	Representative Substrates	Developmental Evolution
PHASE I		
CYP1A2	Acetaminophen, caffeine, theophylline, warfarin	Negligible in fetal liver. Adult levels of activity by approximately age 4 months. Activity exceeds that in adults after age 1 year; gradually declines to adult levels by end of puberty.
CYP2C9	Diazepam, phenytoin, NSAIDs, tolbutamide, S-warfarin	Undetectable to low in fetal liver. Adult levels of activity by age 1–6 months. Activity exceeds that in adults from age 3–10 years; gradually declines to adult levels by conclusion of puberty.
CYP2D6	Numerous, including captopril, codeine, dextromethorphan, haloperidol, metoprolol, propranolol, ondansetron, tricyclics	Undetectable in fetal liver. Expression and activity appear to be stimulated by parturition. Complete maturation may occur by age 1 year, although acquisition of adult activity levels has been reported to occur as late as age 5 years.
CYP3A4	Numerous, including acetaminophen, amiodarone, budesonide, carbamazepine, cyclosporine, erythromycin, lidocaine, nifedipine, tacrolimus, theophylline, verapamil, R-warfarin	Low in fetal liver; replaces CYP3A7 as the predominant isoform following birth. Based on pharmacokinetic and drug disposition studies, activity in children thought to be greater than that in adults. Decline toward adult levels begins at approximately age 4 years. Adult levels reached by end of puberty.
PHASE II		
Uridine 5′-diphosphate glucuronyltransferases (UGTs)	Numerous, including acetaminophen, benzodiazepines, bilirubin, chloramphenicol, dextromethorphan, morphine, naloxone, NSAIDs, propofol, thyroxine	Varies by isoform; difficult to characterize individual isoforms because of overlapping substrate specificities. As a group, activity appears to be deficient in the neonate and infant. Variably reported acquisition of adult levels of activity; anywhere from age 2–30 months, depending on the proposed isoforms involved.
N-acetyltransferase-2 (NAT2)	Caffeine, clonazepam, hydralazine, ioniazid, procainamide	Low activity in neonates and infants. Movement toward adult phenotypes (≈50% fast and 50% slow acetylators) after nearly 3 months of age.
Methyltransferase group (MT)	Catecholamines, captopril, serotonin, spironolactone	S-methylation capacity (TPMT) approximately 50% greater in infants than in adults. Limited evaluating maturation after this point; one Korean study demonstrated adult level activity by age 7–9 years.
Sulfotransferase group (ST)	Acetaminophen, bile acids, chloramphenicol, cholesterol, dopamine, polyethylene glycols, salicylates	At least some isoforms well developed in the infant; compensates for deficient glucuronidation of certain substrates (e.g., acetaminophen).

Substrate listings from Leeder JS, Kearns GL: Pharmacokinetics in pediatrics: implications for practice, *Pediatr Clin North Am* 44:55, 1997. Additional data related to substrates and all remaining data derived from references cited in the text.
NSAID, Nonsteroidal antiinflammatory drug.

not at all evident in fetal microsomes.[44] Several studies, both in vitro and in vivo, suggest an increase in enzyme expression and activity within the first month of life. Following sedation with diazepam, levels of desmethyl diazepam in urine are very low at age 1 to 2 days and increase within the first postnatal week.[44] CYP2C9 protein reaches adult levels in hepatic tissue after age 6 months.[41] Enzyme activity corresponds. By age 1 to 6 months, production of the phenytoin metabolite 5-(4-hydroxyphenyl)-5-phenylhydantoin is comparable to that seen in adults.[45] In fact, CYP2C9 activity appears to supersede that observed in adults by age 3 to 10 years, declining to adult range by the conclusion of puberty.[45] This explains the frequent need for a relatively increased dose of phenytoin in this age group.

CYP2D6. A number of drugs undergo biotransformation by CYP2D6, and some are more relevant to critically or chronically ill children than well children. Enzyme protein levels are undetectable in fetal liver except for those obtained from fetuses delivered by spontaneous or induced abortion. These specimens are far more likely to contain detectable enzyme, suggesting that parturition stimulates expression.[46] Enzyme activity, as evidenced by O-methylation of dextromethorphan, is negligible in fetal hepatic microsomes. Enzyme protein levels increase rapidly after birth, but the time at which they reach adult levels is variably reported in the literature. Levels in hepatic tissue from subjects aged 1 month to 5 years reportedly were only approximately two thirds the adult levels,[7] but another study reported no difference in expression between patients younger than 1 year and those older than 1 year, suggesting that development of this isoform is complete by age 1 year.[47]

CYP3A4. The CYP3A family comprises the largest fraction of measurable CYP450 enzymes in adult liver.[7] In the fetal liver, CYP3A7 is the predominant isoform. After birth, there is a shift between CYP3A7 and CYP3A4, levels of which are negligible in fetal hepatic tissue. The mechanisms of this transition have not been elucidated. In infants and children, the activity of CYP3A4 is generally increased above that in adults. The biotransformation of carbamazepine demonstrates this developmental difference. Studies in children demonstrate that both clearance and production of the metabolite carbamazepine-10,11-epoxide significantly

decrease with increasing age.[48-50] The role that other enzymes, particularly microsomal epoxide hydrolase, which further transforms carbamazepine-10,11-epoxide, play in these developmental differences is uncertain.[35] In addition, although these age-related differences have been described in pediatric patients on monotherapy, coadministration of anticonvulsants that are known to induce CYP3A4 are speculated to skew these findings. Nonetheless, these developmental differences in CYP3A4 activity have been suggested by study of other substrates, among them cyclosporine, which also exhibits increased clearance in children compared with adults.

The development of other phase I enzyme systems has been studied much less extensively. Alcohol dehydrogenase activity is detectable in 2-month fetuses at levels no greater than 3% to 4% of adult activity.[51] Moreover, the level of activity does not approach adult values until after age 5 years.

Aromatic nitroreductase activity is detectable in fetal livers by 7 to 8 weeks of gestation; however, the hepatic activity at midgestation remains low, and no specific postnatal pattern of development has been described. Also, few data exist on the ontogeny of hydrolytic enzymes. Echobichon and Stephens[52] found low levels of blood esterase activity in the fetus and neonate.

Biotransformation (Phase II Reactions). Conjugation reactions, or phase II reactions, synthesize more water-soluble compounds by combining a substance with an endogenous molecule to enhance excretion of that substance. Glucuronide, sulfate, and glycine are the common endogenous molecules to which drugs are bound. A drug must possess a specific functional group, such as a carboxyl, hydroxyl, amine, or sulfhydryl, in order to be conjugated. Alternatively, a drug must acquire one of these functional groups by undergoing phase I metabolism. Phase II enzyme groups have been studied far less than CYP450 enzymes; therefore the ontogeny of phase II enzymes remains relatively elusive.

Glucuronidation is the most common conjugation pathway because of the availability of glucuronic acid and the variety of functional groups with which it can combine. The uridine 5′-diphosphate glucuronosyltransferases (UGTs) participate in the biotransformation of at least 100 drugs (e.g., acetaminophen, morphine, nonsteroidal antiinflammatory drugs [NSAIDs]) and endogenous compounds, including bilirubin and thyroxine. Ready elucidation of the ontogeny of UGT isoforms has been precluded by overlapping specificities. For a detailed summary of available information about the UGT enzyme family, the reader is referred to the review by de Wildt et al.[53]

The activity of a number of UGTs is decreased in the fetus and neonate, as assessed by in vitro studies.[53-55] In addition, there is ample in vivo evidence of deficient glucuronidation in infants and particularly neonates. A profound example of this is the association of "gray baby syndrome" with the drug chloramphenicol, which normally undergoes glucuronidation. Morphine glucuronidation serves as a "probe" for isoform UGT2B7 activity. Studies have demonstrated significantly decreased clearance[56,57] and biotransformation[56] of morphine in neonates. Depending on how values are standardized between pediatric and adult subjects, morphine clearance approximates adult levels at anywhere from age 2 to 30 months.[7,57] Reduced UGT activity during infancy is also reflected in the biotransformation of acetaminophen. Levy et al.[58] demonstrated that 2- to 3-day-old term infants had a limited ability to conjugate acetaminophen with glucuronide, which is the major conjugation pathway in adults. However, this limitation in glucuronidation was compensated for by a well-developed sulfation pathway. This supports the findings of Alam et al.,[59] who showed that rates for glucuronidation are much lower and sulfation much higher with salicylamide and acetaminophen as substrates in children 7 to 10 years old compared with adults.

Studies evaluating bilirubin and chloramphenicol glucuronidation have reported low rates at birth, with adult rates achieved by age 3 years.[59] However, some evidence indicates that phenobarbital may induce glucuronidation in newborns and older children. Talafant et al.[60] administered phenobarbital 10 mg/kg/day to healthy full-term infants for their first 3 days of life. One group received phenobarbital intramuscularly and one group received phenobarbital orally; one group served as a control. These authors described significantly higher urinary glucaric acid concentrations on day 7 in the IM group than in the controls. This finding correlated well with a downward trend in serum bilirubin in the group receiving IM bilirubin. The ontogeny and potential substrates of other phase II enzymes is summarized in Table 116-3.

Additional Factors Affecting Hepatic Biotransformation. Several factors in addition to those of a developmental nature may affect hepatic biotransformation. Although the impact of each on hepatic enzyme systems is incompletely characterized, factors such as genetics, concomitant drug therapy, and critical illness may alter drug biotransformation and, hence, patient response. Genetic variation of a number of hepatic isoenzymes has been described, with corresponding variation in phenotype. For example, 7% to 8% of Caucasian children are characterized as "poor metabolizers" with reference to the enzyme CYP2D6, which may manifest as insufficient metabolism of several categories of drugs, including β-agonists, antidepressants, antipsychotics, antiarrhythmics, and derivatives of morphine.[35] Variants of CYP2C9 have been described, affecting metabolism of drugs such as tolbutamide, NSAIDs, warfarin, and phenytoin.[35] Polymorphism of the phase II enzyme N-acetyltransferase-2 (NAT2) affects half of the Caucasian and African-American populations in North America. In this case, "slow metabolizers" are at increased risk for several adverse drug responses, including drug-induced lupus erythematosus following procainamide or isoniazid therapy and Stevens-Johnson syndrome or toxic epidermal necrolysis following sulfonamide exposure.[35] Finally, several UGT isoforms are subject to genetic mutation. The best known of these genetic variations occur in UGT1 and UGT1A1, producing absent or reduced bilirubin glucuronidation in the case of the former isoenzyme and reduced bilirubin conjugation in the latter. Phenotypically, these mutations manifest as Crigler-Najjar and Gilbert syndrome, respectively. The effect of these UGT polymorphisms with respect to drug metabolism has not been substantially studied.[35] However, sparse data suggest that glucuronidation of drugs may also be affected in these patients.[35,61]

The frequent need for polytherapy in the ICU increases the possibility that hepatic biotransformative enzyme systems will be induced or inhibited, affecting the metabolism of any substrate of that system. A list of drugs known to induce or inhibit hepatic metabolic enzymes was compiled by Leeder

and Kearns.[35] Even less is known about the effect of critical illness on hepatic enzyme function than that of development. Several factors may contribute to altered hepatic metabolism in critically ill patients. Decreases in cardiac output and, consequently, hepatic blood flow reduced clearance of lidocaine in adult patients; in these patients, treatment with dobutamine improved plasma clearance.[62] In vivo studies suggest that certain CYP isoforms, including those in the CYP3A family, are exquisitely vulnerable to hypoxia, demonstrating alteration of activity after as few as 8 hours of hypoxia.[62] The systemic inflammatory response appears to potentially alter CYP activity as well. Mice infected with *Listeria monocytogenes* experienced decreased expression of some CYP450 enzymes, which returned to normal levels after 96 hours.[63] Many inflammatory mediators reduce expression of CYP isoforms, including CYP1A1, CYP2C, CYP2E1, and CYP3A in human hepatocytes.[64] Decreased metabolism of a number of known substrates of CYP450 has been demonstrated in patients with fever induced by infection and drugs and with hypothermia following cardiopulmonary bypass.[62] Of course, linking pharmacokinetic variations in the critically ill patient to impaired hepatic metabolism is difficult in the face of other pathophysiologic alterations.

Drug Elimination

The elimination half-life ($t_{1/2\beta}$) of a drug is commonly used to describe its disappearance from the blood and is measured as the time required for half the amount of drug present in the blood to disappear. As such, $t_{1/2\beta}$ can be used to reflect drug clearance, although changes in V_d also affect this parameter. This and related pharmacokinetic principles are discussed more thoroughly later in the chapter.

Renal Excretion. Most drugs and/or their metabolites are excreted from the body by the kidneys. Renal excretion depends on glomerular filtration, tubular reabsorption, and tubular secretion.[65] The amount of drug that is filtered per unit of time is influenced by the extent of protein binding and renal plasma flow. When the latter is constant, the greater the extent of protein binding, the smaller the fraction of circulating drug that is filtered. The degree of protein binding also influences drug elimination in patients undergoing dialysis in a similar manner; drugs that are highly protein bound are less easily dialyzed.[66,67] This section also examines developmental aspects of renal function and their influence on renal drug excretion.

Renal blood flow and renal plasma flow increase with age as a result of increased cardiac output and reduced peripheral vascular resistance.[68-70] The kidneys of neonates receive only 5% to 6% of the cardiac output compared with 15% to 25% in adults. Renal plasma flow averages 12 mL/min (0.72 L/hr) at birth and increases to 140 mL/min (8.4 L/hr) by age 1 year. If renal plasma flow is corrected for body surface area, adult values are reached before 30 weeks of extrauterine life. Using clearance of para-aminohippurate to estimate renal plasma flow, Calcagno and Rubin[71] demonstrated adult rates by age 5 months.

At birth, glomerular filtration rate (GFR) is directly proportional to gestational age.[72] However, a linear relationship is not evident before 34 weeks of gestation. Inulin clearance rates below 10 mL/min have been described in newborns under 34 weeks of gestation, reflecting a significantly reduced GFR. This process must be considered when administering drugs or fluid to the premature newborn.[72] At birth, GFR for term infants ranges from 2 to 4 mL/min. In the first 2 to 3 days of postnatal life, GFR in term babies increases markedly to rates between 8 and 20 mL/min. During the first several weeks of life, increases in GFR correlate with postconceptual age, not postnatal age.[72] Adult values for GFR (127 mL/min) are reached by age 2.5 to 5 months.[73] The postnatal increase in GFR most likely results from the combined effects of increased cardiac output, decreased peripheral vascular resistance, increased mean arterial blood pressure, increased surface area available for filtration, and increased membrane pore size.[74] In fact, the finding that increases in GFR correlate with postconceptual age suggests that maturational changes are an important factor in the observed increase in glomerular function. The clinical implications for maturation of GFR become apparent when considering drugs that are primarily eliminated by glomerular filtration. Several studies have investigated the pharmacokinetics of aminoglycosides in preterm and term infants. Szefler et al.[75] demonstrated a decreasing $t_{1/2}\beta$ for gentamicin with increasing gestational age in infants younger than 7 days.

Proximal convoluted tubules in the normal kidney of a full-term infant are small in relation to their corresponding glomeruli. This glomerulotubular size imbalance is reflected by functional differences in the transport capacity (secretion) of the proximal tubular cells.[76] Therefore tubular function matures at a slower rate than does glomerular function. Reasons for this reduced functional capacity include not only the small size of the tubules but also a smaller mass of functioning tubular cells, reduced blood flow to the outer cortex, and immaturity of energy-supplying processes. This imbalance continues for the first year of life, after which function of both glomerular and tubular components is comparable to that in healthy, young adults.[5] Processes of both active absorption (i.e., secretion) and passive absorption (i.e., reabsorption) are impacted in the immature kidney.

Many drugs rely on either the organic anion or cation transport systems present in the proximal tubules for renal excretion. Penicillin is actively secreted. Results of pharmacokinetic studies of ampicillin, ticarcillin, benzylpenicillin, and methicillin show that the $t_{1/2\beta}$ for the penicillins varies inversely with gestational and postnatal age.[77-80] In all the studies cited here, $t_{1/2\beta}$ for penicillins was highly variable, but generally decreased to 1 to 2 hours by 2 weeks postnatal age. These observations may be partially explained by findings in animals that the capacity of the pathways responsible for penicillin secretion may undergo substrate stimulation. Substrate stimulation has not been formally studied in human neonates, but evidence indicates that it does occur. Kaplan et al.[78] showed a reduction in $t_{1/2\beta}$ for ampicillin in both preterm and term infants after multiple doses compared with a single dose.

Furosemide is another drug secreted by the proximal tubules. In addition to being filtered, evidence for tubular secretion is inferred from adult data describing reduced rates of plasma clearance and urinary excretion after probenecid administration.[81] Aranda et al.[82] found an eightfold prolongation in $t_{1/2\beta}$ and an eightfold reduction in the elimination rate constant for furosemide in fluid-overloaded term and preterm neonates with normal renal function compared with adults. Peterson et al.[83] evaluated single-dose kinetics for furosemide in preterm and term infants and found a mean $t_{1/2\beta}$ of 19.9 and 7.7 hours, respectively. This is in contrast to a $t_{1/2\beta}$ of 30

minutes in healthy adults. These prolonged plasma half-lives correspond with the prolonged duration of diuretic and saluretic effect seen in infants,[84] although the response to furosemide most likely is dependent on its rate of urinary excretion.

The sensitivity of the kidney to hypoxic and ischemic insult is well known. Because this is one of the most important final common pathways for serious illness in infants and children, it follows that renal functional impairment is relatively frequent in patients in the PICU. Kidney function may be further impaired by the frequent use of nephrotoxic drugs such as amphotericin B and aminoglycosides in PICU patients. Clearly, varying degrees of renal functional impairment seen in critically ill infants and children can seriously complicate drug therapy in this setting.[26,85]

Drug Delivery Systems

As discussed previously, the maintenance of steady-state drug concentration requires that the amount of drug being administered match the amount of drug being cleared from the body. Several factors determine how much of a drug can be administered to any given patient at any given time. Although uncommon in the ICU, the available routes of administration may limit bioavailability and, hence, ultimate drug concentration. In the patient who requires fluid restriction, limitations in the maximal concentration of drugs may prove problematic. In the smallest of patients, full delivery of intravenous drug doses contained in diminutive volumes of vehicle may not be assured. Administration of a drug as a bolus generally ensures that the patient has received the full dose, provided any tubing between the site where the drug is given and where it enters the vein is adequately flushed. In the case of drugs given over a discrete interval or by continuous infusion, the drug delivery system influences the amount of a given drug dose received by the patient. Regardless of the technology used, the amount of drug delivered by a system depends upon the designated flow rate and the amount of tubing between where the drug is introduced and the patient's bloodstream.[21] When a drug is added to a fluid reservoir, delivery also depends on the volume of drug added.[21] An example of the impact of these factors on drug delivery is as follows. If a drug is added to the reservoir in a system where the flow rate is 25 mL/hr, drug delivery may not begin for almost 2 hours and would require nearly 4 hours for completion.[21] Consequently, administering drug in this manner could result in delayed and/or incomplete drug delivery. Additionally, an inability to pin down the timing of drug delivery complicates interpretation of drug levels when monitored.[21]

Fortunately, considerable advances in drug delivery technology have been made over the past 20 years[86] and have been of particular benefit in the PICU. Infusion pumps that provide greater volumetric accuracy have facilitated full delivery of small volumes. In some cases, improvements in infusion continuity have enabled uninterrupted delivery of continuously administered drugs, a fact that is of particular importance for drugs with very short $t_{1/2\beta}$ values (e.g., nitroprusside).[86] It is important that the intensivist have some familiarity with the technology used in his or her unit; this knowledge may be helpful when an unintended response to pharmacotherapy occurs. For a comprehensive review of this technology, the reader is referred to the chapter by Kwan.[86]

Effect of Extracorporeal Therapies on Drug Disposition. Extracorporeal therapies, including hemofiltration, dialysis, and extracorporeal membrane oxygenation (ECMO), can alter drug disposition in affected critically ill patients. Although relatively little study has been devoted to drug disposition in patients on ECMO, evidence supports the idea that this treatment modality alters pharmacokinetics. In neonates and infants, the largest number of studies have looked at the disposition of gentamicin and vancomycin.[87] Increased V_d, increased $t_{1/2}$, and decreased clearance compared with control or post-ECMO values were demonstrated in the majority of these studies.[87-89] In one study investigating vancomycin, only an increased $t_{1/2}$ differentiated ECMO patients from non-ECMO controls.[90] Other drugs, including theophylline,[91] morphine,[92,93] tobramycin,[87] bumetanide,[87] and ranitidine[87] have been shown to increase V_d, decrease clearance, and/or increase $t_{1/2}$ in patients on ECMO. The addition of an extracorporeal reservoir contributes to the increase in V_d, and alterations in hepatic and renal function in ECMO patients impact clearance. Additionally, adhesion of some drugs to circuit hardware may alter serum or blood concentrations. The age of the circuit appears to influence this factor to some extent. Dagan et al.[93] evaluated the "elimination" of drugs following direct injection into two circuits: a new one and a circuit that had been used by a patient for 5 days. A relatively increased elimination of several drugs by the new circuit was described (vancomycin, 36% vs. 11%; gentamicin, 10% vs. 0%; phenobarbital, 17% vs. 6%; phenytoin, 43% vs. 0%; morphine, 36% vs. 16% in the new vs. used circuit).[93] Several other drugs are subject to this phenomenon, including heparin, furosemide, fentanyl, benzodiazepines, propofol, and perhaps morphine.[87] Propofol appears particularly susceptible to this effect. In vitro studies using entire circuits and various individual components report recovery of propofol has been 10 percent or less.[87] In the in vitro studies, priming of the circuit with albumin appears to reduce adsorption of at least some of these drugs.[87] This method of priming may have contributed to the maintenance of serum morphine concentrations in an in vivo study as well.[94] Drug concentrations may be altered when a circuit containing some fraction of that drug is discarded and replaced.[87] Finally, pharmacokinetics may be altered by in-line hemofiltration, which is required in approximately 12% of neonates on ECMO, and by dialysis, which is required by approximately 3% to 4% of these patients.[87]

Pharmacodynamics

In contrast to pharmacokinetics, which operationally describes what the body does to the drug, pharmacodynamics deals with what the drug does to the body.[95] As such, this discipline within pharmacology deals with the mechanisms of action of drugs, their safety profiles, drug-receptor interactions, and receptor-effector coupling phenomena. Infants and children have been described to exhibit different clinical responses to several medications than do adults. One example of this difference is the hyperexcitability children may experience following exposure to antihistamines and barbiturates in contrast to the sedation normally observed in adults.[96] Children also have a greater incidence of dystonic reactions following the administration of dopamine antagonists (e.g., haloperidol, chlorpromazine, metoclopramide), which has been speculated to result from an increased concentration of DA-2 receptors in the young brain.[96] When no pharmacokinetic explanation for different drug responses between children

and adults has been offered, a difference in "sensitivity" has been proclaimed. Variable sensitivity to drugs, including some of the nondepolarizing neuromuscular blocking agents (e.g., pancuronium) and the catecholamines, has been described in infants compared with adults. For example, a decreased sensitivity to dopamine has been observed in infants, manifested by an insignificant change in any physiologic variable (including heart rate) below a dose of 15 μg/kg/min.[96] The formal study of ligand-receptor interactions and their consequences is covered comprehensively in two referenced texts.[97,98] However, the translation of these principles into the practice of medicine is embodied in the discipline of therapeutics. Just as important developmental changes determine the related absorption, distribution, metabolism, and excretion of drugs, ontogenetic changes in drug responsiveness account for both the qualitative and quantitative differences observed in efficacy and toxicity when drugs are used in infants and children. Unfortunately, the latter have not been evaluated with the same intensity that has characterized our assessment of developmental changes in pharmacokinetics.[99,100] Actions of drugs in the immature individual may be altered for a variety of reasons, including altered numbers of receptor sites compared with mature individuals, altered affinity of the receptor for its primary ligand or agonists, and/or altered receptor-effector coupling resulting in altered drug responsiveness. Additional work is necessary to bring this level of sophistication to the clinical setting.

Effect of Disease on Drug Action

During serious illness, substantial changes may occur in receptor function, tissue architecture, and postreceptor function that ultimately are responsible for changes in drug action. These often result from vascular volume or electrolyte derangements and from the effects associated with derangements in acid-base status. Nevertheless, conditions such as pulmonary fibrosis and cardiomyopathy may be associated with diminished responsiveness to drugs acting on the affected organ. Infection with *Haemophilus influenzae* type B has been associated with decreased pulmonary β_2-receptor function with a resultant increase in airway resistance.[101,102] Protracted use of catecholamines may result in down-regulation of functional β-receptors in target organs, requiring frequent dose increases to achieve the maintained desired pharmacologic effect.[103-105]

Finally, remember that most drugs used in the PICU are potent agents that have the potential to cause serious side effects.[106] Unfortunately, drug toxicity in a critically ill patient may be an amplified event. Such patients are the least likely to be able to tolerate such effects. Thus the therapeutic index for most of the drugs used commonly becomes increasingly narrow as the patient's condition warrants more aggressive therapy.[107]

Pharmacokinetic Principles

Evaluation of the Plasma Concentration-Time Curve

The application of pharmacokinetic principles to patient care should permit rational drug dosing and result in effective pharmacotherapy. Most of the drugs used in clinical medicine are metabolized via linear first-order kinetic processes (Figure 116-2). This means that a constant percentage of drug is removed from the body per unit of time. Virtually all of the pharmacokinetic parameters used on a routine basis can be derived from a plot of serum/plasma concentration versus time, which then is converted to a semilogarithmic display (Figure 116-3). The straight, terminal portion of the former represents the elimination phase for the drug, and its slope is the elimination rate constant K_e (Table 116-3 and Figure 116-4). The elimination half-life for the drug $t_{1/2\beta}$ (see Figure

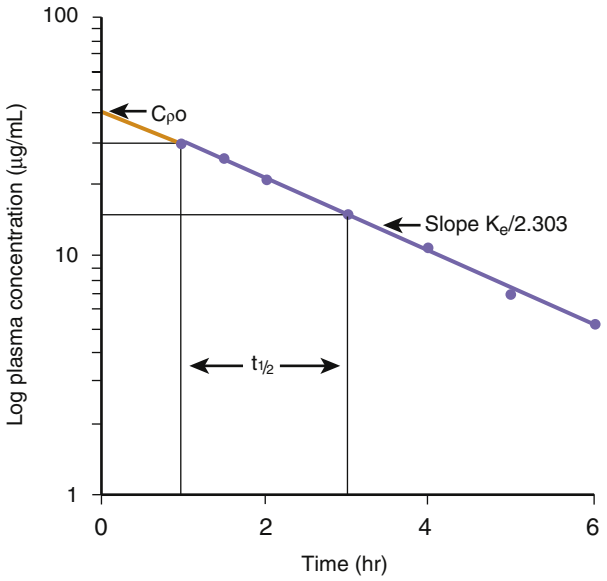

Figure 116–2. First-order elimination. Plasma concentration versus time curve for a drug eliminated via first-order kinetics. Note the elimination half-life is depicted as the time required for the drug concentration to be reduced by half. A constant fraction of the drug in the body is eliminated in each equal interval of time.

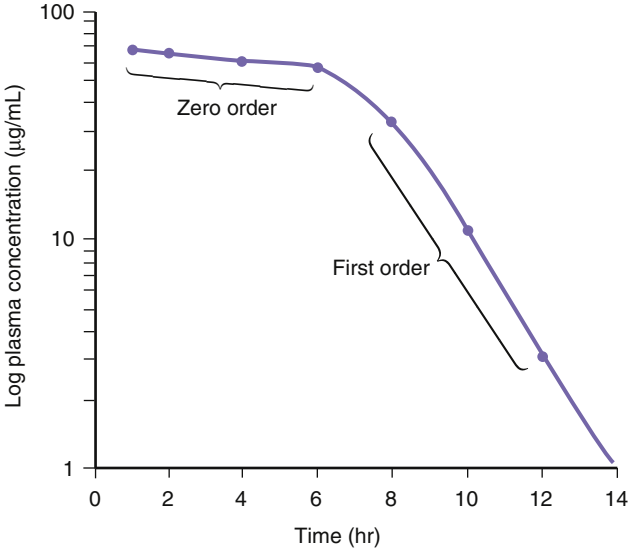

Figure 116–3. Michaelis-Menten kinetics. Log plasma concentration versus time curve for a drug showing saturation of the elimination mechanism. Initially, a constant amount of drug is eliminated per unit time rather than a constant fraction of drug per unit time. This initial phase is said to show zero-order elimination. Later, the plasma concentration falls below the saturating level and the elimination process becomes first order.

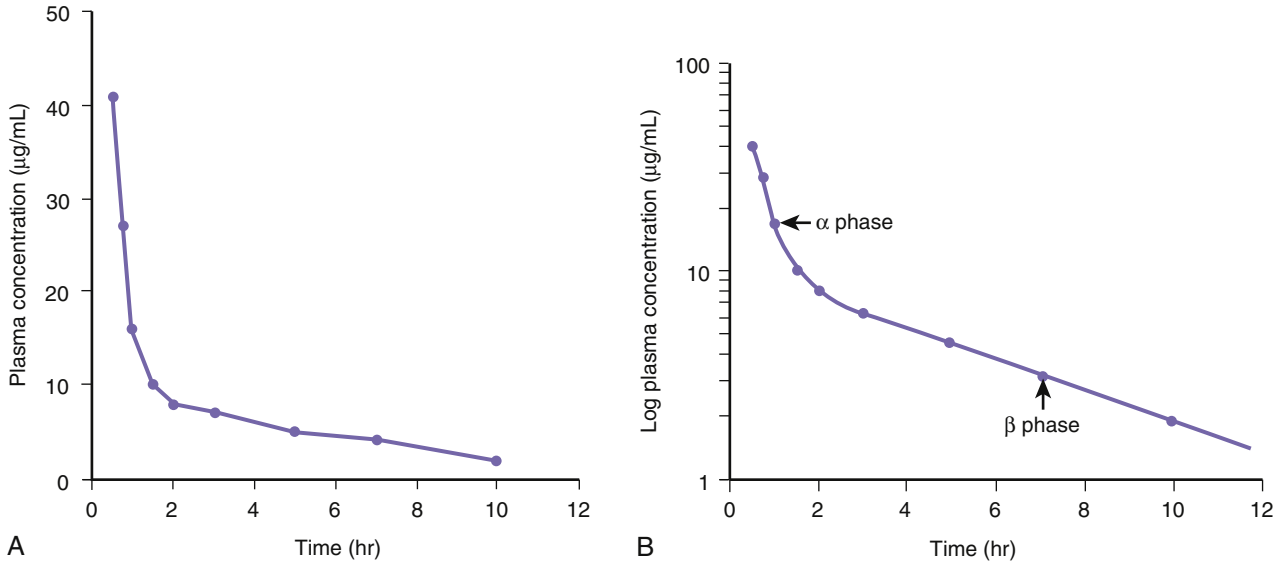

Figure 116–4. Two-compartment model. **A**, Plasma concentration versus time curve presented using rectangular coordinates. **B**, Semilogarithmic transformation of the data shows a biphasic curve rather than a straight line. This is thought to represent the interaction between two compartments: plasma and extracellular fluid space. The upper portion of the curve is called the α *phase* and is thought to represent drug distribution. The lower portion is termed the β *phase* and is thought to represent actual drug elimination. Slope of the β phase = –K/2.303.

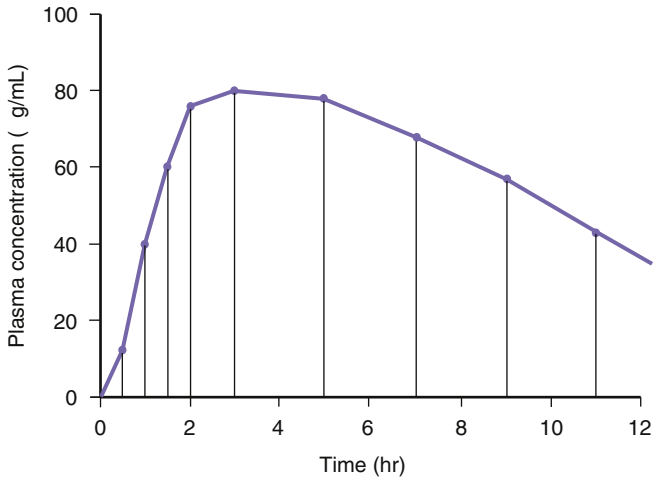

Figure 116–5. Trapezoidal rule. Plasma concentration versus time curve for a drug after oral administration. The area under the curve (AUC) represents the total amount of an individual dose that is absorbed. This area can be calculated by dividing the curve into a series of trapezoids, calculating the area for each, and summing all of the areas.

116-2) then can be determined directly by inspection of the semilogarithmic graph as the time required for the concentration to decrease by half, or it may be calculated from the exponential decay curve considerations once K_e is determined:

$$t_{1/2\beta} = \frac{0.693}{K_e}$$

The area under the serum concentration versus time curve (AUC) can be determined by applying an approximate integration formula, most commonly the trapezoidal rule.[108] This method involves the description of a given plasma concentration-time curve as a series of straight lines, which enables the curve to be divided into a number of trapezoids (Figure 116-5). The area of each trapezoid can be easily calculated, and the sum of all such areas equals the area under the AUC. The latter value is important in deriving two other values of clinical importance: bioavailability and clearance of the drug. Finally, by extrapolating the terminal elimination phase of the curve b to time 0, the intercept on the Y axis denotes the concentration that would have resulted if the total dose of the drug had instantaneously distributed throughout the body (Figure 116-6). This concentration, termed C_o, can be used to determine the apparent volume of distribution of the drug V_d, using the following equation:

$$V_d = \frac{D}{C_o}$$

where *D* is the dose administered.

In children, a number of important compounds demonstrate saturation kinetics at clinically useful doses (Box 116-5). In this case, the drugs appear to have longer half-lives at higher concentrations. For these drugs, the relationship between serum concentration and time is better described by the values V_{max} and K_m than by V_d and Cl.[19,109] The most important drug demonstrating this type of biodisposition is phenytoin.[110] With this drug, a small increase in dose may result in a large increase in serum concentration. Disease states and drug interactions can pose particular problems for patients receiving drugs cleared by saturable processes. A patient with liver dysfunction may have decreased V_{max} for a given drug compared with a healthy child. Consequently, saturation of metabolic elimination may occur at a lower concentration than normal.

Applied Pharmacokinetics

Use of pharmacokinetic parameter estimates is essential to the development of proper dosing regimens, the effective use of the drug analysis laboratory, and ultimately in optimization of drug therapy. Among the available parameters, the most important in the PICU are clearance (Cl), volume of distribution (V_d),

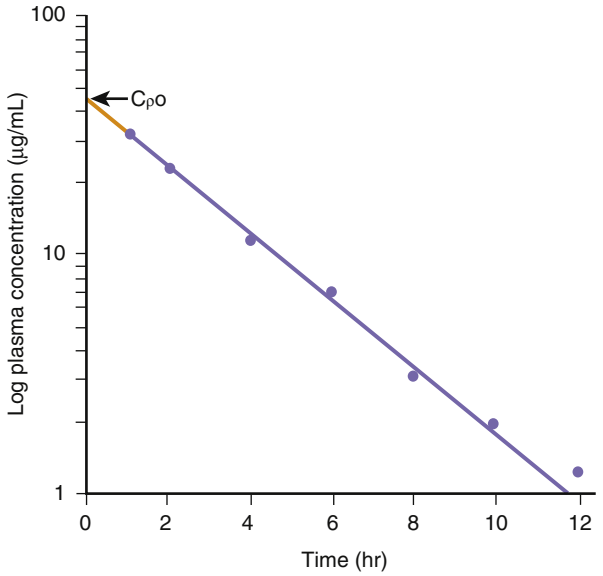

Figure 116–6. Log plasma concentration versus time curve depicting Cp_0. This is a semilogarithmic plot of plasma drug concentration versus time after intravenous infusion of drug. This drug shows one-compartment, first-order elimination as indicated by the single straight line. Extrapolation of the line back to time zero yields an estimate of Cp_0 or the drug concentration that would result if the total dose was administered and distributed immediately throughout the body. If the dose administered is known and the C_0 ascertained, the apparent volume of distribution V_d of the drug administered can be calculated.

Box 116–5 Drugs Demonstrating Saturation Kinetics in Infants and Children

Caffeine
Chloramphenicol
Diazepam
Ethanol
Furosemide
Indomethacin
Mezlocillin
Phenytoin
Salicylate

and half-life ($t_{1/2\beta}$). In addition, if oral therapy is contemplated, bioavailability (F) must be considered. Each of these parameters can be used for mathematically describing the biodisposition of a drug under steady-state conditions.

Bioavailability

The concept of bioavailability was discussed extensively in the section related to drug absorption. For most drugs administered intravenously, the bioavailability is 100% and F = 1. In clinical terms, the "relative" bioavailability of a drug is most important. Bioavailability F is defined as the ratio of the AUC for the drug given by a nonintravenous route (AUC_{Oral}) to the AUC of the same drug administered intravenously (AUC_{IV}):

$$F = \frac{AUC_{Oral}}{AUC_{IV}}$$

Relative bioavailability can be used to convert from one route of administration to another. For example, the relative bioavailability of theophylline is 1. Therefore in switching from intravenous to oral dosing, the same total daily dose of theophylline should be administered. In contrast, relative bioavailability of furosemide is approximately 0.5. Thus in switching from intravenous to oral administration, the dose of the drug should be doubled to maintain the same diuretic effect.

Half-Life

Elimination half-life of a drug is a hybrid term that is a function of both clearance and volume of distribution:

$$t_{1/2\beta} = \frac{0.693}{K_e} = \frac{0.693 V_d}{Cl}$$

This is the pharmacokinetic parameter most commonly used by clinicians, but it is often misconstrued to signify drug elimination. However, as shown in the equation, either a change in Cl or a change in V_d can result in a change in $t_{1/2\beta}$. The therapeutic implications of these alterations are clearly different. It is also apparent that if pathophysiologic changes result in offsetting changes in V_d and Cl, the elimination half-life could remain unaffected in the face of significant disease. The most important clinical application of half-life is as a determinant of drug dosing. Four to five half-lives are required for a drug to reach steady-state plasma concentration at any given dose. This is true whether therapy is being initiated or the dose is being changed.

Apparent Volume of Distribution

The volume of distribution V_d describes the apparent volume of the compartment into which the drug distributes. It must be emphasized that this value has no physiologic significance. Rather, it serves as a parameter estimate that permits the calculation of the dose of drug (i.e., loading dose) required to achieve a desired plasma concentration:

$$C_p = \frac{Dose}{V_d}$$

It should be noted that calculation is independent of the drug's clearance and half-life.

Total Body Clearance

As previously noted, clearance is a useful parameter for determining the amount of drug needed to maintain a desired steady-state plasma concentration. Because by definition the rate of drug elimination at steady state is equal to the rate of drug administration, then[20,33,108]

Elimination rate = $C_p \times Cl$, where C_p is the average steady-state plasma concentration:

$$\text{Administration rate} = (F \times D) / \tau$$

where D = dose and τ = dosing interval.
At steady state:

$$C_p \times Cl = (F \times D)/\tau$$

or, rearranging:

$$C_p = (F \times D)/(Cl \times \tau)$$

where the solutions provide the average steady-state plasma concentration. It is obvious from the equation that to maintain a steady-state plasma concentration, disease-associated changes in Cl must be compensated by changes in dose D or interval τ.

Critical Care Therapeutics

In the treatment of critically ill infants or children, consideration must be given to both developmental and disease processes. Thus at first glance it seems an overwhelming task to develop therapeutic strategies that would be both safe and effective in treating these patients. Nevertheless, two approaches can be identified that lend themselves to the rational care of these patients: target concentration strategy and target effect strategy.[111]

Target Concentration Strategy

The target concentration strategy can be considered for drugs that are used chronically to treat clinical problems that manifest themselves intermittently (Box 116-6). Such problems include reversible reactive airway disease, seizures, and cardiac dysrhythmias. Application of this therapeutic strategy requires recognition that certain target serum concentrations are associated with either the therapeutic or the toxic effects attributed to a given pharmacologic agent. It is important to remember that these target concentration ranges are determined using population-based data rather than individual patient data. Therefore the so-called therapeutic or toxic ranges may not be strictly applicable to the patient currently being treated. However, they serve as useful guides for the initiation and ongoing monitoring of therapy. As part of this ongoing monitoring, effective use of the drug analysis laboratory is essential. To apply the target concentration strategy, physicians must have some knowledge of the pharmacokinetics of the drug being used (Box 116-7). Such knowledge includes an awareness of any active metabolites that may be involved in the expression of the drug's therapeutic activity.

The approach to treatment of the patient in whom the target concentration strategy is to be used requires that the physician have an expectation regarding the clinical manifestations of drug efficacy and drug toxicity before any therapy is initiated. This should be accompanied by an awareness of the appropriate sampling times for the various drugs and an overall understanding that drug "levels" are guides to therapy rather than therapeutic endpoints in themselves. Therapeutic drug monitoring does not substitute for other means of patient evaluation. Effective drug dosing using the target concentration strategy requires a familiarity with the pharmacokinetic parameters previously described and the effective use of the drug analysis laboratory. When a target plasma concentration is known, an initial dose can be chosen. Under some circumstances, it may be desirable to achieve the target concentration immediately. In these instances, the initial dose is termed a *loading dose* and calculated as:

$$\text{Loading dose} = \frac{C_p \times V_d}{F}$$

where C_p is the target concentration.

Use of a loading dose is not always appropriate. Under certain circumstances, the calculated loading dose can result in toxic plasma concentrations before tissue distribution. The alternative is to begin therapy with what is termed the *maintenance dose*:

$$\text{Maintenance dose} = \frac{C_p \times \tau \times V_d}{F}$$

Box 116–6 Principles of the Target Concentration Strategy in Drug Therapy

- Strategy may be effective for drugs used on a chronic basis to treat diseases that manifest signs and symptoms intermittently.
- Caregivers must have some knowledge of the pharmacokinetics of the drugs being used.
- A relationship between drug or metabolite concentration in the sampled biologic fluid and therapeutic efficacy or clinical toxicity must have been established.
- Appropriate sampling time must be known and a reliable assay must be available.
- Target concentrations must be used as guides; treat patients, not drug levels.

Box 116–7 Drugs Used in the Target Concentration Strategy

Antiarrhythmic agents: amiodarone, procainamide, quinidine, lidocaine
Anticonvulsant agents: phenytoin, phenobarbital, valproic acid, carbamazepine, pentobarbital
Antibiotics: aminoglycosides, chloramphenicol, vancomycin (±)
Methotrexate
Cyclosporine
Antipyretics: acetaminophen, salicylate
Theophylline

When therapy is initiated with a maintenance dose, dosing for a total of four to five half-lives will be required to reach the desired steady-state plasma concentration. In contrast, when used in conjunction with a loading dose, the maintenance dose should maintain the plasma concentration attained with the loading dose.

Effective use of therapeutic drug monitoring in the critical care setting requires integration of certain characteristics of the drugs to be used, the laboratory where drug analysis occurs, and physician behavior. The drug selected for therapeutic drug monitoring should be one from which a relatively sustained and constant effect is expected over a comparatively long period of time. Monitoring should be limited to drugs characterized by wide interindividual variation in pharmacokinetics, as well as those that manifest a narrow therapeutic index. Finally, it is imperative that a set of data exists to relate the clinical effects of the drug directly to its concentration in the serum.

For drugs fulfilling these criteria, sensitive and specific assays for determination of their concentrations in various types of biologic fluids must be available. Moreover, this service must be provided with a turnaround time that is appropriate to the type of therapy being rendered. Thus it may be appropriate to provide aminoglycoside serum concentration determinations with a 24-hour reporting schedule; however, the safe and effective adjustment of theophylline dosing requires that serum concentrations be available within 1 hour from the time the blood is drawn. In addition, the results provided by any laboratory must be internally consistent. Standard curves must be checked frequently, and this quality assurance information must be available to all physicians on request.

Use of the target concentration strategy places heavy demands on the physician. Values for commonly used pharmacokinetic parameters describing absorption, distribution, and elimination should be known or readily available. The physician must be aware of conditions in which these pharmacokinetic parameter estimates may be altered and the extent to which these alterations may affect therapy. The physician must have a working knowledge of the average steady-state concentrations of drug in serum associated with both drug effectiveness and drug toxicity. Moreover, the pathophysiologic conditions that may alter these concentration-response relationships must be understood. Finally, clinical experience and sound judgment must prevail. Therapy must consist of an ongoing commitment to treat patients and not drug levels.

Target Effect Strategy

The target effect strategy embodies the therapeutic approach most commonly practiced in the PICU. In fact, the therapeutic strategy allows for rational application of most of the drug classes required in the intensive care setting to the pediatric patient (Box 116-8). Application of the target effect strategy requires that the clinician determine a therapeutic endpoint before initiating drug treatment and accept a commitment to monitor for both drug effectiveness and toxicity. In using this approach, the clinician must have a reasonable understanding of the pharmacodynamic actions of the drugs to be used, including their side-effect profiles. Moreover, the impact of both ontogeny and disease on drug action must be considered. Once therapy is started, the dose is increased until the desired effect is achieved, unless the sequential increase in drug dose results in no increase in therapeutic benefit and the desired effect is not achieved or drug toxicity supervenes. The amount of time taken in dosage escalation is dictated by the clinical circumstance at hand. In some circumstances, days of adjustments may be acceptable, whereas in others minutes may be too long. Nevertheless, inherent in this strategy is a belief that responses to drugs are dose-related and that any concept of a preexisting maximal dose is precluded. Thus if either lack of efficacy or toxicity becomes apparent, the mandated response is to *change* the drug.

Box 116–8 Classes of Drugs Used in the Target Effect Strategy for Critically Ill Children

Anticoagulants
Catecholamines
β-Lactam antibiotics
Diuretics
Corticosteroids
Oxygen
Anxiolytics, sedatives
Neuromuscular blockers
Vasodilators
Antihypertensives
Inotropes: amrinone

In summary, rational therapeutics for the critically ill child must account for the impact of development and disease on drug action. The scenario suggests use of short-acting drugs with large therapeutic indexes and requires that expectations regarding drug effects be ascertained prospectively. This approach mandates rigorous attention to monitoring but ultimately ensures that the dosage used will be sufficient to achieve the desired response.

Molecular Mechanisms of Drug Actions: From Receptors to Effectors

Catherine Litalien and Pierre Beaulieu

PEARLS

- Receptors play a central role in determining the nature of the pharmacologic effects produced by a drug.
- Most drugs and endogenous compounds (e.g., hormones, neurotransmitters) exert their action by binding to a receptor or by modulating an ion channel.
- G proteins are a superfamily of proteins that allow transduction between activated receptor (by an agonist) and different intracellular effectors, such as enzymes or ion channels, relaying signals from more than 1000 receptors. G protein–coupled receptors represent the target, directly or indirectly, of approximately 50% of all current therapeutic agents.
- Continued exposure of a receptor to an agonist often results in progressive loss of receptor responsiveness, with a diminished receptor-mediated response over time. This is called *desensitization*.
- Calcium is critically important as a regulator of cell function. It exerts its control on cellular function through its ability to regulate the activity of many different proteins, such as channels, transporters, and transcription factors. In the majority of cases, a calcium-binding protein serves as an intermediate between Ca^{2+} and the regulated functional protein.
- The role of inheritance in the individual variation of drug response is increasingly recognized with the identification of polymorphisms in genes encoding drug-metabolizing enzymes, drug targets, and proteins involved in signal transduction. Studies evaluating the effects of single nucleotide polymorphisms (SNPs) for a given gene will need to consider specific haplotypes or combination of haplotypes because individual SNPs may have poor predictive power as pharmacogenetic loci.

Optimizing drug response is a challenging task that clinicians confront on a daily basis. This is particularly true for those caring for critically ill patients, in whom many factors influencing drug response are being more commonly recognized. These include reduced absorption, variable drug distribution, decreased metabolism and elimination, as well as alterations in drug receptors, signaling mechanisms, and effectors.[1-3] In recent years, advances in molecular pharmacology have shed more light on the processes that transduce extracellular signals into intracellular messages that control cell function. This has led to the elucidation of multiple points at which modulation of signal transduction, either by pharmacologic agents or diseases, can occur. Also, there has been an ongoing recognition of the role of inheritance in the individual variation of drug response with the identification of polymorphisms in genes encoding drug-metabolizing enzymes, drug targets (e.g., receptors, enzymes), and proteins involved in signal transduction.[4-6]

This chapter provides a detailed overview of how drugs work at the molecular level and how this complex system is influenced by genetic factors, developmental changes, disease processes, and the environment (Figure 117-1). Ultimately, the objective is to help pediatric intensive care physicians better tailor the pharmacotherapy they use: that is, choose the right drug, or combination of drugs, for the right patient to achieve maximal efficacy with no or minimal toxicity. This chapter does not address signaling pathways involved in diseases per se.

Targets For Drug Action

The initial step in the cascade of biochemical events resulting in drug action mostly consists in the binding of drugs to specific cellular targets. These can be broadly divided into four categories: (1) receptors, (2) ion channels, (3) enzymes, and (4) carrier proteins (Figure 117-2). The vast majority of important drugs act on one of these types of proteins.

Receptors

Receptors are the most frequent drug target. They can be defined as the sensing elements in the system of chemical communication that coordinate the function of all different cells in the body, the chemical messengers being the various hormones, neurotransmitters, other mediators, or drugs. Ligands

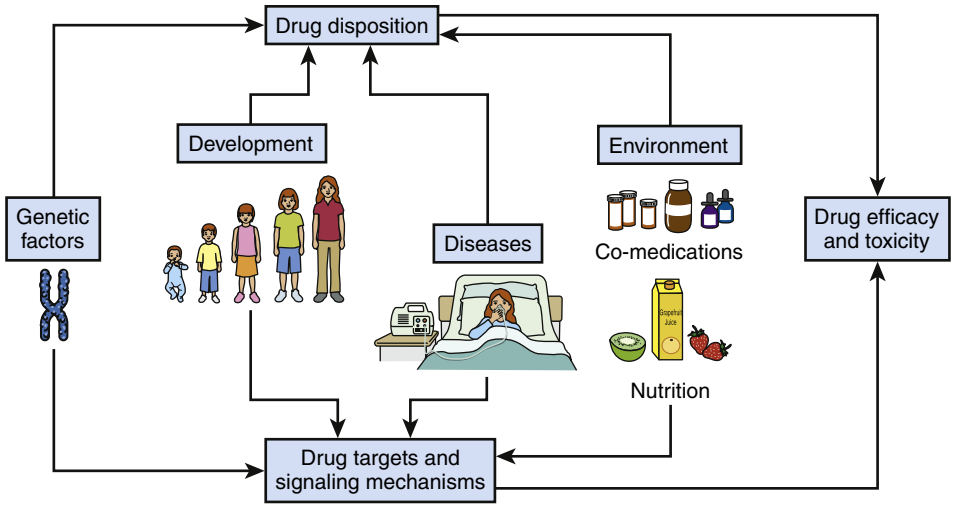

Figure 117–1. Relationships among genetic factors, development, diseases, and the environment and drug efficacy and toxicity.

(e.g., hormones, drugs) that bind with receptors are termed *agonists* if their binding results in the expected effect and are termed *antagonists* if binding stops or decreases an agonist-induced activity.[7] Administration of a receptor antagonist in the absence of agonist results in no effect because antagonists bind to receptors but do not activate them. An antagonist is said to be *surmountable* when maximal response to the agonist can be restored by raising the agonist concentration (parallel displacement of the agonist dose-response curve to the right). Likewise, an antagonist is said to be *insurmountable* when even high concentrations of the agonist are not able to elicit the maximal expected agonist response (Figure 117-3, *A*). The terms *competitive* and *noncompetitive* do not describe a pharmacologic behavior per se; rather, they refer to the receptor binding site of the antagonist with regard to that of the agonist. A competitive antagonist binds to the same site as the agonist on the receptor, whereas a noncompetitive antagonist has its own binding site separate from that of the agonist and makes the receptor refractory to the agonist. Both *competitive* and *noncompetitive* antagonists can be *insurmountable.*

The duration of action of an *insurmountable* antagonist depends mostly on synthesis of new receptors, which can take several days. This may have clinically important consequences. For example, phenoxybenzamine, an *insurmountable* α-adrenergic receptor antagonist sometimes used in stage I Norwood procedures to balance the pulmonary and systemic circulations, can produce symptomatic hypotension in some patients. The attenuation or reversal of the decrease in systemic vascular resistance it produces may not be achieved with an α-adrenergic receptor agonist such as dopamine (high dose) or norepinephrine, depending on the dose of phenoxybenzamine given. In such circumstances, the use of a pressor agent that does not act through the α-adrenergic receptor such as vasopressin, which binds on V_1 receptors of smooth muscle cells, must be considered.[8]

Partial agonists are ligands that bind to the same receptor as full agonists but have less intrinsic capacity to produce a response as strong as full agonists, despite full receptor occupancy (Figure 117-3, *B*). The exact mechanism that accounts for the blunted maximal response seen with partial agonists is unknown. Simultaneous administration of a partial agonist and a full agonist prevents the maximal response usually observed with the full agonist alone because partial agonists have the ability to occupy the receptor population (Figure 117-3, *C*). Finally, inverse agonists are ligands that reduce the level of constitutive activation encountered in some receptor systems (Figure 117-3, *D*).[9]

Receptors play a central role in determining the nature of the pharmacologic effects a drug produces. First, receptors bind with only one or a limited number of structurally related ligands, thus ensuring that the final effect seen in a normal setting occurs only in response to defined stimuli. Second, for a given dose or concentration of a drug, the drug's affinity to bind to the receptor and the total number of available receptors directly influence the maximal effect a drug can produce. Third, drugs differ in their intrinsic activity in regard to their receptors (e.g., partial agonist vs. full agonist). Thus the magnitude of the response to any drug is proportional to both the extent of receptor occupancy and the intrinsic activity of the receptor itself, resulting in different dose or concentration relationships for different agonists.

Ion Channels

Ion channels are molecular machines that serve as principal integrating and regulatory devices for the control of cellular excitability. Different types of ion channels have been described: channels responding to electrical (voltage-dependent ion channels), mechanical, or chemical (ligand-gated ion channels) stimuli; ion channels controlled by phosphorylation/dephosphorylation mechanisms; and G protein–gated ion channels. Most ion channels are of the voltage-dependent type and consist mainly of Na^+, K^+, and Ca^{2+} channels. Drugs can affect ion channel function directly by binding to the channel protein and altering its function or indirectly through G proteins and other intermediates. Lidocaine is a good example of a drug that directly affects voltage-gated Na^+ channels by blocking the channel and thus Na^+ entry into the cell. Channel-linked receptors (ligand-gated ion channels) are discussed below.

Enzymes

Enzymes are a specialized class of proteins responsible for catalyzing chemical reactions within the cell and thus are ideal drug targets. Most drugs that alter enzymes activity are

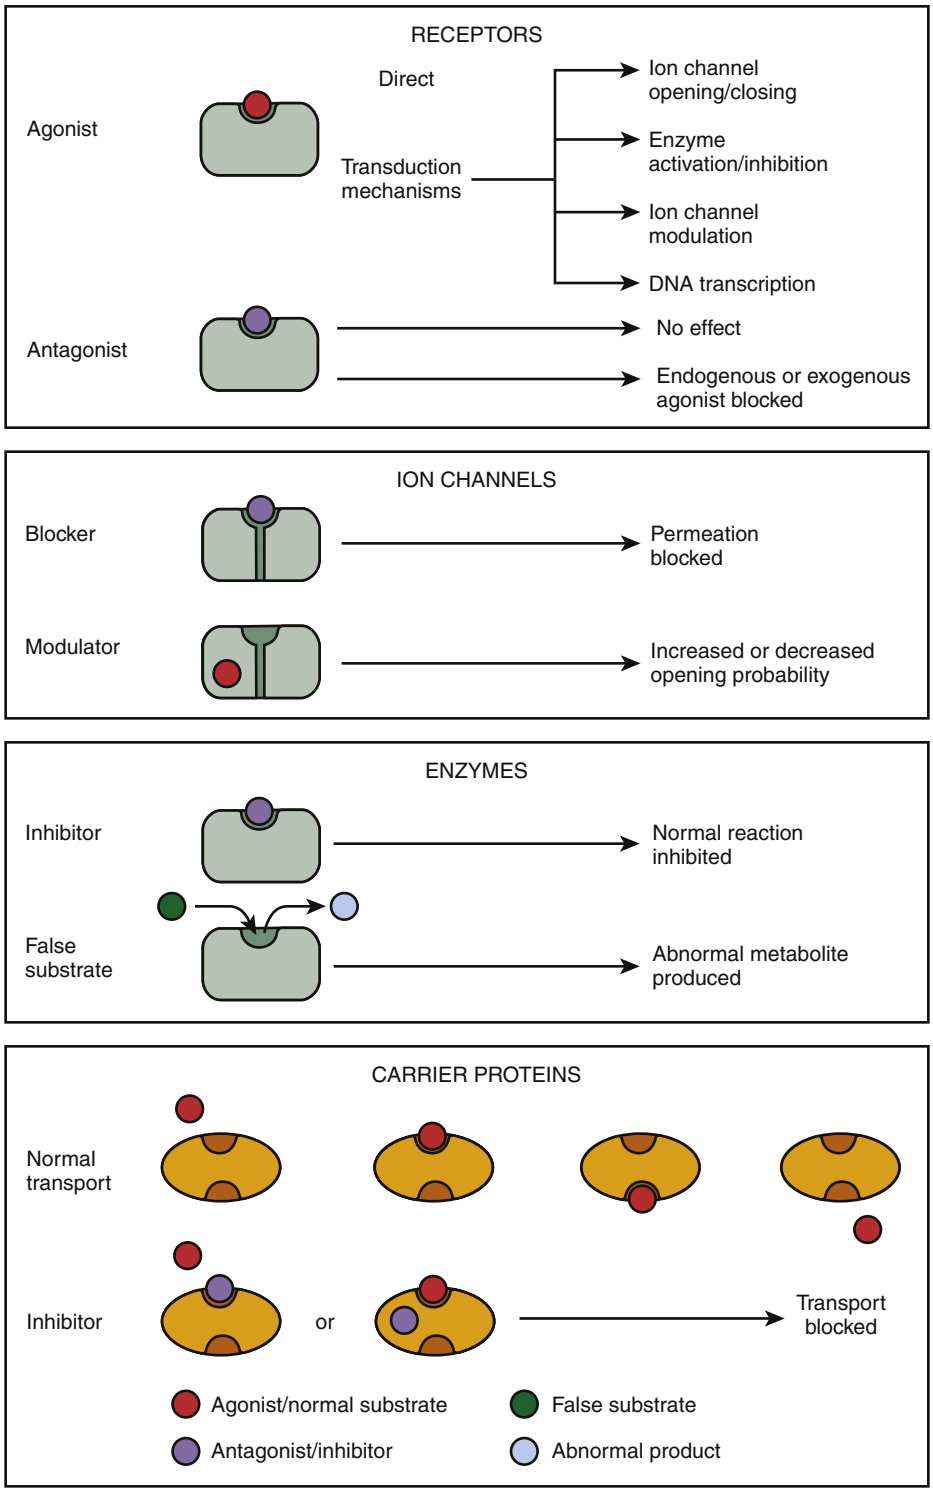

Figure 117–2. Targets for drug action. *(Modified from Rang HP, Dale MM, Ritter JM, et al:* Rang and Dale's pharmacology, *ed 6, Philadelphia, 2007, Churchill Livingstone.)*

substrate analogues of enzymes that inhibit their activity either reversibly (e.g., angiotensin-converting enzyme inhibitors acting on peptidyl dipeptidase) or irreversibly (e.g., acetylsalicylic acid acting on cyclooxygenase). Drugs may also prevent the normal functioning of enzymes. Fluorouracil, an anticancer drug, is a good example of such drug; it is converted into an abnormal nucleotide that inhibits thymidylate synthetase, thus blocking DNA synthesis.

Carrier Proteins

Several biologic elements, such as ions and small organic molecules, are not lipid soluble enough to cross the plasma membrane and require a carrier protein to be transported. In most cases, the transport of organic molecules is coupled to the transport of ions (usually Na^+), either in the same direction (symport) or in the opposite direction (antiport). The carrier

proteins embody a recognition site that makes them specific for a particular permeating species; these recognition sites can also be targets for drugs whose effect is to block the transport system.[25] Indeed, some drugs, such as cardiac glycosides (e.g., digoxin), bind to these carrier proteins and interfere with the transport system. Digoxin is a typical example of drugs that produce their effect by inhibition of an ion pump: blockade of the Na^+/K^+ ATPase pump.

Table 117-1 shows the targets of some pharmacologic agents commonly used in the pediatric intensive care unit.

Receptor Type and Regulation

Classification of Receptors

Four families of receptors, three cell surface receptor types and one nuclear receptor, have been described (Figure 117-4).

Most transmembrane signaling is accomplished by only a few molecular mechanisms, each of which has been adapted to transduce many different signals. These protein families include cell surface receptors and receptors within the cell as well as enzymes and other components that generate, amplify, coordinate, and terminate postreceptor signaling.

G Protein–Coupled Receptors. In 1994, Alfred G. Gilman and Martin Rodbell were awarded the Nobel Prize in Physiology or Medicine for their discovery of G proteins and their role in signal transduction in cells.[10] G proteins are a superfamily of propeller proteins that allow the transduction between the activated receptor (by an agonist) and different intracellular effectors such as enzymes or ion channels, relaying signals from more than 1000 receptors.[11] G protein–coupled receptors (GPCRs), also known as *metabotropic receptors*, are in fact the first component of the cellular amplification cascade (Figure 117-5). Indeed, the activation of target enzymes through GPCRs leads to the synthesis of numerous second messengers, which in turn activate other enzymes. The intervention of the second messenger system allows for the diversity of the cellular targets (see below). GPCRs represent the target, directly or indirectly, of approximately 50% of all current therapeutic agents.[12]

Three major families of GPCRs are defined based on their amino acid sequence: family 1, the largest one, includes receptors for rhodopsin, monoamines (such as β-adrenergic receptors), neuropeptides, opioids, and chemokines. Family 2 consists mainly of receptors for peptides with a large molecular weight, such as calcitonin and secretin. Family 3

Table 117–1 Targets of Drugs Commonly Used in Critically Ill Children

Drug	Receptor	Agonist	Antagonist
RECEPTORS			
Adenosine	Adenosine	√	
Atropine	Muscarinic		√
Bosentan	ET_A, ET_B		√
Clonidine	α_2-Adrenergic	√

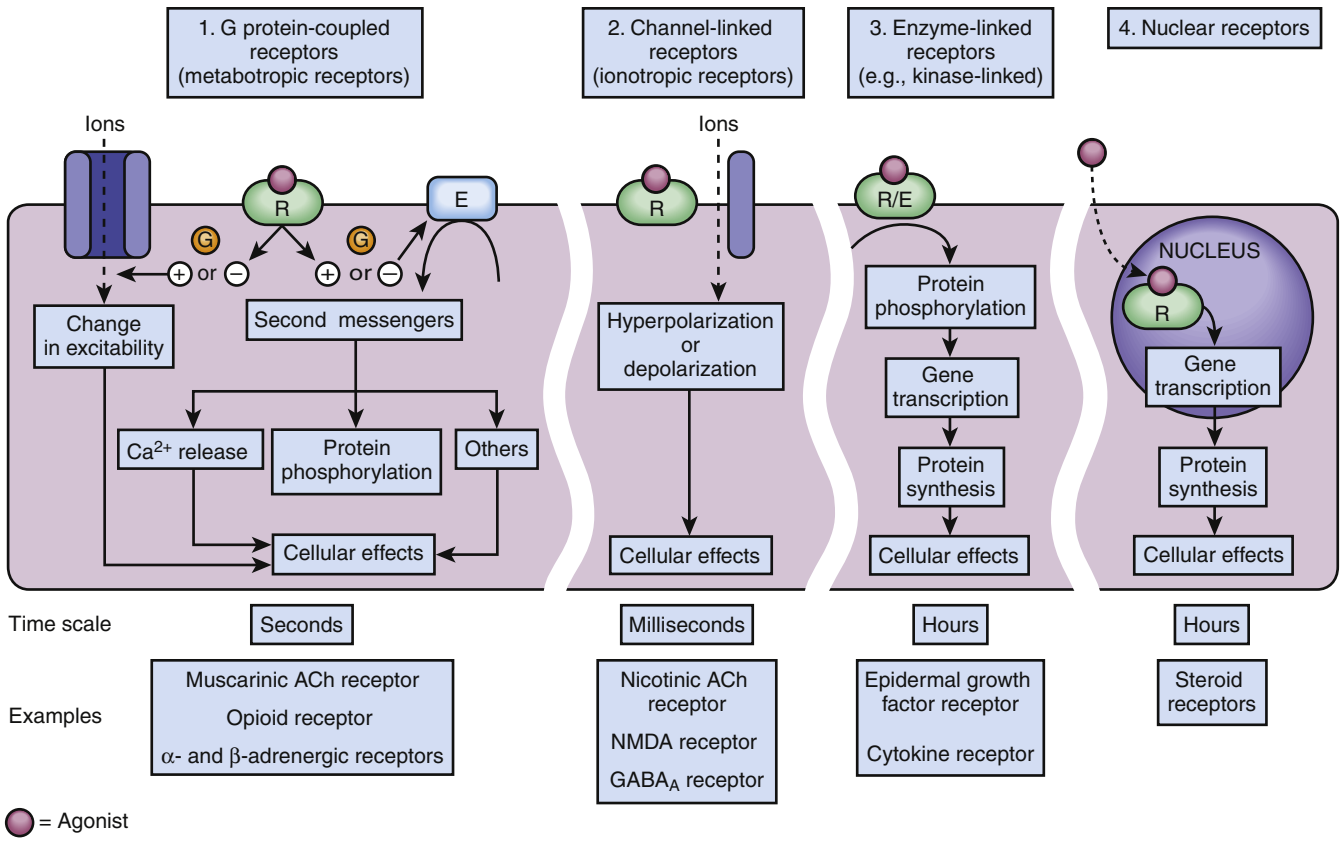

Figure 117–4. Four families of receptors are classically described: G protein–coupled receptors, channel-linked receptors, enzyme-linked receptors, and nuclear receptors. *ACh*, Acetylcholine; *E*, enzyme; *G*, G protein; *GABA*, γ-aminobutyric acid; *NMDA*, *N*-methyl-D-aspartate; *R*, receptor. *(Modified from Rang HP, Dale MM, Ritter JM, et al:* Rang and Dale's pharmacology, *ed 6, Philadelphia, 2007, Churchill Livingstone.)*

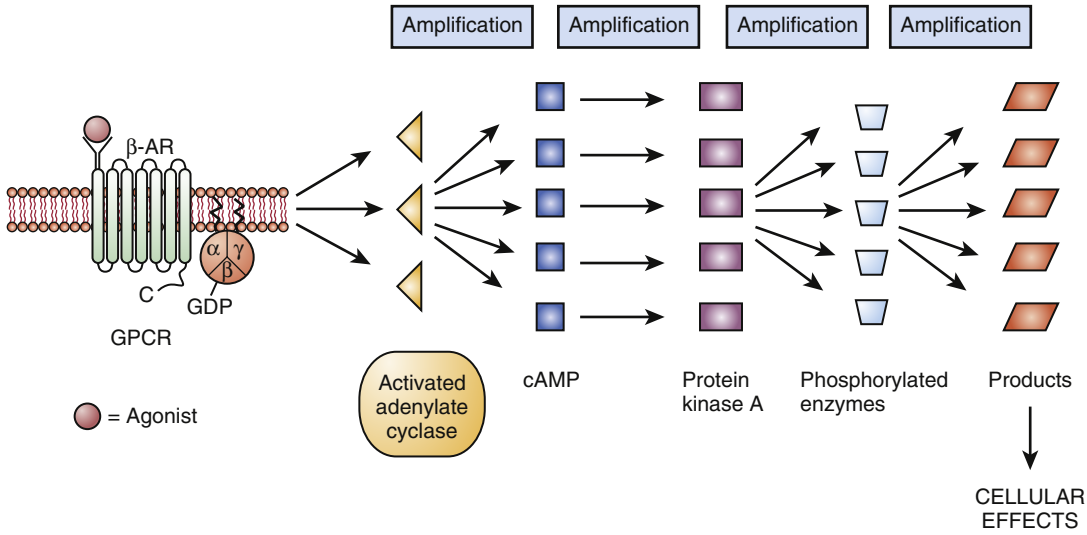

Figure 117–5. Cellular amplification cascade. After binding to a G protein–coupled receptor (*GPCR*), a ligand (agonist) activates a target enzyme (adenylate cyclase), which synthesizes a second messenger (*cAMP*). The latter then activates other enzymes (protein kinases) that phosphorylate proteins and mediate specific cellular effects. *β-AR,* β-adrenergic receptor; *GDP,* guanosine diphosphate.

has, among others, receptors for glutamate (metabotropic), γ-aminobutyric acid$_B$ (GABA$_B$), and extracellular calcium. Despite these differences, the families of GPCRs share characteristic structural and functional features. All GPCRs share a common serpentine structure consisting of seven transmembrane domains with three extracellular and three intracellular loops. The extracellular regions are involved in ligand binding, and the intracellular regions are primarily involved in signaling.[13] The latter are coupled to a heterotrimeric guanine-nucleotide-binding regulatory protein (G protein) located on the cytoplasmic portion of the cell membrane and are made of three subunits. Each G protein is composed of an α-subunit

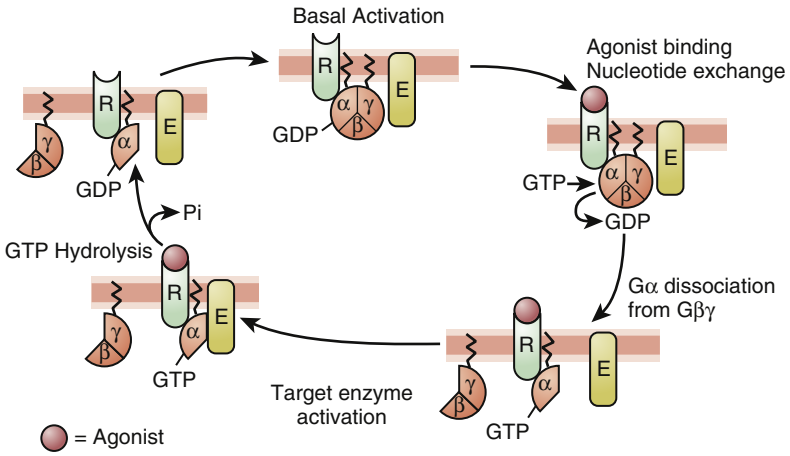

Figure 117–6. Functional cycle of the G proteins. The receptor (*R*) becomes activated after binding of an agonist. Guanosine diphosphate (*GDP*) bound to the G protein is replaced by guanosine triphosphate (*GTP*), and the α-subunit of the G protein dissociates from βγ-subunit complex. The α-subunit/GTP complex binds to the target enzyme (*E*) or ion channel, whereas the βγ-subunit complex stimulates several other downstream effectors. The GTPase activity of the α-subunit is increased when the target enzyme or ion channel is bound, leading to hydrolysis of the bound GTP to GDP, whereupon the α-subunit reunites with βγ-subunit complex and the agonist dissociates from the receptor.

that is loosely bound to a tightly associated dimer made up of β- and γ-subunits. The activity of a trimeric G protein is regulated by the binding and hydrolysis of guanosine triphosphate (GTP) by the α-subunit (Figure 117-6).

Each of the three subunits is encoded by a separate gene selected from at least 20 α, six β, and 12 γ genes, respectively. The α-subunit is essential in the "receptor-effector" coupling. Various α-subunits define different G protein trimers (G_s = stimulatory G protein, G_i = inhibitory G protein, G_o = other G protein, etc.), each of which regulates a distinctive set of downstream signaling pathways. Table 117-2 shows some examples of GPCRs with their trimeric G protein along with their target enzymes or ion channels and second messengers. Some receptors act by way of more than one type of G protein trimer (e.g., μ opioid receptor). Approximately 50% of the GPCRs couple to G_i/G_o proteins, approximately 25% couple to G_s, and about the same amount couple to G_q proteins.[14] G_s proteins (made of α_s-subunits) can activate adenylate cyclase and are inhibited by the cholera toxin. In contrast, G_i proteins (made of α_i-subunits) can inhibit adenylate cyclase and open K^+ channels and are inhibited by the pertussis toxin.

Small G proteins are monomeric G proteins with molecular weight of 20 to 40 kDa. As with heterotrimeric G proteins, their activity depends on the binding of GTP. More than 100 small G proteins have been identified. They are classified into different families: Ras, Rho, Rab, Rap, Ran, and ARF. They play key roles in numerous cellular functions such as cell division, proliferation, differentiation, vesicle trafficking, cytoskeletal reorganization, and gene expression.[15]

Channel-Linked Receptors. Also known as *ligand-gated ion channels* or *ionotropic receptors,* channel-linked receptors mediate fast responses, affecting ion fluxes and membrane potential. These receptors possess four distinct characteristics: (1) activation by an agonist or inactivation by an antagonist; (2) flux of ions across a central pore; (3) ion selectivity, and (4) fluctuation among open, closed, and inactivated states. Broadly speaking, two types have been identified: receptors of excitatory mediators and receptors of inhibitory mediators.

Receptors of excitatory mediators (glutamate, aspartate, and acetylcholine), which comprise the *N*-methyl-D-aspartate [NMDA] (Figure 117-7, *A*) and the nicotinic acetylcholine receptors, are receptors whose activation provokes depolarization of the cell, leading to propagation of the action potential and ultimately secretion of a neuromediator and muscular contraction, for example. These receptors are permeable to monovalent and divalent cations, mainly Na^+, K^+, Ca^{2+}, and magnesium (Mg^{2+}). Ketamine, a dissociative anesthetic, is a noncompetitive surmountable NMDA receptor antagonist that acts by preventing the opening of ion channels by glutamate. In addition, the potential neuroprotective effects of ketamine appears to be mediated via NMDA receptor blockade.

Receptors of inhibitory mediators, the activation of which provokes hyperpolarization of the cell and therefore decreases

Table 117–2 Examples of GPCRs with their Trimeric G Protein, Target Enzyme and/or Ion Channel, and Second Messengers

GPCR	G Protein	Target Enzyme/Ion Channel	Second Messengers

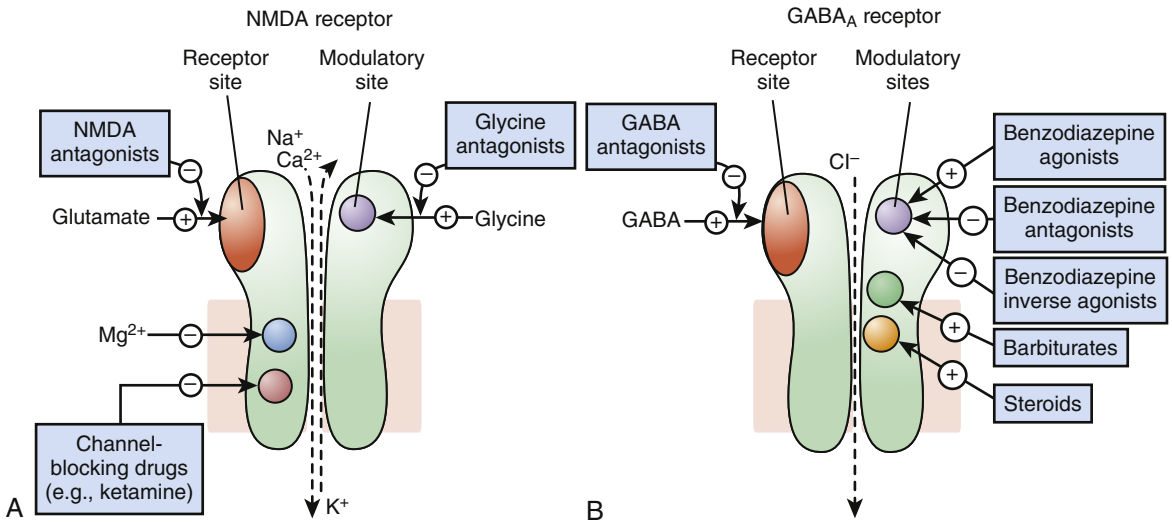

Figure 117–7. Two important members of the channel-linked receptors, the NMDA receptor (**A**) and the $GABA_A$ receptor (**B**). The main sites of drug action on these receptors are shown. *GABA*, γ-Aminobutyric acid; *NMDA*, *N*-methyl-D-aspartate. *(Modified from Rang HP, Dale MM, Ritter JM, et al:* Rang and Dale's pharmacology, *ed 6, Philadelphia, 2007, Churchill Livingstone; and Nestler EJ, Hyman SE, Malenka RC:* Molecular neuropharmacology, *New York, 2001, McGraw-Hill.)*

cellular excitability, are a group that includes $GABA_A$ (Figure 117-7, *B*) and glycine receptors. These ligand-gated ion channels are selective for anions such as chloride (Cl^-) or phosphorus (PO_4^{3-}). GABA is the major inhibitory neurotransmitter in the central nervous system, and drugs that potentiate GABAergic inhibition in the brain, such as benzodiazepines and barbiturates, result in sedation and hypnosis.[7] Benzodiazepine agonists enhance Cl^- ion conductance induced by GABA by increasing the frequency of channel-opening events, whereas barbiturates seem to do so by increasing the duration of the GABA-gated channel openings. Both classes of agents bind to sites on the $GABA_A$ molecule that are different from each other and also from the GABA receptor site.

Enzyme-Linked Receptors. Enzyme-linked receptors have an extracellular ligand-binding domain linked to an intracellular domain that possesses an intrinsic catalytic activity. This large and heterogeneous group of membrane receptors can be divided into four subfamilies according to their catalytic activity (tyrosine kinase, guanylate cyclase, tyrosine phosphatase, and serine/threonine kinase). Cytosolic enzymes presenting an activity similar to that of enzyme-linked receptors are also considered to belong to this family of receptors (e.g., soluble guanylate cyclase receptors activated by nitric oxide [NO]).

Tyrosine kinase receptors include receptors for neurotrophin,[16] growth factors (epidermal growth factor [EGF], platelet-derived growth factor [PDGF]), as well as insulin and many other trophic hormones. These receptors shift from an inactive monomeric state to an active dimeric state upon agonist binding (dimerization). This is followed by autophosphorylation of the intracellular domain of each receptor and binding of SH2-domain proteins that are themselves phosphorylated. Depending on the receptor subtype, SH2-domain proteins allow the phosphorylated receptor to activate other functional proteins, which eventually results in stimulation of gene transcription, or are enzymes such as phospholipases, leading to the formation of second messengers (see below). One important pathway involved in the transduction mechanisms of tyrosine kinase receptors include the Ras/Raf/mitogen-activated protein (MAP) kinase pathway which is important in cell division, growth, and differentiation (Figure 117-8).

Unlike tyrosine kinase receptors, cytokine receptors do not usually possess intrinsic kinase activity; instead, they associate with cytosolic Janus kinases (JAKs). After dimerisation of the receptors that occurs after binding of the cytokine, JAKs phosphorylate tyrosine residues on the receptor, which then result in the binding of another set of proteins called *signal transducers and activators of transcription* (STATs). The bound STATs are themselves then phosphorylated by the JAKs and dimerize and dissociate to migrate in the nucleus and activate gene expression to regulate diverse biologic processes controlling the synthesis and release of many inflammatory mediators, growth, development, and homeostasis.

Guanylate cyclase–linked receptors are unique because they synthesize their own second messengers upon agonist binding. The natriuretic peptide receptors, including atrial natriuretic peptide (ANP), brain natriuretic peptide (BNP), and C-type natriuretic peptide (CNP) receptors, belong to this family (Figure 117-9). The extracellular NH_2-terminal constitutes the binding domain. There is a short transmembrane segment whose role is to anchor the receptor protein to the membrane. The intracellular domain is made of two different entities: (1) a protein kinase homology domain whose function is to control and relay receptor activation to the catalytic domain, and (2) a guanylate cyclase catalytic domain, also known as *particulate guanylate cyclase,* involved in the synthesis of cyclic guanosine monophosphate (cGMP) from GTP.[17] In addition to this particulate guanylate cyclase (the membrane form of the enzyme), an intracellular soluble form exists. It is a heterodimer consisting of α- and β-subunits, both of which are necessary for enzyme activity, and is expressed in most tissues, though not uniformly.[18] It is activated by intermediate substances derived from the biosynthesis of eicosanoids (prostaglandins and leukotrienes) and by NO and NO donors such as sodium nitroprussate and nitroglycerin (see below). Guanylate cyclases and cGMP-mediated signaling cascades play a central role in the regulation of diverse

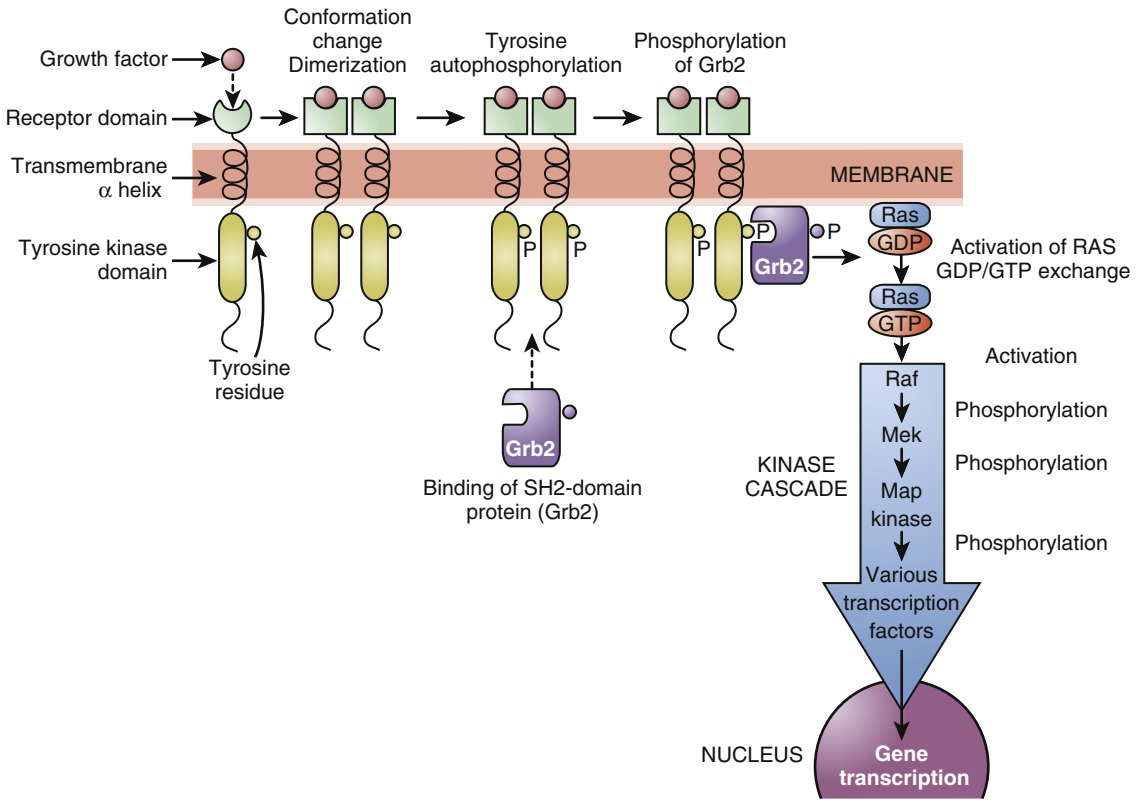

Figure 117–8. Functioning of kinase-linked receptors. The main steps are dimerization of the receptor, autophosphorylation, and phosphorylation of targeted proteins. The growth factor pathway is shown with the kinase cascade involving the successive phosphorylation of many enzymes (Raf, Mek, Map kinase), eventually leading to gene transcription. *GDP*, Guanosine diphosphate; *GTP*, guanosine triphosphate. *(Modified from Rang HP, Dale MM, Ritter JM, et al:* Rang and Dale's pharmacology, *Philadelphia, ed 6, 2007, Churchill Livingstone.)*

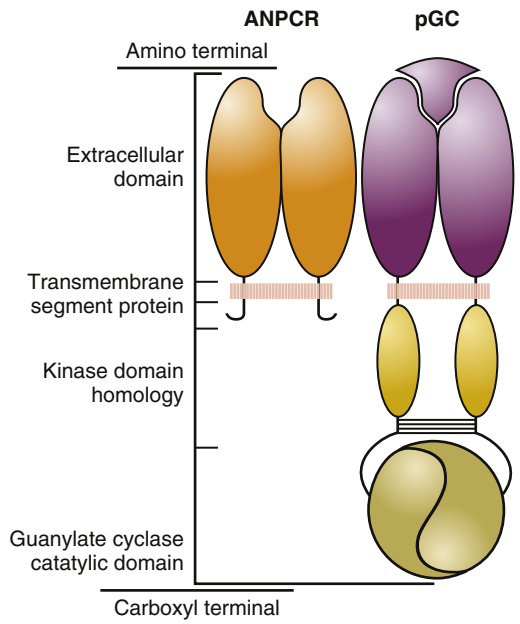

Figure 117–9. Molecular structure of the natriuretic peptide receptors. *Left*, Atrial natriuretic peptide–C receptor (*ANPCR*) is a clearance receptor that does not possess the kinase and guanylate cyclase domains. It plays a role in the catabolism of natriuretic peptides. *Right*, Typical particulate guanylate cyclase receptor (*pGC*) (ANP-A or -B receptor) is shown with its extracellular dimeric protein-binding domain. The intracellular domain consists of a protein kinase homology domain and a guanylate cyclase catalytic domain.

pathophysiologic processes, including vascular smooth muscle motility, intestinal fluid and electrolyte homeostasis, and retinal phototransduction.[19]

Nuclear Receptors. Nuclear receptors belong to a family of functionally and structurally related proteins. They regulate gene expression and are not associated with a membrane. Their principal mechanism of action is shown in Figure 117-10. The agonist, which must be lipid soluble, diffuses into the cell and binds to the nuclear receptor located either in the cytosol or in the nucleus. The complex agonist-activated receptor then binds on high-affinity sites on DNA, hormone response element (HRE), situated on the promoter region of genes whose transcription can then be induced or suppressed. Because gene transcription is at their origin, these effects are slow to develop.

Endogenous agonists for these receptors include steroid and thyroid hormones as well as agents such as retinoic acid and vitamin D. The most commonly used drugs that target these receptors include exogenous steroids and lipid-lowering agents. For many of theses receptors, the corresponding hormone or vitamin has not been identified; these receptors are therefore referred to as *orphan nuclear receptors.*

Receptor Regulation

Continued exposure of a receptor to an agonist often results in a progressive loss of receptor responsiveness, with a diminished receptor-mediated response over time. This is called *desensitization* (or tachyphylaxis) and is classified into two forms. Homologous desensitization is a process in which only

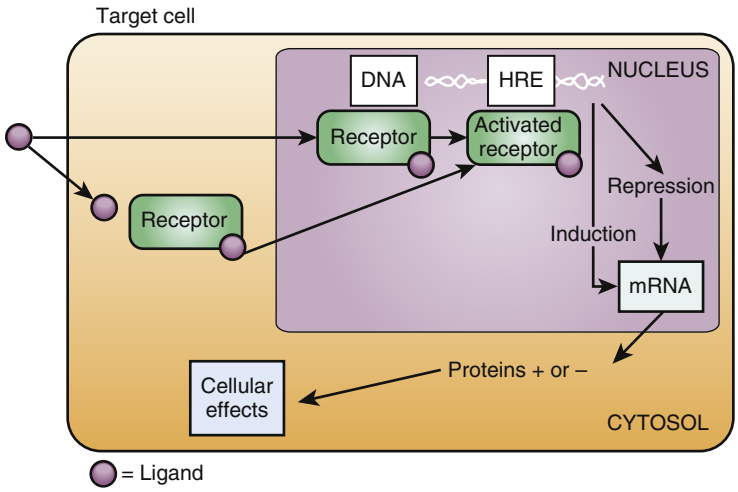

Figure 117–10. Activation and action of nuclear receptors, located either in the cytosol (e.g., steroid receptors) or in the nucleus (e.g., vitamin D receptor). *DNA*, Deoxyribonucleic acid; *HRE*, hormone response element.

the activated receptor is "turned off" or desensitized, whereas heterologous (cross-) desensitization refers to processes in which the activation of one type of receptor can result in the desensitization of other types of receptors. Interaction of the receptor with an antagonist prevents the occurrence of desensitization.

In general, desensitization occurs in three ways (Figure 117-11, *A*): (1) inactivation or uncoupling of the receptor, which is usually the result of receptor phosphorylation and occurs within seconds to minutes of agonist exposure; (2) sequestration of the receptor in endosomes (from there, the receptor is recycled to the cell membrane); and (3) downregulation, which is characterized by receptor endocytosis and destruction in lysosomes with a net loss of receptors in the cell (at the cell membrane and within the cell). It develops more slowly than uncoupling, taking hours to days.[20] In addition to receptor degradation, decreased synthesis of the receptor also contributes to this process. Downregulation is responsible for the decreased responsiveness to prolonged exogenous catecholamine infusion frequently seen in the critical care population.[21] Desensitization is usually reversible, within minutes (inactivation) to hours (sequestration/downregulation) of removal of the agonist depending on the specific receptor and cell type, the concentration of the agonist, and the duration of the exposure to the agonist.

Homologous desensitization of GPCRs results from these three distinct and coordinated processes (Figure 117-11, *B*).[22] It begins within seconds of exposure to the agonist and is initiated by phosphorylation of the receptor by G protein–coupled receptor kinases (GRKs) and second messenger–dependent protein kinases (protein kinase A [PKA], and protein kinase C [PKC]). Once phosphorylated, the receptor binds with high affinity to members of the arrestin gene family, the β-arrestins. The β-arrestin binding prevents the receptor–G protein interaction, leading to termination of signaling by G protein effectors (receptor inactivation or uncoupling). The receptor-bound β-arrestin can also act as an adapter protein to couple the receptor to clathrin-coated pits, inducing receptor-mediated endocytosis or sequestration. Subsequently, the receptor is either recycled to the cell membrane or degraded (receptor downregulation). Resensitization of a GPCR requires its dephosphorylation and dissociation from its agonist. In contrast to homologous desensitization, heterologous desensitization of GPCRs occurs when inhibition of one GPCR is induced by the activation of another GPCR. One well-recognized mechanism is the phosphorylation of one GPCR by second messenger–dependent protein kinases (PKA and PKC) activated by any other GPCRs. Such phosphorylation of the receptor impairs receptor–G protein coupling and leads to the inactivation of the receptor. However, it is becoming increasingly clear that receptor phosphorylation is not the exclusive mediator of heterologous desensitization and that events downstream are involved.[23]

As GPCRs, channel-linked and enzyme-linked receptors are desensitized following prolonged or repeated agonist exposure. Channel-linked receptors are phosphorylated by second messenger–dependent protein kinases while tyrosine kinase receptors are internalized.

Upregulation refers to the increase in receptor sensitivity seen in the setting of lack of agonist stimulation or prolonged presence of a receptor antagonist. This is best exemplified by a phenomenon seen when a β-adrenergic blocking agent such as propranolol is administered for a long period of time and abruptly discontinued. Because a greater number of sensitized β-adrenergic receptors become available for stimulation by endogenous agonists, rebound hypertension is observed.

Signal Transduction Mechanisms: Intracellular Messengers and Effectors

After binding of an agonist to receptors such as GPCRs or enzyme-linked receptors, the signal transduction mechanisms from the membrane first involve the production of second messengers such as cyclic adenosine monophosphate (cAMP), cGMP, arachidonic acid and its metabolites, diacylglycerol (DAG), inositol 1,4,5-triphosphate (IP_3), and Ca^{2+}. These, in turn, activate protein kinases and calcium-binding proteins, all of which result in different biologic effects (Figure 117-12). Thus the synthesis and degradation of intracellular second messengers are described first, followed by a review of the role of protein kinases and calcium-binding proteins in the transduction mechanisms.

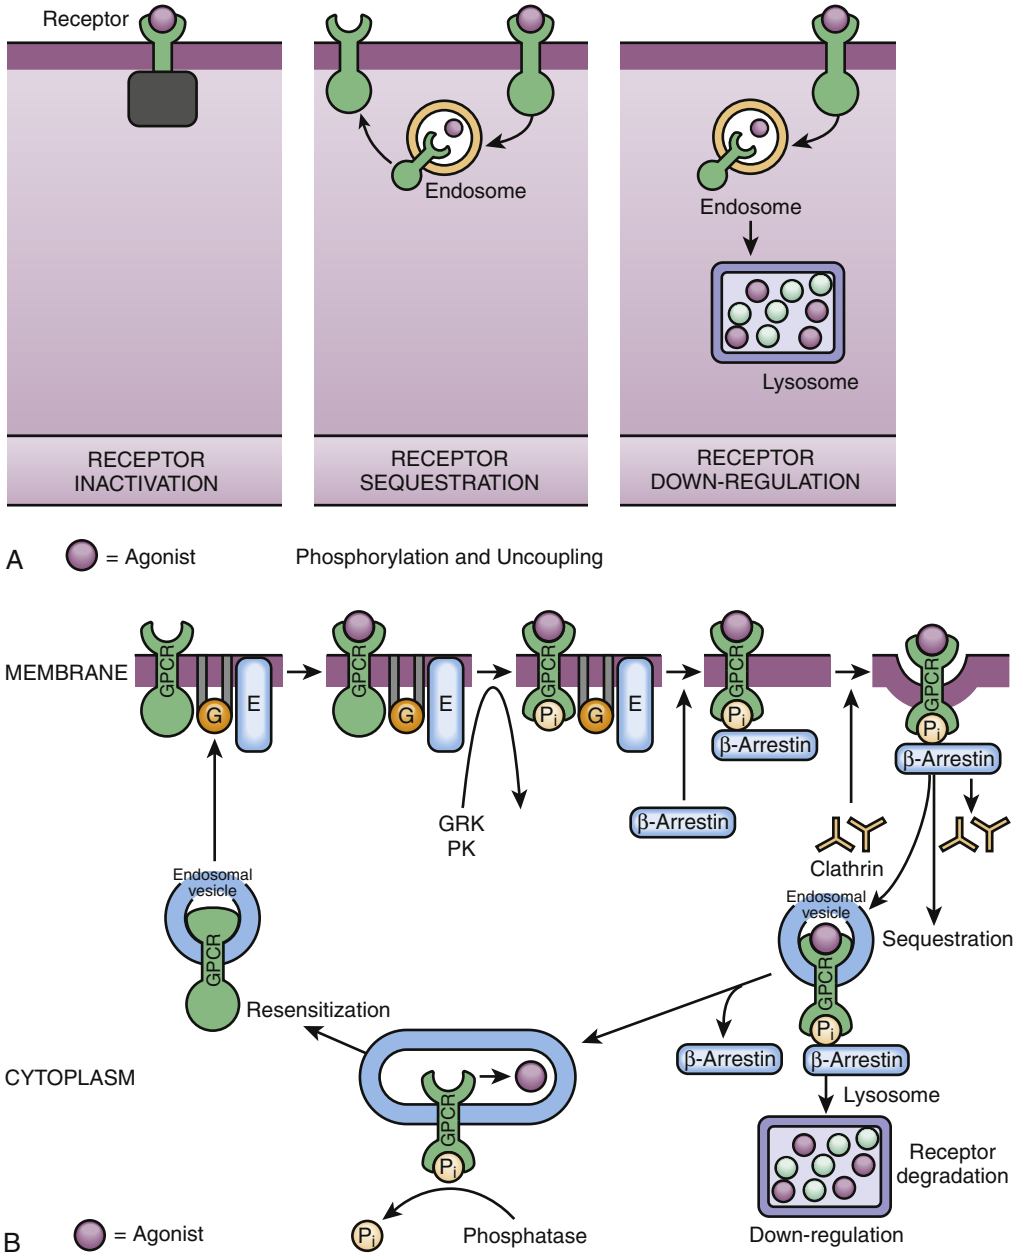

Figure 117–11. Desensitization in response to an agonist. **A,** Ways in which receptors can become desensitized to an agonist. **B,** Homologous desensitization of GPCR. *E*, G proteins effectors; *G*, G protein; *GPCR*, G protein-coupled-receptor; *GRK*, G protein-coupled receptor kinase; *PK*, second-messenger-dependent protein kinases. Second Messengers

Cyclic Adenosine Monophosphate

This pathway is involved in signal transduction initiated by binding of agonists to GPCRs. cAMP is synthesized from adenosine triphosphate (ATP) after the action of adenylate cyclase, which is a transmembrane glycoprotein of the cell membrane. To date, nine forms of adenylate cyclase (types I to IX) have been identified by molecular cloning, and several have described features that are hypothetical.[24] cAMP regulates many aspects of cellular function (cell division and differentiation, ion transport, etc.) by one common mechanism involving activation of protein kinases. These, in turn, regulate the function of many different cellular proteins by catalyzing the phosphorylation of serine and threonine residues. Phosphorylation can then either activate or inhibit target enzymes or ion channels.[25] As previously mentioned, receptors coupled with G_s proteins stimulate adenylate cyclase and produce an increase in cAMP, whereas receptors coupled with G_i proteins inhibit adenylate cyclase and reduce cAMP.

The degradation of cAMP is catalyzed by phosphodiesterases leading to the production of 5′-AMP, an inactive product. Phosphodiesterases are a complex family of enzymes divided into 11 groups according to mechanism of regulation, selectivity for the substrate (cAMP and/or cGMP), preferential localization, and sensitivity to various inhibitors.[26] In critically

Figure 117–12. ill children, milrinone, used for its positive inotropic effect and vasodilating properties, is a phosphodiesterase inhibitor selective for the type III isoenzyme.

Cyclic Guanosine Monophosphate

As discussed above, guanylate cyclase is part of the cytosolic portion of some transmembrane receptors (membrane form) but also exists as a cytosolic enzyme (soluble form) activated by various molecules, including NO. Stimulation of guanylate cyclase results in the accumulation of cGMP. This second messenger then regulates complex signaling cascades through immediate downstream effectors, including cGMP-dependent protein kinases (e.g., protein kinase G [PKG]), cGMP-regulated phosphodiesterases (mainly type II and III), and cyclic nucleotide-gated ion channels (cells of the retina), which eventually leads to a variety of physiologic effects.[27] For example, NO readily passes across the target cell membrane and activates soluble guanylate cyclase in vascular smooth muscle, resulting in increased cGMP production with the regulation of various downstream targets such as protein kinases and ion channels, which culminates in vasodilatation.

As with cAMP, the degradation of cGMP into inactive GMP is catalyzed by phosphodiesterases. In pulmonary and penile vascular smooth muscle cells, phosphodiesterase type V is responsible for the degradation of cGMP; inhibition of this enzyme results in an accumulation of cGMP in the cytosol with smooth muscle relaxation and vasodilatation. As such, phosphodiesterase type V inhibitors (e.g., sildenafil) are widely recognized as efficacious for the treatment of erectile dysfunction in men and have been shown to induce pulmonary vasodilatation both in children and adults and are part of the new strategies available for the treatment of pulmonary hypertension.[28-30]

Arachidonic Acid and Its Metabolites

Arachidonic acid and its metabolites (prostaglandins and leukotrienes) are now considered intracellular messengers.[31] Arachidonic acid is a component of membrane phospholipids released either in a one-step process, after phospholipase A_2 (PLA_2) action, or a two-step process, after phospholipase C and DAG lipase actions. Arachidonic acid is then metabolized by cyclooxygenase (COX) and 5-lipoxygenase, resulting in the synthesis of prostaglandins and leukotrienes, respectively. These intracellular messengers play an important role in the regulation of signal transduction implicated in pain and inflammatory responses. Corticosteroids inhibit PLA_2 activity, whereas nonsteroidal antiinflammatory drugs inhibit COX activity.

Diacylglycerol and Inositol Triphosphate

Phospholipase C is the target enzyme for some GPCRs (phospholipase C-β) as well as enzyme-linked receptors such as tyrosine kinase receptors (phospholipase C-γ). It splits phosphatidylinositol, a membrane-bound phospholipids, into DAG and IP_3, both of which function as second messengers. The most important function of DAG is to activate the membrane-bound PKC, which catalyzes the phosphorylation of a variety of intracellular proteins. IP_3 binds to and opens an IP_3-gated Ca^{2+} release channel on the endoplasmic reticulum membrane, which results in an increase in free intracellular Ca^{2+} concentration ($[Ca^{2+}]_i$).

Calcium ions

$[Ca^{2+}]_i$ is critically important as a regulator of cell function. Indeed, an increase in $[Ca^{2+}]_i$ is the most important intracellular messenger signaling pathway known in biologic

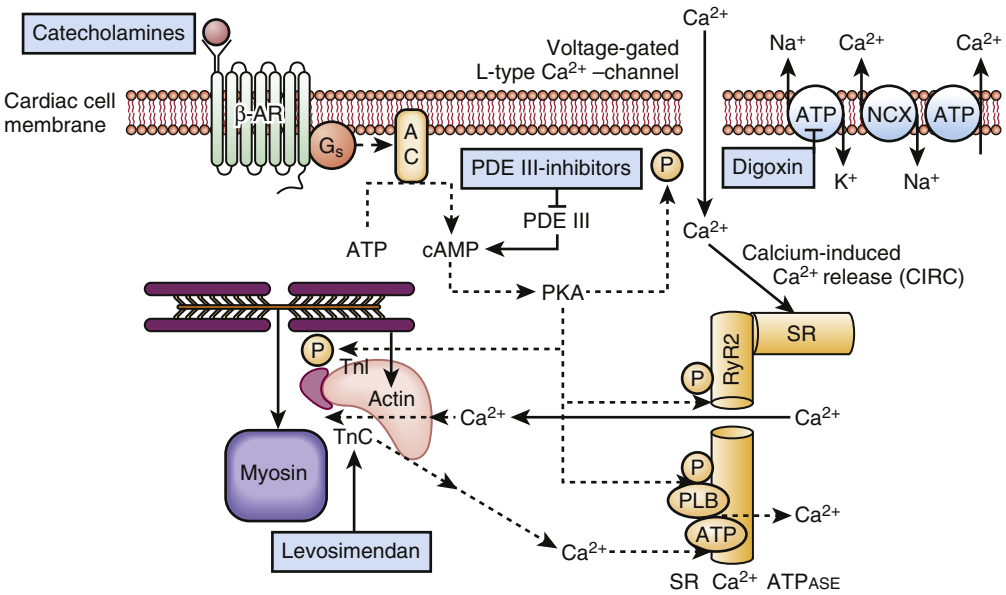

Figure 117–13. Cardiac excitation-contraction coupling and molecular targets of therapeutic agents with positive inotropic and lusitropic effects. (*Note:* Under physiologic conditions, NCX works mainly in the Ca^{2+} extrusion mode; however, if intracellular Na^+ concentration is elevated, as it is the case with digoxin, it can work in the Ca^{2+} influx mode.) *AC*, Adenylate cyclase; *ATP*, adenosine triphosphate; *β-AR*, β-adrenergic receptor, *cAMP*, cyclic adenosine monophosphate; G_s, stimulatory G protein; *NCX*, Na^+/Ca^{2+} exchanger; *P*, phosphorus; *PDE*, phosphodiesterase; *PKA*, protein kinase A; *PLB*; phospholambam; RyR_2, cardiac/isoform 2 ryanodine receptor; *SR*, sarcoplasmic reticulum; *TnI*, troponin I; *TnC*; troponin C. *(Modified from Toller GT, Stranz, C: Levosimendan, a new inotropic and vasodilating agent,* Anesthesiology *104:556–569, 2006.)*

systems. When $[Ca^{2+}]_i$ is at its baseline value, few proteins have an affinity sufficient to bind to Ca^{2+}. Once membrane signaling occurs, an increase in $[Ca^{2+}]_i$ results, derived from either the extracellular space or from the lumen of the endoplasmic reticulum, and allows binding of proteins to Ca^{2+}. Finally, this binding can trigger contraction, secretion, a modification in metabolism regulation, or several other effects depending on the cell type involved. To maintain a low resting $[Ca^{2+}]_i$, Ca^{2+} is permanently expulsed from the cytosol into the extracellular compartment or into the endoplasmic reticulum via a Ca^{2+}-ATPase and Na^+/Ca^{2+} exchanger.

Phosphorylation of Proteins

Many receptor-mediated signals produce variations in the concentration of second messengers, such as cAMP, cGMP, arachidonic acid, DAG, IP_3, and Ca^{2+}, as previously discussed. These can then modify the activity of other proteins, mainly protein kinases and calcium-binding proteins.

Protein Kinases

Protein kinases are enzymes located in the cytoplasm that phosphorylate proteins. The main protein kinases consist of PKA, PKG, and PKC[32] as well as tyrosyl protein kinases (part of tyrosine kinase receptors). They are distinguished from each other by the different intracellular second messengers involved in their regulation and by the selective substrates they use. They all have a binding site for Mg^{2+}-ATP (phosphate donor) and for substrate protein as well as various regulatory sites. Phosphorylation of these proteins is short lived because protein phosphatases rapidly dephosphorylate proteins previously phosphorylated by protein kinases, thus terminating the intracellular signal.

Calcium-Binding Proteins

Calcium exerts its control in cellular function by virtue of its ability to regulate the activity of many different proteins, such as channels, transporters, and transcription factors. In the majority of cases, a calcium-binding protein serves as an intermediate between Ca^{2+} and the regulated functional protein. Calcium-binding proteins represent a large group of cytosolic proteins and include the calmodulin and annexin (or lipocortin) families.

Multiple Drug Targets Within an Organ System: The Myocardium

To understand the molecular mechanisms behind therapeutic agents that increase contractility and accelerate relaxation within the myocardium, cardiac excitation-contraction coupling, where Ca^{2+} is the essential second messenger, should be reviewed (Figure 117-13).[33] During the depolarization phase of the cardiac action potential, Ca^{2+} enters the cell through voltage-gated L-type Ca^{2+} channels. Ca^{2+} entry triggers Ca^{2+} release from the sarcoplasmic reticulum (SR) through a SR membrane ion channel—the cardiac/isoform 2 ryanodine receptor (RyR2). This process is known as *calcium-induced Ca^{2+}release* (CICR). The combination of Ca^{2+} influx and release raises $[Ca^{2+}]_i$, allowing Ca^{2+} binding to troponin C (TnC), which permits cross-bridging between actin and myosin and ultimately contraction. For relaxation to occur $[Ca^{2+}]_i$ must decline, allowing Ca^{2+} to dissociate from TnC. This requires Ca^{2+} transport out of the cytosol by four pathways: SR Ca^{2+}-ATPase (the main one), sarcolemmal Na^+/Ca^{2+} exchanger, sarcolemmal Ca^{2+}-ATPase, and mitochondrial Ca^{2+} uniport. SR Ca^{2+}-ATPase activity is modulated by phospholamban, an endogenous inhibitor. Under physiologic conditions, there is no net gain or loss of cellular Ca^{2+} with each contraction-relaxation cycle.

There are two main ways to pharmacologically increase the strength of cardiac contraction (see Figure 117-13)[33,34]: (1) by increasing the amount of $[Ca^{2+}]_i$ available for binding to TnC or (2) by increasing the sensitivity of myofilaments to Ca^{2+}.

1. *Catecholamines and phosphodiesterase type III inhibitors (PDEIII inhibitors).* β-Adrenergic receptor stimulation by catecholamines activates a GTP-binding protein (G_s), which stimulates adenylate cyclase to produce cAMP, whereas PDEIII inhibitors (e.g., milrinone) prevent cAMP degradation. The resulting increase in cAMP activates PKA, which, in turn, phosphorylates intracellular targets, including voltage-gated L-type Ca^{2+} channels, RyR2, phospholamban, and troponin I (TnI). Phosphorylation of voltage-gated L-type Ca^{2+} channels enhances Ca^{2+} entry into the cytosol with subsequent increase in CICR from the SR and contraction (positive inotropic effect of catecholamines and PDEIII inhibitors). In contrast, phosphorylation of phospholamban activates SR Ca^{2+}-ATPase with increase Ca^{2+} transport from the cytosol back to the SR and thus promotes relaxation (positive lusitropic effect of catecholamines and PDEIII inhibitors). This action also contributes to the overall gain in cardiac excitation-contraction coupling by increasing the SR Ca^{2+} content available for the next contraction. However, such increased loading of the SR with Ca^{2+} may be a key factor in the development of Ca^{2+}-mediated arrhythmias.[35] The lusitropic effect of catecholamines and PDEIII inhibitors is also mediated by phosphorylation of TnI, which decreases the affinity of myofilaments for Ca^{2+}.
2. *Digoxin.* Digoxin enhances myocardial contractility, although modestly, by inhibiting the Na^+/K^+-ATPase pump with a resultant mild increase in intracellular Na^+. This increase of Na^+ subsequently inhibits the extrusion of Ca^{2+} from the cytosol outside the cell by the sarcolemmal Na^+/Ca^{2+} exchanger. Ca^{2+} not extruded from the cytosol is stored in SR and allows increased release of Ca^{2+} during the next contraction.
3. *Ca^{2+}sensitizers.* More recently, Ca^{2+}sensitizers (e.g., levosimendan), a new class of inotropic agents, have been developed. They improve cardiac contractility by binding to TnC and stabilizing its interaction with Ca^{2+}, which results in prolonged interaction of actin-myosin filaments. One possible limitation of some Ca^{2+} sensitizers is worsening diastolic function due to facilitation of cross-bridging at diastolic Ca^{2+} concentrations. However, this does not appear to be the case of levosimendan because its binding to TnC depends on $[Ca^{2+}]_i$ (i.e., when $[Ca^{2+}]_i$ increases during systole, it facilitates actin-myosin interaction, and when $[Ca^{2+}]_i$ decreases during diastole, it does not). One potential beneficial effect of theses agents compared with catecholamines and PDEIII inhibitors comes from the fact that they do not increase $[Ca^{2+}]_i$ and, as such, have neutral effects on myocardial oxygen demand and heart rhythm.[34]

Drug Response and Genetic Polymorphisms

The same medication, at a given dose, can produce different responses in different patients in regard to both efficacy and toxicity. This is termed *interindividual variability.* It is estimated that genetic factors can account for 20% to 95% of variability in drug disposition and effects.[36] Most genetic variations involve single-nucleotide polymorphisms (SNPs); that is, the exchange of a single nucleotide in the DNA sequence. Small insertions and deletions, variable-number tandem repeats, gene deletions, and gene duplications can also take place. Depending on where SNPs occur, they can result in no change in the protein amino acid sequence (silent polymorphism or synonymous SNP) or in a change in the coded amino acid sequence (nonsynonymous SNP) that can have no functional consequence or can result in altered protein function. The latter can have significant clinical and/or therapeutic implications. In addition, given that genes often present many SNPs, it has become increasingly recognized that single SNPs fail to predict drug responses, whereas combinations of SNPs on a given chromosome (specific haplotype) are clinically more significant and can better determine drug effects.[37]

Each person has two alleles for each gene, one from each parent. One form of the allele that is the dominant wild-type allele (functional allele) from one parent may be expressed more than the recessive mutant allele (allele with reduced function or nonfunctional allele) from the other parent. Two identical alleles result in a homozygous dominant or recessive trait of that gene, whereas a combination of two different alleles leads to a heterozygous trait. Thus a particular protein, such as an enzyme or a receptor, encoded by a gene with polymorphism may be expressed in different amounts. Therefore it is easy to comprehend that a drug response can be altered by genetic polymorphisms occurring in genes that encode drug-metabolizing enzymes, drug targets (e.g., receptors, enzymes), drug transporters, and/or proteins involved in signal transduction.[38] An example of how genetic variants in multiple genes might affect drug dose or drug therapy selection is shown in Figure 117-14.

Genetic Polymorphisms and Drug Disposition

Many major enzymes involved in phase I and phase II drug metabolism have known polymorphisms leading to phenotypic differences (i.e., clinically significant alteration in drug-metabolizing enzyme activities).[36] For a specific polymorphic drug metabolizing enzyme, homozygous individuals for the wild-type allele exhibit normal enzymatic activity (extensive metabolizers), heterozygous individuals may have reduced enzymatic activity (heterozygous extensive/intermediate metabolizers), and homozygous individuals with the mutant allele have low enzymatic activity (poor metabolizers). For some enzymes (e.g., CYP2D6), individuals have ultrarapid metabolism as a result of gene duplications of functional alleles (ultrarapid metabolizers). The clinical consequences of such polymorphisms may be fourfold: (1) poor metabolizers can have an enhanced drug effect, either therapeutic or toxic, resulting from higher plasma concentrations of a given drug; (2) poor metabolizers can experience a diminished drug effect resulting from the inability of a prodrug to be converted into the active metabolite due to low enzymatic activity; (3) ultrarapid metabolizers can experience diminished drug effect resulting from markedly lower plasma concentrations of a given drug; and (4) ultrarapid metabolizers can experience enhanced drug effect from an excessive conversion of a prodrug into the active metabolite as a result of supranormal enzymatic activity. Codeine is a good example of the clinical impact of CYP2D6 polymorphism. CYP2D6 catalyses

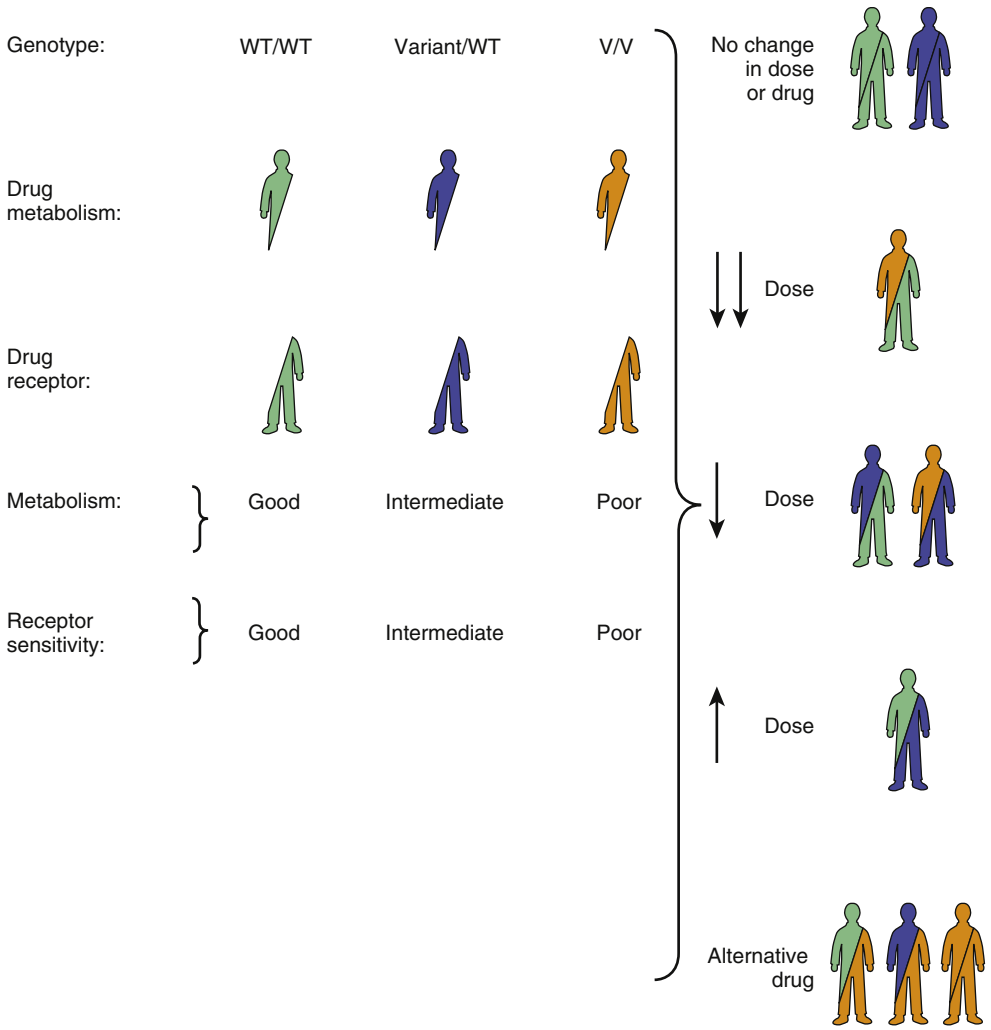

Figure 117–14. Patient genotypes and treatment modifications. The simplest form of polygenic drug response is illustrated, in which the genes encoding the predominant pathway for drug inactivation and the principal receptor for pharmacologic effects exhibit genetic polymorphism that has functional consequences. For the purpose of illustration, both are assumed to be inherited as autosomal codominant traits, with the variant form of each gene (*V*) encoding a protein that is nonfunctional or less sensitive to the prescribed medication. Thus those who inherit wild-type alleles (*WT*) have the highest rate of metabolism (drug inactivation) and therefore require the standard dose to achieve optimal concentrations, assuming they comprise the majority of patients (i.e., were the population studied when establishing the standard dose). This example also assumes that drug receptors encoded by the variant allele are less responsive to treatment and that patients heterozygous for the receptor gene would benefit from exposure to higher drug concentrations and that those who are homozygous for the variant receptor allele will be refractory to any concentration of the medication. *(Modified from Johnson JA, Evans WE: Molecular diagnostics as a predictive tool: genetics of drug efficacy and toxicity,* Trends Mol Med *8:300–305, 2002.)*

the biotransformation of codeine into morphine, the active compound. CYP2D6 poor metabolizers are at increased risk of experiencing inadequate analgesia as a failure to convert codeine into morphine, whereas CYP2D6 ultrarapid metabolizers may be at increased risk for opioid-related adverse effects as a result of increased formation of morphine from codeine.[39,40]

Genetic Polymorphisms and Drug Targets and Signaling Mechanisms

More recently, genetic polymorphisms in signaling mechanisms involving GPCRs and enzymes have been identified.[41-43] These polymorphisms can result in either decreased or enhanced agonist efficacy and can influence drug response. Mutations in G proteins have also been shown to cause certain diseases.[44] The genetic variation occurring in the genes of β_1-adrenergic receptors is a good example of how polymorphisms in drug target and signal transduction genes can alter drug effects. These polymorphisms can potentially affect the pharmacologic response of drugs commonly used in the pediatric intensive care unit, such as catecholamines, and are discussed further below.

As mentioned previously, the β_1-adrenergic receptor is coupled to the stimulatory G_s, which mediates chronotropic and inotropic responses to catecholamines by an increase in cAMP. Two nonsynonymous SNPs (a serine [Ser] to glycine [Gly] substitution at codon 49 and an arginine [Arg] to glycine [Gly] substitution at codon 389) occur in the gene encoding the β_1-adrenergic receptor.[4] In vitro studies suggest that both polymorphisms have functional consequences with the Gly49 form of the receptor, resulting in greater agonist-promoted downregulation than the Ser49 form and the Arg389 form of the receptor, resulting in slightly greater basal and twofold to threefold higher agonist-stimulated adenylate cyclase activity than the Gly389 form. Recent in vivo

studies have demonstrated that these polymorphisms, either as single SNP or haplotype, are important determinants of antihypertensive response to β-adrenergic receptor blockade. Individuals homozygous for Arg at codon 389 experience a significantly larger decrease in blood pressure in response to atenolol and metoprolol compared with those who carry the variant allele.[45,46] The underlying hypothesis is that hypertensive patients who are homozygous for Arg389 have hypertension predominantly mediated through the adrenergic nervous system and thus have a greater antihypertensive response to β-adrenergic receptor blockers.

Of specific interest for the care of critically ill patients, an in vitro study using isolated human myocardial tissue expressing receptor variants of the Arg389Gly polymorphism showed significantly increased inotropic potency to norepinephrine in tissue from individuals homozygous for Arg at codon 389 compared with individuals homozygous for Gly at codon 389. Tissue cAMP levels were also greater in the former group, whereas cAMP-dependent protein kinase activity was the same in both variants.[47]

Drug Response and Development

From birth through puberty, dramatic developmental changes occur that can have a profound impact on drug disposition and action. Most studies have evaluated the effect of age on pharmacokinetics, revealing clinically important differences compared with adults.[48,49] The ontogenesis of important drug-metabolizing enzymes, the cytochrome P450 enzymes, is a good example of how development affects drug disposition and how age is an important determinant in selecting appropriate doses (see Chapter 110 and Table 117-3). Even though developmental changes are also expected to affect the different players involved in pharmacodynamics, scarce data concerning the ontogenesis of specific drug targets, signal transduction mechanisms, and intracellular messengers are currently available. To date, human studies have mainly dealt with receptor expression (and not function), mostly in the brain and have found age-related differences in terms of receptor density and regions of the brain where receptors are expressed.[50-52] The exact consequences of all these differences are unknown, but it is speculated that they may play a role in organ maturation as well as in the pathophysiology of diseases and drug response.

Drug Response and Disease

Although a vast literature exists regarding the effects of diseases on drug pharmacokinetics, limited data are available about pharmacodynamic changes occurring as a consequence of illness. Of particular interest for the critically ill population is the myocardial hyporesponsiveness to catecholamines observed during sepsis. Sepsis, which is associated with elevated circulating catecholamine levels, induces a disruption at various levels of the β-adrenergic signaling cascade (Figure 117-15).[3] Postulated mechanisms, mainly derived from animal studies, include inactivation of catecholamines by superoxide, decreased β-adrenergic receptor density, decreased stimulatory G-proteins (G_s), and increased inhibitory G-proteins (G_i) (β_2-adrenergic receptor

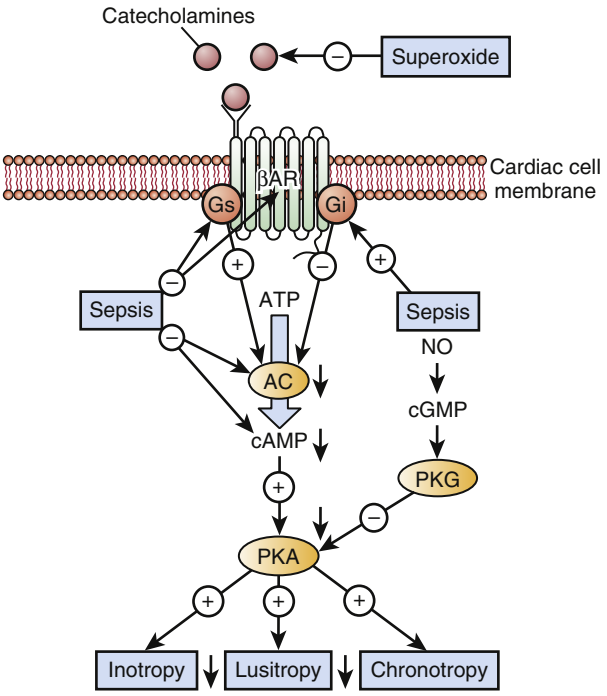

Figure 117–15. Sepsis-induced alterations in the the β-adrenergic signaling cascade. *AC*, Adenylate cyclase; *ATP*, adenosine triphosphate; *βAR*, β-adrenergic receptor, *cAMP*, cyclic adenosine monophosphate; *cGMP*, cyclic guanosine monophosphate; G_i, inhibitory G protein; G_s, stimulatory G protein; *NO*, nitric oxide; *PKA*, protein kinase A; *PKG*, protein kinase G. *(Modified from Rudiger A, Singer M: Mechanisms of sepsis-induced cardiac dysfunction,* Crit Care Med *35:1599–1608, 2007.)*

in rat ventricular cardiomyocytes can couple to G_i; whether human cardiac β-adrenergic receptors can do the same is unknown[53]). These changes result in decreased activity of adenylate cyclase and reduced levels of cAMP. In addition, NO released during sepsis activates soluble guanylate cyclase with increased cGMP and activation of PKG, which in turn inhibits PKA. These alterations ultimately lead to decreased contractility, impaired myocyte relaxation, and reduced chronotropy.

Conclusion

Even though knowledge of how drugs work at a molecular level has grown tremendously over the past decade, continued elucidation of normal signal transduction physiology and of the effects of genetics, development, and disease states on the functional integrity of receptors, signaling pathways, and effectors should improve and refine pharmacologic interventions administered to critically ill children. To optimize the efficacy/toxicity ratio, both genetic and nongenetic factors, including the patient's age, sex, organ function, ethnicity, concomitant therapy, drug interactions, nature and severity of the disease, comorbid conditions, and the use of extracorporeal device (e.g., extracorporeal membrane oxygenation) should be taken into account to individualized pharmacotherapy in the PICU setting.

Adverse Drug Reactions and Drug-Drug Interactions

Wade W. Benton, Adam W. Brothers, Christa C. Jefferis Kirk, Gretchen A. Linggi Irby, and Christopher M. Rubino

PEARLS

- Although adverse drug events in ambulatory pediatric patients may be relatively uncommon, epidemiologic studies in inpatient settings confirm that the problem is just as important for children as it is for adults. Overall, the incidence of adverse events in pediatric inpatients can range from 5% to 21% of hospital admissions, which is higher than the estimated incidence of approximately 4% in adults.
- The pediatric intensive care provider is confronted daily with potentially hazardous drug-drug interactions in the critical care setting. The ability to recognize every potential drug-drug interaction in the pediatric critical care setting is nearly impossible; however, in most cases, drug-drug interactions are predictable and preventable, with appropriate dosage modifications or avoidance of combinations.
- Prescription medications are the most common cause of iatrogenic seizures. Drug-related factors that may contribute to seizures are the intrinsic epileptogenicity of the agent, factors that influence serum levels (dose, schedule, route), and factors that affect central nervous system drug levels (lipid solubility, molecular weight, ionization of the drug, protein binding, transport by endogenous systems).
- Parenteral administration of drug therapy poses a potential source of drug-drug interactions in the pediatric/neonatal intensive care unit. In this scenario, polypharmacy arising from an extensive problem list and limited intravenous access conspire to force the mixing of various drug solutions. However, disparate physicochemical properties and varying administration times preclude the indiscriminate admixing of numerous drugs.

Adverse drug reactions in the pediatric critical care setting are a potential contributor to the morbidity and mortality of patients.[1-5] Although adverse drug reactions in ambulatory pediatric patients may be relatively uncommon, epidemiologic studies in inpatient settings confirm that the problem is just as important for children as it is for adults.[3-7,9] There is substantial evidence that suggests the incidence of adverse drug reactions may be more common than in adults. Many of the therapeutic agents used in the pediatric critical care setting have not been studied and evaluated for safety and efficacy. Intensive care physicians should have a heightened awareness of the incidence of adverse drug reactions so they can assist with recognizing and ultimately preventing adverse drug reactions. Patients in the intensive care unit are predisposed to adverse drug reactions due to the incidence of single and multiple organ failure. Impairment in metabolism (hepatic function) and clearance (renal function) of therapeutic agents increases the incidence of adverse drug reactions. In order to alleviate adverse drug reactions, pediatric intensivists need to be aware of the complications associated with drug therapy in the pediatric critical care patient.

Steps are now being taken to help prevent adverse reactions caused by the lack of knowledge of how a given drug affects children, but remaining issues still cause children to be more susceptible to adverse drug reactions. It is common practice to use weight-based dosing, which adds another layer of complexity to drug therapy in children. For example, many parenteral therapies require dilution of stock solutions, providing an opportunity for errors. Finally, sick infants and children may have reduced ability to survive iatrogenic events if and when they occur. Publications have brought to light the importance of adverse drug events in adults and their impact on the health care system in general.[9] Although adverse drug events in ambulatory pediatric patients may be relatively uncommon, epidemiologic studies in inpatient settings confirm that the problem is just as important for children as it is for adults.[3-7,9] Overall, the incidence of adverse events in pediatric inpatients can range from 5% to 21% of hospital admissions,[2-5] which is higher than the estimated incidence of approximately 4% in adults.[10,11]

Defining Adverse Drug Reactions

One of the difficulties in reviewing the literature on adverse drug reactions is how they are defined. There are many different examples of what constitutes an adverse drug reaction. Many professional organizations have tried to standardize exactly how an adverse drug reaction is defined. The World Health Organization (WHO) defines an adverse drug reaction as any response to a drug that is noxious and unintended and that occurs at doses normally used in humans for prophylaxis, diagnosis, or therapy of disease or for modification of physiologic function.[12] The Joint Commission on Accreditation of

Healthcare Organizations (JCAHO) defines an adverse drug reaction as an undesirable response associated with use of a drug that compromises therapeutic efficacy, enhances toxicity, or both.[13]

For reporting purposes, the Food and Drug Administration (FDA) categorizes a serious adverse event (events relating to drugs and devices) as one in which "the patient outcome is death, life-threatening (real risk of death), hospitalization (initial or prolonged), disability (significant, persistent, or permanent), congenital anomaly, or required intervention to prevent permanent impairment or damage."[14] The American Society for Health-System Pharmacists (ASHP) defines a significant adverse drug reaction as any unexpected, unintended, undesired, or excessive response to a drug that[15]:

- Requires discontinuing the drug (therapeutic or diagnostic)
- Requires changing drug therapy
- Requires modifying the dose (except for minor dosage adjustments)
- Necessitates admission to a hospital
- Prolongs stay in a health care facility
- Necessitates supportive treatment
- Significantly complicates diagnosis
- Negatively affects prognosis
- Results in temporary or permanent harm, disability, or death

The ASHP also defines what is not an adverse drug reaction as follows:

- Side effects
- Drug withdrawal
- Drug abuse syndrome
- Accidental poisoning
- Drug overdose complications

The mechanisms by which adverse drug reactions occur can be divided into type A and type B. Type A mechanisms usually are thought of as preventable, predictable, and related to the pharmacologic action of the medication. Knowledge of the effects caused by the medication can predict the likelihood of an adverse drug reaction occurring. Appropriate monitoring of the medication can assist in preventing adverse drug reactions.[16-18] Type B mechanisms usually are considered to be unavoidable and not predictable. These reactions normally are uncommon and not related to the pharmacologic action of the medication. Idiosyncratic and hypersensitivity reactions are common type B reactions.[16-18]

A critical factor in assessing adverse drug reactions is establishing a causal relationship between the suspected drug and the adverse reaction.[19] Identification of adverse drug reactions can be arbitrary. Some of the confounding factors are the ambiguous characteristics of the reactions, the fact that patients usually are taking more than one medication at the time of the reaction, and the inability to perform definitive cause and effect tests.[19] There have been numerous attempts to try to formalize the process.[18-21] Karch and Lasagna[19] designed decision tables that can identify a potential reaction, assess the certainty of a link between the drug and the event, and evaluate the underlying cause of the reaction. These provide a framework for systematic evaluation of potential adverse drug reactions and reduce the ambiguity that, at present, characterizes the assessment of adverse drug reactions. Kramer et al.[21] devised an operational assessment using an algorithm with six axes to assess the probability of an adverse drug reaction occurrence. A scoring system for each axis and an overall score help delineate the likelihood that an adverse drug reaction has occurred. Similarly, Naranjo et al.[18] developed an adverse drug reaction probability scale using 10 questions answered positively (yes), negatively (no), or unknown to determine the likelihood that an adverse drug reaction had occurred. The Naranjo method has been shown to improve the reproducibility of adverse drug reactions assessments.

An FDA algorithm that assesses the characteristics of the event (temporal relationship, dechallenge, rechallenge, and relationship to disease) has been presented.[20] The algorithm contains four questions to assess the likelihood that an adverse drug reaction had occurred:

1. Did the reaction follow a reasonable temporal sequence?
2. Did the patient improve after stopping the drug?
3. Did the reaction reappear on repeated experience (rechallenge)?
4. Could the reaction be reasonably explained by known characteristics of the patient's clinical state?

The categories *remote, possible, probable,* and *highly probable* are used based on the answers to the four questions.

Comparisons of the different methods have been conducted. Michel and Knodel[22] compared the Kramer, Naranjo, and FDA methods. The Kramer method was considered to be the standard of practice at the time, and Naranjo and FDA methods both compared favorably. The Naranjo method was shown to be simpler and less time consuming. The lack of a numerical score in the FDA algorithm caused the authors to decide there was a need for more data to recommend its use over Naranjo method, even though the FDA algorithm was less time-consuming than either method.[22] Busto et al.[23] compared the Kramer and Naranjo methods. The two methods were determined to be equal in terms of reproducibility, but the Kramer method was more complex.

Once an adverse drug reaction is identified, appropriate reporting is critical. Reporting can occur by several mechanisms. The event can be reported through the health care systems adverse drug reaction program as mandated by the JCAHO. This program usually is coordinated by the pharmacy department. Another avenue is to contact the drug manufacturer, as all companies have a mechanism for documenting adverse drug reactions. Finally, severe and significant reactions can be reported to the FDA through the MedWatch program.

Adverse Drug Reactions by Organ System

Renal

Nephrotoxicity accounts for nearly 7% of all adverse drug reactions.[11] Several factors place the renal system at risk for adverse drug reactions. The renal system is responsible for elimination of many drugs and metabolites, of which several are known nephrotoxins. Additionally, the renal vascular system receives approximately 20% to 25% of resting cardiac output. Therefore the kidneys are exposed to high concentrations of drugs and diagnostic agents. Although the renal system is highly vulnerable to nephrotoxicity, there are only a few mechanisms by which nephrotoxins can induce injury. These mechanisms include hemodynamically mediated nephrotoxicity, tubular necrosis, interstitial nephritis, obstructive nephropathy, and vascular toxicity. Many nephrotoxins can injure the kidney through more than one mechanism.

A variety of drugs are associated with acute tubular necrosis, including aminoglycosides, cisplatin, amphotericin B,

radiocontrast media, cyclosporine, and intravenous (IV) immunoglobulins.[24-26] Acute tubular necrosis is one of the most common renal disorders associated with drug therapy. Minimizing risk factors for nephrotoxicity with these agents is imperative (i.e., administration of a saline load and repletion of volume have proved beneficial in reducing toxicity).[27] Table 118-1 provides a more complete list of medications associated with tubular necrosis.

Several drugs are implicated in alteration of renal blood flow. Some of the most common include angiotensin-converting enzyme inhibitors (ACEIs) (e.g., enalaprilat), nonsteroidal antiinflammatory drugs (NSAIDs) (e.g., ketorolac), β-adrenergic antagonists (e.g., propranolol), and calcineurin inhibitors (e.g., cyclosporine).[7,28-35] ACEIs can induce renal insufficiency in patients suffering from any process that decreases renal blood flow, including bilateral renal artery stenosis or unilateral stenosis with a single kidney.[36] The mechanism involves inhibiting the conversion of angiotensin I to angiotensin II, which results in dilation of the efferent arterioles, with resultant decreased glomerular capillary hydrostatic pressure and reduced glomerular filtration. The incidence of ACEI-induced renal failure in patients with renovascular hypertension ranges from 20% to 38%.[34] NSAIDs inhibit prostaglandin synthesis, which leads to reduced renal blood flow and reduced glomerular filtration. The incidence of renal insufficiency is most common in patients with chronic renal disease, hypovolemia, sepsis, and use of concomitant nephrotoxic drugs.[28,30-33,35] NSAID-induced renal toxicity is reversible if the toxic agent is discontinued immediately.[36] Table 118-1 provides a more complete list of drugs associated with hemodynamic renal failure.

Acute interstitial nephritis is another common source of drug-induced nephrotoxicity. It is reported to cause 3% to 8% of all cases of acute renal failure.[37] The clinical presentation of acute interstitial nephritis can appear anywhere between 2 and 44 days after initiation of the offending therapy.[38,39] Typical clinical symptoms include fever, skin rash, and flank tenderness.[38,39] Common laboratory findings include hematuria, sterile pyuria, and eosinophilia.[37] Histologic findings of acute interstitial nephritis include interstitial infiltrate of lymphocytes, plasma cells, eosinophils, and neutrophils.[37-39] Prompt discontinuation of the offending drug from therapy is recommended, and administration of corticosteroids may improve recovery.[40] Table 118-1 lists some medications associated with acute interstitial nephritis.

Renal tubular obstruction is associated with renotubular precipitation of endogenous products, drugs, and their metabolites. Formation of uric acid precipitates after chemotherapy can result in renal obstruction. Hydrating patients prior to chemotherapy, urinary alkalinization, and use of allopurinol or rasburicase can help prevent uric acid precipitation. Rhabdomyolysis can cause intratubular precipitation of myoglobin and lead to acute renal failure. Terbutaline overdose has resulted in rhabdomyolysis-induced renal failure.[41] Drugs associated with formation of crystals include acyclovir, sulfonamides, mannitol, pentobarbital, methotrexate, and dextran.[42-45]

Aminoglycosides are used frequently for treatment of gram-negative infections. All aminoglycosides have been shown to be toxic to the proximal renal tubules.[50] Aminoglycoside nephrotoxicity is related to dose, high trough concentrations, and prolonged therapy.[50] The drug-induced nephrotoxicity normally manifests as nonoliguric renal failure.[47] Several risk factors for developing aminoglycoside nephrotoxicity include the need for intensive care, decreased albumin, poor nutritional status, prolonged therapy, hypovolemia, pneumonia, shock, preexisting liver or kidney disease, and elevated initial steady-state drug concentrations.[47,48] In addition, vancomycin, piperacillin, furosemide, amphotericin B, and cephalosporins when administered concomitantly with aminoglycosides are associated with an increased risk for developing nephrotoxicity.[47] Predicting nephrotoxicity based on the risk factors stated is an extremely complicated, inexact task.[47,49] Typically, aminoglycoside nephrotoxicity is reversible upon discontinuation of the offending agent.[50,51]

Drug-induced nephrotoxicity is a common serious adverse drug reaction that can lead to morbidity and lengthen hospital stays.[52] It is important to recognize potential nephrotoxins before initiating therapy and to evaluate therapeutic options. It is also important to monitor therapy appropriately for signs of toxicity and to modify therapy as needed.

Table 118–1 Drugs Causing Nephrotoxicity

Tubular Necrosis	Interstitial Nephritis	Hemodynamic-Mediated Renal Failure
Aminoglycosides	Allopurinol	Angiotensin-converting enzyme inhibitors
Amphotericin	Aminoglycosides	Cyclosporine
Carboplatinum	Aztreonam	Mannitol
Cephalosporins	Captopril	NSAIDs
Cisplatin	Carbamazepine	Propranolol
Cyclosporine	Cephalosporins	Radiologic contrast agents
Mannitol	Cimetidine	Tacrolimus
Methoxyflurane anesthesia	Ciprofloxacin	
NSAIDs	Cyclosporine	
Pentamidine	Erythromycin	
Radiologic contrast agents	Interferon-α	
	NSAIDs	
	Penicillins	
	Phenobarbital	
	Phenytoin	
	Ranitidine	
	Rifampin	
	Sulfonamides	
	Tacrolimus	
	Thiazide and loop diuretics	
	Valproic acid	
	Vancomycin	
	Warfarin	

NSAID, Nonsteroidal antiinflammatory drug.

Hepatic

The liver is the most critical organ in drug toxicity due to its major role of metabolism and elimination of foreign substances. This renders it a target for drug toxicity. It is well documented that acetaminophen causes intrinsic hepatotoxicity following acetaminophen overdose. However, a variety of medications cause drug-induced hepatotoxicity. It often is difficult to determine the source of unexplained liver injury, so detailed examination of past and current drug therapies is needed to rule out possible drug-related causes. Most hepatotoxicity associated with drugs is idiosyncratic in nature and has a rate usually less than 1 per 10,000 exposed patients. The pathogenesis of drug-induced liver disease is mediated either

through an immune response or direct cell damage.[53,54] In many cases, this hepatotoxicity is idiosyncratic, meaning not predictable or dose-related, in contrast to drugs like acetaminophen and isoniazid/iproniazid, for which toxicity is related to dose.[53,54]

The mechanism of toxicity for drug-induced liver injury generally involves the accumulation of drugs or their metabolites which cause direct cell damage, target mitochondrial function, or trigger an immune response. The initial stress or immune reaction leads to mitochondrial permeability transition, which is either a direct pathway (intrinsic) mediated by cell damage or is triggered by the death receptor amplified pathway. The mitochondrial impairment will determine if the hepatocytes dies by apoptosis or necrosis. Measurements of alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase (ALP), and total bilirubin are important measurements in assessment of drug-induced liver injury. It has been estimated that one tenth of the Hy's law cases (defined as bilirubin elevated to twice the upper limit of normal [ULN] and transaminase three times ULN) with hyperbilirubinemia or jaundice die or require transplant.[55,56] In severe cases of drug-induced hepatic injury, jaundice and hepatic failure may ensue.[54] Typically drug-induced hepatic disease occurs expectedly as a result of high-dose therapy of a known hepatotoxin or unexpectedly as a result of an idiosyncratic reaction to a drug not associated with hepatotoxicity. Overall, children are less prone to drug-induced liver disease than are adults.[58] However, specific hepatotoxins have been shown to afflict children more than adults. Reye syndrome is a hepatocellular disease that has been associated with aspirin use in children.[59] Valproate hepatotoxicity occurs more frequently in children younger than 2 years who have preexisting neurologic or physical defects.[60]

Drug-induced hepatic disease can occur by a variety of mechanisms, including hepatocellular, cholestatic, and vascular. These injuries are associated with intrinsic or idiosyncratic hepatotoxins. Intrinsic hepatotoxins typically show a dose-related toxic effect. Idiosyncratic hepatic disease is an unpredictable reaction that can occur by immune-mediated hypersensitivity, metabolically or both. Hypersensitivity reactions in the liver can cause cell injury to hepatocytes. The reactions do not correlate with dosage and are difficult to anticipate. This immune-mediated reaction results from antigenic complexes that stimulate T lymphocytes, which can result in hepatic injury. These reactions can be accompanied by fever, skin rash, lymphadenopathy, and eosinophilia.[54] The reactions typically resolve upon discontinuation of therapy and resurface when therapy is rechallenged.[54] Metabolic idiosyncrasy occurs when a compound that is metabolized to nontoxic metabolites and eliminated in the majority of patients is metabolized to a toxic metabolite in a small number of patients because of genetic differences in metabolism (such as with isoniazid).[60] Box 118-1 lists a number of agents that are associated with drug-induced hepatotoxicity.

Box 118–1 Drugs that Cause Hepatotoxicity

Acetaminophen
Amoxicillin-clavulanic acid
Carbamazepine
Erythromycin
Isoniazid
Ketoconazole
Labetalol
Nitrofurantoin
NSAIDs
Phenobarbital
Phenytoin
Rifampin
Sulfonamides
Terbutaline
Tetracyclines
Trazodone
Valproate
Voriconazole

Cardiovascular

Adverse cardiovascular reactions have been noted to be one of the most common types of adverse drug event in pediatric patients.[61] Several medications are associated with adverse cardiovascular effects and the mechanisms are often thought to be related to the agents' pharmacologic action. These effects are potentiated by four general physiological pathways: electrolyte and fluid imbalances; receptor-mediated sympathomimetic effects; alterations of the electrophysiology of the cardiac tissue; and drug-induced cardiotoxicity.

Medications can affect electrolyte and volume status by direct action on electrolyte receptors or indirectly by affecting prostaglandin release or the renin-angiotensin-aldosterone system. Dramatic changes in fluid and electrolyte status caused by these medications can lead to severe changes in blood pressure, heart rate, or cardiac rhythms. Nonsteroidal antiinflammatory drugs, corticosteroids, diuretics, nesiritide, fenoldopam, and certain immunosuppressant agents, such as cyclosporine and tacrolimus, are all medications that can alter fluid and electrolyte balance.[62-67]

Pediatric patients in the intensive care unit often require vasopressive medications; however, it is important to be aware that many cardiovascular toxicities have been observed with use of vasopressors and most of these toxicities stem from their receptor-mediated effects (Table 118-2). The α-adrenergic agonism of the sympathomimetics produces palpitations, ectopic heartbeats, sinus tachycardia, and ventricular arrhythmias.[68] The direct effect on myocardial tissues may be manifested as electrocardiographic (ECG) changes, such as a reduction in T-wave amplitude, which have been reported during epinephrine infusions in normal individuals. Increased myocardial oxygen demand may precipitate an infarction, especially in individuals with underlying cardiac disease. A dramatic rise in heart rate and peripheral vascular resistance may produce severe hypertension, which could lead to cerebral hemorrhage or hemiplegia. Excessive α-adrenergic stimulation may produce vasoconstriction so severe in the extremities, kidneys, or liver that tissues become ischemic or necrotic. Gangrene of the extremities is reported with high doses of dopamine in patients with underlying occlusive vascular disease. Vasopressin can cause severe vasoconstriction and has been associated with digital loss and splanchic ischemia.[69] Extravasation of most sympathomimetic agents may lead to tissue necrosis.[70] The sedative dexmedetomidine, though not classified as a vasopressor, has α_2-adrenergic agonistic properties and has effects similar to the medication clonidine. When

Table 118–2 Adverse Effects of Vasopressor Medications by Adrenergic Receptor Affinity

Medication	Affected Adrenergic Receptor	Associated Adverse Effect
Dopamine	<10 μg/kg/min: β_1 >10 μg/kg/min: β_1 and α	Vasoconstriction, tachycardia, arrhythmias Extravasation causes ischemia
Dobutamine	β_1: selective	Increased heart rate, arrhythmias, ↑ myocardial oxygen demand
Epinephrine	<10 μg/kg/min: β_1 >10 μg/kg/min: α	Vasoconstriction, tachycardia, arrhythmias, tissue ischemia, cerebral hemorrhage, ↑ myocardial oxygen demand Extravasation causes necrosis
Isoproterenol	β: nonselective ($\beta_1 > \beta_2$)	Tachycardia, arrhythmias, hypotension, ↑ myocardial oxygen demand
Norepinephrine	α and β_1 (α > β_1)	Potent vasoconstriction, arrhythmias, tissue ischemia Extravasation causes necrosis
Phenylephrine	α	Systemic vasoconstriction, hypertension, bradycardia
Vasopressin	V1 vascular receptor	Potent vasoconstriction, tissue ischemia

From Goembiewski JA: Vasopressors used in the crtical care setting, *J Peri Anesth Nurs* 18:414-416, 2003; and Vetter VL, editor: *Pediatric cardiology: the requisites in pediatrics,* Philadelphia, 2006, Mosby Elsevier.

using dexmedetomidine, it is important to monitor patients for hypotension, arrhythmias, and bradycardia.[66a]

As noted above, ECG changes can be the side effect of many medications through various mechanisms of action and may lead to dangerous arrhythmias Ventricular arrhythmias in infants and children, unlike adults, are relatively uncommon. The most commonly reported arrhythmias in pediatric patients include conduction disturbances or supraventricular tachyarrhythmias (e.g., atrial tachycardia and junctional tachycardia). A common class of agents whose cardiovascular toxicities stem from its effect on cardiac rhythms are the cardiac glycosides. Digoxin can produce a large array of dysrhythmias; the most common in adults includes unifocal or multifocal ventricular premature complexes and nonparoxysmal atrioventricular junctional tachycardia.[71] Sinus bradycardia and a sick sinus syndrome-like effect have been reported as digoxin-induced adverse effects.[72] The narrow therapeutic index of this drug class is of special concern in the pediatric population. Another class of medications that requires close ECG monitoring is the antiarrhythmic medications. These medications have mechanisms of action that manipulate cardiac action potential and therefore have the ability to produce dysrhythmias.[73,75] The most common types of dysrhythmias associated with the antiarrhythmic medications in all classes are bradyarrhythmias, torsades des pointes, and reentry rhythms.[75] An increased incidence of such problems in patients treated for attention deficit and hyperactivity disorder also warrants heightened surveillance for adverse cardiac effects in this population. The central nervous stimulants used to treat this condition can lead to tachyarrhythmias and have been associated with sudden cardiac death.[76]

Although ventricular arrhythmias are uncommon in pediatric patients, the risk of torsades de pointes is still of concern in this population. Torsades de pointes is a life-threatening subset of arrhythmias and is characterized on electrocardiogram by lengthening of the QT interval and waxing/waning QRS amplitude. Certain medications can increase the risk for this arrhythmia by blocking potassium conductance on the rapid (Ikr) and slow (Iks) receptors within potassium ion channels. This creates a delayed ventricular repolarization and can lead to multiple ventricular reentrant loops. Risk factors for drug-induced torsades de pointes include high doses of associated medications (Box 118-2); underlying structural

heart disease; prolonged QT interval at baseline; prolonged QT noted immediately after giving associated medication; and concurrent hypokalemia or hypomagnesemia.[78] A notable exception to these risk factors would be the medication quinidine. Torsades de pointes is typically noted at lower medication concentrations and can be observed later in therapy. Most commonly, the antiarrhythmics, tricyclic antidepressants, and fluoroquinolones are general classes of agents that demonstrate the potential to prolong the QT interval.[79,80] Another concern when administering these medications is pharmacokinetic drug-drug interactions or pathophysiologic alterations in elimination. Any biochemical mechanism that increases the concentration by inhibition of cytochrome isoenzymes or decreased clearance of the associated medication has the ability to potentiate this type of arrhythmia.[81] Recently, several medications have been removed from the market due to fatal arrhythmias secondary to torsades de pointes. The FDA now requires all medications to be screened for their affinities to Ikr/Iks receptors to determine the potential for torsades de pointes. Current practice guidelines recommend avoiding high-risk medications if the patient has a baseline QTc greater than 450 msec and to discontinue or reduce the dose of the medication if the QTc increases to 560 msec or greater after initial medication administration.[78]

Anthracycline antineoplastic agents illustrate a specific pattern of direct toxicity to myocardial tissue. Drugs in this class include doxorubicin, epirubicin, and idarubicin. Acute cardiotoxicity may be manifested as arrhythmias, whereas long-term adverse effects are generally related to the magnitude of cumulative drug exposure, with cardiomyopathy being most common. There may also be the delayed development of cardiotoxicity, as children who have endured anthracycline therapy may exhibit signs of abnormal cardiac function anywhere between 4 and 20 years after exposure.[82] These defects include abnormal right ventricular wall motion, impaired myocardial growth and contractility, conduction abnormalities such as QT prolongation, and congestive heart failure.[82] Severe anthracycline toxicity cannot be reversed, and such a diagnosis leads to a poor prognosis and high mortality. Heart transplantation may be the only option in such cases.[82] Due to the severity of anthracycline cardiac toxicity and the clear association with total cumulative dose received, anthracycline lifetime dosage should be documented for each patient so that cumulative dose thresholds are not exceeded.

Central Nervous System

Prescription medications are the most common cause of iatrogenic seizures.[83] Drug-related factors that may contribute to seizures include the intrinsic epileptogenicity of the agent, factors that influence serum levels (dose, schedule, route), and factors that affect central nervous system (CNS) drug levels (lipid solubility, molecular weight, ionization of the drug, protein binding, transport by endogenous systems).[84] Patient-related factors may influence the risk for drug-induced seizures, such as preexisting epilepsy, neurologic abnormality, decreased drug elimination capacity (renal, hepatic), and conditions that disrupt the blood-brain barrier.[84] There are several medications used within the intensive care unit setting that have been implicated to cause seizures. Due to the complexity of care for many intensive care patients, increasing practitioner awareness of the medications that can induce seizures, as well as their mechanisms, should allow practitioners to recognize and diagnosis patients more effectively (Table 118-3).

Phenothiazine tricyclic antidepressants (chlorpromazine, thioridazine) may cause seizures.[83] Meperidine may induce seizures because of accumulation of the normeperidine metabolite, especially in patients with renal insufficiency.[83] Rapid administration of fentanyl can cause seizures.[83] Several antiinfective and immunosuppressive medications, such as the β-lactam antibiotic, imipenem; high-dose metronidazole; isoniazid; cyclosporine; and chlorambucil induce seizures.[83] Any of the antiepileptic drugs themselves can be implicated in worsening seizure activity. This usually occurs when higher than normal concentrations are used. Seizures also may be precipitated by medication withdrawal.[84] Withdrawal of antiepileptic drugs may cause seizures because of either subtherapeutic levels or too rapid removal of the agent.

Drug-induced headache can be caused by many medications. Headaches can be acute or chronic. They may be caused by use and abuse of the agent.[85] Headache may occur during substance withdrawal. Many medications cause acute headaches, including NSAIDs (e.g., indomethacin), vasodilators (e.g., β-blockers, calcium channel blockers, angiotensin-converting enzyme inhibitors), immunomodulators (e.g., cyclosporine, tacrolimus, antithymocyte globulin), cytotoxic agents (intrathecal methotrexate, interferon-α_1, interleukin-2), and antimicrobials (e.g., amphotericin-B, tetracycline, sulfonamides).[85,86] Chronic headaches may be caused by overuse and abuse of simple analgesics, narcotics, and combination analgesics with barbiturates/sedatives and ergotamine.[86]

Numerous drugs may cause sedation. Drug-induced sedation usually is an extension of the pharmacologic action of the medication. This effect frequently is transient and diminishes with continuation of therapy. Sedation can result from excessive dosage of the medication and can be managed by decreasing the dose of medication. Excessive sedation may occur with combination therapy.

Ototoxicity usually is iatrogenic.[77] The main sites of action of ototoxic drugs are the cochlea, vestibulum, and stria vascularis.[87] Several medications cause ototoxicity, with salicylates and aminoglycosides the most commonly implicated.[87,88] Other agents involved are cisplatin, loop diuretics, erythromycin, and vancomyin.[87,88] The effect is usually dose-dependent.[77,87,88] High-dose and long-term therapy are common risk factors for aminoglycoside-induced ototoxicity.[87,88] For aminoglycosides, streptomycin is mostly vestibulotoxic and neomycin is more cochleotoxic.[88] Cisplatin is the most ototoxic of the antineoplastic agents.[88] Ethacrynic acid has the greatest potential for causing ototoxicity for the loop diuretics.[88] Appropriate dosing and monitoring of agents associated with ototoxicity are important for prevention and early detection.

Hematologic

The most common and serious adverse drug reaction resulting from chemotherapy with cytotoxic agents is bone marrow suppression. The decline in hematopoiesis results from injury to rapidly dividing stem cells and can lead to secondary morbidities. For example, neutropenia predisposes a patient to opportunistic infections and sepsis. Chemotherapy-induced thrombocytopenia may render a patient vulnerable to hemorrhage in the CNS or gastrointestinal (GI) tract.

Table 118–3 Medications That Can Induce Seizures

Medication	Potential Mechanism of Action	Comments
Acyclovir[306]	Neurotoxicity	Renal impairment and parenteral administration increases the incidence
Antipsychotics[307]	Decreases seizure threshold	Increased incidence with high doses and rapid dose adjustments
Carbapenems[308]	Potentiates seizure activity through the inhibition of GABA receptor	Caution in patients with CNS disorders and renal dysfunction Imipenem has higher incidence compared with meropenem, ertapenem, doripenem
Cephalosporins[309]	Inhibition of GABA receptor	Ceftazidime > ceftriaxone > cefuroxime and cefotaxime
Cyclosporine[310]	Unknown but may involve the release of the potent vasoconstrictor endothelin from endothelial cells which induce microvascular damage and/or changes in permeability of the blood-brain barrier	More common with high doses Increased incidence with hypocholesterolemia and hypomagnesemia
Cytarabine[311]	Cerebral dysfunction	Increased incidence with intrathecal administration
Fluoroquinolones[312]	Unknown but may involve inhibition of GABA receptor	History of seizures and use of NSAIDs associated with increased risk of seizures
Flumazenil[313]	May precipitate benzodiazepine withdrawal; inhibition with seizure medications	Use in caution with patients with underlying seizure disorder
Meperidine[83,307]	CNS excitation from toxic metabolite (normeperidine); blockade of serotonin	Common reaction with renal impairment and high doses
Metronidazole[309]	Penetrates the blood-brain barrier	Cumulative high dose and prolonged use
Penicillins[314]	Irritation of nervous system	Use in caution with infants, rapid IV infusions, and renal impairment
Tacrolimus[315-317]	Neurotoxicity	May be secondary to local vasoconstriction mediated by endothelin; elevated levels and hepatic impairment may increase the risk of neurotoxicity
Theophylline[83]	CNS toxicity	Serum concentrations >25 μg/mL have been noted to induce seizures

Severe anemia may lead to dizziness, fatigue, hypotension, and myocardial infarction.[89] In addition to bone marrow suppression, some antineoplastics may produce thrombotic and hemorrhagic coagulation toxicities. For example, L-asparaginase has been reported to induce changes in the von Willebrand factor multimer in children and thereby promote platelet aggregation.[82]

Respiratory

Respiratory adverse effects are relatively uncommon but are among the most serious adverse events. Due to the seriousness of some of the drug-induced respiratory adverse events, which could be life-threatening, intensive medical interventions are often required. Numerous agents have been known to cause lung disease. In 1975, only 19 agents were implicated with pulmonary complications.[90,91] There are now over 350 agents that have been identified as having the potential to induce respiratory complications.[90,91] The number of agents known to cause pulmonary adverse reactions continues to expand each year. Recognition of drug-induced pulmonary disease may be challenging due to the presence of confounding variables often associated with these patients that may result in the underdiagnosis of both acute and chronic lung disease.[92] Some of the confounding factors in the diagnosis of drug-induced pulmonary disease include preexisting pulmonary conditions such as bronchopulmonary dysplasia and asthma,[93] the use of oxygen,[94] and concurrent medications.

Virtually any drug can cause pulmonary infiltrates as part of a general hypersensitivity reaction. Azathioprine, 6-mercaptopurine, procarbazine, penicillamine, phenytoin, carbamazepine, and sulfasalazine are medications commonly involved in hypersensitivity pulmonary reactions.

Bronchoconstriction is one of the most common drug-induced pulmonary reactions. The two main risk factors for the development of drug-induced bronchospasm include a previous history of reactive airway disease and chronic obstructive lung disease.[93,95] There are several classes of medications that are associated with this clinically significant reaction. Analgesics and NSAIDs are two of the most common medications that can precipitate bronchospasm.[95] Other agents include antimicrobials (e.g., sulfonamides), cardiovascular agents (e.g., β-adrenergic antagonists and ACEIs), and excipients (e.g., preservatives, coloring agents, antioxidants).[95,96] The extensive list of medications suspected of causing or exacerbating bronchospastic reactions demonstrates the need to be aware of drug-induced causes of acute episodes, especially in patients with a history of preexisting lung conditions.

Opiates are commonly prescribed to pediatric intensive care patients. Acute respiratory failure secondary to a noncardiogenic pulmonary has been reported with the use of opiates including methadone, morphine, and codeine.[96] Aspirin

has also been identified to cause pulmonary toxicity. High concentrations of aspirin can lead to increased vascular permeability causing pulmonary edema. A syndrome of massive fluid retention and pulmonary edema may be seen with interleukin-2 administration. All-trans-retinoic acid may cause acute lung disease secondary to massive total body fluid accumulation.

Chronic pneumonitis/fibrosis is a relatively common syndrome associated with drug-induced pulmonary reactions and is manifested by slowly progressive symptoms of cough and dyspnea.[96] Nitrofurantoin is associated with pulmonary fibrosis, most commonly in patients receiving chronic, high-dose therapy and/or patients with renal insuffiency.[97] A delayed presentation (months to years after discontinuation of or the start of therapy) is the most common form of fibrosis seen with amiodarone,[98] but it also may cause an acute fibrosis manifesting within the first few weeks of therapy.[97,98] Many cytotoxic agents have been known to cause pulmonary fibrosis including bleomycin, carmustine (BCNU), mitomycin, mitomycin/vinca alkaloid combination therapy, and cyclophosphamide. Risk factors for this reaction to cytotoxic agents are cumulative dose, age at treatment, and radiation therapy.

Endocrine and Metabolic

Due to the complexity of the biochemical processes that influence the endocrine and metabolic balance of the body, several medications have the potential to create alterations in neuroendocrine hormonal production, binding, transport, and signaling. Additionally medications may create changes in hormonal counter-regulatory efforts. The most common types of medication-induced endocrine disorders are modifications in carbohydrate metabolism, electrolyte and calcium abnormalities, drug-induced thyroid changes, and alterations in acid-base status.[99] Variations in carbohydrate metabolism are commonly seen with many medications and are clinically manifested as alterations in blood glucose. Table 118-4 lists the multitude of medications associated with hypoglycemia or hyperglycemia subdivided by neuroendocrine effect.[99-109]

Hypoglycemia occurs most commonly with overtreatment with insulin or diabetic medications, while hyperglycemia results from medications that either increase glucose production or decrease the effects of exogenous insulin.[99,110,111] Decreased insulin secretion, changes in liver glucose metabolism and production, and increased insulin resistance are the most common mechanism of drug-induced hyperglycemia.[99] Glucocorticoid usage is commonly associated with hyperglycemia and glycosuria.[112] Corticosteroids increase blood glucose via hepatic gluconeogenesis and by increasing peripheral insulin resistance.[113] This adverse drug reaction appears to be dose-dependent and usually is reversible upon discontinuation of therapy.[113] Patients on high-dose, long-term glucocorticoid therapy are at significant risk for suppression of the hypothalamic-pituitary-adrenal axis.[114,115] Symptoms of adrenal insufficiency include arthralgias, dizziness, hypotension, nausea, and weakness.[114]

Drug-induced electrolyte disturbances can occur with a variety of pharmaceutical agents. Several medications are associated with initial or worsening hypokalemia, hyperkalemia, hyponatremia, hypernatremia, and hypomagnesemia (see Table 118-4).[99,116-131] Hyponatremia and hypernatremia are often secondary to depletional or dilutional effects of medications or drug-induced changes in antidiuretic hormone.[99,118] Hypokalemia is directly affected by medications that increase potassium excretion or that increase Na-K-ATPase activity, causing potassium influx into the cells. Drug-induced hyperkalemia can develop when medications lead to decreased Na-K-ATPase activity, aldosterone deficiencies, and resistance to aldosterone.[99,116] Medications that affect the renal tubules of the kidneys, such as amphotericin B and cyclosporine, have been associated with severe hypomagnesemia.[120] Antiepileptic agents, citrated solutions, foscarnet, and intravenous diltiazem have all been associated with critical hypocalcemia due to effects on either vitamin D metabolism or calcium reuptake mechanisms.[121-127] Electrolyte disorders represent a common adverse drug reaction and can greatly complicate therapy. Accordingly, frequent monitoring of electrolytes is warranted for patients on multiple drug therapy.

Electrolyte abnormalities are noted with the use of amiodarone; however, it is most commonly known for its adverse effects on the thyroid gland. Due to the large amount of iodine in amiodarone (3 mg of iodine/100 mg of drug), it has a counterregulatory effect on the production of thyroid hormones.[99] In patients in more developed countries, where iodine-deficiency is rare, use of amiodarone is associated with hypothyroidism; however, in countries where iodine-deficiency is more common; amiodarone can cause thyrotoxicosis.[129,130] It is important to obtain baseline thyroid studies prior to starting therapy and to continually monitor them throughout treatment.

Although uncommon, prolonged use of nitroprusside can result in methemoglobinemia and cyanide or thiocyanate toxicity.[132,133] Thiocyanate or cyanide toxicity is uncommon but can occur in patients suffering from kidney or hepatic failure or in patients receiving high-dose or prolonged infusions of nitroprusside.[134] An early indicator of thiocyanate or cyanide toxicity is metabolic acidosis.[135] Other medications associated with anion gap metabolic acidosis include chloramphenicol, epinephrine, norepinephrine, papaverine, and salicylates.[136,137]

Several life-threatening adverse drug reactions with propofol use in both the pediatric and critical care setting have been reported. In 2001, the FDA communicated a warning against off-label use of propofol for sedation in pediatric intensive care.[138,139] The FDA concern came from reviewing data of a randomized, controlled clinical trial evaluating the safety and efficacy of propofol versus standard sedation regimens in pediatric intensive care patients. Approximately 10% of patients treated with propofol died compared with 4% of children receiving standard treatment. Although large case series have reported the safe use of propofol without adverse effects,[140] given the risks of mortality with propofol infusion syndrome, prolonged propofol infusions are not recommended in the pediatric ICU setting.

Dermatologic

Erythema multiforme major, Stevens-Johnson syndrome, and toxic epidermal necrolysis are severe cutaneous reactions. They are characterized by the triad of symptoms of mucous membrane erosions, target lesions, and epidermal necrosis with skin detachment.[141] Drugs are frequently cited as the cause of these reactions. The more severe the reaction, the

ACE, Angiotensin converting enzyme; *ARBs*, angiotensin II receptor blockers; *HAART*, highly active antiretroviral therapy; *NSAIDs*, nonsteroidal antiinflammatory drugs; *SIADH*, syndrome of inappropriate antidiuretic hormone.

more likely it is drug-induced.[141] Numerous medications are implicated as the cause of these reactions, such as antiepileptic agents, antibiotics (e.g., sulfonamides), allopurinol, and NSAIDs (e.g., piroxicam).[141,142] For most agents, the pathogenesis is unknown. However, with sulfonamides and antiepileptics, the cause can be linked to a toxic metabolite that, in predisposed patients with a genetic defect, can bind covalently to proteins and elicit an immune response that causes a cutaneous reaction.[141]

Hypersensitivity syndrome reaction is a multisystem idiosyncratic reaction that manifests as fever, rash, and symptomatic or asymptomatic involvement of internal organ systems (liver, kidney, lungs, spleen, muscles, pancreas, lymph nodes, and blood).[142,143] Reactions usually occur with first exposure to medication, with initial symptoms occurring 1 to 6 weeks after exposure.[141] Aromatic antiepileptic agents (carbamazepine, phenobarbital, phenytoin, primidone) form a toxic metabolite that causes a secondary immune or hypersensitivity reaction.[143,144] Lamotrigine, valproic acid, and ethosuximide are other antiepileptics that may cause reactions. Sulfa drugs (dapsone, sulfasalazine, sulfonamide), allopurinol, and diltiazem also are implicated in hypersensitivity reactions.[143]

Drug rashes are the cutaneous manifestation of drug hypersensitivity. "Red neck" or "red man" syndrome, which is associated with the rapid infusion of vancomycin, is a histamine reaction and not a true allergic reaction. Prolongation of the administration prevents this reaction. β-Lactams and sulfamethoxazole are other common agents that cause rash.[97]

β-lactam antibiotics (most commonly) and sulfamethoxazole are medications known to cause anaphylaxis. The signs and symptoms of this immunoglobulin E–mediated allergic reaction are pruritus, urticaria, cutaneous flushing, hives, angioedema, bronchospasm, nausea, vomiting, diarrhea, nasal congestion, rhinorrhea, laryngeal edema, and hypotension. Several medications are associated with a drug-induced lupus-like reaction. Procainamide, hydralazine, isoniazid, nitrofurantoin, and griseofulvin are some of the agents involved.[97,141] Determination of the reaction is based on symptom resolution with drug discontinuation, absence of idiopathic lupus, development of antibodies, and one clinical symptom of lupus.[141]

Drug-Drug Interactions

The pediatric intensive care physician is confronted daily with potentially hazardous drug-drug interactions in the critical care setting. A potential drug-drug interaction can be defined as "the possibility that one drug may alter the intensity of pharmacological effects of another drug given concurrently. The net result may be enhanced or diminished effects of one or both of the drugs or the appearance of a new effect that is not seen with either drug alone."[145] The ability to recognize every potential drug interaction in the pediatric critical care setting is nearly impossible. Given the extent of polypharmacy that occurs, the potential risk is significant. Of the thousands of documented drug-drug interactions, only a small fraction are clinically significant.[146] The ability to differentiate between clinically significant and insignificant interactions requires an understanding of their mechanisms. In most cases, drug-drug interactions are predictable and preventable with appropriate dosage modifications or avoidance of combinations.

The magnitude of drug-drug interactions is measured by the intensity of the response. Drugs with narrow therapeutic indexes are especially susceptible to drug-drug interactions, because small alterations in exposure can lead to large changes in response. Typically, drugs with large therapeutic indexes are at minimal risk for clinically significant drug-drug interactions.

Drug-drug interactions can occur by three different mechanisms of action: pharmacokinetic, pharmacodynamic, and pharmaceutical. Pharmacokinetic drug-drug interactions can be defined as "interactions which affect a target drug through alterations in their absorption, distribution, metabolism, or excretion; the result may be an increase or decrease in the concentration of drug at the site of action."[145] Pharmacodynamic interactions are defined as interactions at a common receptor site or that have additive or inhibitory effects as a result of actions at different sites.[145] Pharmaceutical interactions or incompatibilities "occur when drugs interact in vitro so that one or both are inactivated."[147]

The ability to distinguish significant drug-drug interactions in the critical care setting is vital to patient care. The following discussion emphasizes the mechanism underlying various drug-drug interactions and identifies clinically significant interactions among therapeutic classes.

Pharmacokinetic Drug-Drug Interactions

The most common and well-studied etiology of drug-drug interactions occurs through pharmacokinetic interactions. Pharmacokinetic interactions can occur throughout the entire pharmacologic spectrum and can potentially affect the absorption, distribution, metabolism, or elimination of the compound of interest. However, drug-drug interactions are only important when they impact the resulting drug exposure to such an extent that the patient experiences an alteration in the expected drug effect, either through diminution of drug effect (when drug exposure is decreased) or through predisposition to adverse effects (when drug exposure is increased). It is important to recognize that the dearth of pharmacokinetic information available for most drugs in children often makes recognition of drug-drug interactions difficult. However, a thorough understanding of the mechanisms behind these interactions can create an index of suspicion that is necessary to identify potential interactions clinically.

Interactions Affecting Drug Absorption (Enteral Absorption)

Several factors determine the rate and extent of oral absorption of drug products. Drug-drug interactions affecting enteral absorption occur through several mechanisms with a common end result: alteration of availability of the drug at its primary site of absorption. The most common mechanisms include adsorption or complexation of the target drug by other drugs or by food, alterations in the ionization of the drug through pH changes, and perturbation of normal GI function (e.g., motility, bacterial colonization, mesenteric blood flow). In the critical care setting, adsorption and complex formation are the most likely causes of decreased enteral drug absorption. Commonly prescribed drugs (e.g., sucralfate and kaolin pectin) are implicated in causing decreased absorption of other drugs by adsorbing target drugs and rendering them unavailable for absorption across the GI barrier.[147a,148,149] Food, especially enteral feeding products, is capable of causing adsorption of drugs. Considerable controversy surrounds the potential for this interaction in the case of phenytoin; the clinical importance of this interaction is still debatable.[150] Although less commonly prescribed in the pediatric setting, tetracyclines and quinolone antibiotics have long been known to cause drug complexes with metallic cations such as iron and calcium, resulting in a decreased effect of both the supplement and the antibiotic.[151,152]

Because only un-ionized drug is available for absorption through the intestinal (or gastric) mucosa, the pH at the site of GI absorption must be considered. In theory, absorption of weakly basic drugs such as penicillins or sulfonamides would be enhanced when given in the presence of concomitant H_2-antagonists or proton pump inhibitors for GI prophylaxis. However, most clinical investigations show this interaction is insignificant.[153-155] Logically, weakly acidic drugs such as phenobarbital would be expected to have reduced enteral absorption under the same circumstances; however, this has not been confirmed clinically.

Alterations in the structure or function of the GI tract are not often the cause for drug-drug interactions but nonetheless are important to consider. Drugs that affect gastric emptying or intestinal transit time can reduce or prolong the residence time of a drug at its site of absorption, potentially altering its systemic availability. Alterations in the normal bacterial flora of the gut can affect the absorption of drugs that are metabolized by these bacteria to active (or inactive) forms. Digoxin is the most common example of a drug whose absorption can be affected through

this mechanism.[156-158] Alterations in mesenteric blood flow potentially could impact the absorption of any drug administered enterally, but this has never been shown clinically. Although controversial, the ability of indomethacin to affect mesenteric blood flow has been cited as a theoretical reason to withhold feeds and enteral drugs in children being treated for patent ductus arteriosus.[159,160]

Interactions Affecting Drug Absorption (Alternative Sites of Absorption)

Drug-drug interactions can occur when drugs are administered by nonenteral routes. A common concern in the intensive care unit setting is "compatibility" of drugs given by the IV route, whether the drugs are to be coadministered in the same IV bag or through common IV access lines. This concept is covered in greater detail in the section on pharmaceutical drug-drug interactions. Theoretically, intramuscular or subcutaneous absorption could be reduced when patients are receiving doses of vasopressor agents necessary to maintain blood pressure, secondary to reduced peripheral blood flow. Finally, it is common practice to instruct patients on combination therapy for asthma to administer β-adrenergic agonists prior to controller medications (inhaled steroids, mast cell stabilizers) because their bronchodilatory effects may help to maximize absorption of the controller medication in the distal bronchial tree. However, an improvement in patient outcome secondary to this approach has never been proven.

Interactions Affecting Drug Distribution (Protein or Tissue Binding)

Because the majority of drugs are bound to plasma proteins or tissue binding sites, the most commonly cited mechanisms for drug-drug interactions affecting distribution are those that involve protein or tissue binding. Several examples exist in which one drug displaces an object drug through competitive inhibition at a protein or tissue binding site. However, in most cases, the impact of the drug-drug interaction is minimal. The amount of free (active) drug may increase temporarily, but the free level falls back to its previous equilibrium as the clearance of drug subsequently increases. Most cases of increased free drug concentrations secondary to protein binding displacement occur when the displacing drug also inhibits the metabolism or excretion of the displaced drug. For example, probenecid not only displaces bound ceftriaxone from albumin binding sites but also inhibits the active secretion of the drug in the kidney, resulting in increased ceftriaxone concentrations.[161] The clinical implications of this interaction are minimal because of the wide therapeutic index for ceftriaxone.

Alterations in Total Body Water

An important mechanism for drug-drug interactions affecting drug distribution that often is overlooked is alteration of body fluid composition. Severe dehydration can be caused iatrogenically, either through fluid restriction or overzealous diuretic use. In these cases, drug concentrations can be increased several-fold, resulting in untoward effects. Conversely, the volume of distribution of drugs can be increased significantly by increasing total body water. This can have the effect of decreasing drug concentrations to subtherapeutic levels. Drugs that distribute primarily in total body water, such as aminoglycosides, are particularly susceptible to these types of effects.[162]

Interactions Affecting Drug Metabolism

The majority of clinically relevant drug-drug interactions can be linked to an alteration in drug metabolism. The two major pathways for drug metabolism in humans are the phase I oxidative pathway and the phase II conjugation reactions. Inhibition or induction of the phase I pathway is the most studied mechanism of drug-drug interactions, especially in relation to the cytochrome P450 system of enzymes. Table 118-5 lists the drugs that affect cytochrome P450 enzymes and those metabolized by the various clinically relevant isoforms. Evaluation of a drug's potential to affect the P450 system is now an integral part of new drug development, and many of the older drugs have been studied extensively, such that these interactions often are predictable in adults. In fact, drug-drug interactions now are exploited clinically in human immunodeficiency virus (HIV) therapy through the use of low-dose ritonavir.[163-165] However, the relative lack of formal pediatric studies makes predicting the impact of a particular interaction difficult in a given child. Factors that must be considered include the state of maturation of the particular isoform and the presence of compensatory pathways. In general, it is reasonable to assume that a reaction that occurs in adults will also occur in children; proper action should be taken as necessary.

One important consideration is timing of drug-drug interactions secondary to P450 enzyme inhibition and/or induction. In general, enzyme inhibition results from competitive inhibition at the enzyme binding site and, therefore, becomes clinically relevant as soon as the offending drug reaches sufficient concentrations in the liver. Consequently, upon discontinuation of the offending drug, enzyme inhibition abates as the drug concentrations fall. Drugs with short half-lives have a relatively short offset of effect, whereas those with longer half-lives can cause significant effects for prolonged periods after discontinuation. In contrast, enzyme induction results from an increase in the amount of enzyme synthesized by hepatic cells. Thus, there is a lag between the time an inducer is introduced and the onset of induction effect. As expected, the offset of effect also is somewhat prolonged.

Because phase II reactions rarely are rate-limiting, their potential to be the cause of clinically significant drug-drug interactions is low. However, the potential does exist for drugs to inhibit conjugation, thus impeding the conversion of object drugs to their inactive metabolites. A classic example is the interaction between high-dose ascorbic acid and acetaminophen. Ascorbic acid competitively inhibits the sulfation of acetaminophen, resulting in accumulation of the glucuronide metabolite.[166]

Interactions Affecting Drug Excretion

The primary means for elimination of drugs or their metabolites is through renal excretion. The process of renal excretion involves three mechanisms: glomerular filtration (GFR), active tubular secretion, and tubular reabsorption. All three mechanisms can be affected by drug-drug interactions.

Alterations in GFR secondary to drug-drug interactions most often result from alterations in renal blood flow. Drugs that act to reduce renal blood flow, such as cyclosporine or NSAIDs, can reduce GFR and thereby increase the blood concentration of drugs eliminated by this route.[35,167-170]

*Several drugs are listed as both P-glycoprotein (Pgp) inhibitors and inducers because their effects on Pgp expression can be concentration or duration related.

Conversely, drugs that improve renal blood flow could increase GFR and decrease plasma concentrations of drugs eliminated through the kidneys. As its name implies, active tubular secretion is an active process whereby drugs bind to receptors and are transported across the tubular cells to be excreted. Drugs that compete for these binding sites may inhibit the secretion of other drugs, causing increased concentrations. The two most commonly cited inhibitors of active tubular secretion are probenecid (inhibits the site for weak acids such as penicillin) and cimetidine (inhibits the site for weak bases such as procainamide). These reactions are rarely of clinical significance, although the probenecid–penicillin interaction has been used therapeutically to increase penicillin serum concentrations.[171-174] Tubular reabsorption is a passive process whereby drugs are reabsorbed into the systemic circulation from the lumen of the distal tubules. As with enteral absorption, only un-ionized molecules are available for reabsorption. Therefore drugs that alter the pH of the urine have the potential to alter tubular reabsorption of other drugs. A common example is phenobarbital, a weakly acidic drug. In overdose situations, sodium bicarbonate is administered to alkalinize the urine in the hopes that phenobarbital will become more ionized in urine, resulting in reduced tubular reabsorption and more rapid excretion. However, the effectiveness of this practice is not clear.[175]

Interactions Affecting P-Glycoprotein Receptors

Research in the oncology field has led to the identification of an important drug transporter that is ubiquitous throughout the human body, namely, P-glycoprotein (Pgp). Pgp can be found in renal tubule cells, hepatic cells, in the blood-brain barrier, and in mucosal cells of the intestines, the pancreas, and adrenal glands. Table 118-5 lists drugs that are inhibitors and/or substrates for Pgp. In general, Pgp is believed to serve a protective function by transporting molecules out of the body or, in the case of the blood-brain barrier, out of the CNS. This is manifested in the gut by Pgp-mediated secretion of molecules back into the intestinal lumen after absorption, in the kidney by active tubular secretion, in the liver by active secretion into the bile, and in the CNS by active removal of molecules out of the CNS. Those drugs that inhibit Pgp are expected to increase the concentrations of substrates (either in plasma or the CNS). To date, few clinically relevant interactions have been identified because of the relatively low inhibitory activity of most known drugs. However, because of their ability to aid in the treatment of multiply drug-resistant carcinomas, potent Pgp inhibitors are being developed and will be used therapeutically in the near future.[176,177]

Pharmacodynamic Drug-Drug Interactions

A pharmacodynamic drug-drug interaction can be defined as the combination of two or more drugs with additive, synergistic, or antagonistic pharmacodynamic effects. Additive pharmacodynamic interactions occur routinely when two or more drugs of the same class are given in combination, as in the case of antihypertensive medication or anticonvulsants. A synergistic interaction occurs when the combination of two drugs has an effect greater than the sum of their individual effects. One example of a clinically relevant synergistic interaction is the

use of aminoglycosides in combination with β-lactam antibiotics. In theory, combining a cell-wall active agent (β-lactam antibioitic) with an agent that inhibits bacterial protein synthesis (aminoglycoside) can achieve a greater antibiotic effect than the sum of the two individual effects. Although difficult to prove clinically, in vitro and animal studies have validated this theory.[178-180] Most antagonistic drug-drug interactions are more appropriately defined as pharmacokinetic interactions because they result from some alteration in drug concentrations, either in plasma or at the effect site. Antagonistic interactions that are truly pharmacodynamic in nature most often result from competitive inhibition at the receptor site for drug activity. Use of flumazenil to reverse benzodiazepine-induced sedation is an example of an antagonistic pharmacodynamic drug-drug interaction used clinically.[181,182,183]

Drug-Drug Interactions in Intravenous Admixtures

Parenteral administration of drug therapy poses a potential source of drug-drug interactions in the pediatric/neonatal intensive care unit. In this scenario, polypharmacy arising from an extensive problem list and limited IV access conspire to force the mixing of various drug solutions. However, disparate physicochemical properties and varying administration times preclude the indiscriminate admixing of numerous drugs into a single parenteral aliquot. In practice, both intermittently scheduled drugs and continuous infusions are often given concurrently at the Y-site of intravenous tubing, via different lumens in the same IV line, or through a different IV access altogether. This drug delivery strategy helps to reduce the contact time among different drug, electrolyte, and/or nutrient solutions. The majority of infusions require 15 to 60 minutes, a time frame in which most drugs will remain stable when they are infused with other drugs. Infusion of drugs with known incompatibilities could have serious consequences when administered to the patient. Introduction of a precipitate to venous circulation could produce adverse effects such as phlebitis and pulmonary embolism.[184] Admixing of IV drug solutions may lead to incompatibilities that could have serious consequences when administered to the patient. Factors influencing the coadministration of drugs include a limited number of IV access sites, an extensive drug therapy regimen, time constraints, and the need to administer other lengthy infusions (e.g., blood products).

Incompatibilities result from chemical reactions that may or may not be visible. Physical incompatibilities are easily identifiable because they illustrate any one of the following visual phenomena: precipitation, complexation, turbidity, color change, evolution of gas, or separation of the solution into distinct immiscible layers.[185] On the other hand, instability occurs when a mixture of drug solutions chemically reacts to yield a different species or degradation product, either of which could be pharmacologically inactive or even toxic. The rate at which these reactions occur adds another variable in determining whether or not two drug solutions can be infused together and for what duration. Generally, incompatibility is defined as a 10% decomposition of one or more components in an admixture in less than 24 hours.[185] Drug solutions typically are pH-buffered to optimize the solubility of the drug. Admixing solutions may alter the pH of the chemical environment and result in inactivation or visually ascertained incompatibilities such as precipitation. Reduction-oxidation reactions among incompatible drugs may lead to activation or generation of a toxic molecule. Salting out of drugs occurs when nonelectrolytes and weakly hydrated ions are exposed to strong electrolyte solutions. Chelation of drugs in incompatible admixtures can lead to inactivation or formation of insoluble complexes.

Drug-Drug Interactions by Therapeutic Class

As opposed to many other classes of drugs, the most common mechanism of cardiovascular drug-drug interactions results through alterations in pharmacodynamics. The potential for two drugs to act upon the same receptor subtype sets the stage for pharmacodynamic interactions, which can be antagonistic, additive, or synergistic in nature.

Cardiovascular Agents

Sympathomimetic amines (epinephrine, norepinephrine, phenylephrine, dopamine, dobutamine, ephedrine, and isoproterenol) are particularly susceptible to pharmacodynamic drug-drug interactions. The extent and significance of these interactions depend upon the selectivity of both the object drug and precipitant drug for adrenergic receptor types. β-adrenergic antagonists generally antagonize the cardiac and bronchodilating effects of the sympathomimetics.[70] However, propranolol and other nonspecific β-adrenergic antagonists (Table 118-6) may enhance the vasoconstriction produced with epinephrine. As a result, the patient may experience hypertension and bradycardia.[79,80] Labetalol possesses both α_1-adrenergic and nonspecific β-adrenergic antagonistic activity, which produces an increase in diastolic blood pressure and a decrease in heart rate when given during an epinephrine infusion.[79,80] Metoprolol and possibly other β_1-cardioselective antagonists have minimal effects on the pressor response when given concomitantly with epinephrine.[79,80] Other classes of drugs can interact with the sympathomimetics. α-adrenergic antagonists (e.g., phentolamine), when added to a regimen containing a sympathomimetic, reduce vasoconstriction and attenuate the increase in blood pressure.[70] Tricyclic antidepressants (e.g., imipramine) tend to increase the vasopressor response to sympathomimetics such as epinephrine and norepinephrine and catecholamines such as phenylephrine. The effect has been shown to produce severe and persistent hypertension in patients receiving phenylephrine.[70,79,80] Ergot alkaloids may potentiate the

Table 118–6 β-Blocker Receptor Selectivity

Modified from Hoffman BB: Adrenoreceptor-activating and other sympathomimetic drugs. In Katzung BG, editor: *Basic and clinical pharmacology,* Stamford, CT, 1998, Appleton & Lange.

vasopressor effects of sympathomimetics with pronounced α-adrenergic activity (e.g., epinephrine, norepinephrine, phenylephrine).[70,79,80] Antihistamines (diphenhydramine) and tricyclic antidepressants tend to inhibit tissue uptake of epinephrine and norepinephrine. They also can increase adrenoreceptor sensitivity to epinephrine.[70]

General anesthetics (e.g., sevoflurane) and halogenated hydrocarbons (e.g., halothane) tend to increase cardiac irritability and sensitize the myocardium to the arrhythmogenic effects of sympathomimetics. Tachycardia and arrhythmias (ventricular premature contractions and fibrillation) are reported with concurrent administrations.[70] Atropine also tends to block the reflex bradycardia produced by epinephrine, norepinephrine, and phenylephrine. This effect in turn augments the pressor response.[70] Finally, concurrent administration of dopamine and intravenous phenytoin (fosphenytoin) produces hypotension and bradycardia in case reports and animal studies. Cardiovascular status should be monitored closely when these medications are given concomitantly.[79,80]

The pharmacologic effect of vasodilators, such as sodium nitroprusside, minoxidil, hydralazine, and diazoxide, are augmented by both β-adrenergic antagonists and diuretics. The decreased systemic vascular resistance and resultant reduction in mean arterial pressure provide stimuli for a compensatory increase in sympathetic nervous system activity. Normalization of blood pressure to the set point then is mediated by an increase in cardiac contractility, increased heart rate, and stimulation of the renin-angiotensin-aldosterone (RAA) pathway. β-Adrenergic antagonists prevent this sympathetic outflow and thereby enhance the vasodilator and hypotensive response. Diuretics also block the compensatory sodium retention from the RAA pathway and thereby reduce the increase in mean arterial pressure that would have been produced from plasma volume expansion.[186] Caffeine, on the other hand, increases renin secretion.[187] Caffeine may attenuate the hypotensive response to vasodilators. The combination of sodium nitroprusside and sildenafil may produce additive hypotensive effects. Studies have shown sildenafil to be effective in treatment of pulmonary hypertension and chronic lung disease in pediatric and neonatal critical care.[138,188] The increased use of this medication, especially in cardiac patients, has necessitated heightened surveillance of potential interactions. Contact between sodium nitroprusside molecules and erythrocytes or the vascular wall results in generation of nitric oxide. Nitric oxide subsequently stimulates the cyclic guanosine monophosphate (cGMP) second messenger system in vascular smooth muscle upon activation of soluble guanylyl cyclase. The molecular process of increasing intracellular concentrations of cGMP translates to vasodilation and the resultant physiologic effect of reduced blood pressure. Sildenafil augments the response to cGMP through selective inhibition of type 5 phosphodiesterase, the enzyme that catalyzes degradation of cGMP. Therefore sildenafil can react similarly with other drugs (nitroglycerin, hydralazine) that promote the generation of a nitric oxide species. However, preliminary animal studies suggest that concomitant administration of sildenafil with nitroglycerin does not result in a dose-reducing effect for nitroglycerin. Sildenafil is metobolized by the cytochrome P450 3A4 enzymes which causes significant interaction potential with CYP3A4 inhibitors. Concentrations of sildenafil have been increased by as much as 182% when combined with erythromycin.[189] It is recommended to monitor patients closely for increased hypotensive effects of sildenafil if concomitant administration of CYP3A4 inhibitors, such as macrolides, cimetidine, or azole antifungals, cannot be avoided. Although the mechanism of action is unclear, concomitant administration of indomethacin with hydralazine may reduce the hypotensive effect of hydralazine.[190]

The antiarrhythmic drugs amiodarone, disopyramide, and quinidine are substrates for the CYP3A4 isoform of the P450 enzyme system. Plasma levels of these antiarrhythmics may increase and produce adverse effects when combined with CYP3A4 inhibitors such as the macrolide antibiotics (clarithromycin, erythromycin, azithromycin), the azole antifungals (fluconazole, itraconazole, ketoconazole, voriconazole), and other miscellaneous inhibitors such as cyclosporine, the calcium channel blockers (diltiazem and verapamil), and grapefruit juice. Conversely, plasma levels decrease when therapy is combined with drugs that are known enzyme inducers, including phenobarbital, carbamazepine, phenytoin, oxcarbazepine, primidone, and rifampin. The antiarrhythmic drugs flecainide, mexiletine, and propafenone are substrates for CYP2D6. Concomitant therapy with enzyme inhibitors of CYP2D6, including amiodarone, cimetidine, diphenhydramine, fluoxetine, paroxetine, haloperidol, propafenone, and quinidine, could result in toxicity.[79,80]

As a substrate for Pgp, digoxin exhibits reduced renal and nonrenal clearance when a Pgp inhibitor is added to the drug regimen. The plasma levels of digoxin may double or quadruple, demanding close monitoring for digoxin toxicity. Pgp inhibitors include amiodarone, clarithromycin, cyclosporine, diltiazem, erythromycin, ketoconazole, itraconazole, propafenone, quinidine, and verapamil.[79,80]

Pharmacodynamic interactions with drugs that modulate atrioventricular (AV) nodal conduction may produce clinically significant adverse effects, which include heart block, bradycardia, and other arrhythmias. Concurrent therapies with the antiarrhythmic agents, calcium channel antagonists, and β-adrenergic antagonists should be monitored closely or even reevaluated.[191] Patients with severe electrolyte imbalances may be susceptible to digoxin toxicities. Hypokalemia, hypomagnesemia, and hypercalcemia are all conditions that may be drug-induced. Therefore, drugs may interact with digoxin in an indirect manner through alteration of electrolyte homeostasis. The loop diuretics, thiazide diuretics, amphotericin B, corticosteroids, laxatives, and sodium polystyrene sulfonate may contribute to digoxin toxicity.[70]

Calcium channel antagonists have been implicated in several common pharmacokinetic drug-drug interactions involving the CYP3A substrates. In addition, inhibitors of CYP3A can cause significant interactions with calcium channel antagonists. These interactions can lead to lower diastolic blood pressure, higher heart rates, and other vasodilation-related side effects.[192-196] Inducers of CYP3A4 are implicated in the reduced efficacy of calcium antagonists.[191] Droperidol affects cardiac repolarization, prolongs the QT/QTc interval, and, when concurrently administered with calcium channel antagonists, increases the risk of QT/QTc prolongation, torsades de pointes, and cardiac arrest.[197] Concomitant administration of fentanyl and nicardipine can result in severe hypotension.[198] Awareness of potential drug-drug interactions is necessary when administering calcium channel antagonists.

β-Adrenergic antagonists are associated with a variety of pharmacodynamic and pharmacokinetic drug-drug

interactions. Concomitant use of a β-adrenergic antagonist and verapamil or diltiazem can result in additive negative inotropic effects and can potentiate conduction abnormalities.[199,200] Abrupt withdrawal of clonidine when concomitantly used with an β-adrenergic antagonist can exaggerate rebound hypertension symptoms associated with clonidine withdrawal.[201-203] The probable mechanism of this interaction is unopposed α-adrenergic agonism. Use of amiodarone with β-adrenergic antagonists potentates bradycardia, sinus arrest, and AV block.[198] Fentanyl anesthesia in combination with β-adrenergic antagonists and calcium channel antagonists has been noted to cause hypotension.[198a]

Angiotensin-converting enzyme inhibitors have been implicated in a variety of drug-drug interactions. Electrolyte disturbances are a major source of complications with these drug-drug interactions. Potassium-sparing diuretics (spironolactone) in combination with ACEIs cause increases in serum potassium levels.[204] Nesiritide, a medication often used to treat decompensated heart failure, can suppress the renin-angiotensin-aldosterone system; therefore, it is important to monitor patients for severe hypotension when concurrently administering this medication with ACEIs.[205]

Loop diuretics induce hypokalemia and hypomagnesemia and, when administered concomitantly with droperidol, may precipitate QT prolongation.[197] In addition, furosemide may produce digitalis toxicity when administered concurrently with digitalis therapy through this same mechanism.[141,207] There is increased risk for nephrotoxicity and ototoxicity when furosemide and aminoglycosides are administered concurrently.[208]

Anticonvulsant Medications

The antiepileptics constitute a drug class that has the potential to be involved in a large array of drug-drug interactions. These interactions are mainly pharmacokinetic in nature and usually involve induction, inhibition, or competition among substrates for various isoforms of the cytochrome P450 enzyme system. Fortunately, these drugs typically are monitored using blood concentrations. Appropriate therapeutic drug monitoring can aid in the avoidance of adverse events secondary to drug-drug interactions. Table 118-5 lists the isoforms for which the various antiepileptics are substrates, inducers, or inhibitors.

In the intensive care unit setting, phenytoin is generally administered intravenously in the form of the water-soluble prodrug, fosphenytoin. Phosphatases in red blood cells and the liver catalyze the conversion of fosphenytoin to its active form phenytoin. Fosphenytoin generally has a serum half-life of 8 to 15 minutes.[209] Once fosphenytoin is converted to phenytoin, it is susceptible to all of the potential drug-drug interactions that affect orally administered phenytoin. Approximately 95% of phenytoin is metabolized in the liver by the CYP2C9/10 and CYP2C19 isoforms of the cytochrome P450 enzyme system to produce the inactive hydroxylated metabolite parahydroxyphenylhydantoin.[209] The CYP2C9/10 isoform is the main pathway of metabolism for this drug. Phenytoin metabolism is reduced and plasma levels increased via competition with other drugs that are substrates for CYP2C9 and CYP2C19, such as amiodarone, fluconazole, valproic acid, omeprazole, and fluoxetine. Conversely, phenytoin may competitively inhibit the metabolism of these drugs. Drugs that inhibit CYP2C9 reduce clearance of phenytoin and consequently increase plasma concentrations.[210] Examples include fluconazole, ketoconazole, cotrimoxazole, amiodarone, and valproate. Omeprazole, cimetidine, and fluoxetine are inhibitors of CYP2C19 and thus can increase phenytoin plasma concentrations.[210] In addition to serving as a substrate to CYP2C9/10 and CYP2C19, phenytoin can induce their activity. Moreover, phenytoin induces CYP3A4 and uridine diphosphate glucuronosyl transferase (UGT) activity.[209] It may take 1 to 2 weeks for maximum induction of these enzymes when phenytoin therapy is started and, conversely, the same amount of time for deinduction once the drug is discontinued.[210] Phenytoin exhibits a high degree of protein binding (≥90%) to serum proteins, mainly albumin, so displacement from its binding sites may produce clinically significant changes in free phenytoin concentration.[209] The free fraction is the pharmacologically active portion of the total phenytoin concentration in plasma. Populations in whom increased proportion of free drug may be found include neonates, patients with uremia, hyperbilirubinemia, or hypoalbuminemia, and/or patients taking concurrent anionic drugs and metabolites.[209,211,212] During the hospital course of critically ill children who experienced traumatic head injuries, protein binding and phenytoin metabolism are altered.[213] The free fraction of phenytoin may increase over time in patients with acute head injury.[214] Such a clinical condition makes this particular population of patients especially susceptible to potential protein displacement interactions with other highly protein-bound drugs, such as valproic acid. The potential clinical significance of this interaction is an increased risk for phenytoin toxicity.

Phenobarbital is a substrate for CYP2C9, CYP2C19, and CYP2E1. The CYP2C19 isoform serves as the primary pathway for metabolism.[209] Phenobarbital is converted to 5-p-hydroxyphenyl-5-ethyl-barbituric acid, an inactive species, and further conjugated with glucuronic acid or sulfuric acid for excretion in urine.[209] Phenobarbital has the potential to induce CYP2C9 and CYP3A4 enzymes.[215] The time frame for induction and deinduction of the P450 enzyme system depends upon phenobarbital's half-life, with induction beginning 1 week after initiating phenobarbital therapy and deinduction beginning 1 week after phenobarbital is discontinued. Maximum induction occurs in approximately 2 to 3 weeks. Phenobarbital also induces UGT.[210] Addition of phenobarbital or phenytoin to a regimen of methadone, which may be used in the intensive care unit for the purpose of weaning from long-term opiate sedation, may present a potential for significant drug-drug interaction. Induction of CYP2C9 and CYP3A4 leads to increased clearance of methadone. The reduced plasma concentration of methadone could result in signs of methadone withdrawal. In transplant patients, phenobarbital may reduce cyclosporine concentrations, which may lead to concerns regarding adequate immunosuppression. Another significant drug interaction involves the abrupt withdrawal of phenobarbital in a patient maintained on both phenobarbital and warfarin. In such a scenario, blood levels of warfarin may increase and lead to increased risk of bleeding. During maintenance of such a regimen, phenobarbital induces the same enzymes responsible for warfarin metabolism. As a result, warfarin dosing is adjusted based upon phenobarbital-mediated inhibition of the hypoprothrombinemia response.

The main pathway for metabolism of carbamazepine is through the CYP3A4 isoform. CYP1A2 and CYP2C8 also are sites for metabolism but are considered to play lesser roles. It is believed that carbamazepine may also be a substrate for

CYP2C19.[210] Carbamazepine is metabolized to a 10,11-epoxide, which also possesses pharmacologic activity. Carbamazepine may undergo inactivation by hydroxylation and conjugation along another pathway. The 10,11-epoxide is further metabolized to inactive compounds for elimination. Carbamazepine induces CYP1A2, CYP2C9, CYP3A4, and UGT; therefore carbamazepine may reduce the plasma concentrations of drugs that are substrates for these isoforms. Carbamazepine illustrates autoinduction, the induction of its own metabolism through CYP3A4. Autoinduction is apparent in the initial weeks of carbamazepine therapy and doubles its rate of clearance within this time frame. Induction begins within the first week of therapy and maximizes at approximately 3 weeks.[210]

Concomitant therapy with drugs that are substrates, inducers, or inhibitors of the same isoforms involved in carbamazepine clearance changes its plasma concentration. Macrolide antibiotics (e.g., erythromycin, clarithromycin, troleandomycin) inhibit the CYP3A4 enzymes, which results in elevated carbamazepine plasma levels and a consequent decrease in 10,11-epoxide.[210] Calcium channel blockers (especially verapamil and diltiazem) also inhibit CYP3A4 and have similar effects on carbamazepine plasma levels.

Oxcarbazepine undergoes extensive metabolism through the liver to an active metabolite, 10-monohydroxy (MHD). The main pharmacological properties of oxcarbazepine are due to its active metabolite MHD. This antiepileptic medication, oxacarbazepine, is a weak inhibitor of CYP2C19 and strong inducer of CYP3A4/5 isoforms. When oral contraceptives, dihydropyridine calcium antagonists, and cyclosporine are each given concomitantly with oxcarbazepine, decreased drug levels were shown, due to the induction of CYP3A4/5 isoforms.[216]

The isoforms of the P450 enzyme system that metabolize valproic acid include CYP2C9 and CYP2C19, both of which represent minor pathways. The main route of metabolism for valproic acid involves glucuronidation by UGT and β-oxidation.[209] Valproate inhibits drugs that are metabolized by CYP2C9, such as phenytoin and phenobarbital. In addition to being a substrate for UGT, valproic acid inhibits drugs that are metabolized by this enzyme, such as lorazepam and lamotrigine. Felbamate, on the other hand, inhibits β-oxidation, resulting in reduced clearance of valproic acid.[210] Valproic acid also exhibits a high degree of protein binding to plasma albumin (90%), making protein displacement interactions likely with other highly protein-bound drugs.[209]

The main pathway for metabolism of lamotrigine is UGT-mediated glucuronidation. Lamotrigine is capable of inducing its own metabolism, with maximum autoinduction observed within 2 weeks. Autoinduction typically results in a 17% reduction in plasma blood levels.[217] Through their action on UGT, carbamazepine, phenytoin, and phenobarbital reduce plasma concentrations of lamotrigine when given concomitantly. Lamotrigine, on the other hand, reduces valproic acid plasma levels when added to a regimen containing valproic acid. Concentrations may be reduced by as much as 25% in the course of a few weeks.[209] When added to carbamazepine therapy, lamotrigine promotes increases in plasma levels of the 10,11-epoxide active metabolite of carbamazepine.[210]

Antiinfective and Antimicrobial Agents

Antimicrobial agents are commonly used in the intensive care unit to treat patients with serious infections. Some drug-drug interactions involve antimicrobial agents, but most are not clinically significant.[97] Some interactions involve complexation of the antimicrobial, such as quinolones (ciprofloxacin, levofloxacin) binding to multivalent cations (aluminum, calcium, magnesium, iron).[218,219] This interaction can be avoided by administering the drugs at separate times. Ciprofloxacin may interact with theophylline and caffeine, inhibiting their metabolism by the cytochrome P450 system. This interaction does not occur with third generation (levofloxacin) and fourth generation (gatifloxacin, moxifloxacin) quinolones.[219] Cyclosporine levels may be increased with concurrent use of ciprofloxacin. Monitoring of cyclosporine levels or changing to another antibiotic to which the pathogen is susceptible are ways to manage this interaction.

Many drug-drug interactions occur with macrolide antibiotics. Erythromycin may cause interactions through inhibition of the cytochrome P450 enzymes (1A, 3A). Erythromycin may increase serum levels of theophylline, warfarin, carbamazepine, cyclosporine, midazolam, tacrolimus, and hydroxymethylglutaryl coenzyme A reductase inhibitors (e.g., lovastatin, simvastatin, atorvastatin).[135,220,221] Clarithromycin also inhibits cytochrome P450 enzymes and may increase the serum levels of carbamazepine, theophylline, caffeine, cyclosporine, warfarin, valproate, and midazolam.[220,221] Azithromycin is an azalide (macrolide subclass) that does not demonstrate cytochrome P450 complexation, so it has less drug interaction potential. No major drug-drug interactions have been shown with azithromycin and carbamazepine, theophylline, or midazolam.[220] Interactions with cyclosporine and warfarin are limited to case reports, so monitoring of serum levels and international normalized ratio (INR), respectively, is prudent when using this combination.[222]

Rifampin is a cytochrome P450 enzyme inducer that is involved in many drug-drug interactions. Rifampin may decrease serum concentrations of chloramphenicol, isoniazid, amiodarone, cyclosporine, prednisolone, and warfarin.[223,224] These interactions often complicate multidrug regimens for treatment of active tuberculosis.

Antifungal agents are used in the critical care setting for treatment and prophylaxis of systemic mycoses. The majority of drug-drug interactions with antifungals occur within the azole derivatives via inhibition of biotransformation. Azole derivatives inhibit sterol 14-α-demethylase, which is a hepatic microsomal cytochrome P450-dependent system. Unfortunately, this mechanism results in significant drug-drug interactions. Azole antifungals are known inhibitors of cytochrome P450 isoenzymes, although the specific CYP isoforms and potency of inhibition vary among agents.[106,225] Table 118-5 provides a description of cytochrome P450 isoforms inhibited by the azole antifungals. Clinically significant interactions with azoles occur most frequently with agents that have narrow therapeutic windows and are metabolized by cytochrome P450 enzymes. Clinically significant interactions can occur when azole derivatives are administered with CYP3A substrates such as midazolam,[194,225] tacrolimus,[226] sirolimus,[227] cyclosporine,[228] nifedipine,[192] felodipine,[192,229] diltiazem,[227] and alfentanil.[230] Benzodiazepines that rely on the CYP3A4 enzyme for biotransformation are predisposed to drug-drug interactions with CYP3A inhibitors. The benzodiazepines most prone are alprazolam, diazepam, midazolam, and triazolam.[195,231,232] Ketoconazole, a potent inhibitor of CYP3A, increases the area under the concentration–time curve (AUC) of oral midazolam by 16-fold.[195,229,233-236]

Whenever ketoconazole, itraconazole, voriconazole, or fluconazole is administered with midazolam, patients must be monitored for increased response to midazolam and altering the dosage or discontinuing therapy considered. Diazepam metabolism is mediated by CYP3A and CYP2C19 and is also prone to interactions with azole derivatives.[237] Fluconazole and voriconazole have the potential to cause clinically significant drug-drug interactions with compounds that are metabolized via CYP3A, CYP2C9, and CYP2C19; therefore caution should be exercised when administering fluconazole or voriconazole with diazepam. Warfarin is a racemic mixture compound for which most pharmacodynamic activity occurs with the S-isomer, whose metabolism is dependent on CYP2C9, which is inhibited by fluconazole and voriconazole.[227,238] This interaction is significant, and appropriate dosage modifications or alteration of therapeutic agents must be considered. The calcium channel antagonist class is metabolized by CYP3A isoenzymes and has the potential for interactions with azole derivatives.[229] Concomitant use of fluconazole and rifabutin has resulted in rifabutin toxicities from increased serum concentrations because of inhibition of cytochrome P450 isoenzymes.[8] Similar interactions are expected with voriconazole and itraconazole. Azole derivatives increase serum concentration of both phenytoin (after administration of fosphenytoin) and carbamazepine.[238a,239] There is the potential for decreased efficacy of azole derivatives used in combination with rifampin, an inducer of the cytochrome P450 isoenzyme system.[240]

In addition to being CYP3A inhibitors, ketoconazole and itraconazole are substrates and inhibitors of Pgp.[196,241] Drug-drug interactions mediated via Pgp typically are important determinants of bioavailability, liver metabolism, and kidney excretion.[242,243] Thus ketoconazole and itraconazole with dual CYP3A and Pgp inhibition could greatly impact the bioavailability of dual substrate drugs.[196,244] Diltiazem, verapamil, saquinavir, cyclosporine, and tacrolimus are dual CYP3A and Pgp substrates.[59,245] Clearance of digoxin, a Pgp substrate, is decreased with coadministration of itraconazole.[246] An increase in digoxin trough concentration is likely the result of impaired renal tubular secretion via inhibition of Pgp.[246]

Concomitant administration of amphotericin B with cyclosporine, tacrolimus, or aminoglycosides results in increased nephrotoxicity.[247,248] Concomitant use of digoxin and amphotericin B products results in digitalis toxicities attributed to potassium depletion mediated by amphotericin B.[249] Antifungal therapy is associated with a variety of potentially significant drug-drug interactions. Therapeutic drug monitoring is necessary in the critical care setting, but additional awareness is warranted when antifungal agents are being used.

Anesthetic Agents and Sedatives

Several agents are used for anesthesia and sedation in the pediatric critical care setting. Many of these drugs have clinically significant drug-drug interactions. The ability to recognize potential drug-drug interactions related to the use of anesthetic agents or sedatives in the pediatric critical care setting requires a fundamental understanding of the agent's clinical pharmacology. Benzodiazepines are a class of sedatives that are particularly susceptible to drug-drug interactions because of their route of biotrans-formation.[193,194,250] CYP3A4 plays a major role in the metabolism of midazolam, triazolam, and alprazolam, and caution should be exercised when combining these agents with CYP3A modulators.[251-253] As mentioned previously, concomitant use of systemic antifungals and benzodiazepines results in a known clinically significant drug-drug interaction, caused by azole antifungals inhibiting the CYP3A isoenzyme.[193-195,250] Midazolam, a short-acting benzodiazepine used in the pediatric critical care setting, is almost exclusively metabolized via the CYP3A pathway. Interactions are most prominent with oral midazolam therapy because of the role of intestinal metabolism.[193-195] However, significantly increased plasma levels have been observed when intravenous midazolam is administered with fluconazole.[193-195] Additionally, clarithromycin and erythromycin have been proven to significantly decrease systemic clearance of intravenous and oral midazolam.[195,254,255] Azithromycin, another macrolide, does not appear to increase plasma concentrations of oral midazolam.[235] Propofol has been shown to decrease the clearance of midazolam by 37%, possibly by competitive inhibition of CYP3A4.[256] Concomitant administration of verapamil or diltiazem with oral midazolam is associated with dramatic increases in AUC and the maximum concentration (C_{max}).[234] Inducers of CYP3A can drastically decrease plasma concentrations of midazolam. Rifampin, a potent inducer of CYP3A and Pgp expression in the gut mucosa, can cause dramatic decreases in plasma concentrations of oral midazolam.[234,255] Other inducers of CYP3A enzymes implicated in significant interactions with midazolam are carbamazepine and phenytoin.[252] Diazepam, a benzodiazepine with long-acting metabolites, is prone to drug-drug interactions with inhibitors or inducers of CYP2C19 or 3A4. Because the primary route of metabolism for lorazepam is through glucuronidation, this agent is associated with fewer potential pharmacokinetic drug-drug interactions.[231]

The potential for pharmacodynamic drug-drug interactions also exists with the sedative agents. Concomitant use of barbiturates and benzodiazepines causes additive respiratory and CNS depression. This additive mechanism is mediated via allosteric conformational changes at the γ-aminobutyric acid (GABA) site, which regulates the opening of chloride channels, causing the neurons to become hyperpolarized and resistant to excitation.[257] The dosage of midazolam and other benzodiazepines often is reduced by 30% to 50% when they are administered concomitantly with opioid analgesics.[258] Flumazenil competitively inhibits the activity of benzodiazepines at its recognition site on the GABA-benzodiazepine receptor complex.[259] It does not reverse the CNS effects of GABA-mimetic agents such as barbiturates, propofol, and other general anesthetics.[259]

Clonidine, an α_2-adrenergic agonist agent with sedating properties, when used concomitantly with propofol, reduces the induction concentrations required for loss of consciousness.[260] Propofol can inhibit the clearance of alfentanil and act synergistically with opioids.[261,262] Caution should be exercised when using propofol in combination with drugs that lower seizure threshold, such as meperidine and enflurane.[263]

Neuromuscular blocking agents have some significant drug-drug interactions.[264] Concomitant use of intravenous antibiotics such as aminoglycosides or clindamycin has the potential to intensify the neuromuscular blockade produced by neuromuscular blocking agents.[264] Phenytoin has been shown to increase pancuronium requirements. Additionally,

inhalation anesthetic agents can potentiate neuromuscular blockade.[264]

Analgesic Agents

A variety of agents are used for analgesia in the pediatric critical care setting. Patients receiving opioid analgesia are particularly susceptible to drug-drug interactions. Whenever an opiate agonist is administered with an agent that has CNS depressant effects, augmented effects or toxicity are possible. Therefore vigilance in monitoring for drug-drug interactions is necessary when administering these agents to help ensure that safe and effective analgesia is achieved. Analgesic pharmacokinetic drug-drug interactions can mediate clinically relevant effects. CYP3A is involved in the metabolism of methadone and alfentanil.[255] Methadone metabolism is induced by rifampin and results in enhanced clearance of methadone.[266,267] One study of adults demonstrated an approximately fourfold increase in methadone clearance, with methadone clearance ranging from 0.538 L/h/kg when administered with rifampin to 0.126 L/h/kg when methadone was administered alone.[268] This effect could provoke withdrawal symptoms in patients receiving methadone.[266] In addition, phenobarbital, phenytoin, carbamazepine, nevirapine, and efavirenz have the potential to decrease methadone blood concentrations.[269,270] Rifampin significantly lowers alfentanil plasma concentrations by the same mechanism.[255] Inhibition of CYP3A can result in increased plasma levels of methadone.[267] For example, fluconazole inhibits metabolism of methadone[267] and alfentanil.[230] Fluconazole decreased the clearance of alfentanil approximately 58% following intravenous fluconazole administration in healthy adults.[230]

Pharmacodynamic drug-drug interactions can result in synergic effects or antagonism. When a pure opiate agonist and a partial agonist/antagonist are used in combination, there is a risk for decreased clinical effects. For example, morphine (pure μ agonist) and nalbuphine (partial agonist/antagonist) used in combination can result in decreased opiate effect. This can have profound effects on analgesia and result in withdrawal symptoms for patients on long-term analgesia therapy.[271,272] Analgesic opioid therapy is associated with several side effects that can be heightened by drug-drug interactions, such as respiratory depression, hypotension, decreased GI motility, nausea, and vomiting. Use of a pure opioid antagonist, such as naloxone, is needed for reversal of undesirable effects. Most clinically significant drug-drug interactions associated with analgesics are pharmacodynamic in origin.

Anticoagulants

Warfarin is involved in a multitude of drug-drug interactions, including alterations in protein binding, in hepatic metabolism by the cytochrome P450 system, in bacterial flora of the GI tract, and of the clotting cascade (Table 118-7). Aspirin, chloral hydrate, ibuprofen, and sulfamethoxazole can displace warfarin from protein binding sites, making more free fraction of warfarin available and hence augmenting anticoagulation. Warfarin metabolism may be inhibited by amiodarone,

Table 118–7 Medication Interactions that Modify the Anticoagulant Effect of Warfarin

Increased INR	Decreased INR	Increased Risk of Bleeding	Increased Risk of Thrombosis
CYP450 inhibition via 2C9: (unless otherwise noted)	**CYP450 induction via 2C9:** (unless otherwise noted)	**Alterations in platelet function:**	**Alterations in warfarin metabolism or absorption:**
Antidepressants:	Carbamazepine	*Antiplatelet agents:*	Cholestyramine
Fluvoxamine	Phenytoin	Aspirin	Griseofulvin
Sertraline	Phenobarbital	Clopidrogrel	Nafcillin
Antiinfectives:	Rifampin	Ticlodipine	Ribavirin
Azole Antifungals (2C9/3A4)		Cimetidine	Sucralfate
Cotrimoxazole		Fish oil	
Fluoroquinolones (1A2/3A4)		*Antifibrinolytics:*	**Prothrombotic**:
Isoniazid		Alteplase	Estrogens
Macrolides		Streptokinase	OCPs
Metronidazole		Urokinase	Phytonadione

NSAIDs, Nonsteroidal antiinflammatory drugs; *OCP*, oral contraceptive pills; *SSRI*, selective serontonin reuptake inhibitor.

Modified from Hansten PD: Oral anticoagulants and drugs which alter thyroid function, *Drug Intell Clin Pharm* 14:331–334, 1980; Liu A, Stumpo C: Warfarin drug interactions among older adults, *Geriatrics Aging* 10(10):643–646, 2007; and Holbrook AM, Pereira JA, Labris R et al: Systemic overview of warfarin and its drug and food interactions, *Arch Intern Med* 165(10):1095–1106, 2005.

sulfamethoxazole, metronidazole, azole antifungals, macrolide and quinolone antibiotics, and isoniazid, resulting in decreased effect.[272] Phenobarbital, rifampin, and phenytoin can induce the metabolism of warfarin and decrease its effect. Most antibiotics have the potential to decrease synthesis of vitamin K-dependent clotting factors and potentiate warfarin's effect.[272,273] Other medications including NSAIDs and antiplatelet medications can exacerbate the adverse effects of warfarin by directly affecting the clotting cascade. Phytonadione (vitamin K) antagonizes the anticoagulation effect of warfarin.[215] Careful monitoring of bleeding and coagulation parameters (prothrombin time and INR) can help prevent serious adverse drug reactions. Many drug-drug interactions can occur when initiating warfarin therapy or when adding other medications to existing warfarin therapy. Clinically, it is recommended to use adjusted starting doses of warfarin when initiating therapy while patients are receiving medications with the potential for interaction.

Heparin has the potential to interact with other agents that increase the risk of bleeding or thrombosis. Common interactions include oral anticoagulants (warfarin) and platelet inhibitors (e.g., aspirin, dextran, ibuprofen, and other agents that interfere with platelet aggregation). Concurrent administration of heparin and nitroglycerin has been associated with lower aPTT values.[274] More recently, antifibrinolytic agents, which can enhance the anticoagulant effects of heparin, have become one of the primary treatments of larger arterial or intra-atrial clots. Heparin effectiveness can also be altered by the administration of additional clotting factors found in fresh frozen plasma and antithrombin III. Though concomitant anticoagulation with heparin is often indicated with antifibrinolytic agents and blood products, it is important to adjust heparin infusion rates and monitor the patient's response when combining these medications. Agents that may enhance the risk of hemorrhage with enoxaparin include anticoagulants and platelet inhibitors.[275,276] Additionally, medications that adversely affect renal clearance can prolong the elimination half-life of enoxaparin and increase the risk of adverse effects.[277]

Immunosuppressive Agents

Therapeutic agents that modulate the immune system are frequently involved in drug-drug interactions. Most immunosuppressive agents possess narrow therapeutic indexes and therefore require therapeutic drug monitoring.[278] As a result, a sophisticated knowledge of clinical pharmacology is required to evaluate the clinical relevance of potential drug-drug interactions involving these drugs. Drug-drug interactions most commonly encountered with immunosuppressive drug therapy revolve around the inhibition or induction of the CYP3A enzymes. Cyclosporine, tacrolimus, prednisone, and sirolimus, all CYP3A substrates, are most prone to these types of pharmacokinetic drug-drug interactions.[279,280] Cyclosporine is extensively metabolized in the liver and GI tract, which explains its low bioavailability. Known CYP3A inhibitors have been used intentionally to maintain therapeutic levels in patients with high presystemic metabolism of cyclosporine.[281] Medications that inhibit CYP3A metabolism should be used with caution in patients taking cyclosporine, tacrolimus, or sirolimus because of the narrow therapeutic index of these agents; dosing adjustments of immunosuppressive therapy may be required. Erythromycin, clarithromycin, voriconazole, fluconazole, posaconazole, itraconazole, ketoconazole, diltiazem, verapamil, indinavir, and ritonavir inhibit CYP3A metabolism.[191,196,282,283] Concomitant administration of sirolimus and cyclosporine increases sirolimus exposure, likely due to shared CYP3A and Pgp metabolic pathways.[284] Several drugs can induce the metabolism of cyclosporine, tacrolimus, sirolimus, and prednisone. Rifampin causes induction of CYP3A and Pgp,[285] leading to clinically significant decreases in cyclosporine and tacrolimus plasma concentrations.[285,286] Although not considered to be a narrow therapeutic index medication, mycophenolate serum concentrations are affected by concurrent administration with cyclosporine. Cyclosporine decreases enterohepatic recirculation of mycophenolic acid neccesitating higher mycophenolate doses to achieve serum concentrations equivalent to that of the drug given alone or with tacrolimus.[287]

Pulmonary and Respiratory Medications

β_2-Adrenergic agonists (e.g., albuterol, levalbuterol, terbutaline) are useful agents for treatment of asthma. Drug-drug interactions can occur when β_2-adrenergic agonists are used in combination with β_1-adrenergic antagonists, especially the nonselective antagonists. A possible decreased β_2 effect could precipitate asthma symptoms. The nonselective antagonists include propranolol, nadolol, and labetalol (see Table 118-6). Agents such as atenolol, esmolol, and metoprolol are relatively selective for β_1 receptors at usual therapeutic doses and therefore are potentially safer to use in combination with β_2-adrenergic agonists. However, these agents may lose their selectivity at higher doses. One potential side effect of the β_2-adrenergic agonists is hypokalemia, which can be enhanced with concurrent use of loop and thiazide diuretics. Monitoring of potassium levels is recommended when these agents are used concurrently.[215]

Antineoplastic Agents

Administration of a live vaccine (e.g., oral polio virus and measles, mumps, and rubella) should be avoided in patients receiving chemotherapeutic agents. Immunosuppression from chemotherapeutic regimens predisposes a patient to active infection when inoculated with a live vaccine. Severe and fatal infections from the combination are reported.[288] Administration of a live vaccine should not be attempted for at least 3 months after all chemotherapeutic agents are discontinued and the patient is in remission.[289]

Potential drug-drug interactions involving the cytochrome P450 enzyme system can be identified by pinpointing the substrates for the various isoenzymes of the mixed function oxidases among the antineoplastic agents. For example, the vinca alkaloids vincristine, vinorelbine, and vinblastine are substrates for CYP3A4. Known inhibitors and inducers of CYP3A4 increase and decrease plasma levels, respectively. Toxicities are more likely when vinca alkaloids are administered with classic CYP3A4 inhibitors such as the azole antifungals, macrolide antibiotics, calcium channel blockers (e.g., diltiazem and verapamil), quinupristin/dalfopristin, and cyclosporine. The azole antifungals modulate the metabolism of cyclophosphamide, increasing overall parent drug and metabolite exposure. Fluconazole increases the cyclophosphamide AUC by inhibiting CYP2C9 metabolism that leads to formation of the toxic metabolite acrolein, in effect reducing potential adverse drug effects.[290] However, the inhibition of the CYP3A4 metabolic pathway by itraconazole increases

formation of the precursor to the acrolein metabolite, increasing toxicity risk.[291] Antiepileptic drugs that are known inducers of the cytochrome P450 enzyme system may contribute to therapeutic failure with chemotherapeutic agents. In one study of pediatric patients with high-grade glioma, the presence of enzyme-inducing anticonvulsants increased irinotecan clearance.[292]

Multiple drug resistance in cancer cells has been attributed to the expression of a Pgp efflux transmembrane transport protein.[177] This protein offers a potential target for future directed therapies in cancer treatment. Agents that modulate the activity of Pgp currently are under development and may provide a drug interaction that favorably increases the efficacy of antineoplastic agents.[293] Coadministration of etoposide and cyclosporine, for example, results in elevation of the mean AUC of etoposide. Etoposide is a CYP3A4 substrate, whereas cyclosporine is both a CYP3A4 and Pgp inhibitor.[294] Inhibitors of the efflux pump, Pgp, increase the cytotoxicity of the vinca alkaloids, anthracyclines, epipodophyllotoxins, and taxanes.[295] Itraconazole, clarithromycin, verapamil, and cyclosporine are known to inhibit Pgp.[79,80] Currently, attempts to obviate the increased toxicity associated with greater drug exposure due to Pgp inhibition have limited clinical application of these therapies.[79,80,293]

Colony-stimulating factors are often used to treat the ensuing neutropenia that accompanies cancer chemotherapy. Patients with lymphomas undergoing their first cycle of vincristine and receiving treatment with filgrastim or sargramostim are at risk for developing a severe atypical neuropathy. The neuropathy has been described as a severe, sharp, burning pain in the feet and appears to occur more commonly in lymphoma patients receiving this combination than in patients receiving vincristine alone.[296] The mechanism of action of this interaction is unclear.

Methotrexate elimination is governed by the kidneys by both filtration and active secretion. The process of tubular secretion requires both a carrier and energy, finite resources that create a saturable process. Competition among other drugs for secretion may lead to reduced clearance of methotrexate with consequent manifestations of toxicity. Concurrent administration of methotrexate with any of the penicillins (piperacillin, amoxicillin, etc.) has demonstrated this capacity.[46,297,298] The NSAIDs, aspirin, and other salicylates all increase the likelihood of methotrexate toxicity by this same mechanism.[33,298a,299-303] Inhibition of renal prostaglandin synthesis and the resultant reduction in renal perfusion also are suggested to contribute to renal toxicities seen with methotrexate because this drug persists in renal tissue for weeks.[70] Proton pump inhibitors may exhibit another mode of interaction on the level of renal elimination. By inhibiting the transmembrane H^+/K^+-ATPase pump, they may decrease active secretion of methotrexate.[304] The antineoplastic activity of methotrexate stems from its inhibition of dihydrofolate reductase, the enzyme that catalyzes reduction of folic acid to tetrahydrofolic acid. In turn, tetrahydrofolic acid serves as a building block for purine and DNA synthesis. The clinician should be aware of other drugs that act along this pathway (e.g., cotrimoxazole and pyrimethamine) because these agents may contribute to the toxicities associated with methotrexate therapy.[70,305]

VII Chapter 119

Airway Management

Ann E. Thompson and Rosanne Salonia

PEARLS

- Safe management of the critically ill child's airway requires an understanding of the anatomic and physiologic changes that occur from birth through adolescence, recognition of congenital and acquired airway abnormalities, appreciation of the pathophysiologic consequences of airway manipulation, and preparation for airways that are potentially difficult to manage.
- Laryngoscopy and intubation are potent physiologic stimuli that are associated with severe discomfort, profound cardiovascular and cerebrovascular changes, and increased airway reactivity.
- Recognizing and preparing to manage a difficult airway are essential for the prevention of potentially lethal complications of intubation.
- The approach to intubation must be tailored to specific circumstances, such as a full stomach, elevated intracranial pressure, cervical spine injury, and upper airway obstruction.
- Alternative approaches to airway management, such as the lighted stylet, laryngeal mask airway, cricothyrotomy, retrograde intubation, and tracheostomy, may be lifesaving.

Accurate assessment and safe management of the airway of a critically ill child is the essential first step in providing effective intensive care. It requires understanding of the anatomic and physiologic changes that occur from birth through adolescence, recognition of congenital and acquired airway abnormalities, appreciation of the pathophysiologic consequences of airway manipulation, and preparation for airways that may potentially be difficult to manage.

Anatomic Considerations

The configuration of the child's airway changes dramatically from birth to adulthood (Figure 119-1). The nose is the site of nearly half of the total respiratory resistance to air flow at all ages. The infant's nose is short, soft, and flat, with small, nearly circular nares. The nasal valve, the narrowest portion of the nasal airway, approximately 1 cm proximal to the alar rim in newborns, measures only about 20 mm^2.[1,2] By 6 months, dimensions of the nares have nearly doubled, but they are still easily occluded by edema, secretions, or external pressure. Although an infant is perhaps not as much the obligate nose breather as commonly assumed, signs of airway obstruction frequently develop when the infant's nose is blocked.[3,4]

In infancy the mandible is small and the basicranium (which provides the roof of the nasopharynx) is flat, creating a small oral cavity. Over the years of its development, the jaw grows primarily down and forward, with the ramus increasing in height and width. The posterior portion of the basicranium develops a progressively more rounded configuration through childhood, which results in a larger nasal airway to meet the need for increased air flow (and provides a chamber for the resonance of adult speech).

Under normal conditions, the genioglossus muscle and other muscles of the pharynx and larynx help maintain airway patency. Both tonic and phasic inspiratory activity synchronized with phrenic contraction have been noted in animal and human studies. In particular, the genioglossus increases the dimensions of the pharyngeal airway by displacing the tongue anteriorly.[5] In the infant and young child, the tongue is large relative to the bony structures surrounding it and the cavities they form. Relatively little displacement is possible at any time, and loss of tone during sleep, sedation, or central or peripheral nervous system dysfunction is more likely than in older patients to allow the tongue to relax into the posterior pharynx and cause upper airway obstruction.

The infant larynx is high in the neck at birth, with the epiglottis at the level of the first cervical vertebra and overlapping the soft palate. This approximation of structures, in combination with the relatively large tongue and small mandible, probably contributes to the vulnerability to airway obstruction in infants and young children. By 6 months the epiglottis has moved to about the level of the third cervical vertebra and is separate from the palate. It continues to descend to its adult position at about the fifth or sixth cervical vertebra by early adolescence. The infant epiglottis is soft and omega shaped, in contrast with the more rigid, flatter adult structure, and it has greater potential to occlude the airway. The immature larynx is funnel shaped, with the subglottic portion angled posteriorly relative to the supraglottic portion rather than forming a straight vertical column, as seen in adults. The larynx tapers to the cricoid cartilage, the narrowest point in the child's extrathoracic airway.

The internal dimensions of the trachea in a newborn are approximately one third those of an adult, and absolute

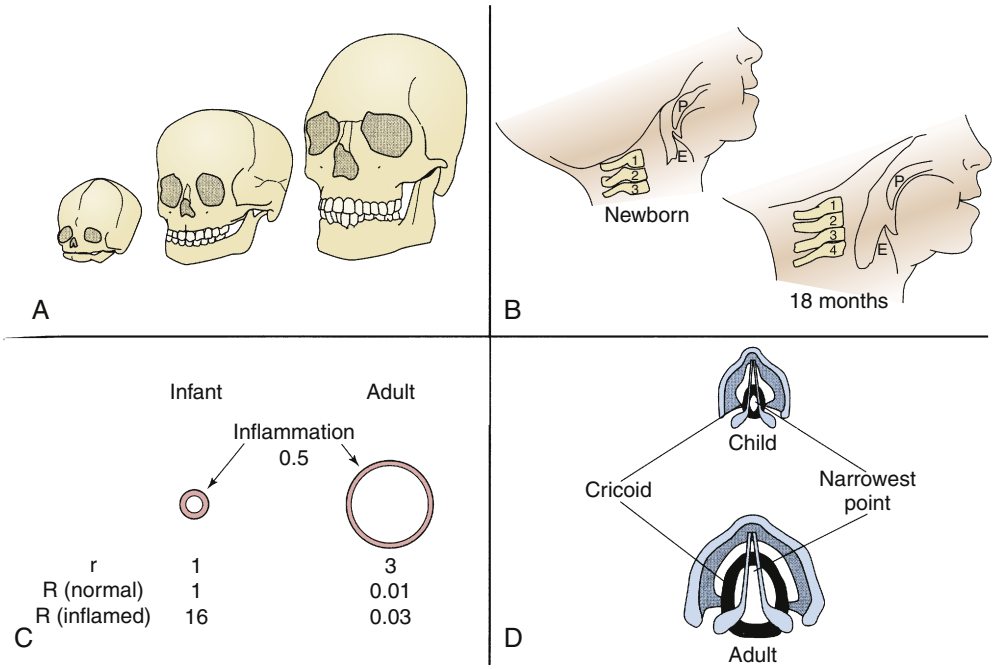

Figure 119–1. Characteristics of the pediatric airway. **A,** Changes in mandibular shape from infancy through adolescence. **B,** The epiglottis is initially cephalad in infancy, then descends throughout childhood. *E,* Epiglottis; *P,* palate. **C,** Edema has a much greater effect on airways resistance in the young child than later in life. *r,* Relative radius of the trachea; *R,* relative airways resistance. **D,** The cricoid is the narrowest portion of the airway until age 8 to 10 years.

resistance to air flow is higher in newborns than in older children and adults. Because the most important factor determining resistance (R) is the radius (r) of an airway (R proportional to 8 l/r^4), small changes in airway diameter in infants or young children as a consequence of edema or secretions have a far greater effect on resistance than similar changes in larger patients (see Figure 119-1).

Basic Airway Management

Airway management depends on a brisk assessment of the patient's breathing and knowledge of the likely progression of the airway problem, that is, deterioration versus improving function. In virtually any setting in which respiratory difficulty is suspected, oxygen should be administered until the specific abnormality can be identified and adequately treated. Although extreme hypercarbia usually is well tolerated, hypoxia is routinely catastrophic and is not necessarily obvious on initial examination. From the alveolar air equation, it is obvious that hypercarbia produces hypoxia at low fraction of inspired oxygen (Fio_2) (Table 119-1). If the patient is breathing spontaneously, attention is directed first to signs of upper airway obstruction, including absence of audible or palpable air flow, stertorous sounds, stridor, or a rocking chest and abdominal motion rather than the normal, smooth rise and fall that should occur with inspiration and expiration.

An alert child with normal neuromuscular function usually instinctively assumes a body position that minimizes upper airway obstruction. However, a child with an altered level of consciousness or severe neuromuscular weakness may be unable to maintain a patent airway because of the inability to alter his or her position or maintain adequate glossopharyngeal muscle tone.

Table 119–1 Impact of Providing Supplemental Oxygen During Hypercarbia on Alveolar Oxygen Tension

Alveolar gas equation:	$P_{AO_2} = Fio_2 (PB - P_{H_2O}) - Paco_2/0.8$
Room air, normocarbia:	$P_{AO_2} = 0.21 (760 - 47) - 40/0.8 = 99$ mm H_2O
Room air, hypercarbia:	$P_{AO_2} = 0.21 (760 - 47) - 80/0.8 = 50$ mm H_2O
Supplemental O_2, hypercarbia:	$PA_{O_2} = 0.4 (760 - 47) - 80/0.8 = 185$ mm H_2O

Fio_2, Fraction of inspired oxygen; *P_{AO_2},* partial pressure of oxygen, alveolar.

Nasopharyngeal Airway

A nasopharyngeal airway that extends through nasal passages to the posterior pharynx and beyond the base of the tongue often is adequate to relieve obstruction and is tolerated by most patients, even those who are conscious (Figure 119-2). An appropriate-size airway extends from the nares to the tragus of the ear and is of the largest diameter that passes through nasal passages without causing blanching of the skin surrounding the nares. The airway tube should be well lubricated before placement. Risks of nasopharyngeal airways include nasal ulceration, bleeding, laceration of friable lymphoid tissue, rupture of a pharyngeal abscess, laryngospasm, and potential passage through the cribriform plate in patients with basilar skull fractures. Topical vasoconstricting agents reduce but do not eliminate the risk of bleeding. Like other nasal tubes, use of nasal airways increases the risk of sinusitis;

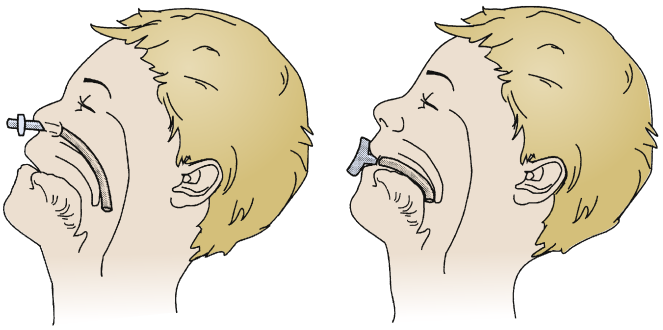

Figure 119–2. Nasopharyngeal and oropharyngeal airways in good position.

therefore, contraindications to their use include severe coagulopathy, cerebrospinal fluid (CSF) leaks, and basilar skull fractures.

Oropharyngeal Airways

Oropharyngeal airways displace the base of the tongue from the posterior pharyngeal wall and break contact between the tongue and palate (see Figure 119-2). Size selection is important. An excessively long airway may encroach upon the larynx and cause laryngospasm. An airway that is too short may actually push the tongue posteriorly and exacerbate obstruction. If the airway is held at the side of the face with the flange just anterior to the incisors, the tip should be at or near the angle of the mandible. The airway should be positioned following the curve of the tongue while the tongue is held down and forward with a tongue depressor. Inserting the airway with its concave side facing the palate and then rotating it may traumatize the oral mucosa or damage teeth. Oral airways are poorly tolerated in any patient with a functional gag reflex and may induce vomiting. As a consequence, they are of little more than temporary value in the critically ill child. They may support a patent airway for bag-valve-mask ventilation in preparation for intubation.

Oxygen Delivery Devices

Nasal Cannulas

Nasal cannulas consist of two hollow prongs projecting from a hollow face piece. Humidified oxygen (100%) flows from a standard source, effectively delivering a pharyngeal concentration of 25% to 40% after mixing with variable amounts of room air. The cannulas are easy to use, often readily tolerated, lightweight, economical, and disposable and take advantage of the humidifying properties of the nasopharynx. Flow typically is limited to only 3 to 5 L/min because of the extent to which relatively dry gas flow cools and dries the nasal airway. The use of nasal cannulas is limited by the relatively low oxygen concentration that can be delivered. High-flow nasal cannulas can deliver up to 40 L/min of warmed, humidified gas and are generally very well tolerated, although the noise level for the patient can be high. The oxygen concentration delivered is higher than with simple nasal cannulas. High-flow nasal cannulas generate positive distending pressure similar to that provided by nasal continuous positive airway pressure. The pressure generated is dependent on the interaction among the flow rate, patient size, and anatomy of the patient's airway, but it is probably limited to 4 to 5 cm H_2O.[6,7] At least in infants, positive pressure generation requires a closed mouth.[8]

Oxygen Hoods

Oxygen hoods are cylinders or boxes that enclose an infant's or small child's head. Oxygen enters through a gas inlet port, and exhaled gas leaves primarily through the opening for the neck. Hoods provide up to 80% to 90% oxygen, good humidification, and controlled temperature. They allow easy access to the child for other care. Tents for older children provide the same environment advantages but allow less ready access to the patient and usually provide only 21% to 50% oxygen. Both have the disadvantage of being very noisy for the patient and are much less commonly used than in the past.

Masks

A variety of masks are available for delivering oxygen. Simple masks fit loosely. The oxygen concentration delivered varies, depending on the patient's inspiratory flow rate and the oxygen flow into the system. Partial rebreathing masks incorporate some sort of reservoir, usually a bag below the chin. Provided that flow into the system exceeds the patient's minute ventilation and that the bag does not collapse on inspiration, little carbon dioxide is inhaled, and concentrations of oxygen up to about 60% can be achieved. Nonrebreathing masks must fit snugly. They incorporate a mask, reservoir, and one-way valves that vent expired gas but do not permit inspiration of room air. As a result, they can deliver close to 100% oxygen.

Noninvasive Positive Pressure Ventilation. Continuous positive airway pressure (CPAP) delivers high concentrations of oxygen and maintains positive airway pressure in the spontaneously breathing patient. CPAP is applied with an oxygen source connected to either a tight-fitting nasal or full-face mask or helmet in children or via nasal prongs in the neonate and older infant. CPAP offers the benefit of maintaining alveolar expansion and decreases work of breathing for many patients, particularly those with pulmonary parenchymal disease, as well as for some patients with airway obstruction related to poor upper airway tone or laryngeal, tracheal, or bronchomalacia.

Like CPAP, bilevel positive airway pressure (BiPAP) can be provided by mask, but it requires a ventilator to assist with flow delivery. The patient's inspiratory effort triggers the BiPAP machine to deliver decelerating flow in order to reach a preset pressure, defined as inspiratory positive airway pressure. When a patient's own inspiratory flow falls below a preset amount, ventilatory assistance ceases and maintains expiratory airway pressure at a predetermined value (typically between 5 and 10 mm Hg). Uses in the pediatric intensive care unit (PICU) include upper airway obstruction, atelectasis, exacerbations of neuromuscular disorders, support for mild to moderate respiratory failure, and as an assist in weaning patients from invasive mechanical ventilation.

Both CPAP and BiPAP offer the advantage of providing respiratory support without endotracheal intubation but require that the child tolerate a close-fitting mask. A more extensive discussion of CPAP and BiPAP is available in Chapter 49, Mechanical Ventilation and Respiratory Care.

Establishing a Functional Airway

A patient who is apneic or in very severe respiratory distress requires ventilation assisted initially with a bag and mask. Probably no skill is more important for the intensivist than the ability to provide effective manual bag-mask ventilation. It can be lifesaving while preparation for endotracheal intubation proceeds or when intubation cannot be accomplished. Effective technique requires positioning the patient adequately to open the upper airway, achieving a good mask-face seal, inserting an oral or nasal airway if needed, and generating an adequate tidal volume, coordinating manual breaths with patient efforts when they are present. Poor technique results in ineffective oxygenation and ventilation, gastric insufflation, and increased risk of aspiration.

If the child is too weak or obtunded to maintain pharyngeal tone independently, the head should be placed on a thin cushion to cause slight cervical spine flexion and gentle extension at the atlantooccipital joint. In infants, the large occipitofrontal diameter makes the cushion unnecessary, although a thin pad under the shoulders may be useful. It appears that aligning the external auditory meatus with the sternal notch is a reasonable guide to appropriate positioning. Current recommendations are to avoid overextending the baby's very flexible cervical spine, which may stretch and compress the trachea and potentiate, rather than relieve, obstruction. Studies have questioned the existence of this phenomenon but to date have included a very small number of infants, all with normal airways.[9] Appropriate head tilt separates the tongue from the posterior pharyngeal wall. If airway obstruction persists, the chin can be pulled forward by encircling the mandible behind the lower incisors between the thumb and fingers. The most effective means of relieving functional obstruction is the so-called *triple airway maneuver:* With the fingers behind the vertical ramus of the jaw, the mandible is displaced downward, forward, and finally upward again until the mandible and lower incisors are anterior to the maxilla. This action effectively pulls the tongue forward and away from the pharyngeal wall.

In some patients, establishing a functional airway is sufficient to allow resumption of effective spontaneous ventilation. In other patients, steady positive airway pressure is necessary to overcome residual obstruction. If breathing remains inadequate, manual ventilation is necessary. Effective ventilation requires a good mask fit. The mask should sit smoothly on the bridge of the nose and the bony prominence of the chin. It is important to avoid airway occlusion with the mask or hand or pressure on eyes, soft nasal structures, or branches of the trigeminal and facial nerves. A good mask fit is predictably difficult in a patient without teeth, a very flat or prominent nose, or micrognathia. Insertion of a nasal or oropharyngeal airway may help maintain an adequate airway. Once a good mask fit is ensured, ventilation may be assisted.

Two types of bags are in general use: self-inflating resuscitation bags and standard anesthesia bags. Because self-inflating bags vary substantially, specific directions for their use must be followed carefully. All bags incorporate an adapter to connect to a mask or endotracheal tube, a bag, a pressure-relief valve, and a port for fresh gas inflow. Most bags designed for children have pressure-relief valves designed to pop off at 35 to 45 cm H_2O pressure to prevent excessive volume delivery and subsequent barotrauma. In patients with very poor compliance or increased airway resistance, it may be necessary to bypass this valve temporarily to provide effective ventilation. Most systems incorporate valves that prevent rebreathing. Fresh gas flows through the valve on spontaneous inspiration (negative pressure) or on creation of positive pressure by squeezing the bag (Figure 119-3). Exhaled gas is vented to

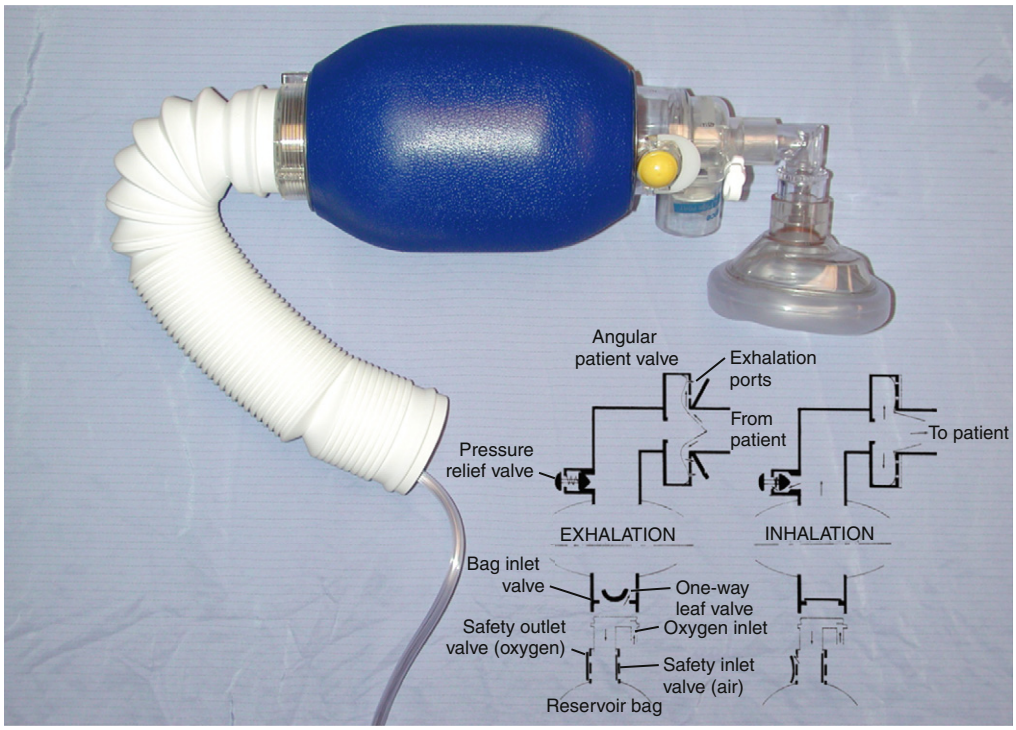

Figure 119–3. Self-inflating manual ventilation bag with tubing as a reservoir. **Inset** shows function of one type of valve, permitting manual positive pressure breathing, or spontaneous breathing, but requiring generation of negative pressure by the patient to open the valve. Simply holding the mask over the patient's face does not provide supplemental oxygen.

the atmosphere. Not all systems allow spontaneous breathing; those that do demand that the patient generate at least a little negative pressure, so a good mask fit is necessary. Holding the mask above the patient's face provides no supplemental oxygen. The percentage of oxygen delivered depends on the percentage of oxygen from the source, the fresh gas flow rate, and the respiratory rate, which determines the time available for the bag to refill. Most systems require some sort of reservoir assembly in addition to the self-inflating bag to prevent entrainment of room air. With a reservoir, 100% oxygen may be delivered; without a reservoir, most deliver less than 50%.

Anesthesia bags require flow from a source of gas under pressure in order to expand. Many variations have been reviewed extensively in the anesthesia literature. These circuits depend on the location of the fresh gas inflow and overflow valves, the rate of fresh gas flow, the respiratory rate, tidal volume, carbon dioxide production, and whether ventilation is spontaneous or controlled. Many ICUs use the Mapleson D configuration, with the fresh gas source attached just distal to the patient connection. The overflow valve is proximal to the reservoir bag. During expiration, the patient's exhaled tidal volume mixes with fresh gas flowing into the system and accumulates in the tubing and bag. With sufficiently high fresh gas flow, alveolar gas is washed to the overflow valve and eliminated from the circuit. The system requires higher fresh gas flow to avoid rebreathing during spontaneous ventilation than during controlled breathing, but a safe rule of thumb recommends fresh gas flow two to three times the minute ventilation. During controlled ventilation, a minimum of 100 mL/kg/min ensures that carbon dioxide elimination is proportional to minute ventilation.[10,11] At flows less than 90 mL/kg/min, increasing ventilation may only increase CO_2 rebreathing.

Endotracheal Intubation

The pediatric intensivist is frequently called upon to intubate critically ill patients when brief periods of ventilation with a bag and mask are inadequate to reverse the underlying disorder. Few of these intubations are performed under the optimal conditions commonly attainable in the operating room, that is, relatively healthy children with empty stomachs who have previously been sedated and are intubated in a controlled environment with all members of the team experienced in and prepared for airway management. Instead, patients are often critically unstable and require intubation suddenly, often in settings where the procedure is not routine. Intubation often is viewed only as a means to an end, namely, mechanical ventilation. However, it is associated with profound physiologic effects that may dramatically affect the patient. The intensivist's appreciation of these factors and ability to minimize the adverse physiologic consequence of airway manipulation may as decisively determine patient outcome as his or her skill in providing the intensive care that follows.

Indications

Respiratory Failure

Respiratory failure may result from dysfunction at any point along the ventilatory pathway. To provide appropriate support and to avoid hazards specific to the individual disorder, airway intervention must be tailored to the underlying cause. Outside the operating room, the need for intubation is most commonly associated with respiratory failure resulting from upper or lower airway or pulmonary parenchymal disorders that require mechanical ventilation. Respiratory failure is defined in terms of excessive work of breathing or inadequate oxygenation (in the absence of cyanotic congenital heart disease) or carbon dioxide elimination. Box 119-1 contains one set of criteria for intubation.

Hemodynamic Instability

Patients with hemodynamic instability often benefit from assisted ventilation. The need for controlled ventilation as a component of cardiopulmonary resuscitation is obvious. In addition, early intubation in anticipation of impending cardiovascular collapse may prevent catastrophic tissue hypoxia. Redistribution of blood flow away from respiratory muscles, especially the diaphragm, in patients with marginal cardiac output may improve perfusion of other vital organs, including the heart, and help prevent cardiac arrest.[12-16]

Neuromuscular Dysfunction

For additional information on neuromuscular dysfunction, see Chapter 58.

Neuromuscular dysfunction or severe chest wall instability (or deformity) may cause failure of the bellows apparatus for breathing.[17] Initially, tidal volume remains normal or at least sufficient to maintain normal blood gas tensions, but vital capacity and maximal inspiratory and expiratory pressures decrease. Inability to take a deep breath or cough forcefully risks progressive segmental or lobar atelectasis, inability to clear secretions, bronchial obstruction, and possible major airway obstruction with sudden severe hypoxia or carbon dioxide retention. Increasing weakness results in progressively smaller tidal volumes, loss of upper airway tone, and, ultimately, inadequate minute ventilation. Bulbar dysfunction may lead to aspiration as a result of impaired swallowing and inadequate cough.

Measurement of ventilatory reserve provides a better assessment of the patient's need for ventilatory assistance than does arterial blood gas tensions alone. Maximum negative inspiratory pressure and vital capacity are two simple, commonly

Box 119–1 Indications for Intubation

1. Pa_{O_2} <60 mm Hg with fraction of inspired oxygen ≥0.6 (in absence of cyanotic congenital heart disease)
2. Pa_{CO_2} >50 mm Hg (acute and unresponsive to other intervention)
3. Upper airway obstruction, actual or impending
4. Neuromuscular weakness
   - Maximum negative inspiratory pressure ≥20 cm H_2O
   - Vital capacity <12–15 mL/kg
5. Absent protective airway reflexes (cough, gag)
6. Hemodynamic instability (cardiopulmonary resuscitation, shock)
7. Controlled therapeutic (hyper)ventilation
   - Intracranial hypertension
   - Pulmonary hypertension
   - Metabolic acidosis
8. Pulmonary toilet
9. Emergency drug administration

used tests for this purpose. A variety of other measures also help assess respiratory "strength," but most are difficult to perform in sick, uncooperative infants and children. Patients with diffuse neuromuscular weakness of any cause, spinal cord dysfunction above the level of T6, or loss of phrenic nerve or diaphragm function are particularly prone to respiratory failure.[18] Because of the extreme compliance of their chest walls and relative ineffectiveness of intercostal muscles, infants younger than approximately 6 months tolerate diaphragmatic paralysis poorly.[19-23]

Many patients with neuromuscular weakness respond well to noninvasive forms of ventilatory support.[17,24] Decisions about the best approach to airway management should be based on the nature and likely progression of the illness, the child's maturity and level of consciousness, and the timing of the onset of respiratory insufficiency. In an emergency, endotracheal intubation is likely to be safest, with transition to noninvasive support when careful planning allows.[24]

Failure of Central Nervous System Regulation of Ventilatory Drive

Failure of central nervous system regulation of ventilatory drive may prompt intubation (see Chapters 54 and 57). Centrally mediated hypoventilation is manifest as CO_2 retention, usually in the absence of increased work of breathing. On occasion the decision to support ventilation may be based on observing abnormal ventilatory patterns in anticipation of neurologic deterioration. Loss of protective airway reflexes, including the cough and gag reflexes, can result from central nervous system depression, cranial nerve abnormalities, or severe motor weakness. In such patients, intubation is indicated to prevent aspiration. Intubation may be appropriate in anticipation of the need to protect the airway and support ventilation during deep sedation for procedures or diagnostic studies.

Other Indications

Intubation is indicated as a step toward therapeutic controlled (hyper)ventilation (e.g., in patients with increased intracranial pressure [ICP] or pulmonary hypertension) or to support spontaneous hyperpnea in patients with metabolic acidosis and other conditions. Patients with profuse, thick, or tenacious secretions (e.g., as a result of bacterial pneumonitis or smoke inhalation) may benefit from an artificial airway as a means of providing effective suction. Impaired mucociliary clearance occurs in patients exposed to high oxygen concentrations or other airway irritants (including particulate and gaseous components of smoke), those experiencing severe hypoxia or hypercarbia, and, paradoxically, those who have airway trauma induced by endotracheal intubation and suctioning. Endotracheal intubation also provides an effective means of delivering drugs during cardiopulmonary resuscitation when venous or intraosseous access is not available (see Chapter 34).

Physiologic Effects of Intubation

Laryngoscopy is a potent physiologic stimulus (Box 119-2).[25,26] At the very least, laryngoscopy is uncomfortable, causing significant pain and severe anxiety, especially in children who cannot understand or accept the need for it. Laryngoscopy causes an increase in systemic blood pressure and heart rate initiated by pressure on the back of the tongue or lifting the epiglottis.[27] This effect is augmented by endotracheal intubation and suction.[28] Nodal or ventricular dysrhythmias may occur. Sensory impulses triggering this reflex probably are carried along the vagus nerve supplying the base of the tongue, epiglottis, and trachea. The efferent limb is less well defined but most likely is the product of enhanced sympathetic activity. Infants respond more variably than do older patients. Hypertension develops in most patients, but a few become hypotensive, especially if they are hypoxic.[29] They may demonstrate moderate-to-severe bradycardia rather than tachycardia, perhaps as a consequence of their greater parasympathetic tone. Sedation and light anesthesia decrease but do not obliterate the hypertension and tachycardia; surface anesthesia and deeper general anesthesia are more effective.[30] Children with previous hypertension display an exaggerated vasopressor response. Sedation and neuromuscular blockade during airway manipulation in infants minimizes the associated bradycardia and systemic hypertension.[31-35] The impact of positive pressure ventilation on cardiac performance depends on the underlying disorder (discussed in Chapter 26) but should be carefully considered in preparation for intubation.

Box 119–2 Potential Physiologic Effects of Laryngoscopy and Intubation

Pain
Tachycardia
Anxiety
Bradycardia
Hypoxia
Systemic hypertension
Hypercarbia
Decreased systemic venous return
Increased intraocular
Decreased jugular venous pressure return
Increased intragastric pressure
Increased intracranial pressure
Laryngospasm
Bronchoconstriction
Pulmonary hypertension

Laryngoscopy and intubation are potent stimulators of laryngospasm and may cause bronchoconstriction, especially in patients with a history of reactive airway disease. Increased airway resistance probably results from parasympathetic stimulation, with release of acetylcholine and stimulation of muscarinic receptors on airway smooth muscle, especially large central airways.

During intubation, oxygen delivery to the patient is commonly interrupted. Ineffective breathing or apnea increases the likelihood of hypoxia, especially in children, with their relatively low functional residual volume and higher basal metabolic rate. Patients with severe pulmonary disease and abnormally low functional reserve capacity are at particular risk.[31,34] During apnea, carbon dioxide tension increases at a rate of 3 to 4 mm Hg/min in healthy, sedated adults and probably more rapidly in children, particularly those with severe cardiopulmonary disease or increased metabolic rate resulting from fever, sepsis, or pain.[36,37]

ICP rises immediately during laryngoscopy even in patients without intracranial pathology before changes in blood gas

Box 119–3 Recognizing the Difficult Airway

History

Midline clefts or high arched palate
Limited temporomandibular joint mobility
Micrognathia
Nasal obstruction
Limited neck mobility
Laryngotracheal abnormalities (congenital or acquired)

tensions occur.[30,32,38,39] Cerebral metabolic rate and blood flow increase. Hypoxia, hypercarbia, and diminished jugular venous drainage, particularly in struggling patients, contribute further to increases in cerebral blood volume and increased intracranial pressure. Although normally very transient, such intracranial hypertension may predispose patients with coagulopathies or vascular malformations to intracranial hemorrhage. Systemic hypertension in patients with impaired autoregulation of the cerebral circulation (e.g., sick infants or patients with a variety of intracranial disorders) and impedance to jugular venous return by jugular compression, pneumothorax, or coughing and struggling stress both the arterial and venous sides of the cerebral circulation. In patients with poor intracranial compliance, this effect is exaggerated and prolonged. In infants without primary central nervous system disease, muscle paralysis (even without sedation or analgesia) effectively blocks the rise in ICP associated with intubation.[34] The systemic hypertensive response is generally unaffected by neuromuscular blocking agents but can be modified by analgesia and sedation or intravenous anesthesia.

Patients with severe pulmonary hypertension are at high risk for adverse effects of laryngoscopy. Decreased oxygenation and progressive hypercarbia lead to elevated pulmonary artery pressure. The noxious stimulus of visualizing the airway in itself may precipitate life-threatening hypertension.

Recognition of a Difficult Airway

Recognition of a difficult airway is important if potentially lethal surprises in airway management are to be minimized (Box 119-3). Although the intensivist is usually focused on the immediate physiologic disturbances affecting the patient, careful preparation and as thorough an evaluation of each individual patient as is possible is critical. Key components of the history and physical examination, as well as the clinical scenario, can provide insight into potential problem airways. A history of difficult intubations in the past or episodes of upper airway obstruction (including snoring or sleep apnea) suggest structural abnormalities that may or may not be evident at the moment. Recent tonsillectomy and adenoidectomy, cleft palate repair, or any prolonged surgical procedure resulting in oral edema or bleeding increase the likelihood of difficulty. Examining facial structure is essential, and inspecting the child's profile is particularly important because significant abnormalities may not be fully apparent on frontal view alone (Figure 119-4). Certain genetic syndromes are associated with craniofacial anomalies, midline defects, or neuromuscular disorders that may make successful intubation via standard techniques exceptionally difficult. Treacher Collins syndrome (mandibulofacial dysostosis), Goldenhar syndrome (oculoauriculovertebral dysplasia), Down syndrome, Pierre Robin syndrome, and the mucopolysaccharidoses, such as Hurler syndrome and Hunter syndrome, are a few of the syndromes that have characteristic features that suggest the high probability of facing a challenging airway. Isolated micrognathia, macroglossia (glossoptosis), facial clefts, midface hypoplasia, prominent upper incisors or maxillary protrusion, facial asymmetry, a high arched narrow palate, a small mouth, and a short, muscular neck or morbid obesity are features that can interfere with effective bag-mask ventilation or visualization of the larynx. Limited temporomandibular joint or cervical spine mobility may make laryngoscopy and tube placement very difficult. Midface instability or upper airway bleeding, edema, airway or neck masses, and foreign bodies are additional reasons for concern.[40]

Several classification systems assist with recognition and classification of the adult patient with a difficult airway. Although never validated in pediatrics, they provide a useful framework for assessing infants and children. The Mallampati classification (Figure 119-5) assesses visualization of upper airway structures prior to intubation— particularly the uvula, soft palate, and faucial pillars—as a guide to the likely ease of intubation. Mallampati class 1 allows visualization of the uvula, soft palate, and faucial pillars; in class 2, faucial pillars and soft palate are visualized but the uvula is obstructed by the base of the tongue; in class 3 only the soft palate is visualized; and in class 4 the soft palate is not seen. Difficult intubation is more likely associated with classes 3 and 4. This scale can be used with cooperative children, and an approximate evaluation may be obtained by observing many crying infants and young children.

The Cormack laryngeal view grade score is shown in Figure 119-5, *B*. Because the Cormack system requires an attempt to visualize the larynx, it is more valuable as a tool for describing difficulty once it has been encountered than for predicting it. The Cormack score is grade 1, full view of vocal cords and glottis; grade 2, partial view of vocal cords and glottis; grade 3, only the epiglottis is seen; and grade 4, the glottis and epiglottis are not visualized. Grades 3 and 4 predict difficult direct laryngoscopy.[41] Although these classification systems are helpful in a controlled environment, particularly the preoperative area of a hospital, they are recognized as having limited utility in the emergent situations often encountered in the ICU, and their ability to predict the degree of difficulty with intubation in children is not well established.[42]

Ability to visualize the faucial pillars, soft palate, and uvula usually predicts an uncomplicated intubation, but this may be difficult to assess in a sick, uncooperative child.[43] Children with severe hypoxia, severe hypovolemia, or other causes of hemodynamic instability, such as intracranial hypertension, a

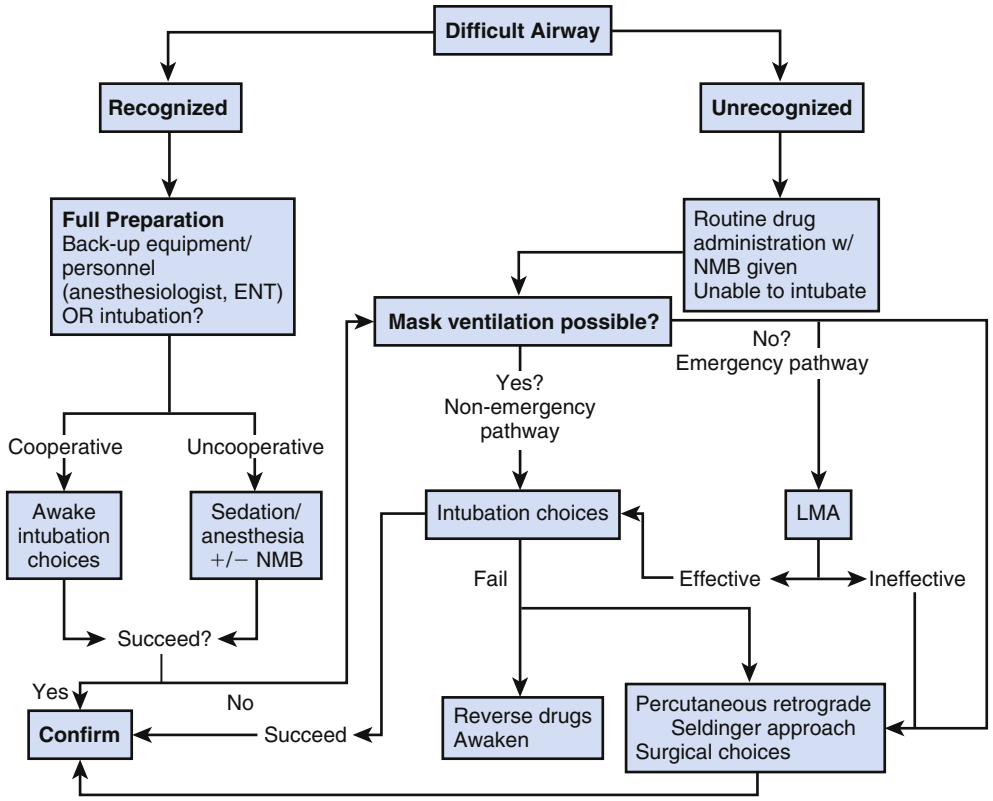

Figure 119–6. Modification of the American Society of Anesthesiologist's difficult airway algorithm. *(From Practice guidelines for the management of the difficult airway: an updated report by the American Society of Anesthesiologists Task Force on Management of the Difficult Airway,* Anesthesiology *98:1269, 2003.)*

full stomach, or some combination of these conditions, present added difficulties that must be considered.

When airway problems are anticipated, the intensivist should approach intubation with a plan specific to the difficulty noted and with a backup strategy in mind.[44,45] Extra equipment should be on hand, including a variety of laryngoscope blades, forceps, tubes, bronchoscopes, tracheostomy or cricothyrotomy trays, and additional skilled personnel as needed.[46] If sedation is required, agents that can be reversed pharmacologically are desirable and should be titrated slowly to the desired effect. Figure 119-6 shows a modification of the American Society of Anesthesiologist's difficult airway algorithm and provides an approach to managing the difficult airway.[47] A similar plan is necessary at the time of extubation, with serious consideration given to extubation in the operating room or with an airway exchange catheter left in place to facilitate reintubation if necessary.

Process of Intubation

All equipment for intubation must be available prior to the procedure (Figure 119-7). A source of suction and appropriate catheters, oxygen and necessary tubing, ventilation bag, mask, laryngoscope and proper-sized blade with a well-functioning light, endotracheal tubes of the expected size and larger and smaller sizes, airway forceps, stylet, and a means of securing the endotracheal tube should be present at the head of the bed so that the intubator does not need to look away from the patient. A functioning intravenous catheter for drug infusion is essential in all but the most extreme emergencies.

Laryngoscope handles are available in standard adult and pediatric sizes. The smaller diameter of the pediatric handle makes it easier to manipulate, particularly when intubating infants and very young children. Blades of many descriptions are available. The most important characteristic is length. Inexperienced operators often select a blade that is too short, making visualization of the larynx difficult. Excessively long blades make it difficult to avoid pressure on the upper lip and teeth. Straight blades provide good exposure in infants and young children. The slightly curved tip of the Miller blade makes visualization of the larynx possible without actually lifting the epiglottis. The broader blade and bore of the Wis-Hipple blade helps displace soft tissues in the young infant's oropharynx. The Miller No. 2 blade is especially versatile in a broad age group (i.e., children about 3 to 10 years of age). In older children, use of a curved blade is often works best. If a cuffed endotracheal tube is to be used, a curved Macintosh No. 2 or 3 blade is effective in the majority of patients and may provide more room to manipulate a cuff in the oropharynx.

Selecting the proper tube size (diameter) is important, both to achieve effective mechanical ventilation and to prevent tracheal injury. A variety of formulas are in use, with the most common being that of Cole: Tube size (inner diameter) = (Age [years]/4) + 4. For infants, no formula is very accurate. Table 119-2 gives reasonable guidelines. Individual differences require that the tube size be modified for each child so that the tube passes easily and allows gas to leak around it at roughly 15 to 30 cm H_2O pressure but fits snugly enough to allow delivery of adequate mechanical breaths at a given chest compliance.

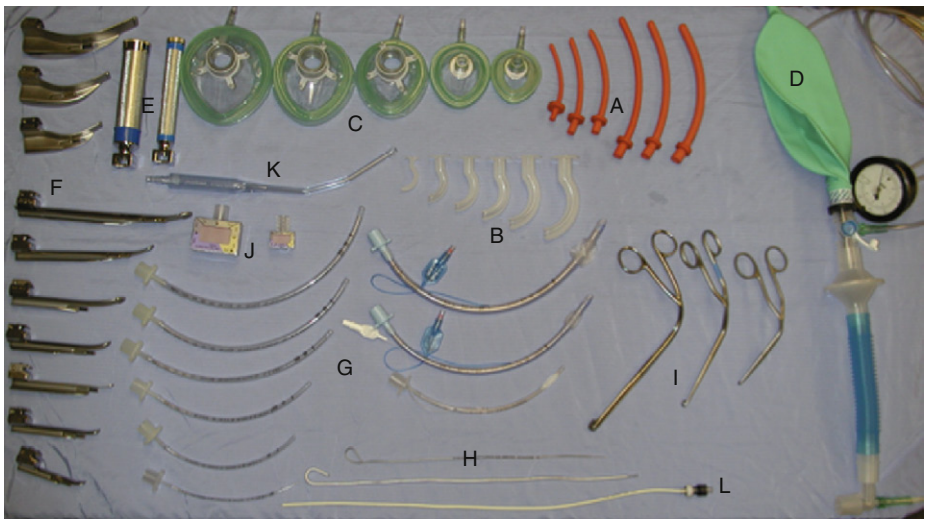

Figure 119–7. Equipment for intubation, showing a variety of sizes available for pediatric patients. *A,* Nasopharyngeal airways. *B,* Oral airways. *C,* Masks. *D,* Anesthesia (Mapleson) bag. *E,* Laryngoscope handles. *F,* MacIntosh (curved) and Miller (straight) laryngoscope blades. *G,* Uncuffed and cuffed endotracheal tubes. *H,* Endotracheal tube stylets. *I,* Magill forceps. *J,* End-tidal CO_2 detectors. *K,* Yankauer suction. *L,* Tube changer.

Table 119–2 Guidelines for Endotracheal Tube Diameter in Infants and Children

Age	Internal Diameter	Orotracheal Length (cm)	Nasotracheal Length (cm)
Premature	2.0–3.0	6–8	7–9
Newborn	3.0–3.5	9–10	10–11
3–9 mo	3.5–4.0	11–12	11–13
9–18 mo	4.0–4.5	12–13	14–15
1.5–3 y	4.5–5.0	12–4	16–17
4–5 y	5.0–5.5	14–16	18–19
6–7 y	5.5–6.0	16–18	19–20
8–10 y	6.0–6.5*	17–19	21–23
11–13 y	6.0–7.0*	18–21	22–25
14–16 y	7.0–7.5*	20–22	24–25

Ideal tube size varies according to age, height, weight, specific airway anatomy, and ventilatory requirements of a child. In general, an air leak around the tube at 15 to 30 cm H_2O pressure is desirable.
*Cuffed tube.

Traditional teaching has held that use of cuffed endotracheal tubes is not necessary or appropriate in young pediatric patients (younger than 8 years) because the narrow diameter of the trachea at the cricoid ring allows a fairly snug fit without a cuff, and a cuff may make tracheal injury at that level more likely. In addition, the bulk of the cuff usually requires using a tube of 0.5 mm smaller diameter, with the associated increased resistance to gas flow and greater risk of occlusion. Cuffed tubes are routinely recommended for children older than 8 to 10 years because the cricoid ring has been replaced by the triangular opening of the vocal cords as the narrowest point in the airway (see Figure 119-1). In addition, the greater elastic recoil of the lungs and chest wall of older patients may demand higher airway pressures for effective ventilation.

However, cuffed tubes of all sizes are available and may be useful in patients in whom consistent minute ventilation is essential (e.g., in the presence of severely elevated ICP or very reactive pulmonary vasculature) or those requiring relatively high airway pressures. Although data are limited, evidence is growing that cuffed tubes can be used in young children without higher incidence of airway complications.[48-52] The modern low-pressure, high-volume cuff requires a much lower pressure to obtain a seal than did the endotracheal tube cuffs of the past. When a cuffed tube is used, great care should be taken to inflate it with the "minimum occlusive volume," the minimum volume required to "just seal" the gas leak around the tube during mechanical inspiration and prevent mucosal ischemia and subsequent tracheal damage. Potential advantages of cuffed tubes include decreased likelihood of multiple intubations to identify the correct size and avoidance of changing the endotracheal tube of a critically unstable patient if lung disease worsens. In addition, absence of a significant leak around the endotracheal tube (ETT) may decrease the likelihood of flow-triggered ventilator autocycling. The ability to occlude the leak also facilitates pulmonary function testing and indirect calorimetry.

Pharmacologic Agents Facilitating Intubation

Although intubation often is possible without use of drugs, the physiologic and psychological benefits of their use usually outweigh the disadvantages.[53,54] Analysis of data in the pediatric National Emergency Airway Registry shows that intubation success rate is higher when both sedation and neuromuscular blockade are used.[55] This finding is equally true in neonates, in whom sedation and neuromuscular blockade are still commonly not used, with no evidence they are harmful.[56] In neonates the predominance of evidence indicates that use of neuromuscular blockade is associated with a lower risk of intracranial hemorrhage and pulmonary airleak.[57] Excellent technical airway skills are an absolute prerequisite, however, because loss of control of the airway invites catastrophe. Drugs facilitating intubation are listed in Table 119-3.

Table 119–3 Drugs Facilitating Intubation

Drugs	Dose	Duration	Comments
INTRAVENOUS ANESTHETICS			
Thiopental	4–7 mg/kg IV	5–10 min	Anesthesia, apnea, myocardial depression, decreased venous tone, ↓ $CMRO_2$, ↓ CBF, ↓ ICP, ↓ IOP
Etomidate	0.3 mg/kg IV	3–5 min	Anesthesia, adrenal suppression (↑mortality in sepsis?), minimal CV effect, apnea, ↓ $CMRO_2$, ↓ CBF, ↓ ICP
Ketamine*	1–2 mg/kg IV; 4–6 mg/kg IM	10–15 min	Anesthesia, ↑ systemic arterial pressure, ↑ HR, ↑ ICP, ↑ IOP, hallucinations, laryngospasm, bronchodilation
Propofol	1–3.5 mg/kg IV, then 0.05–0.3 mg/kg/min	10–15 min	↓ Systemic arterial pressure, ↓ $CMRO_2$, ↓ CBF, ↓ ICP, metabolic acidosis
SEDATIVES/ANALGESICS			
Fentanyl*	2–5 μg/kg IV	30–90 min	Analgesia, respiratory depression, cardiovascular stability, occasional bradycardia, or chest wall rigidity
Remifentanil	1–3 μg/kg, then 0.25–1 μg/kg/min		Analgesia, respiratory depression, cardiovascular stability
Morphine*	0.1–0.2 mg/kg IV	2–4 h	Analgesia, respiratory depression, ↓ systemic arterial and venous tone, ↓ systemic blood pressure
Midazolam*	0.1–0.3 mg/kg IV	1–2 h	Amnesia, sedation or euphoria, ± cardiovascular stability, occasional respiratory depression
Lorazepam	0.1–0.3 mg/kg IV	2–4 h	Sedation, anxiolysis, minimal cardiovascular effect
NEUROMUSCULAR BLOCKING AGENTS			
Rocuronium*	0.6–1.2 mg/kg IV	15–45 min	Minimal cardiovascular effect, prolonged duration in liver failure
Vecuronium*	0.1–0.3 mg/kg IV	30–75 min	Minimal cardiovascular effect, prolonged effect in hepatic failure
Cis-atracurium	0.1 mg/kg, then 1–5 mg/kg/min	20–35 min	Metabolized by plasma hydrolysis, mild histamine release
Atracurium	0.5 mg/kg	30–40 min	Metabolized by plasma hydrolysis, mild histamine release
Succinylcholine*	1–4 mg/kg IV	5–10 min	↓ HR, K^+ release in neuromuscular disease, trauma or burns, masseter spasm, malignant hyperthermia, myoglobinuria

Duration of effect is only approximate and varies with age and physiologic state of the patient.
*Agents may be given intramuscularly but will have slower onset and more variable duration of effect.
CBF, Cerebral blood flow; *$CMRO_2$,* cerebral metabolic oxygen requirement; *CV,* cardiovascular; *HR*, heart rate; *ICP*, intracranial pressure; *IM,* intramuscular; *IOP*, intraocular pressure; *IV*, intravenous.

Anticholinergic Agents

Anticholinergic agents decrease oral secretions and prevent bradycardia, particularly in young infants, although their use is not universally recommended. Atropine (0.02 mg/kg) and glycopyrrolate (0.01 mg/kg intravenously) are both effective. Scopolamine provides amnesia, decreases secretions, and prevents bradycardia. The drying effect commonly requires approximately 15 to 30 minutes and is rarely achieved in emergency intubation.

Sedative and Analgesic Agents

Most patients benefit from some degree of sedation. Drugs commonly used include intravenous anesthetic agents, anxiolytic agents, and narcotic analgesics. The appropriate choice in a particular patient depends on the child's hemodynamic status, level of anxiety, and underlying disease process.

Thiopental is a short-acting barbiturate that can provide deep anesthesia, obliterating awareness of the intubation process. It decreases cerebral oxygen consumption and thereby sharply lowers cerebral blood flow (CBF) and ICP. However, it is also a potent myocardial depressant; it decreases peripheral vascular resistance and may precipitate cardiovascular collapse in patients with myocardial dysfunction or hypovolemia. At anesthetic doses (4 to 7 mg/kg), it reliably causes apnea.

Etomidate is another short-acting intravenous anesthetic that causes rapid loss of consciousness (at 0.3 mg/kg) and respiratory depression, although it is less potent than thiopental. It also decreases cerebral oxygen consumption, CBF, and ICP, but without significant detrimental effects on cardiovascular function and with less respiratory depression than thiopental. These characteristics have led to its increased use for emergency intubation.[58,59] It has no analgesic properties and may be best combined with a narcotic analgesic. Adverse effects include vomiting, myoclonus, and lowering of the seizure threshold. With continuous infusion for sedation, it can cause adrenal insufficiency, making it inappropriate for long-term use in the ICU.[60] Growing evidence suggests it may suppress adrenal function even after a single dose, particularly in patients with sepsis and shock, raising questions about its use in these settings.[61-70]

Ketamine is another potent nonnarcotic analgesic and anesthetic that has been used safely in children in the critical care setting.[71,72] It increases heart rate, systemic blood pressure, and cardiac output and is a fairly potent bronchodilator. However, myocardial depression may be apparent after

administration to patients with catecholamine depletion. It may be of particular value in patients with status asthmaticus or other reasons for bronchospasm and may have a beneficial effect in sepsis. Spontaneous ventilation is preserved in most patients, but laryngospasm may occur.[73] Although in the past it has been considered inappropriate for patients with intracranial hypertension because of evidence that it increases cerebral metabolic rate, blood flow, and ICP, more recent studies indicate that it may be used safely in these patients, although no clear consensus has emerged.[74] Emergence delirium and hallucinations occur frequently and may be prolonged and recurrent, particularly in adolescents and young adults. Use of ketamine for a variety of procedures in children has been successful, with little reported difficulty with neuropsychiatric complications, but follow-up in most studies has been short and superficial.[75-80] Whereas the majority of patients do not suffer severe disturbances, those who do may have severe and prolonged distress. Benzodiazepines or barbiturates may decrease the incidence and severity of such adverse effects and the incidence of vomiting, although the data in children are limited and conflicting.[75,81,82]

Propofol is an ultra-short-acting agent with rapid onset and offset unless given by continuous infusion. It causes respiratory depression, desaturation, and systemic hypotension secondary to its negative inotropic effects and peripheral venous and arterial vasodilation. Its role in airway management of critically ill children is limited because of these effects. It has gained widespread acceptance as an anesthetic agent in children, however, and has been used extensively for procedural sedation.[83,84] Use in the ICU for more than approximately 6 hours is not recommended because of its still unexplained association with metabolic acidosis, cardiovascular collapse and death, propofol syndrome, among pediatric ICU patients.[85-87] Current labeling warns against its use for prolonged sedation in children.

The benzodiazepines, including diazepam and midazolam, relieve anxiety, produce sedation in most children, and provide amnesia for noxious procedures. They do not relieve pain. They have relatively little hemodynamic effect in most patients and rarely interfere with spontaneous breathing at therapeutic doses. Although they decrease cerebral oxygen consumption, their effect on cerebral metabolism is much less pronounced than that of thiopental. They are best combined with a narcotic analgesic when used for intubation in order to decrease the discomfort and pain associated with laryngoscopy and passage of the tube.

Narcotics commonly used for intensive care include morphine, fentanyl, and some of the ultra-short-acting agents such as remifentanil. They cause respiratory depression in a dose-dependent fashion and increase intracranial blood flow in proportion to the increase in $Paco_2$. If hypercarbia is prevented, they decrease cerebral metabolic rate and blood flow. In the setting of altered cerebral autoregulation, they may not protect the patient from alterations of CBF.[88,89] Morphine causes histamine release and peripheral vasodilation and may precipitate systemic hypotension. Fentanyl is approximately 100 times more potent than morphine but does not release histamine and has little hemodynamic effect, even at anesthetic doses. Large doses given rapidly can cause bradycardia or chest wall rigidity. Remifentanil is a rapid-onset, ultra-short-acting opiate that is even more potent than fentanyl and may have potential benefit in intubation for procedures.

Neuromuscular Blocking Agents

Neuromuscular blocking agents cause reversible paralysis, facilitating visualization of the airway and insertion of the endotracheal tube in an atraumatic fashion. Most drugs in use are nondepolarizing relaxants with very similar action. Differences are primarily in their hemodynamic effects, metabolism, and excretion.[90,91] Vecuronium and rocuronium are the agents most commonly used. Both are amino-steroid agents. Vecuronium has virtually no hemodynamic effect. Its duration of action varies depending on the patient's age, approximately 70 minutes in infants and 35 minutes in older children. It is metabolized exclusively by the liver. Rocuronium provides good intubating conditions nearly as rapidly as succinylcholine (in about 45 to 90 seconds)[92-94] without the adverse effects. Its duration is longer at 15 to 45 minutes (and longer in infants).[95-97] Like vecuronium, it has minimal hemodynamic effect, is metabolized by the liver, and largely is excreted in bile (with a small amount excreted by the kidneys). Atracurium and cis-atracurium, both benzylquinolinium agents, also have minimal hemodynamic effects in most patients but may cause histamine release and hypotension in some persons. Metabolism occurs by spontaneous plasma hydrolysis; thus neither renal nor hepatic function is necessary for elimination. Its duration of action is short at about 15 to 20 minutes.

The only depolarizing relaxant in clinical use is succinylcholine. Its only advantage is its rapid onset of action (45 to 60 seconds) and brief duration of action (5 to 10 minutes). Muscle fasciculations occur at the onset of action in patients older than 4 years and may increase intracranial, intraocular, and intragastric pressure. Defasciculating doses of a nondepolarizing neuromuscular blocker prior to succinylcholine administration minimize such effects. Massive hyperkalemia may occur following its use in patients with spinal cord injury, severe burns, crush injuries, or neuromuscular disease. More recently, the spread of acetylcholine receptors outside of the neuromuscular junction, the mechanism presumed to underlie the massive hyperkalemic response previously noted, has been recognized to occur in many forms of critical illness associated with immobility, placing many critically ill patients at risk.[98] It is a known trigger for malignant hyperthermia and frequently causes myoglobinuria in otherwise healthy children. The U.S. Food and Drug Administration has issued a warning against its use for routine intubation in children because of these complications. Although it is frequently used for emergency intubations and is widely recommended,[54,99,100] the difference in time to conditions for intubation between succinylcholine and rocuronium is small (~30 seconds), very rarely of clinical significance, and inadequate to justify the added risk in the vast majority of cases. Moreover, the time to critical hemoglobin desaturation in the case of a failed airway is shorter than its duration of action, especially in children, so its shorter duration of action does not provide a meaningful advantage over nondepolarizing blockers.[101]

A more extensive discussion of anesthetic agents and their use is given in Chapters 122, 123, and 124.

Orotracheal Intubation

When all equipment is ready, an assistant is assigned to monitor the child's color, heart rate, blood pressure, and oxygen saturation and to administer drugs when ordered. The child

is placed supine with the head in the "sniffing" position. The infant's large occipitofrontal diameter naturally results in good position most of the time, but a small pad under the shoulders may be helpful. In older children, a thin pad under the occiput helps establish slight neck flexion (Figure 119-8). The head is extended to align the oral, pharyngeal, and laryngeal axes as much as possible. Spontaneous or manual ventilation with supplemental oxygen is maintained as drugs to facilitate intubation are given. Many patients requiring emergency intubation have severely impaired gas exchange and may require several minutes of breathing 100% oxygen, often with positive inspiratory and end expiratory pressure.[102] Applying cricoid pressure during manual ventilation helps minimize gastric distension by air (Figure 119-9).[103] After the drugs take effect, the pharynx is suctioned and stomach contents are aspirated. The patient is again briefly oxygenated, and the mask is removed. In a fully relaxed patient in good position, the mouth falls open. It can be opened more widely with caudad pressure on the chin by the intubator's left fifth finger as the laryngoscope is introduced into the right-hand corner of the mouth. In an unsedated patient or when the mouth opens abnormally, it may be necessary to open the jaw with the often recommended scissorlike use of the right thumb and forefinger, but this action places the intubator at risk of both trauma and infection and should be avoided when possible.

The laryngoscope is gently advanced into the pharynx and leftward, sweeping the tongue out of the way. Holding the handle at a 45-degree angle to the bed and lifting along the line of the handle to avoid pressure on the lips, teeth, or alveolar ridge, the intubator displaces the mandible until the vocal cords are in view (Figure 119-10). Application of gentle cricoid pressure by an assistant may be helpful. Once the larynx is clearly visualized, the tube is advanced from the right corner of the mouth into the larynx (not through or along the blade itself). The nearly universal tendency to plumb the depths of the child's airway with extra centimeters of tube results in main stem intubation. Unfortunately, the recommendation to use three times the ETT size for appropriate depth of tube placement for a child results in malposition in 15% to 25% of patients.[104] Placement is likely to be better if the intubator is careful to place the appropriate markings near the tip of the endotracheal tube at the level of the cords. If such markings are absent, careful attention to advancing the tip of the tube only a few centimeters (2 to 4 cm) beyond the cords prevents main stem intubation.

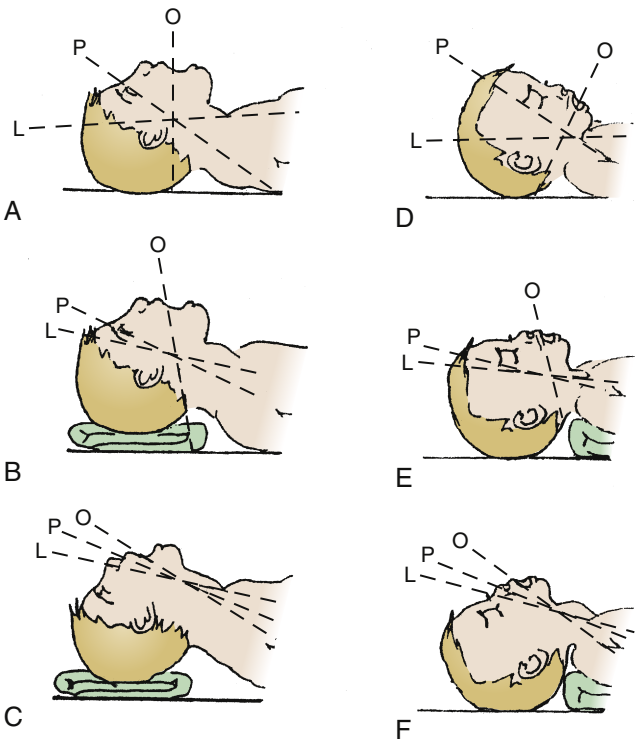

Figure 119–8. **A,** Positioning of the young child and infant for laryngoscopy and tracheal intubation. **B,** Placing the child's head on a thin pad flexes the neck slightly and helps align the pharyngeal and laryngeal axes. **C,** Extension of the atlantooccipital joint (into the sniffing position) further aligns the oral axis with the pharyngeal and laryngeal axes. **D,** Before the age of approximately 3 years, the child's large frontal occipital diameter makes the pad beneath the head unnecessary, but a small pad under the shoulders (**E**) may improve alignment of the pharyngeal and laryngeal axes. **F,** As with the older child, head extension improves alignment of the oral, pharyngeal, and laryngeal axes. *(From McAllister JD, Gnauck KA: Rapid sequence intubation of the padiatric patient. Fundamentals of practice,* Emerg Med *46:1249–1284, 1999.)*

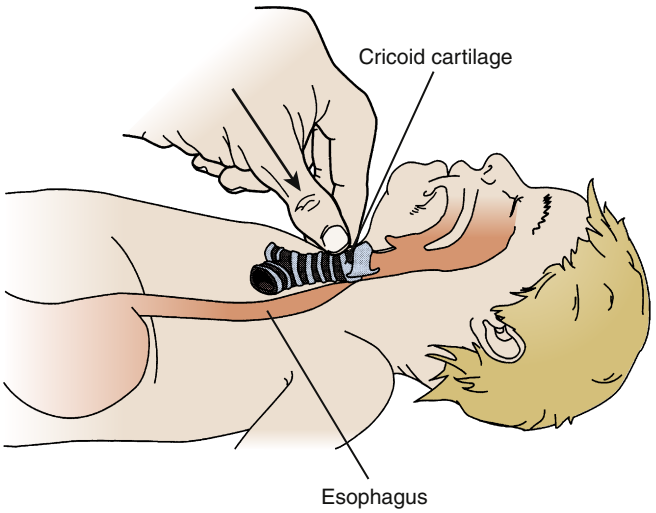

Figure 119–9. Sellick maneuver. Pressure on the cricoid cartilage occludes the esophagus or hypopharynx.

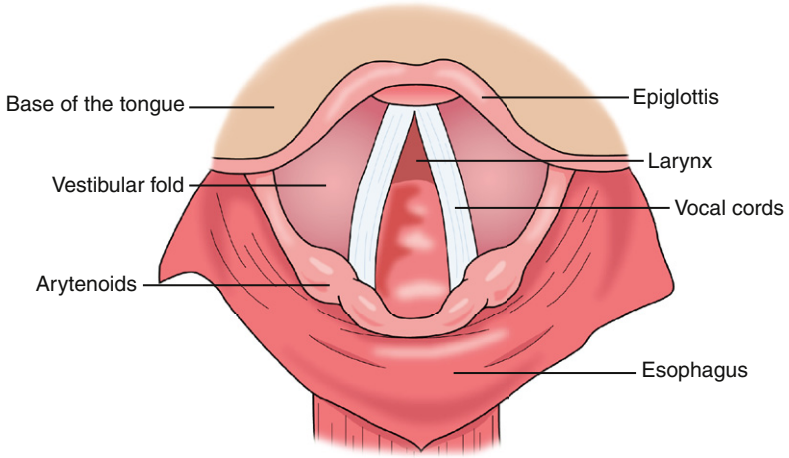

Figure 119–10. Glottic area view via laryngoscopy.

With the tube in place, the child again receives manual ventilation with oxygen, and the presence of an appropriate leak is documented. Correct tracheal placement of the tube is suggested by observation of moisture condensing in the tube, good chest excursion, symmetrical breath sounds, and effective oxygenation. The most reliable means of ensuring proper placement, following clear visualization of the tube passing between the vocal cords, is documentation of carbon dioxide in expired gas (by capnometry or a disposable CO_2 detector). Only in the settings of full cardiac arrest or extremely low pulmonary blood flow can the endotracheal tube be in the airway without detection of expired carbon dioxide. Under other conditions, malposition of the tube, most commonly in the esophagus, must be assumed. It is important to remember that capnometry does not ensure correct positioning within the airway: carbon dioxide will be detected with the tube anywhere from a bronchus to above the vocal cords. Documenting location of the tip of the tube between the thoracic inlet and T4 on chest radiograph, with the head in a neutral position, is important. (The tip will descend deeper into the trachea with neck flexion and move upward with neck extension.[105,106] With the endotracheal tube in good position an inflated cuff often can be palpated at the sternal notch when quick pressure is applied to the sentinel balloon. The tube is secured, avoiding pressure on the lips, particularly at the angle of the mouth, and keeping the vermilion border of the lip free of tape.

Nasotracheal Intubation

If nasotracheal intubation is preferred, it should generally follow orotracheal intubation so that an assistant can ventilate the child while the somewhat more difficult intubation is accomplished. A topical vasoconstricting agent such as phenylephrine 0.25% or oxymetazoline 0.05%, sprayed into the nasal fossa, minimizes the risk of bleeding. In most children a tube of the same diameter as the oral tube can be gently advanced along the floor of the nasal cavity, essentially directly posteriorly, into the nasopharynx with firm, but not brutal, pressure. With the oral tube in the left corner of the mouth, the laryngoscope is again advanced into the pharynx until the oral tube is visualized passing through the cords and the tip of the nasal tube is seen in the nasopharynx. The nasal tube is advanced until it lies directly above the cords, anterior to the oral tube. Use of Magill forceps may facilitate this maneuver. When the nasal tube is in good position to enter the larynx, the assistant removes the oral tube and helps advance the nasal tube. Difficulty advancing the tube after it has passed the vocal cords may be overcome by rotating the tube or flexing the neck. The tube then is secured; pressure on the septum or anterior rim of the nares should be avoided.

Although an orotracheal tube usually is placed more rapidly in emergencies, it often stimulates gagging, makes mouth care difficult, and it is more easily kinked or bitten. Anchoring the tube often is difficult because of saliva, and tongue movement may contribute to palatal or tracheal erosion and increase the likelihood of accidental extubation. Trauma to lips, teeth, tongue, and other oropharyngeal structures may occur. Nasotracheal intubation is more comfortable for most conscious patients, causes less stimulation of the gag reflex, is more easily secured, and prevents the problem of biting in patients with seizures, decerebrate rigidity, or extreme agitation. However, bleeding, adenoid injury, sinusitis, and trauma to the nasal turbinates, septum, or nares may occur with nasotracheal intubation, and the risk of sinusitis is greater than with orotracheal tubes.[107,108] Contraindications to nasotracheal intubation include coagulopathy, maxillofacial trauma, CSF leak, and basilar skull fracture.

Videolaryngoscopy

Videolaryngoscopy allows visualization of the larynx without requiring a direct line of sight aligning the oral, pharyngeal, and tracheal axes. In the setting of a difficult airway, video assistance improves visualization and more rapid intubation in adults. Visualization in children is also improved, but experience published to date suggests that the first-pass success rate is lower and time to intubation is longer than with direct laryngoscopy, at least in patients in whom airway visualization is only moderately difficult.[109,110] On the other hand, studies of simulated difficult airway management in infants have shown improved intubation rates without a longer time to intubation.[111] At present, it appears that these devices may be most valuable in very difficult situations, including cervical spine instability and craniofacial abnormalities, rather than as an advance in routine laryngoscopy.[112]

The videolaryngoscope also provides a useful opportunity for teaching airway skills. A duplicate video image allows an instructor to view the attempted intubation in real time and provide immediate guidance and evaluation.

Flexible Fiberoptic Bronchoscopy

Flexible fiberoptic bronchoscopy is an effective means of securing a difficult airway, especially in patients with cervical spine instability or those in whom limited jaw mobility or oropharyngeal lesions prevent good visualization of the larynx.[40,45,113] Assuming the operator's clinical proficiency, the procedure almost always is successful, with little or no trauma to the patient. The nasal route is routinely chosen because it is easier to use, better tolerated, and safer for the instrument than other routes. A topical vasoconstrictive agent and local anesthetic are applied to the nasal mucosa. The endotracheal tube is advanced through the nose into the nasopharynx, and the flexible scope is threaded through it. The scope is advanced through the vocal cords, and the tube is passed over it into the trachea. (Alternatively, the tube with its connector removed may be threaded retrograde over the scope. The scope is advanced through the nose, to the nasopharynx, and through the larynx into the trachea. The endotracheal tube is advanced over the bronchoscope into good position.) The bronchoscopist then visualizes and secures the position of the tube in the trachea and carefully withdraws the scope.

Extubation

Extubation is appropriate when the conditions for intubation are no longer present. In general, this means that the work of breathing has decreased to a level manageable by the patient. In most cases, this situation occurs when oxygenation is adequate with the administration of 40% oxygen or less; spontaneous tidal volume is greater than 3.5 mL/kg; the patient can sustain a normal $Paco_2$ without mechanical breaths with a near normal respiratory rate for age and without the use of accessory muscles; secretions are manageable; upper airway reflexes are intact; and neuromuscular function is sufficiently good to achieve an adequate vital capacity and maximum inspiratory pressure (Table 119-4).[114] Although standard teaching holds that extubation is most likely to be successful when there is an air leak around the ETT at less than 30 cm H_2O, recent study indicates that the presence or absence of a leak is a poor predictor of the success of extubation.[115] If intubation was for relief of upper airway obstruction, direct inspection revealing more normal anatomy is of particular value, and the significance of a leak may be greater. In patients with a previously difficult to manage airway, extubation over a tube changer or in the operating room, with surgical support available, should be considered.[116]

Before extubation, the child is given nothing by mouth for 4 to 6 hours. The tube and pharynx are suctioned thoroughly, and the child is ventilated with 100% oxygen to provide a reservoir of oxygen as a buffer against laryngospasm at extubation. With the lungs fully inflated, the endotracheal tube is removed, and the child is provided with humidified oxygen and observed closely.

Postextubation stridor is common and may range from mild to life-threatening. Children younger than 4 years are most frequently affected by postextubation stridor. Factors contributing to airway edema include a tight endotracheal tube or cuff, traumatic or repeated intubations, excessive movement of the tube (or patient), preexistent airway abnormalities, and airway infection.[117] Cool mist or humidified oxygen is sufficient treatment for children with mild symptoms. Nebulized racemic epinephrine (0.5 mL of a 2.25% solution in 2.5 mL of saline solution delivered intermittently or continuously) effectively relieves more severe upper airway obstruction in most children, probably by local vasoconstriction. Only the l-isomer in the racemic formulation is biologically active. Epinephrine available for cardiovascular use is as safe, effective, and less expensive if half the racemic dose is used. Following its use, edema may recur, so close observation must continue. The value of corticosteroids is more controversial, in part because most studies do not differentiate multiple causes of croup.[118-120] Patients at high risk for post-extubation stridor (e.g., those with multiple intubation attempts) appear most likely to benefit.[121-123] Dexamethasone (0.3 to 0.5 mg/kg every 6 hours for 1 or 2 days) is recommended in selected cases.

The work of breathing through a narrowed upper airway can be decreased by inhalation of a low-density gas mixture. Oxygen in helium is less dense than air or pure oxygen and permits higher inspiratory flow at lower resistance. Helium-oxygen mixtures are commercially available, usually providing 20% oxygen in 80% helium. More oxygen can be added to the mix as needed. Although traditional teaching holds that at least 70% helium is necessary to decrease airway resistance enough to make a clinical difference in the work of breathing, experience demonstrates value at considerably lower concentrations.

If pharmacologic treatment is ineffective, noninvasive ventilatory support may be useful in preventing the need for reintubation, but meticulous attention to the patient's work of breathing is critical to recognize potential catastrophic airway obstruction. Reintubation with a smaller tube for 12 to 24 hours may be necessary, and continued dexamethasone treatment and sedation to minimize agitation and further trauma to the airway may permit resolution of symptoms. Persistent symptoms are an indication for diagnostic laryngotracheobronchoscopy.

Table 119–4 Threshold Values for Low (≤10%) and High (≥25%) Risk of Extubation Failure

Variable	Low-Risk Value (≤10%)	High-Risk Value (≥25%)
V_{tspon} (mL/kg)	≥6.5	≤3.5
Fio_2	≤0.30	>0.40
Paw (cm H_2O)	<5	>8.5
OI	≤1.4	>4.5
FrVe (%)	≤20	≥30
PIP (cm H_2O)	≤25	≥30
C_{dyn} (mL/kg/cm H_2O)	≥0.9	<0.4
V_t/T_i (mL/kg/sec)	≥14	≤8

C_{dyn}, Dynamic compliance; *Fio_2*, fraction of inspired oxygen; *FrVe*, fraction of total minute ventilation provided by the ventilator; *OI*, oxygenation index; *PIP*, peak ventilatory inspiratory pressure; *V_{tspont}*, spontaneous tidal volume indexed to body weight; *V_t/T_i*, mean inspiratory flow.

Complications of Endotracheal Intubation

Complications of intubation can be divided into those related to placement of the artificial airway, those that occur while the endotracheal tube is in place, and those related to extubation or appearing late (Table 119-5). Immediate complications usually are related to the underlying disease process, the physiologic effects of laryngoscopy and intubation, or direct trauma to airway structures. The child's general condition, tube size, cuff pressure, movement, airway infection, systemic perfusion, duration of intubation, and attention to meticulous airway care are factors influencing the development of problems during maintenance of the airway.[124] Laryngospasm, aspiration, and failure (or inability) to deflate a cuff cause complications at extubation. Although laryngeal or tracheal injury may be obvious at the time of intubation, symptoms may be delayed 2 to 6 weeks.

Prolonged Intubation

The safe duration of endotracheal intubation in infants and children is not clear. Since the 1950s, the accepted period has increased from less than 12 hours to an undefined much longer period. Subglottic stenosis is reported to occur in 1% to 8% of infants after prolonged intubation, but a similar incidence has been noted after intubation for less than 1 week.[125] In older infants, children, and adults, it is becoming clear that there is no clear "safe" period. Complications can occur immediately at intubation or may not be seen after many weeks or even months with an endotracheal tube in place.[126] The decision to switch to tracheostomy should not be based on an arbitrary time limit but rather on the relative advantages and disadvantages of one artificial airway over another in each individual patient.

Special Circumstances

Full Stomach

Patients with a full stomach are at high risk for aspiration of gastric contents during airway manipulation, particularly if protective airway reflexes are impaired. Much of the morbidity associated with aspiration can be attributed to the effects of acid aspiration. Aspiration of fluid with a pH below 1.8 is associated with a very high incidence of severe pulmonary dysfunction and death. Aspiration of fluid with a pH between 1.8 and 2.5 produces symptoms of moderate severity. When fluid with a pH above 2.5 is aspirated, sequelae are less a consequence of the acid than of other characteristics of the material

Table 119–5 Complications of Endotracheal Intubation

Immediate	Maintenance	Extubation/Late
PHYSIOLOGIC		
Hemodynamic instability	Obstruction	Laryngospasm
Dysrhythmias	Sinusitis	Gagging, vomiting
Apnea	Otitis (similar to immediate)	Aspiration
↓ P_{AO_2}		Sore throat
↑ P_{aCO_2}		Dysphonia, aphonia
Coughing		
Laryngospasm		
Gagging, vomiting, regurgitation, aspiration		
↑ Intracranial pressure		
↑ Intraocular pressure		
TRAUMATIC		
Nasal septum laceration, perforation	Lip, tongue ulceration	Laryngeal or tracheal granuloma
Nasal turbinate injury	Nares ulceration	Vocal cord paralysis
Tooth loss or injury	Palatal erosion, cleft formation	Subglottic stenosis

aspirated.[127] Other risk factors include the volume aspirated, the presence and nature of particulate food particles, contamination by bacterial pathogens, underlying pulmonary or systemic disease, and immunosuppression.[128]

Food particles may physically obstruct small or even large central airways, with the expected alterations in lung volume in segments distal to the obstruction. In addition, certain foods may cause severe local inflammatory changes. Bacterial contamination of the upper gastrointestinal tract secondary to bowel obstruction or even antacid administration greatly increases the risks of respiratory infection following aspiration.

Patients who have eaten shortly before intubation (<6 hours) should be assumed to have a full stomach. In addition, those with bowel obstruction, pharyngeal or upper gastrointestinal bleeding, trauma, or acute onset of illness within 6 hours of eating and those who are pregnant or who have ileus or tense abdominal distension from any cause should be considered to have a full stomach.

Although delaying airway manipulation might be the measure most certain to prevent aspiration, such an approach is not a realistic option in most situations confronting the intensivist. In a conscious child, the volume of gastric contents can be minimized by suction through a relatively large-gauge nasogastric tube, but complete emptying of the stomach, particularly of large food particles and blood clots, is rarely possible. Although H2 antagonists such as famotidine or ranitidine effectively decrease both the volume and acid content of gastric secretions, an adequate effect requires 60 to 90 minutes following administration of these agents. Neither antacid nor H2 blockers decrease the volume of gastric contents already present in the stomach. Anticholinergic agents such as atropine or glycopyrrolate also reduce gastric acidity but slowly and less effectively than the H2 antagonists. In addition, they may decrease gastroesophageal sphincter tone and appear to have no value in preventing the acid aspiration syndrome.

Antacids can effectively neutralize gastric pH. However, when aspirated, particulate antacids (aluminum and magnesium hydroxides) produce inflammatory changes as severe as gastric acid and food particles. Clear antacids, such as sodium citrate or Alka-Seltzer, appear to provide true protection. They effectively increase gastric pH and, when aspirated, appear to produce damage no more severe than that caused by normal saline solution. However, their use has not become common clinical practice.

Intubation is at once protective of the patient vulnerable to gastric aspiration and itself a risk to the patient. In an alert child with intact protective airway reflexes, it may be appropriate to pass a nasogastric tube to decrease the volume of gastric contents. A clear antacid (e.g., sodium citrate, 10 to 30 mL) can be administered orally or through the tube, which then is removed. In a child with impaired reflexes, no effort to pass a nasogastric tube should be made because of the risk of inducing vomiting or regurgitation with subsequent aspiration.

The intensivist should examine the patient's airway to be as certain as possible that intubation will not be difficult, as discussed previously. If intubation likely will be straightforward, a rapid-sequence intubation is indicated (Box 119-4). The goal of this method of intubation is to minimize the likelihood of vomiting or regurgitation and the time between loss of protective reflexes and correct positioning of the endotracheal tube. The sequence consists of preoxygenation, administration of an intravenous sedative or anesthetic with immediate cricoid pressure, pharmacologic paralysis, and endotracheal intubation. Properly applied, cricoid pressure probably decreases the likelihood of insufflation of gas into the stomach or regurgitation of gastric contents into the trachea and may improve visualization of the larynx (see Figure 119-9).[103,129-131] On the other hand, excessive pressure may actually increase the likelihood of vomiting, occlude the trachea, or make visualization more difficult.

The patient spontaneously breathes 100% oxygen by mask for 3 to 5 minutes before further manipulation. If the child can cooperate and has relatively normal gas exchange, four deep breaths provides a reasonable pulmonary reservoir of oxygen. However, in patients with severe pulmonary parenchymal disease, improvement in oxygenation may be limited and require a longer period of oxygenation.[132] If other factors in the child's condition permit, next steps in the rapid sequence intubation should be delayed until hemoglobin saturation reaches 100% or oxygenation reaches a plateau. Once preoxygenation is complete, the anesthetic or sedative is administered by rapid intravenous infusion, cricoid pressure is applied immediately by an assistant, and, as consciousness is lost, a muscle relaxant is given. The mask supplying oxygen is kept in place until the patient becomes apneic, but no effort to assist ventilation is made in order to avoid gastric distension and regurgitation. Once the patient is flaccid and apneic, the intensivist performs laryngoscopy and intubates the patient. Using a stylet in the endotracheal tube facilitates rapid intubation. Only after correct tube position is verified and the tube cuff, if present, is inflated should cricoid pressure be relieved and manual ventilation begun. In the case of unexpected difficulty intubating the patient and evidence of progressive hypoxemia, manual ventilation between attempts may be necessary but should be done with continued cricoid pressure.

Box 119–4 Rapid-Sequence Intubation for Full Stomach

Indications

Food intake <4–6 hours before intubation
Pharyngeal or upper gastrointestinal bleeding
Intestinal obstruction or ileus (includes acute onset of illness)
Tense abdominal distension
Pregnancy

Relative contraindications

"Difficult" airway
Profuse hemorrhage obscuring visualization
Upper airway obstruction
Increased intracranial pressure

Procedure

Prepare *all* necessary equipment, including suction devices
Allow patient to breathe 100% oxygen for 3 minutes
Direct assistant to apply cricoid pressure
Rapid intravenous infusion of anesthetic or sedative/analgesic and neuromuscular blocking agents
Allow patient to continue to breathe oxygen until apneic
Avoid manual ventilation to minimize gastric distension
Perform laryngoscopy and orotracheal intubation with stylet in endotracheal tube
Confirm endotracheal tube placement
Release cricoid pressure

The "classic" combination of drugs used for rapid sequence induction/intubation is sodium thiopental (4 to 6 mg/kg) and succinylcholine (1 to 4 mg/kg) with a prior defasciculating dose of a nondepolarizing muscle relaxant such as vecuronium. In hemodynamically unstable patients, alternative drugs include ketamine or a benzodiazepine alone or in combination with a short-acting narcotic. As previously discussed, etomidate has been a popular agent, but growing evidence suggests its use is inappropriate in patients with shock, especially with presumed sepsis. Succinylcholine has multiple undesirable adverse effects (as noted previously) that may include increased intragastric pressure. Most of the nondepolarizing relaxants, when given in amounts two to three times the usual intubating dose, produce good conditions for intubation nearly as quickly as does succinylcholine (60 to 90 seconds) and without adverse effects but lasting longer. Rocuronium is the current best alternative, with its rapid onset and short duration of action. Table 119-3 lists suggested drugs and doses.

Increased Intracranial Pressure and Neurologic Dysfunction

The intensivist is frequently called upon to intubate children with severe central nervous system dysfunction resulting from infection, hemorrhage, trauma, hydrocephalus, or mass lesions, any of which may be associated with actual or imminent intracranial hypertension and herniation. The pathophysiology of such disorders is discussed in depth in Section IV.

In most circumstances the intensivist can observe signs of elevated ICP or recognize settings where the likelihood is high, but there is no clinical measure of its severity. Current guidelines recommend intubation for patients with a Glasgow Coma Scale score of 8 or less.[133] Intubation under these conditions should be undertaken with the recognition that it is a likely stimulus for further and potentially lethal intracranial hypertension. The most immediate means of lowering ICP involves decreasing CBF (volume) through hyperventilation. Unfortunately, the process of intubation likely will decrease minute ventilation and increase cerebral blood volume for this and other reasons, as previously discussed.

Under normal circumstances, CBF is closely coupled to the cerebral metabolic oxygen requirement ($CMRo_2$). Cerebral oxygen consumption and blood flow increase with increasing body temperature, motor activity, pain or other noxious stimuli, and seizure activity. Blood flow also increases rapidly when Pao_2 falls below 50 to 60 mm Hg and linearly as $Paco_2$ increases over a wide range. With intact autoregulation, blood flow is independent of systemic blood pressure except at very high or low levels, but when autoregulation is impaired, mean arterial pressure may affect CBF over a much broader range. Elevated intrathoracic pressure during struggling, coughing, or Valsalva maneuvers may impede jugular venous drainage and result in intracranial venous congestion.

Laryngoscopy and intubation are powerful noxious stimuli. In the awake unsedated child and even in the severely obtunded patient, laryngoscopy and intubation likely will precipitate vigorous struggle, coughing, pain (anxiety), and marked evidence of autonomic stimulation.[25,38,39,134] In most patients, sympathetic discharge predominates with tachycardia, hypertension, and diaphoresis. In the infant, vagal stimulation often predominates with resulting bradycardia.

Even in the lightly anesthetized patient, laryngoscopy itself and then intubation are associated with hypertension, tachycardia, and increased ICP. As might be predicted, massive surges in ICP are more likely to occur in patients suspected of having borderline or high baseline ICP before intubation than in those with intracranial pathology with well-compensated or previously controlled pressure. Arterial hypertension may precipitate further hemorrhage in the child with a vascular malformation, coagulopathy, or bleeding into a tumor. ICP waves may reduce cerebral perfusion pressure to ischemic levels or cause frank herniation.

Given the risk of life-threatening systemic and intracranial hypertension in these patients, it is clear that laryngoscopy and intubation should be undertaken with every effort to minimize stimulation and associated struggle.[89,135-137] In general, this implies ensuring excellent oxygenation, ventilation, and intubation under protection of profound sedation or anesthesia, with the assistance of neuromuscular blockade (Box 119-5). Neurologists and neurosurgeons are frequently loathe to relinquish the opportunity to examine the patient following intubation, but the risk of life-threatening intracranial hypertension justifies temporarily obscuring the neurologic examination. In most cases, adequate assessment is possible before intubation, and diagnostic studies require deep sedation for a period afterward.

The patient is provided 100% oxygen by bag and mask. An anesthetic or sedative agent in combination with a neuromuscular blocking agent is given, and manual ventilation is initiated to lower ICP as much as possible before airway manipulation. Although extreme hyperventilation may decrease CBF to ischemic levels, current guidelines support ventilation to a $Paco_2$ of approximately 30 to 35 mm Hg for patients with intracranial hypertension.[138]

In the hemodynamically stable patient, thiopental provides relatively deep anesthesia associated with a rapid decline in $CMRo_2$, CBF, and ICP.[135,137] Alternative agents include

Box 119–5 Intubation for Increased Intracranial Pressure

- Prepare equipment
- Monitor heart rate, blood pressure, and arterial oxygen saturation
- Provide 100% oxygen and assisted ventilation as tolerated by patient
- Consider possible difficult airway
- If no airway contraindications, administer anesthetic and neuromuscular blocking agents:
  - Associated cardiovascular compromise or hypovolemia:
    - Midazolam (0.2–0.3 mg/kg IV) and fentanyl (5–10 μg/kg IV) plus lidocaine (1.0–1.5 mg/kg IV) and rocuronium (0.6–1.2 mg/kg IV) or other relaxant; consider etomidate (0.3 mg/kg IV)
  - No associated cardiovascular compromise or hypovolemia:
    - Thiopental (4–6 mg/kg IV) plus lidocaine (1.0 mg/kg IV), plus rocuronium (0.6–1.2 mg/kg IV) or other relaxant
- Ventilate patient until drug effect achieved (consider short-term hyperventilation in patients with signs of critically elevated intracranial pressure)
- Perform laryngoscopy and orotracheal intubation

IV, Intravenous.

narcotic analgesics alone or in combination with a benzodiazepine, which has less hemodynamic effect but also less effect on $CMRo_2$ unless given in anesthetic doses.

Etomidate is widely used in patients with suspected intracranial hypertension. Its ability to decrease CBF without apparent detrimental effect on systemic hemodynamic stability makes it a useful agent, although concerns about its effect on adrenal function, perhaps even following a single dose, require caution in the patient with sepsis or shock. Because it lacks analgesic properties, combining it with an intravenous narcotic agent should be considered.

Lidocaine, 1 to 1.5 mg/kg, decreases $CMRo_2$ and modestly decreases the systemic and intracranial hypertensive response and the cough reflex, as long as a dose below the seizure-producing threshold is used. Effective serum concentrations are obtained more quickly and at lower doses by the intravenous route than when the agent is administered endotracheally. The available literature addresses patients fully premedicated and monitored undergoing neurosurgical procedures or patients already intubated, ventilated, and monitored in the ICU. Studies addressing intubation in the acute setting are lacking and unlikely to be accomplished.[138-142]

Although the classic recommendation has been to avoid ketamine in patients with elevated ICP because of its potential to further increase pressure, newer studies suggest that ketamine may be safe in this population. It does, however, increase systemic blood pressure and CBF and most likely should be avoided in patients at risk of failed autoregulation until further evidence is available.[74,143-145] In addition, evidence that ketamine is associated with neuronal injury in immature animal models supports continued caution with respect to its use in patients with elevated intracranial pressure.

In nearly all patients, orotracheal intubation is preferred because it is accomplished quickly and easily with less risk of prolonged manipulation and interrupted ventilation. Nasotracheal intubation is contraindicated in patients with basilar skull fractures and CSF leaks as a potential source of infection or even perforation of the cribriform plate and intracranial tube placement.

Cervical Spine Instability

Flexion and extension of the head on the neck occur between the atlas (C1) and the basiocciput. Rotation occurs between the atlas and axis (C2), as the thin arch of the atlas pivots around the odontoid process. Below the axis, the cervical vertebrae articulate with each other anteriorly at the intervertebral disks and posteriorly at the facet joints. Further neck flexion and extension occur at these joints. Anterior and posterior ligaments complete the stable spine.

Spinal cord injury generally occurs as a result of bony fracture, compression, or disruption of cervical ligaments. In young children, actual ligamentous disruption or bony fracture is not necessary for severe cord injury, even transection, to occur; extreme stretching, as may occur in acceleration or deceleration injury, is sufficient.[146-148] Instability results from disruption of both the anterior and posterior columns. Congenital or degenerative anatomic abnormalities, penetrating wounds, or expanding mass lesions in the spinal canal may compromise cord integrity.

During routine intubation, the intensivist flexes the neck and extends the head. In children with known or suspected cervical spine injury or instability resulting from other causes (e.g., Down syndrome or rheumatoid arthritis), manipulating the head and neck for intubation risks extending the existing condition or injury and may precipitate new problems. Cervical spine films and knowledge about the nature of the traumatic event help define the precise injury and predict maneuvers most likely to do harm, but such information rarely is complete and may be falsely reassuring.

The ideal approach to intubation in this setting is controversial.[149-152] Although evidence in cadavers, in addition to common sense, indicates that typical airway maneuvers can cause anterior or posterior subluxation or widening of the disk space, evidence in patients is lacking.[153] Axial traction increases distraction and even subluxation in some patients[154]; in others traction is helpful. However, information about the appropriate amount of force or the correct plane in which it should be applied is rarely sufficient to make a timely informed decision. Therefore immobilization of the head and neck in the midline without traction is recommended.

Current advanced trauma life support guidelines no longer recommend blind nasotracheal intubation.[155,156] Orotracheal intubation is more reliably accomplished and less time-consuming than blind nasotracheal intubation and is associated with far fewer complications, including tube malposition and bleeding, even in adults.[157] The high anterior location of the pediatric larynx makes nasotracheal intubation even more difficult in young children. As a result, it is rarely a necessary or desirable choice for emergency airway stabilization in children.

Just as manipulation of the airway for intubation may risk additional cord injury, patient movement can cause additional damage. Few children of any age will tolerate awake intubation by any route without violent struggle. Even heavily sedated patients likely will cough upon stimulation of the airway.

Patients with spinal cord injuries are at risk for extreme hyperkalemia and resulting dysrhythmias or cardiac arrest following administration of succinylcholine. This response occurs from approximately 48 hours to 6 to 9 months after injury. Cervical injury often also disrupts sympathetic nervous system outflow and results in unopposed vagal tone and severe bradycardia. For these reasons, in most instances intubation is best accomplished in these patients via the orotracheal route, using an intravenous anesthetic or combination of sedative and analgesic agents, atropine, and a nondepolarizing neuromuscular blocking agent with an assistant immobilizing the head and neck in neutral position with one hand over the ear on each side of the head. If time, equipment, and available expertise permit, fiberoptic bronchoscopy may assist visualization of the larynx and intubation with minimal head or neck movement.[158]

If orotracheal or nasotracheal intubation cannot be accomplished because of associated facial or airway injuries or other technical obstacles, cricothyrotomy or primary tracheotomy may be indicated. However, no data support either the necessity or safety of routinely using a surgical approach before attempting orotracheal intubation.

Upper Airway Obstruction

Upper airway obstruction may result from many disorders (see Chapter 39). When symptoms are related to loss of oropharyngeal muscle tone, changing the patient's position,

reversing the effects of a drug, or placing a nasal airway may be sufficient, if the duration of the underlying process likely will be brief. However, when airway structures likely are severely or progressively distorted by edema, inflammation, trauma, or another space-occupying process, achieving an endotracheal airway is necessary.

Patients should be allowed to assume whatever position is most comfortable. Supplemental oxygen is provided at the maximum concentration possible, but a young child's anxiety should not be heightened with an overly aggressive approach with a mask. Contrary to popular belief, breathing can be assisted in nearly all cases by application of positive pressure, initially with continuous positive airway pressure and then gradually with assisted breaths.

In general, no action should be taken that compromises the child's ability to breathe spontaneously until the capacity to control ventilation is certain. In particular, use of neuromuscular blocking agents is dangerous and inappropriate until after the airway is controlled. Distortion of the airway may be so extreme that recognition of landmarks for intubation is impossible, and loss of pharyngeal tone in such patients may remove the last barrier to complete airway occlusion. However, reducing a child's anxiety with cautious sedation (with a reversible agent) may decrease peak inspiratory flow rate and symptoms of obstruction and make it easier to assist breathing and establish an artificial airway. When possible the child is gently lowered to a supine position (or to 30 degrees) and intubated by the orotracheal route. When time and available expertise permit, intubation in the operating room using an inhalational anesthetic in a high oxygen concentration allows spontaneous breathing until the patient is deeply anesthetized and untroubled by airway manipulation. This method may be especially helpful in cases of supraglottitis. In most cases, the proper tube size is 0.5 to 1.0 mm smaller in diameter than predicted for age because of airway inflammation and edema, and no leak will be present.

Extubation usually is well tolerated when a leak has developed.

Facial and Laryngotracheal Injury

Children with facial injuries present airway problems nearly as varied as the injuries themselves. Appropriate management depends primarily on accurate assessment of airway patency at presentation, the rate of bleeding (if any) into the airway, and the amount of additional swelling and distortion likely to occur later. Evaluation of possible ocular and intracranial injury must proceed simultaneously.

Profuse bleeding, unstable facial fractures, or aspiration of blood, gastric contents, or teeth causes early respiratory distress. Maxillary fractures may result in a free-floating maxilla with occlusion of the nasopharynx and pressure on the tongue. Isolated mandibular fractures often cause trismus but rarely cause airway obstruction or interfere with visualization of the larynx.

Airway management begins with suctioning blood and debris from the mouth and pharynx. If permitted by other injuries, the child is placed with the head down and turned to the side. The tongue and maxilla are pulled forward manually if necessary. A spontaneously breathing patient receives oxygen by mask and may not require further intervention before surgery. Patients with persistent obstruction may require an immediate artificial airway.

In most cases, orotracheal intubation is accomplished first. If ventilation can be assisted with bag and mask and bleeding is controlled, the patient may be sedated, paralyzed, and intubated with full stomach precautions. If bag-mask ventilation exacerbates airway obstruction, awake intubation may be necessary. Uncontrollable bleeding, inability to visualize the larynx, or violent struggle in a child with cervical spine instability or evidence of increased ICP may make a primary tracheostomy desirable. Nasotracheal and nasogastric tubes are avoided until the possibility of a basilar skull fracture and CSF leak is eliminated.

Laryngotracheal injuries may be subtle or dramatic. They should be suspected in children with a history of anterior neck trauma and often cause hoarseness, stridor, subcutaneous emphysema, pneumothorax, or pneumomediastinum. Aerosolized epinephrine may temporarily decrease swelling and provide a little extra time to evaluate the airway and plan intervention. Awake intubation with cautious sedation and topical anesthesia that is conducted under direct vision by laryngoscopy or fiberoptic bronchoscopy minimizes the risk of sudden, complete obstruction or creation of a false passage adjacent to the airway.

Open Globe Injury

Children with penetrating eye injuries may require emergency intubation for respiratory failure resulting from associated injuries or other underlying problems. Management in these cases seeks to prevent increased intraocular pressure with subsequent extrusion of the vitreous and permanent blindness. Intraocular pressure can be increased by struggling, crying, coughing, straining, or rubbing the eye. Hypoxia and hypercarbia can increase intraocular pressure. In general, central nervous system depressants lower intraocular pressure, with the possible exception of ketamine. Intubation should be performed smoothly under full muscle relaxation if possible, taking into consideration associated injuries and the risk of a full stomach.

The child should be preoxygenated with 100% oxygen, taking care not to apply pressure to the eye with the mask. Efforts to empty the stomach are delayed until the patient is fully relaxed and intubated. In hemodynamically stable patients, thiopental or other rapidly acting sedatives/anesthetics are administered, followed by a nondepolarizing neuromuscular blocking agent if other airway anatomy permits. Succinylcholine, a depolarizing relaxant, has been associated with increased intraocular pressure, even in the absence of fasciculations. As in patients with head trauma, a combination of sedative and analgesic agents may replace thiopental if hemodynamic stability is uncertain. Lidocaine supplements the effect of other agents in blunting the rise in intraocular pressure that may occur even during a smooth intubation. Heavy sedation or paralysis should be maintained following intubation until after repair.

Alternative Approaches to the Airway

Lighted Intubation Stylet (Light Wand)–Assisted Intubation

A number of lighted intubation stylets have become available in the past decade. Each uses transillumination of the neck to guide placement of an endotracheal tube. The devices consist

of a handle containing the power source and a malleable wand (stylet) with a light at the tip. Pediatric versions accommodate tubes as small as 3.5 mm.

Use of the lighted stylet for intubation is a technique recommended for use in patients with airways that are difficult to manage. Reported experience in children is limited, but the technique has been successful in the hands of both highly skilled and novice operators.[159-163] The equipment is fairly simple to use and easy to learn. It does not require visualization of the airway, is less stimulating than laryngoscopy, allows nasal or oral intubation, and is portable and relatively inexpensive. Reported series indicate that mucosal and dental injuries are uncommon, and sore throat is less of a problem than following standard laryngoscopy.[164] Because intubation may be accomplished from the patient's side, it may be useful in awkward settings such as emergency transport vehicles.

Potential disadvantages include trauma to the upper airway and larynx. Anything that obscures transmission of light through the anterior neck interferes with its use, including scarring, massive edema, subcutaneous emphysema, or mass lesions. Profuse bleeding or thick airway secretions that obscure the bulb also interfere with effective use.

A lubricated lighted stylet is inserted through an endotracheal tube of desired size until the light is just short of the end of the tube, and the tube is firmly attached. The tube and stylet are bent to approximately 90 degrees, just proximal to the cuff if present. Dimming the room lights improves appreciation of the transillumination. The intubator may stand at the head of the bed or to the side of the patient. The head is extended. A shoulder roll may be useful. The mandible and tongue are pulled forward and upward by the intubator, and the styletted tube is introduced into the patient's mouth in the midline. It is advanced into the pharynx, while the operator observes transillumination of the soft tissues of the neck. Entry into the airway typically is recognized by the presence of a focused glow of light in the midline below the thyroid prominence; more diffuse light suggests esophageal placement. The tube is advanced until the light is at the level of the sternal notch. The lighted stylet is withdrawn and placement is confirmed with capnography.

Nasal intubation is possible with the light wand. In this case, the trocar is removed to increase the flexibility of the device. When a glow is noted above the thyroid prominence, the tube is likely in the vallecula. The epiglottis can be moved out of the way with a jaw thrust, allowing further advancement of the tube into the trachea. An alternative is to flex the patient's neck, as is sometimes necessary with visualized nasotracheal intubation.

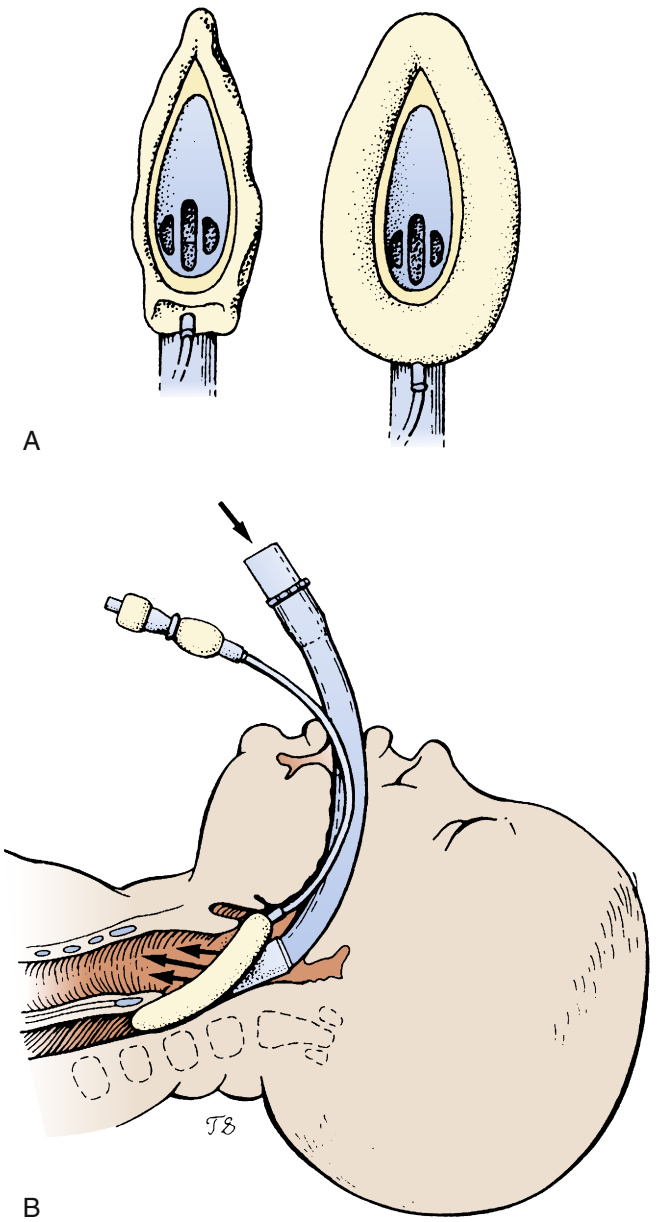

Figure 119–11. LMA. **A,** Mask portion of the airway with the rim deflated for insertion (*left*) and inflated (*right*). **B,** LMA in position, with the rim inflated around the laryngeal inlet. *(From Efrat R, Kadari A, Katz S: The laryngeal mask airway in pediatric anesthesia: experience with 120 patients undergoing elective groin surgery,* J Pediatr Surg *29:206, 1994.)*

Laryngeal Mask Airway

The laryngeal mask airway (LMA) is a relatively new and fairly safe means of securing a difficult to manage airway in an infant or child.[165-167] It was designed to provide a supraglottic airway device that would offer the benefit of noninvasive ventilation. Its use rapidly gained acceptance in anesthesiology and has been incorporated into the American Academy of Anesthesiology difficult airway algorithm.[46] It consists of a small mask with an inflatable rim and a tube with a "universal adaptor," which permits attachment to a resuscitation or anesthesia bag or ventilator (Figure 119-11). The original LMA consists of a wide-bore tube designed to sit in the hypopharynx and is attached to an inflatable bowl-shaped base that bypasses the tongue, sits around the epiglottis, conforms to the shape of the larynx, and provides a low-pressure seal around the supraglottic area.[168] The LMA is available in a wide range of sizes, allowing use in very small infants to very large adolescents and adults. Choice of LMA size is based on weight: size 1 for patients weighing 2.5 to 6.0 kg, size 2 for patients weighing 6.0 to 30 kg, and size 3 for patients weighing more than 30 kg.[169,170] Since the initial development of the LMA, several other types have been designed, including the flexible LMA, intubating LMA, disposable LMA, and ProSeal LMA, not all of which are available in pediatric sizes.[171]

The insertion technique can be learned quickly by physicians and other providers, including emergency transport personnel, often more quickly than endotracheal intubation. Experience with a mannequin appears to be effective training. Once in place, the LMA can serve as a means of ventilating the patient until the desired definitive airway can be established. It can facilitate subsequent tracheal intubation, if desired, either with blind technique or via fiberoptic bronchoscopy.

Insertion of the LMA does not require muscle relaxation or the use of a laryngoscope and is therefore considered a "blind" technique. Topical anesthesia, with lidocaine spray or lidocaine jelly applied to the inflatable rim, is helpful in patients with intact protective airway reflexes who are awake. With the rim deflated or partially inflated, the LMA is advanced along the posterior pharyngeal wall with the dorsum of the mask facing the palate until resistance of the upper esophageal sphincter is encountered. The cuff is then inflated, forming a seal around the laryngeal outlet, and the attached tube is connected to a source of oxygen and positive pressure (Figure 119-12).

Proper placement is essential but is most uncertain in infants requiring the LMA size 1, most likely because the margin of error for placement in the small pharynx is so small. In general, the risk of downfolding the epiglottis, thus occluding the trachea, is greater in children than in adults. Successful placement depends on the shape and tone of the pharynx, adequate matching of the cuff, the palatopharyngeal curve and shape of the posterior pharynx, the extent to which anterior structures (such as tonsils) obliterate the curve, the position of the head and neck, efficacy of digital manipulation, and the depth of anesthesia/sedation, muscle relaxation, or loss of airway reflexes.[166] Tissue trauma is uncommon, and the need to manipulate the cervical spine during placement is minimal. In most patients the autonomic response to placement is less pronounced than with laryngoscopy and intubation. On the other hand, the device does not fully protect against aspiration in the setting of a full stomach. In addition, it may not be effective in patients with glottic or subglottic pathology.

Although its primary use is in the operating room, growing experience demonstrates that the LMA can be lifesaving in a variety of other settings when no other nonsurgical means of maintaining an airway is successful, particularly in patients with anatomically abnormal airways.[172] Success with airway management in the operating room with children with airways that are anticipated to be difficult to manage, including patients with Pierre Robin, Treacher Collins, and Goldenare syndromes, suggests that the LMA would be valuable for managing such patients in emergency settings such as the emergency department or ICU. The ease and rapidity of insertion and decreased gastric air insufflation during resuscitation make it a valuable tool when intubation fails during adult resuscitation.[173] The current Pediatric Advanced Life Support

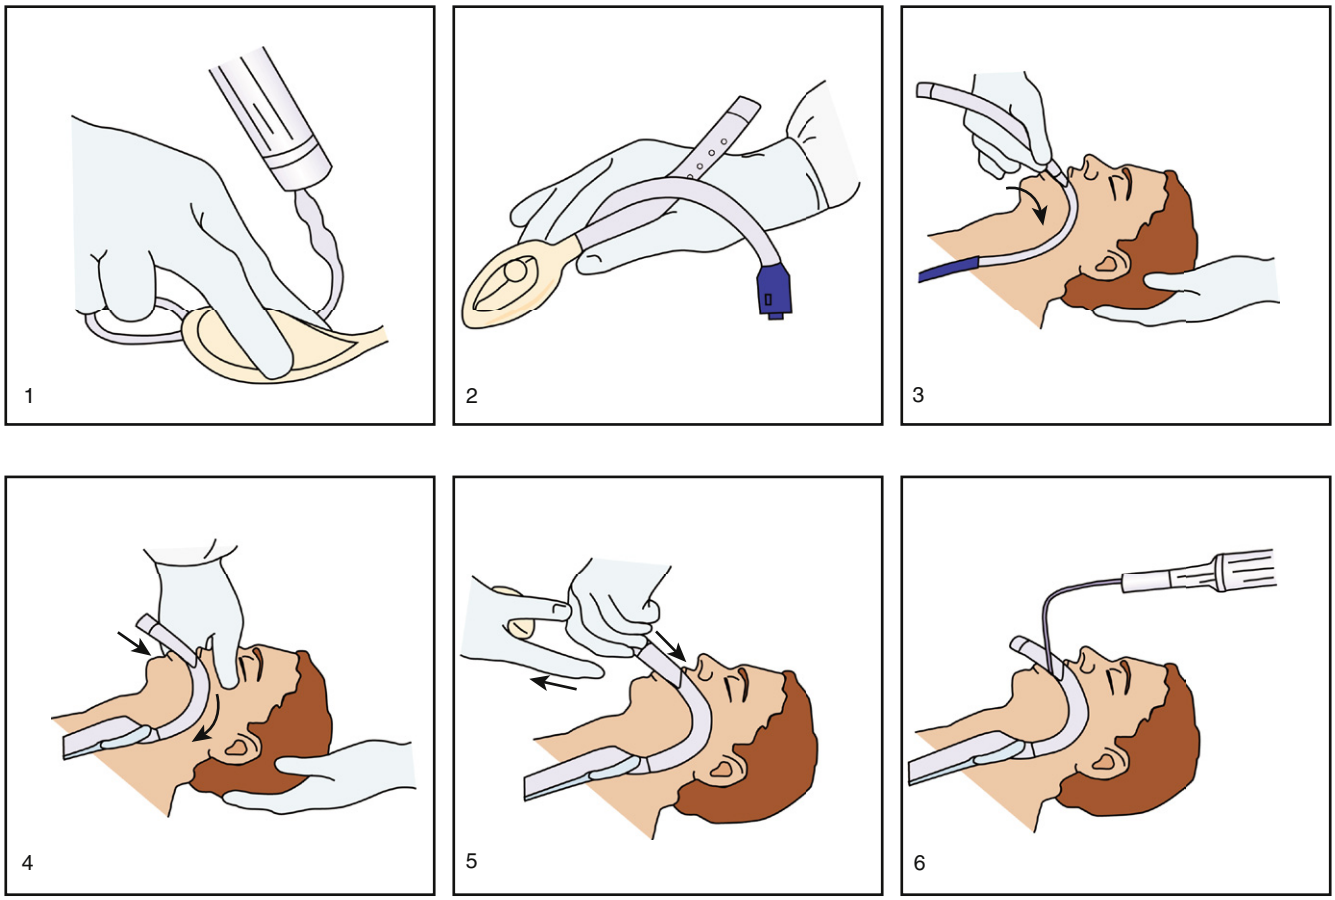

Figure 119–12. Inserting the LMA. Preoxygenate the patient as necessary. *1,* Deflate the cuff against a flat surface with index finger and middle finger on either side of the bowl. *2,* Hold the LMA like a pen, with the index finger at the junction of the tube and mask. *3 and 4,* Insert the LMA into the mouth and advance, following the palate and posterior pharyngeal wall until resistance is met. *5,* Let go of the mask and tube. *6,* Inflate the cuff, allowing the device to move into correct position. *(Modified from* Ambulance technician study, *http://www.ambulancetechnicianstudy.co.uk/.)*

textbook supports the LMA as an effective alternative to intubation during resuscitation when inserted by trained providers.[174] In neonatal resuscitation, when face mask ventilation or intubation is not successful, the LMA provides a means of rapidly improving oxygenation and heart rate. It is not, however, effective for aspirating meconium and may be inadequate for infants with severely noncompliant lungs. Use by prehospital personnel has been effective for critically ill adults, but experience in children in the field has not been reported.[175,176]

The LMA is poorly tolerated by patients with intact protective reflexes, so its use is largely limited to those with severely depressed levels of consciousness or heavy sedation or anesthesia. Lidocaine jelly on the inflatable rim or lidocaine pharyngeal spray may promote tolerance in patients with active airway reflexes. A disadvantage with use of the LMA is the inability to use airway pressures greater than approximately 20 mm Hg to prevent air leaking around the mask and to avoid gastric distention, and therefore it is not an optimal airway device in patients with severe subglottic airway obstruction, parenchymal disease requiring high ventilatory pressures, or in obese persons.[177] It also is not the ideal technique to use in a patient with a full stomach because its design does not prohibit aspiration of gastric contents. However, in an emergency situation the benefit of providing oxygenation and ventilation via an LMA outweighs the risk of an aspiration event. Other scenarios that may limit placement of the LMA include excessive neck extension, limited mouth opening, or excessive application of cricoid pressure.[177]

Although the seal is somewhat protective, patients with a full stomach remain at risk for aspiration. Positive airway pressure should be minimized as much as possible and a nasogastric tube passed to decrease gastric distension. Cricoid pressure may further decrease the risk of aspiration but also may interfere with proper LMA placement. If desired, an endotracheal tube can be inserted through the mask, either blindly or with fiberoptic bronchoscopy.[178]

Tracheostomy

Indications for tracheostomy include structural abnormalities of the upper airway requiring surgery, laryngeal trauma or complex craniofacial injury, severe facial burns, congenital anomalies lacking surgical treatment, vocal cord paralysis, and iatrogenic injury to the upper airway. Severe chronic neurologic dysfunction with impaired protective reflexes is an additional indication. Even in the absence of evidence of upper airway damage, tracheostomy may be performed to provide a more comfortable airway, which simultaneously allows airway protection, respiratory support, and greater patient mobility so that nutritional, developmental, and psychosocial needs may be met, especially, but not only, in patients undergoing chronic ventilation.[179-182]

Tracheostomy spares laryngeal and subglottic structures from the trauma of an artificial airway, particularly in active or thrashing patients. Tracheostomy tubes are less likely to be inadvertently dislodged or to become obstructed, but if either problem occurs early following tracheostomy, it is more likely to be catastrophic. Because the tube is inserted below the cricoid ring, it often is possible to use a larger tracheostomy tube than endotracheal tube. Nevertheless, a larger leak around the tube may interfere markedly with effective ventilation in patients requiring high airway pressures.

Complications in the early postoperative period include bleeding, subcutaneous air dissection, pneumothorax, pneumomediastinum, injury to the recurrent laryngeal nerve, and death, usually as a consequence of loss of control of the airway intraoperatively or an unrecognized complication from the preceding list. Nearly all pediatric patients can and should be intubated before tracheostomy. Prior intubation decreases the incidence of most technical problems. Exceptions include patients with complex facial or airway injuries or deformities and those in whom no other means of establishing an airway have been successful. Wound colonization occurs rapidly. Bacterial infection may occur, rarely involving major cervical and mediastinal structures. Swallowing difficulty is common and may result from the tube and fixation tapes limiting excursion of the larynx. Aspiration may result from alteration of the laryngeal closure reflex.

Tracheostomy tube obstruction or accidental dislodgment is suspected when the patient becomes agitated and shows signs of increased respiratory distress, a suction catheter no longer passes freely, manual ventilation is ineffective, or, in case of dislodgment, the child is suddenly able to vocalize. In such cases the tube should be removed and replaced with a new one. The child is placed supine with the head and neck extended. Oxygen is delivered to the nose, mouth, and tracheal stoma. If manual ventilation is necessary, the stoma can be occluded to allow bag-mask ventilation as previously described. A fresh tracheostomy tube is inserted, initially directly posteriorly and then caudad. Replacement with a smaller tube or endotracheal tube may be necessary if resistance is encountered. Resistance to passage of a suction catheter or ineffective ventilation following replacement of a tracheostomy tube, particularly in the first 7 to 10 days postoperatively, is highly suggestive of creation of a "false passage" in a tissue plane outside the tracheal lumen. Reestablishing tracheal cannulation may require surgical intervention. Life-threatening pneumothorax or pneumomediastinum occurs frequently in such patients.

Late complications include granuloma or stricture formation at the stoma or where the tip of the tube meets the tracheal wall. Persistent posterior wall pressure may cause tracheoesophageal fistula formation. Erosion into the innominate artery is another rare occurrence, usually when the tracheostomy incision is below the third tracheal ring. The importance of an experienced, well-trained staff immediately available to address problems is supported by data demonstrating that mortality related to tracheostomy is significantly lower when performed in a children's hospital and decreases with increasing volume.[183]

Decannulation occurs when the indications for tracheostomy are no longer present. Diagnostic laryngotracheobronchoscopy before a planned decannulation permits identification of problems likely to interfere with effective breathing, including granulation tissue, severely stenotic areas, or vocal cord abnormalities. If none is present, the indwelling tube is replaced with successively smaller tubes until the smallest available is in place and the child is breathing well. If no distress occurs, the tube is removed and the stoma is covered.

Cricothyrotomy and Retrograde Intubation

Although airway management by endotracheal intubation is possible and endotracheal intubation is the appropriate first choice in the vast majority of pediatric patients, intubation is

not possible or should not be done on certain occasions. Such situations include massive facial trauma, oropharyngeal hemorrhage or presence of a foreign body, or severe upper airway obstruction.[184] Cricothyrotomy is an alternative to tracheostomy for rapidly establishing an airway in apneic or severely distressed patients.

The child's head and neck are extended with a roll under the shoulders. The cricothyroid membrane is palpated between the inferior margin of the thyroid cartilage and the superior edge of the cricoid cartilage. With one hand (or an assistant) stabilizing the larynx and trachea, the membrane is punctured in the midline with a large angiocatheter, the stylet is withdrawn, and the catheter is connected to a source of oxygen using the connector to a size 3 endotracheal tube. Kits are available that facilitate cricothyrotomy using the Seldinger technique. Oxygenation is rapidly improved in spontaneously breathing patients, but carbon dioxide elimination is minimal. Transtracheal jet ventilation is effective through such catheters, provided that the upper airway permits passive exhalation; otherwise, severe hyperinflation and life-threatening barotrauma are certain.

Retrograde intubation can be accomplished by this approach. Once the cricothyroid membrane has been punctured and the catheter has been placed in the tracheal lumen, a long wire from a vascular access kit is advanced cephalad into the mouth. With the wire firmly secure, an ETT may be advanced into the trachea. Once the tube is in the tracheal lumen, the wire is withdrawn and the tube is further advanced into the desired position. If the wire is insufficiently stiff to permit passage of the tube into the trachea, an ETT exchanger can be advanced over the wire first, followed by the ETT.

In adults and adolescents, a small horizontal incision over the cricothyroid membrane is an alternative approach. Once the membrane is incised, it is spread vertically, and a standard tracheostomy or ETT is inserted into the tracheal lumen. This approach is not recommended in infants and young children except in highly skilled hands because of the potential for grave injury to a small, soft trachea or nearby neurovascular structures.

Complications are similar to those of tracheostomy. Complication rates of 10% to 40% are reported in adults.[184] Few experiences have been reported in pediatric patients, particularly in younger children.

VII Chapter 120

Organ System Considerations that Affect Anesthetic Management

Antonio Cassara and Peter J. Davis

PEARLS

- The anesthetic care of intensive care unit patients involves the extension of principles of medical management used in the operating room.
- The anesthesiologist caring for a critically ill child must have an understanding of the desired therapeutic endpoints and a knowledge of the patient's preexisting condition.
- For the intensive care physician, a patient returning to the intensive care unit after surgery frequently requires an altered management plan. The physiologic perturbations of surgery and anesthesia frequently change the focus and direction of medical management. The intensive care physician must understand not only the events that occur in the operating room but also the rationale for using anesthetic agents and anesthetic techniques.
- Prompt recognition of the propofol infusion syndrome and discontinuation of the infusion is key to increased survival. Early administration of hemodialysis and perhaps even extracorporeal support improves survival.
- Thromboelastography is a point-of-care test that provides a global dynamic assessment of hemostasis within 60 minutes. It is used successfully for the guidance of blood component therapy in liver transplantation.
- Recombinant activated factor seven (rFVIIa, NovoSeven) has been used to control life-threatening hemorrhage in nonhemophiliac patients. Rapid reconstitution and low volume make it easy to infuse; however its shorter half-life in children necessitates higher doses to achieve the same plasma levels as in adults.

Cardiovascular Performance

For the anesthesiologist, knowledge of the hemodynamic characteristics that have ensured adequate organ perfusion in the pediatric intensive care unit (PICU) and the interventions that the intensive care physician has used to optimize the patient's cardiovascular function is essential to choosing the appropriate anesthetic.

Changes with Development

Cardiac assessment of the PICU patient requires a knowledge of normal cardiovascular growth and development and an understanding of the influence of disease and the effects of anesthesia on cardiovascular function. The myocardium of the neonate is less compliant than that of the adult and the neonate's cardiac output depends primarily on the heart rate. Cardiac output increases substantially with age, whereas cardiac index (cardiac output divided by body surface area) ranges from 2.5 to 4.2 L/min/m^2 throughout life. Sympathetic innervation of the neonatal heart is not fully developed, and myocardial catecholamine stores are limited.[1] The response of the neonatal heart to vasoactive drugs is attenuated and the capacity for peripheral vasoconstriction during hypovolemia is reduced, probably because of the immature baroreceptor and α-adrenergic receptor systems.[2] Systemic vascular resistance is normally 800 to 1200 dynes • sec/cm^{-5} at birth and reaches the adult value of 1600 by 1 to 2 years of age. Systolic and diastolic blood pressures increase nonlinearly with age.

Pulmonary vascular resistance decreases dramatically after birth as hypoxemia-induced vasoconstriction is attenuated. During the first weeks of life, pulmonary vascular resistance continues to decrease, and by 6 to 8 weeks of age pulmonary artery pressure and resistance have reached adult values. Mean right atrial (central venous) pressure normally is 1 to 5 mm Hg. Mean left atrial pressure is 2 mm Hg greater than mean right atrial pressure throughout life. Heart rate decreases markedly during the first few months of life and then decreases gradually until adulthood. Oxygen consumption (VO_2) increases from approximately 4.6 mL/kg/min in the term newborn infant to 7 mL/kg/min by 10 days of age and 8 mL/kg/min by 4 weeks of age. Oxygen consumption gradually decreases with age, reaching an adult value of 234 mL/min/1.7 m^2 (140 mL/min/m^2 or 3.3 mL/kg/min).

Effects of Disease

Disease states can affect cardiovascular performance by their effects on the pulmonary and peripheral vasculatures and by their direct effects on the myocardium. Changes in myocardial compliance and filling pressures can profoundly influence myocardial performance. In addition, factors associated with disease states such as hypoxia, hypercarbia, acidosis, and hypothermia can affect pulmonary and systemic vascular resistances and thereby further modify myocardial function. The effects of changes in preload (i.e., the effects of fluid challenges) on the patient's blood pressure, cardiac output, and stroke volume and the clinical effects of changes in afterload

on heart rate and myocardial contractility all influence the anesthesiologist's care of critically ill children.

Effects of Anesthetic Agents

Anesthetic agents affect myocardial performance. During induction of anesthesia, potent inhaled agents such as halothane and isoflurane are associated with higher incidences of bradycardia, hypotension, and cardiac arrest in infants and children than in adults.[3] These cardiovascular depressant effects appear to be more pronounced in infants than in older children. Diaz and Lockard[4] found that more than 70% of healthy newborns had greater than 30% decrease in systolic blood pressure during induction with halothane, whereas Friesen and Lichtor[3] noted that infants 1 to 6 months of age had a 40% decrease in mean atrial pressure and a 30% decrease in heart rate when they received a halothane and nitrous oxide anesthetic. In a study of healthy children, 1.5 to 12 years of age, undergoing halothane anesthesia, Barash et al.[5] noted that systolic blood pressure and heart rate decreased in a dose-dependent manner. Similar hemodynamic effects are noted in infants anesthetized with isoflurane.[6]

Because it can be problematic to insert invasive monitors in unsedated, awake children, much of the information about the potent inhaled anesthetic agents and their effects on the determinants of cardiac output is derived from animal studies. In a neonatal piglet model, Boudreaux et al.[7] noted that the major adverse effect of halothane was its negative inotropic effect and not its negative chronotropic or unloading activity. In similarly designed studies, Schieber et al.[8] observed that, although isoflurane reduced contractility and decreased blood pressure and systemic vascular resistance more than did equipotent concentrations of halothane, cardiac index was better preserved in the isoflurane-anesthetized animals. Thus when compared with halothane, the direct myocardial depressant effect of isoflurane is offset by its effect on the peripheral vasculature, which results in afterload reduction.

Desflurane and sevoflurane are two new potent inhalational anesthetic agents. Because of their low blood solubility, they afford patients rapid induction and rapid awakening.[9-14] Desflurane has a blood gas solubility coefficient (0.42) that is similar to nitrous oxide in children. However, desflurane's pungent airway properties result in a high incidence of laryngospasm, coughing, and hypoxemia that limit its utility as an induction agent in nonintubated children.[14] The cardiovascular profile of desflurane is age dependent.[12] Compared with awake values, arterial blood pressure decreased in children anesthetized with 1 minimal alveolar concentration (MAC) of desflurane by approximately 30%, whereas the heart rate decreased or remained the same. Thus at 1 MAC, desflurane, like isoflurane and halothane, appears to attenuate the baroresponse in children. Weiskopf et al.[15] demonstrated that rapid increases in desflurane from 0.55 to 1.66 MAC in adults can transiently increase arterial blood pressure and heart rate. This cardiovascular excitation is associated with an increase in sympathetic and renin-angiotensin system activity.

Information on the hemodynamics of sevoflurane in children suggests that sevoflurane (blood gas coefficient of 0.68) appears to produce the same hemodynamic effects as isoflurane.[10] In adults anesthetized with sevoflurane or isoflurane, administration of exogenous epinephrine had similar dysrhythmogenic properties.[16] In a study of children, using echocardiograms, in which sevoflurane and halothane were compared at equal MAC, Holzman et al.[17] noted sevoflurane had fewer myocardial depressant effects than sevoflurane.

The synthetic opioids may offer more hemodynamic stability than the inhaled anesthetic agents.[18-20] Robinson and Gregory[21] were the first to report the safety and efficacy of high-dose fentanyl anesthesia in children, in a study of premature infants undergoing patent ductus arteriosus ligation. In subsequent reports on pediatric patients, Hickey and Hansen[22] documented the safety of opioid anesthesia in children with complex congenital heart disease. Although these investigators noted that high doses of fentanyl (50 and 75 μg/kg) decreased heart rate and mean arterial pressure (MAP) by 7% and 9%, respectively, in patients with bidirectional shunts, opioids had a salutary effect on pulmonary vascular resistance, increasing transcutaneous oxygenation by 45%.

Because of the prolonged respiratory and sedative effect associated with moderate- and high-dose administration of fentanyl and its congeners, shorter-acting opioids may offer the advantage of more predictable control with a similar cardiovascular profile than the longer-acting opioids. Remifentanil, a new synthetic opioid agonist with an ultrashort half-life, has been introduced into clinical practice. Remifentanil is metabolized by plasma and tissue esterases. It is independent of organ elimination. Consequently, its kinetic parameters do not change with the duration of infusion. This flat, context-sensitive half-time coupled with its ultrashort half-life (7 to 10 minutes) allow better drug effect predictability. Pharmacokinetic studies in children demonstrate faster clearances and larger volumes of distribution in neonates compared with older infants and children. In vitro studies by Olgatree et al.[23] have demonstrated that remifentanil has no significant direct negative inotropic effects on the myocardium and that β-adrenergic stimulation of the heart remains intact. Comparative studies of remifentanil to inhaled anesthetic agents in children undergoing pyloromyotomy surgery suggest that the short half-life of remifentanil may be beneficial with regard to postoperative respiratory changes.[24,25] Because of remifentanil's ultrashort half-life and its nonaccumulation with prolonged infusion, it may be a beneficial agent for the short-term (less than 12 hours) sedation of infants and children in the PICU setting. However, the rapid development of tolerance and cost issues will likely preclude its use for longer periods of time.

Dexmedetomidine, a sedative analgesic that has become increasingly popular, like clonidine is an α_2-adrenergic agonist and is highly selective with a α_2/α_1 ratio of 1600:1. Stimulation of these receptors in the central nervous system (CNS) and the spinal cord produces sedation, anxiolysis, analgesia, deceased MAC of inhalational anesthetic agents (increased sensitivity), decreased renin and vasopressin levels with increased diuresis, decreased sympathetic tone with decreased heart rate and blood pressure.[26] Dexmedetomidine has a rapid distribution phase (6 minutes) and an elimination half life of 2 hours.[27] Petroz et al.[28] demonstrated that children, 2 to 12 years of age, have similar pharmacokinetics to adults. Rodarte et al.[29] studied the pharmacokinetics in infants 1 to 24 months of age. He concluded that infants have a faster clearance of dexmedetomidine than adults (27 mL/kg/min versus 13 mL/kg/min). A loading dose of 1 μg/kg and continuous infusions of 0.2 to 0.7 μg/kg/hr have been used in various clinical scenarios to produce sedation-analgesia. The most common

adverse events are hypotension and bradycardia, whichare enhanced in the presence of cardiac comorbidities or when dexmedetomidine is used with other medications that have negative chronotropic effects (propofol, succinylcholine, digoxin, pyridostigmine).[30-32] When a loading dose of dexmedetomidine is administered, there is a biphasic response. The initial response is an increase in blood pressure with a decrease in heart rate, followed by a decrease in blood pressure and a further decrease in heart rate.[33] This biphasic effect is thought to be due to dexmedetomidine's initial ability to stimulate peripheral postsynaptic α_{2b}-adrenergic receptors resulting in vasoconstriction, followed by the more intense central CNS effects on α_{2a}-adrenergic receptors causing sympatholysis. Bloor et al.[33] administered boluses of 0.25, 0.5, 1.0, and 2.0 μg/kg to healthy volunteers and noted a decrease in mean arterial blood pressure (MAP) respectively of 14%, 16%, 23%, and 27%. Cardiac output decreased 20% following a loading dose of 1 μg/kg in the first minute and returned to 90% of baseline after 60 minutes. When a loading dose of 2 μg/kg was administered, cardiac output decreased by 60% and returned to 85% of baseline after 1 hour. Venn et al.[34] studied the effects of dexmedetomidine in 66 patients with comorbidities who were in the ICU, mechanically ventilated, and who received a loading dose of 1 μg/kg followed by a continuous infusion of 0.2 to 0.7 μg/kg/hr. Hypotension and bradycardia (≥30% decrease from baseline) was observed in 18 of the 66 patients. Reports of bradycardia and sinus arrest have also been noted by Ingersoll-Weng.[31] Khan et al.[35] reported similar effects of dexmedetomidine during anesthesia with isoflurane. The majority of the effects occurred with end-tidal isoflurane levels greater than or equal to 1%. Animal studies and studies on isolated human papillary muscle have demonstrated no direct negative inotropic effects on myocardial contractility.[36] The sympatholytic effects of dexmedetomidine on pediatric patients have been evidenced by Muktar et al.[37] Thirty infants and children undergoing CPB were randomized to receive dexmedetomidine (1 μg/kg load followed by a continuous infusion of 0.5 μg/kg/hr) or placebo. Plasma cortisol norepinephrine, epinephrine, and glucose levels were significantly less in the dexmedetomidine group.

Propofol is a sedative hypnotic that is widely used as an induction agent in anesthesia. It is also used as a continuous infusion for prolonged sedation in the ICU. Its popularity in the ICU setting comes from its rapid clearance that allows quick awakening for rapid weaning or neurologic evaluation. Propofol is suspended in a lipid emulsion, which when administered by a continuous infusion results in a significant lipid load. Induction doses for anesthesia vary from 2 to 3 mg/kg, while ICU sedation doses vary from 50 to 250 μg/kg/min. Induction doses of propofol can cause a 10% to 15% decrease of MAP as well as bradycardia, especially when coadministered with other vagotonic drugs. Propofol has a modest negative inotropic effect, due to antagonism of β-adrenergic receptors and calcium channels.[38] Since 1992, there have been increasing reports of a fatal adverse reaction that has been termed the Propofol Infusion Syndrome (PRIS).[39] To date, 61 cases (32 pediatric and 29 adult) have been reported, and there have been 20 pediatric and 18 adult deaths.[40] PRIS is characterized by severe intractable bradycardia that leads to cardiac failure, severe metabolic acidosis, hyperlipidemia, rhabdomyolysis with consequent hyperkalemia, and renal failure.[41] Prolonged propofol infusions (more than 48 hours) and infusion rates greater than 4 mg/kg/hr have been linked to PRIS. Priming factors such as critical illness (respiratory failure and traumatic brain injury) and triggering factors such as catecholamine and steroid infusion are associated with the syndrome.[44] The underlying mechanism of PRIS is not well understood. It is speculated that high doses of propofol inhibit the mitochondrial respiratory chain. As a result, there is a decreased ATP production and a decreased mitochondrial lipid metabolism, with an accumulation of toxic long fatty acid chains that are arrhythmogenic.[45-47] Management of PRIS is very difficult and consists of prompt recognition and interruption of the infusion. Aggressive cardiac resuscitation must be initiated early on with high dose inotropes, fluid administration, and the use of pacing devices. The early administration of hemodialysis and hemofiltration together with ECMO has improved survival.[48-50]

Anemia and Transfusion

Concerns about transfusion-related disease transmission have forced clinicians to reassess transfusion criteria. Rothstein[51] previously recommended that in patients younger than 3 months of age, hemoglobin concentration should be greater than 10 g/dL, whereas in children older than 3 months, a hemoglobin concentration of 9 g/dL was adequate. Slogoff[52] concluded that in normovolemic adults, a hematocrit of 20% (hemoglobin 7 g/dL) is adequate. Carson et al.[53] retrospectively reviewed mortality in 125 adult surgical patients who refused blood transfusion for religious reasons. Mortality correlated inversely with preoperative hemoglobin level and directly with operative blood loss. No operative deaths occurred among patients with a preoperative hemoglobin level above 8 g/dl and an operative blood loss of less than 500 mL.

Transfusion guidelines should anticipate age-related changes in the oxygen dissociation curve. P_{50} (partial pressure of oxygen at which hemoglobin is 50% saturated with oxygen) is lower in newborns than in adults. In a child 1 year of age, the P_{50} is higher than in normal adults. By 9 to 12 years of age, the P_{50} has decreased to adult values. These age-related changes in hemoglobin's affinity for oxygen alter oxygen unloading to the peripheral tissues.

Minimum acceptable hemoglobin (and approximate hematocrit) levels can be inferred from anticipated tissue oxygen delivery (Table 120-1). A hemoglobin concentration of 7 to 8 g/dL (hematocrit 21% to 24%) is reasonable for adults and children based on the previous discussion. Minimum values chosen for infants should be more conservative (i.e., ensure greater oxygen delivery to tissues) than those for older patients. This takes into consideration the higher oxygen consumption of infants and provides them with a larger margin of safety against hypoxic injury. Infants younger than 2 months probably require a hemoglobin level of 13 g/dL (hematocrit of 40%); infants older than 3 months require a hemoglobin level of 7 g/dL (hematocrit of 21%). Infants aged 2 to 3 months are in a transitional phase, and minimum hemoglobin levels are more difficult to predict. These values are intended as guidelines only; each patient must be considered individually.

Patients with chronic anemia increase oxygen delivery by increasing cardiac output. Although the potent inhaled anesthetic agents decrease myocardial function and cardiac output and thereby decrease oxygen delivery, these side effects

Table 120–1 Hemoglobin Requirement for Equivalent Tissue Oxygen Delivery

	P_{50} (mm Hg)	Hb for Equivalent O_2 Delivery (g/dL)						
Adult	27	7	8	9	10	11	12	13
Infant >3 mo	30	5.7	6.5	7.3	8.2	9.0	9.8	10.6
Neonate <2 mo	24	10.3	11.7	13.2	14.7	16.1	17.6	19.1

Data from Motoyama EK, Zigas CJ, Troll G: Am Soc Anesthesiol (abstract), 1974.

are offset by the decrease in oxygen consumption that occurs in anesthetized patients. The need to transfuse blood in the perioperative period frequently is determined by the patient's underlying hemodynamic stability, the type of surgery anticipated, and the known risks of administering blood products. In general, unless the procedure is minor, blood should be available for all ICU patients. Because ICU patients frequently are monitored with invasive catheters, serial measurements of hematocrit or hemoglobin usually can be obtained during the operative procedure to determine whether transfusion is warranted.

Respiratory Failure

When respiratory failure is present, the anesthesiologist must be aware of its precipitating factors. Acute respiratory distress syndrome (ARDS) is a clinical syndrome of respiratory distress, poor pulmonary compliance, and hypoxemia that usually occurs after a nonpulmonary condition such as shock, trauma, sepsis, or an unexplained condition leading to pulmonary parenchymal disease and respiratory failure. Direct mortality from respiratory failure is approximately 10% to 20%; overall mortality may be as high as 65%. ARDS was first described as a clinical entity occurring in pediatric patients in 1980.[54] Recognized factors predisposing pediatric patients to the development of ARDS include severe infection, cardiac arrest, shock, and aspiration. Although the cause of this condition is uncertain, the fundamental defect in the lung is injury to the pulmonary capillary endothelial cells, leading to interstitial and, ultimately, alveolar pulmonary edema. This pulmonary vascular leakage results in hypoxemia, decreased pulmonary compliance, increased pulmonary vascular resistance, and venoarterial shunting.

The mainstays of treatment are endotracheal intubation, continuous positive-pressure ventilation with positive end-expiratory pressure (PEEP), and supplemental oxygen. Invasive monitoring by arterial, central venous, and pulmonary arterial cannulation may be necessary to optimize preload and cardiac output in the presence of high PEEP and high transpulmonary pressures. The patient's requirements for oxygen, PEEP, and pulmonary toilet must be understood preoperatively. Patients with poor pulmonary compliance challenge the ability to maintain adequate intraoperative ventilation. Preoperative knowledge of the interaction of PEEP with the adequacy of ventilation and cardiovascular function is an important concern of the anesthesiologist. Anesthetic agents can modify not only cardiovascular function, but also respiratory function, by their effect on hypoxic pulmonary vasoconstriction. Patients with ARDS may rely in part on regional hypoxic pulmonary vasoconstriction to minimize intrapulmonary shunting. Shifting of pulmonary blood flow away from atelectatic lung regions has been well described. The administration of vasoactive drugs and potent inhaled anesthetic agents inhibits hypoxic pulmonary vasoconstriction and therefore may exacerbate hypoxemia by increasing intrapulmonary shunting.[55,56]

Table 120–2 Signs of Intracranial Hypertension in Infants and Children

Infants	Children	Infants and Children
Irritability	Headache	Decreased consciousness
Full fontanelle	Diplopia	Cranial nerve (III and VI) palsies
Widely separated cranial sutures	Papilledema	Loss of upward gaze (setting sun sign)
Cranial enlargement	Vomiting	Signs of herniation, Cushing triad, pupillary changes

Neurologic Injury

The leading form of pediatric trauma is traumatic brain injury (TBI), which accounts for 36% of traumatic deaths in the USA.[57,58] Eighty percent of trauma patients have central nervous system injury, and in 60% of these patients, the CNS injury is the most severe. It is estimated that 185 of every 100,000 children experience head trauma requiring hospitalization.[58,59] Poor outcomes have been associated with early hypotension, low Glasgow Coma Scale score, altered cerebral blood flow (CBF), hyperglycemia, and deranged autoregulation.[59] Neurologic injury may be the primary insult resulting from trauma. However, secondary cerebral injury may result from the development of intracranial hypertension and resultant cerebral ischemia. Recognition and control of elevated intracranial pressure (ICP) are key elements to preventing neurologic deterioration and patient morbidity. Secondary traumatic brain injury can be characterized by an array of biochemical, cellular, and molecular events that are associated with ischemia, excitotoxicity, energy failure, and cell death cascades, all of which result in cerebral swelling, axonal injury, inflammation, and regeneration.[60]

Intracranial Pressure

The signs of intracranial hypertension in infants and children are listed in Table 120-2. The presence of these signs and symptoms, in conjunction with the baseline findings on neurologic examination, may dramatically alter the patient's anesthetic care. The anesthesiologist must be aware of ongoing interventions to control ICP. Control of cerebral

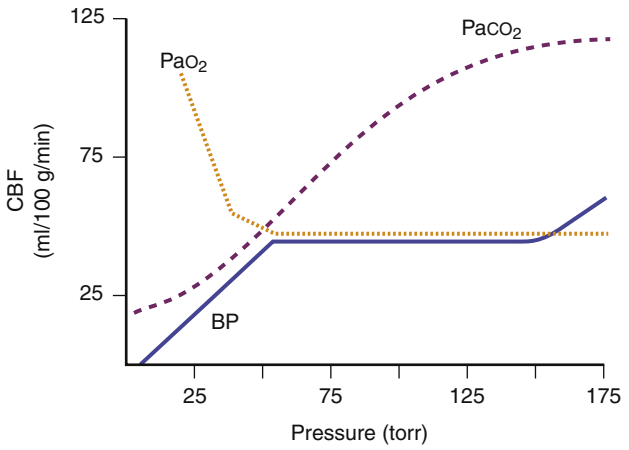

Figure 120–1. Cerebral blood flow *(CBF)* changes resulting from alterations in $Paco_2$, Pao_2, and blood pressure. The other two variables remain stable at normal values when the remaining variable is altered. *(Modified from Shapiro HM: Intracranial hypertension: therapeutic and anesthetic considerations,* Anesthesiology *43:445, 1975.)*

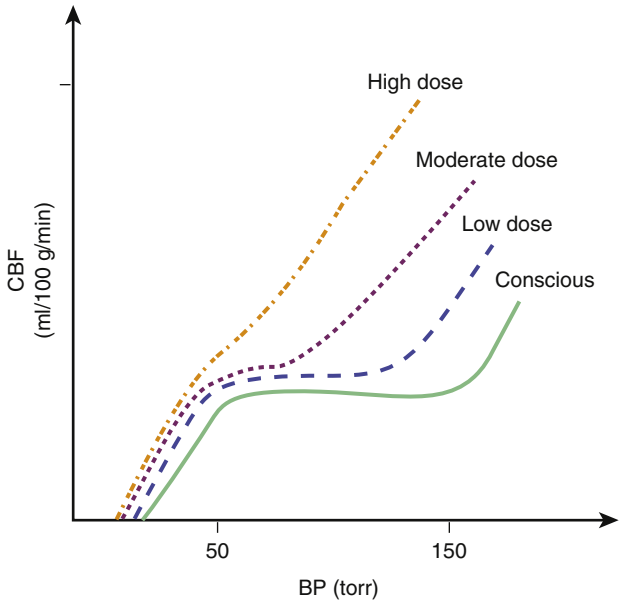

Figure 120–2. Volatile anesthetics and autoregulation. Schematic representation of the effect of a progressively increased dose of a typical volatile anesthetic agent on cerebral blood flow *(CBF)* autoregulation. Both upper and lower thresholds are shifted to the left. *(Modified from Drummond K, Shapiro HM: Cerebral physiology. In Miller R, editor:* Anesthesia, vol 2, *ed 3, New York, 1990, Churchill Livingstone.)*

perfusion pressure is essential for maintaining neurologic function in pathologic states. Cerebral perfusion pressure is expressed as the difference between MAP and the highest value obtained out of the following: central venous pressure, intrathoracic pressure, or ICP. Thus in the presence of intracranial hypertension (ICP ≥15 to 20 mm Hg), higher systemic blood pressures must be achieved to prevent cerebral ischemia. Intracranial compliance depends on the volumes of the intracranial contents, cerebral tissue, blood, and extracellular fluid. The most dynamic of these is the blood compartment. Changes in cerebral blood volume are mediated primarily through changes in cerebral vascular resistance. Cerebral vascular resistance is affected by both intracranial and extracerebral factors.

Regulation of Cerebral Blood Flow

The normal brain receives 15% of cardiac output. Kennedy and Sokoloff[61] determined that healthy children have a high CBF (100 mL/100 gm/min), this value decreases to adult values of 50 mL/100 gm/min during the teenage years. Cerebral blood flow regulation depends primarily on the local chemical and metabolic milieu, particularly the concentrations of hydrogen ion, adenosine, and prostanoids. Production of these compounds correlates with normal cerebral activity and metabolic rate. Neurogenic and myogenic components also have minor roles in regulating cerebral vascular resistance.

Extracerebral factors that can change cerebral vascular resistance and CBF include the arterial partial pressures of carbon dioxide ($Paco_2$) and oxygen (Pao_2), MAP, and various drugs (Figure 120-1). Cerebral circulation is very sensitive to variations of $Paco_2$, and has been studied using transcranial Doppler ultrasound.[62] CBF varies linearly by 2% to 4% for every variation of 1 mm Hg of $Paco_2$. Data from anesthetized children show that CO_2 vasoreactivity is higher than in adults (13.8% vs. 10.3% change).[63] Low blood pressure decreases cerebral vascular vasoreactivity.[63] As $Paco_2$ is rapidly lowered toward 20 mm Hg, there is marked cerebral vasoconstriction and reduction in both CBF and ICP. Theoretically, an acute decrease in $Paco_2$ below 20 mm Hg may be detrimental by reducing CBF enough to cause cerebral ischemia. The salutary effects of acute hyperventilation on ICP are diminished over time because acute changes in cerebrospinal fluid pH are normalized in approximately 6 hours. Arterial oxygenation within the normal clinical range has little effect on cerebral vascular resistance. However, Pao_2 less than 50 mm Hg results in cerebral vasodilation and increased CBF. Hyperoxia in excess of 300 mm Hg may produce cerebral vasoconstriction.

Cerebral autoregulation is a homeostatic process by which the brain maintains a constant CBF over a MAP range from 60 to 150 mm Hg in adults. At an MAP less than 60 mm Hg, symptoms of cerebral ischemia may appear. If the upper limit of MAP for autoregulation is exceeded, the resultant increase in CBF may cause cerebral edema. The autoregulatory curve may shift in the presence of chronic hypertension, intracranial tumors, head trauma, or shock states. This renders the brain more susceptible to ischemic effects.[63] The range of MAP over which autoregulation of CBF occurs in infants and children likely shifts in tandem with age-related changes in normal systemic blood pressures and cerebral perfusion pressures. Raju et al.[64] suggest that an infant's mean cerebral perfusion pressure is approximately equal to its gestational age in weeks and that this estimate holds true for growing preterm infants up to 5 weeks after birth.

Effects of Anesthetics on Cerebral Blood Flow

In general, the potent inhaled anesthetic agents impair autoregulation and may cause hypotension and increased CBF (Figure 120-2). Consequently, they must be used cautiously, if at all, in patients with evidence of traumatic brain injury.

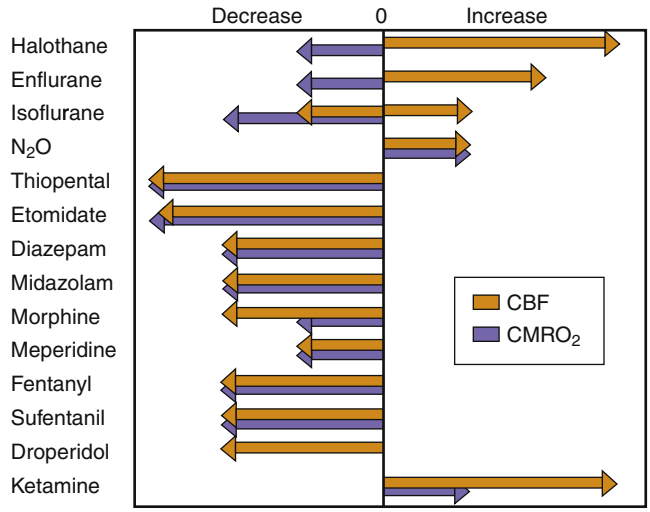

Figure 120–3. Effects of anesthetic agents on cerebral blood flow *(CBF)* and cerebral metabolic rate of oxygen ($CMRo_2$). *(Modified from Cucchiara RF, Block S, Steinkeler JA: The effects of anesthetic agents on cerebral blood flow and cerebral metabolism: anesthesia for intracranial procedures. In Barash PG, Cullen BF, Stoelters SK, editors:* Clinical anesthesia, *Philadelphia, 1989, JB Lippincott.)*

Halothane and enflurane at 1 MAC abolish cerebral autoregulation. Isoflurane impairs autoregulation less than halothane.[65] The effects of anesthetic agents on CBF and cerebral metabolism are summarized in Figure 120-3. In general, the perfect agent would decrease both CBF and cerebral metabolic rate of oxygen ($CMRo_2$). The potent inhaled agents (halothane, enflurane, and isoflurane) "uncouple" the normal relationship between CBF and metabolism and cause marked cerebral vasodilation. Isoflurane is the only inhaled anesthetic agent with which CBF actually may decrease when concomitant hyperventilation to $Paco_2$ of 20 to 25 mm Hg is used.[66] Whereas nitrous oxide alone is known to cause mild cerebral vasodilation and to increase $CMRo_2$ (probably related to inadequate anesthetic depth), these effects are easily countered by the addition of intravenous sedatives, hypnotics, and narcotics. There are limited data regarding the effects of the two newest inhaled agents, sevoflurane and desflurane, on intracranial dynamics. Although the effects of desflurane on CBF have been studied, there is relatively little information regarding the effects of sevoflurane on CNS physiology in human subjects. Artru et al.[67] noted that desflurane increases CSF pressure in animals. Ornstein et al.[68] showed that in patients with intracranial mass lesions, desflurane and isoflurane have similar effects on CBF. The electroencephalographic effects of desflurane are similar to those of isoflurane, with prominent burst suppression occurring at 1.24 MAC.[69]

In volunteers using transcranial Doppler, Bedforth et al.[70] noted that at 1 MAC of desflurane, cerebral autoregulation was impaired and that at 1.5 MAC autoregulation was abolished. In a separate study of adult non-neurosurgical patients, Bedforth et al.[71] noted that the introduction of desflurane following induction of anesthesia with propofol impaired cerebral autoregulation more than with equi-MAC doses of sevoflurane. In contrast, in studies of static and dynamic compliance of autoregulation, Strebel et al.[72] noted that, at 1.5 MAC desflurane and 1.5 MAC sevoflurane, autoregulation was impaired but propofol (200 μg/kg/min) had no effect. Muzzi et al.[73] showed that 1 MAC of desflurane in adults with supratentorial lesions increases ICP as opposed to 1 MAC of isoflurane. Desflurane may alter CSF dynamics. Desflurane does not appear to change CSF absorption but does increase CSF production.[73]

In a study of patients undergoing non-intracranial neurosurgical procedures, Summors et al.[74] noted that dynamic cerebral autoregulation using transcranial Doppler ultrasonography is better preserved during 1.5 MAC sevoflurane than 1.5 MAC isoflurane anesthesia. Others noted similar findings with sevoflurane and isoflurane. In patients studied at 0.5 and 1.5 MAC, the dose-dependent vasodilatory effect was less for sevoflurane.[75,76] Nishiyama et al.[77] assessed comparative cerebral vasodilatory responsiveness to CO_2 during either sevoflurane or isoflurane anesthesia. Nishiyama et al.[71] noted in a group of adult patients that changes in CBF caused by changes in CO_2 are greater during isoflurane anesthesia. However, attempts to decrease ICP by decreasing CO_2 were more successful with isoflurane than with sevoflurane. In addition to cerebral vascular autoregulation, sevoflurane use is associated with epileptiform activity. In pediatric patients with and without a preexisting history of epilepsy, induction by sevoflurane of tonic, clonic, and silent seizures during the induction and maintenance of anesthesia is reported.[78-80]

For the anesthesiologist, knowledge of the patient's ICP and cranial compliance and an understanding of the pathophysiology of the CNS lesion are important for planning appropriate anesthetic management.[81] In experimental animals, Statler et al.[81] demonstrated that isoflurane had more neuroprotective effect than fentanyl in rats that had undergone controlled cortical impact lesions. Hendrich et al.[82] quantified CBF using labeled magnetic resonance imaging in normal rats anesthetized with fentanyl, isoflurane, or pentobarbital. In this study, CBF values were found to be approximately 2.5 to 3 times lower in most regions analyzed during anesthesia with either fentanyl (with N_2O/O_2) or pentobarbital versus isoflurane (with N_2O/O_2). In addition, these investigators noted that CBF was heterogeneous in rats anesthetized with isoflurane (with N_2O/O_2) but relatively homogenous in rats anesthetized with either fentanyl (with N_2O/O_2) or pentobarbital. In previous human studies with opioid anesthesia, opioids maintained static cerebral autoregulation. Engelhard et al.[83] subsequently demonstrated that remifentanil, a mu-opioid agonist with unique pharmacokinetic properties, when combined with low-dose propofol maintains both static and dynamic compliance of cerebrovascular autoregulation. Propofol also has been used to alter CNS dynamics.[84] Positron emission tomography suggests that propofol produces global metabolic depression.[85,86] Like thiopental, propofol decreased $CMRo_2$, CBF, and ICP. Cerebral responsiveness to arterial CO_2 appears to be preserved during propofol anesthesia.[87,88]

Hepatic Dysfunction

An assessment of liver function is important for two aspects of anesthetic management. The liver is a major site of drug metabolism and is involved in homeostasis of the coagulation system. Anesthesia and surgery may exacerbate liver dysfunction in patients with preexisting liver disease and,

in some instances, may cause life-threatening hepatic failure. Although the cause of hepatic dysfunction in surgical patients is unknown, it may be related to decreases in hepatic blood flow. Consequently, anesthetic drugs and techniques that may decrease hepatic blood flow should be avoided if possible.

Effects of Anesthetics on Hepatic Blood Flow

Blood flow in the splanchnic circulation can be altered by numerous factors. Mechanical ventilation, by altering the normal relationship between splanchnic venous outflow and venous outflow from the kidney and lower extremities, may affect splanchnic blood flow. The changes associated with mechanical ventilation can be further exacerbated by increasing tidal volume and applying PEEP.[89] Carbon dioxide concentration also influences splanchnic blood flow.[90] Various anesthetic agents may have different effects on hepatic blood flow.[91] Gelman et al.[92] showed that hepatic oxygen supply is better maintained during isoflurane than during halothane anesthesia. In addition, in hypoxic rat models, the incidence of hepatic centrilobular necrosis was least with isoflurane compared with halothane, nitrous oxide, and fentanyl. Although anesthetic agents can decrease hepatic blood flow, Gelman et al.[92] demonstrated that the decrease in hepatic blood flow is small compared with the decrease associated with the surgical stress of a laparotomy. Surgical procedures involving traction and manipulation of the abdominal viscera are associated with the release of various vasoactive compounds that may further alter splanchnic blood flow. In sevoflurane-anesthetized dogs, Frank et al.[93] demonstrated that hepatic arterial blood flow was maintained, portal blood flow was decreased, and total hepatic blood flow was unchanged. In desflurane-anesthetized dogs, hepatic artery blood flow was maintained, portal blood flow was decreased, and total hepatic blood flow was reduced.[94]

Effects of Liver Disease on Pharmacokinetics

In addition to the effects of anesthetic agents on the liver, hepatic disease affects the pharmacology of anesthetic agents. Little is known about the pharmacologic properties of anesthetic agents in pediatric patients with liver disease.[95,96] Although the liver is the major site of drug biotransformation, the effects of hepatic dysfunction on drug elimination and disposition are inconsistent.[97] The degree of liver dysfunction and a drug's ability to bind to plasma proteins are important variables in determining drug kinetics in patients with liver disease. For drugs with a high hepatic extraction ratio, hepatic clearance is sensitive to changes in hepatic blood flow, whereas for drugs with a low hepatic extraction ratio, hepatic drug clearance is a function of intrinsic hepatic enzyme activity and protein binding.[97] Thus the reported inconsistent effect of liver disease on drug pharmacology may be a function of the heterogeneous pathophysiology of liver disease with respect to hepatocellular function, protein binding, and hepatic blood flow. Table 120-3 compares opioid pharmacokinetics in patients with and without liver disease. Note that the effects of hepatic disease are variable with respect to the pharmacokinetics of opioids. Remifentanil, a μ-opioid agonist that undergoes plasma and tissue esterase metabolism, is unaffected, with respect to its pharmacokinetic profile, by liver disease.[98,99]

The pharmacokinetics of neuromuscular blocking agents (NMBAs) in adults have been well studied. Of the nondepolarizing NMBAs, pancuronium, vecuronium, and atracurium are significantly metabolized. Of these agents, only pancuronium and vecuronium pharmacokinetic profiles are altered by liver disease. In a study of children with moderate-to-severe liver dysfunction, Brandom et al.[100] showed that liver failure has no effect on atracurium pharmacokinetics. Mivacurium is a benzylisoquinolium diester metabolized by plasma cholinesterase. It is an NMBA of short duration. Greene et al.[101] noted

Table 120–3 Pharmacokinetics of Narcotics

Drug	Disease	Vd	$t_{1/2\beta}$	Clearance

that the severity of disease did not correlate with the duration of mivacurium blockade in pediatric patients with liver disease compared with controls. However, mivacurium's initial recovery and overall recovery from neuromuscular blockade did correlate inversely with the concentration of plasma cholinesterase.

Cisatracurium is a stereoisomer of atracurium. In patients with normal hepatic and renal function, the duration of action of cisatracurium is similar to that of atracurium. DeWolf et al.[102] noted that although the kinetic profile of cisatracurium differed in patients with liver failure compared with control patients, the duration of clinical effectiveness was similar for the two groups of patients. In patients with hepatic failure, clearance of rocuronium is reduced, and the volume of distribution is increased. Consequently, the elimination half-life is prolonged.

The Role of the Liver in Coagulation

The liver has a dual role in the coagulation system. It synthesizes proteins necessary for the coagulation cascade, and it functions as a clearing mechanism of the fibrinolytic system. Because coagulopathies are common in patients with liver disease and because hemostasis is paramount in any surgical procedure, coagulation monitoring and knowledge of the clinical effects of blood products on the coagulation system provide important information. Surgical procedures in which massive volumes of blood are transfused frequently result in dilutional thrombocytopenia. The need for platelet transfusions is a function of the amount of blood transfused and the initial platelet count. The appropriate use of blood products is discussed elsewhere in this textbook. For patients with severe hepatic dysfunction undergoing surgical procedures, as well as for patients with normal coagulation profiles who are anticipated to need transfusion of more than one blood volume, an adequate supply of blood products must be available before surgery is started.

Thromboelastography (TEG) has been in use for more than 60 years.[103] Developed during the Second World War, it has had a revival with the advent of transplantation and the ability to perform more complex surgeries. Moreover, new technology has made this point-of-care test easier to execute, more reliable, and reproducible.[104,105] TEG is a global dynamic assessment of hemostasis that can yield information on several different components of coagulation within 60 minutes. Its use for the guidance of blood component therapy in liver transplant has been demonstrated.[106,107] TEG measures the static viscoelastic properties of whole blood. As a clot begins to form in the sampling cup, the viscoelastic properties of the sample increase and an increase in amplitude is registered on the tracing. At the end of the test a characteristic trace with two arms is created.[108] Various measurements are derived from the tracing (Figure 120-4).[109] The R-time is the time in minutes from the start of the sample run until the first traces of clot mesh are detected (defined as an increase in amplitude of 2 mm). R-time generally reflects factor levels. The K-time is the time elapsed between the amplitudes of 2 and 20 mm on the TEG tracing and reflects velocity of clot formation. The α-angle is the slope drawn from r to k. The angle reflects fibrinogen activity. The maximum amplitude (MA) is the greatest vertical amplitude. It reflects clot strength and indirectly assesses platelet number and function and fibrin formation. The clot lysis index (A60) is the amplitude 60 minutes after the MA is achieved. It represents fibrinolytic activity. Alternatively, lysis 30 (Ly30) can be used, which assesses fibrinolysis at a shorter time interval.

Andrew et al.[110] demonstrated that the coagulation system of newborns is immature and undergoes a maturational process in the first year of life, during which time factor levels reach near adult levels. Clinical practice, however, shows that this does not expose neonates and infants to increased bleeding during surgery. Paradoxically, TEG tracings of healthy newborns show that neonates initiate and develop clots faster than adults.[111] R-time is significantly shorter despite a prolonged aPTT when compared to adults. MA values are also increased when compared to adults. An explanation of this can be due to the presence of adult levels of factors VIII and XIII, vonWillebrand factor, and platelets, already at birth, and lower levels of inhibitors, especially antithrombin III. This imbalance could promote faster activation and a more resistant clot.[111]

Thromboelastography has facilitated solid organ transplantation, and much of our understanding of the relation of TEG with the coagulation cascade has come from patients undergoing liver transplantation. Patients during liver transplants are frequently in a hypocoagulable state, with an increased risk for perioperative bleeding. The reasons for this hypocoagulable state included decreased synthesis of coagulation proteins, decreased platelet number and function, and increased fibrinolysis secondary to decreased hepatic clearance of TPA.[112] TEG tracings can reflect this state with prolonged r-time, decreased α-angle and decreased MA. During the anhepatic phase (when the liver is removed), fibrinolysis increases and there is further deterioration of the MA and the α-angle. The A60 is also decreased. The TEG tracing shows signs of hyperfibrinolysis. With the absence of the liver, there is no hepatic clearance of TPA and, in addition, low levels exist of the plasmin inhibitor α_2-antiplasmin.[113] When the donor liver is reperfused (reperfusion phase), a reperfusion coagulopathy can further affect hemostasis. Increased amounts of plasminogen activators released by the damaged endothelium of the donor liver and the presence of exogenous heparin in the donor liver are the cause. TEG tracings can show extreme levels of hyperfibrinolysis, and the r-time can be further prolonged. TEG analysis with heparinase sample cups demonstrates the contribution of heparin to the coagulopathy by a partial correction of the tracing when compared to the native without heparinase.[114]

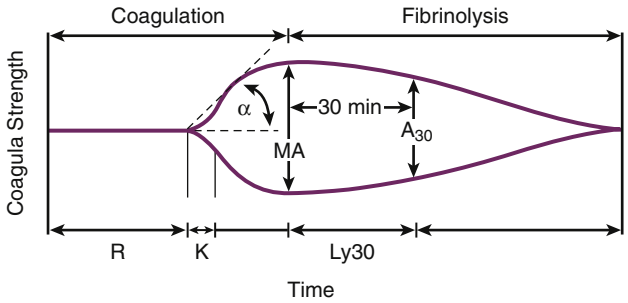

Figure 120–4. R reflects coagulation factor activites, K and α show fibrinogen and coagulation formation, MA indicates platelet function, Ly30 reflects fibrinolysis, A30 is the amplitude after MA. *(Modified from Raikvam H, et al: Thromboelastography,* Transfus Apher Sci *40:119-123, 2009.)*

In 1985, Kang et al.[107] devised a protocol for blood component therapy guided by TEG tracings. This protocol dictated that an r-time of ≥15 min needed 2 units of FFP, an MA of ≤40 mm needed 10 units of platelets, and when the α-angle was ≤45° or there was no improvement with the above blood component therapy, 6 units of cryoprecipitate was given. When blood requirements of this group were compared to a historical control group, they found that the TEG-monitored received 33% less blood. In addition, TEG can be used as an in vitro test to predetermine the effectiveness of the antifibrinolytic agents tranexamic acid and epsilon aminocaproic acid (EACA).[115,116]

Recombinant activated factor VII (rFVIIa, NovoSeven) is an analogue of the naturally occurring activated Factor VII and is a powerful hemostatic agent. It is approved by the FDA for use in patients with congenital or acquired hemophilia with inhibitors who are actively bleeding or for prophylaxis prior to invasive surgery or procedures.[117,118] rFVIIa directly enhances thrombin generation, locally at the site of endothelial damage where tissue factor is exposed, and indirectly on the activated platelet surface, creating the thrombin burst generating enormous amounts of fibrin mesh in the proximity of the damaged vasculature.[119,120] Since its marketing in the United States in 1999, there has been an exponential increase of publications regarding the off-label use for life-threatening hemorrhages of various origins in nonhemophiliac patients, giving rFVIIa a potential role as a universal hemostatic agent.[121] The lack of randomized trials for off-label use of rFVIIa in children makes it difficult to evaluate its efficacy and safety. At present, the only randomized trials are in children with hemophilia where a standardized treatment regimen of 90 μg/kg every 2 hours was administered until hemostasis was obtained.[118] Its fast reconstitution and low volume leads to rapid administration without risk of fluid overload. There is, however, intersubject variability, and its short half-life in children (1.32 hours vs. 2.72 hours in adults)[122] increases costs, because higher doses are necessary to achieve the same plasma levels as in adults.[123] There are several case series describing the use of rFVIIa in children with severe liver failure.[124-126] Varying doses from 40 to 100 μg/kg were used as a last effort to correct severe bleeding after failure of conventional blood component therapy. Pediatric liver transplants have a higher incidence of vascular graft thrombosis because of the smaller caliber of the vascular grafts, and it is feared that the administration of rFVIIa can increase the incidence of vascular graft thrombosis. Kalicinski et al.[127] reviewed 89 consecutive patients, aged 1 to 20 years, who underwent cadaveric liver transplant. Twenty-eight of these patients had a high risk of intraoperative blood loss and received rFVIIa prior to transplant. When compared to the 61 patients that had no increased intraoperative risk of blood loss, they noted no difference in blood loss, operating time, reexploration, and hospital stay. Interestingly no thromboembolic events were observed in the group that received rFVIIa, while in the 61 patients that did not receive rFVIIa, three had hepatic artery thrombosis, two had portal vein thrombosis, and one had hepatic vein thrombosis. The authors suggest that despite the use of rFVIIa, the overall hemostatic balance remains modestly hypocoagulable.[127] Currently, there are no laboratory tests that can predict the clinical response to rFVIIa. Most clinicians are using the prothrombin time to monitor its hemostatic effect, although it does not reflect in vivo responses.[128] Hendricks et al. reported monitoring the effects of rFVIIa by TEG analysis.[129] Both onset of clot formation and amplitude and clot stability improved after administration of rFVIIa.

Renal Failure

One major function of the kidneys is the regulation of fluid and electrolyte balance. Hyponatremia and hyperkalemia, the electrolyte disorders seen most often in patients with renal failure, are discussed briefly. Management of fluid and electrolyte abnormalities associated with renal failure is reviewed elsewhere in this textbook. However, some aspects of fluid and electrolyte disturbance have implications for anesthetic management.

Fluid and Electrolyte Disturbances

In clinical practice, it is desirable to maintain serum sodium concentrations greater than 125 mEq/L. At lower levels, symptoms including irritability, personality change, muscle weakness, and depressed deep tendon reflexes may occur. More severe hyponatremia (≤120 mEq/L) may cause cerebral edema and may be associated with nausea, vomiting, confusion, convulsions, hypothermia, and even death. In addition, anesthetic requirements may decrease significantly in the presence of serum and CSF hyponatremia.

Hyperkalemia may produce well-recognized electrocardiographic changes, including symmetrical peaking of the T wave, ST-segment depression, and heart block. Ventricular fibrillation or asystole may result from extreme hyperkalemia. This has been observed after the use of depolarizing NMBAs such as succinylcholine, which further increase plasma potassium concentrations by increasing muscle plasma membrane permeability.

The acidosis associated with renal failure would not be expected to interfere with reversal of neuromuscular blockade. Miller and Roderick[66] demonstrated that metabolic alkalosis, but not metabolic acidosis, may prevent neostigmine-induced antagonism of pancuronium. The mechanism proposed depends on simultaneous decreases in calcium and potassium levels. Whether the hypocalcemia associated with renal failure clinically affects reversal of NMBAs remains to be demonstrated. In the event of prolonged neuromuscular blockade, dialysis should easily remove both NMBAs and anticholinesterase agents used for reversal of blockade. Both classes of drugs are highly ionized compounds.

Perioperative dialysis may be required to control hyponatremia, fluid overload, hyperkalemia, or severe acidosis in the surgical patient with renal failure. When possible, dialysis should be accomplished shortly before surgery to optimize the patient's preoperative status. The goals of dialysis should not include dehydration. Patients who are dehydrated may become hypotensive during induction and maintenance of anesthesia. Laboratory evaluations including electrolytes may need to be evaluated following dialysis and prior to anesthetic care.

Renal Drug Metabolism

The kidneys also function in drug elimination. The effects of renal failure on drug disposition and elimination are of particular interest to the anesthesiologist. Nondepolarizing NMBAs

are the major class of anesthetic agents excreted primarily by the kidneys. Drugs that are almost exclusively eliminated by the kidney (e.g., gallamine and metocurine) should be avoided in the presence of renal failure. Pancuronium accumulates despite its partial hepatic metabolism and biliary excretion and may demonstrate as much as a fivefold increase in elimination half-life in anephric patients. The intermediate-duration NMBAs vecuronium and atracurium should be considered for use in patients with renal failure.[130,131] Although vecuronium depends primarily on hepatobiliary excretion with only 20% primarily excreted by the kidney, its active hepatic metabolites are dependent on renal excretion and may accumulate with repeated dosing in patients with renal dysfunction. Therefore it may result in prolonged blockade, depending on the degree of renal failure or insufficiency. Atracurium elimination occurs by Hoffmann elimination and ester hydrolysis in the plasma. Because these processes are independent of renal and hepatic function, the elimination half-life of atracurium is constant regardless of failure of these organs.[100,132] Atracurium metabolism produces laudanosine, which is associated with seizures in laboratory animals at high plasma concentrations.[133] Data in human subjects indicate that the risk of such seizures probably is not clinically relevant. ICU patients receiving atracurium infusions for up to 219 hours had maximum plasma concentrations well below the threshold for canine seizures and showed no evidence of cerebral excitation.[134] The effects of renal failure on this scenario are not documented. Mivacurium is a bisquarternary benzylisoquinolinium diester, nondepolarizing NMBA that is metabolized by plasma cholinesterase. It is a mixture of three optical isomers. Mivacurium at a dose of 0.15 mg/kg prolonged neuromuscular blockade by a factor of 1.5 in patients with renal disease compared to patients with normal renal function.[135]

Cisatracurium is one of the stereoisomers of atracurium and is thought to be three times more potent than atracurium but with a similar duration of action. Like atracurium, cisatracurium is metabolized by Hoffmann elimination, and the drug does not accumulate. Its duration of action is not prolonged in patients with renal failure.[136] Rocuronium is a monoquaternary steroidal NMBA of rapid-to-intermediate onset of action and intermediate duration. The clinical duration of rocuronium is similar to that of vecuronium. It has a rapid onset of action, but in patients with renal disease, the onset of action is decreased by 30% to 40% and its duration of action is prolonged and variable.[137,138]

The anticholinesterase agents used to reverse neuromuscular blockade (neostigmine, pyridostigmine, and edrophonium) are eliminated primarily by the kidney, and renal failure markedly prolongs their duration of action. In the absence of renal function, the reversal of neuromuscular blockade induced by atracurium and vecuronium should not be complicated by recurrence of blockade.

Opioids are metabolized primarily by the liver. Thus renal failure should not have a major effect on the primary clearance of opioids, although the metabolism of some opioids (meperidine and morphine) results in pharmacologically active metabolites that are water soluble and undergo renal elimination. As such, the elimination and hence the clinical effects of these agents may be prolonged, especially after repeated dosing or continuous infusions in patients with renal dysfunction. The pharmacokinetics of fentanyl, sufentanil, and alfentanil in children appear to be minimally affected by chronic renal failure.[139,140] Morphine glucuronide accumulates at higher plasma concentration in patients with chronic renal failure.[141,142] Normeperidine, the major metabolite of meperidine, may accumulate and cause prolonged respiratory depression and seizures.

Of the inhaled anesthetic agents, isoflurane is probably the safest for patients with renal failure. It is not metabolized to fluoride ion or associated with potential renal toxicity, as are enflurane and methoxyflurane. It also is not associated with bromide ion production, as is halothane. Although bromide is not a renal toxin, it may account for persistent sedation. The metabolic breakdown of desflurane is insignificant. Less than 1% of the absorbed dose is metabolized. Sevoflurane, however, undergoes metabolic breakdown into organic and inorganic compounds. Inorganic fluoride is a potential cause of nephrotoxicity with the prolonged administration of sevoflurane. Studies with methoxyflurane show that plasma inorganic fluoride levels greater than 50 μmol/L are associated with nephrotoxicity. However, plasma levels may not accurately predict nephrotoxicity. Kharasch et al.[143] demonstrated that inhalational anesthetic agents are metabolized within the kidney by the cytochrome P-450 system and that various anesthetic agents are metabolized differently within the kidney. Consequently, it appears that intrarenally produced fluoride. and not the plasma fluoride level. may explain the relationship of nephrotoxicity to anesthetic metabolism. These data suggest that agents that do not undergo primarily metabolism in the kidney (sevoflurane) are less likely to result in nephrotoxicity than older agents that were metabolized by the kidneys (methoxyflurane). The newer agents, sevoflurane and desflurane have been studied in patients with and without renal disease. Desflurane is a polyfluorinated ethyl ether that does not undergo in vivo metabolism. Studies in both animals and humans suggest that desflurane has no hepatic or renal toxic effect; however, it does interact with dry carbon dioxide absorbants and produces carbon monoxide.[144] Sevoflurane is a polyfluorinated methylisopropyl ether that undergoes in vivo degradation to difluorovinyl products and fluoride ion. In addition, sevoflurane undergoes degradation by the CO_2 absorber system to form fluoromethyl-1-1-difluoro-1-(trifluoromethyl) vinyl ether, also known as compound A. Both compound A and free fluoride ions have potential nephrotoxic effect. However, clinical studies in patients with normal renal function and those with abnormal renal function demonstrate that changes in kidney function following sevoflurane anesthesia are similar to changes that occur after desflurane, isoflurane, or enflurane anesthesia.[145-151]

Remifentanil is an opioid agonist that is metabolized by plasma and tissue esterases. The metabolic product of remifentanil metabolism has a potency of 1/3400 of its parent compound. It is independent of organ elimination, and its extremely rapid metabolism does not allow for drug accumulation. Ross et al.[152] reported the pharmacokinetic properties of remifentanil in children. Its ultrashort half-life (less than 7 minutes) allows patients a rapid recovery from anesthesia. Because it is independent of organ elimination, the pharmacokinetic profile of remifentanil is unchanged in either renal or hepatic insufficiency.[153] Remifentanil also demonstrates a flat, context-sensitive half-time. Thus the length of time remifentanil is infused does not affect the time to patient recovery when infusion is discontinued.[154,155]

In addition to the fluid and electrolyte problems and pharmacologic concerns posed by renal failure, the presence or development of renal failure per se may affect perioperative outcome. In adults, perioperative renal failure is associated with mortality rates as high as 70%. Similar data from children are lacking. However, in a study of pediatric patients undergoing liver transplantation, the 1-year survival rate in patients with renal failure was 53% compared with 81% for patients in whom renal failure did not develop.[156]

Intravenous Alimentation

ICU patients frequently receive intravenous hyperalimentation for nutritional support. Intravenous hyperalimentation regimens should be adjusted in anticipation of surgery. Surgical trauma results in accelerated protein catabolism. Administration of glucose to traumatized patients does not have the protein-sparing effect observed during starvation. The capacity of postoperative patients to handle exogenous glucose loads is impaired as a result of the neuroendocrine response to injury.[157] Hyperglycemic, hyperosmolar, nonketotic coma (HHNKC) is reported as a cause of delayed awakening after anesthesia. In two reports, the patients had diabetes mellitus, and they returned to the baseline level of consciousness within 1 to 3 postoperative days after appropriate therapy. Bedford[158] reported the fatal development of HHNKC postoperatively in a nondiabetic patient who received high-dose steroid therapy for thrombotic thrombocytopenic purpura.

Conversely, abrupt interruption of hyperalimentation containing high concentrations of dextrose may result in hypoglycemia, the signs and symptoms of which may be undetected in an anesthetized patient. Therefore optimal preoperative preparation should include weaning of glucose-containing solutions to concentrations less than or equal to 10% for a period of several hours before surgery or the decrease in the hyperalimentation to approximately 50% of its baseline rate during the surgical procedure. During this weaning period of dextrose and intraoperatively, interval monitoring of serum glucose is mandatory. Such a practice should help prevent the problems of hyperglycemia and hypoglycemia. In addition, glucose concentrations less than or equal to 10% may be administered peripherally, thus facilitating central access for administration of fluid volume, vasopressors, and/or resuscitation medications. Glucose concentrations greater than 10% should be administered only through a central cannula; when administered peripherally, these solutions may result in intense thrombophlebitis associated with venous extravasation.

Although the perioperative administration of fat emulsions used for hyperalimentation has not been shown to increase anesthetic risk, routine anesthesia practice is to discontinue their use. Potential complications of intravenous lipids include hepatobiliary injury, pancreatitis, and hypoxemia resulting from interstitial lipoid pneumonitis with alveolar capillary block.

Anesthesia Principles and Operating Room Anesthesia Regimens

Joseph D. Tobias

Intraoperative anesthetic can be provided by one of five techniques, which include local anesthesia (sometimes referred to as "local only," monitored anesthesia care (MAC), peripheral nerve blockade, neuraxial techniques (spinal or epidural anesthesia), and general anesthesia. Local anesthesia involves the infiltration of a surgical site with a local anesthetic agent to render the site insensitive to pain. This may be done solely by the surgeon without the involvement of an anesthesia provider. MAC involves monitoring a patient with standard monitors in accord with guidelines of the American Society of Anesthesiologists (ASA monitors, see below) and administering a sedative and/or analgesic agent intravenously to provide anxiolysis, sedation, and analgesia. MAC is frequently combined with either infiltration of the surgical site with a local anesthetic agent or a regional anesthetic technique. MAC is provided using a combination of a drug with amnestic properties (midazolam or propofol) combined with a drug to provide analgesia (an opioid such as fentanyl). During MAC, spontaneous ventilation is maintained during the procedure, thereby eliminating the need for endotracheal intubation and controlled ventilation. The depth of sedation may range from a state in which the patient is awake and relaxed with the ability to respond to verbal stimuli to a state of deep sedation where a painful stimulus is required to elicit a response. Peripheral nerve blockade and neuraxial anesthesia are frequently considered together under the title of regional anesthesia. A peripheral nerve block involves the placement of a local anesthetic agent around a nerve or group of nerves (plexus) to render specific dermatomes insensitive to pain. Examples of plexus blockade include cervical plexus blockade for superficial and deep neck surgery, brachial plexus blockade for upper extremity or shoulder procedures, or lumbar plexus blockade for hip or leg surgery.[1-3] Intravenous regional anesthesia, the Bier block, is another example of a peripheral nerve block that can be used to provide surgical anesthesia. A Bier block involves the intravenous injection of a dilute local anesthetic into a vein of an extremity after that extremity has been exsanguinated by wrapping it with a bandage and then occlusion with a tourniquet. Although the latter technique is generally successful and easy to accomplish, it may not be feasible in younger children except when combined with deep sedation. Given the use of an occlusive tourniquet, its duration is limited to 60 to 70 minutes due to tourniquet pain. The major concern with the Bier block is that the dose of local anesthetic used approaches the toxic limits and should the tourniquet fail, cardiovascular or central nervous system (CNS) consequences from the local anesthetic agent may occur. Neuraxial anesthesia involves the injection of a local anesthetic agent into either the subarachnoid or epidural space. This reasults in blockade of the spinal cord and its accompanying nerve roots to render an entire region of the body (lower abdomen, pelvis, perineum, or lower extremities) insensitive to pain. Examples of neuraxial anesthesia include spinal, epidural, and caudal anesthesia.[4,5] In infants and children, a regional anesthetic technique such as a peripheral nerve block or epidural anesthesia can be used instead of general anesthesia in patients with comorbid diseases that significantly increase the risk of anesthesia. More frequently, the regional anesthetic technique is combined with a general anesthetic as part of a balanced anesthetic technique and continued into the postoperative period by use of a continuous infusion via the catheter to provide postoperative analgesia.

When a general anesthesia is used, it should include the four requisites of amnesia, analgesia, muscle relaxation, and attenuation of the sympathetic nervous system's response to surgical trauma. The phases of general anesthesia include induction, maintenance, and emergence. The induction of anesthesia can be carried out with the intravenous administration of an anesthetic agent (thiopental, propofol, ketamine, or etomidate) or via the inhalation route with an inhalational anesthetic agent such as sevoflurane. Advantages of an intravenous induction include the rapid onset of anesthesia and avoidance of issues associated with inhalation induction including claustrophobia from anesthesia mask placement and the odor of the inhalational anesthetic agent. In pediatric patients, the inhalation induction of anesthesia is frequently chosen to avoid the need for obtaining intravenous access on an awake child. However, when inhalation induction is carried out without intravneous access, airway and cardiovascular issues may arise which may mandate immediate treatment without intravenous access. In such cases, if intravenous access cannot be rapidly obtained, it may be feasible to use the intramuscular (IM) route for a select number of medications (atropine, succinylcholine). However, more aggressive resuscitation such as the administration of

epinephrine for hemodynamic compromise may require the use of intraosseous access (IO).[6] Fortunately, the majority of problems during inhalation induction can be easily reversed with appropriate airway techniques or the administration of IM medications. Hemodynamic compromise including cardiac arrest was more common with the use of halothane, given its negative inotropic and chronotropic properties.[7] However, halothane is no longer used in the practice of anesthesia, having been replaced by sevoflurane. Even if intravenous access is present, the inhalational induction of anesthesia may be chosen as it allows the maintenance of spontaneous ventilation even during deep planes of anesthesia (deep enough to allow for direct laryngoscopy and endotracheal intubation). Such a technique may be used if there is a question regarding the ability to bag-valve-mask ventilate the patient, such as for patients with compromised airways from infection, tumor, or anatomic abnormalities. Following anesthetic induction, one progresses into the maintenance phase of general anesthesia. This can be achieved by the administration of intravenous agents, inhalational agents, or, most often, a combination of the two (balanced anesthesia). An example of a balanced technique includes some combination of inhalational (nitrous oxide and an inhalational anesthetic agent), a continuous infusion of an intravenous anesthetic (propofol), a nondepolarizing neuromuscular blocking agent (NMBA), and an opioid. In most circumstances, the choice of maintenance anesthesia is based on the presence of comorbid features and the preferences of the anesthesiologists.

Preoperative Evaluation

Regardless of the type of procedure, the patient's status, and the anesthetic technique that is planned, a preoperative evaluation should be performed. In many centers, such an evaluation is performed well in advance of the anticipated surgical procedure in a specialized clinic to allow for specific preoperative interventions or preparation that may be required to allow for the safe completion of the anesthetic care and surgical procedure. Alternatively, in low-risk patients without accompanying comorbid diseases, the preoperative evaluation can be performed the day of surgery. The latter may also be required for patients admitted to the hospital or those presenting for emergent or urgent surgical procedures.

The preoperative evaluation includes a history of present illness, past medical problems including drug allergies, a past surgical and anesthetic history, and a review of the patient's current and perhaps past medical record and medication list. For elective surgical procedures, the status of comorbid conditions should be optimized prior to the surgical procedure. The latter may not be feasible for urgent or emergent cases. The physical examination is directed primarily at the central nervous system, cardiovascular system, and respiratory system, including an examination of the airway. The preoperative evaluation can identify many of the patients with a difficult airway which may preclude successful endotracheal intubation using standard techniques of direct laryngoscopy. An airway history should be obtained seeking medical, surgical, and anesthetic factors that may indicate a difficult airway. Examination of previous anesthesia records is helpful, although a patient's airway may change with growth or the development of comorbid conditions. A physical examination of the airway is performed to detect physical characteristics associated with a difficult airway such as a large tongue, small mouth, short neck (shortened thyromental distance), recessed mandible, limited extension or flexion of the neck, limited mouth opening, and difficulty visualizing the uvula and tonsillar pillars when the patient opens their mouth. Risk of airway access is assessed using the Mallampati grading system. Visualization of the entire uvula and tonsillar pillars (Mallampati grade I) suggests that endotracheal intubation will be uncomplicated while failure to visual the tonsillar pillars and the soft palate (Mallampati grade IV) suggests that endotracheal intubation will be difficult. Based on the preoperative evaluation, an ASA Physical Status classification is assigned to the patient based on his or her comorbid features and associated medical conditions (Table 121-1).[8] The physical classification is based on the physical condition of the patient and does not include the planned surgical procedure. Laboratory tests and additional investigations are ordered based on the positive findings obtained during the history and physical examination and on the complexity of the surgical procedure.[9] The routine preoperative testing of all patients for elective surgery has been shown to be unjustified and expensive. In the absence of comorbid conditions, for surgical procedures with limited chance of significant blood loss, no laboratory or radiologic evaluation is necessary. Although commonly performed, routine testing of coagulation function has been shown to be of limited value without an antecedent history of bleeding problems.[10] The most common coagulation disorder that may cause problems intraoperatively is von Willebrand disease; however, it cannot be identified on routine coagulation screening, which is limited to a prothrombin time (PT), partial thromboplastin time (PTT), and an international normalized ratio (INR). Another area of ongoing controversy is the need for routine preoperative pregnancy testing in postmenarchal patients. Given the theoretical potential for anesthetic agents to be teratogenic and the risks of spontaneous abortion, the history should

Table 121–1 ASA Physical Status Classification

Classification	Description	Example
1	Normal healthy patient	—
2	Mild systemic disease with no functional limitation	Mild asthma, acyanotic congenital heart disease (atrial septal defect)
3	Severe systemic disease with functional limitation	Sickle cell disease, cystic fibrosis, palliated cyanotic congenital heart disease
4	Severe systemic disease that is a constant threat to life	Advanced stages of muscular dystrophy, cyanotic congenital heart disease with pulmonary hypertension
5	Moribund patient not expected to survive without operation	Perforated bowel with sepsis and shock
6	Brain-dead patient; organs are being removed for donor purposes	—
E	Emergency operation	—

include specific questioning about the potential for pregnancy including the patient's last menstrual cycle. In addition, there is increasing use of a point-of-care urine pregnancy testing in many centers. Further testing such as pulmonary function tests, electrocardiography, and echocardiography are based solely on the presence of comorbid conditions following the preoperative visit, including the history and physical examination. The planned management of anesthesia is discussed with each patient, and risks and possible complications are reviewed. Options and plans for postoperative pain management are discussed. The history and informed consent complete the preoperative evaluation.

NPO Guidelines

Although the aspiration of gastric contents is an uncommon event, the consequences may be severe, including pneumonitis, respiratory failure, or even death. Classical teaching states that the severity of the aspiration injury relates to the volume aspirated as well as its pH, with severe complications occurring with the aspiration of a volume 0.4 mL/kg or greater or a pH of 2.5 or less. Although aspiration may occur in any setting, patients at risk include parturients, obese patients, diabetics, patients who have received opioids, patients with gastrointestinal disease (reflux, obstruction), patients with altered mental status, patients with intraabdominal pathology (acute abdominal emergencies including appendicitis) and patients in whom difficult airway management is anticipated. These factors may predispose to aspiration by limiting the patient's ability to protect their own airway, decreasing the normal barrier to aspiration (lower esophageal sphincter tone), increasing gastric volume, or delaying gastric emptying.[11,12] Patients who have the highest incidence of perioperative aspiration are those with a high ASA physical status classification (III, IV, or V) and those having emergency surgery. The majority of aspirations occur during the induction of anesthesia or following tracheal extubation when the patient has lost his or her protective airway reflexes.

Classically, keeping patients *nil per os* (NPO) has been the mainstay of therapy to prevent acid aspiration. In the past, patients were fasted for 8 to 12 hours before surgery to reduce the volume of gastric contents at the time of induction of anesthesia and to decrease the risk of aspiration pneumonitis. This preoperative fast does not take into account differences in gastric emptying of clear liquids and solids. More recently, based on several investigations, there has been a significant revision in the perioperative fasting rules, especially for infants and children. It has been demonstrated that clear liquids have a gastric emptying time of 1 to 2 hours, while solids have an unpredictable gastric emptying time that may be greater than 6 hours.[13-16] The ingestion of clear liquids up to 2 hours before surgery does not increase gastric fluid volume or acidity.[13-16] As a result, the liberalization of guidelines for ingestion of clear liquids for elective surgery of otherwise healthy patients has been recommended.[17,18] A survey of anesthesiologists in the United States has shown that 69% have either changed their NPO policy or are flexible in their practice in allowing clear liquids before elective operations in children.[19] Suggested guidelines as recommended by the American Society of Anesthesiologists for patients with no known risk factors include no solid food for at least 6 hours before surgery and unrestricted clear liquids until 2 hours before surgery. Oral medications may be given 1 to 2 hours before surgery with a small sip of water.

Although on theoretical grounds, several maneuvers may be indicated in patients with risk factors for acid aspiration, there is limited if any evidence-based medicine to demonstrate their efficacy in preventing perioperative aspiration. Many centers routinely use preoperative medications to decrease the acidity of the gastric fluid (H_2-antagonists or proton pump inhibitors) and speed gastric emptying (metoclopramide). To be effective, it is recommended that these medications be administered 60 to 90 minutes prior to anesthetic induction. Alternatively, a nonparticulate antacid (sodium bicitrate) can be given immediately prior to anesthetic induction, a common practice in obstetrical anesthesia. Additionally, in patients at risk for acid aspiration, rapid sequence induction is practiced. This involves the use of a rapidly acting neuromuscular blocking agent (see below) with an anesthetic induction agent and the application of cricoid pressure. As the cricoid is the only complete ring of the trachea, it can be gently pushed posteriorly to effectively occlude the esophagus and prevent passive regurgitation of gastric contents when consciousness is lost during anesthetic induction. This practice is commonly referred to as rapid sequence induction or intubation (RSI). In its pure form, RSI involves preoxygenation, the administration of medications for neuromuscular blockade and anesthetic induction, and the performance of endotracheal intubation without bag-valve-mask ventilation, as the latter may distend the stomach and predispose to regurgitation. A modification of this technique, known as a modified RSI, uses gentle bag-valve-mask ventilation to maintain oxygenation while waiting for the anesthetic agents to take effect. The modified RSI may be used more commonly in pediatric anesthesia, as even brief periods of apnea without bag-valve-mask ventilation may result in precipitous decreases in oxygenation due to the low functional residual capacity and high metabolic rate for oxygen in young children and infants.

Preoperative Medication

There are several categories and uses of preoperative medications (Table 121-2). The most common use of a preoperative medication is to provide sedation and anxiolysis prior to transport to the operating room. Preparing the patient for surgery includes psychological preparation and, frequently, pharmacological premedication. Psychological preparation includes the preoperative visit and an interview by the anesthesiologist. Pharmacologic premedication may be given orally or, rarely, intramuscularly 1 to 2 hours before the induction of anesthesia or intravenously in the immediate preoperative period. Popular choices include benzodiazepines such as midazolam or occasionally, α_2-adrenergic agonists such as clonidine or dexmedetomidine. A frequently used agent and route of administration is the oral administration of the benzodiazepine midazolam to ease separation from parents and improve mask acceptance for inhalation induction. This is generally necessary when children are at least 9 to 18 months of age and begin to manifest stranger anxiety. Given alterations in bioavailability when administered by the oral route, doses of 0.3 to 0.5 mg/kg are required.

Additional preoperative medications may be used in patients with certain comorbid features, such as the use of H_2-antagonists, proton pump inhibitors, or motility agents to increase

Table 121–2 Types and Uses of Premedications

Type of Medication	Purpose
Benzodiazepine	Sedation, anxiolysis, amnesia—eases parental separation
α_2-Adrenergic agonists (clonidine, dexmedetomidine)	Sedation, anxiolysis—decrease intraoperative anesthetic needs
Opioids	Analgesia during invasive procedures
Anticholinergic agent (atropine, glycopyrrolate)	To prevent bradycardia, blunt airway reflexes, dry secretions
Inhaled β-adrenergic agonists (albuterol) and anticholinergic agents (ipratroprium)	Prevention or relief of bronchospasm
Inhaled lidocaine	Prevent airway reflexes during awake fiberoptic intubation, direct laryngoscopy or bronchoscopy
H_2-antagonists, proton pump inhibitors	Decrease pH of stomach contents
Promotility agents such as metoclopramide	Decrease volume of gastric secretions
Antiemetic agents (scopolamine patch, neurokinin-1 inhibitors)	Prevention of perioperative nausea and vomiting

gastric pH and decrease gastric volume in patients at risk for acid aspiration; inhaled β-adrenergic agonists (albuterol) or anticholinergic agents (ipratropium) may be administered to patients with reactive airway diseases (asthma, recent upper respiratory infection, or chronic obstructive pulmonary diseases). Anticholinergic agents may be used to dry airway secretions in patients requiring fiberoptic intubation.

Monitoring

The standards for intraoperative anesthetic monitoring have been outlined by the American Society of Anesthesiologists. Monitoring standards are the same regardless of whether the case entails a general anesthetic, regional anesthetic (peripheral nerve block, spinal or epidural), or monitored anesthesia care. The standards according to the ASA include an oxygen analyzer, noninvasive blood pressure cuff, continuous ECG, pulse oximeter, end-tidal carbon dioxide analyzer, precordial or esophageal stethoscope, temperature probe, and a ventilator disconnect alarm. Based on the medical condition of the patient and the surgical procedure, more elaborate and invasive monitoring may be added to these standard monitors, such as a urinary catheter; catheters for measuring intraarterial, central venous, and pulmonary artery pressures; and transesophageal echocardiography. Although there are no strict guidelines dictating which patients should have invasive monitors placed, there have been recommendations set forth for the adult population. These recommendations must be taken in context of the limited data available comparing outcomes, for instance, in patients managed perioperatively with or without pulmonary artery (PA) catheters.[20,21] The ASA recommends considering three variables including disease severity, magnitude of the surgical procedure, and practice setting when assessing benefit versus risk of PA catheters.[22] Additional information regarding structural and functional issues of the myocardium may be obtained by the use of transesophageal echocardiography (TEE). TEE is used with increasing frequency in the adult population. There are now specific curriculae in cardiac anesthesia fellowships to teach the skills necessary for performance of TEE. The practice has been encouraged by the American Board of Anesthesiology, which recognizes such training and provides the opportunity for credentialing through the completion of a written examination. The strongest indications for perioperative transesophageal echocardiography that are supported by evidence-based medicine include cardiac surgery procedures such as repair of valvular lesions (insufficiency or stenosis) or congenital lesions, assessments and repairs of thoracic aortic aneurysms and dissections, pericardial window procedures, and the repair of hypertrophic obstructive cardiomyopathy.[23] For noncardiac surgery, intraoperative transesophageal echocardiography is indicated to evaluate acute, persistent, and life-threatening hemodynamic disturbances in which ventricular function and its determinants are uncertain and which have not responded to treatment, especially when placement of a PA catheter is not feasible.

In addition to standard ASA monitors, there is growing interest in the development and potential use of "depth of anesthesia" monitors. Although controversial, the potential impact of such monitors is highlighted by the results of several trials which demonstrate that intraoperative awareness may occur in anywhere from 0.1% to 0.2% of all patients, with even higher incidences in specific procedures including trauma, cardiac, obstetrical, and emergency surgery. Several manufacturers have marketed or are developing monitors which provide the anesthesia provider with a numerical value against which anesthetic agents are titrated. There are currently five such monitors, including the Bispectral Index (BIS monitor, Aspect Medical, Newton, MA); the Narcotrend (MonitorTechnik, Bad Bramstedt, Germany), which is currently available only in Europe; Patient State Analyzer (PSA 4000, Baxter Healthcare, Deerfield, IL); SNAP (Everest Medical, Minneapolis, MN); and Auditory Evoked Potential Monitor (AEP Monitor, Danmetter Medical). To date, the one that has received the most clinical use is the BIS monitor. The BIS is a modified electroencephalographic monitor that uses a preset algorithm based on intraoperative data obtained from adults to evaluate the electroencephalogram. The BIS number is determined from three primary factors, including the frequency of the electroencephalographic waves, the synchronization of low and high frequency information, and the percentage of time in burst suppression. Part of the simplicity and attraction of the BIS monitor is that the depth of sedation/anesthesia is displayed numerically, ranging from 0 to 100, with 40 to 60 being a suitable level of anesthesia to ensure amnesia and lack of recall. With the use of BIS monitoring, a decreased incidence of awareness has been demonstrated, as well as a decrease in the total amount of anesthetic agent used.[24-26] Additional studies have suggested faster recovery times and faster discharge times from the postanesthesia care unit; all of which may translate into reduced perioperative costs.[26,27] Although not considered the standard of care as of yet for intraoperative anesthesia care, the ASA does recommend the availability of such monitors whenever general anesthesia is provided. Given the success of such monitors in

the perioperative arena, there is ongoing interest in the application of such technology in the ICU and the procedural sedation arena.[28-30]

The Pharmacology of Anesthetic Agents

Local Anesthetic Agents

The local anesthetic agents can be divided into two chemically distinct classes: esters and amides. Local anesthetic agents in the amino ester class include procaine, chloroprocaine, and tetracaine. Amino amides used clinically include lidocaine, mepivacaine, prilocaine, bupivacaine, levobupivacaine, and ropivacaine. Several clinically important differences exist between these two classes of local anesthetic agent, including site of metabolism, plasma half-lives, adverse effect profile (CNS vs. cardiac toxicity), and allergic potential. Amino esters are metabolized by plasma cholinesterases, while amino amides undergo hepatic metabolism.

The mechanism of action for the majority of local anesthetic agents involves blockade of sodium channels in the nerve membrane, thereby preventing depolarization. The nonionized portion of the local anesthetic agent penetrates the lipid membrane, while the ionized portion reversibly blocks the inner aspect of the sodium channel. Local anesthetic agents differ in intrinsic potency, onset of action, duration of action, and their ability to produce differential sensory and motor blockade. Potency is determined primarily by lipid solubility (high lipid solubility is directly related to potency).[31] Bupivacaine and tetracaine are examples of local anesthetic agents with high lipid solubility and hence high potency. The onset of action is determined primarily by the pK_a with onset being most rapid in those agents with a pKa closest to physiologic pH.[32,33] With a pKa close to physiologic pH, the percentage of the un-ionized form is greater, thereby increasing passage through the nerve membrane. Lidocaine has a pK_a of 7.7 and at a pH of 7.4, 35% exists in the un-ionized base form yielding a relatively rapid onset of blockade. In contrast, tetracaine has a pK_a of 8.6 with only 5% in the un-ionized form at a tissue pH of 7.4, resulting in a slower onset of blockade than lidocaine. Duration of action is determined primarily by the degree of protein binding to receptors in the sodium channel.[34] Local anesthetic agents bind to protein receptors in the sodium channels. High protein binding and therefore a prolonged duration of action are characteristic of bupivacaine, levobupivacaine, tetracaine, and ropivacaine. Duration of action is also influenced by the degree of vasodilation produced by the local anesthetic.[35] Vasodilatation results in increased blood flow to the area and therefore an increased removal of the agent from the depot in the tissues. The local anesthetic agents also differ in their differential effects on sensory versus motor nerves. Bupivacaine and ropivacaine demonstrate this property, which is very beneficial for postoperative analgesia administered through an epidural catheter so that patients are able to ambulate with minimal discomfort.

When performing regional anesthesia, the goal is to place the local anesthetic agent as close as possible to the nerve or plexus that needs to be anesthetized. A recent addition to the armamentarium of the anesthesiologist has been the use of ultrasound to visualize the individual nerve roots or the plexus that is to be anesthetized.[37-40] This technology is also being used for neuraxial techniques including spinal and epidural anesthesia. The advantages of this technology are not only an increased success rate of various regional anesthetic techniques, but also the ability to provide blockade with a decreased dose of the local anesthetic agent. Additional factors that must be considered when using these agents are the maximal allowable dose of the agent, the impact when a vasoconstrictor such as epinephrine is added to the solution, and the effect of the site of administration. Increasing the dose of a local anesthetic (increased concentration or volume) yields a faster onset of effect, a longer duration of action, and a greater depth of blockade.[41] However, higher plasma concentrations of the local anesthetic agent will also be achieved, thereby increasing the risks of toxicity (discussed later).

Given the catastrophic effects of local anesthetic toxicity, mechanisms to avoid it and prevent its occurrence are mandatory during the performance of regional anesthetic techniques in infants and children. Epinephrine (5 μg/mL or a concentration of 1:200,000) is added to the local anesthetic solution during performance of a regional anesthetic technique to cause local vasoconstriction, thereby decreasing the vascular absorption of the drug and also to serve as a marker of inadvertent systemic injection.[41-43] However, the ability of epinephrine to prolong the duration of action depends on the local anesthetic used and the site of administration. More importantly, epinephrine is used as a marker for inadvertent systemic injection. Even with negative aspiration for blood, there is the potential for inadvertent intravascular administration, thereby suggesting the use of a test dose. The test dose entails the administration of 3 mL of the 5 μg/mL epinephrine solution or a total epinephrine dose of 15 μg. If this amount of epinephrine is injected intravascularly, it can generally be detected by changes in heart rate, blood pressure, or the ST-T wave segments of the electrocardiogram and will thereby alert the practitioner that inadvertent intravascular injection is occurring.[44]

The site of injection of the local anesthetic agent also has a significant impact on the clinical effects including duration of action and vascular uptake (plasma concentrations). The shortest durations of action occur with either intrathecal injection for spinal anesthesia or subcutaneous administration. The longest duration of action and onset of blockade are seen with major peripheral nerve blocks (brachial or lumbar plexus blockade).[45,46] The vascular absorption of the local anesthetic agent and its plasma concentration are also dependent on the site of administration. The highest plasma concentration occurs following an intercostal nerve block or interpleural analgesia followed in order by caudal epidural, lumbar or thoracic epidural, brachial plexus, peripheral nerve blockade, subarachnoid, and subcutaneous infiltration.[47]

During performance of regional anesthesia, the greatest risk of morbidity and mortality results from the achievement of toxic plasma concentrations of the drug. Local anesthetic-induced systemic toxicity affects the CNS and the cardiovascular (CV) system. The differential effects on these two organ systems and the plasma concentration at which toxic effects are noted vary according to the agent. With most local anesthetic agents, CNS toxicity occurs at doses and blood levels below those that produce cardiovascular toxicity. The latter provides some degree of safety, as the CNS symptoms (seizures) are generally more amenable to treatment than the cardiovascular effects (arrhythmias and conduction blockade). Death from local anesthetic toxicity is most commonly the result of the

cardiovascular effects of these agents with adverse effects on cardiac electrical and mechanical activity.[48] Bupivacaine produces cardiac arrhythmias by inhibiting the fast sodium channels and the slow calcium channels in the cardiac membrane. Hypercarbia, acidosis, and hypoxia potentiate the negative chronotropic and inotropic effects of high plasma concentrations of local anesthetic agents. These effects are so profound that resuscitative measures for ventricular tachycardia/fibrillation including standard ACLS protocols may be ineffective. Anecdotal case reports have suggested the potential role of various agents such as amiodarone for refractory ventricular arrhythmias. More recently, anecdotal human data and animal studies have suggested that intralipid solutions may be used to bind the local anesthetic agent, thereby resulting in return of spontaneous circulation. Current recommendations from the ASA include easy and ready access to 20% intralipid solutions whenever large doses of local anesthetic agents are used for regional anesthetic techniques. Given the risks of morbidity and mortality from local anesthetic toxicity, avoidance of toxicity is the goal through careful calculation of the dose, use of the lowest necessary dose (concentration and volume), use of a test dose with epinephrine to identify inadvertent intravascular injection, intermittent aspiration to identify vascular penetration, and slow incremental injection of the dose.

Intravenous Anesthetic Agents

The intravenous anesthetic agents in common clinical use include the barbiturates (thiopental, methohexital, and thiamylal), propofol, etomidate, and ketamine. These agents are used to induce (bolus administration) and/or maintain (continuous infusion) the general anesthetic state. In lower doses, agents in this class such as propofol can be used by continuous infusion to provide MAC while maintaining spontaneous ventilation. Although any of the intravenous anesthetic agents will induce anesthesia, the choice of the agent and its dose are based on the clinical scenario, the anticipated duration of the surgical procedure, and the patient's underlying hemodynamic status.

Thiopental, propofol, and etomidate mediate their anesthetic properties through interactions with the γ-aminobutyric acid $(GABA)_A$ receptor complex. These interactions lead to enhanced activity of the inhibitory neurotransmitter system (GABA).[49-52] Activation of the $GABA_A$ receptor increases the transmembrane movement of chloride, resulting in hyperpolarization of the postsynaptic cell membranes. Ketamine's analgesic and anesthetic effects are the result of its interactions with the *N*-methyl-D-aspartate (NMDA) system, which is activated by glutamate, an excitatory transmitter, as well as by other sites within the CNS, including those involved with opioid and cholinergic transmission.[53-55] The intravenous anesthetic agents result in somewhat varying end-organ effects. The barbiturates, propofol, and etomidate reduce cerebral metabolism ($CMRO_2$), cerebral blood flow (CBF), and intracranial pressure (ICP). As such, they are valuable agents in the practice of neuroanesthesia or in critically ill patients with increased ICP. When compared with propofol or the barbiturates, etomidate may be preferred in patients with abnormal cardiovascular function as it provides greater hemodynamic stability. As a result, etomidate maintains cerebral perfusion pressure (CPP = MAP – ICP), whereas propofol and thiopental may decrease MAP through their effects on systemic vascular resistance (vasodilatation) as well as direct negative inotropic properties. Thiopental, and perhaps etomidate and propofol, may possess "neuroprotective" properties secondary to reducing $CMRO_2$, which improves the ability of the brain to tolerate incomplete ischemia during procedures such as carotid endarterectomy or the temporary occlusion of cerebral arteries during an aneurysm repair.[56,57] Ketamine's direct effects on ICP remain controversial, with the older literature suggesting that ketamine may directly increase cerebral blood flow and ICP. However, recent studies suggest that ketamine has limited effects on CBF and ICP, especially when given in combination with other anesthetic agents including midazolam.[72-74]

Propofol, midazolam, and the barbiturates have similar effects on the electroencephalogram (EEG). Initial low doses with low brain concentrations result in transient high-frequency activity followed by lower-frequency, higher-amplitude waveforms at high brain concentrations, and eventually burst suppression and even electrical silence with high enough doses. These effects, which are similar to those produced by the potent inhalational anesthetic agents, have been studied in enough detail and are consistent enough that algorithms have been developed that can analyze the EEG patterns and thereby determine the depth of anesthesia. These algorithms are used by several different monitoring systems to provide modified EEG monitors, which are used clinically to evaluate the depth of anesthesia. Although controversial, it is these monitors that are purported to have efficacy in avoiding intraoperative awareness during anesthetic care.

Most intravenous anesthetics have anticonvulsant properties. Various of the barbiturates and propofol have been incorporated into algorithms for the treatment of refractory status epilepticus.[61,62] Opposite effects are generally seen with etomidate, which can produce involuntary myoclonic movements from an imbalance of inhibitory and excitatory influences in the thalamocortical tract. Etomidate also stimulates the EEG resulting in increased amplitude and frequency.[63] Myoclonic movements and opisthotonic posturing have also been reported following the administration of propofol. These movements are attributed to propofol's antagonism at glycine receptors in subcortical structures.

The intravenous anesthetic agents also have dose-dependent effects on ventilatory function. Thiopental, propofol, etomidate, and midazolam result in a decrease of tidal volume and minute ventilation as well as a rightward shift of the CO_2 response curve. As with many of the end-organ effects of the anesthetic agents, the respiratory depressant effects may be magnified in patients with comorbid conditions (chronic respiratory or cardiovascular disease) and when coadministered with other medications that are respiratory depressants (inhalational anesthetic agents, opioids, phenothiazines). Given these effects on central control of ventilation, a transient period of apnea generally occurs following an anesthetic induction dose of any of these agents. In contrast to the respiratory effects of propofol, etomidate, and the barbiturates, in the absence of comorbid diseases, ketamine can generally be expected to result in minimal respiratory depression in clinically relevant doses and may preserve airway protective reflexes.[64,65] Ketamine also stands apart from the other intravenous anesthetic agent in that the release of endogenous catecholamines following its administration results in bronchodilatation, thereby making it a suitable

induction agent in patients who are actively wheezing or at risk for reactivity during airway manipulation. Propofol has also been shown to have beneficial airway effects in patients with airway reactivity. In a prospective trial, 77 adult patients were randomized to receive one of three agents: propofol (2.5 mg/kg), etomidate (0.4 mg/kg), or thiopental (5 mg/kg) for anesthetic induction and tracheal intubation.[66] Following endotracheal intubation, respiratory resistance was lower with propofol when compared to either etomidate or thiopental. Additional evidence for the beneficial effects of propofol on airway reactivity are provided by Pizoz et al., who randomized asthmatic or nonasthmatic patients to anesthetic induction with thiopental/thiamylal (5 mg/kg), methohexital (1.5 mg/kg), or propofol (2.5 mg).[67] In asthmatic patients, the incidence of wheezing was 45% with thiopental/thiamylal, 26% with methohexital, and 0% with propofol. In nonasthmatic patients, the incidence of wheezing was 16% with thiopental/thiamylal and 3% with propofol. The potential beneficial effects of propofol on airway reactivity are further supported by animal studies.[68,69] The proposed mechanism for these effects are a decrease of intracellular inositol phosphate, resulting in a depression of intracellular calcium availability.

During anesthetic induction or maintenance, the intravenous anesthetic agents can depress the cardiovascular system resulting in hypotension by various mechanisms. These include a reduction of central and/or peripheral autonomic nervous system activity, blunting compensatory baroreceptor reflexes, decreasing preload, systemic vasodilatation, or directly depressing myocardial contractility. Hemodynamic function during the induction of anesthesia may also be affected by comorbid cardiovascular disease, intravascular volume status, resting sympathetic nervous system tone, concomitant medications (angiotensin-converting enzyme inhibitors, β-adrenergic antagonists), and the administration of other agents used for anesthetic care including opioids and benzodiazepines. An induction dose of thiopental causes a variable decrease in cardiac output, systemic vascular resistance, and arterial pressure. The decrease in cardiac output is the result of vasodilation as well as direct myocardial depression. This effect is generally well tolerated in patients with adequate cardiovascular function, but can be exaggerated with preexisting cardiovascular disease, necessitating the use of a lower dose of thiopental or, preferably, the use of alternative agents in patients with compromised cardiovascular function. Propofol demonstrates cardiovascular depressant effects similar to or greater than those of thiopental. Propofol is a direct myocardial depressant and reduces systemic vascular resistance. Significant cardiovascular responses following propofol are more common with high doses, in hypovolemic patients, in elderly patients, and in patients with significant cardiovascular disease.[71,72] The deleterious cardiovascular effects of propofol can be attenuated by the administration of calcium chloride (10 mg/kg).[73] Additional cardiovascular effects from propofol may result from its augmentation of central vagal tone leading to bradycardia, conduction disturbances, and asysole.[74,75] The negative chronotropic effects of propofol are more common when it is administered with other medications known to alter cardiac chronotropic function (fentanyl or succinylcholine). Although the relative bradycardia may be beneficial in elderly patients at risk for myocardial ischemia, it may be detrimental if cardiac output is heart rate dependent.

In contrast to the negative inotropic effects of propofol and the barbiturates, etomidate causes minimal cardiovascular depression and may be used for anesthetic induction in patients with significant cardiovascular disease.[76,77] As etomidate has little effect on systemic vascular resistance, it may be used in patients with cyanotic congenital heart disease in whom pulmonary blood flow is dependent on mean arterial pressure. Although suppression of adrenal cortical function occurs even following a single bolus dose of etomidate through inhibition of the activity of 17-α hydroxylase and 11-β hydroxylase, it remains controversial whether such effects are of clinical significance.[78,79] However, the risk: benefit ratio of this effect must be entertained when etomidate is chosen for anesthetic induction. Additionally, although still used as a single induction dose in patients with comorbid cardiovascular disease, repeated doses or continuous infusions are not recommended.[80]

The cardiovascular effects of ketamine are different from those of the other intravenous anesthetic agents. Ketamine stimulates the cardiovascular system by activation of the sympathetic nervous system and the release of endogenous catecholamines.[81] Anesthetic induction doses of ketamine (1 to 2 mg/kg) generally increase heart rate and MAP. Although the indirect effects of ketamine include the release of endogenous catecholamines and stimulation of the sympathetic nervous system, ketamine is a direct myocardial depressant. In most clinical scenarios, the indirect effects compensate for the direct negative inotropic effects. However, in critically ill patients who have depleted their endogenous catecholamines, cardiovascular collapse may occur.

The pharmacokinetic profile of the intravenous anesthetic agents is characterized by a rapid onset of CNS effects secondary to the high lipid solubility of these agents and the high percentage of cardiac output perfusing the brain. The termination of the central CNS effect results from redistribution of the drug from the central to the peripheral compartment. It is not dependent on primary metabolism and elimination of the drug from the body. Most intravenous anesthetics are metabolized in the liver and excreted in the kidney. Some metabolites are active, such as desmethyldiazepam (diazepam) and norketamine (ketamine), and may result in prolonged effects especially with repeated dosing or the use of continuous infusions. There is a wide variation in the elimination half-lives of intravenous anesthetic agents because of differences in clearance. Drugs with short elimination half-lives include propofol, etomidate, ketamine, and midazolam, whereas thiopental has a long elimination half-life. Propofol is widely used, especially in ambulatory surgery centers, because of its short duration of action, fast recovery time, and early discharge potential.[82,83] This rapid recovery results in less "hangover" effect or residual drowsiness following outpatient surgical procedures, thereby facilitating return to work and resumption of activities of daily life.

Opioids

There are various roles for the opioids in the perioperative and anesthetic management of patients. The commonly used opioids are pure agonists that are selective for μ (mu) opioid receptors located at discrete sites throughout the spinal cord and the CNS.[84] However, they are generally combined with either an inhalational anesthetic agent or an intravenous

anesthetic agent (total intravenous anesthesia or TIVA). This combination is necessary as even when administered in doses sufficient to produce profound analgesia and apnea, the opioids do not consistently produce amnesia in healthy patients.[85] Therefore other agents are required to ensure amnesia during the intraoperative care of patients. Intraoperatively, the opioids are used to blunt the sympathetic stress response to surgical trauma, decrease the requirements for inhalational or intravenous anesthetic agents, and provide postoperative analgesia.

Although discrete differences in the chemical structure exist in the intravenous opioid agents, when used clinically, the clinically relevant differences include their potency, onset of action, duration of action, lipid solubility, hemodynamic effects, and metabolic fate (Table 121-3).[86,87] During the conduct of general anesthesia, the synthetic agents including fentanyl and its derivatives are frequently chosen, given their brief duration of action, ability to effectively blunt the hemodynamic changes related to the surgical stress response, and limited cardiovascular effects. However, other opioids including morphine may be chosen, given their longer duration of action with the ability to provide postoperative analgesia during the transition from general anesthesia to the awake state (emergence). Morphine is the least lipophilic of the commonly used opioids and therefore it has a slower onset of action than the more lipophilic synthetic opioids such as fentanyl. Morphine, like all of the opioids except for remifentanil, undergoes hepatic metabolism. In part, morphine is converted to morphine-6-glucuronide (M6G), a water-soluble metabolite with a potency far greater than that of the parent compound. However, given that it is water soluble, M6G does not rapidly pass through the blood-brain barrier into the CNS and therefore has limited clinical effects. In patients with renal insufficiency or failure, a significant amount of M6G can accumulate and result in respiratory depression.

Meperidine has a potency that is approximately 10% that of morphine with a similar half-life of 2 to 3 hours. Hepatic metabolism produces normeperidine, a metabolite that may accumulate in renal insufficiency. High plasma concentrations of normeperidine may cause seizures. Given these concerns and the higher incidence of psychomimetic effects with meperidine, our current clinical practice does not include its use except in low doses (10 mg) to treat postanesthesia shivering. Hydromorphone has a potency that is 6 to 8 times that of morphine with a half-life of 2 to 3 hours. As there are no active metabolites of hydromorphone, it may be an effective alternative to morphine in patients with renal insufficiency. When compared with morphine, hydromorphone causes less histamine release and may be an effective alternate agent when pruritus occurs with morphine use.

The synthetic opioids, including fentanyl, sufentanil, and alfentanil, are very potent, highly lipid-soluble drugs with rapid onsets of action and short durations of action. Hepatic metabolism does not result in active metabolites. Fentanyl is 100 times as potent as morphine, while sufentanil has 10 times the potency of fentanyl. The pharmacokinetics of fentanyl and sufentanil are similar, with both drugs being short-acting at low doses and longer-acting at higher doses. Alfentanil is less potent than sufentanil and fentanyl and has a very rapid onset of action and short duration of action. Because its elimination half-life is substantially less than that of sufentanil and fentanyl, it is suitable for multiple dosing and continuous infusions and is popular for ambulatory surgery in many centers. Remifentanil is the newest of the synthetic opioids. It is the first true ultrashort-acting opioid.[88] It has a rapid onset of activity and undergoes ester metabolism, which results in a short, predictable duration of action. Its elimination half-life is 8 to 10 minutes and its potency is comparable to fentanyl. It is administered as a continuous infusion and remains short-acting regardless of the duration of the infusion. Unlike the other opioids, which have longer half-lives and a variable duration of effect in neonates and infants, the duration of action and half-life of remifentanil is constant across all age ranges, thereby making it a suitable agent in neonatal anesthesia.

The opioids play a key role in anesthesia practice. Fentanyl, sufentanil, and alfentanil are common components of various anesthetic techniques. They have replaced their predecessors (morphine and meperidine) because of their faster onsets of action, shorter and more predictable duration of action, and minimal hemodynamic side effects. For general anesthesia, they reduce the surgical stress response and the associated cardiovascular responses to endotracheal intubation and surgical stimulation. They potentiate the hypnotic effects of barbiturates and benzodiazepines. They produce a dose-related decrease in the need for the potent inhalational anesthetic agents, thereby facilitating recovery from prolonged anesthetic cases. High-dose opioid techniques are commonly used in cardiac surgery because the synthetic opioids produce a smooth induction process, provide hemodynamic stability, suppress the hemodynamic responses to various surgical stimulations, reduce the production of stress hormones, and provide a smooth transition to mechanical ventilation at the end of the case.

As with all medications used in the practice of anesthesia, there are several adverse effects related to opioid administration. Opioids produce a dose-related depression of the ventilatory response to CO_2 and blunt the response to hypoxia through a direct effect on the medullary respiratory centers.[89] Increasing plasma concentrations result in a slowing of the respiratory rate that is initially offset by an increase in tidal volume. Equianalgesic doses of all opioids (fentanyl, morphine, meperidine, etc.) produce equivalent degrees of respiratory depression. Opioid-induced respiratory depression is antagonized by pain, movement, and opioid antagonists such as naloxone. When postoperative respiratory depression related to opioids occurs, small incremental doses of naloxone

Table 121–3 Potency and Half-Life of Opioids

Agent	Potency	Half-Life	Active Metabolites
Morphine	1	2–3 hours	Yes
Meperidine	0.1	2–3 hours	Yes
Hydromorphone	5	2–4 hours	No
Oxymorphone	10	2–4 hours	No
Methadone	1	12–24 hours	No
Fentanyl	100	20–30 minutes	No
Sufentanil	1000	20–30 minutes	No
Alfentanil	20	10–15 minutes	No
Reminfentanil	100	5–8 minutes	No

(1 μg/kg every 2 to 3 minutes) may be used to reverse opioid-induced respiratory depression without reversing analgesia. Given that the clinical half-life of naloxone is 20 to 30 minutes, repeated doses or a continuous infusion may be needed if longer acting opioids (morphine, meperidine, or hydromorphone) have been administered. Longer acting opioid antagonists (nalmefene) are now clinically available; however, there is limited clinical experience with their use in the pediatric population. Opioid reversal using naloxone can result in undesirable or dangerous hemodynamic responses such as hypertension, tachycardia, and myocardial infarction. The potential for such effects must be weighed against the anticipated benefits of opioid reversal.

Opioids generally produce minimal cardiovascular effects at usual analgesic doses. With higher doses, when combined with other anesthetic drugs, or in patients with comorbid features, opioids may produce bradycardia and a decrease in SVR, resulting in hypotension. The synthetic opioids may result in bradycardia from stimulation of the central nuclei of the vagus nerve, leading to prolonged AV conduction and direct depression of the SA node, while peripheral vasodilation results from depression of the vasomotor centers in the medulla.[90,91] Patients with elevated levels of sympathetic tone (hypovolemia, CHF) are more likely to become hypotensive after opioids. Although anesthetic techniques using high doses of the synthetic opioids may result in bradycardia and peripheral vasodilation, given that there is no direct negative inotropic effect, these techniques are effective for patients with myocardial pathology including patients undergoing cardiovascular surgery for whom high-dose fentanyl (25 to 75 μg/kg) is a frequently chosen anesthetic technique. Decreases in blood pressure with such techniques result from a decrease in SVR and are usually easily treated with a direct acting α-adrenergic agonist such as phenylephrine. Morphine may result in more profound venodilatation, leading to decreased venous return, decreased cardiac output, and hypotension. Meperidine, given its structural similarity to atropine, may result in a mild tachycardia.

Inhalational Anesthetic Agents

A unique aspect of intraoperative anesthetic care is the administration of inhalational anesthetic agents, including nitrous oxide (N_2O), halothane, enflurane, isoflurane, sevoflurane, and desflurane. Although their anesthetic properties are similar, the potent inhalational anesthetic agents can be divided into two chemically distinct classes (alkanes and ethers). Halothane is an alkane (a two-carbon chain) while the other four agents (enflurane, isoflurane, desflurane, and sevoflurane) are ethers. The potent inhalational anesthetic agents are volatile liquids and are administered to the patient via a vaporizer on the anesthesia machine. Nitrous oxide is administered either from a central hospital source or from E cylinders on the anesthesia machine. Flows of nitrous oxide and oxygen are mixed in varying concentrations and then directed through the vaporizer to pick up the desired concentration of the potent inhalational anesthetic agent.

The potency of inhalational anesthetic agents is measured by MAC (minimum alveolar concentration). MAC is defined as the percent of the inhalational anesthetic agent that is required to prevent 50% of patients from moving in response to a surgical stimulus. The lower the MAC, the more potent the inhalational agent. Halothane is the most potent inhalational anesthetic agent, followed in order by isoflurane, enflurane, sevoflurane, and desflurane. Nitrous oxide has a very low potency (MAC of 110%) and must be combined with other intravenous sedatives/analgesics/anesthetics or a potent inhalational anesthetic agent to fulfill the prerequisites (unconsciousness, analgesia, muscle relaxation, decrease in sympathetic nervous system activity) of a general anesthetic. As 1.5 to 2.5 MAC of an agent is required to maintain anesthesia solely with a potent inhalational anesthetic agent, in most clinical scenarios, 1.0 to 1.5 MAC of an inhalational anesthetic agent is combined with N_2O, opioids, or intravenous anesthetic agents to provide maintenance anesthesia during a surgical procedure.

Nitrous oxide (N_2O) was the first of the inhalational anesthetic agents to be discovered. Although there has been a decline in its use with the introduction of newer inhalational anesthetic agents with low blood-gas solubility partition coefficients (desflurane, sevoflurane), it remains a common component of intraoperative anesthetic regimens and is also used in some centers for procedural sedation. Depending on the concentration administered, N_2O can provide sedation and analgesia or a weak anesthetic level. In concentrations of 70%, N_2O will render the majority of patients amnestic and provide moderate to significant analgesia. However, only minor surgical procedures can be performed with N_2O and O_2 alone and its amnestic properties are not a given, thereby necessitating its combination with other agents. When used as the sole agent, N_2O causes minimal respiratory and cardiac depression.[92] Recovery from N_2O sedation is rapid given its low blood-gas solubility coefficient. During recovery, high concentrations of O_2 are needed to avoid diffusion hypoxia.[93] As N_2O diffuses from the blood into the alveoli, its alveolar concentration rises, thereby decreasing the effective concentration of oxygen, which can lead to "diffusion hypoxia." N_2O diffuses into and expands gas-containing closed spaces in the body (obstructed bowel, pneumothorax, middle ear, pneumocephalus, pulmonary artery catheter balloons, and air emboli).[96]

When used for procedural sedation on repeated occasions, N_2O can lead to inactivation of methionine synthetase, an enzyme necessary for vitamin B_{12} metabolism, leading to bone marrow impairment with megaloblastic anemia and deterioration of the posterior columns of the spinal cord and neurologic impairment.[94,95] These effects may occur not only in patients, but also in health care workers with chronic exposure, thereby mandating effective scavenging of exhaled gases to avoid environmental pollution whenever N_2O is administered.

When administered in appropriate inspired concentrations, all of the potent inhalational anesthetic agents (halothane, isoflurane, enflurane, desflurane, and sevoflurane) provide the basic components of a general anesthetic including amnesia, analgesia, skeletal muscle relaxation, and control of the sympathetic nervous system. Despite their use for over 150 years in clinical anesthetic care, the exact site and mechanism of action of these agents remains elusive. Recent work suggests that they stabilize critical proteins, possibly the receptors of neurotransmitters.[97] Although these agents all provide general anesthesia, their end-organ effects can be quite varied, thereby dictating their use in various clinical scenarios. In infants and children, given the potential stress that may be inflicted by placement of an intravenous cannula, anesthetic induction

may be carried out by the inhalation route with placement of the intravenous cannula after the patient is anesthetized. As halothane and sevoflurane are less pungent to the airway than the other agents, they are the only agents used for the inhalation induction of anesthesia. Although halothane had been the time-honored agent for inhalation induction of anesthesia in infants and children, it has recently been removed from the market and replaced by sevoflurane due to sevoflurane's significantly lower incidence of bradycardia, myocardial depression, and cardiac arrest. In fact, surveys evaluating the etiology of cardiac arrest during general anesthesia in infants and children have implicated halothane as the primary factor responsible for many of these events.

All of the potent inhalation anesthetic agents cause a dose-related depression of cardiovascular and respiratory function. With increasing anesthetic depth, there is a rightward shift of the CO_2 response curve with a progressive decrease in alveolar ventilation, characterized by a reduction in tidal volume in spontaneously breathing patients and an increase in $PaCO_2$. Beneficial effects on the airways include a direct effect on bronchial smooth muscle with bronchodilatation making them effective agents both intraoperatively and outside of the operating room for the treatment of patients with refractory status asthmaticus.[98]

The potent inhalational anesthetic agents decrease mean arterial pressure, myocardial contractility, and myocardial oxygen consumption. The exact changes in cardiac output, systemic vascular resistance, and heart rate vary from agent to agent and with the inspired concentration of the agent that is administered. Isoflurane and desflurane result primarily in vasodilatation and a decrease in SVR with reflex tachycardia. Direct negative chronotropic effects predominate with sevoflurane and halothane, leading to a lowering of heart rate. As mentioned previously, this effect is less with sevoflurane than with halothane. Because of its alkane structure, halothane sensitizes the myocardium to catecholamines and can cause dysrhythmias, especially when there is associated hypercarbia or high circulating catecholamines. The latter is of clinical significance when epinephrine-containing local anesthetic agents are administered to patients anesthetized with halothane.

The potent inhalational anesthetic agents cause a dose-dependent decrease in CNS activity, depressing EEG activity and reducing cerebral metabolic oxygen consumption. Enflurane and sevoflurane can activate the EEG and produce clinical and EEG evidence of seizure activity at high concentrations. Such problems are exacerbated by the hypocarbia that may occur if there is hyperventilation during anesthetic induction. CBF increases via a reduction in cerebral vascular resistance, which can lead to an elevation of ICP in patients with compromised intracranial compliance. The effect on ICP is least with isoflurane and can be blunted by hyperventilation and hypocarbia. These effects make isoflurane a common choice for neurosurgical anesthesia. These agents also have peripheral neuromuscular effects; they potentiate the effects of the neuromuscular blocking agents, and along with succinylcholine are triggering agents for malignant hyperthermia.

In addition to the parent compound, metabolic products may be responsible for the toxicity of the potent inhalational anesthetic agents. For halothane, 15% to 20% of halothane is metabolized, compared to 5% to 10% for sevoflurane, 2% to 3% for enflurane, 0.2% for isoflurane, and less than 0.1% for desflurane. In the early days of inhalational anesthesia, hepatic toxicity was a significant concern and existed into the modern era with halothane. Hepatotoxicity occurs from an immune-mediated reaction following exposure to halothane, enflurane, isoflurane, or desflurane.[99-102] However, given the limited metabolism of enflurane, isoflurane, and desflurane, the risk of hepatotoxicity is extremely low. The mechanism of hepatotoxicity relates to the metabolic product, TFA or trifluroacetic acid, acting as a hapten. It binds to hepatocytes and induces an immune-mediated hepatitis. The metabolic pathway of sevoflurane is different and does not result in the production of TFA. Risk factors for halothane hepatitis include prior anesthetic exposure, female gender, age 35 years or more, and obesity.[103,104] Albeit rare, specific issues related to renal function must be considered during anesthetic care. Most importantly, alterations related to cardiac output due to the inhalational anesthetic agents may secondarily decrease renal blood flow and result in renal damage. As with other end organs, the kidneys may be damaged by the agent itself or by its metabolites. Additionally, both enflurane and sevoflurane contain fluoride around their carbon atoms, which can be released during metabolism.[105] Fluoride concentrations in excess of 50 μmol/L can result in decreased glomerular filtration rate and renal tubular resistance to vasopressin, with nephrogenic diabetes insipidus. Although high levels of serum fluoride may occur following the prolonged administration of sevoflurane, clinical signs of nephrotoxicity are extremely rare. This is postulated to be the result of the low blood: gas partition coefficient of sevoflurane and its rapid elimination from the body or the fact that sevoflurane, unlike older agents such as methoxyflurane, does not undergo metabolism in the kidney, but only in the liver. Therefore, unlike methoxyflurane, there is no local renal release of fluoride, thereby limiting the risk of toxicity. Although high serum fluoride concentrations have been documented with prolonged enflurane administration, this agent is no longer commonly used in clinical anesthesia practice. An additional concern regarding the potential nephrotoxicity of the potent inhalational agents is unique to sevoflurane, in particular a unique metabolite, a vinyl ether also known as compound A. Compound A is produced during the metabolism of sevoflurane and its reaction with the soda lime in the carbon dioxide absorber of the anesthesia machine.[106-108] Compound A concentrations are increased by several factors including a high inspired concentration of sevoflurane, low fresh gas flows through the system (<2 L/min), increasing temperatures of the soda lime canister, decreased water content of the CO_2 absorbent, and high concentrations of potassium or sodium hydroxides in the CO_2 absorbent. Although of potential concern when studied in laboratory animals, there are no clinical data to suggest the nephrotoxic potential of compound A, which suggests that such concerns should not limit the use of sevoflurane, even in patients with preexisting renal dysfunction.

Neuromuscular Blocking Agents

The reader is referred to Chapter 122 for a complete review of the use of neuromuscular blocking agents (NMBAs). The following section will deal briefly with those aspects of NMBA administration that relate specifically to perioperative anesthetic care. Intraoperatively, skeletal muscle relaxation may be required for the successful completion of a surgical procedure (exploratory laparotomy), may be required briefly for

endotracheal intubation, or may be used to ensure patient immobility in situations where inadvertent movement may be detrimental (craniotomy). Although frequently administered during the perioperative period, many surgical procedures can be performed without the administration of NMBAs. NMBAs have no effect on the level of consciousness, provide neither amnesia nor analgesia, and do not alter the dose of other medications required to induce and maintain general anesthesia. When NMBAs are used, the patient requires an adequate level of general anesthesia and in the intensive care unit an adequate level of sedation. This is especially important since clinical signs of inadequate anesthesia (movement) are abolished. It is also important to recognize that the airway must be controlled when NMBAs are used These agents are contraindicated if there is any concern regarding one's ability to control ventilation. One additional caveat regarding the administration of NMBAs is that although problems are rare, NMBAs are high on the list of agents responsible for intraoperative anaphylactic reactions (along with antibiotics and latex).

Neuromuscular blockade may be used only to facilitate endotracheal intubation or may be continued throughout the surgical procedure to provide surgical relaxation. When ongoing neuromuscular blockade is required, incremental doses which are approximately one fourth to one fifth of the initial intubating dose are administered based on the response obtained using neuromuscular blockade monitoring. Alternatively, a continuous infusion of short or intermediate acting agents is occasionally used.

Given that repetitive doses or an infusion may result in excessive levels of neuromuscular blockade, monitoring of neuromuscular transmission is used to predict optimal conditions for endotracheal intubation, adequacy of surgical muscle relaxation, effectiveness of reversal of neuromuscular blockade, and to guide dosing of NMBAs during intraoperative care. The goal of such monitoring is to allow incremental titration of NMBAs to maintain the desired level of blockade while maintaining sufficient neuromuscular function to allow reversal of residual neuromuscular blockade at the completion of the surgical procedure.

To accomplish monitoring of neuromuscular blockade, a supramaximal electrical stimulation from a peripheral nerve stimulator is delivered to electrodes placed over the distribution of a peripheral nerve. This can be accomplished using the ulnar nerve at the wrist or elbow, the common peroneal nerve as it passes over the head of the fibula, or the facial nerve. As any of these involve electrical stimulation, they are painful and should only be performed in an appropriately anesthetized patient. Although various patterns of electrical stimulation of the peripheral nerve (single twitch, train-of-four [TOF], double-burst suppression, tetanus, and posttetanic stimulation) have been advocated in the literature, TOF monitoring remains the technique used most commonly in clinical anesthesia practice. Two electrical stimuli are delivered each second for 2 seconds to give four twitches or a TOF. Despite its acceptance and use in everyday anesthesia practice, TOF monitoring is relatively nonspecific in that up to 70% to 80% of the acetylcholine receptors must be blocked in order to achieve any visible decrement in the TOF. The goal of monitoring is to ensure that some residual neuromuscular function is present at the completion of the surgical procedure so that the effects can be reversed. The goal of reversal is for the patient to sustain minute ventilation and maintain a patent airway to allow for tracheal extubation.[109,110] In most clinical circumstances, one or two twitches of the TOF must be present to allow for effective pharmacologic reversal. A TOF of 0.7 or greater, where the fourth twitch is 70% or more of the height of the first twitch, is evidence of adequate reversal. Other tests of adequacy of reversal include a sustained response to tetanus, a sustained head lift for 5 to 10 seconds, and strong grip strength. In infants, sustained hip flexion is a useful clinical sign. Patients demonstrating profound blockade (no response to electrical stimulation) should not be reversed until some evidence of return of neuromuscular function has occurred. Despite adequate reversal, recurrence of partial paralysis resulting in respiratory insufficiency or upper airway obstruction may occur during the postoperative period. Reversal of residual neuromuscular blockade is accomplished using drugs that inhibit acetylcholinesterase (edrophonium, neostigmine, or pyridostigmine). By inhibiting acetylcholinesterase, these medications result in the accumulation of acetylcholine at the nicotinic (neuromuscular junction) and muscarinic sites, thereby increasing the competition between acetylcholine and the NMBA for the α subunits of the nicotinic cholinergic receptor. As these medications also inhibit acetylcholinesterase at muscarinic sites, they must be coadministered with an anticholinergic agent such as atropine or glycopyrrolate to prevent bradycardia or asystole. An inadequate response to the anticholinesterase medication with residual weakness may be secondary to excessive blockade at the time of reversal, allowing inadequate time since the administration of the reversal drug, an altered acid-base or electrolyte status, hypothermia, effects of other medications, or impaired clearance of NMBAs from the plasma secondary to renal or hepatic dysfunction.

Intraoperative Anesthetic Care

Maintenance Anesthesia

The current chapter has discussed the perioperative care of a surgical patient from the preoperative evaluation through premedication, monitoring, and the induction of general anesthesia. Once the airway has been secured and ventilation/oxygenation established, maintenance anesthesia is provided for the duration of the surgical procedure. Given the variety of inhalational anesthetic agents, intravenous anesthetic agents, opioids, and NMBAs available, there are several combinations of agents that can be used to provide the prerequisites of general anesthesia. The choice of agent varies widely and is determined by personal preferences and experiences of the anesthesia provider, the patient's comorbid features such as underlying cardiovascular function, the anticipated duration of the surgical procedure, the postoperative requirements (will the patient's trachea be extubated at the completion of the procedure; is ongoing postoperative analgesia required?), and the operative setting (is rapid turnover of cases desirable and are rapid awakening and hospital discharge needed?).

In most scenarios, the baseline level of anesthesia is provided by either a potent inhalational anesthetic agent or propofol and supplemented with intermittent dosing or a continuous infusion of an opioid. If ongoing neuromuscular blockade is required, a continuous infusion of a short-acting agent or intermittent dosing of an intermediate- to long-acting agent can be used. Although controlled ventilation is most commonly practiced, there are many surgical procedures for which spontaneous ventilation is acceptable. The use of

spontaneous ventilation is more common in the outpatient setting where endotracheal intubation is less common and general anesthesia is provided using a mask or an laryngeal mask airway. In addition to commonly monitored hemodynamic parameters, spontaneous ventilation provides a very effective means of assessing the depth of anesthesia by respiratory rate and provides the optimal parameter for dosing of opioids. When spontaneous ventilation is used, opioids can be dosed based on the patient's respiratory rate to ensure that an appropriate amount is administered to provide postoperative analgesia while avoiding overdosing and postoperative respiratory depression.

Intraoperative Fluid Management

In addition to monitoring hemodynamic and respiratory function, the anesthesiologist must also maintain fluid, electrolyte, and glucose homeostasis during anesthetic care. Intraoperative fluid management uses isotonic crystalloid solutions such as lactated Ringer solution (LR), normal saline (NS), or Plasmalyte to provide ongoing maintenance fluids and replace preoperative deficits, intraoperative third-space losses, and blood losses when blood therapy is not necessary. Third-space losses may be relatively trivial during superficial procedures (2 to 3 mL/kg/hr) or significant (10 to 15 mL/kg/hr) for intraabdominal procedures. Although generally considered an isotonic fluid, LR has only 130 mEq of sodium per liter and therefore is relatively contraindicated in patients at risk for cerebral edema, including the multiple trauma patient. Large volumes of NS, although effective in supporting the serum sodium, can result in a dilutional acidosis. These issues have led to the consideration of using a combination of NS and LR or the use of a more balanced solution such as Plasmalyte, which contains 140 mEq/L of sodium, physiologic amounts of chloride, and gluconate/acetate as buffers. Given their distribution between the intravascular and extravascular space, if blood therapy is not administered, blood loss is routinely replaced as 3 mL of crystalloid for each 1 mL of blood loss. Alternatives to isotonic crystalloid solutions include synthetic and natural colloids such as hydroxyethyl starch, albumin, or gelatins (these are not currently available in the United States). As with resuscitation in other areas, there are currently no studies demonstrating the superiority of any of these solutions over standard isotonic crystalloids and it is likely that the crystalloid-colloid debate will continue for many years. Potential drawbacks to the use of hydroxyethyl starch solutions including hetastarch solutions (Hespan or Hexted) includes the potential for platelet dysfunction when amounts greater than 15 to 20 mL/kg are administered. This reversible platelet dysfunction results from alterations in the potency of von Willebrand factor caused by the hydroxyethyl starch solutions.

During the postoperative period, especially in pediatric patients, given the potential for the development of postoperative hyponatremia, fluids more hypotonic than half-normal saline are rarely indicated. For short surgical procedures when a Foley catheter is not inserted, aggressive fluid therapy with replacement of the preoperative deficit is not necessarily required since bladder distention during emergence from anesthesia may be quite uncomfortable for the patient. Additionally, specific surgical procedures such as intracranial neurosurgical procedures and thoracic procedures or underlying cardiovascular dysfunction may mandate that the patient "be kept dry" to improve the intraoperative and postoperative course. However, in many other surgical procedures, especially intraabdominal cases, burn debridement, or other cases with significant third-space losses, the administration of significant amounts of isotonic crystalloids may be required to maintain intravascular volume status. Except for the neonatal population or patients chronically receiving parenteral nutrition fluids, dextrose-containing fluids are rarely administered. In high-risk patients, those receiving glucose-containing fluids, and diabetics, intermittent monitoring of blood glucose may be indicated. Although a review of the perioperative care of the diabetic patient is beyond the scope of this chapter, recent evidence has demonstrated that the postoperative outcome of such patients may be improved by tight perioperative glucose control. With the availability of rapid bedside testing, the rapid and intermittent determination of blood glucose concentrations is feasible.

Postoperative Care

Postoperative Analgesia

Various factors may interfere with the delivery of effective postoperative analgesia. Inadequate pain relief following surgery generally results from inappropriate methods of administration rather than ineffective analgesic agents. Although frequently used in the past for the delivery of opioids in the delivery of postoperative analgesia, the intramuscular route should be abandoned, as several factors result in inadequate analgesia including variable absorption and unpredictable plasma opioid concentrations, in addition to the child's reluctance to ask for pain medications due to the pain associated with IM injections.[111] Fortunately, the area of acute and postoperative analgesia has been an area of intense research that has resulted in the development of new techniques and refinement of treatment strategies.[112] Current modalities to provide better postoperative analgesia include intravenous patient-controlled analgesia (PCA) and the use of epidural and spinal local anesthetics and/or opioids. Although introduced into the adult population, these techniques are now widely applied across all age ranges in pediatric patients. PCA involves the self-administration of small doses of opioids to obtain and maintain analgesia. Analgesia occurs when the plasma opioid concentration reaches the minimum effective analgesic concentration (MEAC). With PCA, patients titrate the opioid to their own MEAC and can thereby maintain consistent analgesia.[113-115] Numerous studies have demonstrated improved analgesia, fewer adverse effects, and decreased opioid consumption with the use of PCA. Prior to the initiation of PCA, the patient receives a loading dose of the opioid administered either intraoperatively or postoperatively as multiple small doses of an opioid to achieve the MEAC. Once this is accomplished, the PCA is started and a dose of opioid is self-administered at a specific interval or lockout period (generally 5 to 10 minutes) as needed by the patient. Additionally, a continuous infusion can be added to the PCA regimen, although it has been suggested that this negates the safety feature of PCA in which no opioid is delivered if the patient is too sleepy to push the button. With the continuous infusion, opioid is infused regardless of the patient's demand, which may increase the incidence of adverse effects including respiratory depression.

In addition to the use of opioids, acetaminophen and nonsteroidal antiinflammatory agents (NSAIDs) play a significant

role in the control of postoperative pain. NSAIDs, acetaminophen, and salicylates act through the inhibition of the enzyme cyclooxygenase, thereby blocking the synthesis of prostaglandins. In distinction to opioids, these agents demonstrate a ceiling effect so that once a specific plasma concentration is achieved, no further analgesia is provided by increasing the dose. These agents are classified according to their chemical structure as (1) para-amino phenol derivatives (acetaminophen), (2) NSAIDs (ibuprofen), and (3) salicylates (acetylsalicylic acid, choline magnesium trisalicylate).[116] When considering the para-aminol phenol derivatives, acetaminophen has a significant role in the management of acute pain, while phenacetin is no longer used, given its potential toxicity profile (renal papillary necrosis). Although currently available only as an oral or rectal medication in the United States, the prodrug (propacetamol) is available in Europe and elsewhere throughout the world for intravenous administration. FDA approval is anticipated soon for the use of intravenous acetaminophen in the United States. Commonly used NSAIDs include either ibuprofen for oral administration or ketorolac for intravenous administration. An intravenous preparation of ibuprofen has recently received FDA approval for the treatment of pain and the control of fever in adults. The reader is referred to reference 116 for a more in-depth discussion of the prostaglandin synthesis inhibitors.

The prostaglandin synthesis inhibitors are used alone for minor pain, combined with weak opioids (codeine or oxycodone) for oral administration to control moderate pain, or added to parenteral opioids and regional anesthetic techniques for severe pain. In the last scenario, their use does not replace opioids or neuraxial techniques, but rather provides adjunctive analgesia, thereby lowering the total amount of opioid required. As the majority of opioid-related adverse effects are dose-related, modalities that decrease total opioid consumption play a significant role in decreasing or preventing opioid-associated adverse effects. When used for this purpose, the prostaglandin synthesis inhibitor is administered around-the-clock and not on an as-needed basis.

Regional anesthetic techniques including either neuraxial blockade (epidural or spinal analgesia) or peripheral nerve blockade can be continued into the postoperative period to provide effective analgesia, while avoiding the potential adverse effects associated with parenteral opioid therapy. Epidural and spinal local anesthetics provide profound analgesia; however, undesirable side effects of the use of high concentrations of local anesthetics include blockade of the sympathetic nervous system with hypotension, urinary retention, blockade of motor function, and risks of local anesthetic toxicity from systemic absorption. Epidural and spinal opioids can provide intense, segmental, localized analgesia without sensory, motor, or sympathetic nervous system effects, although their adverse effects profile may include respiratory depression, nausea, pruritus, sedation, and urinary retention. As a result, a combination of low-dose epidural local anesthetics and opioids are commonly used to take advantage of their synergistic effects and limit the side effects of each. Fentanyl and morphine are commonly used opioids, and bupivacaine is the usual local anesthetic of choice. The lipid solubility of the opioid predicts its clinical behavior. Fentanyl is very lipid soluble, penetrating the dura and rapidly binding to spinal cord opioid receptors, which produces a fast onset of action but a short duration of action. Significant vascular absorption of fentanyl also occurs, decreasing its epidural effect and reducing its advantage over parenteral administration. Morphine is lipid-insoluble and has a slower onset of action, but a much longer duration of action. However, given its hydrophilic nature, morphine remains in the cerebrospinal fluid for a longer period of time with cephalad spread and the risks of delayed respiratory depression for up to 24 hours after neuraxial administration, thereby mandating ongoing monitoring of respiratory function during this time. Other methods of postoperative analgesia include the use of long-acting local anesthetic agents for either wound infiltration or peripheral nerve blockade. Examples of peripheral nerve blockade include brachial plexus blocks for upper extremity pain, femoral nerve blocks for femur and knee surgeries, sciatic nerve blocks for analgesia below the knee, and intercostal nerve blocks for thoracic and abdominal surgeries. Options include the placement of a catheter to allow for a continuous infusion during the postoperative period and provide long-term analgesia for up to 3 to 5 days.

Conclusions

The perioperative care of pediatric patients begins with the preparation of the operating room site as well as the preoperative evaluation of the patient. The complexity of the latter varies tremendously based on the presence of comorbid conditions. These coexisting conditions as well as the requirements of the surgical procedure influence the techniques used for intraoperative monitoring. In its simplest form, a general anesthesia includes amnesia, analgesia, muscle relaxation, and attenuation of the sympathetic nervous system's response to surgical trauma. The phases of general anesthesia include induction, maintenance, and emergence. The induction of anesthesia can be carried out with the intravenous administration of an anesthetic agent or via the inhalation route, with an inhalational anesthetic agent such as sevoflurane. In pediatric patients, the inhalation induction of anesthesia is frequently chosen to avoid the need for obtaining intravenous access on an awake child. Following anesthetic induction, one progresses into the maintenance phase of general anesthesia. This may include the administration of intravenous agents, inhalational agents, or, most likely, the a combination of the two. Following the successful completion of the surgical procedure, a plan is determined for the postoperative delivery of analgesia, including some combination of intravenous opioids, agents to inhibit prostaglandin formation, or a regional anesthetic technique. For complex surgical procedures, tracheal intubation and mechanical ventilation may be continued into the postoperative period, while tracheal extubation and resumption of spontaneous ventilation is the general rule for the majority of surgical procedures. Regardless of the type of anesthesia administered, close monitoring of hemodynamic and respiratory function is continued into the postoperative period either in the ICU or a specialized postanesthesia care unit.

VII Chapter 122

Neuromuscular Blocking Agents

Joseph D. Tobias

PEARLS

- As neuromuscular blocking agents (NMBAs) result in blockade of skeletal muscle function, these agents cause cessation of ventilatory function, mandating airway control and the institution of mechanical ventilation. Inability to manage the airway via the provision of bag-mask ventilation and endotracheal intubation will result in hypoxia and death. These agents should not be used if there is any question as to the normalcy of the airway and the ability to successfully accomplish bag-mask ventilation and endotracheal intubation.
- We would recommend the use of the term neuromuscular blocking agent rather than muscle relaxant as the latter seems to imply some implicit type of sedative property, which of course these agents do not have. Rather, it seems appropriate to use the term "NMBA," thereby identifying in their name their mechanism of action and further emphasizing that they are devoid of sedative and analgesic properties.
- NMBAs can broadly be divided into two separate classes based on their mechanism of action. Depolarizing agents such as succinylcholine mimic the action of acetylcholine at the neuromuscular junction and activate or depolarize the muscle, whereas nondepolarizing agents such as pancuronium or rocuronium block the effects of acetylcholine at the neuromuscular junction, acting as competitive antagonists.

In the pediatric intensive care unit (PICU) setting, there may be circumstances in which total prevention of movement is necessary, thereby mandating the use of neuromuscular blocking agents (NMBAs) (Box 122-1).[1] Although these agents can be used as a single dose to facilitate endotracheal intubation, more prolonged administration may be needed in specific circumstances. A survey from the PICU setting suggests that the prolonged administration of these agents is used most commonly as an adjunct in the control of intracranial pressure (ICP).[2] With an improved understanding of the techniques for providing sedation and analgesia in the PICU setting and data demonstrating not only their adverse effect profile, but also their lack of efficacy in specific clinical scenarios, there has been a decrease in the prolonged administration of NMBAs.

Given their potential for adverse effects, it is recognized that NMBAs should be used only when absolutely indicated, only after appropriate training in their pharmacology, and only after obtaining the knowledge and skills needed to treat adverse effects related to their use. Furthermore, it may be appropriate to avoid the use of the term *muscle relaxant,* which seems to imply some implicit type of sedative property that, of course, these agents do not have. Rather, these agents should be thought of as NMBAs, thereby identifying in their name their mechanism of action and further emphasizing that they are devoid of sedative and analgesic properties. Given their action (blockade of skeletal muscle function), these agents will cause cessation of ventilatory function, mandating airway control and the institution of mechanical ventilation. Inability to manage the airway via the provision of bag-mask ventilation and endotracheal intubation may result in hypoxia and death. These agents should not be used if there is any question as to the normalcy of the airway and the ability to successfully accomplish bag-mask ventilation and endotracheal intubation. In the absence of comorbid disease processes that alter the sensorium, patients receiving NMBAs are unable to move and yet totally aware. These agents provide no amnestic, analgesic, or sedative properties, and should not be used without the coadministration of an amnestic agent (i.e., benzodiazepine or barbiturate).

The Neuromuscular Junction

Normal neuromuscular transmission results from the release of acetylcholine from the nerve terminal, its movement across the synaptic cleft, and subsequent binding to the postsynaptic nicotinic receptor on the sarcolemma of the skeletal muscle (Figure 122-1). Acetylcholine is synthesized in the cytoplasm from acetyl coenzyme A and choline and stored in synaptic vesicles in the axonal terminals of the presynaptic membrane. Depolarization of the axonal membrane results in the opening of calcium channels (P channel) and the movement of calcium through channels in the presynaptic membrane, resulting in the fusion of the synaptic vesicles with the axonal membrane and the release of acetylcholine into the synaptic cleft. The P channel is blocked by cations such as magnesium and lithium, but not by calcium channel antagonists. As such, the concurrent administration of magnesium or lithium will potentiate the effect of NMBAs, and the excessive administration of either cation can have significant effects on normal neuromuscular function. After its release from the synaptic vesicles, acetylcholine diffuses across the synaptic cleft and binds to acetylcholine receptors on the postsynaptic membrane (sarcolemma). The acetylcholine receptor (nicotinic receptor on the sarcolemma) is a pentameric protein

composed of five subunits. There are five classes of subunits (alpha, beta, gamma, delta, and epsilon) each of which is coded for by a different gene. During various stages of development or in pathologic disease states, the composition of the acetylcholine receptor may change. The normal variant of the acetylcholine receptors found in adults includes two alpha subunits combined with one each of the beta, delta, and epsilon subunits. Binding of an acetylcholine molecule to each of the two alpha subunits is necessary for opening of the channel and depolarization of the sarcolemma. Immature and denervated acetylcholine receptors have a gamma subunit instead of the epsilon while a demyelinated neuromuscular junction contains acetylcholine receptors composed of a pentamer of alpha$_7$ subunits. The importance of these variants is that their response (opening of the ion channel) is dramatically different from the normal adult variant of the acetylcholine receptor. These differences can result in devastating consequences following the administration of succinylcholine (see below). The acetylcholine receptor occupies the space from the outside of the muscle through the cell membrane to the inside and thereby regulates the transmembrane movement of ions. It converts the chemical stimulus (acetylcholine) into an electrical impulse (depolarization of the sarcolemma). Stimulation of the acetylcholine receptors opens ion channels allowing the movement of small, positively charged cations such as sodium, potassium, and calcium. The sodium influx depolarizes the muscle membrane leading to excitation-contraction coupling, with the release of calcium from the sarcoplasmic reticulum and muscle contraction. Cessation of muscle contraction and repolarization occurs when acetylcholine is metabolized by a specific enzyme, acetylcholinesterase, which is present in the synaptic cleft. This repolarization sets the muscle for the next round of depolarization and excitation-contraction coupling.

Box 122–1 Reported Indications for Neuromuscular Blockade in the PICU

Facilitation of procedures or diagnostic studies:
- Endotracheal intubation
- Central line placement
- Radiological imaging (MRI, CT scanning)

Immobilization during interhospital or intrahospital transport

Intensive care indications:
- Facilitate mechanical ventilation
- Control increased intracranial pressure
- Eliminate shivering (especially during therapeutic hypothermia)
- Decrease peripheral oxygen utilization
- Control severe agitation unresponsive to adequate sedation
- Maintain immobilization after surgical procedures
- Decrease the risk of pulmonary vasospasm in patients with pulmonary hypertension
- Manage patients with tetanus

Neuromuscular Blocking Agents: Depolarizing Agents

The two general classes of NMBAs (depolarizing and nondepolarizing agents) differ in their basic mechanism of action. Depolarizing agents such as succinylcholine (suxamethonium in Europe and the United Kingdom) mimic acetylcholine, binding to the acetylcholine receptor at the neuromuscular junction, and activating it. As succinylcholine is resistant to degradation by acetylcholinesterase, there is sustained occupation of the receptor and thereby failure of repolarization,

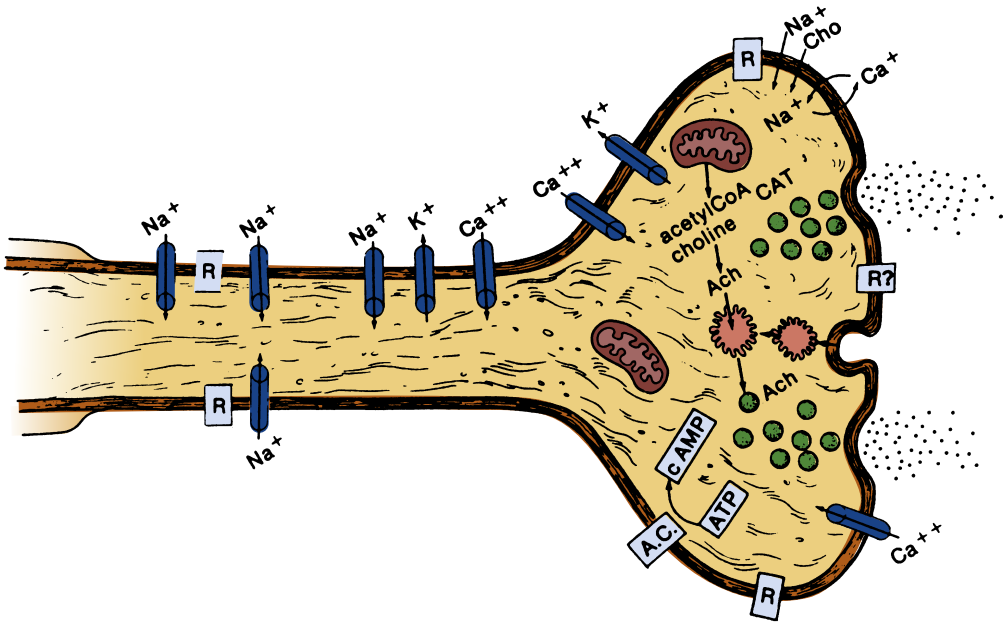

Figure 122–1. Scheme of a motor nerve terminal. The proximal zone, immediately next to the last segment of myelin, is shown as rich in sodium channels (*Na⁺*) that may be activated by cholinergic receptors (*R*). A midzone contains enzyme systems related to metabolism and transmission (*CAT*, choline acetyl transferase; *A.C.*, adenylate cyclase). Some of these are dependent on the entry of sodium and choline (*Cho*), processes that are linked and may be modulated by a cholinergic receptor. Between the proximal and midzone, the terminal is shown as having a variety of ion channels, but as being rich in potassium channels. The final zone, that of release, is sketched as having calcium channels and perhaps having muscarinic or nicotinic receptors (*R?*) that can modulate the release of transmitter (*Ach*).

resulting in a more prolonged duration of neuromuscular blockade. This action of succinylcholine accounts for the clinical effects that are seen, which include the initial muscle fasciculations followed by flaccid paralysis that generally lasts 5 to 10 minutes, the time necessary for the degradation of succinylcholine by pseudocholinesterase. The onset of action of succinylcholine is more rapid than any of the nondepolarizing agents, with neuromuscular blockade occurring in 30 to 45 seconds, thereby allowing for rapid control of the airway by endotracheal intubation. Succinylcholine undergoes rapid redistribution and metabolism by the plasma enzyme pseudocholinesterase (plasma cholinesterase), which limits its clinical duration to 5 to 10 minutes.

In isolated cases, a congenital or acquired deficiency of pseudocholinesterase can lead to a prolonged duration of action. In general, there may be issues with the total amount of the enzyme (quantitative defect) or the efficacy of the enzyme (qualitative defect).[3] Quantitative problems are generally acquired while qualitative issues are inherited. The inherited form of pseudocholinesterase deficiency results in a qualitative defect in the enzyme. It is an autosomal recessive trait with an incidence of 1 in 2500 to 3500. Only homozygotes have a clinically significant prolongation of the effect of succinylcholine, with neuromuscular blockade lasting up to 4 to 8 hours following a single normal intubating dose of succinylcholine (1 to 2 mg/kg). Disease states that lead to a quantitative decrease in pseudocholinesterase levels include severe liver disease, myxedema, pregnancy, protein-calorie malnutrition, and certain malignancies. Drugs and medications can also affect pseudocholinesterase levels, including chemotherapeutic agents such as cyclophosphamide and echothiopate ophthalmic drops. Deficiency can also result from recent plasmapheresis as the enzyme is removed with the plasma. Treatment is aimed at prompt identification by noting failure of the return of the train-of-four (TOF) with peripheral nerve stimulation (see below). The possibility of such an occurrence stresses the need to ensure return of neuromuscular function following the administration of succinylcholine prior to the administration of a nondepolarizing agent. If such a problem is suspected, primary therapy includes continuation of ventilatory support until the patient's muscle strength returns and the provision of amnesia with a benzodiazepine or some other anesthetic agent. Although the patient cannot move, he or she will be aware and awake once the effects of the anesthetic induction agents have diminished. The enzyme plasma cholinesterase is contained in fresh frozen plasma (FFP); however, due to the infectious disease risk with the use of blood products, reversal through the administration of FFP cannot be recommended.[4-6] More recently, purified human plasma cholinesterase has also been used in such circumstances; however, such a practice is expensive and not available in most centers.

Despite its rapid onset and cessation of effect, the potential adverse effects associated with succinylcholine can be devastating and even fatal (Box 122-2). Direct effects on cardiac rhythm have been described following the administration of succinylcholine, including bradycardia, tachycardia, and atrial or ventricular ectopy.[7] Succinylcholine has a chemical structure similar to two molecules of acetylcholine and may result in bradycardia from activation of cardiac muscarinic receptors. This effect is especially common in infants and children, in patients who are anesthetized with halothane (given its negative chronotropic effects), in the presence of hypoxemia, with intravenous as compared to intramuscular administration, when succinylcholine is given concurrently with other medications that have negative chronotropic effects (propofol, fentanyl), and with repeated doses. Therefore, in these scenarios, succinylcholine should always be preceded by an anticholinergic agent such as atropine. The bradycardic effects of succinylcholine may also be accentuated by hypothermia and by elevated ICP. Arrhythmias may also be seen. Although common, occurring in up to 50% of patients, they are generally short-lived and of no clinical significance. The use of an anticholinergic agent will decrease, but not eliminate the incidence of arrhythmias. As with the potential for bradycardia, arrhythmias tend to be more common with repeated doses of succinylcholine.

As succinylcholine activates the acetylcholine receptor prior to producing neuromuscular blockade, depolarization of the muscle end plate occurs, with contraction of the muscle fascicles or fasciculations. These fasciculations are responsible for the myalgias that may occur following succinylcholine administration.[8] Although not a significant issue when succinylcholine is used to emergently secure the airway, these fasciculations can result in severe muscle pain; therefore many advise against the use of succinylcholine for outpatient surgery when such issues may interfere with activities of daily living and return to work. The severity of the fasciculations can be diminished by the administration of a small dose of a nondepolarizing agent (curare 0.03 to 0.05 mg/kg, rocuronium 0.05 mg/kg, or pancuronium 0.01 mg/kg) prior to succinylcholine. The dose of the nondepolarizing agent is generally one tenth of the recommended dose for endotracheal intubation.[9] This is referred to as a *defasciculating dose*. The technique is commonly used in the operating room when succinylcholine is administered to adults, as a means of preventing or attenuating the postoperative myalgias that may occur with succinylcholine. One advantage of fasciculations is that their cessation signals that neuromuscular blockade is complete and the patient's trachea can be intubated.

Defasciculation is not commonly used in the pediatric population for several reasons: (1) children less than 6 years of age do not fasciculate; (2) the use of the defasciculating dose delays the onset of paralysis and increases the succinylcholine dose requirement; (3) in patients with severe respiratory or hemodynamic compromise, the defasciculating dose can cause a significant degree of neuromuscular blockade leading to respiratory insufficiency or laryngeal incompetency with

Box 122–2 Adverse Effects of Succinylcholine

Arrhythmias

Increased intragastric pressure
Increased intracranial pressure
Diffuse myalgias
Myoglobinuria
Malignant hyperthermia
Prolonged paralysis with pseudocholinesterase deficiency
Hyperkalemia (see Box 122-3)

the risk of aspiration; and (4) full efficacy may require up to 2 to 3 minutes, thereby making the technique less optimal when emergent securing of the airway is necessary. If a defasciculating dose is used in patients who are awake and coherent, they should be warned that they may feel effects of the medication, such as diplopia from effects of the drug on the extraocular muscles. Additionally, some patients may feel effects on the muscles of ventilation and complain of shortness of breath.

In addition to myalgias, the fasciculations caused by succinylcholine may result in a transient increase in plasma creatinine phosphokinase (CPK) and myoglobin level. Myoglobinemia occurs most commonly (in up to 40% of patients) when there is concomitant administration of general anesthesia with halothane. In these patients, levels high enough to result in myoglobinuria have been reported in 8% of patients.[10] The rise in plasma CPK and myoglobin levels does not occur with intramuscular administration and may be attenuated by the administration of a defasciculating dose of a nondepolarizing agent (see above). These effects should be differentiated from the potentially lethal complication of rhabdomyolysis, which may occur in patients with specific disorders of the neuromuscular junction and in malignant hyperthermia (see later discussion). These latter disorders absolutely contraindicate the use of succinylcholine. Fasciculations may also increase intragastric (IGP) and intraocular pressure (IOP). The transient and minimal rise in intragastric pressure is generally of limited clinical significance and does not increase the risk of vomiting or passive regurgitation during endotracheal intubation. In the emergency setting, when succinylcholine is chosen for endotracheal intubation, rapid sequence intubation will be used, with the application of cricoid pressure to protect against acid aspiration. The contraction of extraocular muscles leads to an increase in intraocular pressure following the administration of succinylcholine. The increase is transient, with a return of the IOP to baseline within 5 to 8 minutes. Given this effect, administration to patients with an open globe injury is generally contraindicated due to the theoretical risk of causing extrusion of the intraocular contents. Although succinylcholine has been safely administered to such patients,[11] standard practice generally considers the presence of an open globe injury a contraindication to its use.

The effects of succinylcholine on intracranial pressure and its use in patients with altered intracranial compliance remain controversial. Succinylcholine increases ICP not only through the production of muscle fasciculations and increased venous tone, but also via a direct cholinergic mechanism due to activation of muscle spindles in the peripheral skeletal musculature.[12] The effects on ICP are generally mild and transient. Given its rapid onset (30 to 45 seconds), succinylcholine allows for rapid endotracheal intubation and control of arterial oxygenation and ventilation. As the latter are primary determinants of ICP, any mild increase due to the direct effects of succinylcholine are rapidly controlled. Succinylcholine's effects on muscle spindles have also been postulated as an explanation of the CNS activation and dreaming that has been reported during general anesthesia in patients who received succinycholine.[13] The dreaming has not been associated with awareness or recall.

Succinylcholine has also been shown to occasionally result in a transient increase in the tone of the masseter muscles. This effect may be seen in all of the peripheral skeletal musculature, but may be accentuated in the masseter muscles, resulting in what is clinically known as masseter spasm. The effect is generally mild and can be overcome by manual opening of the mouth.[14] A defasciculating dose of a nondepolarizing agent may abolish this phenomenon. In rare circumstances, the masseter spasm may be severe, preventing mouth opening and precluding standard oral endotracheal intubation. It has been suggested that patients who manifest masseter spasm to this degree are at risk for malignant hyperthermia (MH), a rare inherited disorder of muscle metabolism which, if untreated, is generally fatal (see below). The data regarding the relationship between masseter spasm and MH are conflicting. In a prospective evaluation with monitoring of masseter muscle tone, patients who developed significant increases in masseter muscle tone did not proceed to develop MH.[15] However, retrospective series have suggested that the development of masseter spasm may be a prelude to MH, thereby clouding the issue as to how to deal with such patients.[16] In the emergency situation, should patients develop masseter spasm following the administration of succinylcholine, patients should be monitored for signs of MH including hypercarbia, hyperthermia, tachycardia, and rhabdomyolysis with myoglobinuria. Treatment with dantrolene is suggested should there be a concern regarding the development of MH (see below).

The major concerns with succinylcholine are its potential to trigger malignant hyperthermia and its ability to cause massive hyperkalemia if administered to patients with various comorbid disease processes. MH is an inherited (autosomal dominant) disorder of muscle metabolism with abnormalities of the ryanodine receptor (the calcium release channel of the sarcoplasmic reticulum of skeletal muscle). The point mutation of the ryanodine receptor leads to ongoing release of calcium and therefore sustained muscle contraction following exposure to succinylcholine or a potent inhalational anesthetic agent. During MH, ongoing muscle contraction and metabolism leads to hyperthermia, acidosis, tachycardia, hypercarbia, and rhabdomyolysis with secondary hyperkalemia. Treatment includes discontinuation of the triggering agent, treatment of hyperthermia and the biochemical derangements including acidosis and hyperkalemia, and administration of dantrolene, which blocks ongoing calcium release from the sarcoplasmic reticulum. Therefore, in clinical scenarios where succinylcholine may be administered, ready access to dantrolene is recommended.

The other major concern with succinylcholine is the occurrence of lethal hyperkalemia in patients with certain underlying disorders or comorbid diseases (Box 122-3).[17] The reader is referred to reference 17 for a full discussion of the hyperkalemic response following succinylcholine. While many of the disorders listed in Box 122-3 are readily apparent, such as the muscular dystrophies, the occurrence of cardiac arrest following succinylcholine administration to apparently healthy children has led to a restructuring of the recommendations for the use of succinylcholine. The problem is that some children with muscular dystrophy may not manifest symptoms until they are 4 to 6 years of age. If succinylcholine is administered to these children during perioperative care or other clinical scenarios, lethal hyperkalemia can occur. Because of such problems, the current recommendations are that succinylcholine should only be used for emergency airway management when rapid endotracheal intubation is necessary, when there is a concern about the ability to provide endotracheal intubation (potentially or documented difficult airway), or when

intramuscular administration is needed because an appropriate intravenous access cannot be secured. Also of concern in the pediatric population are patients with relatively rare genetic, chromosomal, or metabolic defects in whom the effects of succinylcholine have not been evaluated. In such settings, the risk/benefit ratio of succinylcholine must be fully examined. In many of these patients, the use of a rapidly acting, nondepolarizing agent may be the best option. However, succinylcholine is generally an acceptable option in patients with cerebral palsy and related problems. Regardless of the clinical scenario, if problems occur following the administration of succinylcholine, hyperkalemia should be suspected and the resuscitation tailored to treat it.

In emergency situations when intravenous access cannot be readily obtained, succinylcholine can be administered intramuscularly in a dose of 4 to 5 mg/kg. Intramuscular administration will result in neuromuscular blockade sufficient to allow for endotracheal intubation in 2 to 3 minutes and will rapidly (less than 30 seconds) treat laryngospasm occurring during anesthetic induction when intravenous access is not available, thereby allowing for effective bag-valve-mask ventilation. In this scenario, it is generally recommended that succinylcholine be administered into the deltoid muscle as the onset times are more rapid than with administration into the quadriceps. Alternatively, administration into the tongue or the submental space has been suggested as blood flow to this area is generally well-maintained even when peripheral vasoconstriction has occurred. Unlike intravenous administration, there is limited risk of bradycardia with IM administration.[18] However, the IM route is not recommended in patients with conditions that decrease cardiac output or blood flow to the muscles such as shock or bradycardia. In the latter situation, the onset of action will be significantly delayed. Given these concerns, IM administration is generally not recommended in critically ill children and intraosseous administration (1 to 2 mg/kg) should be considered when IV access is not available.[19]

Currently, the package insert and good clinical practice allow for the administration of succinylcholine when there may be a potentially difficult airway, in the emergency situation when rapid securing of the airway is necessary (full stomach when a rapid sequence intubation is performed), and when there is no intravenous access (IM administration), provided that there is no contraindication to its use (see Box 122-3 and reference 17). When dealing with the potentially difficult airway or unrecognized difficult airway, the major advantage of succinylcholine is that there should be return of normal neuromuscular function within 10 minutes as opposed to 60 minutes following a 1 mg/kg intubating dose of rocuronium (see later discussion). Dosing recommendations for succinylcholine vary from 1 to 2 mg/kg.[20] Larger doses are not likely to improve intubating conditions, and they slightly prolong the duration of action.

Box 122–3 Conditions Associated with Hyperkalemia After Succinylcholine Administration

Preexisting hyperkalemia
Muscular dystrophy
Burns
Metabolic acidosis
Paraplegia/quadriplegia
Denervation injury
Metastatic rhabdomyosarcoma
Parkinson disease
Disuse atrophy/prolonged bedrest
Polyneuropathy
Degenerative CNS disorders
Purpura fulminans
Tetanus
Guillain-Barré syndrome
Myotonia dystrophy
Prolonged administration of nondepolarizing NMBA

Neuromuscular Blocking Agents: Nondepolarizing Agents

The nondepolarizing NMBAs act as competitive antagonists at the neuromuscular junction, and block the effects of acetylcholine at the receptor. Unlike succinylcholine, these agents do not activate the acetylcholine receptor and therefore do not result in fasciculations. Nondepolarizing NMBAs are commonly used in the operating room to facilitate endotracheal intubation and to provide ongoing muscle relaxation for specific surgical procedures such as exploratory laparotomy. When used to provide ongoing neuromuscular blockade in the operating room or the intensive care unit, these agents can be administered by intermittent bolus dosing or by continuous infusion. There are two basic chemical structures of the nondepolarizing NMBAs available for clinical use: aminosteroid and benzylisoquinolinium compounds (Box 122-4). The difference in their chemical structure has limited clinical significance. Of more importance are differences regarding onset, duration of action, cardiovascular effects, metabolism, metabolic products, and cost. These principles will be reviewed in the remainder of this chapter.

The first nondepolarizing NMBAs (curare, gallamine, metocurine), which were introduced into clinical practice in the 1940s, are rarely, if ever, used in today's clinical practice. The past 20 years have seen a rapid growth in the development and introduction of nondepolarizing NMBAs for clinical use. As these agents have more favorable profiles (onset times, recovery times, metabolic fate), they have displaced the original group introduced in the 1940s. However, with the introduction of new agents comes the potential for unrecognized morbidity and even mortality related to adverse physiologic

effects. This potential is illustrated by the introduction and subsequent withdrawal of rapacuronium (see below). Given the potential for problems with succinylcholine, the search continues for a nondepolarizing NMBA with similar onset and cessation of action.

Pancuronium

Pancuronium is an aminosteroid compound. It is generally available in a solution containing 1 mg/mL of pancuronium, although other concentrations are available, depending on the manufacturer. The common clinical dose, 0.1 to 0.15 mg/kg, provides adequate conditions for endotracheal intubation in approximately 90 to 120 seconds. Although the higher end of the dosing range may speed the onset time to acceptable conditions for endotracheal intubation, the clinical duration is prolonged from 40 to 60 minutes to 70 to 80 minutes. Given its duration of action, pancuronium is considered a long-acting NMBA (Box 122-5). The effective dose in 95% of children (ED_{95}) is 52 μg/kg during halothane anesthesia and 81 to 93 μg/kg during opioid-based anesthesia. The latter is more applicable to the PICU setting.[21] Further study has shown that the ED_{95} in children is slightly higher than that of adolescents (77 μg/kg).[22] Following a dose of 70 μg/kg, the onset of neuromuscular blockade occurs more quickly in children when compared to adults, with 90% twitch ablation occurring at an average of 2.4 minutes in children and 4.3 minutes in adults.[23] The time to return of the twitch height to 10% of baseline was 25 minutes in children and 46 minutes in adults.

Vagal blockade and release of norepinephrine from adrenergic nerve endings results in an increase in heart rate and blood pressure. Intraoperatively, this effect can be used to balance the negative chronotropic effects of certain anesthetic agents such as fentanyl and halothane. However, there may be a slight proarrhythmogenic effect for atrial tachyarrhythmia in patients with comorbid diseases or when used with other agents that increase heart rate. Elimination is primarily renal (80%), resulting in a significantly prolonged effect in patients with renal insufficiency or failure. Hepatic metabolism is primarily hydroxylation, with production of an active 3-OH metabolite that retains approximately half of the neuromuscular blocking effects of the parent compound. The 3-OH metabolite is also dependent on renal excretion, thereby further prolonging the effect in the setting of renal insufficiency or failure.

Given its long half-life, pancuronium is generally administered intermittently to provide ongoing neuromuscular blockade in the PICU setting. One prospective study has evaluated dosing requirements in the PICU population.[24] The study cohort included 25 patients, ranging in age from 3 months to 17 years and in weight from 3.2 to 68 kilograms. Pancuronium was administered as an initial bolus dose of 0.1 mg/kg, followed by an infusion starting at 0.05 mg/kg/hr. The infusion was titrated up and down to maintain one to two twitches on TOF testing (see below). Pancuronium infusion requirement averaged 0.07 ± 0.03 mg/kg/hr for the 1798 hours of the infusion. Approximately 70% of the time, the infusion requirements were within the range of 0.05 to 0.08 mg/kg/hr. Seven patients were receiving anticonvulsant agents, including pentobarbital, carbamazepine, felbamate, valproic acid, phenytoin, and phenobarbital. Increased pancuronium infusion requirements were noted in these patients (0.14 ± 0.06 vs. 0.056 ± 0.03 mg/kg/hr) and in patients that received pancuronium for more than 5 days. The requirements on day 1 were 0.059 mg/kg/hr versus 0.083 mg/kg/hr on day 5. Upon discontinuation of the infusion, time to spontaneous recovery of neuromuscular function (return of the TOF to baseline and sustained tetanus to 50 Hz) varied from 35 to 75 minutes. No adverse effects directly related to pancuronium were noted. The authors concluded that pancuronium could be effectively administered by continuous infusion to provide neuromuscular blockade in the PICU setting and that it provided a cost-effective alternative to other available agents.

Box 122–5 Duration of Action of NMBAs

Short-Acting (10 Minutes)
Succinylcholine
Mivacurium
Rapacurium

Intermediate-Acting (20–40 Minutes)
Atracurium
Vecuronium
Cis-atracurium
Rocuronium

Long-Acting (60–90 Minutes)
Pancuronium
Pipecuronium
Doxacurium

Vecuronium

Like pancuronium, vecuronium is an aminosteroid compound. It was released for clinical use in the 1980s. Despite minor differences in pharmacologic structure from pancuronium, its plasma clearance is two to three times as rapid. Vecuronium is available as a powder (10 mg), which in common clinical practice is diluted to a concentration of 1 mg/mL. Given the added step of mixing the solution and thereby introducing another step during which a mistake may occur, some practitioners have voiced preference for other agents which are premixed.

At doses of 0.1 to 0.15 mg/kg, acceptable intubating conditions are provided in 90 seconds, with a clinical duration of action of 30 to 40 minutes, making it an intermediate-acting agent.[25] Increasing the dose to 0.3 mg/kg speeds the onset time to acceptable conditions for endotracheal intubation to 60 to 75 seconds, but also prolongs the duration of neuromuscular blockade to 60 to 90 minutes. Even with higher doses, vecuronium is devoid of cardiovascular effects. Metabolism is primarily hepatic (70% to 80%); however, hepatic metabolism results in the production of pharmacologically active metabolites, which are water soluble and therefore dependent on renal excretion. These metabolites possess roughly half of the neuromuscular blocking effects of the parent compound. This combined with the 20% to 30% renal excretion of the parent compound results in a prolonged clinical duration in patients with renal insufficiency. Given its 70% to 80% dependency on hepatic metabolism, the duration of action is also prolonged with hepatic insufficiency. Additionally, due to immaturity of the hepatic microsomal enzymes, a prolonged duration can be expected in neonates. Vecuronium in doses of 0.1 and

0.15 mg/kg maintained neuromuscular blockade at greater than or equal to 90% of baseline for 59 and 110 minutes in neonates and infants, 18 and 38 minutes in children, and 37 and 68 minutes respectively in adolescents.[26] The opposite effect occurs with the chronic administration of anticonvulsant agents, with resistance to the neuromuscular blocking effects and increased dose requirements in patients receiving phenytoin.[27] A similar effect has been reported with other anticonvulsant agents and NMBAs of the aminosteroid group. Given its lack of hemodynamic effects and its current availability in generic form, thereby providing a cost-effective agent for neuromuscular blockade, vecuronium remains a commonly used agent when administered by continuous infusion for ongoing neuromuscular blockade in the pediatric ICU setting.

Rocuronium

Rocuronium is one of the newer aminosteroid NMBAs, having been released for clinical use in the early to mid 1990s. It is available in a solution containing 10 mg/mL of rocuronium in 5 or 10 mL vials. The usual dose for endotracheal intubation (0.6 mg/kg), has a duration of action of 20 to 40 minutes, making it an intermediate-acting agent; however, larger doses (1 to 1.2 mg/kg) are frequently used during rapid sequence intubation, as the onset time at that dose has been shown to approximate that of succinylcholine (see below). As with other agents, the duration of action increases when larger doses are administered, so that 60 to 90 minutes of neuromuscular blockade occurs following a dose of 1.0 mg/kg. A mild vagolytic effect, less intense than that seen with pancuronium, may increase heart rate by 10 to 20 beats per minute. Bolus dosing may also raise mean arterial pressure.

Rocuronium is primarily metabolized by the liver, without the production of active metabolites. Its clinical duration is prolonged and its clearance decreased in patients with hepatic insufficiency or failure. Despite its primary dependence on hepatic elimination, there are mixed results in both adults and children regarding the duration of its effects in patients with renal insufficiency or failure. When comparing adults with and without renal failure, Robertson et al. reported that there was prolongation of the clinical duration (time to recovery of the first twitch of the TOF to 25% of baseline) from 32 to 49 minutes following a dose of 0.6 mg/kg in patients with renal failure.[28] The same investigators reported no difference in the pharmacodynamics in adults with and without renal failure with the use of a smaller dose (0.3 mg/kg).[29] With the smaller dose of 0.3 mg/kg, the onset time was 4 minutes and neuromuscular blockade was reversible at 20 minutes. When comparing adults with renal failure and those with normal renal function, Cooper et al. reported that following rocuronium (0.6 mg/kg), onset time (65 ± 16 vs. 61 ± 25 seconds), clinical duration (55 ± 26.9 vs. 42 ± 9.3 minutes), and spontaneous recovery (time for return of the final twitch of the TOF to 70% of baseline) were all prolonged (99 ± 41 vs. 73 ± 24 minutes).[30] Following an initial dose of 0.3 mg/kg, pediatric patients with renal failure had a longer onset time (139 ± 71 vs. 87 ± 43 seconds); however, there was no difference in the clinical duration.[31] More specific pharmacokinetic data and an explanation for the apparent prolonged elimination half-life of rocuronium in renal failure patients are provided by Szenohradszky et al. in their evaluation of rocuronium in a cohort of 10 adult patients undergoing renal transplantation.[32] Following a dose of 0.6 mg/kg, although the total plasma clearance and the volume of the central compartment did not differ between renal failure and control patients, the volume of distribution at steady state was larger in patients with renal failure; this resulted in a longer elimination half-life with renal failure (97.2 ± 17.3 vs. 70.9 ± 4.7 minutes). A summary of these studies demonstrate a slightly prolonged onset time with rocuronium and a prolonged elimination half-life (and therefore a prolonged clinical effect) in the presence of renal failure. The current data suggest that these findings result from alterations in the volume of distribution rather than primary alterations in clearance due to renal effects. The prolonged duration of action may be clinically significant with doses of 0.6 mg/kg or more, and can be minimized with doses of 0.3 mg/kg. However, with the smaller doses, onset times for successful endotracheal intubation will be prolonged to 2 to 3 minutes.

Given its dependence on hepatic metabolism, alterations in clearance are likely not only in patients with primary hepatic diseases, but also in neonates and infants, due to the immaturity of the hepatic microsomal enzymes. When comparing infants (0.1 to 0.8 years) and children (2.3 to 8 years), plasma clearance is decreased (4.2 ± 0.7 vs. 6.7 ± 1.1 mL/kg/min), the volume of distribution is increased (231 ± 32 vs. 165 ± 44 mL/kg), and the mean residence time is increased (56 ± 10 vs. 26 ± 9 minutes).[33] Also of note, the plasma concentration required to exert a 50% neuromuscular blocking effect is decreased in neonates and infants compared to older children (1.2 ± 0.4 vs. 1.7 ± 0.4 mg/mL). The latter effect, which indicates that the neuromuscular junction of neonates and infants is more sensitive to the effects of NMBAs, is not specific for rocuronium and is seen with all NMBAs. Similar results were reported by Rapp et al., as they reported progressive increases in the clinical duration with a decrease from 5 to 12 months, to 2 to 4 months, to 0 to 1 months of age.[34] The effect was further magnified when increasing the dose from 0.45 to 0.6 mg/kg. The authors also reported excellent or good intubating conditions in all infants with doses of 0.45 mg/kg and ablation of the twitch response at 15 to 30 seconds in neonates, thereby demonstrating a rapid onset even with the use of lower doses (0.45 mg/kg). As with other medications that undergo primary hepatic metabolism, the clinical effects of rocuronium are prolonged in neonates and infants. Metabolism and clinical effects approach those of the adult population by 6 to 12 months of age. In the neonate or younger infant, acceptable conditions for endotracheal intubation can be achieved at 45 to 60 seconds with doses of 0.3 to 0.45 mg/kg.

Rocuronium's welcome in the clinical arena has been expedited by its major clinical advantage over other nondepolarizing NMBAs, a rapid onset. Clinical studies have demonstrated acceptable conditions for endotracheal intubation in the majority of older children and adolescents within 60 seconds following a dose of 1.0 mg/kg. Of the currently available nondepolarizing NMBAs, only rocuronium has an onset of action that approaches that of succinylcholine. The remainder of the NMBAs require 90 to 120 seconds to provide conditions acceptable for endotracheal intubation, even when larger doses are used. In both the pediatric and adult populations, various studies have demonstrated that rocuronium in a dose of 1 mg/kg provides acceptable intubating conditions within 60 seconds in the majority of patients.[35-37] Mazurek et al.[36] prospectively compared the onset times of rocuronium (1.2 mg/kg) and succinylcholine (1.5 mg/kg) in a cohort of

26 children. Anesthesia was induced with thiopental (5 mg/kg). Endotracheal intubation attempts were started 30 seconds after the administration of the agent. Time to endotracheal intubation was comparable between the two groups, being 41.8 ± 2.9 seconds (range, 36 to 45 seconds) with succinylcholine and 40.2 ± 4.0 seconds (range, 33 to 48 seconds) with rocuronium. However, the conditions for endotracheal intubation were slightly less favorable with rocuronium; seven were excellent, five were good, and one was fair versus 10 that were excellent, two that were good, and one that was fair with succinylcholine. Scheibner et al.[37] compared conditions for endotracheal intubation provided by three of the commonly used NMBAs (rocuronium 0.6 mg/kg, vecuronium 0.1 mg/kg, and atracurium 0.5 mg/kg).[37] Endotracheal intubation was attempted every 30 seconds. Conditions for all of the endotracheal intubations were graded as excellent or good, 60 seconds after rocuronium, 120 seconds after vecuronium, and 180 seconds after atracurium. Although a larger dose of rocuronium speeds the onset time to acceptable conditions for endotracheal intubation, there is also a prolonged duration of action (60 to 80 minutes) unlike that of succinylcholine (5 to 10 minutes). The longer duration of action may be problematic should difficulties arise with the performance of endotracheal intubation, resulting in a "cannot intubate/cannot ventilate" scenario. Additionally, in patients with traumatic brain injury or other conditions resulting in alteration of mental status, the neurologic examination will be lost for 60 to 80 minutes following rocuronium in doses of 1 mg/kg. Despite these issues, because of its rapid onset, rocuronium remains the drug of choice for rapid sequence intubation when there are concerns regarding the use of succinylcholine.

Various investigators have evaluated potential techniques to speed the onset of rocuronium without the need to increase the dose. Although there was no difference noted in the time to 50% blockade (42 ± 14 vs. 45 ± 10 seconds) or onset time when comparing rocuronium 0.6 mg/kg administered with either ketamine 1.5 mg/kg or thiopental 4 mg/kg in parturients, tracheal intubation at 50% blockade was easily performed in all patients in the ketamine group while it was difficult in 75% of patients who received thiopental.[38] Munoz et al. demonstrated a significant decrease in the onset time of rocuronium (0.6 mg/kg) in patients who received ephedrine (70 μg/kg), 30 seconds prior to the start of rapid-sequence induction compared to patients receiving placebo (72 ± 19 vs. 98 ± 31 seconds).[39] Ephedrine indirectly increases cardiac output through the release of endogenous catecholamines. The increase in cardiac output increases blood flow and therefore drug delivery to the skeletal muscle, thereby accelerating the onset time.

As with other NMBAs such as vecuronium, priming may accelerate the onset times of rocuronium.[40] In a cohort of 84 children randomized into one of 4 groups: saline followed by rocuronium 0.45 mg/kg, rocuronium 0.045 mg/kg followed by rocuronium 0.405 mg/kg, saline followed by rocuronium 0.6 mg/kg, or rocuronium 0.06 mg/kg followed by rocuronium 0.054 mg/kg, the median onset times and 95% confidence in the four groups were 122.5 (8 to 186), 92.5 (68 to 116), 85 (60 to 142), and 55 (48 to 72) seconds, respectively, thereby demonstrating a clinical advantage of priming regardless of whether the total dose was 0.45 or 0.6 mg/kg. However, as noted previously, there may be issues with priming, including the potential to induce upper airway or respiratory muscle weakness with the potential for aspiration, airway obstruction, or hypoventilation, especially in critically ill patients—even with the small priming dose—as well as the need to wait 60 seconds for the full effect of the priming dose.

Given its rapid onset and lack of adverse effects, most notably rhabdomyolysis and hyperkalemia with underlying neuromuscular disorders, the use of rocuronium via the IM route instead of succinylcholine in the treatment of emergencies such as laryngospasm during anesthetic induction when IV access is lacking could be clinically helpful. However, when evaluating onset and recovery times following IM rocuronium, adequate or good-excellent intubating conditions took an average of 2.5 minutes in infants following a dose of 1 mg/kg and 3 minutes in children following a dose of 1.8 mg/kg.[41] The clinical duration was 57 ±13 minutes in infants and 70 ± 23 minutes in children. The authors also demonstrated a more rapid and predictable onset with IM administration into the deltoid as compared to the quadriceps muscle, an effect similar to that noted with succinylcholine (see above). Given these onset times, the authors cautioned that IM rocuronium was not an alternative to IM succinylcholine for the emergent treatment of laryngospasm.

An additional issue with rocuronium in clinical practice is pain on injection through a peripheral IV cannula.[42] Although the issue may be of limited significance in the PICU setting given the clinical scenarios in which this agent is administered, pretreatment (defasciculation etc.) is occasionally used when rocuronium is administered. Additionally, the practitioner should be aware of this problem, as even when rocuronium is administered immediately after the induction agent for endotracheal intubation, limb withdrawal and grimacing may be seen. The incidence of pain on injection with rocuronium has been reported to be as high as 50% to 80%, with a higher incidence in women than men. As with propofol, various techniques have been suggested to prevent or lessen this problem including diluting the rocuronium solution to 0.5 mg/mL instead of the commercially available 10 mg/mL or the preadministration or coadministration of various pharmacologic agents including lidocaine, ketamine, dexmedetomidine, thiopental, magnesium, alfentanil, and ondansetron. All of these have met with varying degrees of success. When rocuronium is coadministered with thiopental into the same IV site, a precipitate may form and occlude the IV cannula or tubing. This problem can be prevented by thoroughly flushing the IV site between the thiopental and the rocuronium. As with the other aminosteroid NMBAs, chronic anticonvulsant therapy causes resistance to the neuromuscular blocking effects of rocuronium.[43]

Although used most commonly by bolus injection for rapid-sequence endotracheal intubation, there has been one publication addressing the use of rocuronium infusions in the PICU setting.[44] In a cohort of 20 PICU patients, rocuronium was administered by continuous infusion to maintain 1 to 2 twitches of the TOF. The duration of the rocuronium infusion varied from 26 to 172 hours with a total of 1492 hours of administration. Following the initial bolus dose of 0.6 mg/kg, there was an increase in heart rate of 24 beats/minute and a modest increase in blood pressure (maximum increase in systolic blood pressure of 24 mm Hg). The infusion requirements on day 1 varied from 0.3 to 0.8 mg/kg/hr (0.76 ± 0.3 mg/kg/hr). When evaluating all patient days, the infusion requirements varied from

0.3 to 2.2 mg/kg/hr (0.95 ± 0.4 mg/kg/hr). The infusion requirements were 0.5 to 0.8 mg/kg/hr in 45 of the 64 patient days (70%) and 0.3 to 1.0 mg/kg/hr in 58 of the 64 patient days (90%). As with other agents, there was an increase in infusion requirements over time. In 14 patients who received rocuronium for 3 days or more, infusion requirements increased from 0.65 mg/kg/hr on day 1 to 0.84 mg/kg/hr on day 3, and in five patients that received rocuronium for 5 days, the infusion requirements increased from 0.67 mg/kg/hr on day 1 to 1.2 mg/kg/hr on day 5. When the infusion was discontinued, spontaneous return of neuromuscular function occurred in 24 to 44 minutes (31 ± 12 minutes). No adverse effects related to the use of rocuronium were noted.

Pipecuronium

Pipecuronium is structurally related to the other aminosteroids including pancuronium and vecuronium. Like vecuronium, it is devoid of cardiovascular effects. Following the clinically recommended dose for endotracheal intubation of 0.07 mg/kg, onset times vary from 2 to 3 minutes with a longer duration of action (70 to 80 minutes) than pancuronium. Pipecuronium is eliminated primarily by the kidneys (80%), with the remainder of the elimination dependent on hepatic metabolism. Unlike the other previously mentioned aminosteroid NMBAs, there is little enthusiasm for or clinical information concerning the use of pipecuronium in the pediatric population.

Rapacuronium

As mentioned previously, there remains a clinical need for a nondepolarizing NMBA whose onset and offset parallel that of rocuronium. In an effort to meet this need, rapacuronium was introduced into the clinical arena in 1998. The initial clinical experience demonstrated a rapid onset, paralleling that of succinylcholine or larger doses of rocuronium, with a recovery time of less than 10 minutes, thereby offering a significant clinical advantage over rocuronium. Hemodynamic effects included a mild tachycardia like other aminosteroid NMBAs related to a vagolytic effect. Metabolism was hepatic, with the presence of active metabolites that were dependent on renal excretion although they did not appear to result in a clinically significant duration of action in the presence of renal failure or insufficiency.

Unfortunately, with increased clinical use came the recognition that profound and even potentially fatal bronchospasm were associated with its administration. Although initially postulated to be the result of an inadequate depth of anesthesia, subsequent studies suggested a direct effect on the cholinergic receptors of the airway. In a retrospective review of their clinical data base, Rajchert et al.[45] reported that bronchospasm occurred in 12 of 287 (4.2%) patients receiving rapacuronium. Five of the episodes with rapacuronium resulted in an inability to move the chest with no exhaled end-tidal CO_2 following endotracheal intubation. The risk of bronchospasm was 10.1 times greater with rapacuronium compared to other NMBAs. Additional clinical data demonstrating the potential for alterations in respiratory compliance and resistance were reported in a prospective trial in 20 adults randomized to receive either cis-atracurium or rapacuronium.[46] Rapacuronium was administered following endotracheal intubation and the provision of general anesthesia by the continuous infusion of propofol and remifentanil. No changes in compliance or resistance of the respiratory system were noted with cis-atracurium; however, following rapacuronium administration, peak inflating pressure increased from 22 ± 6 to 28 ± 9 cmH_2O, compliance decreased from 108 ± 43 to 77 ±41 mL/cmH_2O, peak inspiratory flow rate decreased from 0.43 ± 0.11 to 0.39 ± 0.09 L/sec, peak expiratory flow rate decreased from 0.67 ± 0.10 to 0.59 ± 0.09 L/sec, and tidal volume decreased from 744 ± 152 to 647 ± 135 mL. Proposed mechanisms for rapacuronium's effects on airways have focused on alterations in cholinergic function with antagonism of the M_2 muscarinic receptor, augmentation of acetylcholine effects at the M_3 muscarinic receptor, and potentiation of vagal nerve and acetylcholine-induced bronchoconstriction.[47-49] The M_2 muscarinic mechanism may be of particular interest, as various NMBAs have been shown to have differing degrees of activity at this receptor. These effects have been reported with pipecuronium, but not with rocuronium.[50] During normal function at the neuromuscular junction of smooth muscle including the airway, some of the acetylcholine that is released diffuses back to the prejunctional (M_2) receptor and shuts off ongoing acetylcholine release. Thus the M_2 receptor is a negative feedback receptor that regulates acetylcholine release. With blockade of the M_2 receptor, there may be exaggerated release of acetylcholine and hence exaggerated muscle contraction or bronchospasm. Although rapacuronium was removed from the market in 2001, there may be other NMBAs in the clinical development process and their potential activity at the M_2 receptor warrants investigation.

Mivacurium

Although it has currently disappeared from the US market, mivacurium may still be available outside of the United States. Mivacurium is a benzylisoquinolinium NMBA and is the shortest-acting of the nondepolarizing NMBAs. It is available in a premixed solution containing 2 mg/mL of mivacurium. Following a dose of 0.2 mg/kg, onset times vary from 2 to 3 minutes with a duration of action of approximately 10 minutes. In a cohort of 62 children anesthetized with nitrous oxide and fentanyl, mivacurium infusion rates to maintain neuromuscular blockade were 375 ± 19 $\mu g/m^2$/min with a spontaneous recovery time ($T_4/T_1 \geq 0.75$) of 9.8 ± 0.4 minutes.[51] There was no evidence of accumulation during prolonged infusions. Mivacurium is metabolized by plasma cholinesterases. Prolonged blockade can occur in the same clinical situations described with succinylcholine, including congenital and acquired deficiencies of this enzyme system.[52,53] The metabolites of mivacurium, which are renally excreted, have limited neuromuscular blocking properties. Like all of the benzylisoquinoliniums, mivacurium can produce histamine release. In children, the histamine release may be associated with flushing and erythema of the skin; however, the hemodynamic effects are generally of limited clinical significance.[54]

Mivacurium's role in clinical practice has been for brief procedures (less than 10 minutes), in either the operating room or PICU, when neuromuscular blockade is required. Mivacurium can be a useful agent to provide a brief duration of neuromuscular blockade for direct laryngoscopy in the PICU patient to follow the progression of epiglottitis or some other airway problem and then provide spontaneous return of neuromuscular function without the use of reversal

agents. In the intraoperative setting, the avoidance of the need to reverse residual neuromuscular blockade with neostigmine (see below) may be beneficial as a means of limiting postoperative nausea and vomiting.

A second potential use for mivacurium has been in combination with other nondepolarizing NMBA to provide a rapid onset of neuromuscular blockade and yet avoid the prolonged duration seen when large doses of vecuronium (0.3 mg/kg) or rocuronium (1 to 1.2 mg/kg) are administered.[55,56] Onset times to 90% neuromuscular blockade were 39 ± 2.3 seconds with 1 mg/kg succinylcholine and 48 ± 3.5 seconds with vecuronium 0.16 mg/kg and mivacurium 0.2 mg/kg.[55] Conditions for endotracheal intubation were graded as excellent in 10 of 10 patients in both groups. Despite the rapid onset, recovery times were prolonged with the combination of vecuronium and mivacurium. Similar results were reported with a combination of mivacurium 0.2 mg/kg and rocuronium 0.6 mg/kg.[56] Although onset time was comparable to that of succinylcholine, the recovery time (49.0 ± 9.6 minutes) was prolonged.

Mivacurium may also been potentially advantageous in patients with underlying neuromuscular disorders (i.e., muscular dystrophy). In such patients, prolonged neuromuscular blockade may occur following even a single dose of an intermediate-acting agent such as vecuronium, atracurium or cis-atracurium. Therefore the use of an agent with the shortest possible clinical duration may be beneficial.[57-59] When compared with healthy control subjects, although there was no difference noted in the onset times, patients with Duchenne muscular dystrophy demonstrated only a modest prolongation of the clinical effect of mivacurium.[57] The median times for recovery of the first twitch of the TOF to 10%, 25%, and 90% of baseline in controls and patients with muscular dystrophy were 8.4 versus 12.0 minutes, 10.5 versus 14.1 minutes, and 15.9 versus 26.9 minutes. Similar results were demonstrated by Tobias and Atwood in their cohort of seven children with Duchenne muscular dystrophy. Following a dose of 0.2 mg/kg, time to recovery of the first twitch varied from 12 to 18 minutes. They also noted significant interpatient variability with infusion requirements varying from 3 to 20 μg/kg/min. Five of the 7 patients required 10 μg/kg/min or less, further demonstrating increased sensitivity to this agent in patients with muscular dystrophy. Of note, there was no correlation with infusion requirements and the patient's preoperative motor function.

Atracurium

Atracurium is a nondepolarizing NMBA of the benzylisoquinolinium class that was released for clinical use in the 1980s. It is supplied in a 10 mg/mL solution. Following a dose of 0.6 mg/kg, acceptable conditions for endotracheal intubation are achieved in 2 to 3 minutes with complete twitch suppression for 15 to 20 minutes, followed by another 10 to 15 minutes with a variable degree of blockade (twitch height, 5% to 25%). Spontaneous recovery ($T_4/T_1 \geq 0.7$) occurs in 40 to 60 minutes. As with all of the NMBAs, the use of a smaller dose (0.3 to 0.4 mg/kg) is feasible, but will prolong the time to the onset of acceptable conditions for endotracheal intubation as well as shorten the recovery time. Atracurium's recovery profile makes it an intermediate-acting agent. When compared with vecuronium, approximately five times as much atracurium is required to provide the same degree of neuromuscular blockade. As with other NMBAs of the benzylisoquinolinium class, atracurium can lead to histamine release. Although facial flushing and cutaneous erythema may occur as with mivacurium, effects on heart rate and blood pressure are generally minimal following doses up to 0.6 mg/kg.[60] With larger doses, hypotension may occur. In the pediatric-aged patient, histamine release is less frequent and less profound than in adults and even when histamine release occurred, no hemodynamic changes were noted.[61] Following its introduction into clinical practice, ongoing safety surveillance demonstrated no difference in the adverse effect profile of atracurium related to histamine release when compared with other NMBAs.[62] Extremely rare anecdotal case reports exist regarding anaphylactoid reactions with severe bronchospasm temporally related to its administration; however, a true causal relationship cannot be proven as the patients also received thiopental during anesthetic induction.[63]

Atracurium undergoes spontaneous degradation via a process known as Hofmann elimination as well as ester hydrolysis. Therefore, its duration of action is unchanged by either renal or hepatic insufficiency. Because of these properties, it rapidly gained favor for providing neuromuscular blockade in intensive care unit patients. For this purpose, it is most commonly used by continuous infusion (see below). The metabolites of atracurium do not possess significant neuromuscular blocking properties. However, one of the metabolic byproducts of Hofmann degradation, laudanosine, has been shown to be epileptogenic in animals. The actual concentration required to cause seizures in humans is unknown and no formal study has ever documented problems from high laudanosine levels. Laudanosine is renally excreted and its accumulation in patients with renal insufficiency is at least a theoretical concern.

Infusion requirements to maintain clinical neuromuscular blockade, defined as a single twitch height of 1% to 10% of baseline, averaged 9 μg/kg/min during a nitrous oxide-opioid–based anesthetic.[64] Recovery remains predictable and stable regardless of the duration of the infusion. Within 30 minutes of discontinuation of the infusion, twitch height had spontaneously recovered to $T_4/T_1 \geq 0.7$.[65] Reversal with neostigmine (see below) is generally available within 10 to 15 minutes of discontinuing an infusion or following the administration of a single dose of 0.6 mg/kg. When compared to a longer-acting agent such as pancuronium, spontaneous recovery following a continuous infusion occurred at an average time of 15 minutes (range, 6 to 34 minutes) with atracurium compared to 25 minutes (range, 10.5 to 37 minutes) with pancuronium.[66] Given its intermediate duration of action and stable recovery profile,atracurium has been used safely and effectively in patients with neuromuscular disorders including myasthenia gravis, myotonic dystrophy, and muscular dystrophy[67,68]; however, prolonged neuromuscular blockade of 3 to 4 hours has also been reported following a single dose of 0.6 mg/kg. In the PICU, similar recovery profiles have been reported. In a cohort of 20 infants and children requiring neuromuscular blockade for 10 to 163 hours during mechanical ventilation, the mean dose of atracurium was 1.4 mg/kg/hr (range, 0.44 to 2.4 mg/kg/hr).[69] When no TOF could be elicited, the time required for the first twitch to become evident with discontinuation of the infusion was 13.8 minutes (range, 1 to 38 minutes). The authors reported that there was no correlation between the recovery time and the dose that was being

administered; however, they did note a faster recovery time when the infusion had been administered for more than 48 hours. Given its non-organ-dependent elimination, atracurium has also been used in pediatric patients following orthotopic liver transplantation.[70] Recovery time ($T_4/T_1 \geq 0.7$) when the infusion was discontinued averaged 23.6 minutes (range, 12 to 27 minutes) and was not prolonged compared to the general pediatric population.

As with rocuronium, administration with thiopental may result in precipitation and occlusion of the intravenous cannula, necessitating flushing the line with normal saline between these two agents. Given its dependence on Hofmann elimination, a temperature-dependent process, elimination will be prolonged during induced or inadvertent hypothermia.[71] During induced hypothermia (32° C) in a cohort of children, the atracurium infusion requirement was 784 μg/kg/hr or 56% of that in normothermic children (1411 μg/kg/hr). Recovery time was also prolonged to 2.86 times that seen in normothermic patients. A similar effect has been reported with the use of cis-atracurium during hypothermia (see following section).

Cis-atracurium

Cis-atracurium is one of the 10 stereoisomers that comprise atracurium. It is six to eight times as potent as atracurium, but devoid of clinically significant histamine release and hemodynamic effects.[72] Cis-atracurium is available as a 2 mg/mL solution. Like atracurium, cis-atracurium is an intermediate-acting neuromuscular blocking agent, with a duration of action of 20 to 30 minutes following a bolus dose of 0.2 mg/kg. Acceptable conditions for endotracheal intubation are provided in approximately 2 minutes. In a cohort of 80 adult patients, cis-atracurium in doses of 0.1, 0.15, and 0.2 mg/kg provided acceptable conditions for endotracheal intubation in 4.6, 3.4, and 2.8 minutes with a clinically effective duration of 45, 55, and 61 minutes.[73] In a cohort of 27 infants (1 to 23 months of age) and 24 children (2 to 12.5 years of age), the onset time to achieve maximal blockade following a dose of 0.15 mg/kg was more rapid in infants (2.0 ± 0.8 versus 3.0 ± 1.2 minutes, $P = .0011$).[72] The clinical duration (recovery to 25% of baseline) was longer in infants (43.3 ± 6.2 versus 36.0 ± 5.4 minutes; $P < .0001$). Once neuromuscular recovery began, the rate of recovery was similar between the two groups. However, de Ruiter et al.[74] reported no difference in the ED_{50}, ED_{95}, or the infusion rate required to maintain 90% to 99% block when comparing 32 infants (0.3 to 1 year of age) and 32 children (3.1 to 9.6 years of age). The ED_{50} in the two groups was 29 ± 3 versus 29 ± 2 μg/kg, the ED_{95} was 43 ± 9 versus 47 ± 7 μg/kg, and the infusion rate required to maintain 90% to 99% blockade in the two groups was 1.9 ± 4 versus 2.0 ± 0.5 μg/kg/min.

A prospective study evaluated cis-atracurium dosing requirements in 15 PICU patients ranging in age from 10 months to 11 years and in weight from 4 to 28 kg.[75] The cis-atracurium infusion was adjusted to maintain one twitch of the TOF. Infusion requirements varied from 2.1 to 3.8 μg/kg/min (average, 3.1 ± 0.6 μg/kg/min) on day 1, from 2.9 to 8.1 μg/kg/min (average, 4.5 ± 1.6 μg/kg/min, $P < .01$ compared to day 1) on day 3, and from 1.4 to 22.7 μg/kg/min during all patient days. The highest infusion requirements were noted following the administration of the drug for prolonged periods of time (150 and 224 hours). When the infusion was discontinued, spontaneous return of neuromuscular function was noted in 14 to 33 minutes. Effective neuromuscular blockade was provided and no adverse effects related to cis-atracurium were noted. In particular, no hemodynamic changes were noted with bolus dosing. Odetola et al.[76] evaluated the dosing requirements of cis-atracurium in a cohort of 11 PICU patients, ranging in age from 0 to 2 years. The duration of the infusions varied from 14 to 122 hours (64.5 ± 36 hours). The infusion requirements to maintain 90% to 95% neuromuscular blockade were 5.36 ± 3.0 μg/kg/min. Laudanosine concentrations during the infusion were 163.3 ± 116 ng/mL. As in the previous study, there was an increase in dose requirements over time and no hemodynamic effects were noted with cis-atracurium.

Reich et al. compared vecuronium and cis-atracurium, administered by continuous infusion, to provide neuromuscular blockade following surgery for congenital heart disease in a cohort of 19 patients less than 2 years of age.[77] The NMBA was administered to maintain one twitch of the TOF. Median infusion times were 64.5 hours for cis-atracurium and 46 hours for vecuronium (P = not significant). Median recovery time, defined as a normal TOF without fade, was shorter with cis-atracurium than with vecuronium (30 minutes versus 180 minutes, $P < .05$). Recovery time was more than 4 hours in three of nine patients who received vecuronium. Two of these patients had high vecuronium plasma concentrations, while the other had an elevated 3-OH vecuronium level. There was no difference in time to tracheal extubation, intensive care unit stay, or hospital stay.

As with other NMBAs, resistance to the effects of cis-atracurium may be seen in patients treated with anticonvulsant agents.[78] Time to recovery of T_1 to 25% of baseline was 69 ± 13 minutes in patients not receiving anticonvulsant medications, 64 ± 19 minutes in those receiving acute therapy with anticonvulsants, and 59 ± 19 minutes in those receiving chronic anticonvulsant therapy. As with atracurium, altered clearance and decreased infusion requirements occur with hypothermia.[79] During induced hypothermia (34° C) to control increased ICP, cis-atracurium infusion requirements were 1.7 μg/kg/min and increased to 3.4 μg/kg/min with return to normothermia.

Doxacurium

Doxacurium is the benzylisoquinolinium derivative with the longest duration of clinical activity. It is the most potent of the clinically available NMBAs, with approximately twice the potency of pancuronium or pipecuronium. Following a dose of 0.05 mg/kg, its duration of action is 80 to 90 minutes. The ED_{95} in children is 30 μg/kg, approximately 1.5 times that reported for the adult population.[80] Elimination is primarily renal, with a small percentage dependent on hepatic excretion. The duration of action is prolonged in patients with either hepatic or renal insufficiency. Despite it being a benzylisoquinolinium derivative, it is primarily devoid of histamine-releasing properties and cardiovascular or hemodynamic effects. To date, there has been limited use of this agent in the PICU population.

Reversal of Neuromuscular Blockade

Although neuromuscular blockade is necessary for many surgical procedures and used for various indications in the PICU setting, even a small residual amount of blockade may

compromise ventilation or upper airway patency in the critically ill patient or during the immediate postoperative period. In the operating room setting, residual neuromuscular blockade is frequently reversed at the completion of the procedure to ensure adequate strength to maintain airway patency and ventilatory function following extubation of the trachea. In the PICU setting, reversal of neuromuscular blockade is less common. In most clinical scenarios, when there is no longer a need for neuromuscular blockade, the agent is discontinued and spontaneous recovery is allowed. The latter is generally appropriate in the PICU setting, as ongoing tracheal intubation and mechanical ventilation will likely be provided for some period of time following the discontinuation of the NMBA. However, in a smaller percentage of patients, tracheal extubation coincides with discontinuation of the NMBA, thereby mandating the use of a reversal agent.[81]

Reversal of neuromuscular blockade is possible only with nondepolarizing NMBAs. Additionally, some degree of residual neuromuscular function is necessary to allow for effective reversal of neuromuscular blockade. In general clinical practice, this means that there should be 1 to 2 twitches in the TOF or that the T_1 has recovered to 25% of its baseline height. Therefore, reversal with a drug that inhibits acetylcholinesterase is not feasible immediately after the administration of an NMBA. Rather, depending on the dose, some time is necessary, which is generally 15 to 30 minutes with intermediate-acting agents.

The drugs used to reverse neuromuscular blockade inhibit the enzyme acetylcholinesterase. This, in turn, provides more acetylcholine to compete with the NMBA at the nicotinic receptor of the neuromuscular junction. The commonly used acetylcholinesterase inhibitors or "reversal agents" include neostigmine, pyridostigmine, and edrophonium. Despite a similar mechanism of action, the clinical effects (onset, duration, etc.) of these agents differ. Neostigmine and pyridostigmine are hydrolyzed by acetylcholinesterase. During this process, the enzyme is carbamylated and inactivated. Edrophonium does not breakdown the enzyme acetylcholinesterase, rather it competitively and reversibly inhibits its function. The difference in the molecular mechanism of these agents has little impact on clinical use or practice. With these three agents, the peak plasma concentration is achieved at 5 to 10 minutes following bolus administration, followed by an elimination half-life of 60 to 120 minutes. Clearance is markedly reduced in the setting of renal failure or insufficiency. There is a marked difference in the onset times of the three reversal agents. The onset of peak effect is 1 to 2 minutes with edrophonium, 7 to 11 minutes with neostigmine, and 16 minutes with pyridostigmine.[82,83] An additional difference is the efficacy of these agents when reversing intense blockade (≥90%), in that neostigmine is more effective than either edrophonium or neostigmine.

Adverse effects associated with the use of reversal agents generally relate to their inhibition of acetylcholinesterase at sites away from the neuromuscular junction. These agents should always be preceded by an anticholinergic agent such as atropine or glycopyrrolate, since the inhibition of acetylcholinesterase occurs not only at nicotinic receptors (neuromuscular junction), but also at muscarinic receptors. Therefore, unless preceded by an anticholinergic (antimuscarinic) agent, bradycardia and asystole can occur. The time course of the bradycardic effects varies based on the onset time of the agents. As such, if edrophonium is used, glycopyrrolate should be administered first and followed in 1 to 2 minutes by edrophonium, given that the onset time of glycopyrrolate is longer than that of edrophonium. The onset time of glycopyrrolate correlates well with that of neostigmine and pyridostigmine and therefore these agents may be administered at the same time. Given that the onset of atropine is rapid, it may be administered with any of the three reversal agents. Other adverse effects related to the reversal agents included augmentation of cholinergic function in the gastrointestinal tract (salivation, diarrhea, nausea, and vomiting) and the respiratory tract (bronchospasm). Although the anticholinergic agents may block salivation and alterations in airway tone, their efficacy in blocking the increased gastrointestinal motility are somewhat limited.

More recently, there has been development of a novel agent for reversal of neuromuscular blocking agents. However, this drug has not achieved approval from the United States Food and Drug Administration as of the end of 2010. The agent, suggamadex, is a cyclodextrin, and, instead of inhibiting the enzyme acetylcholinesterase, it forms a tight 1:1 complex with the steroidal neuromuscular blocking agents. It has been shown to rapidly and effectively reverse rocuronium and vecuronium and perhaps even pancuronium.[84,85] There is a limited dissociation rate so that the reversal is maintained. Unlike with acetylcholinesterase inhibitors, reversal using suggamadex is feasible even with intense blockade, thereby providing the potential for the rapid reversal of neuromuscular blockade in the "cannot intubate— cannot ventilate" scenario. Future studies are needed to fully evaluate this medication in the pediatric population.

Monitoring Neuromuscular Blockade

In the operating room, NMBAs may be used as a single dose at the start of the case to facilitate endotracheal intubation or by repeated doses or a continuous infusion to provide ongoing neuromuscular blockade. Some means of monitoring neuromuscular blockade is necessary since administration of excessive doses may mandate the use of postoperative mechanical ventilation until neuromuscular blockade has worn off or can be reversed. Additionally, given concerns regarding prolonged paralysis, monitoring neuromuscular function may also be considered in the PICU setting.

Monitoring may include some combination of visual, tactile, or electronic means of measuring the residual neuromuscular function following electrical stimulation. The technique, most commonly used by anesthesiologists in the operating room to monitor the degree of neuromuscular blockade, is peripheral nerve stimulation or TOF monitoring. TOF monitoring involves placement of standard electrocardiographic electrodes over a peripheral nerve. The nerves most commonly used are the facial, ulnar, or common peroneal, which results in corresponding movement in the muscles of the face, hand, or leg. In some circumstances, direct stimulation of the muscle may occur, giving the false impression that an appropriate amount of neuromuscular blockade has not been achieved. To avoid such problems, it may be appropriate to place the TOF monitor and assess the twitch response prior to the administration of the initial dose of the NMBA. The electrodes of the TOF monitor are connected to a hand-held peripheral

nerve stimulator that delivers two stimuli per second at 50 mA for 2 seconds. A total of four stimuli are administered over 2 seconds, hence the term *train-of-four*. As this is painful, it should only be performed in patients that are anesthetized or sedated. Depending on the number of acetylcholine receptors that are occupied by the nondepolarizing NMBA, there will be anywhere from zero to four responses or twitches. Despite the availability of other more sophisticated machines to monitor the degree of neuromuscular blockade in the operating room and ICU setting, these monitors are generally used only for clinical research purposes; in clinical practice in either the operating room or the PICU, TOF monitoring remains the technique that provides the most useful information with limited requirements for training and equipment.

In clinical practice, the TOF monitoring is combined with clinical assessment at the end of the case to ensure that the patient is strong enough for extubation. Following reversal of neuromuscular blockade, clinical assessment of strength is combined with neuromuscular monitoring. These latter measures become necessary as residual weakness may be present despite apparent reversal using TOF monitoring. Techniques of clinical assessment to evaluate the presence of residual neuromuscular blockade include measurement of negative inspiratory force (NIF) or maximum inspiratory pressure (MIP), hand grip, or head lift. Although head lift and hand grip require the ability to follow a simple command, the measurement of NIF does not. The technique involves measuring the inspiratory force that the patient can generate against an occluded airway. The test can be completed with a simple manometer attached to the 15 mm adaptor of the ETT. Initial studies suggested that a NIF of at least −20 cm H_2O indicated sufficient muscle strength to maintain an adequate minute ventilation.[86] Subsequently, a value of −25 to −30 cm H_2O became the generally accepted value for use in clinical practice. However, subsequent work suggested that although strength was adequate to maintain minute ventilation, it may not be adequate to maintain upper airway patency and therefore, the use of voluntary responses (head lift for 5 seconds or hand grip) were suggested as adjuncts to ensure adequate reversal of neuromuscular blockade.[81] In infants, reflex leg lift (both legs lifted off of the operating room table) was shown to correlate with a mean NIF or MIP of −51 cmH_2O; therefore the authors concluded that this was a sign of adequate reversal of neuromuscular blockade in infants.[87] Given the variability of these responses and their correlation with reversal of neuromuscular blockade, the best clinical approach may be the use of several clinical maneuvers if TOF monitoring is not available. The literature suggests that the ability to maintain a sustained head lift for 5 seconds is the most sensitive clinical tool.[81]

In the ICU setting, given the degree of neuromuscular blockade that is induced, voluntary measures of muscle strength are not adequate and therefore, titration of NMBAs should be guided by the use of TOF monitoring. The technique may allow the use of the lowest possible dose of agents and theoretically avoid complications such as prolonged blockade (see below). In a prospective randomized trial in 77 adults, TOF monitoring (maintaining one twitch of the TOF) was compared with clinical parameters (patient breathing over the preset ventilator rate) as a means of titrating NMBAs.[88] TOF monitoring resulted in a lower total dose and lower average infusion rate of vecuronium as well as a more rapid recovery once the infusion was discontinued. A subsequent study in adults revealed a decreased incidence of persistent neuromuscular weakness when using TOF monitoring.[89]

Although data are lacking to clearly demonstrate the superiority of TOF monitoring in the PICU setting, its use is suggested as a means of titrating the administration of NMBA agents. Of note is the significant interpatient variability that has been reported in the PICU setting and the inability, therefore, to ensure an appropriate dose without some monitoring modality. The choice of the number of twitches to maintain has not been prospectively studied. The majority of the clinical evidence suggests that maintaining one twitch of the TOF ensures an adequate degree of neuromuscular blockade while potentially limiting the incidence of persistent neuromuscular weakness. However, the least amount of blockade that can be clinically tolerated is suggested. In some patients, maintaining two twitches may be acceptable, especially with the use of an appropriate degree of sedation and analgesia.

No study has evaluated the best nerve (facial, ulnar, common peroneal) to monitor. In clinical practice, any accessible nerve can be used. However, several patient and technical factors may affect the response. As such, whenever feasible, placement of the monitor prior to the institution of neuromuscular blockade is suggested to ensure that a TOF can be obtained prior to the administration of the NMBA. If no response is obtained, the technique should be evaluated by first evaluating the monitor (faculty monitor, electrodes, or batteries). Is the electrode too far from the nerve (improper placement, edema, obesity)? If these technical problems are ruled out, the infusion can be decreased by 10% to 15% and the TOF measured again in 2 hours. When two or more twitches are noted, if the patient is stable and a more profound degree of blockade is not required, ongoing observation is suggested. If a deeper level of blockade is required, a bolus equivalent to the hourly infusion rate should be administered and the infusion increased by 10% to 15%.

Adverse Effects of Neuromuscular Blockade

As with any medication used in the PICU patient with comorbid diseases, adverse effects may occur with NMBAs. Perhaps the most devastating of these adverse effects is the inability to provide adequate ventilation following the administration of a medication that induces apnea. Therefore, these medications should never be used if there is any suspicion that the airway cannot be controlled. In rare circumstances, endotracheal intubation using direct laryngoscopy may be impossible and in even rarer circumstances, adequate bag-mask ventilation cannot be provided. In such scenarios, death or permanent CNS morbidity will result with the administration of NMBAs. Measures to avoid such problems include an assessment of the airway prior to the administration of these agents and a knowledge of the "cannot intubate— cannot ventilate" algorithm as outlined by the American Society of Anesthesiologists.

Various physical characteristics may suggest that direct laryngoscopy and intubation will be difficult, including micrognathia, a short neck, limited neck mobility (flexion/extension), limited mouth opening, a large tongue, and a small mouth. An additional tool is the Mallampati grade which describes the ability to visualize the tip of the uvula and the tonsillar pillars. If there is a suspicion that endotracheal

intubation using direct laryngoscopy will not be possible and there is time, other techniques to control the airway are suggested. Some of the more commonly used approaches to the difficult airway in infants and children have been outlined by Davidson et al.[90] More importantly, the techniques needed for the "cannot intubate— cannot ventilate" scenario should be understood and available in any situation in which NMBAs are being administered. Aside from repositioning the patient or using a direct type of laryngoscope, physicians using NMBAs should have a working knowledge of the laryngeal mask airway as it can be used to rescue patients when direct laryngoscopy, endotracheal intubation, and bag-mask ventilation fail.[91]

Other adverse effects from NMBAs relate to the elimination of routine physiologic functions. Eye care with the use of artificial tears or lacrilube at fixed intervals during the administration of NMBAs is necessary to avoid drying of or damage to the cornea. Additionally, repositioning of the patient at frequent intervals is needed to avoid pressure sores. For prolonged immobility, the use of special mattresses may be considered as an adjunct to frequent patient moving. Passive range of motion may also be indicated with splinting to prevent forearm and ankle contractures, while sequential compression devices may be indicated to prevent deep vein thrombosis. Ineffective coughing and clearance of secretions mandates the implementation of suctioning protocols to limit the risk of nosocomial pneumonias. Alterations in functional residual capacity, dead space, and ventilation-perfusion ratios may result in ventilatory issues including hypoxemia or hypercarbia and the need to adjust ventilatory parameters.

As noted previously, although NMBAs prevent movement, they provide no degree of sedation or analgesia. As such, the most important monitor of the depth of sedation, the clinical score, is eliminated. Therefore, some other measure of the depth of sedation may be required. In the majority of clinical situations, physiologic parameters such as heart rate or blood pressure are used as a means of titrating sedative and analgesic agents. However, issues arise in critically ill patients in whom alterations in heart or blood pressure may not occur in response to stress or pain. In this patient population, exogenous vasopressors may be in use and thereby eliminate the reliability of physiologic parameters. In the operating room setting, the availability of depth of anesthesia monitors is recommended and it is suggested that their use be considered in patients at high risk for awareness. Despite the rare occurrence of such events, means for their prevention of awareness during the use of neuromuscular blocking agents in the pediatric ICU appear indicated given the consequences of such problems.

In the operating room setting, depth of sedation or anesthesia monitors are available. To date, there are no data in the PICU to demonstrate their efficacy in preventing recall during the use of neuromuscular blocking agents. The bispectral index is a processed electroencephalographic parameter expressed as a numeric value ranging from 0 (isoelectric EEG) to 100 (awake, eyes open, no sedative agent). In the pediatric population, its intraoperative use has been suggested to decrease the incidence of awarness.[92] In the PICU population, the BIS value has been shown to correlate with the depth of sedation assessed using various clinical scoring systems.[93,94] BIS monitoring has been used to evaluate the depth of sedation in a cohort of 12 PICU patients receiving NMBAs.[95] BIS monitoring was used for a total of 476 hours in the patients and revealed that the desired depth of sedation (BIS number 50 to 70) was achieved 57% of the time. The BIS number demonstrated a deeper than desired depth of sedation (BIS number ≤49) 35% of the time and an inadequate depth of sedation in patients receiving neuromuscular blockade (BIS number ≥71) 8% of the time. Additional sedation was sometimes administered by the bedside nurse on the basis of clinical judgment (he or she was not allowed to view the monitor). At 64% of the times this was done, the BIS number was greater than or equal to 71; at 31% of the times, it was 50 to 70; and at 5% of the times, it was 49 or less. Although no long-term follow-up or assessment of awareness was pursued, the authors concluded that physiologic parameters are not a viable means of assessing the depth of sedation during the use of NMBAs.

The adverse effect that has received the most attention in the adult population with the administration of NMBAs is residual neuromuscular paralysis. In clinical practice, it appears that there are two distinct entities that may account for prolonged neuromuscular paralysis including (1) prolonged recovery from neuromuscular blockade related to excessive dosing or delayed clearance of the parent compound or metabolites due to renal or hepatic issues, and (2) what is now termed the acute quadriplegic myopathy syndrome (AQMS).[95,96] The former generally resolves spontaneously over time with the eventual clearance of the parent compound or its metabolites. In clinical practice, it is defined as a prolonged recovery time of more than 100% of the predicted parameter. In distinction, AQMS presents with acute paresis, myonecrosis with increased levels of plasma markers demonstrating muscle breakdown such as creatinine phosphokinase (CPK), and abnormal electromyography (EMG) with the demonstration of reduced compound motor action potential amplitude, decreased motor nerve conduction, and evidence of acute denervation. Clinical findings include flaccid paralysis, relative preservation of extraocular movements, decreased deep tendon reflexes, respiratory insufficiency, intact sensory function, and normal findings in the cerebrospinal fluid. Recovery may require weeks to months, with the need for prolonged rehabilitation care, and tracheostomy with chronic ventilatory support. Although initially reported only with aminosteroid compounds, it has also been subsequently reported with the benzylisoquinolinium derivatives. It remains to be determined whether the relative majority of reports with the use of the aminosteroid compounds relates to the current clinical practice which favors the use of these agents or to some particular vulnerability related to these agents.

Given that CPK values are elevated in up to 50% of patients with AQMS, periodic screening of patients receiving ongoing neuromuscular blockade may be indicated. Additionally, given that the syndrome is reported following the prolonged, continuous infusion of NMBAs, it has also been suggested that drug holidays or periodic interruption of the infusion be considered. However, there are no data to demonstrate that such practice will alter the incidence of AQMS, and the withdrawal of neuromuscular blockade must be considered on a risk-benefit ratio. Obviously, termination of the use of NMBAs is suggested whenever it is clinically feasible, given their adverse effect profile. Other factors and comorbid processes that may contribute to the development of AQMS include nutritional deficiencies, coadministration of other medications (cyclosporine, corticosteroids, aminoglycosides), hyperglycemia, hepatic or renal insufficiency, and electrolyte disturbances.

The association is most profound with the coadministration of NMBAs and corticosteroids, thereby suggesting a heightened awareness in such patients.[97] In addition to AQMS, other conditions to consider in the differential diagnosis of patients with prolonged weakness following the use of NMBAs include neuromuscular conditions (myasthenia gravis, Eaton-Lambert syndrome, Guillain-Barré syndrome), acquired or primary myopathic conditions (mitochondrial myopathy, steroid myopathy), central nervous system injury, spinal cord injury, critical illness polyneuropathy, disuse atrophy, and electrolyte or metabolic disturbances. Critical illness polyneuropathy may be confused with AQMS. It is a combined motor and sensory neuropathy that results from ischemia of the microvasculature of the nerves, which is seen most commonly in patients with multisystem organ failure. The EMG demonstrates a pattern different from that seen in AQMS.

Summary: Neuromuscular Blocking Agents in the PICU

In addition to their use in the operating room, specific situations may arise that mandate the use of neuromuscular blocking agents in the pediatric ICU (see Box 122-1). Although these agents are generally administered as intermittent bolus doses in the operating room, in the PICU, a more stable baseline level of neuromuscular blockade may be desired and therefore a continuous infusion may be used. When choosing an agent for use in the PICU population, the major issues include cardiovascular effects, metabolism, and cost. Since many of the patients in the PICU have some degree of hemodynamic instability, agents that cause excessive histamine release should be avoided. Additionally, the presence of hepatic or renal insufficiency may affect metabolism or elimination or the parent compound as well as its metabolites. In the absence of end-organ dysfunction, pancuronium offers an inexpensive means of achieving neuromuscular blockade. Its vagolytic effect will result in tachycardia with an increase in heart rate of 10 to 20 beats per minute above baseline. Given its duration of action, intermittent dosing is feasible. With its availability in generic form, vecuronium provides another cost-effective option in the PICU setting while eliminating the tachycardia that is seen with pancuronium. Although vecuronium and pancuronium are generally effective and inexpensive in patients without end-organ dysfunction, significant alterations in infusion requirements occur in patients with renal insufficiency/failure (pancuronium and vecuronium) or hepatic insufficiency/failure (vecuronium). Atracurium or cis-atracurium may be a more appropriate choice in patients with hepatic or renal failure since such problems do not alter dosing requirements of either agent.[99]

In the PICU setting as in the operating room, adjustment of the dose based on monitoring with a peripheral nerve stimulator is recommended. Regardless of the agent used, significant interpatient variability with up to tenfold variation in infusion requirements may be noted. The variability results not only from interpatient variability, but also from various associated conditions that may increase or decrease the sensitivity to NMBAs (Boxes 122-6 and 122-7). Based on this knowledge, the recommended doses (Table 122-1) for the various NMBAs are starting guidelines and the infusion should be increased or decreased as needed to maintain one twitch of the TOF or to provide the required depth of neuromuscular blockade. An

Box 122–6 Factors that Increase Sensitivity to NMBAs

Medications

Inhalational anesthetic agents
Local anesthetic agents
Antibiotics (aminoglycosides)
Antiarrhythmic agents (quinidine, procainamide)
Calcium channel blockers
β-Adrenergic antagonists
Chemotherapeutic agents (cyclophosphamide)
Diuretics (furosemide)
Dantrolene
Lithium, magnesium
Cyclosporine

Underlying Disorders

Electrolyte disturbances (hypokalemia, hypermagnesemia, hypocalcemia)
Hypothermia
Respiratory acidosis
Metabolic alkalosis
Myasthenia gravis
Eaton-Lambert syndrome
Muscular dystrophy
Multiple sclerosis
Amyotrophic lateral sclerosis
Poliomyelitis

Box 122–7 Factors that Decrease Sensitivity to NMBAs

Medications

Anticonvulsant agents (phenytoin, carbamazepine)
Aminophylline

Underlying Conditions

Hypercalcemia
Burns
Prolonged administration of NMBAs

Table 122–1 Suggested Starting Guidelines for the Continuous Infusion of Neuromuscular Blocking Agents

Agent	Dose	Comments
Pancuronium	0.06–0.08 mg/kg/h	Vagolytic effect, primary renal excretion
Vecuronium	0.1–0.15 mg/kg/h	No cardiovascular effects, hepatic metabolism to active metabolites that are renally excreted
Rocuronium	0.6–0.8 mg/kg/h	Mild vagolytic effect, hepatic metabolism
Atracurium	1–1.5 mg/kg/h	Mild histamine release, non-organ-dependent elimination
Cis-atracurium	0.2 mg/kg/h	No cardiovascular effects, non-organ-dependent elimination

additional problem that occurs in the ICU patient who receives NMBAs for a prolonged period of time is the development of tachyphylaxis or an increased dose requirement over time. The primary cause is an upregulation of acetylcholine receptors in patients who are chronically exposed to NMBAs. Dodson et al. demonstrated an increased density of acetylcholine receptors in muscle from patients who had received prolonged infusions of NMBAs.[100] Prolonged neuromuscular blockade, like partial or complete deafferentation, leads to proliferation of acetylcholine receptors at the neuromuscular junction. This problem requires that the dose of the NMBA be increased over time to maintain the same amount of neuromuscular blockade.

Given their adverse effect profile, it is recommended that NMBAs be administered only when aggressive attempts at sedation have failed to provide the desired level of patient immobilization. An ongoing assessment regarding the need for continuing such therapy is suggested with discontinuation of the medication as early as is feasible. Specific protocols should be in place to ensure appropriate care of the patient who is receiving neuromuscular blockade, with attention toward the provision of adequate sedation and analgesia, eye care, prevention of pressure sores, and pulmonary toilet. Given the variability in requirements that is present in the PICU setting, monitoring with the TOF is recommended.

Sedation and Analgesia

Christopher M.B. Heard and James E. Fletcher

PEARLS

- A wide selection of sedation and analgesia options is available in the pediatric intensive care unit.
- No ideal sedative agent exists for all patients.
- Most children do well with a combination of opiates (fentanyl) and supplementation with benzodiazepines either by infusion (midazolam) or on an as-required basis (lorazepam) to provide adjunct anxiolysis and amnesia.
- Postoperatively, patients require adequate analgesia, which may include the use of epidural anesthesia or patient-controlled analgesia.
- In circumstances in which the ability to perform a rapid neurologic examination is required, use of short-acting agents such as remifentanil, propofol, or isoflurane may be warranted.
- All sedative agents result in tolerance with prolonged use. The intensive care physician must be aware that withdrawal may occur with the prolonged use of these agents (i.e., more than 3 to 5 days).
- A proactive treatment plan with methadone at the equivalent dose can effectively and safely prevent opiate withdrawal in the patient in the pediatric intensive care unit.

Sedation is an integral part of patient management in the pediatric intensive care unit (PICU). It is necessary to minimize the perception of and response to anxiety and pain. Children who are not adequately sedated or who are experiencing pain may become tachycardic and hypertensive. They also may become agitated and as a result endotracheal tubes and central lines may become dislodged. Conversely, oversedation can cause cardiovascular depression and ileus and may interfere with a comprehensive neurologic examination. In patients who undergo prolonged sedation, tolerance and tachyphylaxis develop, which lead to increasing sedative requirements.

Patients may recall their stay in the ICU. Many patients remember having an endotracheal tube or having their lungs mechanically ventilated. Nightmares and hallucinations also have been reported.[1] Either single-drug therapy or inadequate dosing may be associated with a higher incidence of recall in the patient receiving neuromuscular blocking agents. [2] In adults, delusional memories and an underlying anxiety state were predictors of the development of a posttraumatic stress disorder after sedation in the ICU.[3] Delusional memories were reported much more frequently than factual memory, probably because most patients have difficulty correctly remembering the events that occur during their stay in the ICU. In pediatric patients, recall of the PICU experience also has been reported.[4] More than 66% of pediatric patients remembered their stay in the PICU. Eighteen percent had bad memories, 16% remembered mechanical ventilation and anxiety, and 29% remembered pain from a procedure or movement. Overall the recollections of patients in the PICU were considered negative in approximately 15% of the patients. Sleep disturbance also was a problem.

Various scoring systems are often used to guide sedation. The most widely used is the Ramsay scale.[5] The patient's level of consciousness is classified as one of six scores (Table 123-1). The nurse at the bedside assesses the patient and then changes the sedation regimen as necessary to achieve the desired level of sedation. The ideal level of sedation varies from patient to patient, but in general, most intensive care physicians seek to maintain patients in a sleepy but easily awakened state. A Ramsay score of 2 to 3 seems to be ideal as the clinical end point for sedation. Deeper sedation should be reserved for select patients who are often younger, are receiving neuromuscular blocking agents, or have a head injury. The use of a sedation scoring system to guide sedation of surgical critical care patients has been evaluated for cost-effectiveness. Use of scoring systems has proved to save costs in the ICU.[6] Because the patient can be weaned more rapidly from the ventilator through better control of the sedation level, the number of days a patient is connected to a ventilator is reduced. The COMFORT score, which is composed of eight variables (each with five categories), also has been validated for use in the PICU to assess sedation level in children. Use of this system, however, is more complicated and time consuming.[7]

Many scoring systems are subjective and are limited by interobserver variability. The more objective methods may be too cumbersome for routine use. A simple scoring system has been devised that is easy to use and minimizes subjectivity and observer variability.[8] This system is the Brussels sedation scale. It is similar to the Ramsay scale, but the Brussels scale levels that correspond to the Ramsay scale levels 4 and 5 are better differentiated (Table 123-2).

The Bispectral Index (BIS) is a processed electroencephalogram (EEG) monitor that measures the hypnotic effects of anesthetics and sedatives. The BIS is an empirical, statistically derived measurement. The BIS monitor reports a single

Table 123–1 Ramsay Scale

Level	Description
1	Patient awake, anxious, and agitated or restless or both
2	Patient awake, cooperative, oriented, and tranquil
3	Patient awake, responds to command only
4	Patient asleep, brisk response to light glabellar tap or loud auditory stimulus
5	Patient asleep, sluggish response to light glabellar tap or loud auditory stimulus
6	Patient asleep, no response to light glabellar tap or loud auditory stimulus

Table 123–2 Brussels Sedation Scale

Level	Description
1	Unable to be aroused
2	Responds to painful stimulation (trapezius muscle pinching) but not auditory stimulation
3	Responds to auditory stimulation
4	Awake and alert
5	Agitated

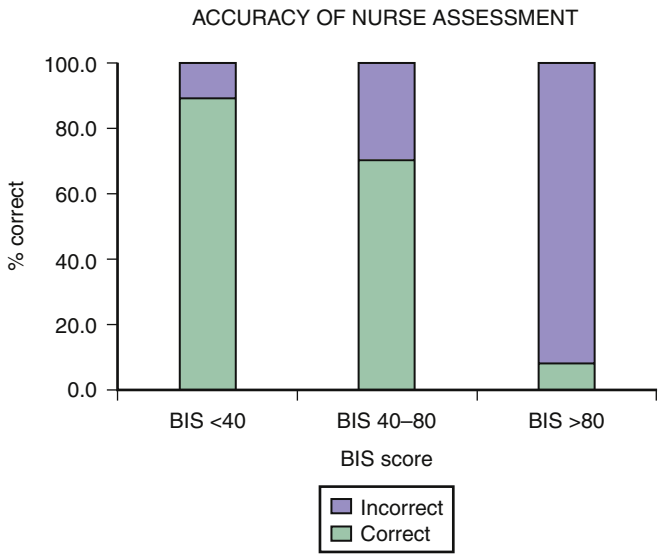

Figure 123–1. Nurse sedation assessment of the paralyzed patient. *BIS,* Bispectral index.

number from 0 to 100 that represents an integrated measure of cerebral electrical activity. The BIS has been validated as a measure of hypnosis in adults in the operating room and ICU.[9] More recently it has been validated in the PICU.[10] The BIS is an exciting new approach to EEG processing. It measures a state of the brain, representing the degree of alertness. It does not measure the concentration of a particular drug.[11] A number of 100 on the BIS score indicates that the patient is fully awake, while a number less than 40 is suggestive of a deep hypnotic effect. A BIS value of less than 60 in surgical patients was not associated with a recall of intraoperative events.[12] The use of the BIS monitor in adult surgical patients and in older pediatric patients has shown a reduction in anesthesia requirements and a shorter recovery time. The BIS monitor has been studied in several adult ICU populations. These studies have shown a correlation between the BIS score and a variety of sedation scores.[13]

One of the main difficulties with clinical sedation scoring systems is their inability to assess depth of sedation in the patient receiving neuromuscular blocking agents (NMBAs). Patients who require NMBAs in the operating room are considered to be at increased risk of awareness during anesthesia.[14] This problem also exists for the sedated patient with paralysis in the PICU. It is well known that the clinical signs of inadequate anesthesia or sedation are not reliable,[15] and many other reasons account for alterations in the heart rate, blood pressure, perfusion, and pupillary responses in the PICU patient. In a study using the BIS in pediatric patients with paralysis,[16] researchers found that in more than 8% of the sedation assessments in which patients were thought to be adequately sedated by the bedside nurse, their BIS scores were greater than 80 (Figure 123-1). This score reflected a significant risk of awareness. The BIS correlates well with the Ramsay scale in the sedated child and may be a useful monitor to prevent inadequate sedation in a child with paralysis.

Although the BIS monitor is used in many institutions, the question of whether its use can prevent awareness under anesthesia is still debated. A recent study enrolled 2000 adults whose anesthesia was either titrated to a BIS score of less than 60 or by the end-tidal inhalational concentration of the anesthetic agent to at least 0.7 minimum alveolar concentration (MAC).[17] Postoperatively all patients were interviewed to assess their intraoperative awareness. This study found two cases of awareness in each group. The MAC values in both groups were the same. The BIS was greater than 60 in one case of awareness. Although the BIS monitor was not able to reduce this low incidence of awareness, the level of anesthesia between the groups was very similar. This study was severely underpowered to show any benefit. However, the combination of end-tidal monitoring and BIS monitoring may be helpful in reducing intraoperative awareness.

Another potential concern with using the BIS monitor is its relevance or reliability for the pediatric patient. Research thus far showing correlation with the myriad of sedation scoring systems used in the PICU is limited by the limitations of these scoring systems. Furthermore, the lack of continuous sedation assessment by these scoring systems, as is possible with BIS monitoring, makes comparison difficult. Also of concern is whether the EEG analysis algorithms used in the BIS monitor are applicable to the pediatric brain. This issue needs further evaluation before the BIS monitor can be considered a "standard" in the PICU. Finally, a limitation of the BIS monitor is that it is less reliable when used with certain hypnotic agents such as ketamine, dexmedetomidine, nitrous oxide, xenon, and opiates.

Other processed EEG sedation assessment monitors are now available. The SNAP IITM monitor[18] uses a different spectrum of EEG frequency analysis. Little difference between the BIS and the SNAP IITM monitors has been shown thus far. Currently little experience has been reported with the SNAP IITM monitor in pediatric patients.

Table 123–3 Classification of Opiate Receptors and Subtypes

Subtype	Prototypic Drugs	Actions
Mu_1	Opiates and most opiate peptides	Supraspinal analgesia including periaqueductal gray matter, nucleus raphe magnus, and locus coeruleus
		Prolactin release
		Acetylcholine turnover in brain
		Catalepsy
Mu_2	Morphine	Respiratory depression
		Dopamine turnover in brain
		Gastrointestinal tract transit
		Most cardiovascular effects
Delta	Enkephalins	Spinal analgesia
		Dopamine turnover
Kappa	Dynorphin	Spinal analgesia
		Inhibition of antidiuretic hormone
		Sedation
Sigma	N-allynormetazocine	Psychotomimetic effects

Opioids and Analgesia in the Pediatric Intensive Care Unit

Sedation in the PICU is most commonly achieved with a mixture of opioids and benzodiazepines (BZDs). Although many synthetic and naturally occurring opioids exist, morphine is considered the agent against which others are compared. The primary source of morphine is opium obtained from the opium poppy (*Papaver somniferum*), which also produces alkaloids such as codeine, thebaine, papaverine, and noscapine. Opiates are substances derived from opium; the term opioid also describes substances derived from opiates (e.g., oxycodone) but also includes substances that are created synthetically but have properties that are similar to those of opiates (e.g., fentanyl and methadone) and endogenous ligands. The terms often are used interchangeably because the pharmacologic effects fall into the same category. Opioids are agonists at various opioid receptors, for which several endogenous ligands exist. There are three major classes of receptors: mu (μ), kappa (κ), and delta (δ). The opioid receptors possess the same general structure of an extracellular N-terminal region, seven transmembrane domains, and an intracellular C-terminal tail structure. Subtypes of each receptor (e.g., μ_1, μ_2) exist (Table 123-3), as do less well-characterized opioid receptors ε, λ, τ, and ξ.

Most of the therapeutic and adverse effects can be accounted for by agonist activity at the μ-receptor, which is responsible for analgesia, respiratory depression, pupillary constriction, and euphoria. At the cellular level, μ-receptor activation alters ionic permeability to K^+, causing hyperpolarization and depression of excitability in the neuronal system. Associated effects on cholinergic, adrenergic, serotonergic, and dopaminergic neurotransmitter systems are seen within the central nervous system (CNS). These receptors are found at multiple sites along pain pathways including the spinal cord, midbrain, thalamus, and the cortex. At the spinal cord level, pain reflexes (nociceptive) are depressed by receptors in the substantia gelatinosa, which are mostly presynaptic and inhibit the release of substance P from C-fiber nerve terminals and account for the effectiveness of intrathecally and epidurally administered opioids. In the midbrain the analgesic effect is mediated in the periaqueductal gray matter through ascending fibers and also descending fibers that modulate the function of the dorsal horn. Acetylcholine, γ-aminobutyric acid (GABA), norepinephrine, and serotonin also are involved in these pain-modulating pathways. Peripheral opioid receptors also have been shown and can be expressed in response to inflammation.[19] The intraarticular injection of morphine produces analgesia following arthroscopy through activation of opioid receptors located on white blood cells.[20]

The endogenous ligands for the opioid receptors are the enkephalins, endorphins, and dynorphins. They have a morphine-like effect that can be specifically antagonized by the μ-receptor antagonist naloxone. The endomorphins have potent analgesic and gastrointestinal (GI) effects. At the cellular level, they activate G proteins ([35S] GTP gamma-S binding) and inhibit calcium currents.[21] Pro-opiomelanocortin is the precursor for β-endorphin (as well as adrenocorticotropic hormone and melanocyte-stimulating hormone). β-Endorphin, itself very active, also includes the amino acid sequence for met-enkephalin, although the main precursor is proenkephalin A, which contains four copies of met-enkephalin and one copy of leu-enkephalin. The met-enkephalin sequence also gives opioid activity to a number of other larger peptides. Proenkephalin B (prodynorphin) gives rise to the dynorphin series and contains three leu-enkephalin sequences. Local application of these endogenous substances to the brain provides effects that are similar to those of opiates. They do not function as analgesics because the administration of naloxone does not cause pain in the normal state. They are released during periods of sustained pain, stress, or activity to modulate physiologic pathways, including those involved with pain. Therefore they are probably important to the physiologic condition of the patient in the ICU.

Specific Opioid Agonists

Morphine

Morphine is an opiate, and its primary therapeutic actions are sedation and analgesia; anxiolysis and euphoria also may occur. These four therapeutic effects may be exploited to the benefit of the patient. These actions are mediated through the periaqueductal gray matter, the ventromedial medulla, and the spinal cord. The reduction of nociceptive reflexes occurs all over the body, even below a completely transected spinal cord. In addition to increasing the sensory threshold for pain, morphine may decrease the hurting aspect (or unpleasantness) of pain. A patient given morphine may say something such as, "I have just as much pain, but it doesn't distress me as much." It blunts most types and intensities of pain, although some forms of neuropathic pain are relatively resistant. The resulting analgesia may be potent enough to abolish diagnostic symptoms and signs. The sedative effects reduce higher cortical function, cause difficulty in concentration, and cause

a sense of drowsiness and dream-filled sleep. Higher doses will cause a state of unconsciousness or coma. The rate of respiration is reduced with a resultant fall in minute ventilation despite an accompanying increase in depth of breathing. This effect is associated with a decreased responsiveness to carbon dioxide (CO_2) and is additive to the decreased CO_2 response seen during sleep. In some circumstances respiratory drive may be restricted to hypoxic stimulation of the carotid chemoreceptors; this is the most serious dose-related adverse effect of morphine. It can occur at doses used clinically for analgesia. In general, all opiates produce the same degree of respiratory depression when given in equipotent doses and for any given level of analgesia. Opioids do not have anticonvulsant properties, whereas meperidine (and its metabolite normeperidine) may lower the seizure threshold.

Another CNS effect of morphine is pupillary constriction due to a central effect on the oculomotor nucleus. Nausea results from stimulation of the chemotrigger zone; however, opioids also depress the vomiting center, so the final effect is unpredictable. Nausea and vomiting are much more frequent in ambulatory patients than in patients confined to a hospital bed. Stress-related endocrine responses can be modified by morphine. It decreases the release of several hormones including adrenocorticotropic hormone, antidiuretic hormone, prolactin, growth hormone, and epinephrine. The neuroendocrine stress response that is normally seen with trauma and surgery may be blunted. Itching may be caused by histamine release, but it also may be due to opiate receptor activation in the spinal cord.[22]

Morphine's effects on smooth muscle cause constipation. It reduces the intestinal propulsion activity through its central and peripheral effects. The central effects may be mediated by the vagus nerve. The direct smooth muscle relaxation and the increased local cholinergic transmission can be partly reversed by naloxone. This decreased motility is the basis of several over-the-counter antidiarrheal preparations including diphenoxylate, a μ-agonist that does not cross the blood-brain barrier and thus acts as a peripheral opioid agonist. Morphine also causes an increase in biliary tract tone, which may cause biliary colic, as well as increased tone in the bladder detrusor muscle and vesical sphincter. Urinary retention is common with opioids and occurs in 55% of children receiving spinally administered opioid and 20% receiving intravenous (IV) opioid.[23]

Morphine has been studied extensively in term and preterm neonates. Glucuronidation is present in term babies and in many preterm ones. The half-life of morphine, however, is 2 hours in children, 6.5 hours in term neonates, and 9 hours in the preterm child because of reduced clearance. Volume of distribution did not vary with age.[24] Morphine causes histamine release and can cause peripheral vasodilatation. Infused at analgesic doses, it has little effect on the cardiovascular system, but skin flushing is not uncommon with rapid IV administration. The histamine-releasing potential should be considered in patients with asthma, especially during an acute exacerbation, and in patients with unstable cardiovascular systems for whom safer alternatives, such as fentanyl, exist.

Dosing recommendations in the ICU include a bolus dose of 0.05 to 0.1 mg/kg and an infusion of 0 to 30 μg/kg/h. Fifty percent of these doses should be used if the patient is younger than 3 months of age. The pharmacokinetics of various opiates is outlined in Table 123-4. All opiates are weak bases and are moderately ionized at pH 7.4. Oral morphine is effective but undergoes hepatic first-pass metabolism, which is variable among patients. The oral dose for acute pain is two to five times the IV dose, while with long-term use the oral dose is 1.5 to 2.5 times the IV dose.

Table 123–4 Opiate Pharmacokinetics

Drug	Elimination Half-Life (hr)	Volume Distribution (SS) (L/kg)	Clearance (mL/kg/min)	Protein Binding (%)
Morphine	2.2	3.3	15	30
Meperidine	3.2	2.8	5	58
Fentanyl	3.1	3.2	8	79
Sufentanil	2.7	1.7	13	92
Alfentanil	1.2	0.3	2.8	89

SS, Steady state.
Modified from Baresh PG, Cullen BF, Stoelting RK et al, editors: *Clinical anesthesia*, ed 2, Philadelphia, 1992, JB Lippincott.

Morphine is metabolized to morphine-3-glucuronide (M3G) and M6G in the liver. M3G is the major metabolite and has little morphine-like activity, although some research has suggested that M3G may be associated with an antinociceptive effect, accounting for failure of analgesia during long-term use.[25] In contrast, M6G is many times more potent than morphine itself.

Morphine undergoes significant first-pass hepatic metabolism, whereby after a single parenteral dose, only morphine is initially active. After a single dose by mouth (PO), both morphine and M6G are active. With long-term oral use, M6G accumulates until its analgesic effect is greater than that of morphine. A similar effect can be anticipated with long-term morphine infusion in the patient in the PICU. The glucuronides are excreted by the kidney, together with only a small amount of free morphine. Ninety percent of total urinary excretion occurs within 24 hours.

Tolerance, defined as an increase in the dose required to create the same response, is a potential problem with all opiates. Tolerance is mainly limited to the depressant actions of morphine, including analgesia, respiratory depression, anxiolysis, and drowsiness. Tolerance of morphine's inhibition of bowel motility and pupillary constriction is minimal. The mechanism of tolerance appears to involve the degree and duration of both μ- and κ-receptor occupancy. It appears more rapidly after continuous infusion, and cross-tolerance to other opiates is common, although anecdotal evidence suggests that when opioids are switched, a dose reduction may be possible because cross-tolerance sometimes appears incomplete.[26] Receptor downregulation also may occur, as well as altered metabolism with an increased M3G/M6G ratio. Simultaneous blockade of *N*-methyl-D-aspartate receptors has been shown to be effective in reducing the development of tolerance.[27] Clinical tolerance appears uncommon with an exposure of less than 3 days, but after prolonged administration, doses 10 to 20 times that which would cause respiratory arrest in nontolerant patients may be tolerated.

Meperidine

Meperidine has one tenth the potency of morphine. Compared with other common opioids, meperidine has more CNS excitatory effects including tremors, muscle spasm, myoclonus,

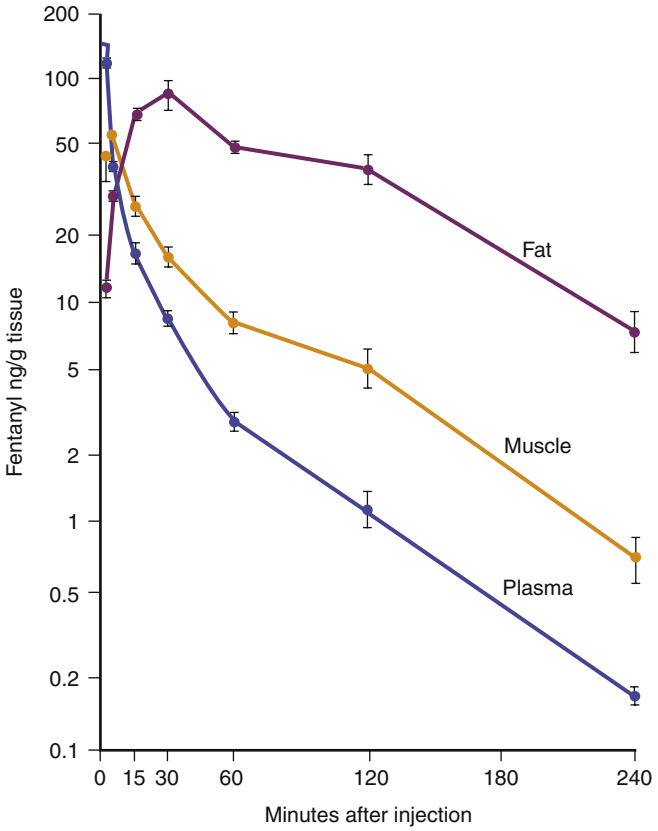

Figure 123–2. Initial fentanyl redistribution.

psychiatric changes, and seizures. These effects may be due to a central serotoninergic effect.[28] It is metabolized by the liver to normeperidine, which is twice as toxic as meperidine and has a longer half-life (15 hours). Normeperidine accumulation is enhanced in patients with an induced cytochrome P450 system. Meperidine has a shorter duration of action (2 to 3 hours) and has a more rapid onset because of its increased lipid solubility compared with morphine. Meperidine is unique among opioids because of its local anesthetic properties, which are capable of providing surgical spinal analgesia.[29] A small dose (0.125 to 0.25 mg/kg) of meperidine may be used to treat postoperative shivering.

Fentanyl

Fentanyl is one of the most commonly used opiates in the ICU. It is a synthetic derivative of meperidine without many of its unwanted side effects. It is a potent μ-agonist and is 100 times more potent than morphine. It has a rapid onset and cessation because of its high lipid solubility (Figure 123-2). Fentanyl may be administered by several routes, including IV, intramuscular (IM), transmucosal,[30] and subcutaneous (SC) when venous access is inadequate. Skeletal muscle rigidity (which can occur with all synthetic opiates) is well described in the literature. It is mediated through the CNS and is an idiopathic response usually associated with a large bolus dose (≥5 μg/kg). It improves with the administration of NMBAs and is reversible with naloxone. Fentanyl has limited cardiovascular effects. Moderate bradycardia is the most common hemodynamic effect. Fentanyl does not cause histamine release. Dosing in the ICU is either by bolus (1 to 2 μg/kg) or infusion (1 to 4 μg/kg/h with higher doses as tolerance develops). The short duration of effect of a single dose of fentanyl is not due to metabolism but rather to rapid redistribution. Maximum brain concentration after a bolus is achieved within 90 seconds. Then, because of rapid redistribution, the plasma level falls by 50% in 30 minutes, and the result is a clinical duration of effect of a single dose of approximately 30 minutes. Fentanyl then accumulates in fat, where it is stored and slowly released with a longer elimination half-life of about 4 hours (longer than morphine). Marked respiratory depression occurs within 120 seconds, and a single dose of 5 μg/kg will cause apnea in 50% of patients. Also, fentanyl is metabolized by the liver to nor-fentanyl and hydroxy fentanyl derivatives, both of which are thought to be inactive. In the operating room, high-dose fentanyl is commonly used for cardiac anesthesia and for anesthetization of other unstable patients. A loading dose of 50 μg/kg, followed by 0.5 μg/kg/min, will occupy all opioid receptors and produce a state of anesthesia. Many cases of awareness with patients under anesthesia have been documented, however, even when these high doses of fentanyl were used.

Sufentanil

Sufentanil is another synthetic opiate that has actions and therapeutic effects that are similar to those of fentanyl. It is five to ten times more potent than fentanyl and is the most potent opioid in clinical practice, posing a high risk of apnea with bolus administration. Dosing recommendations include bolus dosing of 0.2 to 0.4 μg/kg or an infusion of 0.2 to 1 μg/kg/h.

After a single bolus, sufentanil has kinetics similar to that of fentanyl with a short duration of clinical effect of approximately 30 minutes. However, with prolonged use, sufentanil accumulates less and is associated with a more rapid recovery after infusion because of its smaller volume of distribution and similar clearance. When the patient is receiving high doses of fentanyl, sufentanil is useful to conserve infusion volume.

Alfentanil

Alfentanil is another synthetic opiate with a rapid onset. It is five times less potent than fentanyl. Although it is less lipid soluble than fentanyl because of its low pKa (negative logarithm of the acid ionization constant), a higher percentage of the drug is present in the active unionized form, which results in a rapid onset. Because of its low volume of distribution, alfentanil has a short elimination half-life, which results in a short duration of action (5 to 10 minutes). Dosing regimens include boluses of 5 to 10 μg/kg if there is spontaneous respiration or 20 to 50 μg/kg if the patient's lungs are ventilated. Alfentanil is a useful agent for preventing the hypertensive or increased intracranial pressure (ICP) response to intubation. As with all synthetic opiates, there is a risk of muscle rigidity with the higher dosing. Infusion dosing includes 0.2 to 1 μg/kg/min for patients receiving mechanical ventilation. Postinfusion recovery is quicker with alfentanil than with fentanyl. It is useful by infusion and safe to use in patients with hepatic or renal failure.

Codeine

Codeine has a chemical structure and effects that are similar to those of morphine and is commonly used as an oral medication for cough suppression or mild to moderate pain relief. A

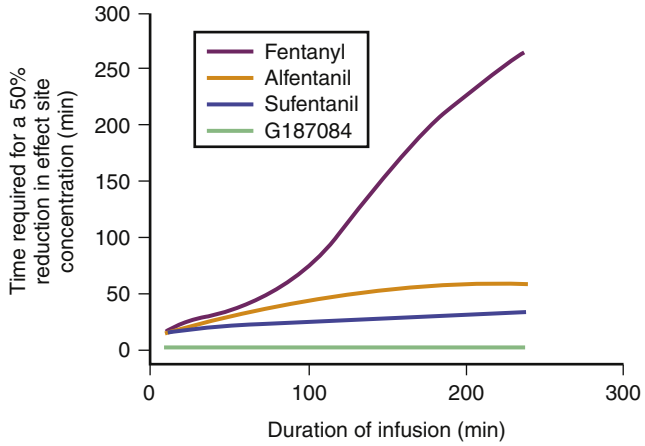

Figure 123–3. Context-sensitive half-life.

large part of its effects are due to the metabolism of codeine to morphine. Ten to twenty percent of patients lack a metabolic pathway to convert codeine to morphine, which results in an unpredictable effect. Dosing is 0.5 to 1 mg/kg. Constipation is a major adverse effect, and some patients report having a vague peculiar or unpleasant feeling when they take codeine. This drug can be habit-forming. It can be given orally, IM, or rectally. Rapid IV use may result in cardiovascular collapse. Rectally administered codeine has been shown to have as rapid an onset as IM codeine, but it yields lower peak levels in children.[31] Codeine has been the analgesic of choice by neurosurgeons because of the belief that pupillary signs are maintained with use of this drug. Morphine has been shown to be a more effective analgesic, however, in patients with head injuries.[32]

Remifentanil

Remifentanil is one of the newest synthetic opiates available. It was designed to be metabolized by plasma esterases to provide a short half-life. It is a potent μ-agonist with mild κ and δ effects. It is substantially more potent than fentanyl. It is supplied as a white lyophilized powder that contains glycine (it should not be used for epidural or spinal analgesia). The metabolism is by nonspecific esterases not affected by pseudocholinesterase deficiency. The metabolite, a weak μ-agonist, is excreted by the kidney. The kinetics of remifentanil is different from those of most opiates used in the ICU. It has a short half-life that is due to metabolism rather than to redistribution. Therefore remifentanil has what is known as a context-sensitive half-life. The elimination half-life for remifentanil is about 8 minutes. With an infusion of remifentanil, the half-life does not increase but remains constant. With opiates such as fentanyl and alfentanil (Figure 123-3), the clinical effect half-life increases with time until it reflects the elimination half-life of between 2 and 4 hours.

Kinetics reported for neonates are similar to those reported for adults. The continuous infusion rate depends on the degree of sedation/analgesia required (0.1 to 0.5 μg/kg/min for sedation; 0.75 to 2 μg/kg/min for balanced anesthesia; 4 μg/kg/min for loss of consciousness). Remifentanil has effects on the cardiovascular system that are similar to those of fentanyl. Remifentanil causes a mild bradycardia and a slight decrease in blood pressure,[33] which may be prevented with glycopyrrolate. No histamine release occurs. Remifentanil is a potent respiratory depressant. For spontaneous respiration, a low continuous infusion dose (without a bolus) should be used (0.1 μg/kg/min). Sedation can be effectively managed by continuous infusion without the need for a bolus because of the short half-life. An increase or decrease of infusion rate is rapidly reflected by a change in the degree of sedation, which is important to note. Most other opiate sedatives require bolus dosing to achieve a rapid change in effect. This type of dosing is neither appropriate nor needed for remifentanil.

Remifentanil has the usual opiate adverse effects; however, because of the short half-life, they have only brief clinical effect. Remifentanil may prove to be a safe and effective choice for PICU sedation in patients with severe renal or hepatic disease; however, the potential exists for glycine accumulation in patients with renal failure. It is an option only for those who require overnight ventilation or for those patients in whom a rapid awakening may be required for neurologic assessment. Remifentanil has been shown to reduce cerebral oxygen use and reduce cerebral blood flow if the CO_2 is maintained in a normal range.[34] Remifentanil is currently an expensive option and should not be considered for every patient. Also, because of its short duration, the postoperative patient may need an alternative analgesic after extubation. Rapid development of opiate tolerance with remifentanil has been described in healthy volunteers[35] and also when used in the ICU setting. This rapid tolerance has also been described in postoperative scoliosis patients[36]; however, the increased morphine requirements described probably reflect the initial postoperative need to achieve an adequate morphine blood level rather than any acute tolerance.

Hydromorphone

Hydromorphone is a hydrogenated ketone of morphine. It is seven times as potent as morphine with a similar onset and duration of action. It causes less histamine release than morphine and may be used in patients who report pruritus due to morphine. Like morphine, hydromorphone undergoes hepatic metabolism; however, there are no active metabolites that are dependent on renal excretion. As such, it may be an effective alternative in patients with renal insufficiency or failure.

Tramadol

Tramadol is an opiate analgesic that relieves pain by binding to opiate receptors and by inhibiting the reuptake in the CNS and spinal cord of norepinephrine and serotonin, two pain-modifying neurotransmitters. Tramadol does not have antiinflammatory effects. Its use is indicated in cases of moderate to severe pain.[37] Despite being a narcotic-like agent, the Food and Drug Administration (FDA) has not classified tramadol as a controlled substance. Dosage (not FDA approved for patients younger than 16 years) is an initial oral dose of 1 to 2 mg/kg every 6 hours and should not exceed 6 mg/kg/day. An IV preparation is available outside of the United States. Patients with a creatinine clearance less than 30 mL/min should not receive a dose more often than once every 12 hours, with a maximum dose of 3 mg/kg/day. The dose for patients with cirrhosis or hepatic dysfunction is 1 mg/kg every 12 hours. Patients undergoing dialysis can receive their dose on the day of dialysis because only 7% of the drug is

removed by the process. The adverse effects of tramadol most often involve the CNS and the GI tract. Patients may become dependent on tramadol. Abuse is possible, and it should not be given to opiate-dependent patients. Seizures have been seen in patients receiving high single oral doses of 10 mg/kg; this danger is even greater in patients with epilepsy and in anyone taking monoamine oxidase inhibitors and neuroleptic agents that lower the seizure threshold. Respiratory depression may occur if the recommended dosage is consistently exceeded or if another centrally acting depressant drug (e.g., alcohol) or an anesthetic is given concurrently. Because of the possibility of withdrawal symptoms, patients should not abruptly discontinue use of tramadol. Tramadol is not a useful drug for sedative action.

Table 123-5 provides conversion doses for some commonly used oral opiates. A summary of IV doses of different opiates is provided in Table 123-6.

Opiate Antagonists

Several opiate antagonists are available. The most commonly used is naloxone, which is a specific and sensitive receptor antagonist of all opiate receptors. Dosing can be either low dose (1 μg/kg) or high dose in an emergency situation (10 μg/kg). If the drug cannot be administered intravenously, then it can be given intramuscularly, intranasally, or into the midventral surface of the tongue. When naloxone is being used for a long-acting agonist, an infusion may be necessary because its half-life is only 30 to 81 minutes (mean of 64 ± 12 minutes). In neonates, the half-life has been reported as 3.1 ± 0.5 hours; however, this prolonged effect is likely to be offset by a concomitant increase in the duration of action of the opioid for which the naloxone is given. No effect is seen in the healthy patient in the absence of administered opioids; however, in the setting of sepsis in the ICU, a vasopressor effect may occur, presumably because of an interaction with endogenous opioids released in response to stress. Nalmefene, a longer-acting antagonist, can be given through IV, IM, and SC routes. It has a redistribution half-life of 41 minutes and a terminal half-life of 10.8 hours in adults and somewhat less in children. Thus reappearance of the antagonized opioid is unlikely if it is given in an adequate dose.[38]

Table 123–5 Dose Equivalents: Short Acting

Drug	Oral	Parenteral
Morphine	0.5 mg/kg q4h	0.15 mg/kg q3h
Hydromorphone	0.1 mg/kg q4h	0.02 mg/kg q4h
Codeine	4 mg/kg q3h	
Hydrocodone	0.5 mg/kg q3h	
Oxycodone	0.5 mg/kg q3h	
Meperidine	5 μg/kg q2h	1.5 mg/kg q2h
Fentanyl		1.5 μg/kg q2h

Incidental Pain Syndromes in the Pediatric Intensive Care Unit

In addition to the techniques used to sedate children to facilitate their PICU management, many children will have pain related to their underlying condition. Many different options are available for controlling pain in the pediatric patient (Box 123-1). The pharmacologic management of pain should follow the traditional World Health Organization analgesic ladder, which begins with a nonopioid analgesic such as a nonsteroidal antiinflammatory drug or acetaminophen, followed by a weak opioid such as hydrocodone added to the nonopioid, and then moves on to a strong opioid such as morphine or hydromorphone as needed. When taken orally, a sustained-release preparation is often useful once the dose requirement has been determined. The dose requirement of a strong opioid is variable in the patient taking opioids for a prolonged period, and failure to appreciate this variability is a common cause for therapeutic failure. In addition, once a dose requirement is known, the analgesic should be given to preempt pain rather than to relieve pain as required. At each level of analgesic use, the addition of adjuvant medications should be considered. Adjuvant drugs fall into six groups: antidepressant, anticonvulsant, neuroleptic, steroid, stimulant, and local anesthetic. Of the tricyclic antidepressants, nortriptyline is available in a liquid form. The tricyclic antidepressants are indicated for neuropathic pain, particularly when the patient describes a burning pain. Also useful for neuropathic pain are the anticonvulsant agents gabapentin, pregabalin, and carbamazepine. These drugs often work best when the pain is described as shooting or lancinating. Neuropathic pain may result from tumor invasion, vincristine therapy, cytomegalovirus

Table 123–6 Summary of Opiate Dosing

Drug	Relative Potency	Bolus Dose	Initial Infusion Rate	Active Metabolites
Morphine	1	0.1 mg/kg	0.04 mg/kg/h	M6G
Meperidine	0.1	1 mg/kg	NA	Normeperidine
Fentanyl	100	1 μg/kg	1 μg/kg/h	None
Hydromorphone	7	0.015 mg/kg	0.005 mg/kg/h	None
Sufentanil	500	0.2 μg/kg	0.2 μg/kg/h	None

infection, or human immunodeficiency infection. Neuroleptic drugs, including chlorpromazine and trimeprazine, may be useful in the management of nausea, anxiety, and pruritus. Steroids benefit mood, inflammation, nausea, appetite, nerve swelling/entrapment, and vasculitis. When opioid sedation is interfering with quality of life, a stimulant such as an amphetamine may restore energy and alertness while allowing ongoing analgesia from the opioid. Sometimes pain can be managed by local anesthetic, placed by peripheral nerve block, topically, or as a neuraxial block.

Patient controlled analgesia (PCA) has become the mainstay of postoperative pain relief in children because of its efficacy and safety. However, its use is limited by the child's ability to understand how to use the PCA pump. Proxy PCA (PCA-P) has been used for younger children or those with cognitive impairment.[39] The use of the PCA by the nurse or the caregiver may override the "safety net" that the PCA has. The use of PCA-P has been associated with greater need for rescue interventions; however, it is often used in sicker children. When PCA-P is used, careful evaluation and rigorous monitoring is needed.

Sickle Cell Crisis

Sickle cell disease differs from cancer and acquired immune deficiency syndrome in that intermittent episodes of severe pain occur, requiring urgent intensive treatment. A good review of this subject has been published.[40] Chronic pain also may be present because of long-term tissue and bone damage from periods of ischemia during past crises, including persisting myocardial ischemia. Patients may be receiving long-acting opioids or may have had repeated exposure to opioids with past crises. Patients with a sickle cell disease crisis that involves the chest or brain are likely to be admitted to the PICU. Chest crises result from the sickling of erythrocytes in the pulmonary vasculature and result in hypoxia to the rest of the body and local lung damage. The systemic hypoxia worsens the crisis and is thus self-perpetuating. Chest radiograph changes may be late, and an associated paralytic ileus may be present. Poor pulmonary function may discourage the practitioner from using adequate opioid analgesics out of concern for worsening the hypoxia. However, it is important not to underestimate the need for pain relief and to appreciate that past opioid exposure may have resulted in tolerance to opioids. If IV access is difficult to obtain, morphine may be given subcutaneously or orally. Anecdotal success also has been reported with nebulized morphine.[41]

Opiate Tolerance

The use of opiate infusions in the ICU is associated with the potential for the development of tolerance or dependence.[42] Iatrogenic withdrawal symptoms can occur if the opiates are discontinued abruptly. These effects have been shown to be related to the total dose and duration of fentanyl infusion. A fentanyl infusion of 5 days or a total cumulative dose of 1.6 mg/kg during the hospital stay was associated with a 50% chance of the development of narcotic withdrawal, whereas a fentanyl infusion of 9 days or longer or a total cumulative fentanyl dose of 2.5 mg/kg or more during the hospital stay had a 100% incidence of withdrawal.[43] The rising plasma fentanyl levels caused by increased dosing suggested that increased metabolism or clearance was not responsible for the development of tolerance. A study of patients in a PICU to determine the degree of opiate tolerance has shown a significant increase in opiate dosing required for adequate sedation.[44] The opiate infusion increased by about 80% per week for the first 3 weeks of opiate use. No difference in the rate of opiate increase was found with respect to age of the patient, postoperative status, mode of ventilation, and paralysis.

For patients considered to be at risk of withdrawal, several options are available. If circumstances allow, it is better to start the treatment for withdrawal prevention before the patient has symptoms and signs of withdrawal. Opiate withdrawal is not usually a serious medical problem; it is rarely life-threatening and is self-limited. However, treatment should be started early if possible for patient comfort. In a few circumstances the associated hypersympathetic state may not be good for the patient. The signs and symptoms of withdrawal are nonspecific, and other causes, such as infection, hypoglycemia, hypocalcemia, hyperthyroidism, and hypoxia, should be excluded. Because of the nonspecific nature of the symptoms of opiate withdrawal, several scoring systems have been described to aid with the diagnostic process. The Finnegan score is based on 31 variables and is lengthy. The Lipsitz score is shorter and easier to use than the Finnegan score. Both of these scoring systems, however, were devised for use with neonates, and several of the measurements are not appropriate for patients in the PICU. Currently no validated scoring system exists for assessing opiate withdrawal in the pediatric patient. In the limited number of articles in which opiate withdrawal in the PICU is evaluated, the authors have modified these scores (Table 123-7) in an attempt to provide an objective assessment of the patient.

Recently the assessment of a new score based on a similar set of signs and symptoms, the Withdrawal Assessment Tool,[45] has been proposed. The bedside nurse reviews the patient's chart for the previous 12 hours and performs a short assessment of the child's level of agitation, as well as other signs/symptoms. This review is then followed by an assessment of the response to stimulus and also how quickly the child settles down after the stimulus. A score of 1 is assigned to each assessment (maximum, 12). A score of greater than 3 was associated with a greater likelihood of drug withdrawal. Although this score is new and has limited verification, it probably provides

a better evaluation than just the clinician's "bedside" opinion, especially in complex cases in which both opiate and BDZ withdrawal may occur together.

Several therapeutic options are available for the prevention and treatment of opiate withdrawal. Drugs from the same class are preferable. The FDA has approved methadone for opiate withdrawal. Other agents that may be useful include morphine, clonidine, dexmedetomidine, phenobarbital, paregoric, chlorpromazine, transdermal clonidine patch,[46] and SC fentanyl. Paregoric contains morphine plus papaverine, noscapine, camphor (a CNS stimulant), ethanol (45%), benzoic acid (which competes with bilirubin-binding sites), and glycerin (which causes diarrhea). Paregoric has been used for neonatal withdrawal, but because of its composition, it may cause adverse effects. Chlorpromazine may be useful for GI adverse effects, but hypothermia and hypotension may occur. Haloperidol also may be of use, having minimal respiratory depression and no active metabolites. It also offers cardiovascular stability. Phenobarbital has been used for hyperactive behavior; however, it can cause significant CNS depression, it induces drug metabolism, and it is tolerance/dependence forming.

Methadone seems to be the most suitable agent for treating opiate withdrawal. It has an oral bioavailability of 80% to 90% and an elimination half-life of 12 to 24 hours. It is equipotent to morphine. Methadone has inactive metabolites and is less sedating than morphine while remaining an effective analgesic. Because of its higher bioavailability and reduced first-pass metabolism, the effect of oral doses is more predictable than that of morphine. Methadone has been extensively used in the outpatient management of patients addicted to opiates.

The convenience of the oral route, the less-frequent dosing because of its longer half-life, and the ease of calculating doses because of its equal potency to morphine make methadone attractive for use in the management of opiate withdrawal in children. However, a huge variability exists in recommendations regarding the methadone dose that should be used to prevent opiate withdrawal in children. Several factors are important in the dosing of methadone for conversion from fentanyl. After prolonged IV administration, fentanyl has a potency 100 times that of methadone; it has a metabolic half-life approximately one quarter that of methadone; and if given intravenously, it has a bioavailability 20% greater than orally administered methadone. In a study in which the effectiveness of a fentanyl-methadone conversion protocol was assessed, researchers found that giving 2.4 times the daily fentanyl dose as methadone prevented withdrawal symptoms.[42] The methadone was given intravenously for 24 hours, and the fentanyl dose decreased by 50% on day 1 and by another 50% on day 2, and then it was discontinued. On day 3, the methadone was converted to oral dosing. The methadone was given intravenously initially. Because of its long half-life, oral dosing could take up to 5 days to reach a steady state. The duration of methadone requirement varied from 1 to 4 weeks, depending on the duration of opiate infusion. Methadone was being weaned by 3% to 15% per day with no signs of withdrawal. To date, there have been no published cases of respiratory arrest when methadone has been used for opiate weaning. However, it would appear prudent to initiate the conversion from fentanyl to methadone in the ICU environment in the event that problems arise and to ensure that an adequate dose is given. Once stabilized, the patient may be transferred to the floor and ultimately home, with a clearly described plan for decreasing the methadone dose over time. The weaning plan also should involve the home pediatrician so that patients have access to someone who is familiar with the process. In a follow-up of patients who had received methadone while in the ICU, 38% of patients were discharged home during the weaning process. No problems were associated with the weaning of methadone at home. Stigma regarding methadone use was not expressed by any of the parents.

The use of a clonidine patch also has been evaluated in the PICU. Clonidine has been shown to be effective in the management of nicotine, opiate, and alcohol withdrawal. It decreases sympathetic outflow from the CNS and has a synergistic effect for analgesia, both at the central and spinal level. In one report, eight patients were described after tracheal reconstructive operations. They required postoperative sedation and ventilation for 7 days, which put them at high risk for withdrawal.[20] A clonidine patch was applied 12 hours before extubation, and the patients were weaned off the opiate. The dose used was approximately 6 μg/kg/day of clonidine, and the patch was left on for 7 days. One patch had to be removed because of hypotension. The patch seemed to be effective in preventing withdrawal. Use of the clonidine patch is attractive because of its noninvasive approach, which is desired. However, the use of a transdermal patch prevents titration of effect, and problems with bradycardia, hypotension, hypothermia, sedation, and dysrhythmia may occur.

A confounding issue in many publications and in the clinical management of opiate withdrawal is the potential for simultaneous BZD withdrawal. Most researchers have not been able to separate these two issues. The symptoms of BZD withdrawal differ from those of opiate withdrawal because the BZD symptoms generally include less sympathetic activation. BZD withdrawal symptoms are characterized by agitation and a movement disorder. If BZD withdrawal is a concern, low-dose lorazepam or diazepam may be added to the withdrawal

Table 123–8 Pharmacokinetics of Benzodiazepines

Drug	Elimination Half-Life (hr)	Volume Distribution (SS) (L/kg)	Clearance (mL/kg/min)	Protein Binding (%)
Diazepam	46.6	1.13	0.4	97.8
Midazolam	3.0	1.09	7.5	94

management strategy (Table 123-8). A prospective study of BZD withdrawal[47] following lorazepam infusion (up to 0.3 mg/kg/h) documented BZD withdrawal syndrome in approximately 25% of the children. This withdrawal occurred even when using a 6-day tapering of the lorazepam dose. All the children had been previously weaned off fentanyl infusions. No predisposing risk factors were found for BZD withdrawal with respect to BZD or opiate dosing or duration.

Rapid Opiate Detoxification

Reports have been made of rapid opiate detoxification in the ICU. These procedures have used a form of deep sedation (often with use of propofol or another anesthetic agent) to facilitate opioid withdrawal in patients addicted to the recreational use of opiates.[48] The patients are given high doses of opiate antagonists to displace all opiates from the receptors and then heavy sedation is initiated to reduce the occurrence and effects of the sympathetic stimulation observed with short-term opiate withdrawal. These procedures have been safely performed in the ICU; however, there have been several reports of complications[49] when these procedures were not performed with full ICU support. Currently the effectiveness and safety of 1-day opiate detoxification is still an area of debate.[50] If used, however, it should be combined with an established long-term support plan to optimize long-term success.

In the PICU, deep sedation with propofol has been used to facilitate rapid opiate weaning of ventilator-dependent patients.[51] The use of propofol for up to 3 days allowed a reduction of fentanyl dosing from 24 to 9 μg/kg/h (a 65% reduction). No signs or symptoms of opiate withdrawal were noted, and metabolic acidosis did not develop. Opiate antagonists were not used for this rapid weaning process. However, concern has been raised regarding the long-term administration of propofol, especially in the PICU patient, given the development of the propofol infusion syndrome.

Benzodiazepines

BZDs are among the most commonly used agents for sedation in the ICU. They augment the function of the GABA type A ($GABA_A$) receptor at the postsynaptic membrane. This pentameric protein controls a chloride channel, the opening of which leads to an inhibitory effect due to hyperpolarization of the cell membrane.[52,53] Benzodiazepines bind to BZD receptors, which in the CNS are usually found as part of the $GABA_A$ receptor, enhancing the effect of endogenous GABA.[54] Peripheral BZD receptors[55] are not usually associated with the $GABA_A$ receptor but are a binding site for diazepam and midazolam. These 18-kDa proteins are associated with regulation of cellular proliferation, immunomodulation, porphyrin transport, heme biosynthesis, and anion transport. In particular, they seem important in the regulation of steroid synthesis and apoptosis, and they have a significant effect on the hypothalamic-pituitary-adrenal axis.[56] These latter effects may be pertinent to the physiologic care of patients in the ICU.

BZD receptors are bound by a family of endogenous peptides called endozepines, which have similar effects to the BZDs.[57,58] The expression of this diazepam-binding inhibitor may be relevant to the development of dependence not only on BZDs but also on alcohol and opioids[59] and may therefore be relevant in the drug dependence commonly seen in patients in the PICU who are given these agents continuously. Naturally occurring BZDs have been detected with structures similar to those used clinically.[60] Subsets of $GABA_A$ receptors have been shown to have different effects. Type 1 receptors were responsible for sedation and anterograde amnesia, whereas type 2 receptors mediated anxiolysis. It may be possible to develop selective subtype receptor agonists to provide anxiolysis without sedation, amnesia, or dependence.

The general pharmacologic effects of BZDs are sedation, anxiolysis, euphoria (limbic system), reduced skeletal muscle tone (through spinal BZD receptors), anticonvulsant properties, and neuroendocrine effects. They impair acquisition and encoding of new information, providing anterograde amnesia. They do not have any analgesic properties. They have little direct effect on ICP. Their effects are dose dependent. Patient cofactors including age, concurrent disease, and any cosedation therapy influence responses to BZDs. Paradoxical reactions are reported in which agitation rather than calming is observed.[61] In healthy patients, BZDs have few cardiovascular adverse effects, but in a sick, intensive care population, profound cardiovascular depression may be observed occasionally. BZDs should be used judiciously until the patient response is known.[62] Midazolam has been most often associated with this effect,[63] and research in dogs has shown both negative inotropy and chronotropy, especially when the sympathetic response has been abolished.[64] Clinical use is largely encompassed by discussion of the pharmacologic properties of diazepam, midazolam, and lorazepam.

Specific Benzodiazepines

Diazepam

The first widely used BZD in the ICU was diazepam. Because of its low solubility in water, it is available in the IV or IM form dissolved in propylene glycol. This formulation causes a significant amount of pain and thrombophlebitis with peripheral IV use. A lipid emulsion that has fewer adverse effects is available in the United Kingdom. Diazepam is inexpensive and is effective for short-term sedation; in such cases, accumulation is less of a concern. Diazepam may be given orally because it has good absorption, but absorption tends to be erratic when it is given rectally or intramuscularly. It is highly lipid soluble with a long half-life (24 hours). Metabolism by oxidative biotransformation generates several hypnotically active metabolites with an elimination half-life that may be longer than diazepam, including oxazepam (half-life, 10 hours) and n-dimethyldiazepam (half-life, 93 hours). Delayed recovery has been reported in neonates after they received diazepam,

possibly because of the long half-life of dimethyldiazepam.[65] Prolongation of effects occurs in patients when clearance is reduced because of hepatic dysfunction and when metabolism is inhibited by drugs such as cimetidine and omeprazole.

Midazolam

Midazolam is an imidazobenzodiazepine. It has a short elimination half-life of 2 hours and is water soluble, which means that IV injection is nonirritating. Because of these factors, it has become popular in ICUs for sedation by infusion. Intranasally (0.2 mg/kg), midazolam has proven to be as effective at controlling febrile seizures as IV diazepam (0.3 mg/kg).[66] It has extensive first-pass metabolism and provides less reliable results when given PO, although this route is often successfully used for premedication of children before general anesthesia in doses of 0.5 to 0.75 mg/kg (maximum, 20 mg). It is available in a pleasant-tasting cherry syrup and is effective in 10 to 15 minutes, providing up to 1 hour of adequate anxiolysis, although residual hangover effects may persist.[67] Rectal and sublingual administration has been described.

Midazolam is about eight times more potent than diazepam, with starting dose recommendations of a bolus dose of 0.05 to 0.1 mg/kg[68] and an infusion of 1 to 6 μg/kg/min. Midazolam is metabolized by the cytochrome P450 system subfamily IIIA (nifedipine oxidase), polypeptide 4 (CYP3A4),[69] to hydroxymidazolam (63% potency) and hydroxymidazolam glucuronide (9% potency). Because of the high degree of protein binding (94% protein bound), the free level can be significantly changed with interactions because of the protein binding, which also may occur with heparin. Hepatic or renal failure increases the free fraction by two to three times, and its effect also can be prolonged by the accumulation of active metabolites.[70] The half-life of midazolam in patients in the ICU may be prolonged compared with that in healthy patients.[71] With short-term infusions (<12 hours), it retains a rapid recovery; however, with increased duration of use, the recovery becomes prolonged. Its clearance may be reduced by several commonly used ICU drugs, including calcium channel blockers, erythromycin, and triazole antifungal agents.[72]

Lorazepam

Lorazepam is an alternative water-soluble agent that is well absorbed after both oral and IM administration.[73] It produces sedation for 4 to 8 hours after a single dose. Lorazepam has a slower onset than does midazolam. The elimination half-life is about 14 hours. Metabolism is by glucuronyl transferase, not the cytochrome P450, and there are no active metabolites. This metabolism is unaffected by cimetidine or phenobarbital, which only affects oxidative metabolic pathways. Sodium valproate may inhibit its metabolism.[74] In persons with advanced liver disease, these phase II glucuronidation reactions are better preserved, and the increased half-life seen is due to increases in the volume of distribution rather than to reduced clearance. In patients with renal failure, prolonged half-life is also due to reduced protein binding because clearance is unchanged. No change in metabolism occurs with aging or critical illness. In a comparison of infusions of midazolam and lorazepam, the recovery characteristics were found to be significantly different. In patients receiving lorazepam, it took an average of 260 minutes to return to baseline, whereas in patients receiving midazolam, it took more than six times longer to return to baseline. Lorazepam may be administered by bolus (0.05 to 0.1 mg/kg every 2 to 4 hours) or by infusion (0.05 mg/kg/h). Lorazepam is slightly less expensive than is midazolam.[75] It has been recommended as the BZD of choice for long-term sedation because of its more predictable recovery profile in sick patients in the ICU. Lorazepam for IV use has propylene glycol as a carrier. Risk of a metabolic lactic acidosis exists because of the metabolism of this carrier. Cases of fatal metabolic acidosis from propylene glycol have been reported in neonates taking a particular vitamin preparation. Several other potential ICU drugs may use propylene glycol as a carrier, including some IV preparations of phenytoin and phenobarbital, nitroglycerin, digoxin, and etomidate. Reports of propylene glycol toxicity in adults who received multiple propylene glycol infusions have been made.[76] Care should be taken when lorazepam is infused in patients who receive these other medications. In patients in the PICU, propylene glycol levels have been shown to correlate with the dose of lorazepam received; however, no metabolic abnormalities were detected.[77] Hemodialysis has been used successfully in the management of the lorazepam-associated propylene glycol toxicity.[78]

The metabolisms of different BZDs are intertwined with each other. Most of the agents require an oxidative process first with potentially active compounds before glucuronidation and excretion. The pharmacokinetics for different BZDs is shown in Table 123-8.

Tolerance and Dependence to the Benzodiazepines

Tolerance for and dependence on BZDs can occur as with opiates in the PICU.[79] This effect is not all due to receptor number downregulation.[80] Withdrawal symptoms may be avoided with a slow taper of the medication of 10% per day or by substituting a long-acting oral agent such as diazepam. Acute withdrawal symptoms may include anxiety, insomnia, nightmares, seizures, psychosis, and hyperpyrexia. A postmidazolam infusion phenomenon has been described that includes poor social interaction, decreased eye contact, and a decreased interest in the surroundings. The patient may exhibit choreoathetotic movements with dystonic posturing that can persist for 2 to 4 weeks but will resolve with no sequelae.

Flumazenil

Flumazenil is an imidazobenzodiazepine and is a specific competitive antagonist of the BZD receptor. It has no effect on other drugs such as barbiturates, ethanol, or other GABA-mimetic agents. Flumazenil reverses the hypnotic and sedative effects of BZDs. It has a half-life of approximately 1 hour after a single IV bolus. In patients with hepatic impairment, its half-life and clearance are prolonged, and a significant increase (>50%) of free drug occurs because of reduced plasma protein binding. Renal failure has little effect on the pharmacokinetics of flumazenil. It is indicated for the complete or partial reversal of the central sedative effects of BZDs. Contraindications include patients who have a known hypersensitivity to BZDs, patients with epilepsy who are receiving treatment with BZDs, and persons who have overdosed with a tricyclic antidepressant. The use of flumazenil is often associated with mild to moderate tachycardia and hypertension.

In cases of multiple drug overdose, the use of flumazenil remains controversial. It often is overused in the emergency setting without due concern for potential adverse reactions[81] because of the potential toxic effects (e.g., cardiac arrhythmias or convulsions) of other psychotropic drugs ingested. The toxicity of tricyclic antidepressants becomes apparent as the effects of BZDs are antagonized. Patients should be evaluated for the signs and symptoms of a tricyclic antidepressant overdose; an electrocardiogram (ECG) may be helpful in determining the risks involved.

The dosing information for pediatric patients is limited. The initial suggested dose is 0.01 mg/kg (maximum, 0.2 mg) with incremental doses of 0.005 to 0.01 mg/kg (maximum, 0.2 mg) given every minute up to a maximum cumulative dose of 1 mg. The lower doses are suggested for sedation reversal and the higher doses for BZD overdose. Infusions at 0.05 to 0.01 mg/kg/h have been used.[82] The use of flumazenil in sedated patients in the ICU should be tempered by the potential for an unrecognized BZD dependence, which would increase the risks of adverse effects. If its use is required, then a carefully titrated dose would be appropriate. The half-life of flumazenil is much shorter than that of some of the BZDs it may be counteracting (see Table 123-8). The use of an infusion may be necessary because resedation has been reported after single-bolus use.[83] However, this requirement should not preclude the use of flumazenil in an ICU setting.[84] Flumazenil has been used for the reversal of moderate sedation. In the pediatric population, although it was well tolerated, it was not shown to significantly reduce recovery time.[85] Because flumazenil has a limited duration with the potential for resedation after discharge from medical care, an appropriate period of observation is required before discharge. A study in which researchers monitored the effects of flumazenil after sedation indicated that some of the residual effects of midazolam were still present after reversal.[86] Flumazenil also has been used to treat a paradoxical midazolam reaction[87] and has been shown to be effective in the management of hepatic encephalopathy or hyperammoneamia.[88] A Cochrane Collaboration review of articles pertaining to flumazenil use demonstrated a short-term improvement in hepatic encephalopathy. However, no improvement in recovery or survival was documented. No serious adverse effects were noted.

Chloral Hydrate

Chloral hydrate is a widely used oral hypnotic/sedative agent. It has been used for sedation for radiographic procedures, for EEGs, and in many different health care locations. It was first synthesized in 1832 and used in 1869 as a hypnotic agent. Shortly after, reports of acute and chronic toxicity were published.[89] In 1910, it was labeled as the most dangerous of hypnotics even though heroin and opium were in common use at that time. The addition of ethanol potentiates its effect (street name "Mickey Finn"). It has been used to control agitation in the intensive care nursery and to treat sleep difficulties in older patients.

Chloral hydrate is rapidly and completely absorbed from the GI tract and is immediately converted into the active component, trichloroethanol (TCE), by alcohol dehydrogenase.[90] The plasma levels peaks at 30 to 60 minutes. TCE is 45% protein bound. TCE undergoes glucuronidation with some oxidation to trichloroacetate (TCA). The half-life of TCE is 8 to 12 hours, while that of TCA is 67 hours. In infants and neonates this may be increased by a magnitude of three to four. With multiple dosing, a significant potential exists for accumulation. TCA can displace bound bilirubin from albumin. Its actions include CNS depression with drowsiness and sleep in less than an hour. With an overdose, the patient falls into a deep stupor or coma, and the pupils change from contracted to dilated. At therapeutic levels, the blood pressure and respiratory rate are unaffected. Chloral hydrate has little hangover effect. It has several effects on the cardiovascular system including decreased myocardial contractility, a shortened refractory period, and an increased sensitivity of the heart to catecholamines. It also has effects on mucous membranes. Irritation can cause gastritis, nausea, and vomiting. With overdose, a severe hemorrhagic gastritis with gastric necrosis and esophagitis has been described. Chloral hydrate and ethanol interfere with one another's metabolism through competition for alcohol dehydrogenase. Also, ethanol inhibits the conjugation of TCE, and TCE inhibits the oxidation of ethanol. Coumadin activity may be increased by chloral hydrate. Chloral hydrate is synergistic with other sedative agents. In children receiving amphetamine-based medication, chloral hydrate is contraindicated because there have been rare reports of arrhythmias. The reversal of chloral hydrate with flumazenil has been described; however, a report of ventricular tachycardia with this combination also has been made.

Chloral hydrate is available as capsules, syrup (50 mg/mL), and suppositories. The sedative dose is 25 to 50 mg/kg (PO/by way of the rectum), while up to 100 mg/kg can be safely used in children younger than 5 years with a maximum dose of 1 g. Because of an increased half-life, neonatal dosing should be lower (25 mg/kg). In preterm babies, toxicity resulted when chloral hydrate was used for 3 days; in term babies toxicity resulted when it was used for 7 days. The therapeutic level for TCE is 2 to 12 μg/L; toxicity occurs when the level is more than 25 μg/L. Chloral hydrate provides successful moderate sedation in approximately 90% of patients, but it appears to be less effective in patients older than 2 years. A higher risk of failure with excessive effect can be seen in patients with a history of obstructive sleep apnea or encephalopathy.

Signs of toxicity are usually noted within 3 hours of dosing. Paradoxical excitement also has been described in 6% of patients. There is some evidence that chloral hydrate may be genotoxic and carcinogenic. Mice studies have shown that a single-dose exposure can result in an increased risk of hepatic carcinomas and adenomas.[91] Chloral hydrate overdose produces a clinical picture that is similar to acute barbiturate poisoning. Ataxia, lethargy, and coma occur within 1 to 2 hours. Also, a pearlike odor may be noted. Cardiovascular instability poses the main threat to life. Severe arrhythmias including atrial fibrillation, supraventricular tachyarrhythmia, ventricular tachyarrhythmia, torsades de pointes, and ventricular fibrillation have been described. Chronic use can cause a dependence syndrome. Also, chloral hydrate is not detectable in the blood. TCE levels are measurable, but they are not useful for clinical management, although they can be helpful for retrospective diagnosis. The management of toxicity includes evaluation and monitoring at a medical facility if an amount greater than 50 mg/kg or an unknown amount has been ingested. Two capsules may cause significant toxicity in a toddler, so there is little room for error in the history. Charcoal with intubation should be considered if significant

toxicity is suspected. Standard antiarrhythmic management is often unsuccessful, although esmolol, overdrive pacing, and hemoperfusion have been tried.

Other Agents for Sedation in the PICU Patient

Butyrophenones and Phenothiazines

Haloperidol

Butyrophenones belong to the group of major tranquilizers. Haloperidol is a potent antipsychotic agent with nonspecific dopamine antagonist action. It has little effect on the cardiovascular or respiratory systems. It produces the appearance of calm with minimal hypnotic effect and reduces operant behavior (purposeful movement). The patient appears tranquil and dissociated from surroundings but is readily accessible if spoken to. Haloperidol may mask actual feelings of mental restlessness. It is a potent antiemetic agent (action at the chemotrigger zone) and has no appreciable effect on the EEG. It potentiates analgesics and other sedative agents. Compared with less potent butyrophenones, it has fewer adverse effects. Neuroleptanalgesia, a dissociative form of anesthesia, can be induced when haloperidol is combined with high-dose opiates. This anesthetic state is useful for certain cardiac and neurosurgical procedures that require cardiovascular stability and a responsive patient. It is metabolized to inactive compounds with a half-life of 15 to 25 hours. It is highly protein bound. Hepatic dysfunction increases the half-life because of reduced clearance. Adverse effects include extrapyramidal signs, although acute dystonia is rare. Prolongation of the QT interval is possible with the subsequent risk of ventricular tachycardia.[92] Hepatic toxicity can occur but is rare. Haloperidol is indicated for the treatment of psychoses, Tourette's disorder, and severe behavioral problems in children. In the PICU it is used as a treatment for agitation in patients who are often unresponsive to other more commonly used agents. It also has proved to be effective as part of a sedative withdrawal strategy. Haloperidol is available as syrup, tablets, and an IM preparation. The usual dosage for agitation in children younger than 3 years is 0.01 to 0.03 mg/kg every 4 hours. The maximum daily dose is 0.15 mg/kg/day. Two IM preparations are available: the lactate is for repeated use, and the decanoate is a slow-release monthly formulation. Although not approved by the FDA, the IM lactate form has been given intravenously without problems.

Droperidol

Droperidol is faster acting than haloperidol with a shorter duration of action and a half-life of 2 hours. It is available as an approved IV formulation. With an IV bolus, mild hypotension occurs because of mild α-adrenergic receptor blockade. Droperidol is more sedating than haloperidol and may be used as a sedation adjunct to general anesthesia. It also is used in low doses (0.05 mg/kg) as an antiemetic agent. Concerns exist about the potential for droperidol to cause prolongation of the QT interval and result in ventricular tachycardia.[93]

Chlorpromazine

Chlorpromazine is a weaker antipsychotic agent with general CNS depressant activity. It has an antidopaminergic effect including extrapyramidal adverse effects, lethargy, and apathy with an EEG similar to that of normal sleep. It also causes a decrease in the body's ability to maintain temperature control, shivering is reduced, and it can be useful in patients in hypothermic-induced states. Cardiovascular effects include α-adrenergic receptor blockade with hypotension and postural hypotension, but no effect is seen on the ECG. Respiratory drive and depth are unaffected; however, some dryness of the mucosa may be noted. In the GI tract, its anticholinergic effect causes a decrease in secretions and motility. Liver effects include jaundice, which occurs in 0.5% (recurrence rate, 40%), independent of dose or duration of therapy, and is associated with a rash, fever, and eosinophilia. This syndrome has a low mortality rate and usually resolves quickly upon discontinuation of chlorpromazine. Other effects include antihistamine-like action; local analgesia; a temporary leukopenia; and, rarely, agranulocytosis. Chlorpromazine also has antiemetic properties. Indications include premedication, sedation as part of the lytic cocktail catheterization mixture number 3 (CM3),[94] intractable pain, antipsychosis, treatment of hiccoughs, prevention of succinylcholine pain, and induction of hypothermia (with other active measures). Dosing (0.05-1 mg/kg every 6 hours) may be via the PO, IM, IV, or rectal routes. Chlorpromazine is metabolized both in the gut wall and by the liver. It yields more than 50 metabolites, most of which are inactive.

Other phenothiazine derivatives include prochlorperazine, which has mainly antiemetic properties. Extrapyramidal adverse effects are more common in children younger than 5 years. Dosage is a PO or rectal dose of 0.4 mg/kg every 8 hours and an IM or IV dose of 0.15 mg/kg.

The Lytic Cocktail

The lytic cocktail (CM3) is a mixture of 25 mg/mL of meperidine, 6.5 mg/mL of promethazine, and 6.5 mg/mL of chlorpromazine. Its recommended dose is 0.1 mL/kg of body weight, but significant institutional variations exist. The CM3 was popular as sedation for cardiac catheterization. However, CM3 has been reported to have a high failure rate and lacks several important characteristics of an ideal sedative for children. Dosing cannot be titrated easily and individually. Onset of action is delayed (30 minutes), and duration of effect is protracted (5 to 20 hours). CM3 has no anxiolytic or amnestic properties. Additional caution should also be exercised when this cocktail is used in children with seizure disorders. The metabolite of meperidine and the lowered seizure threshold from the chlorpromazine put the patient at risk. Patients with congenital heart disease with physiologic conditions such as a tetralogy of Fallot or left ventricular outflow obstruction may be put at risk because of systemic vasodilation that causes altered blood flow through shunts, a hypercyanotic spell, or decreased coronary blood flow due to diastolic hypotension.

Neuroleptic Malignant Syndrome

Both the butyrophenones and the phenothiazines have a rare but well-described adverse effect called the neuroleptic malignant syndrome. It is a cluster of adverse effects of antipsychotic medications first described in 1968. It involves the development of hypertonicity with autonomic instability, fever, and cognitive disturbance. The incidence is 0.5% to 1.4% of patients exposed to neuroleptic agents. The true

incidence in children is unknown, however. Several different diagnostic criteria are available. Fever and rigidity present in all cases; other symptoms are shown in Box 123-2. A variety of therapies have been described (Table 123-9).

Baclofen

Baclofen is a p-chlorophenol derivative of GABA analog that has specific agonist activity at the $GABA_B$ receptor. It has a half-life of 2 to 6 hours. Baclofen has inhibitory effects on the brain and spinal cord. At the spinal cord level it suppresses spinal reflexes to result in muscle relaxation. It is widely used as a skeletal muscle relaxant in patients with spasticity, such as cerebral palsy, spinal cord injury, and multiple sclerosis. It is most frequently given PO. Adverse effects include urinary retention, sedation, bradycardia, hypotension, respiratory depression, and apnea. Weakness may limit patient compliance. These side effects are sedative-like characteristics of the drug, which are not useful in clinical practice. Therefore abrupt cessation of long-term baclofen therapy resembles, in part, short-term sedative withdrawal.

Recently, intrathecal baclofen (ITB) has been used with increasing frequency in children to treat spasticity. ITB was first introduced in 1984[95] with a pump delivery system that was available in 1992 for adults. This system allows delivery of the drug to the spinal cord and reduces the dose significantly (1% of oral requirements), limiting systemic adverse effects.[96] Baclofen inhibits the release of serotonin in the brainstem. After long-term use there is accommodation of the serotonin pathways to this long-term inhibition that is consistent with the usually observed increasing doses required for ITB during the first 12 to 18 months of treatment. When this inhibition is abruptly removed, sudden excess release of serotonin occurs. Acute overload of serotonin transmission, such as an overdose of serotonin reuptake inhibitors, can result in confusion, hyperthermia, myoclonus, and autonomic instability. It also has anticholinergic and antihistamine effects that may result in drowsiness; paradoxical excitation has been reported in children. More than 25 case reports[97] of ITB withdrawal have now been reported. ITB withdrawal seems to be more severe if the ITB treatment was for more than 1 year. A review of ITB pumps in 100 patients at a single center[98] has shown that problems with the delivery system are fairly common. Twenty-four percent of patients experienced a problem, with a follow-up period for a maximum of 5.6 years. An average of two problems per patient was reported. Disconnection of the catheter from the implanted pump was the most common problem. Access ports on the pump seemed to increase the risk of problems (16% compared with a 2% disconnection rate); however, these ports make troubleshooting easier. Causes of difficulty with ITB delivery are shown in Box 123-3.

The ITB withdrawal syndrome is interesting because it appears to have many similarities with the neuroleptic malignant syndrome. Prolonged muscle contraction caused by rebound spasticity results in thermogenesis, hyperthermia, and rhabdomyolysis.[99] Patients with ITB withdrawal often are managed initially with broad-spectrum antibiotics as if they have sepsis and multisystem organ failure, with no improvement in

the clinical situation.[100] This treatment results in a delay of the diagnosis of ITB withdrawal. The differential diagnosis of the hypermetabolic state is listed in Box 123-4. The symptoms of ITB withdrawal can be classified into three categories (Table 123-10). Often the first clinical signs are the development of itching and some increase in spasticity. If replacement baclofen is not given, then the symptoms may progress to a severe hypermetabolic state that can be fatal if the cause is not recognized and treated. Of 27 patients reported to the FDA, six deaths were documented.[101] The management of ITB withdrawal requires early diagnosis. It involves supportive ICU care and the onset of baclofen replacement therapy as soon as possible. Box 123-5 provides a guideline for the evaluation of the patient with suspected baclofen withdrawal. A definitive diagnosis may be obtained with measurement of cerebrospinal fluid baclofen levels, but the results probably are not going to be available in the time course of treatment initiation. Although the primary aim should be to replace baclofen, rapid replacement of ITB may not be possible. The required oral baclofen replacement dose may be 50 to 100 times the intrathecal dose, and this dose often is not well tolerated by patients because of adverse effects. IV administration of a BZD should be the initial step in the treatment of baclofen withdrawal. Dantrolene has been used as an adjunct therapy for the increased spasticity.

The use of the potent serotonin antagonist cyproheptadine has been proposed as an alternative treatment adjunct.[102] It improved fever, spasticity, and itching in adult patients with gout who had ITB withdrawal. Dosages of cyproheptadine were in the range of 0.25 mg/kg/day every 6 hours, either PO or IM. In some patients the ITB withdrawal is an elective management problem due to pump removal for infection. In these patients, if a replacement pump cannot be placed, the patient needs to be observed and managed in the ICU to recognize and treat the withdrawal syndrome. The monitoring of creatine phosphokinase (CPK) levels may be helpful in managing withdrawal. In the reported cases of ITB withdrawal, CPK levels have been in the range of 1800 to more than 40,000.[103] Mild elevations in CPK (300 to 500) may be an early marker of inadequate treatment.

Dexmedetomidine

Dexmedetomidine (Precedex) is a selective α_2 adrenergic agonist. It has an effect at receptors in the CNS and peripheral nervous system, as well as in autonomic ganglia. Stimulation of the α_2 receptor decreases the release of norepinephrine, inhibits sympathetic activity, and produces sedation, anxiolysis, and analgesia. It is 1600 times more active at the α_2 receptor than at the α_1 receptor and is thus eight times more selective than clonidine. It is available as a white water-soluble powder in a 100-μg vial. In adults it has a redistribution phase of 6 minutes and an elimination half-life of 2 hours. The pharmacokinetics appears to be similar in the pediatric patient, even after a 24-hour infusion.[104] It is almost completely metabolized in the liver by glucuronidation and P450 pathways to inactive metabolites. In patients with renal failure the pharmacokinetics did not show any prolongation of the terminal half-life; however, these patients were sedated for longer after the infusion was terminated compared with the control group.[105] The prolonged sedation may be related to reduced protein binding of this normally highly protein-bound drug (94%) and thus higher free drug levels in the patient with renal failure. In patients with hepatic dysfunction, reduced clearance has been reported. With patients in severe hepatic failure, a prolongation of the half-life almost three times longer than normal was reported.[106]

Dexmedetomidine has proved to be effective for sedation in the adult intensive care setting.[107] Currently it is only licensed for 24 hours of sedation, although approval for more

Table 123–10 Severity of ITB Withdrawal

Designation	Description
Mild	Pruritic symptoms and increased spasticity
Moderate	High fever, altered mental status, seizures and profound rigidity, autonomic instability
Severe	Rhabdomyolysis, hepatic, renal failure, DIC brain injury, death

DIC, Disseminated intravascular coagulation; *ITB*, intrathecal baclofen.

Box 123–5 Management of Suspected Baclofen Withdrawal

Suspicion in at-risk patients
Administer antipyretics and other cooling techniques for fever
Administer benzodiazepines for seizures or spasticity
Rule out medical causes
Oral baclofen therapy
Contact patient's ITB pump specialist to interrogate the pump and check the reservoir
Abdominal radiographs (anteroposterior/lateral) to check for catheter integrity
Neurosurgical consultation for possible surgical exploration and repair
If catheter appears intact on plain radiographs, consider performing a contrast catheter study to check for catheter integrity
If problem is unresolved, contact manufacturer

prolonged use is pending. The recommended dosage for dexmedetomidine is a loading dose of 1 μg/kg over 10 minutes followed by an infusion of 0.2 to 0.7 μg/kg/h. It appears that in pediatric patients, the higher end of the dose range is required. Doses higher than 1.5 μg/kg/h have not been shown to provide any further sedative action. Advantages of dexmedetomidine include minimal respiratory depression and predictable hemodynamic effects. Because of the reduced sympathetic activity, blood pressure and heart rate fall slightly. Clinical sedation trials have shown a decrease in heart rate of 7% and blood pressure by 10%. It has been infused before, during, and after the extubation process. Hypotension and bradycardia are more likely to occur during the loading phase, which may need to be prolonged or interrupted. Dexmedetomidine cannot be given by rapid IV bolus because hypertension may occur as a result of direct stimulation of α_1-adrenergic receptors. Mild transient hypertension is sometimes noted in adults during the loading phase, although this effect was not noticed in pediatric patients. Long-term use of dexmedetomidine (160 hours) also has now been reported,[108] with no evidence of accumulation. The concern about rebound hypertension after long-term α_2-adrenergic agonist treatment, such as that occurring with clonidine, has not been reported; however, anecdotal reports exist regarding withdrawal phenomena, including hypertension after prolonged infusions.

Sedation from dexmedetomidine often results in a patient who is tranquil yet easily aroused. Reduced analgesic requirements have been reported with its use. The easy arousal may make it a useful agent for when repeat neurologic examinations are required. Several articles concerning the use of dexmedetomidine in the PICU have recently been published. In a retrospective review of 121 patients from a mixed medical and surgical population in the PICU, a decrease of 20% in the dose of BDZ and/or opiates was documented in 80% of the children who received dexmedetomidine.[109] Bradycardia (12%) and hypotension (16%) requiring intervention was described. Another retrospective review of dexmedetomidine use (infused >36 hours) in 35 postoperative pediatric cardiac patients did not show any significant changes in cardiovascular parameters, but a reduction in the postoperative opiate requirements occurred with an equal level of sedation.[109a] At present, a pharmacokinetic phase 2 trial is in progress and a prospective phase 3 study is planned in the near future. These studies should help answer the questions regarding the metabolism, efficacy, and adverse effects of dexmedetomidine in the PICU population. This agent also has been safely used for a variety of noninvasive sedation procedures such as magnetic resonance imaging (MRI), and several cases have been reported of its use as an adjunct to general anesthesia for pediatric patients. It appears to be a useful agent in the management of opiate withdrawal. Furthermore, dexmedetomidine is useful for patients who are difficult to sedate, for treatment of postoperative shivering, and for postanesthesia agitation. Procedural sedation with intranasal (IN) dexmedetomidine also has been reported (dexmedetomidine, 2 μg/kg IN, along with IN sufentanil, 1 μg/kg). Twenty children sedated with IN dexmedetomidine underwent dental restorative treatment without any complications. Sedation onset took approximately 45 minutes with a recovery time of about 1 hour.

Dexmedetomidine is not without adverse effects. It is contraindicated in patients with heart block, and bradycardia has been reported in an infant treated with digoxin who received dexmedetomidine during the infusion phase.[110] It also would appear prudent to avoid its use with other drugs that can reduce arteriovenous node function such as β-blockers and calcium channel blockers, as well as with patients who have severe ventricular dysfunction or hypovolemia, because reduction in sympathetic tone may cause a profound decrease in blood pressure.

Table 123–11 Pharmacokinetics of Intravenous Anesthetic Agents

Drug	Elimination Half-Life (hr)	Volume Distribution (SS) (L/kg)	Clearance (mL/kg/min)	Protein Binding (%)

Ketamine	3.1	3.1	19.1	12
Propofol	1.9	2.3	30	96.8

SS, Steady state.

Propofol

Propofol is a rapid-acting IV anesthetic agent. As a highly lipid-soluble 2,6-diisopropylphenol, it is an oil and is insoluble in water. It is formulated as a 1% aqueous emulsion (1.2% egg phosphatide, 10% soyabean oil, 2.25% glycerol) with a propofol concentration of 10 mg/mL. A water-soluble prodrug form of propofol has been released recently, although no data are available regarding its use in children. Recovery from propofol is rapid because of its short redistribution half-life (α), and it is rapidly cleared by hepatic metabolism in healthy patients after short infusions, making it ideal for short procedures. The elimination half-life is 2 hours (Table 123-11), but the half-life is context sensitive and has been reported to be between 1 and 3 days after a 10-day infusion because of significant body accumulation. The kinetics follows a three-compartment model. The dose for induction of anesthesia in children is 2.5 mg/kg to 3.5 mg/kg; higher doses are required for infants and toddlers. Anesthesia also can be maintained by an infusion. The depth of sedation/anesthesia can be easily titrated, and an infusion rate of 25 to 150 μg/kg/min usually provides adequate sedation.

As with most sedative agents, propofol has adverse effects that may be a concern for the intensivist. It often causes hypotension in the sick child, and in patients dependent on high sympathetic tone to maintain normal blood pressure, even small doses of propofol may result in a significant decrease in blood pressure. The hypotension is mainly caused by vasodilatation, and there is little direct myocardial depressant. Bradycardia also can occur upon the induction of anesthesia. Propofol increases atrial conduction time for neonatal rabbits and prolongs the refractory period. Propofol anesthesia can prevent the induction of known atrial tachycardias in the electrophysiology laboratory, and cases have been reported of conversion of atrial tachycardia to sinus rhythm upon induction of propofol anesthesia. Propofol is a potent respiratory depressant, and it has a useful depressant effect on airway reflexes, which may facilitate endotracheal intubation. The injection of propofol often causes pain, and in the alert patient, strategies to minimize this effect are useful. Most commonly, lidocaine, either mixed with the propofol or injected before the injection of propofol, will markedly reduce the pain.

Propofol sedation in the ICU has several advantages. It acts rapidly and produces an easily controllable level of sedation. Unlike the barbiturates, it provides rapid clinical recovery, even after prolonged infusion. It has antiemetic properties and can provide transient deep sedation if required for procedures. It also has been shown to facilitate sedative synergy with BZDs.[111] In the adult ICU population, propofol has been compared with midazolam for long-term sedation. Both agents provide good sedation, but propofol has the advantage of being more titratable with a faster recovery.[112] Despite the increased drug cost, the use of propofol can reduce overall ICU costs because of a reduction in ventilator weaning time.[113]

Propofol has been used in the ICU as an anticonvulsant for patients with refractory status epilepticus.[114] In a comparison with pentobarbital to provide burst suppression, both drugs were equally effective. Propofol was much more rapid in effect; no difference was found in outcome or ICU support measurements or length of stay.[115] In patients with raised ICP, propofol has the same effects on ICP and cerebral blood flow (CBF) and cerebral metabolic rate of oxygen as barbiturates. It also requires a similar level of hemodynamic support to maintain appropriate blood pressure and cerebral perfusion pressure (CPP). It can produce the same degree of burst suppression that may be required for uncontrolled intracranial hypertension. It also allows rapid changes in the level of sedation, to facilitate neurologic examination. In this regard it is a superior agent. As described later, however, the use of large doses of propofol in the ICU setting may be associated with worsened outcomes.

Special Issue Regarding Long-Term Infusion of Propofol

Several important problems may occur when propofol is used in the PICU. With long-term propofol infusions, a significant amount of lipid may be infused into the patient, with the same consequences as lipid infusions used for hyperalimentation. Hyperlipidemia and triglyceridemia have been reported in up to 10% of patients receiving propofol in the ICU. Pseudohyponatremia or the inability to do routine plasma electrolyte analysis has been described. It is important that the propofol calorie (20 mL/h = 528 kcal/day)[116] and lipid load be included in the nutrition plan for the patient. It may be necessary to reduce enteral feeds or avoid intralipids in selected patients. With high propofol dosing, respiratory acidosis has been reported.[117] The emulsion used for propofol administration is an excellent culture medium at room temperature; cases have been reported of patients with systemic infection caused by propofol during operative procedures.[118] This infection is due to poor aseptic technique in the preparation and use of the propofol syringes and infusion lines. Unusual infective organisms were detected in several patients, and an epidemiological study by the Centers for Disease Control and Prevention found propofol to be the common element.[119] Certain precautions should be followed when propofol is used in the PICU. The staff should be educated to the potential dangers of infection from propofol. The ampule neck should be wiped with alcohol. There are no multidose vials of propofol. Syringes should be disposed of when they are more than 6 hours old, and lines should be changed every 12 hours. Filters are available that can remove many of the potential pathogens, and they are compatible with the lipid-based propofol infusion.

A few episodes of allergy to propofol have been reported; immune reactions, involve both anaphylactic and anaphylactoid types of reactions, are estimated at 1:45,000.[120] Although clinically indistinguishable, the anaphylactic response involves prior exposure to a component of the propofol suspension. Egg allergy has been considered a contraindication to its use. However, the egg phosphatide component found in propofol is not related to the major egg allergen protein ovalbumin.[121] In fact, intradermal testing with propofol in 25 patients allergic to eggs was negative; therefore, current evidence suggest that anaphylaxis is not more likely to develop in patients who are allergic to eggs when they are exposed to propofol. Propofol does not release histamine and is an acceptable agent for use in patients with asthma.

Several new generic formulations of propofol are available. These formulations include different antioxidants, such as metabisulfites, which may have an increased risk of allergic reaction. However, this increased risk has not been borne out.[122] They appear to be equal in efficacy and adverse effects to the propofol solution known by the brand name Diprivan. A new water-soluble prodrug, fos-propofol, has been approved by the FDA and is due for release soon. The onset of action of fos-propofol is significantly slower than for propofol (5 minutes), which may reduce the incidence of hypotension and respiratory depression. A few patients who receive propofol may have dark-green urine due to phenol metabolites; this effect is not a clinical concern.[123]

Propofol Infusion Syndrome

One of the most important concerns is the development of a refractory metabolic acidosis in children who had received propofol sedation in the ICU. This effect was first described in 1992 as a series of five cases[124] with fatal myocardial failure in children with respiratory illnesses requiring ventilation and sedation. Five young patients from different ICUs had croup and went on to have a refractory cardiac failure, bradycardia, and acidosis. A lipemic serum had developed in all patients. They had all received propofol at an average rate of about 8 mg/kg/h for more than 70 hours.

In review, the case reports were not as simple or as complete in their reporting, with several published letters[125] from physicians involved with these patients showing incomplete data in the reporting. Several other case reports of an apparently similar clinical course were then subsequently described in the literature, which was enough evidence for the Committee on Safety of Medicines in the United Kingdom to issue a warning on propofol and its use in pediatric patients. At that time the FDA could not find a causal link between propofol and the deaths in children and did not issue a warning.

This reaction to propofol came to be known as the propofol infusion syndrome (PRIS).[126] It is the sudden or relatively sudden onset of a marked bradycardia resistant to treatment with a least one of the following signs: lipemia, enlarged liver, severe metabolic acidosis, or rhabdomyolysis.

PRIS is unlikely to be due to the carrier emulsion because intralipid has been used extensively in severely ill patients without problems. The propofol metabolites are acidic, highly water soluble, and have a short half-life.

A steady number of case reports of this syndrome have appeared in the literature since the initial description, as well as a couple of studies involving several hundred patients[127,128]

who have not shown any problem with propofol in the PICU. In these studies, lower doses of propofol (4 mg/kg/h) were used, with regular monitoring of the acid base status and triglyceride levels. "Propofol bashing" became popular.[129] There are few drugs that are licensed specifically for the PICU, however, and proper trials are needed to avoid drugs being condemned as hearsay. Subsequently, a randomized, controlled trial of propofol was begun, and after its use in 327 patients, it was reviewed by the FDA.[130] The study was never published, but researchers found that, despite similar pediatric risk of mortality scores, patients who had received either 1% or 2% propofol preparations had a two to three times greater risk of death compared with the control sedative group. This finding led to a letter from AstraZeneca reminding health care workers that propofol was not approved for sedation of pediatric patients.[131]

Much debate still occurs regarding whether there is a safe infusion rate or duration of infusion for propofol in the PICU setting. It has been estimated that a study to show a significant increase in death would require 7000 patients, which would be difficult to accomplish.

PRIS has also now been described in adult patients.[132] These patients had similar cardiac and metabolic findings, often associated with the management of intracranial hypertension. PRIS appeared to be a higher risk if the 2% formulation was used. Patients with raised ICP require deeper levels of sedation and require higher doses of propofol; they also are receiving vasopressor support to maintain the CPP, which puts a further stress on a myocardium that is already failing.

The pathophysiologic cause of PRIS is still poorly understood, but it appears to mimic mitochondrial myopathies. Such patients are generally well until stressed. Rhabdomyolysis and cardiac and hepatic failure then develop in these patients.[133] Case reports have shown some metabolic abnormalities that may be the cause of the cardiac failure and acidosis. One report describes a 10-month-old child who had the syndrome and was successfully treated with hemofiltration and plasmapheresis.[134] Muscle and liver biopsy specimens showed changes consistent with a toxic insult. Analysis also showed a reduction in the cytochrome C oxidase activity in the muscle, with a normal activity in skin fibroblasts, excluding an underlying respiratory chain defect. Profound acidosis with lactic acidosis is found in different types of genetically acquired cytochrome oxidase deficiency. It was postulated that the hemofiltration removed a water-soluble metabolite of propofol that had caused a reversible reduction in the oxidase activity. A second case report[135] also showed a metabolic abnormality. Elevated levels of malonylcarnitine and C5-acyl carnitine were found in a patient with PRIS. This patient was also treated successfully with hemofiltration. These findings are consistent with impaired fatty acid oxidation due to impaired entry of long chain fatty acids into the mitochondria and a failure of the respiratory chain. A review of the pathophysiologic function of the syndrome[136] suggested that propofol increases the activity of malonyl coenzyme A, which inhibits the carnitine palmityl transferase I, so long chain fatty acids cannot enter the mitochondria. Propofol also uncouples oxidation, so the short and medium chain fatty acids cannot be used, even though they have entered the mitochondria and also may inhibit the respiratory chain. Low energy production leads to cardiac and peripheral muscle necrosis.

In pediatric patients it has been suggested that an inadequate calorific intake coupled with a high metabolic demand requires a fully active fatty acid oxidation capacity. Propofol may inhibit this pathway and cause a cellular metabolic failure syndrome to develop. Children have lower glycogen stores and often require higher doses of sedative agents; thus the syndrome is more likely to occur in pediatric patients. A carbohydrate intake of 6 to 8 mg/kg/min should be enough to suppress fat metabolism in the critically ill child. Also, concerns have been raised about the influence of catecholamines and steroids in the development of the syndrome, especially in the adult population.

Propofol is still frequently used for procedural and short-term sedation,[137] but in a recent case report, researchers describe a patient who had PRIS.[138] The patient had received a propofol infusion for 15 hours at 20 mg/kg/h. After a 13-hour propofol-free period, an 8-hour infusion of propofol at 4 mg/kg/h was given, after which the patient had intractable bradycardia and acidosis. This report raises concerns about high-dose, short-term propofol use in the PICU.

In a report on the use of propofol for two cases of refractory status epilepticus, patients aged 7 and 17 years had features similar to the PRIS.[139] Status epilepticus itself can result in neurologic deficit, hypoxia, rhabdomyolysis, cardiac arrhythmias, hyperthermia, metabolic acidosis, acute renal failure, and death. However, these patients received high doses of propofol (18 to 27 mg/kg/h) to achieve burst suppression for more than 48 hours. Rhabdomyolysis and cardiac failure developed in both patients. No monitoring of lipid status or acid base was performed, and propofol was used as the sole agent by practitioners with limited experience with this drug. In light of the reports now appearing in the adult neurointensive care literature with the development of a propofol infusionlike syndrome in adult neurosurgical patients,[140] it would appear that propofol is not the best choice for prolonged sedation for patients with intracranial hypertension. An early indicator of the cardiac instability from PRIS may be changes in the ECG. It has been reported that the development of a right bundle-branch block with convex ST elevation was an early sign of this syndrome.[141]

Propofol remains a useful agent for procedural sedation in the PICU. When compared with midazolam and ketamine, propofol resulted in safe, effective sedation. The patients sedated with propofol awakened almost twice as fast; thus the efficiency of the sedation service was also improved.[142] Propofol is also probably appropriate for overnight sedation, and higher doses should be avoided. It probably should not be used as a solo agent because in those cases tolerance appears to develop more rapidly. If its use is required for a prolonged period, then careful consideration should be given to its risks and benefits. A recent study showed that staff members of some PICUs are still using long-term high doses despite the potential risks involved.[143] Prevention of PRIS could include adequate calorific intake. The dose and duration of propofol should be carefully managed to minimize its use. It would appear from the reports of PRIS in the neurosurgical population that the desire for rapid awakening has propagated the use of propofol coma, rather than using barbiturates. Regular monitoring of the cardiac function, ECG, and CPK are warranted; lipid profile and acid base status may help in early detection. However, these steps may not necessarily prevent mortality from the syndrome.[144] Treatment should

Table 123–12 Features Reported for PRIS, Incidence, and Score

be immediate cessation of propofol. Cardiac support may be difficult because of unresponsiveness to conventional circulatory support. The use of pacing and extracorporeal membrane oxygenation has been reported. Hemodialysis or hemofiltration have been reported as having some success.

An outcome prediction table has been developed for PRIS based on more than 1000 reports from the FDA's Medwatch program, of which 20% were pediatric patients.[145] The features associated with PRIS are shown in Table 123-12. In addition to the individual features, there were several additional scores depending on a combination of features (see Table 123-12). The predicted outcome from these scores is shown in Table 123-13. These predicted outcomes were very close to the actual reported mortality of the analyzed cohort. No independent verification exists at present. However, this article does highlight the variability in features of the PRIS and accounts for the differences in the reported mortality.

Sedation and Analgesia for Procedures

Many procedures performed on children involve pain and anxiety. In many hospitals the administration of sedation and analgesia falls to the pediatric intensive care physician.[146] The pediatric intensive care physician needs to be familiar with guidelines and protocols that are used for moderate sedation outside the ICU setting. Procedural pain accounts for most of the pain experienced by children with malignancies,[147] and many pediatric patients with trauma will require sedation for procedures such as correction in the emergency department of fractured limbs and lacerations.

Table 123–14 States of Altered Consciousness

Designation	Description
1	Minimal sedation (anxiolysis)
2	Moderate sedation/analgesia ("conscious sedation")
3	Deep sedation/analgesia
	General anesthesia

Conscious sedation, now commonly called moderate sedation or more appropriately procedural sedation, is a medically controlled state of depressed consciousness whereby the patient remains responsive to verbal stimuli or, at most, a gentle shaking of the shoulder.[148] It anticipates that protective reflexes will be maintained and that the patient retains a patent airway independently. Neither airway patency nor airway protection should be taken for granted because patients with conditions such as obstructive sleep apnea may obstruct their airway with little sedation and aspiration of food can occur even without sedation. Before moderate sedation is further explored, the insightful words spoken by Burton Epstein, in his "40th Rovenstine Lecture of the ASA" in the fall of 2002, should be considered: "The myth . . . of the achievability of a state of conscious sedation in which pediatric patients are simultaneously responsive to voice stimulus while immobile in the face of pain is just that—a myth."[149] A little consideration will reveal that for painless procedures, anxiolysis will most likely suffice, whereas for painful procedures, pharmacologic elimination of the response to pain will result in a need for general anesthesia. Between these two extremes, the use of local anesthetic agents may modify the response so as to allow potentially painful procedures to be performed during moderate sedation. Another factor to consider is the effect of variation in the level of stimulation, whereby sedation titrated to effect during a painful stimulus becomes excessive once the stimulus is completed. Thus the practitioner treads on a narrow and sometimes impossible pathway when giving moderate sedation. The state of moderate sedation is part of a continuum (Table 123-14) defined by the working groups of the American Academy of Pediatrics (AAP) and the American Society of Anesthesiology (ASA),[150] which encompasses a range from anxiolysis to general anesthesia that is appropriate for surgery. This continuum is difficult to control, and staff administering moderate sedation must be able to appropriately manage any patients who enter a deeper level of sedation than that planned. The goals of sedation are shown in Box 123-6. It is helpful to think of moderate sedation as consisting of several components. A balanced sedation technique will involve amnesia, analgesia, relaxation, and inattention. Different procedures require different degrees of these components (Table 123-15).

Types of Procedures and Preprocedure Evaluation

In many instances sedation may be beneficial in the PICU, such as for the placement of central lines and centesis tubes and during dressing changes. Sedation facilitates the procedure in uncooperative patients and allows long or uncomfortable procedures to be performed. Outside the ICU, both

noninvasive and invasive radiologic examinations[151,152] often require sedation (Box 123-7).

Safety with moderate sedation is largely determined by careful assessment and management of the airway, together with precautions to prevent aspiration of gastric contents. Adequacy of sedation largely depends on appropriate patient selection, the combination of the patients' known medical conditions, past sedation experience, and the nature (particularly pain) of the patients' procedures, coupled with appropriate drug selection. Moderate sedation may be better tolerated than deep sedation or general anesthesia when hemodynamic stability is compromised because many sedative and anesthesia agents induce cardiovascular instability such as vasodilation or myocardial depression. Furthermore, the ability to monitor the patient's neurologic status during the procedure through conversation or instruction may be helpful, especially during invasive neuroradiologic procedures. Moderate sedation may allow an earlier discharge because less sedative is being used and may make the procedure, which would usually require the full operating room environment, possible outside of the operating room.

All patients should be assessed before moderate sedation. Box 123-8 lists the elements that should be included in the assessment. The medical history should include evaluation of the cardiorespiratory system, any history of gastroesophageal reflux, and any previous sedation attempt that failed or any abnormal reaction to sedation. A recent asthmatic attack or

III	A patient with severe or poorly controlled disease state
IV	A patient with severe disease state that is a constant threat to life
V	A moribund patient who is not expected to survive without surgery

respiratory tract infection, poorly controlled seizure disorder, or diabetes may require a change or postponement of the sedation plan. It is recommended that patients be classified according to the ASA preoperative patient classification (Table 123-16). In most circumstances it is generally recommended that patients in ASA class VI and some in class III are not suitable for moderate sedation.

It is prudent to adopt the same guidelines that are used before general anesthesia is administered, in case sedation that is deeper than anticipated occurs. These guidelines are age dependent, and current recommendations are shown in Table 123-17. Despite this, less caution is often reported regarding fasting, without any apparent worsening of outcome. For example, in a survey of 450 radiology departments, 35% had no nothing by mouth (NPO) status requirement for neonates, and 17% used a 2-hour NPO status requirement for infants. For oral contrast studies, most departments sedated the patient within 1 hour of the contrast being swallowed.[153] Consent should be obtained as with any medically indicated procedure or intervention. It should include discussion about the risks and benefits of the procedure and the sedation technique, as well as expectations of outcome and alternatives to the procedure and sedation.

The presedation interview for outpatients or non-ICU patients also should involve giving instructions and information to a responsible person, including postsedation instructions, a 24-hour phone contact phone number, guidelines concerning limitations of activity, and expected postsedation behavior. If moderate sedation is provided for nonscheduled patients, a review of several aspects is important (Box 123-9).

Monitoring During the Procedure

Sedation provided outside the ICU should be performed in a facility/area with the appropriately trained support staff. The staff should have had appropriate training with respect to pharmacology, monitoring, resuscitation (basic and advanced life support), emergency drugs, and cardiac arrest protocols and medications. Advanced cardiac life support and pediatric advanced life support recommendations should be available to be followed.

Monitoring of patients undergoing moderate sedation is an important component of safe, effective sedation. Several different recommendations have been made by the Joint Commission on Accreditation of Healthcare Organizations,[154] the American Board of Anesthesiology, and the AAP. These recommendations have not yet been fully followed by persons providing sedation for children.[155] A study of pediatric dentists after publication by the AAP of its new recommendations found minimal monitoring and documentation of the sedation procedure. Obtaining baseline vital signs is important. Because of the possibility of oversedation, the level of consciousness should be assessed frequently, especially during titration of effect. This level of consciousness is best assessed with the Ramsay scale (see Table 123-1). A sedation record is important for documentation of the drugs used with times and doses and for the monitored measurements that are charted on a time-based record. Monitoring should include pulse oximetry for assessment of the degree of oxygenation and heart rate. The saturation should be maintained by supplemental oxygen. Breathing can be assessed either by monitoring the respiratory rate or by capnography. The blood pressure should be checked at regular intervals during the procedure. A study of 85 pediatric patients with complications after sedation showed that most severe complications resulted from a common pathway involving respiratory depression

Box 123–10 Causes of Sedation Complications

Drug overdose
Inadequate monitoring—during and after
Lack of appropriate skills by staff administering the sedation
Lack of appropriate pharmacology knowledge

leading to respiratory arrest, cardiac arrest, and subsequent severe neurologic devastation. The most common causes for these complications are summarized in Box 123-10. There is no particular drug that is more likely to cause problems. Polypharmacy, especially with three or more drugs, has been shown to be a risk factor for pediatric sedation complications.[156] Dentists using nitrous oxide in combination with other agents appeared to have a higher incidence of problems. If long-acting drugs are used, the patient must be observed for an appropriate length of time. Several reports have been made of respiratory arrest occurring while the child was in the car seat on the way home. Any health care worker providing moderate sedation should be familiar with an emergency algorithm in case problems arise (Figure 123-4).

Many different pharmacologic options are available for moderate sedation in children. The oral route is commonly used in children; it has a slow onset time that avoids a rapid peak effect, but it also gives an unpredictable degree of sedation, which is not easy to titrate. IM administration is painful; however, it is useful in uncooperative patients. The rectal route is nearly always available and has found favor in the past for barbiturate sedation. More contemporaneously, rectal diazepam at 0.2 to 0.5 mg/kg has proved useful in the control of seizures when IV access is not available.[157] Onset can be fairly slow and the duration prolonged. The IV route offers a titratable effect but also adds the danger of acute overdose. The use of intranasal sedation administration has been reported for a variety of drugs. A disposable device such as the Mucosal Aerosol Device can be used. The Mucosal Aerosol Device attaches to a Luer lock syringe and has a soft cone insert for placement in the nares. It creates a fine spray that improves drug delivery and deposition onto the nasal mucosa. Another route of administration is transmucosal administration, such as the fentanyl "lollipop" (ACTIQ). Dosing recommendations are shown in Table 123-18. One must always keep in mind that BZD-opiate or barbiturate-opiate combinations are potent causes of respiratory depression, and extra monitoring and vigilance should be used. With IM and oral medications, adequate time should elapse to allow absorption before a further dose is given to avoid accidental overdose.

As noted in Table 123-15, different procedures require different qualities of sedation. These qualities are found in the array of drugs available to the intensivist (Table 123-19). It may be useful to choose the sedative agent or agents that best fit the particular requirements for the procedure being performed.

Opiate and BZD antagonists should be readily available wherever moderate sedation is being performed. Staff caring for these patients should understand the drug indications and dosing of these medications to reduce any potential delay in their appropriate use. They can quickly and effectively reverse the respiratory depression from excessive doses of sedation.

In some circumstances the services of the anesthesia department may be useful. The anesthesia department has access to other pharmacologic agents such as propofol and nitrous

oxide, as well as the inhalational agents. The ability to use a deeper level of sedation if required is easily obtained with these rapidly acting, short-acting agents. In emergency procedures where the patient's NPO status is unsafe or unknown, patients may need to undergo intubation to protect the airway.

Anesthesiologists have the ability to perform a "needle-less" sedation technique using a gas induction with anesthetic agents; an IV drip may be placed if required when the patient is asleep. This technique is especially useful for repeat procedures in oncology patients. Also, anesthesia personnel are better able to sedate patients whose illness may contraindicate routine moderate sedation protocols (Box 123-11).

Box 123–11 Patients Unsuitable for Moderate Sedation

Premature (<60 weeks' gestation)

GERD
Raised ICP
History of difficult sedation

BPD, Bronchopulmonary dysplasia; *COPD*, chronic obstructive pulmonary disease; *GERD*, gastroesophageal reflux disease; *ICP*, intracranial pressure.

Postprocedure Care and Monitoring

Care of the patient during the recovery period after moderate sedation is important. The patients must be monitored during recovery to ensure adverse events are rapidly recognized and treated. The recovery area should be equipped with appropriate monitors and resuscitation equipment and have a trained individual in attendance. The monitoring should be performed to the same degree as during the actual procedure. Level of consciousness and vital signs should be recorded at regular intervals. A physician who is responsible for the patient must be identifiable and must be easy to contact if required urgently. Patients may be discharged home when they are alert and orientated or when they have returned to baseline if baseline initial mental status was abnormal. Vital signs should be stable and within acceptable limits. A sufficient time should have elapsed if a reversal agent was used (2 hours). Patients should be discharged in the presence of a responsible adult to accompany them home and report any complications. Written instructions should be given to the parent concerning diet, medications, and activities, and a 24-hour contact telephone number also should be given to the parent.

Moderate sedation is safe and frequently used; unconscious sedation is potentially hazardous, and patients who undergo it require careful monitoring. Hospital protocols are useful for a smoothly run, safe sedation policy.[158] Staff should be appropriately trained in sedation and resuscitation basic and advanced life support. When the ASA/AAP recommendations are followed, the risks of a sedation-related complication can be reduced.[159] Individual risk factors include deep sedation and the use of chloral hydrate. When all the recommendations for moderate sedation, including NPO, ASA class, avoidance of deep sedation, sedation level monitoring, and drug use were followed, the adverse event rate was zero.

Sedation for Magnetic Resonance Imaging

The PICU physician is often called upon to provide sedation for a patient in the ICU who is undergoing MRI. Also, many institutions rely on the PICU team to provide a sedation service for other inpatients or outpatients undergoing MRI. Deep sedation is often required for effective sedation of younger children undergoing an MRI scan. The same standards should be adhered to as with any other child undergoing sedation[160] with respect to patient selection, monitoring, and postimaging care.

MRI is an imaging modality that is being increasingly used to aid in the diagnosis of neuroanatomic disorders. The patient is required to lie still within a small space while multiple images are obtained. MRI scanning is performed less rapidly than computed tomography (CT) scanning. Movement by the patient causes degradation of the image quality, and a change in the patient's position may affect the homogeneity of the magnetic field, which is optimized at the beginning of the scan. Studies can take from 45 minutes to more than 2 hours, with individual sequences taking 3 to 10 minutes. The scanner is noisy and the restriction on space and movement can induce claustrophobia in some patients. The patient also may experience a slight increase in temperature. Most adults and older children (older than 6 years) are capable of lying still for the scan. With the use of earplugs and music it is well tolerated. Several groups of patients, however, may require sedation[161] for the scan to be performed (Box 123-12).

Because of the large magnetic field, several unique problems[162] can occur during a scan. These problems include the potential risk of the magnet causing a ferromagnetic object to move or heat up or the induction of an electric current from the radio frequency pulses and switching magnetic gradients used in generating the images. This potential risk results in a significant list of contraindications to MRI (Box 123-13). Sedating these patients also entails several risk factors. The patient is in a remote location, with limited access to and visibility of the airway. Several equipment issues exist as well (Box 123-14). The monitors used must be suitable for use in the MRI suite.[163] They should be nonferromagnetic; the cables should be screened from electromagnetic interference (fiberoptic is ideal); and the signal should be filtered to avoid radio

Box 123–14 Potential Difficulties in MRI

Malfunction of anesthesia or sedation equipment
Malfunction of monitoring
Anesthesia or sedation equipment causing interference with image quality
High-velocity ferromagnetic projectile from loose object
Disruption of electronic devices

frequency interference (which interferes with image quality). Despite the specialized technology that is available, several problems remain. The ECG waveform is frequently altered, and analog information is often lacking during a scanning cycle. The ECG cables may cause burn injury, and special ECG electrodes are required to avoid burn injury. For pulse oximetry to be performed, a special probe is required. Heating of the usual probe may cause burn injury. Fiberoptic connection to the patient is best. Capnography requires long tubing, which results in a prolonged upsweep and delay in displaying real-time measurements. The respiratory rate and trends can still be useful. Any battery-powered monitor requires a nonmagnetic lithium battery. Exposure to the MRI shortens battery life. Most ICU ventilators are not MRI compatible (Servo *i* is available as an MRI compatible model). Some specialized MRI-safe anesthesia machines have a ventilator; however, their use should be restricted to the anesthesia staff who are familiar with the equipment. The IV poles and the equipment carts also should be nonferromagnetic. Any equipment with a transformer (e.g., syringe pumps and IV pumps) must be kept out of the magnetic field. Gas cylinders must be aluminum. The area around any magnet that generates a magnetic field stronger than 5 G should not contain any ferromagnetic items.

Any staff entering the MRI suite should remember to remove any ferromagnetic objects, including keys, watches, pens, and credit cards. Stethoscopes and laryngoscopes also are ferromagnetic. Infusion pumps should be outside the magnetic field, that is, outside the 5-G line. The electric motor in infusion pumps emits electromagnetic radiation and may run at an abnormal speed in the presence of a strong magnetic field. The pump is also a projectile risk. IV infusions through long tubing from outside the scanner can be useful so that the depth of anesthesia can be altered without having to enter the MRI suite. MRI-compatible infusion pumps are now also available. Some of these pumps allow changing infusion rates via electronic hand-held devices without entering the scanning room The ICU patient's infusions can be changed over to these infusion devices while the patient is still in the ICU and then transported to the scanner.

The use of a cuffed endotracheal tube may affect the quality of the MRI image because of metal in the valve of the pilot balloon and reinforcement of the mask airway. With the patient in the ICU, special care must be taken to ensure that all cables and transducers that may be carefully screened and all ferromagnetic objects are removed ("hiding in the sheets"). For invasive vascular pressure to be measured, the transducer should be as far from the patient as is practically possible and separated with a saline-filled pressure line. If cardiac arrest occurs, the patient should be removed from the magnetic field. The defibrillator should be kept outside the magnetic field and checked regularly. A nonferromagnetic code cart is also advisable. It is essential that the code team follow the rules about removing any loose magnetic items before entering the MRI suite or else a lethal projectile may be released. Ventilating the lungs of the ICU patient is often performed by hand ventilation by ICU staff in the MRI suite. The sedation technique is often a continuation of that used in the ICU, especially for a patient who undergoes intubation. In some children single doses of fentanyl or midazolam may be sufficient for a adequate sedation. If deeper sedation is required for patient comfort/cooperation, then IV sedation with supplemental oxygen with propofol is useful. A bolus of 2 mg/kg and an infusion of 100 μg/kg/min is a good method for patients with few medical problems and an easily maintained airway. It results in a rapid recovery with little nausea or vomiting.

Specific Drugs for Sedation

Ketamine

Ketamine is a phencyclidine derivative that provides sedation and analgesia. It results in a state of dissociative (trancelike) anesthesia. It is available in a variety of different dilutions, such as 10 mg, 50 mg, and 100 mg/mL. The latter is the most useful for IM use and the preparation of infusions. For a state of general anesthesia to be induced, a dose of 2 mg/kg IV is required. Onset takes 1 to 2 minutes with anesthesia lasting 10 to 15 minutes. Lower doses may be used for sedation. Anesthesia also can be induced by the IM route with a dose of 10 mg/kg, although onset is slower (5 to 10 minutes) and duration of prolonged effect is 45 to 60 minutes. It is metabolized by the liver and excreted by the kidneys. The half-life is 3.1 hours (see Table 123-11).

The adverse effects of ketamine include hypertension, tachycardia, increased intracranial pressure, and bronchodilation. The bronchodilation is probably due to its sympathomimetic action. It is a direct myocardial depressant, but blood pressure is usually maintained by the sympathetic stimulation that ketamine causes. In critically ill patients who already are using their maximum sympathetic drive, ketamine may cause a decrease in cardiac output or even cardiac arrest. Hallucinations and other psychiatric symptoms are often reported during and after its use in adults, but they occur less frequently in children. Ketamine is a potent sialogogue, and the use of an anticholinergic agent such as glycopyrrolate may be helpful. Its use is contraindicated in patients who cannot tolerate hypertension,[164] have a history of cerebrovascular hemorrhage, have psychiatric disturbances, and have raised ICP. It is a useful agent for sedation for procedures, especially if there is no IV access. It has been used in patients with status asthmaticus as an adjunct bronchodilator both in intubated and nonintubated patients at an infusion rate of 0.5 to 2 mg/kg/h. After discontinuing its use, the patient should receive BZDs to minimize the likelihood of hallucinations and be nursed in a quiet environment. Ketamine cannot be assumed to preserve pharyngeal reflexes any better than other sedatives agents, and apnea and airway obstruction can still occur.[165] NPO guidelines should still be observed.

Etomidate

Etomidate is a carboxylated imidazole that is unrelated to other anesthetic agents. It is a rapidly acting IV anesthetic agent, which, like other rapid-onset anesthetic agents, partitions into the brain within one circulation time and redistributes out of

the brain over the next few minutes. It is available dissolved in 30% propylene glycol as a 2 mg/mL solution. Like propofol, it causes pain on injection. The anesthetic dose is 0.2 to 0.3 mg/kg. It has a favorable adverse effect profile with minimal cardiovascular and respiratory depression. Etomidate is associated with a high incidence of nausea and vomiting after emergence from anesthesia. Its pharmacokinetics are shown in Table 123-11. The greatest disadvantage of etomidate in the intensive care setting is adrenocortical depression due to inhibition of adrenocortical mitochondrial 11-β-hydroxylase.[166] This effect is present in neonates and in adults.[167] The outcome of patients sedated with etomidate is worse than in those using alternative sedation, and steroid deficiency is thought to be the cause.[168]

In the CNS, etomidate suppresses seizure activity, although patients may show excitatory movements not associated with cortical EEG changes suggestive of seizures. The intracranial and intraocular pressures are lowered. It is the drug of choice for patients who are undergoing emergency intubation, those who have head injuries, and those who have a compromised cardiovascular system, and it is safe for use in patients with asthma because there is no histamine release. Etomidate has the highest therapeutic index of any anesthetic agent.

Several case reports of the satisfactory use of etomidate for controlling refractory intracranial hypertension have been published; it is associated with fewer cardiovascular problems than are barbiturates. Nevertheless, caution must be taken concerning the development of a lactic acidosis due to the metabolism of propylene glycol.

Inhalational Anesthetic Agents

The inhalational agents remain the most widely used anesthetics in the operating room, although their mechanism of action is still poorly understood. The following agents are currently in clinical use: enflurane, isoflurane, sevoflurane, and desflurane. Sevoflurane and desflurane are newer agents that currently have limited use in the ICU. Isoflurane remains the most logical choice of inhalational anesthetic in the ICU based on its cost/benefit ratio. As with any drug used in the ICU, it is important to understand the pharmacology, the adverse effect profile, and, in this case, the technical aspects of delivering these agents to the patient. These drugs are all fluorinated hydrocarbons (Figure 123-5). Except for halothane, which is no longer in common clinical use, they are ethyl-methyl esters. Each agent has different physicochemical properties that are important to its properties (Table 123-20).

Nitrous oxide is frequently used by anesthesia personnel as an adjunct. In some institutions it is used as the basis of a hospital pediatric procedural sedation service for children. Patients on the hospital floor undergoing minor to moderately painful procedures are mildly sedated with 50% nitrous oxide (as routinely used in pediatric dentistry); this technique has a good safety profile. A newer anesthetic agent in use in Europe is xenon. This gas has anesthetic properties with very few cardiac adverse effects. It is very expensive to use and requires a specialized fully closed breathing circuit to minimize the amount of gas used. The rate at which a change in inspired concentration is reflected in the brain is determined mainly by the blood/gas solubility. The more soluble the gas is in blood, the slower is the change due to the gas dissolving into the blood and reducing the partial pressure available to equilibrate with the brain. Sevoflurane and desflurane are the least soluble and therefore have the most rapid onset and offset; halothane has the slowest onset. The potency of the agents is represented by the minimal alveolar concentration (MAC). The MAC is the percent of inhaled anesthesia agent required to prevent 50% of anesthetized patients from responding to a surgical incision. The lower the MAC, the more potent the agent is. Halothane is the most potent of the agents used and desflurane is the least potent. The MAC of anesthetic agents is not constant with age. For all the agents it is highest for those aged 1 to 12 months, and the MAC falls throughout childhood to reach adult levels. Neonates show a slightly reduced MAC compared with infants. The oil/water solubility determines the degree of accumulation of the agent within the body fat stores. A highly fat-soluble agent will have larger body stores; therefore recovery from the agent is delayed.

These agents all have significant effects on the cardiorespiratory systems. Although respiration can be controlled, the negative inotropic and vasodilator effects are pronounced and limit the concentrations that can be used. Halothane, the oldest of these agents, has the greatest degree of cardiac depression. Sevoflurane and desflurane have an adverse effect profile similar to that of isoflurane, except that sevoflurane is partly metabolized to a potentially toxic metabolite, compound A, from a reaction with the soda lime used in anesthesia circle systems. For accumulation of compound A to be minimized in the circuit, a fresh gas flow of greater than 2 L/m should be used. Thus sevoflurane is may not be not a good choice for prolonged ICU treatment with this type of circuit. Desflurane has some sympathomimetic effect, especially when the concentration is abruptly increased, and significant tachycardia and hypertension can occur.

Adverse effects of halothane include hypotension, which is due to direct myocardial depression. It also causes bradycardia

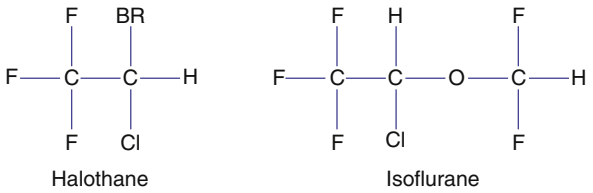

Figure 123–5. Structures of inhalational agents.

Table 123–20 Vapor Characteristics

	Halothane	Isoflurane	Sevoflurane	Desflurane
MW	197.4	184.5	200	168
SVP (mm Hg)	243	240	157	700
Boiling point (8° C)	50.2	48.5	58.5	22.8
MAC (%)	0.75–1.2	1.3–1.85	2.5–3.0	8.0–10
Blood/gas solubility	2.3	1.4	0.68	0.42
Oil/w% metabolized	20	0.2	3.3	0.02

MAC, Minimal alveolar concentration; *MW*, molecular weight; *SVP*, saturated vapor pressure.

because of effects on the sinoatrial node and vagal stimulation. Cardiac arrhythmias may occur, most commonly junctional rhythm. Halothane also sensitizes the myocardium to catecholamines, especially when the patient is hypercapnic or hypoxic. Because these physiologic changes are common in the intensive care patient, the potential for serious interactions with halothane abound. Halothane is metabolized approximately 20% by the liver, and a trifluoroacetic metabolite may cause an immune-mediated fatal hepatitis.[169] Isoflurane causes hypotension mainly because of vasodilation, while maintaining cardiac output. Concern has been expressed about a coronary steal phenomenon occurring in which blood is diverted from a partially obstructed coronary bed served by collateral arteries, due to vasodilation. The evidence for this phenomenon is weak, however, and ischemia is probably due to hypotension rather than a true steal phenomena. Isoflurane vapor is pungent and may cause airway irritation, coughing, and laryngospasm if the patient is not adequately sedated before its use. It is only minimally metabolized (0.2%), and a hepatitis reaction is extremely unlikely.

Malignant hyperthermia is a rare reaction that may occur whenever the halogenated inhalational anesthetics or succinylcholine is given to a patient. It involves the unrestrained entry of calcium into myocytes and consequential consumption of adenosine triphosphate, resulting in metabolic failure. Hypermetabolism, manifested by increased CO_2 production, and acidosis occur. Later the body temperature rises and death from hyperkalemia occurs. Correction of blood chemistry, aggressive cooling, and the administration of dantrolene are urgently indicated.

The metabolism of all the anesthesia agents can result in the production of free fluoride ions. Concentrations of fluoride greater than 50 μmol/L can cause renal dysfunction and a reduced concentrating capacity. This risk would appear to be higher for both halothane and sevoflurane because of their more extensive metabolism. It also may be exaggerated by patients who are prescribed drugs that induce the cytochrome P450 enzyme complex.

Inhalational agents may cause hepatotoxicity in two ways: (1) by metabolism to reactive intermediates that are directly hepatotoxic or (2) through the intermediates that form adducts to hepatic proteins. These new proteins are then recognized as foreign, and an immune response that causes hepatic injury occurs. This is thought to be the mechanism of halothane hepatitis. This form of hepatitis is most common after halothane use; even then it is rare, occurring in 1 of 100,000 cases. It is less common with isoflurane, sevoflurane, or desflurane, which are much less metabolized. This fulminant hepatic failure, which may be fatal, is most common after repeated administrations of halothane in older obese patients. The predominance of reductive halothane pathway metabolism results in a trifluoroacetic acid metabolite that forms a hapten. Halothane hepatitis is also less common in children.

All of the inhalational agents cause cerebral vasodilation, which results in an increase in CBF (because of decoupling of the demand/flow ratio) and ICP. In pediatric patients with raised ICP, there was no difference among isoflurane, desflurane, and sevoflurane with respect to the increase in ICP and CBF.[170] In contrast, IV anesthetics maintain the demand/flow ratio, and CBF and ICP fall, with the exception of ketamine. In addition to an effect of CBF, the arterial blood pressure typically will decrease with anesthesia, and the effect of this on the CPP must be accounted for. In one study, the effect of the decrease in arterial pressure on CPP exceeded the effect of increasing ICP by a factor of 3.[171] With these potential effects on CBF, the use of isoflurane should be carefully considered in patients who have or are at risk of raised ICP. Nevertheless, isoflurane has been safely used in neuroanesthesia with controlled ventilation to a normal $Paco_2$ and an inspired concentration not exceeding 1 MAC.[172]

Isoflurane has two main applications in the PICU: sedation and the management of refractory asthma. Only a few reports have been made of long-term sedative use of isoflurane in the ICU. In an adult study, 40 patients[173] who received an average of 96 MAC hours of isoflurane showed hemodynamic stability, less tachyphylaxis compared with other sedative agents, and a more rapid wean from the ventilator. No evidence was found of renal or hepatic dysfunction with serum fluorides less than 50 μmol/L. In a pediatric study, 10 patients[174] who had been receiving large doses of opiates or BZDs received an average of 130 MAC hours of isoflurane. The range of use was from 1 to 30 days. Fifty percent of the patients experienced a withdrawal-like phenomenon—most commonly, those who had received more than 70 MAC hours of isoflurane. Fluoride levels also were measured, and although they were correlated with the duration of treatment, none was greater than 30 μmol/L. The highest levels were in a patient who was taking both phenytoin and phenobarbitone. Hypotension only occurred in one patient. No hepatic or renal dysfunction occurred. The withdrawal was treated with a combination of BZDs and haloperidol with good effect. Isoflurane also has been used in patients with renal dysfunction, and fluoride levels were not elevated.[175] The starting dose for sedation should be 0.5%; this dose can then be titrated to effect by the ICU team. At levels above 1.5%, other sedative agents and paralytics often are not required.

Multiple case reports of the use of inhalational agents for status asthmaticus in both adults and children have been made. Because of its speed of onset and its bronchodilation effects, isoflurane is a useful adjunct to β_2-adrenergic agonists. If no improvement occurs, or if unacceptable adverse effects occur, then its effects rapidly wane on discontinuation. Isoflurane is recommended for use because of its safer adverse effect profile. No reports of renal or hepatic dysfunction have been made despite its use for often prolonged periods. Hypotension seems to be more common in patients sedated with isoflurane; it is possibly related to increased intrathoracic pressure and the potential for greater preload reduction with vasodilation. Fluid boluses and occasionally vasopressors are often required. Because isoflurane is not an analgesic agent, opiates may be needed for painful or uncomfortable procedures. Also, when the patient is weaned off the isoflurane, additional sedatives will be required. The isoflurane should be started at 0.5% and titrated for effect; doses of up to 2.5% have been reported as safely used.[176]

The inhalational anesthetic agents are liquids at room temperature. A special delivery device called a vaporizer is required to deliver an accurate supply of the vapor. All vaporizers have several features in common. They provide a reservoir of the inhalational liquid with a level indicator and are capable of delivering a constant level of vaporization. Most newer vaporizers also have a color-coded keyed filler (e.g., purple for isoflurane and yellow for sevoflurane) that prevents the accidental filling of the vaporizer with the wrong agent.

This error could result in overdosing the patient because the vaporizer calibration is drug specific. If two vaporizers are accommodated in series on the anesthesia machine back bar, then an interlocking system should be used to prevent the accidental use of both vaporizers. Otherwise, the results would be contamination of the second vaporizer by gas from the first vaporizer and an uncontrolled excess delivery of gas to the patient.

One of the main problems with using these inhalational agents in the PICU is how to deliver them to the patient. One technique is to use an anesthesia machine to deliver the gas to an ICU ventilator with the correct oxygen percentage and inhalational agent. This mixture is delivered from the fresh gas outlet of the anesthesia machine. It is selected by adjustment of the flow rotameters on the anesthesia machine to give the desired oxygen concentration and then selection of the desired inspired concentration of inhalational agent on the vaporizer. Unfortunately, most ICU ventilators will not accept this low-pressure gas supply as their driving gas. The Servo 900C is an exception because it has a low pressure inlet option for the driving gas. High flow rates are required to maintain filling of the bellows of the ventilator; the flow rates must be higher than the minute ventilation. This requirement sometimes results in a limitation of inspired oxygen because the maximum flow of oxygen from the rotameters of the anesthesia machine is 10 to 12 L/m. Also, this process consumes a lot of vapor.

Also available is another Servo ventilator, the 900D, that has a custom-fit vaporizer on the normal high-pressure input. This machine is similar to the 900C, but it has been modified for anesthesia use and also allows hand ventilation with inhalational agents. Often the only alternative is to deliver anesthetic with an anesthesia machine. Anesthesia machine ventilators are not as sophisticated as ICU ventilators, may not be able to deliver appropriate volumes for pediatric patients, and often have limited positive end-expiratory pressure capabilities. The anesthesia machine needs to be checked before use and its correct function should be continually assessed during its use, which requires an understanding of the setup and alarms on the machine and an understanding of the procedures of the appropriate tests. This understanding usually is not within the confines of a pediatric intensivist's scope of practice, and an anesthesiologist should be involved to ensure the safe and effective use of this apparatus.

Whenever inhalational agents are used, the waste gases from the expiratory limb of the ventilator should be scavenged to avoid prolonged exposure of the health care worker to these agents. The Occupational Safety and Health Administration limits occupational exposure to 2 ppm halothane for health care workers.[177] The worker is at risk of becoming sedated, and potential teratogenic effects also exist. Several large studies about prolonged exposure to these agents have not shown any increase in risks for anesthesia personnel with respect to hepatic disease, teratogenesis, spontaneous abortions, psychological difficulties, infertility, neuropathy, or bone marrow depression.[178] Caution also should be taken when filling the vaporizer to avoid spilling the liquid during the process.[179] Two forms of scavenging are available. A passive system involves simply a tube connected to the expiratory limb connected to the outside. This system is at risk of occlusion because of kinking or someone standing inadvertently on the tubing, which will then occlude the expiratory limb of the ventilator. An active system involves an active suction to the expiratory limb, with a safety reservoir bag in series to prevent excess suction pressure from being exposed to the patient.

In the operating room it is routine to monitor the levels of anesthesia agents given with a gas analyzer. This monitoring provides an inspired and expired inhalational agent concentration and is helpful to ensure that the vaporizer is functioning correctly, that the vaporizer has not emptied without being detected, and that the concentration dialed on the vaporizer has reached its effect. When the end-tidal inhalational agent concentration equals the inspired agent, then steady state has been achieved. This steady state normally occurs rapidly with isoflurane, but in a patient with severe asthma due to the severe limitation in airflow gas exchange, achievement of steady state may be delayed.

If the PICU staff is unfamiliar with the delivery system being used for the isoflurane, then it would be appropriate to have staff from the anesthesiology department set up the equipment and ensure that it functions correctly. Failure to configure the delivery system correctly has the potential to cause considerable harm or death. Once the situation has stabilized, an anesthesiologist may not be required at the bedside. However, an anesthesiologist should be available by pager to help troubleshoot any difficulties. In these cases the inspired agent should be monitored continually.

The use of inhalational agents in the PICU involves the use of equipment that may be unfamiliar to pediatric intensive care physicians. Isoflurane appears to be the best choice,[180] and it offers several useful advantages, including the ability to deeply sedate patients (especially those difficult to sedate) without polypharmacy.[181] Although they are currently poorly defined,[182] tolerance and a withdrawal-like syndrome have been described; however, they appear to occur more slowly than with other sedative agents. It may be helpful to have a set of guidelines available for isoflurane use to facilitate its use in the PICU. These guidelines could include equipment use, monitoring requirements, dosing, and treatment of complications.[183] Caution should be used in patients who may have raised ICP because isoflurane may increase CBF. Isoflurane does allow for rapid arousal if neurologic examinations are required.

The Anaesthetic Conserving Device (AnaConDa) is a modified heat moisture exchanger that has been developed to allow the use of inhalational agents in the ICU without requiring high fresh gas flows or specialized ventilators.[184] It is placed in the breathing circuit between the ventilator Y circuit and the endotracheal tube. The liquid anesthesia agent is injected directly into the device using a syringe pump. The device membrane allows for the inhalational agent to be taken up by the inspired gas. On expiration much of the inhalational agent is deposited on the membrane, allowing for an efficient inhalational rebreathing technique. The inspired concentration of the inhalational agent is monitored from the device using a routine gas analyzer. It has been used in several adult ICU trials as well as in a series of three children. Some problems due to excess dosing have been experienced, and the 100 mL dead space of the device, as well as resistance to gas flow, may make its use inappropriate in children. Compared with an inhalational agent vaporizer, there is no percentage inhalational agent dial. The rate on syringe injection determines the percentage of the inhalational agent. This infusion rate is set according at a pre-recommended rate. Initially the inspired concentration is low because of dilution. Differences in minute

ventilation and gas flows may make this pre-recommended rate inaccurate. The injection rate needs to be titrated to the monitored percent of the inspired inhalational agent, which can increase significantly with time, especially until equilibrium is reached. The AnaConDA device is not approved for use in the United States.

Apoptosis

Recent evidence from rodents suggests that most general anesthetics and sedatives, which are either *N*-methyl-D-aspartate receptor antagonists or $GABA_A$ agonists, trigger apoptosis or programmed cell death. Those incriminated include inhalational anesthetic agents (including nitrous oxide), propofol, benzodiazepines, and ketamine. Adjuvants that do not trigger apoptosis include dexmedetomidine, melatonin, and possibly xenon. Interestingly, lithium has been shown to exert an antiapoptotic effect. Massive apoptosis occurs in vulnerable regions of the brain that are responsible for learning and cognition (e.g., the hippocampus, caudate/putamen, thalamus, and others) when these proapoptotic anesthetics are administered during the period of synaptogenesis or the rapid brain growth spurt in young rodents, most notably, during the seventh postnatal day. The severity of the apoptosis depends on the dose of anesthetic and duration of administration. In addition to histologic changes associated with apoptosis (as evidenced by caspases-3 staining), long-term memory loss and cognitive impairment have been demonstrated.

Whether these data are directly applicable to humans has not been established. Primate research suggests that ketamine[185] induces apoptosis in vulnerable young monkeys, although an exposure to ketamine of less than 3 hours duration does not induce significant injury. To date, the studies in humans have been retrospective in design. Four studies have demonstrated conflicting findings on the effects of anesthetics on cognitive function in young children. The most impressive of these retrospective studies is from the twin registry in Denmark[186] in which monozygote twins concordant or discordant for anesthetic exposure before the age of 4 years failed to demonstrate any differences in educational achievement or cognitive impairment years later. A prospective randomized study of general anesthesia versus regional anesthesia for lower abdominal surgery with long-term evaluation of cognitive function in children is currently under way (expected conclusion in 2013) and may help us to understand the risk, if any, of administering these general anesthetics to vulnerable human infants and young children.

Pharmacoeconomics

In today's economical climate it is important to consider the cost of the different sedation options available to the pediatric intensivist (Table 123-21). Most PICUs use a low-cost sedative regimen for the bulk of the sedations required and keep the more expensive options for selected circumstances. Table 123-21 shows the different costs of some of the available agents in the PICU as well as the 24-hour cost for a child weighing 20 kg. They are presented as the cost per kilogram per hour of sedation at equipotent doses. The costs are the lowest hospital drug cost (at the Women's and Children's Hospital of Buffalo) for each agent in its most inexpensive form and exclude preparation, delivery, and equipment issues related to each drug. Fentanyl is inexpensive. For a 20-kg child, it costs $7.49 per day. Midazolam is now a more inexpensive option than is lorazepam. The other synthetic opiates are more expensive to use, and consideration should be given to appropriate indications for their use. A rapid recovery, however, with as quick an extubation as may be possible with remifentanil and early ICU discharge is also a considerable cost factor to be considered. Propofol (which is now available in a generic form) and ketamine are both relatively inexpensive options for ICU sedation, if they are deemed clinically appropriate. The drug costs of isoflurane and sevoflurane are comparable to those of the BZDs; however, they require the availability of a specialized delivery system, which could increase the cost. If a device were available that could deliver these agents at low flows with most of the available ICU ventilators, then inhalational sedation would be a more attractive option.

Table 123–21 Relative Drug Costs of Different ICU Sedative Agents

Drug	Dose	Cost/kg/hr ($)	24-Hour Cost for 20-kg Child ($)
Morphine	50 μg/kg/h	0.002	1.15
Fentanyl	4 μg/kg/h	0.016	7.49
Sufentanil	0.8 μg/kg/h	0.058	27.80
Remifentanil	0.4 μg/kg/min	0.253	121.31
Midazolam	0.1 mg/kg/h	0.02	9.38
Lorazepam	0.1 mg/kg/h	0.028	13.51
Propofol	5 mg/kg/h	0.043	20.87
Ketamine	1 mg/kg/h	0.008	3.89
Dexmedetomidine	0.5 μg/kg/h	0.15	70.62
Isoflurane	0.5% (@ 61 L/min)	0.93	22.30
Desflurane	3% (@ 61 L/min)	29.92	717.79
Sevoflurane	1% (@ 61 L/min)	1.36	32.74
Xenon	30% (proprietary closed circuit)		404.76

VII Chapter 124

Malignant Hyperthermia

Barbara W. Brandom and Mihaela Visoiu

PEARLS

- Malignant hyperthermia (MH) is a muscle disorder first recognized as a complication of general anesthesia with the potent inhalational anesthetic agents.
- The initial signs of MH can also occur postoperatively as fever with excessive metabolic rate and muscle injury.
- Myoglobinuria produces renal injury in about 10% of MH cases. Renal failure is more likely when treatment with dantrolene is delayed.
- Disseminated intravascular coagulation and cerebral edema may complicate fulminant MH.
- After initial treatment with 2.5 to 10 mg/kg of dantrolene, at least 1 mg/kg of dantrolene should be given every 6 hours for four doses because 20% of patients experience an exacerbation or recrudescence of MH within 24 hours after the acute episode.

The physician in the pediatric intensive care unit (PICU) may first encounter a patient with malignant hyperthermia (MH) in transfer from the operating room or from an outpatient facility where general anesthesia was given and treatment for acute MH was begun. Because 20% of patients experience a recurrence of MH in the 24 hours after the initial episode, close observation for a relapse of MH is warranted and administration of dantrolene for at least 24 hours after the initial episode is recommended. Alternatively, the ICU physician may be the first to entertain the diagnosis of MH in a patient admitted to the ICU for medical care or postoperative management.

MH is characterized by hypermetabolism, but there are many causes of fever and muscle injury that are not MH. Regardless of the underlying cause, ICU management should be directed to control critical temperature and complications of rhabdomyolysis. The ICU physician should pursue common diagnoses while directing diagnostic workup for the rare syndrome of MH.

Pathophysiology

In fulminant MH, a dramatic increase in the metabolic rate of genetically abnormal muscle results in muscle injury and multiorgan system failure. The underlying biochemical defect is a sudden, sustained increase in the concentration of calcium ion in the sarcoplasm.[1] Carbon dioxide (CO_2) production increases severalfold. Even with increased minute ventilation, it may not be feasible to maintain normocarbia. Lactic acid production overwhelms the body's buffering capacity. Increased O_2 demand and the concomitant sympathetic response stress the cardiovascular system. High circulating catecholamines may stimulate muscle metabolism and hasten fulminant MH, but MH can occur in the presence of total sympathetic blockade and normal plasma catecholamines. Conversely, dantrolene, which can prevent MH in the susceptible patient, has no effect on stress-induced increases in catecholamines.[2]

MH can progress rapidly to severe mixed acidosis, hyperkalemia, elevated temperature as in heatstroke,[3] and rhabdomyolysis. Renal failure, disseminated intravascular coagulation, cerebral edema, pulmonary edema, dysrhythmias, and cardiovascular collapse are potential consequences of fulminant MH. Even with aggressive treatment, death may ensue. Before dantrolene, the mortality rate of MH was 70%. Symptomatic therapy including mechanical ventilation, active cooling, administration of bicarbonate, expansion of the intravascular volume, and treatment of dysrhythmias can prolong life during an episode of fulminant MH. However, the most effective therapy is intravenous dantrolene.[4]

In the majority of MH-susceptible (MHS) humans, there is a defect in the ryanodine receptor channel (RYR1).[5] Normally, depolarization of the sarcolemma is propagated through the transverse tubule system. There, the dihydropyridine receptor (DHPR), the skeletal muscle L-type calcium channel, undergoes conformational change in response to depolarization. This is coupled to opening of RYR1 through which calcium flows out of the sarcoplasmic reticulum (SR) into the myoplasm. The interaction between DHPR and RYR1 also activates entry of extracellular calcium (ECCE) into the myoplasm. The $\alpha_2\delta_1$ subunit of the DHPR is necessary for sustaining calcium transients in response to repeated action potentials.[6] MHS RYR1 has increased sensitivity to agonists that open the channel[7,8] and decreased sensitivity to inhibitors of RYR1 channel opening. Furthermore, ECCE is greater than normal in myotubes expressing MHS RYR1.[9] Dantrolene inhibits ECCE in both MHS and normal muscle. Store-operated calcium entry (SOCE) is another process, occurring after depletion of SR calcium, that moves extracellular calcium into the myoplasm. SOCE is coupled to RYR1 and decreased by dantrolene.[10]

Genetics

MHS has been described as a syndrome with autosomal dominant inheritance, incomplete penetrance, and variable expressivity. The first-degree relatives of an individual that

has had fulminant MH are considered potentially MHS until they have normal results of in vitro muscle contracture testing with halothane and caffeine (CHCT). Incomplete penetrance means that a person with a MHS mutation may not experience MH during the first or subsequent exposures to MH trigger agents. Multifactorial inheritance may be relevant.[11,12] Variable expressivity means that clinical symptoms of MH vary from minor to fulminant depending on factors such as the anesthetic agents, genetics, and temperature.[13] MHS episodes are more often observed in males.[14,15]

The primary genetic locus of MH (MHS1) is the ryanodine receptor gene (*RYR1*) on chromosome 19q13.1. Variants associated with MHS are found throughout *RYR1*. Fewer than 30 of these met the rigorous criteria (see www.emhg.org) that prove causation of MH. In families with an MH-causative *RYR1* mutation, genetic analysis is a useful initial step in the diagnosis of MHS.[16,17] See www.mhaus.org for addresses of clinical diagnostic testing laboratories in the United States. This pathologic test has been useful to document MH susceptibility in postmortem muscle.

Several different genetic abnormalities are associated with MH. A variant associated with MH susceptibility was found in the α-1 subunit of the DHPR gene (CACNA1S) on chromosome 1q32.[18] This is the MHS 5 locus. It is associated with MH in only a few families as of 2009. Other loci associated with MH susceptibility, MHS 2, MHS 3, and MHS 6, have been identified on chromosomes 17q11-24,19 7q22-24, and 5p respectively. There are not obvious candidate genes at these sites other than the DHPR α_2/δ_1 subunit in 7q22-24, but extensive examination of MHS families has not identified a variant there. It has been suggested that two different genetic loci may be required to produce the MH phenotype in some families.[11,20] Although factors that modify the expression of MHS are not completely determined, active cysteines contribute to redox modulation and nitrosylation of RYR1.[21,22]

Clinical Recognition of a Malignant Hyperthermia Episode in Humans

The initial signs of acute MH are nonspecific (Box 124-1).[23] The first or only MH signs reported to the North American MH Registry in 286 cases were hypercarbia (38%), sinus tachycardia (31%), or masseter spasm (21%).[14] Inappropriately elevated (>38.8° C) or rapidly increasing temperature was one of the first signs in 8.2% and the only initial sign in 3.9%.[14]

However, high temperature was one of the first three signs in 63.5% of cases, with median maximum temperature of 39.1° C. The skin may be mottled and cyanotic and muscles rigid enough to extend the legs. Other signs include tachypnea, sweating, arrhythmias (ventricular tachycardia, ventricular fibrillation), dark urine, and excessive bleeding. Mixed respiratory and metabolic acidosis, hyperkalemia, myoglobinemia, myoglobinuria, and increased serum creatine kinase can be noted. However, rhabdomyolysis does not always occur during acute MH.[24]

In the ICU, a septic patient with kidney disease or chronic lung disease may exhibit fever, tachycardia, mixed respiratory and metabolic acidosis and hyperkalemia. If sepsis, cardiovascular failure, central nervous system injury, heat stroke, or other medical or surgical conditions could have produced the abnormal vital signs, then these other diagnoses must be pursued and treated. MH may not be the most likely diagnosis in general, but recognition of recent exposure to volatile anesthetic agents and/or succinylcholine in a patient with a family history of problems after general anesthesia or muscular diseases associated with MH supports the presumptive diagnosis of MH.

Box 124–1 Positive Findings Consistent with MH

History of recent exposure to trigger agent, including volatile anesthetic agents or succinylcholine
Family or personal history of MH susceptibility
Total body rigidity
Masseter spasm
Inappropriately elevated (38.8° C) or rapidly increasing temperature (>1.5° C over 5 min)
Inappropriate tachypnea
Profuse sweating
Mottled, cyanotic skin
Dark urine, urine dipstick testing shows a positive result from blood without red cells in the sediment and no hemolysis
Unexplained, excessive bleeding
Unexplained ventricular tachycardia or fibrillation
Inappropriate hypercarbia (venous $PaCO_2$ >65 mm Hg, arterial Pa CO_2 >55 mm Hg) if the patient is receiving positive-pressure ventilation or is spontaneously breathing with greater than normal minute ventilation
Arterial base excess more negative than −8 mEq/L
Arterial pH <7.25
Potassium concentration >6 mEq/L
Creatine kinase >10,000 IU/L

MH episodes can be fulminant or abortive. In the operating room, MH can develop rapidly after the administration of succinylcholine in the presence of volatile anesthetic agents, or insidiously during a long anesthetic.[25] When the nonspecific early signs of MH are noted during induction of anesthesia, the potent inhalation anesthetics should be discontinued. This patient is considered to be MH-susceptible until proven otherwise and this episode is called abortive MH. Early termination of inhalation anesthetic agents in the presence of abortive MH may allow spontaneous resolution of the syndrome. On the other hand, there have been cases in which only mild signs of abortive MH occurred intraoperatively, but renal failure, hyperthermia, and death occurred postoperatively with no explanation other than MH.[26]

In a retrospective Danish study of 386,250 anesthesias that occurred over 6.5 years in 87 hospitals, the incidence of fulminant MH was 1 in 250,000 general anesthesias.[27] In this series, there were no cases of fulminant MH during regional anesthesia or "nontriggering" general anesthesia. When only anesthesias that included the administration of succinylcholine and potent inhalational anesthetic agents, such as halothane, isoflurane, and enflurane, were considered, the incidence of abortive MH was 1 in 4200 cases. In this study, abortive MH was defined as a masseter spasm or moderate changes in vital signs with slight metabolic or respiratory acidosis.[27] These clinical signs are not specific for MH.[28] No deaths occurred in the patients with abortive MH in this series.

The fiftyfold difference in incidence between fulminant and abortive MH can be explained by early termination of anesthesia in the presence of abortive MH with resolution of the

syndrome, and perhaps by the fact that although the episode was classified as abortive MH, the patient may not in fact be MH-susceptible. Because MH is a potentially fatal condition that may progress rapidly, the anesthesiologist may be inclined to overdiagnose episodes of abortive MH.

In this retrospective series,[27] there was no information about further anesthetic experience or other pathologic evaluation of MH susceptibility, specifically the results of in vitro caffeine-halothane contracture testing, in those patients who had experienced abortive MH.

A person may have fulminant MH during one anesthesia and no symptoms at all during other similar anesthesias. A patient who survived an episode of fulminant MH is considered capable of having another episode, although he or she may have undergone many anesthesias uneventfully before the first episode of MH. Larach et al. reported that 77 of 152 patients who experienced serious MH episodes had two or more prior unremarkable general anesthesias.[14] Patients with the MH trait are often symptom-free until exposed to the most common triggering agents, the volatile anesthetic agents such as sevoflurane, isoflurane, desflurane, and halothane and the depolarizing neuromuscular blocking agent, succinylcholine. If the pharmacologic triggering agent is eliminated from the patient before the development of profoundly decreased pH in the muscle, rapidly increasing temperature, and shock, the metabolic abnormalities may resolve readily. This sequence of events could be termed abortive MH.

Potential Systemic Complications

Complications were noted in approximately 35% of 181 MH events reported to the North American MH Registry. These included changes in level of consciousness or coma in 9.4%, cardiac dysfunction in 9.4%, pulmonary edema in 8.4%, renal dysfunction in 7.3%, disseminated intravascular coagulation in 7.2%, and hepatic dysfunction in 5.6%.[14] Disseminated intravascular coagulation was associated with a 50-fold increased likelihood of cardiac arrest and an 89-fold likelihood of death.[29] The likelihood of any complication increased 2.9 times for every 2° C increase in maximum temperature and 1.6 times for every 30 minutes of time between the appearance of the first clinical sign of MH and the beginning of dantrolene administration.[14] Other complications reported were compartment syndrome, stroke after cardiac arrest, bilateral brachial plexopathy, generalized muscle weakness, significant muscle loss, and prolonged intubation.[14]

Cerebral edema and coma have been reported in episodes of fulminant MH. Although normal metabolism of the brain was described during episodes of MH, O_2 supply to the central nervous system may be inadequate. Therefore supportive care to the patient during and after an episode of fulminant MH should include measures to document cerebral function and maximize cerebral perfusion.

Ventilatory failure may occur early in an episode of fulminant MH. During a MH episode, desaturation can be also secondary to increased oxygen extraction. The workload of the respiratory system may be further increased by the occurrence of pulmonary edema. Pulmonary edema may be the result of capillary leak. It may be worsened by impaired cardiac contractility in the presence of acidemia. Cardiac dysrhythmias may occur in the presence of marked electrolyte abnormalities. In older patients, there may be foci of myocardial fibrosis as well. It has been hypothesized that such areas of fibrosis are the result of subclinical episodes of MH that produced increased levels of circulating catecholamines.[30] Cardiac contractility can be impaired.

Rhabdomyolysis will occur when the energy supply of the muscle is exhausted. Clinical manifestations include myalgias, swollen extremities, red-to-brown urine due to myoglobinuria, and elevated muscle enzymes. It is noteworthy that enzymes commonly elevated in the blood during hepatic injury including LDH and SGOT will also be released from muscle when creatine kinase (CK) is markedly elevated. Rhabdomyolysis can produce electrolyte imbalance (hyperkalemia, hyperphosphatemia, hypocalcemia), metabolic acidosis, severe hyperuricemia, acute renal failure,[31] and compartment syndrome. Melli et al. reported that the incidence of acute renal failure associated with myoglobinuria was 46%.[32] Massive rhabdomyolysis, producing CK of greater than 20,000 IU/L, may occur in patients with underlying muscular diseases not necessarily related to MH. Thus rhabdomyolysis in the absence of increased metabolic rate, hypercarbia, and metabolic acidosis should not be assumed to be MH. However, the same treatment, including administration of dantrolene acutely, may be helpful to the myopathic patient who experiences rhabdomyolysis in the ICU. It will be helpful to the patient and his or her family if the underlying cause of rhabdomyolysis is determined, because the implications for medical care of relatives differ depending on the pathologic diagnosis (e.g., dystrophinopathy vs. MH).

Hyperthermia in the Pediatric Intensive Care Unit

In the PICU, the most likely cause of fever is a bacterial infection,[33] but elevated temperature can also be the result of trauma, viral infection, lymphoma, and leukemia. Inadequate fluid replacement predisposes to increased core temperature in children.[34] Excessive environmental heat with inadequate opportunity for evaporative heat loss can result in temperature elevation. In some cases increased core temperature can be associated with tachycardia, increased expired CO_2, and metabolic acidosis, which are consistent with the expected increase in metabolic demand produced by fever. This can be so extreme as to mimic MH.

When hyperthermia occurs in a child with history of exposure to succinylcholine or volatile anesthetic agents, MH should be considered in the differential diagnosis. In a retrospective cohort study, conducted to analyze and identify the causes of hyperthermia in the PICU over a 9-year period, Schleelein et al. noted that the incidence of clinically diagnosed MH was low (0.4%).[35] These cases were classified as "definite " or "probable" MH[23] by a Malignant Hyperthermia Association of the United States (MHAUS) hotline consultant.[35] No information about CHCT or other pathologic tests that could support the diagnosis of MH for these patients is available.

Postoperative Fever

Postoperative fever (>38° C, >100.4° F) is common after surgery and usually resolves spontaneously. In establishing a differential diagnosis, it is very helpful to consider the timing of fever onset: immediate, acute, subacute, or delayed. The causes may be infectious or noninfectious. The most common noninfectious cause is a medication reaction, followed

by blood transfusion and by trauma suffered prior to surgery or as part of surgery. The fever due to MH usually starts within 30 minutes after administration of the triggering agent, but has also been reported up to several hours later, after the anesthesia was discontinued.

Some clinical states, such as the increased temperature that accompanies improved circulation after cardiac surgery, share some of the features of MH.[36] These situations may even include rhabdomyolysis, but it is the result of muscular injury from impaired circulation, not usually from a primary muscular disease.

Abortive Malignant Hyperthermia Episodes and Isolated Masseter Spasm

There is controversy about evaluation of the individual who has experienced abortive MH or isolated masseter spasm. Abortive MH could be relatively slowly evolving MH or a group of signs produced by processes completely unrelated to MH. Increased stiffness of the masseter muscles, even to the degree that endotracheal intubation is precluded, can be a normal response to succinylcholine.[37-39] Because MH could develop some minutes to hours after an occurrence of masseter spasm, some anesthesiologists recommend cancellation of an anesthesia after such an occurrence and evaluation of the CK levels at 12 and 24 hours after the incident. Neurologic evaluation and muscle biopsy to rule out susceptibility to MH have also been recommended. Neurologic evaluation is relevant after abnormal intraoperative muscle tension because myotonia may be the underlying diagnosis. A mutation in the muscle sodium channel has been noted in one family evaluated after severe rigidity followed succinylcholine administration.[40] Others recommend discontinuing the triggering agents of MH, careful evaluation of acid-base status, and continuation of the anesthetic and surgical procedure if no further problems are identified. Urine should be checked for the presence of myoglobin. If masseter spasm occurs without significant metabolic or cardiovascular changes, it is unlikely to be followed by fulminant MH.[41] Similarly, the low specificity of the contracture test for MH may produce many false-positive results in such patients.[42]

Rhabdomyolysis

Rhabdomyolysis is characterized by muscle necrosis and the release of intracellular muscle constituents including CK, myoglobin, calcium, and potassium. CK levels greater than five times baseline are a sensitive definition of rhabdomyolysis. Rhabdomyolysis can be due to inherited or acquired causes, and the severity of clinical consequences ranges from asymptomatic increase of serum muscle enzymes to life-threatening hyperkalemia. The most frequent causes are trauma, overexertion, immobilization, alcoholism, vascular insufficiency, and orthopedic surgery. Grand mal seizures, delirium tremens, psychotic agitation, and amphetamine overdose can lead to rhabdomyolysis in individuals with normal muscles.[32] Some drugs such as HMG-CoA reductase inhibitors (statins) and colchicine are directly myotoxic.[32] Rhabdomyolysis may occur in patients with metabolic myopathies such as carnitine palmitoyltransferase deficiency, myophosphorylase deficiency (PYGM) or McArdle disease, myoadenylate deaminase deficiency (AMPD1), mitochondrial myopathy, or malignant hyperthermia susceptibility. Occasionally, patients with structural myopathies can develop acute rhabdomyolysis after strenuous exercise, after exposure to potent inhalation anesthetics, after exposure to other myotoxic drugs, or after a viral infection.

Treatment of an Episode of Malignant Hyperthermia

Remove Trigger Agents

When an episode of MH is suspected, it is prudent to alter, as soon as possible, the anesthetic technique with elimination of all triggering agents. In the operating room, if potent inhalation anesthetic agents were administered, these should be discontinued immediately and a nontriggering anesthetic technique administered. High fresh gas flows of 10 L/min or more, or charcoal filters, are needed to eliminate residual potent inhalational anesthetic agents from modern anesthesia machines. If the physician suspects MH, and especially if blood gas analysis has proven the presence of significant respiratory and metabolic acidosis, dantrolene should be administered immediately and supportive treatment should be started as soon as possible (Box 124-2). Treatment of the life-threatening complications should not detract from the need to continue monitoring the metabolic status and the continued administration of dantrolene, in increasing doses if necessary, until the metabolic state is normal. Resolution of some of these complications may take longer than the adequate treatment of the acute episode of MH.

Administer Dantrolene

Dantrolene, a hydantoin with muscle relaxant properties, has greatly changed the treatment of and risk of death from MH. Before the introduction of dantrolene, Brit and Kalow reported a 36% MH survival rate with symptomatic treatment only.[43] It was thought that dantrolene decreased calcium release from the SR by decreasing the mobility of a calcium ionophore that transports calcium across membranes. Although dantrolene interacts with amino acids 590-609 in the N-terminal fragment of the RYR144, its analog, azumolene, does not alter calcium release from the SR. Dantrolene does decrease both excitation-coupled calcium entry into muscle cells and store-operated calcium entry coupled to RYR1.[9,10] It does not act on the neuromuscular junction or on the passive or active electrical properties of the surface membranes of muscle fibers. Therefore patients given effective doses of dantrolene have normal electromyograms and depressed force of muscle contraction.[45]

Dantrolene for intravenous administration (Dantrium) is supplied in 70 mL vials, containing 20 mg dantrolene sodium and 3 g mannitol. It must be diluted with 60 mL of sterile, preservative-free, distilled water. Dantrolene should be available in all locations where general anesthesia is administered. It should be immediately supplied to other areas of the hospital by the pharmacy. If dantrolene has to be obtained from a central location, such as the pharmacy, it must be stressed that the need for the initial and subsequent doses of drug is urgent. The initial dose of intravenous dantrolene for treatment of MH is 2.5 to 3 mg/kg.[46] More than 10 mg/kg has sometimes been required to return metabolism to normal. As soon as dantrolene is ordered to treat fulminant MH, replacements

Box 124–2 Management of an Acute MH Episode in the ICU

1. Administer high-flow 100% oxygen via a nonrebreathing mask and consider endotracheal intubation.
2. For ventilated patients, administer an Fio_2 of 1.0 and increase minute ventilation to control $Paco_2$.
3. Administer dantrolene (2.5 mg/kg intravenously) over 10 minutes and repeat, until acidosis and muscle rigidity have resolved. Repeat dantrolene (1 mg/kg) every 6 hours.
4. Initiate cooling with ice packs in the axillae and groin, decrease room temperature, use hypothermia blankets, iced intravenous saline solution (10 mL/kg over 10 min, repeated as needed), and lavage body cavities with cold saline solution if temperature is greater than 39° C. Stop cooling when core temperature falls to 38° C.
5. Correct metabolic acidosis with sodium bicarbonate (1–2 mEq/kg initially) and give subsequent doses based on base excess and body weight.
6. Administer calcium chloride (10 mg/kg) or calcium gluconate (100–200 mg/kg) to cardiotoxicity associated with hyperkalemia.
7. Give regular insulin (0.1 U/kg) and glucose (0.3–0.5 g/kg) to correct hyperkalemia.
8. Administer lidocaine (1 mg/kg) to treat ventricular arrhythmias. Consider amiodarone (5 mg/kg IV) for refractory, stable ventricular tachycardia. Do not delay defibrillation or cardiopulmonary resuscitation if indicated by cardiovascular instability.
9. Maintain urine output of 2 mL/kg/hr with aggressive cold fluid administration, furosemide (0.5–1 mg/kg), and additional mannitol (0.25–0.3 g/kg) if needed.
10. Consider quantitative end-tidal CO_2 monitoring.
11. Monitor core temperature (pulmonary artery, esophageal temperature probe, rectal probe).
12. Place arterial catheter for invasive blood pressure monitoring and frequent blood sampling. Consider central venous catheter and/or pulmonary artery catheter if indicated by cardiovascular instability.
13. Repeat venous blood gas and electrolytes analysis until these normalize. Repeat CK at least every 6 hours while the patient is in ICU and then daily until CK returns to normal. Assess glucose, clotting function, hepatic and renal functions, and treat symptomatically. Repeat lactic acid measurement after each dantrolene administration.
14. Consider hemodialysis if indicated.
15. Consider intensive care monitoring for at least 24 hours after MH episode or after recrudescence of MH.
16. Refer the patient for muscle caffeine-halothane contracture testing and consider exam of *RYR1*. Pursue a pathologic diagnosis for other occult myopathies.

should be obtained by the pharmacy. In children, the intravenous infusion of dantrolene, 2.4 mg/kg IV over 10 to 12 minutes, produced stable blood levels of about 3.5 μg/mL for 4 hours, after which a slow decline in plasma concentration occurred (Figure 124-1).[47] It appears that the half-life of dantrolene in the plasma of children is somewhat shorter than in adults: 7 to 10 hours compared with 12 hours, respectively.[45] This is consistent with the recommendation to repeat dantrolene (1 mg/kg) every 6 hours for prophylaxis against recurrence of MH in a child. Immediately after the administration of intravenous dantrolene, one may note a dramatic decrease in heart rate. This is the result of an effect on the underlying hypermetabolic state and is generally a reassuring sign that dantrolene is effectively controlling the episode of MH. However, a modest decrease in heart rate after the administration of intravenous dantrolene may be caused by increased intravascular volume. The other goals of the treatment with dantrolene are complete cessation of tachypnea and muscle rigidity, correction of hypercarbia, hyperthermia, electrolyte disturbances, and blood gas abnormalities. Also, urinary output should be increased and mental status should improve. A flow sheet recording heart rate and rhythm, arterial blood pressure, central venous pressure, minute ventilation, core temperature, urine output, mixed venous blood gas tensions, serum electrolytes, serum glucose, and total fluid intake is useful.

The major side effect of dantrolene is muscle weakness.[45] Muscle weakness is noted in approximately 25% of patients after an acute episode of MH treated with dantrolene. The effects of dantrolene on strength may persist for more than 8 to 12 hours. Severe muscle weakness of variable duration can also be the result of an MH episode and muscle injury. It is likely that when the plasma concentration of dantrolene is sufficient to inhibit an episode of MH, the patient will experience weakness and possibly disequilibrium. The ability to swallow could be compromised. The patient with MH may require intubation and artificial ventilation anyway because of respiratory failure or pulmonary edema. Phlebitis is a common side effect of dantrolene administration, noted in approximately 10% of patients. Giving dantrolene by intermittent bolus rather than by continuous infusion may lessen the incidence of phlebitis noted after dantrolene administration.

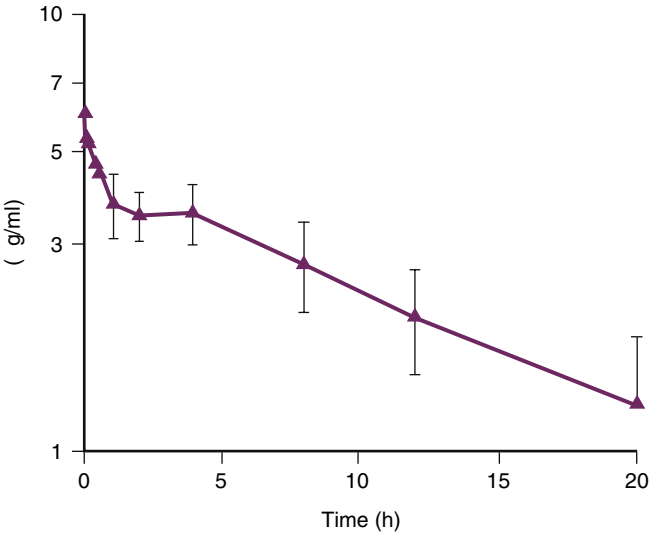

Figure 124–1. Whole blood concentration of dantrolene vs. time in a cohort of children. *(Modified from Lerman J, McLeod ME, Strong HA: Anesthesiology 70:625,1989.)*

If no recurrence is noted in the 24 hours following treatment of MH, the patient is metabolically stable, and weakness is marked, dantrolene administration may be withheld and weaning from supportive therapy begun. If dantrolene must be administered to a patient who is also receiving calcium

channel antagonists, invasive hemodynamic monitoring is necessary. Serum potassium should be closely monitored. Dantrolene may be useful in the treatment of fever and muscle spasticity not associated with MH. Therefore if fever diminishes and abnormal vital signs associated with fever resolve after the administration of dantrolene, the patient did not necessarily have MH.

Symptomatic Treatment

Adjunctive treatment in MH correlates with the severity of abnormal findings. Because pulmonary and cardiovascular compromise is a result of fulminant MH and because the major side effect of dantrolene is muscular weakness, endotracheal intubation and controlled ventilation may be useful in the treatment of an episode of fulminant MH. When calculation of O_2 consumption and CO_2 production is simplified by mechanical ventilation, these values serve as the most appropriate monitor of the adequacy of treatment of an episode of fulminant MH. Minute ventilation should be increased severalfold and O_2 provided as needed. When repeated assessment of blood gases indicates resolution of acidosis, minute ventilation can be normalized. Sodium bicarbonate should be administered liberally to treat metabolic acidosis.

If the core body temperature is elevated, active measures should be taken to cool the patient. In the operating room, drapes should be removed. A water mattress should be placed under the patient and turned to cooling temperatures. Room temperature should be decreased. The most effective means of cooling is the intravenous administration of cold normal saline through a peripheral or central vein. The stomach can be lavaged with iced saline. Ice packs may be placed on the groin and the axillae. Wet cloths and a fan can be used to promote surface evaporation. Active cooling should be stopped when core temperature falls below 38.8° C, to prevent inadvertent hypothermia.

Cardiac dysrhythmias usually stop when the episode is adequately treated with dantrolene. Lidocaine (1 mg/kg) is recommended for treatment of arrhythmias in MH. Amiodarone (5 mg/kg) can be administered for refractory ventricular tachycardia.[48] Hyperkalemia may require aggressive treatment, especially if arrhythmias have occurred or myoglobinuria has compromised renal function.

Administration of calcium gluconate or calcium chloride is an effective initial measure to reverse the cardiotoxicity of hyperkalemia. To produce an intracellular shift of potassium, and also to correct respiratory acidosis, hyperventilation should be initiated as soon as possible. Sodium bicarbonate should be administered, not only to correct metabolic acidosis but also to decrease plasma potassium. Glucose (0.3 to 0.5 g/kg), preferably as a 10% glucose solution with insulin (1 unit per 4 to 5 g glucose[49] or 0.1 unit/kg), will decrease plasma potassium. If hyperglycemia exists, the dose of dextrose should be reduced. Albuterol can be administered to reduce life-threatening hyperkalemia, in the same doses used to treat bronchoconstriction. Alternatively, intravenous β-adrenergic agonists (terbutaline, isoproproterenol, or epinephrine) may also be administered. Furosemide can be used to promote diuresis and treat high serum potassium. Dialysis (hemodialysis and peritoneal dialysis) can treat hyperkalemia, acidosis, and volume overload. Conventional hemodialysis does not remove myoglobin effectively, due to the size of this protein.[50] The use of antioxidants and free radical scavengers such as pentoxifylline, vitamin E, and vitamin C may be justified in the treatment or prevention of myoglobinuric acute renal injury,[51] but more controlled studies are needed. Early hypocalcemia secondary to rhabdomyolysis-induced acute kidney injury should not be treated unless it is symptomatic or severe hyperkalemia is present.[50]

Large losses of intravascular volume may occur, because evaporative loss may be great, edema formation may occur in muscle and other tissues, and mannitol given as part of the formulation of dantrolene may induce significant diuresis. Hypovolemia should be avoided because even mild hypovolemia impairs dissipation of heat produced by increased metabolism.[34] If diuresis is not occurring, additional mannitol should be administered to protect the kidneys from the effects of high concentrations of myoglobin in the urine. Cardiovascular support, in the form of isotonic fluid administration as well as vasopressor and inotropic drugs (epinephrine, phenylephrine, norepinephrine, dopamine) should be administered as soon as possible if indicated.

Urine and Blood Tests in Malignant Hyperthermia

Myoglobin, a heme-containing respiratory protein, is released from damaged muscle and rapidly excreted in the urine. In the presence of inhalation anesthetic agents in healthy children, myoglobinemia occurs within minutes of exposure to succinylcholine. Myoglobinuria occurs when the renal threshold of 0.5 to 1.5 mg/dL is exceeded. Myoglobinuria is suggested by persistent red to reddish-brown urine. At myoglobin levels of 100 mg/dL, urine tests positive for heme by dipstick after centrifugation, whereas the sediment has normal color and tests negative for heme. The dipstick test has a sensitivity of 80% for detection of rhabdomyolysis.[31] Renal injury is frequent when urine myoglobin is more than 1 g/mL. Because the half-life of myoglobin in the plasma is approximately 12 hours, less than the half-life of CK,[52] persistence of myoglobinuria for more than several days suggests that muscle cell integrity continues to be impaired. Patients with chronic myopathies may have moderately raised concentration of plasma myoglobin but not overt myoglobinuria.[52] Patients with chronic myopathies such as muscular dystrophy and inflammatory dystrophies seldom develop acute kidney injury, unless a superimposed event is present.

Marked elevation of CK (typically >10,000 U/L) and other muscle enzymes confirm the diagnosis of rhabdomyolysis. CK increases in the plasma with a slower time course than myoglobin does. There is no defined threshold value of serum CK above which the risk of acute kidney injury is increased. Usually the risk is low when the CK level is less than 15,000 to 20,000 U/L.[53] When coexisting conditions such as sepsis, dehydration, and acidosis are present, acute kidney injury may be associated with CK values as low as 5000 U/L. Serum myoglobin level peaks before serum CK and myoglobin is cleared from plasma more rapidly than CK. Thus it is not unusual to have increased CK without myoglobinuria.

When further evaluation is required to assess for the presence of MH, the test most likely to be helpful is venous blood gas analysis. Oxygen desaturation, hypercarbia, and lactic acidemia in mixed venous blood are the results of the hypermetabolism of MH. Elevated $PaCO_2$ is apparent in mixed venous

blood before it is abnormal in arterial blood during an episode of MH.[4] There is an increase in lactate release from muscle before a decrease in the partial pressure of oxygen in venous blood during an episode of MH.[54] If venous blood indicates significant acidosis, with $PaCO_2$ greater than 60 mm Hg and bicarbonate less than 19 mEq/L,[4] and the history of the patient is consistent with MH, the physician should assume that the patient is experiencing an episode of MH and treat accordingly.

The Course of a Clinical Episode of Malignant Hyperthermia

The case fatality for MH was about 70% to 80% in the 1970s. In 2009, estimates for MH mortality were less than 10%. The initial clinical signs of an impending episode of MH are nonspecific. When MH is fulminant, metabolic and respiratory acidosis, tachycardia with dysrhythmias, a rapid increase in body temperature to 39.5° C or greater, hyperkalemia, myoglobinuria, and a marked increase in serum CK are observed. The patient's medical history and clinical course usually help to differentiate fulminant MH from other medical, metabolic, or endocrinologic crises such as sepsis, porphyria, thyroid storm,[55] and untreated pheochromocytoma (see Box 124-3).

If the triggering agent is removed before the syndrome becomes self-perpetuating, abortive MH could be said to have occurred. In this case, there are only mild signs suggestive of MH: moderate increases in heart rate, blood pressure, and temperature along with a slight respiratory acidosis. Mild metabolic acidosis and moderate increases in serum myoglobin and CK may or may not be present. Masseter spasm may occur.[28] As previously suggested (see "Clinical Recognition of an Episode in Humans"), differentiating an abortive episode of MH from an anesthesia complicated by other factors can be difficult.

Recrudescence

There are cases in which a patient was symptomatically treated for MH with dantrolene, appeared to recover, and then some hours later had another episode of increased metabolic rate. This second episode was sometimes accompanied by remarkable stiffness of the muscles. It is difficult to explain how these episodes occur in the apparent absence of a pharmacologic trigger. Perhaps metabolic derangements in the muscle can become self-perpetuating.

Recrudescence of MH was reported in 20% of cases reported to the MH Registry[56] after initial treatment appeared to be successful. Muscular body type, the presence of temperature increase during the MH episode, and a longer time between the induction of inhalation anesthesia and the first sign of MH were associated with a greater risk of recrudescence.[56] There is no definite or guaranteed time course for these events in the human. Some suggest observing a patient closely for 24 hours after the apparent end of an episode of fulminant MH to allow for the early recognition and treatment of recrudescence. Such patients should be monitored in an ICU setting because of the utility of invasive cardiovascular monitoring in documenting the course of an episode of MH. Recrudescence of MH can progress into fulminant MH and therefore warrants aggressive treatment with dantrolene and supportive therapy.

Box 124–3 Differential Diagnosis of MH in the ICU

Neuroleptic malignant syndrome
Exertional hyperthermia and heat stroke
Serotonin syndrome
Sepsis associated with renal and respiratory failure
Central nervous system injury
Postoperative fever
Thyrotoxicosis
Rhabdomyolysis
Pheochromocytoma
Porphyria
Allergic reaction secondary to medications
Blood transfusion reactions
Administration of hypertonic dye such as diatrizoate
Drug abuse (cocaine, amphetamines, ecstasy)
Drug withdrawal
Iatrogenic overheating
Delirium tremens

Factors that "Trigger" Malignant Hyperthermia

MH is the result of acutely increased intracellular calcium concentrations in muscle. Excitation of the sarcolemma activates the voltage-sensitive dihydropyridine receptor that results in release of calcium through the RYR157 into the cytosol. There are at least two other processes, excitation-coupled calcium release and store-operated calcium release, that also produce increased intracellular calcium. The SR Ca^{2+}-ATPase pumps calcium back into the SR. Theoretically, factors that increase calcium release or impair the removal of calcium out of the sarcoplasm could facilitate the appearance of MH. Because removal of calcium from the sarcoplasm requires ATP, any factor that impairs the formation of ATP could similarly facilitate the appearance of MH.

Potent inhalational anesthetic agents such as sevoflurane, halothane, enflurane, isoflurane, and desflurane have been identified as triggering agents of MH in humans. Depolarizing neuromuscular blocking agents are also potent triggers of MH in humans. Succinylcholine is the only drug of this type currently in common use. Different anesthetics may trigger MH at different rates depending on the combination of agents used. The combination of succinylcholine and potent inhalation anesthetic agents produces more episodes of MH than do potent inhalation anesthetic agents administered without succinylcholine or succinylcholine administered in the presence of nitrous oxide and intravenous anesthetic agents.[27] A number of drugs, such as amide local anesthetics, droperidol, ketamine, calcium, digitalis, methylxanthines, anticholinergics, anticholinesterases, and sympathomimetic drugs, had in the past been considered to be potential triggers of MH in humans, primarily on theoretical grounds. Review of clinical and laboratory[58,59] experience suggests that these drugs are not triggers of MH; however, on rare occasions, MH may occur during an anesthesia in which no trigger agents were administered.

In general, MH in humans differs from porcine MH in that a pharmacologic trigger is usually required for the syndrome to develop. However, there is the possibility that a MH-like syndrome can occur without exposure to anesthesia.[60] This is very rare in humans, but has been observed repeatedly in MH-susceptible animals.[61] In a large, well-investigated human

kindred, two young patients who had the familial mutation associated with MH susceptibility died unexpectedly during febrile illnesses.[20] An athletic adolescent who had an *RYR1* mutation associated with MH died after strenuous exercise.[62] Of 12 unrelated patients with exercise-induced rhabdomyolysis, 10 had in vitro contracture tests that were positive for MH and 3 of these had RYR1 mutations.[63] Others have also reported recurrent myoglobinuria associated with exercise in patients with MH-positive in vitro muscle contracture studies and mutations in the RYR1 gene.[64]

Muscular Diseases Associated with Malignant Hyperthermia

There are a limited number of relatively rare muscular diseases that are closely linked with MH susceptibility. These include central core disease, multiminicore and nemaline rod myopathies,[65] and King-Denborough syndrome.[66] Central core disease (CCD) is a relatively mild congenital myopathy, characterized by motor developmental delay and signs of mild proximal weakness, most pronounced in the hip and girdle musculature. CCD and other congenital myopathies are characterized by early onset and by the presence of chronic, subclinical myopathy. Late onset of symptoms, in the seventh to eighth decade of life, has been reported with some of these conditions.[67] A patient with dystrophinopathy (Duchenne or Becker muscular dystrophy) can develop a hyperkalemic cardiac arrest and exacerbation of rhabdomyolysis after administration of the potent inhalation anesthetic agents. Succinylcholine is expected to elicit hyperkalemic cardiac arrest in such patients through a mechanism unrelated to MH. During initial treatment, such cases can be difficult to differentiate clinically from MH. Indeed, calcium is not handled normally in dystrophic muscle, and RYR1 channels may be part of the problem.[68] In the presence of neuromuscular disease, myoglobinuria may occur after exposure to potent inhalation anesthetics alone [52,69] and is to be expected after succinylcholine administration in patients with muscular dystrophy.[52] A child with myopathy who receives potent inhalation anesthetic agents can develop an increase in postoperative serum CK and potassium concentrations as well as myoglobinuria. These findings are due to the myopathy, not to MH.

Myotonias are a class of inherited skeletal muscle diseases characterized by impaired relaxation after sudden voluntary muscle contraction. There are defects in the chloride, sodium, and calcium channels in the different types of myotonia. The risk for MH is not greater than that of the general population, with the possible exception of hypokalemic periodic paralysis. Many cases of hypokalemic periodic paralysis are associated with variants in the CACNA1S, which codes for the DHPR, the voltage gate of the RYR1. Thus there is a theoretical association between MH and hypokalemic periodic paralysis, which has not been clearly confirmed.[13] To prevent episodes of myotonic contractures, depolarizing neuromuscular blocking agents such as succinylcholine should not be given to patients with myotonia. Other details of preventive management may differ between different forms of myotonia. In general myotonic patients should be maintained normothermic, episodes of anxiety should be avoided, and serum potassium should be documented. If nondepolarizing neuromuscular blocking agents (NMBAs) must be used, a drug with short duration is best and neuromuscular function should be monitored. The use of anticholinesterase drugs has been reported to precipitate myotonia. Neither nondepolarizing NMBAs nor dantrolene will counteract myotonic rigidity. Lidocaine, a sodium channel blocker, may decrease myotonic rigidity.

Exertional heat illness (EHI), exertional rhabdomyolysis (ER), and malignant hyperthermia are all hypermetabolic states, and can have similar manifestations. EHI is a disorder caused by excessive heat production, coupled with insufficient heat dissipation. It can progress to exertional heat stroke (EHS), which includes extreme hyperthermia (core body temperature higher than 40° C or 104° F) associated with central nervous abnormalities (delirium, coma, seizure). EHS can progress to multiorgan failure[70] with rhabdomyolysis. The CHCT can confirm the diagnosis of MHS, but it cannot be used to diagnose the potential for EHI or ER. Because there is a subset of patients who present with heat stroke that are also susceptible to MH, Grogan and Hopkins[71] suggested that these patients undergo testing for MH susceptibility. However, the majority of ER and EHS cases do not have a subclinical myopathy such as MH susceptibility.[71,72]

Patients with mitochondrial disease may develop acidosis and fever and even rhabdomyolysis. All anesthetics depress mitochondrial function, but there is no clear relationship between MH and mitochondrial myopathy.

Evaluation of Patients at Risk

The most efficient way to evaluate a family for MH susceptibility is to first evaluate the index patient with a caffeine-halothane contracture test of living muscle.[73] First-degree relatives of an individual with positive contracture results are assumed to have a 50% probability of also being MH susceptible. This assumption allows definition of the positive predictive value of the contracture test. Elements of the history and physical examination that could strengthen the suggestion that an individual may be susceptible to MH are a history of muscle cramping, heatstroke, hernias, clubfeet, scoliosis, spontaneous dislocation of the hip, eye muscle imbalance, or other minor muscular abnormalities. It must be acknowledged that these findings are nonspecific, but they may occur with greater frequency in individuals susceptible to MH than in the population at large. Similarly, resting CK concentrations may be elevated in MH-susceptible individuals. CK levels, at rest, are of no predictive value in the general population.[74,75] In some populations, more than 25% of the patients with elevated CK levels were not susceptible to MH on in vitro testing.[76] However, if a relative of a patient known to be susceptible to MH has an elevated CK level, that individual has an increased likelihood of being susceptible as well.[75]

Asymptomatic Elevation of Creatine Kinase Values

Nontraumatic exertional rhabdomyolysis (subclinical myoglobinemia, myoglobinuria, and elevation of CK) can be found after physical exertion when energy supply to muscle is insufficient to meet demands. Reasons for an exaggerated response include genetic factors,[77] fiber type, underlying occult myopathy,[78] environmental or behavioral factors such as exertion in humid conditions, and history of sickle cell trait.[79] The many potential causes of an elevated CK concentration should be evaluated by a neurologist.

CK, which is abundant in skeletal muscle, has a key role in energy metabolism. One isoenzyme of CK, the muscle specific CK (CK-MM), attempts to maintain energy homeostasis by providing a steady supply of creatine phosphate, which is critical for sustaining the Ca^{2+}-ATPase of the sarcoplasmic reticulum and other energy dependent enzymes.[80] Heled et al.[78] reported that the genotype of the CK-MM NcoI polymorphism was associated with the risk of having an exaggerated CK response to exercise. The location of the gene encoding this enzyme (chromosome 19q13.2-13.3) is in the same region where *RYR1* is located (19 q13.1)[81] The similar locations of these two genes, the possible association of RYR1 and exertional rhabdomyolysis, and the exaggerated response of CK-MM NcoI polymorphism genotype with exercise suggests a possible association between mechanical work and metabolic stress.

The "Safe" Anesthesia

An anesthesia designed for an individual who is or is suspected of being MH susceptible avoids drugs known to be triggers of MH, including depolarizing neuromuscular blocking agents such as succinylcholine and the potent inhalational anesthetic agents (sevoflurane, halothane, enflurane, desflurane, and isoflurane). Anesthetic regimens considered to be "nontriggering" include any regional anesthetic technique as well as intravenous drugs such as narcotics, barbiturates, benzodiazepines, propofol; nitrous oxide; and nondepolarizing neuromuscular blocking agents. Some intravenous anesthetic agents (e.g., thiopental and althesin) may attenuate or even prevent the initiation of MH in response to halothane. In general, drugs should be selected that have the least potential to increase heart rate (because tachycardia is an early sign of MH) and the least need for pharmacologic antagonism. Although anticholinesterase medications with anticholinergic agents can be administered to patients with susceptibility to MH, it is advisable to avoid drugs that may affect temperature regulation and sympathetic tone to such an extent that it might be difficult to distinguish drug effects from early signs of MH. Despite these concerns, ketamine has been safely administered to MHS patients. No anesthetic regimen is guaranteed to preclude the development of MH in a susceptible individual. There have been case reports of MH in patients who received regional anesthesia or general anesthesia with nontriggering drugs. However, it is to be expected that the incidence of MH will be much lower during the use of anesthetic agents that do not include the "triggering" agents of MH.[27] All anesthetic records should carefully document minute ventilation, core temperature, and fluid therapy. Point-of-care devices should be available to measure blood gases and electrolytes. Drugs and equipment necessary to treat MH should be immediately available.

Testing for Malignant Hyperthermia Susceptibility

In Vitro Caffeine-Halothane Contracture Testing

In vitro caffeine-halothane contracture testing (CHCT) is the only specific lab test of MH susceptibility other than identification of a *RYR1* mutation. At least 2 to 3 months should pass between an episode of suspected MH and the date of muscle biopsy.[82] This test has been described in detail, and the standards for its performance have been accepted by the specialized centers in North America and Europe that perform it.[83,84] The addresses of centers where muscle biopsy and contracture testing can be done can be found at www.mhaus.org and www.emhg.org.

CHCT has a sensitivity of 97% and a specificity of 78%.[85] It was designed to decrease the rate of false negatives. Therefore, it may produce false-positive results. For the in vitro test to be performed according to the North American standards, a sample of skeletal muscle is obtained from the quadriceps. In a test chamber where pH, oxygen tension, and temperature are controlled, the muscle is exposed to 3% halothane for 10 minutes or to caffeine given incrementally to 32 mmol/L. Muscle strips are stimulated supramaximally at 0.2 Hz, and tension is measured with a strain gauge. A video of this procedure can be seen at www.mhaus.org.

A positive result of the halothane contracture test is defined as a contracture of any one of the four to eight muscle strips prepared of greater than 0.2 to 0.7 g in the presence of 3% halothane. (The exact range of abnormal force is determined by each testing site after evaluation of at least 30 healthy controls.) A positive caffeine contracture test is defined as the observation of greater than 0.2 g tension in the presence of 2 mM caffeine, more than 1 g contracture at less than 4 mM caffeine, or an increase in maximal tension of more than 7% above baseline at 2 mM caffeine.

Results may be reported in terms of the caffeine-specific concentration, the concentration of caffeine at which muscle produces a contracture equal to 1 g of tension. As noted, a caffeine-specific concentration of less than 4 mM caffeine is a positive caffeine contracture test.

Reexamination of the results of the caffeine-halothane contracture test produced a statement of the operating characteristics of the test.[83,84] Its negative predictive value is high, but because the specificity of the in vitro test is only 85% at best, the positive predictive value of this test varies greatly depending on the prior probability of the individual being susceptible to MH.[42] As much clinical and laboratory evidence as can be obtained should be used to interpret the results of the muscle biopsy specimen. Many months can be required to confirm a diagnosis of MH susceptibility. Genetic analysis may be helpful if several generations of one family can be examined.

Less Invasive Tests of Malignant Hyperthermia Susceptibility

None of the relatively noninvasive tests of MH susceptibility have proved as sensitive and as specific as the in vitro caffeine-halothane contracture test. Tests that have been evaluated in the past include calcium uptake into frozen muscle, skinned fiber testing, platelet nucleotide depletion, ionized calcium concentration in lymphocytes, force of contracture, and phosphorus nuclear magnetic resonance spectroscopy. Recently, other tests based on RYR1 function in lymphocytes,[86,87] pharmacologic response in muscle cell cultures,[88-90] and microdialysis study of in situ muscle[91] have been proposed. None of these are usefully clinically in 2010.

An alternate to the caffeine-halothane contracture test for confirmation of MH susceptibility is a genetic test of *RYR1*. This was developed by genetic analysis of families in which

several individuals had undergone caffeine halothane contracture tests. Patients who had very strong contracture test results underwent characterization of *RYR1*. The exons in which variants are most commonly found were studied first (the hot spots). Biophysical properties of variants were studied in vitro to confirm that they altered calcium in a manner consistent with causing MH. At the present, more than 300 *RYR1* variants have been documented; of these, only 30 have been formally accepted as causative MH mutations (see www.emhg.org). Therefore the sensitivity of the clinical *RYR1* exam which sequences only the exons in which known causative MH mutations are located is at best 30%. The entire *RYR1* can be sequenced in a CLIA-approved laboratory. Sequencing of the entire gene may detect a variant in 50% to 70% of people who would have positive CHCT results. However, it is difficult to interpret the medical implications of the variants of unknown significance that may be identified. We suggest that professional genetic counseling is appropriate, in concert with consultation with a neurologist, when genetic testing of MH susceptibility is considered. Genetic testing has been useful post-mortem when the clinical circumstances were consistent with fulminant MH. Addresses of the laboratories can be found at www.mhaus.org. Patients with strong contractures in the presence of 3% halothane and no findings on *RYR1* may have a defect in a different protein. If *RYR1* screening fails to identify an MH-causative mutation, that patient should undergo muscle contracture testing to further evaluate MH susceptibility. A normal result on the CHCT is the only method that can currently prove that an individual is not MH-susceptible. Many months can be required to confirm a diagnosis of MH susceptibility.

Neuroleptic Malignant Syndrome and Serotonin Syndrome

NMS has been reported within 7 days after administration of antipsychotic drugs given to treat psychiatric disorders. NMS may occur 2 to 4 weeks after administration of depot neuroleptics and days after intravenous administration of various antipsychotic and antiemetic medications of the phenothiazine and butyrophenone classes.[92] Surgical patients may have received neuroleptics as antiemetics or sedatives. NMS can occur at any age. Silva et al.[93] reviewed the literature on NMS in children. They found 77 cases in patients ranging in age from 0.9 to 18 years, with only 10 patients younger than 10 years of age. NMS can be fatal. It develops insidiously over days. Initial signs include changes in mental status and extrapyramidal function. Sinus tachycardia or oscillation of blood pressure is very common. Muscle rigidity that can be described as "lead pipe," hyperthermia, and increased CK are major manifestations of NMS. Myoglobinuric renal failure due to rhabdomyolysis and respiratory distress are serious complications of NMS.

The treatment of NMS starts with discontinuation of neuroleptic agents as well as institution of supportive treatment to control hyperthermia, sustain vital functions, and prevent renal failure. There is evidence that NMS results from an acute reduction in dopaminergic function in the brain. Medications such as amantadine, bromocriptine, and levodopa have been used in treatment of NMS. Dantrolene, which inhibits muscle contraction and heat production, was reported to be effective in 81% of patients with NMS.[94] Electroconvulsive therapy (ECT) has also been suggested to be therapeutic.

NMS and MH are both drug-induced hypermetabolic syndromes. In the perioperative setting where both anesthetic agents and neuroleptic agents have been used, NMS should also be considered in the differential diagnosis of hyperthermia with rigidity. In contrast to MH, NMS does not appear to occur intraoperatively, because anesthetic agents and neuromuscular blocking agents may inhibit or mask the features of NMS. Both disorders may respond to dantrolene, but only NMS responds to nondepolarizing neuromuscular blocking agents and dopamine agonists.

The potential for susceptibility or cross-reactivity to both MH and NMS in the same patient is unproven. However, five of seven NMS patients who underwent muscle biopsy for in vitro halothane contracture testing had significantly abnormal results. Therefore the recommendation has been made to treat NMS patients as MH-susceptible until proven otherwise. Unfortunately, this can pose anesthetic difficulties during ECT. Succinylcholine, a potent trigger of MH, is a useful drug for lessening the force of the convulsions that accompany ECT. One patient who had experienced NMS did later receive succinylcholine repeatedly for ECT without complications.[95] Therefore it is unclear whether patients who have had NMS should be prevented from receiving anesthetic agents capable of triggering MH when these drugs are otherwise indicated. On the other hand, neuroleptic agents have been considered safe to administer to MHS patients, but there is some risk of hyperthermic reactions.[96]

There is evidence that patients with proximal myotonic dystrophy may be at increased risk for muscular complications after receiving neuroleptic drugs. Schneider et al. reported a patient with this disease who developed muscle stiffness, oculogyric dystonias, and elevated CK after administration of neuroleptic. This patient had a positive contracture test for MH susceptibility.[96]

Serotonin syndrome (SS) is another potentially life-threatening condition associated with increased serotonergic activity in the central nervous system, as a result of stimulation of postsynaptic 5-HT_{1A} and 5-HT_{2A} receptors.[97] It may result from any combination of drugs that increase serotonergic activity, such as amphetamine, cocaine, selective serotonin reuptake inhibitors, tricyclic antidepressants, monoamine oxidase inhibitors, triptans, lithium, dextromethorphan, and ondansetron. The diagnosis of SS in the pediatric population can be difficult. Clinical manifestations include autonomic changes such as tachycardia, hyperthermia, hypertension, diaphoresis, and diarrhea, and increased neuromuscular activity with tremor, muscle rigidity, hyperreflexia, and clonus. In SS, neuromuscular findings are typically more pronounced in the lower extremity,[98] compared with MH where there is a rigor-mortis–like rigidity. When compared with NMS, the distinguishing features of SS, besides the different causative agents, are a rapid onset (within 24 hours),[98] hyperreactivity (tremor, clonus, increase in reflexes), and rapid resolution.[97]

Although there may be similarities in the presentation of MH, NMS, and the SS, they have pathophysiologic differences. Nevertheless, there is experimental evidence in animals that stress-induced MH, more than anesthetic-induced MH, may be mediated in part by 5-HT.[99]

The Malignant Hyperthermia Assocation

The Malignant Hyperthermia Association of the United States (MHAUS, 11 East State Street, Box 1069, Sherburne, NY, 13460-1069; fax 607-674-7910) is a valuable resource for families affected by MH, NMS, or SS and for their physicians. This organization offers information, expert consultation, and referral. MHAUS maintains a 24-hour, professionally staffed telephone line to assist physicians and patients in dealing with MH (1-800-644-9737). All cases of suspected MH and similar heat-related disorders should be reported to the North American Malignant Hyperthermia Registry (telephone 888-274-7899; Web site, www.mhaus.org, MH Registry) to support the continued epidemiologic study of MH.
