Fourth Edition

Pediatric Critical Care

Bradley P. Fuhrman, MD, FCCM
Professor of Pediatrics and Anesthesiology
University at Buffalo School of Medicine
Chief, Pediatric Critical Care Medicine
Women and Children's Hospital of Buffalo
Buffalo, New York

Jerry J. Zimmerman, MD, PhD, FCCM
Professor of Pediatrics and Anesthesiology
Director, Pediatric Critical Care Medicine
Seattle Children's Hospital
Seattle, Washington

Joseph A. Carcillo, MD
Associate Professor of Critical Care Medicine and Pediarics
Children's Hospital of Pittsburgh of UPMC
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Robert S.B. Clark, MD
Chief, Division of Pediatric Critical Care Medicine
Children's Hospital of Pittsburgh of UPMC
Associate Director, Safar Center for Resuscitation Research
University of Pittsburgh
Pittsburgh, Pennsylvania

Monica Relvas, MD, FAAP
Pediatric Critical Care Medicine
Followship Director
Virginia Commonwealth University
Richmond, Virginia

Alexandre T. Rotta, MD, FCCM, FAAP
Director, Pediatric Cardiac Critical Care Program
Riley Hospital for Children, Indiana University
Associate Professor of Clinical Pediatrics
Indiana University School of Medicine
Indianapolis, Indiana

Ann E. Thompson, MD, MHCPM
Professor and Vice Chair for Faculty Development
Department of Critical Care Medicine
Associate Dean for Faculty Affairs
University of Pittsburgh School of Medicine
Medical Director for Clinical Resource Management
Children's Hospital of Pittsburgh
Pittsburgh, Pennsylvania

Joseph D. Tobias, MD
Chief, Department of Anesthesiology & Pain Medicine
Nationwide Children's Hospital
Professor of Anesthesiology & Pediatrics
Ohio State University
Columbus, Ohio

Contributors

Veda L. Ackerman, MD
Associate Professor of Pediatrics
Indiana University School of Medicine;
Associate Medical Director
Pediatric Intensive Care Unit
Riley Hospital for Children
Indianapolis, Indiana

P. David Adelson, MD, FACS, FAAP
Director, Children's Neuroscience Institute;
Division Chief of Pediatric Neurosurgery
Phoenix Children's Hospital;
Clinical Professor of Neurosurgery and Child Health
University of Arizona College of Medicine Phoenix;
Adjunct Professor
School of Biological and Health Systems Engineering
Ira A. Fulton School of Engineering
Arizona State University
Phoenix, Arizona

Rachel S. Agbeko, MD, FRCPCH
Affiliate Senior Clinical Lecturer
Department of Paediatric Intensive Care
Great North Children's Hospital
Royal Victoria Infirmary
Newcastle upon Tyne, Great Britain

Melvin C. Almodovar, MD
Associate in Cardiology
Medical Director, Cardiac ICU
Division of Cardiovascular Critical Care
Department of Cardiology
Children's Hospital Boston;
Assistant Professor of Pediatrics
Harvard Medical School
Boston, Massachusetts

Estella M. Alonso, MD
Pediatric Hepatology
Children's Memorial Hospital;
Professor of Pediatrics
Northwestern University Feinberg School of Medicine
Chicago, Illinois

Raj K. Aneja, MD
Assistant Professor
Departments of Critical Care Medicine and Pediatrics
University of Pittsburgh
Medical Director, Pediatric Intensive Care Unit
Children's Hospital of Pittsburgh of UPMC
Pittsburgh, Pennsylvania

Derek C. Angus, MD, MPH, FRCP
Chair, Department of Critical Care Medicine
The Mitchell P. Fink Endowed Chair in Critical Care Medicine
Professor of Critical Care Medicine, Medicine, Health Policy and Management, and Clinical and Translational Science
University of Pittsburgh School of Medicine and Graduate School of Public Health
Pittsburgh, Pennsylvania

Andrew C. Argent, MBBCh(Wits), MMed(Paeds)(Wits), DCH(SA), FCPaeds(SA), FRCPCH(UK)
Professor, School of Child and Adolescent Health
University of Cape Town;
Medical Director
Paediatric Intensive Care
Red Cross War Memorial Children's Hospital
Cape Town, Western Cape, South Africa

Francois P. Aspesberro, MD
Attending Physician
Seattle Children's Hospital;
Assistant Professor of Pediatrics
University of Washington School of Medicine
Seattle, Washington

Adnan M. Bakar, MD
Fellow, Pediatric Critical Care Medicine
Children's Hospital of New York
Columbia University College of Physicians and Surgeons
New York, New York

Barbara Bambach, MD
Associate Professor
Department of Pediatrics
State University of New York at Buffalo
Roswell Park Cancer Institute
Buffalo, New York

Lee M. Bass, MD
Assistant Professor of Pediatrics
Northwestern University Feinberg School of Medicine;
Division of Gastroenterology, Hepatology and Nutrition
Children's Memorial Hospital
Chicago, Illinois

Hülya Bayir, MD
Associate Professor
Department of Critical Care Medicine
Department of Environmental and Occupational Health
Director, Pediatric Critical Care Medicine Research
Associate Director, Center for Free Radical and Antioxidant Health
Safar Center for Resuscitation Research
University of Pittsburgh
Pittsburgh, Pennsylvania

Pierre Beaulieu, MD, PhD, FRCA
Associate Professor
Department of Pharmacology & Anesthesiology
Faculty of Medicine–University of Montreal
Montreal, Quebec, Canada

Michael J. Bell, MD
Associate Professor of Critical Care Medicine, Neurological Surgery and Pediatrics
Director, Pediatric Neurocritical Care
Director, Pediatric Neurotrauma Center
Associate Director, Safar Center for Resuscitation Research
University of Pittsburgh
Pittsburgh, Pennsylvania

M.A. Bender, MD, PhD
Associate Professor
Department of Pediatrics
University of Washington;
Director, Odessa Brown Children's Clinic Hemoglobinopathy Program
Seattle, Washington

Jeffrey C. Benson, MD
Assistant Professor
Department of Pediatrics
Section of Critical Care Medicine
Section of Pulmonary Medicine
Medical College of Wisconsin;
Assistant Medical Director
Pediatric Intensive Care Unit
Children's Hospital of Wisconsin
Milwaukee, Wisconsin

Wade W. Benton, PharmD
Associate Director, Medical Affairs
Actelion Pharmaceuticals US
South San Francisco, California

Robert A. Berg, MD
Professor of Anesthesiology, Critical Care Medicine, and Pediatrics
University of Pennsylvania School of Medicine;
Division Chief, Critical Care Medicine
Russell Raphaely Endowed Chair of Critical Care Medicine
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Darryl H. Berkowitz, MBBCh
Assistant Professor of Anesthesia
Department of Anesthesiology and Critical Care Medicine
University of Pennsylvania School of Medicine;
Attending Anesthesiologist
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Omar J. Bhutta, MD
Fellow
Pediatric Critical Care Medicine
Seattle Children's Hospital
University of Washington School of Medicine
Seattle, Washington

Katherine C. Biagas, MD, FAAP, FCCM
Associate Professor of Clinical Pediatrics
Interim Director, Pediatric Critical Care Medicine
Director, Pediatric Critical Care Medicine Fellowship
Columbia University College of Physicians and Surgeons
New York, New York

Julie Blatt, MD
Professor of Pediatrics
Pediatric Hematology Oncology
University of North Carolina
Chapel Hill, North Carolina

Douglas L. Blowey, MD
Associate Professor of Pediatrics and Pharmacology
University of Missouri–Kansas City
Children's Mercy Hospitals and Clinics
Kansas City, Missouri

Jeffrey L. Blumer, MD, PhD
Professor of Pediatrics and Pharmacology
Case Western Reserve University
School of Medicine
Cleveland, Ohio

John S. Bradley, MD
Director, Division of Infectious Diseases
Rady Children's Hospital
Associate Clinical Professor
University of California San Diego
San Diego, California

Barbara W. Brandom, MD
Professor
Department of Anesthesiology
University of Pittsburgh School of Medicine;
Director, North American MH Registry of the Malignant Hyperthermia Association of the United States
Mercy Hospital UPMC
Pittsburgh, Pennsylvania

Linda Brodsky, MD
Professor of Otolaryngology and Pediatrics (Retired)
State University of New York at Buffalo;
President, Pediatric ENT Associates
Buffalo, New York

Thomas V. Brogan, MD
Associate Professor
Department of Pediatrics
University of Washington School of Medicine;
Seattle Children's Hospital
Seattle, Washington

Adam W. Brothers, PharmD
Bone Marrow Transplant Clinical Pharmacist
Seattle Children's Hospital
Seattle, Washington

Timothy E. Bunchman, MD
Professor of Pediatric Nephrology
Pediatric Continuous Renal Replacement Therapy Foundation
Grand Rapids, Michigan

Randall S. Burd, MD, PhD
Chief, Division of Trauma and Burns
Children's National Medical Center
Washington, DC

Jeffrey Burns, MD, MPH
Chief
Division of Critical Care Medicine
Children's Hospital Boston;
Associate Professor of Anaesthesia
Harvard Medical School
Boston, Massachusetts

Sean P. Bush, MD
Professor of Emergency Medicine
Director, Fellowship of Envenomation Medicine
Department of Emergency Medicine
Loma Linda University School of Medicine
Medical Center & Children's Hospital
Loma Linda, California

Louis L. Bystrak, PharmD, BCPS
Clinical/Staff Pharmacist
Women & Children's Hospital of Buffalo-Kaleida Health;
Adjunct Instructor, Department of Pharmacy
The University at Buffalo School of Pharmacy and Pharmaceutical Sciences
Buffalo, New York

Angela J.P. Campbell, MD, MPH
Assistant Professor
Pediatric Infectious Diseases
University of Washington
Seattle Children's Hospital
Seattle, Washington

Christopher R. Cannavino, MD
Divisions of Infectious Diseases & Hospital Medicine
Rady Children's Hospital;
Assistant Clinical Professor of Pediatrics
University of California at San Diego;
Director, Pediatrics Clerkship
University of California San Diego School of Medicine
San Diego, California

Joseph A. Carcillo, MD
Associate Professor of Critical Care Medicine and Pediatrics
Children's Hospital of Pittsburgh of UPMC
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Hector Carrillo-Lopez, MD
Professor of Pediatric Critical Care
Pediatric Intensive Care Department
Hospital Infantil de Mexico Federico Gomez
Mexico City, Mexico

Antonio Cassara, MD
Visiting Assistant Professor
Department of Anesthesiology
Children's Hospital of Pittsburgh
Pittsburgh, Pennsylvania

Michael G. Caty, MD, MMM
John E. Fisher Professor of Pediatric Surgery
Department of Pediatric Surgical Services
Surgeon-in-Chief
Women & Children's Hospital of Buffalo;
Professor of Surgery and Pediatrics
Chief, Division of Pediatric Surgery
Department of Surgery
State University of New York at Buffalo
Buffalo, New York

John R. Charpie, MD, PhD
Professor and Division Director
Pediatric Cardiology Department of Pediatrics & Communicable Diseases
C.S. Mott Children's Hospital
University of Michigan
Ann Arbor, Michigan

Adrian Chavez, MD
Director, Pediatric Intensive Care
Hospital Infantil de Mexico Federico Gomez;
Assistant Professor of Pediatric Critical Care & Pediatrics
Facultad de Medicina
Universidad Nacional Autonoma de Mexico
Mexico City, Mexico

John C. Christenson, MD
Professor of Clinical Pediatrics
Director, Ryan White Center for Pediatric Infectious Disease
Director, Pediatric Travel Medicine Clinic
Director, Pediatric Infectious Disease Fellowship Program
Indiana University School of Medicine
Riley Hospital for Children
Indianapolis, Indiana

Jonna D. Clark, MD
Pediatric Critical Care Fellow
Pediatric Critical Care Medicine
Seattle Children's Hospital
Seattle, Washington

Robert S.B. Clark, MD
Chief, Division of Pediatric Critical Care Medicine
Children's Hospital of Pittsburgh of UPMC
Associate Director, Safar Center for Resuscitation Research
University of Pittsburgh
Pittsburgh, Pennsylvania

Katherine C. Clement, MD
Assistant Professor
Department of Anesthesiology
Division of Pediatric Critical Care Medicine
University of North Carolina at Chapel Hill
Chapel Hill, North Carolina

Jacqueline J. Coalson, PhD
Department of Pathology
University of Texas Health Science Center–San Antonio
San Antonio, Texas

Craig M. Coopersmith, MD, FACS, FCCM
Professor of Surgery
Director, 5E Surgical Intensive Care Unit
Associate Director, Emory Center for Critical Care
Emory University School of Medicine
Atlanta, Georgia

Christopher P. Coppola, MD, MBA
Associate Pediatric Surgery
Janet Weis Children's Hospital
Danville, Pennsylvania

Seth J. Corey, MD, MPH
Sharon Murphy-Steven Rosen Research Professor
Department of Pediatrics and Cellular & Molecular Biology
Children's Memorial Hospital & Robert H. Lurie Cancer Center
Northwestern University Feinberg School of Medicine
Chicago, Illinois

Peter N. Cox, MBChB, DCH, FFARCS(UK), FRCP(C)
Associate Chief
Clinical Director, Paediatric Intensive Care Unit
Fellowship Program Director
Department of Critical Care Medicine
Hospital for Sick Children;
Professor, Anaesthesia, Critical Care and Paediatrics
University of Toronto
Toronto, Canada

James J. Cummings, MD
Professor of Pediatrics and Physiology
East Carolina University Brody School of Medicine
Section Head
Neonatal-Perinatal Medicine
University Health Systems of Eastern Carolina
Greenville, North Carolina

Martha A.Q. Curley, RN, PhD, FAAN
Professor and Killebrew-Censits Term Chair
School of Nursing
Anesthesia and Critical Care Medicine
University of Pennsylvania
Philadelphia, Pennsylvania;
Nurse Scientist
Cardiovascular and Critical Care Program
Children's Hospital Boston
Boston, Massachusetts

Marek Czosnyka, MD
Department of Neurosurgery
Cambridge University
Cambridge, England

Christopher A. D'Angelis, MD, PhD
Department of Pathology
State University of New York at Buffalo School of Medicine and Biomedical Sciences
Buffalo, New York

Mary K. Dahmer, PhD
Associate Professor of Pediatric Critical Care
Department of Pediatrics
Medical College of Wisconsin
Milwaukee, Wisconsin

Heidi J. Dalton, MD
Chief, Critical Care Medicine
Phoenix Children's Hospital;
Director, Pediatric/Cardiac ECMO
Phoenix Children's Hospital
Phoenix, Arizona

Stéphane Dauger, Prof
Service de Réanimation et de Surveillance Continue Pédiatriques
Pôle de Pédiatrie Aiguë et de Médecine Interne de l'Enfant
Hôpital Robert Debré
Paris, France;
Assistance Publique
Hôpitaux de Paris et Université Paris
Colombes, France

Peter J. Davis, MD, FAAP
Anesthesiologist-in-Chief
Children's Hospital of Pittsburgh of UPMC;
Professor of Anesthesiology & Pediatrics
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Scottie B. Day, MD
Critical Care Medicine
Cincinnati Children's Hospital Medical Center
Cincinnati, Ohio

M. Theresa de la Morena, MD
Associate Professor of Pediatrics and Internal Medicine
University of Texas Southwestern Medical Center Dallas
Dallas, Texas

Cláudio Flauzino de Oliveira, MD, PhD
University of São Paulo
Instituto da Criança, Faculty of Medicine
São Paulo, Brazil

Sonny Dhanani, BSc(Pharm), MD, FRCPC
Assistant Professor
Pediatric Critical Care
Children's Hospital of Eastern Ontario
University of Ottawa
Ottawa, Ontario, Canada

Emily L. Dobyns, MD, FCCM
Associate Professor
Department of Pediatrics
Section of Pediatric Critical Care Medicine
University of Colorado, Denver
Health Sciences Center
Aurora, Colorado

Elizabeth J. Donner, MD, FRCPC
Staff Neurologist
Department of Neurology
The Hospital for Sick Children;
Assistant Professor, Department of Paediatrics (Neurology)
University of Toronto
Toronto, Canada

Lesley Doughty, MD
University of Cincinnati
Cincinnati, Ohio

Didier Dreyfuss, MD
Institut National de la Santé et de la Recherche Médicale
UFR de Médecine, Université Paris Diderot
Paris, France;
Assistance Publique, Hôpitaux de Paris
Hôpital Louis Mourier
Service de Réanimation Médicale
Colombes, France

Christine Duncan, MD, MMSc
Instructor
Pediatric Hematology/Oncology
Dana-Farber Cancer Institute
Boston, Massachusetts

Philippe Durand, MD
Service de Réanimation Pédiatrique et Néonatale
Hôpital de Bicêtre
Assistance Publique, Hôpitaux de Paris
Colombes, France

Susan Duthie, MD
Associate Medical Director
Pediatric Critical Care
University of California San Diego Rady Children's Hospital
San Diego, California

Howard Eigen, MD
Billie Lou Wood Professor of Pediatrics
Indiana University School of Medicine;
Vice Chairman for Clinical Affairs
Director, Section of Pulmonology, Critical Care and Allergy
Riley Hospital for Children
Indianapolis, Indiana

Waleed M. Maamoun El-Dawy, MBBCh
Clinical Instructor in Pediatrics
East Carolina University Brody School of Medicine;
Fellow-in-Training, Neonatal-Perinatal Medicine
University Health Systems of Eastern Carolina
Greenville, North Carolina

Steven Elliott, MD
Research Resident
Center for Surgical Care
Children's National Medical Center
Washington, DC

Helen M. Emery, MBBS
Division Chief
Program Director
Department of Rheumatology
Seattle Children's Hospital
Clinical & Translational Science
Seattle, Washington

Mauricio A. Escobar Jr., MD
Pediatric Surgeon
Pediatric Surgical Services
Mary Bridge Children's Hospital and Health Center
Tacoma, Washington

Jacqueline M. Evans, MD, PhD
Assistant Professor
Children's Hospital Los Angeles
Los Angeles, California

Kate Felmet, MD
Assistant Professor of Critical Care Medicine and Pediatrics
University of Pittsburgh School of Medicine;
Medical Director
Critical Care Transport Team
Children's Hospital of Pittsburgh
Pittsburgh, Pennsylvania

Jeffrey R. Fineman, MD
Professor of Pediatrics
Chief, Pediatric Critical Care Medicine
Investigator, Cardiovascular Research Institute
University of California San Francisco
San Francisco, California

Ericka L. Fink, MD
Assistant Professor
Division of Pediatric Critical Care Medicine
Children's Hospital of Pittsburgh of UPMC
Pittsburgh, Pennsylvania

Richard T. Fiser, MD
Professor of Pediatrics
Division of Pediatric Critical Care Medicine
University of Arkansas for Medical Sciences College of Medicine;
Medical Director, ECMO Program
Arkansas Children's Hospital
Little Rock, Arkansas

Frank A. Fish, MD
Professor of Pediatrics and Medicine
Director of Pediatric Electrophysiology
Division of Pediatric Cardiology
Vanderbilt University
Nashville, Tennessee

James E. Fletcher, MBBS, MRCP, FRCA
Department of Anesthesiology
Children's Healthcare of Atlanta
Atlanta, Georgia

Michael J. Forbes, MD
Critical Care
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Amber E. Fort, DO
Clinical Instructor in Pediatrics
East Carolina University Brody School of Medicine
Fellow-in-Training, Neonatal-Perinatal Medicine
University Health Systems of Eastern Carolina
Greenville, North Carolina

Norman Fost, MD, MPH
Professor, Department of Pediatrics
Department of Medical History and Bioethics
University of Wisconsin School of Medicine and Public Health
Madison, Wisconsin

Joel E. Frader, MD
A. Todd Davis Professor of General Academic Pediatrics
Department of Pediatrics
Children's Memorial Hospital;
Professor, Medical Humanities and Bioethics
Northwestern University Feinberg School of Medicine
Chicago, Illinois

Deborah E. Franzon, MD
Associate Medical Director
Clinical Assistant Professor
Pediatric Critical Care
Lucile Packard Children's Hospital at Stanford
Palo Alto, California

F. Jay Fricker, MD
Division Chief, Pediatric Cardiology
Congenital Heart Center
University of Florida
Gainesville, Florida

Stuart Friess, MD
Assistant Professor
Department of Anesthesiology and Critical Care Medicine
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Bradley P. Fuhrman, MD, FCCM
Professor of Pediatrics and Anesthesiology
University at Buffalo School of Medicine;
Chief, Pediatric Critical Care
Women & Children's Hospital of Buffalo
Buffalo, New York

Xiomara Garcia-Casal, MD
Assistant Professor
Division of Pediatric Intensive Care
Department of Pediatrics
Arkansas Children's Hospital
University of Arkansas for Medical Sciences
Little Rock, Arkansas

France Gauvin, MD
Associate Professor
Division of Pediatric Intensive Care
Department of Pediatrics
Sainte-Justine Hospital
Université de Montréal, Canada
Montréal, Canada

J. William Gaynor, MD
Associate Professor of Surgery
University of Pennsylvania School of Medicine;
Attending Surgeon
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Eli Gilad, MD
Pediatric Intensive Care Unit
Wolfson Medical Center
Holon, Israel

James C. Gilbert, MD
Director of Pediatric Surgical Services
Department of Surgery
Huntsville Women and Children's Hospital
Associate Clinical Professor of Surgery
Department of Surgery
University of Alabama School of Medicine
Huntsville, Alabama

Nicole S. Glaser, MD
Associate Professor
Department of Pediatrics
University of California Davis
School of Medicine
Sacramento, California

Stuart L. Goldstein, MD
Professor of Pediatrics
University of Cincinnati College of Medicine
Division of Nephrology and Hypertension & The Heart Institute
Director, Center for Acute Care Nephrology
Cincinnati Children's Hospital Medical Center
Cincinnati, Ohio

Denise M. Goodman, MD
Associate Professor
Pediatric Critical Care Medicine
Northwestern University Feinberg School of Medicine
Chicago, Illinois

Ana Lía Graciano, MD, FAAP
Pediatric Critical Care Medicine
Children's Hospital Central California
Academic Division Chief Pediatric Critical Care, Pediatric Residency Program
University of California at San Francisco-Fresno
Fresno, California

Björn Gunnarsson, MD
Department of Anesthesiology and Intensive Care
Akureyri Hospital;
Assistant Professor
University of Akureyri
Akureyri, Iceland

Cecil D. Hahn, MD, MPH, FRCPC
Staff Neurologist
The Hospital for Sick Children;
Associate Scientist
Program in Neuroscience and Mental Health
The Hospital for Sick Children Research Institute;
Assistant Professor
Department of Paediatrics (Neurology)
University of Toronto
Toronto, Ontario, Canada

Mark Hall, MD
Ohio State University
Columbus, Ohio

Melinda Fiedor Hamilton, MD, MSc
Assistant Professor of Critical Care Medicine and Pediatrics
Department of Critical Care Medicine
Children's Hospital of Pittsburgh of UPMC;
Director, Pediatric Simulation
The Pediatric Simulation Center of Children's Hospital of Pittsburgh of UPMC
Associate Director, Pediatric Programs
Peter M. Winter Institute for Simulation, Education, and Research
Pittsburgh, Pennsylvania

Yong Y. Han, MD
Assistant Professor
Department of Pediatrics and Communicable Diseases
University of Michigan Medical School
Ann Arbor, Michigan

Cherissa Hanson, MD
Assistant Professor of Anesthesiology
Pediatric Critical Care Medicine
Director, Pediatric Rapid Response System
University of North Carolina at Chapel Hill
Chapel Hill, North Carolina

Cary O. Harding, MD
Associate Professor
Molecular and Medical Genetics
Oregon Health & Science University
Portland, Oregon

Mary E. Hartman, MD
Department of Critical Care Medicine
University of Pittsburgh
Pittsburgh, Pennsylvania

Jan A. Hazelzet, MD, PhD, FCCM
Assistant Professor
Pediatric Intensive Care
Erasmus MC
Rotterdam, The Netherlands

Christopher M.B. Heard, MBChB, FRCA
Clinical Associate Professor
Anesthesiology, Pediatric Critical Care, Community & Pediatric Dentistry
Women & Children's Hospital of Buffalo
Buffalo, New York

Ann Marie Heine, PharmD
Clinical Pharmacy Coordinator
Department of Pharmacy
Women & Children's Hospital of Buffalo;
Adjunct Clinical Instructor
The University at Buffalo School of Pharmacy and Pharmaceutical Sciences
Buffalo, New York

Lynn J. Hernan, MD
Associate Professor, Department of Pediatrics
SUNY at Buffalo;
Director, PICU
Pediatric Critical Care
Women & Children's Hospital of Buffalo
Buffalo, New York

Jeremy S. Hertzig, MD
Fellow
Pediatric Critical Care Medicine
Seattle Children's Hospital
Seattle, Washington

Mark J. Heulitt, MD
Professor of Pediatrics, Physiology and Biophysics
College of Medicine
University of Arkansas for Medical Sciences
Little Rock, Arkansas

Julien I.E. Hoffman, BSC Hons(Wits), MD(Wits), FRCP(London)
Professor of Pediatrics (Emeritus)
Senior Member, Cardiovascular Research Institute
University of California San Francisco
San Francisco, California

James C. Huhta, MD
Professor
Women's Health and Perinatology Research Group
Institute of Clinical Medicine
University of Tromsø
Tromsø, Norway;
Medical Director, Perinatal Services
All Children's Hospital
St. Petersburg, Florida
Lead Physician, Fetal Cardiology Working Group
Pediatrix Medical Group
Sunrise, Florida

Rebecca Ichord, MD
Associate Professor, Neurology & Pediatrics
University of Pennsylvania School of Medicine;
Director, Pediatric Stroke Program
Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Andrew Inglis, MD
Associate Professor of Otolaryngology
Head and Neck Surgery
University of Washington School of Medicine
Seattle Children's Hospital
Seattle, Washington

Gretchen A. Linggi Irby, PharmD
Intensive Care Unit Clinical Supervisor
Seattle Children's Hospital
Seattle, Washington

Brian Jacobs, MD, FCCM
Critical Care Medicine
Children's National Medical Center
Washington, DC

David Jardine, MD
Associate Professor
Department of Anesthesiology and Pediatrics
University of Washington
Seattle, Washington

Alberto Jarillo-Quijada, MD
Head, Respiratory Therapy Service
Department of Pediatric Intensive Care
Hospital Infantil de México Federico Gómez
Mexico City, Mexico

Etienne Javouey, MD
Service de Réanimation et d'Urgences Pédiatriques
Hôpital Femme Mère Enfant des Hospices Civils de Lyon
Bron, France

Christa C. Jefferis Kirk, PharmD
Intensive Care Unit Clinical Pharmacist
Seattle Children's Hospital
Seattle, Washington

James A. Johns, MD
Professor of Pediatrics
Pediatric Cardiology Training Program Director
Division of Pediatric Cardiology
Monroe Carell, Jr. Children's Hospital at Vanderbilt
Vanderbilt University
Nashville, Tennessee

Prashant Joshi, MD
Associate Professor of Clinical Pediatrics
Fellowship Director
Pediatric Critical Care Medicine
Women & Children's Hospital of Buffalo
Buffalo, New York

Richard J. Kagan, MD, FACS
Chief of Staff
Shriners Hospitals for Children;
Professor of Surgery
University of Cincinnati College of Medicine
Cincinnati, Ohio

Prince J. Kannankeril, MD, MSCI
Assistant Professor of Pediatrics
Division of Pediatric Cardiology
Vanderbilt University
Nashville, Tennessee

Robert K. Kanter, MD
Professor of Pediatrics
Director Critical Care & Inpatient Pediatrics
SUNY Upstate Medical University
Syracuse, New York

Oliver Karam, MD
Fellow
Division of Pediatric Intensive Care
Department of Pediatrics
Sainte-Justine Hospital
Université de Montréal, Canada
Montréal, Canada

Kevin R. Kasten, MD
Surgical Resident
University of Cincinnati College of Medicine
Cincinnati, Ohio

Michael Kelly, MD
Assistant Professor of Pediatrics
Division of Pediatric Critical Care Medicine
Residency Program Director
Department of Pediatrics
Robert Wood Johnson Medical School
New Brunswick, New Jersey

Paritosh C. Khanna, MD, DMRE, MBBS
Pediatric Neuroradiologist
Seattle Children's Hospital
Member, Center for Integrative Brain Research
Seattle Children's Research Institute
Assistant Professor of Radiology
University of Washington School of Medicine
Seattle, Washington

Patrick M. Kochanek, MD
Professor and Vice Chairman
Department of Critical Care Medicine
Director, Safar Center for Resuscitation Research
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Keith C. Kocis, MD
Professor of Anesthesia, Pediatrics, and Biomedical Engineering (Adjunct)
Division of Pediatric Critical Care Medicine
PCCM Fellowship Director
The University of North Carolina at Chapel Hill
Chapel Hill, North Carolina

Samuel A. Kocoshis, MD
Professor, Department of Pediatrics
University of Cincinnati College of Medicine;
Director, Nutrition and Intestinal Transplantation
Division of Gastroenterology, Hepatology, and Nutrition
Cincinnati Children's Hospital Medical Center
Cincinnati, Ohio

Ildiko H. Koves, MD, FRACP
Assistant Professor
Division of Endocrinology and Diabetes
Seattle Children's Hospital
Seattle, Washington

Thomas J. Kulik, MD
Senior Associate in Cardiology
Children's Hospital Boston
Associate Professor of Pediatrics
Harvard Medical School
Boston, Massachusetts

Vasanth H. Kumar, MD
Assistant Professor of Pediatrics
Department of Pediatrics
State University of New York at Buffalo;
Associate Medical Director, NICU
Women & Children's Hospital of Buffalo
Buffalo, New York

Jacques Lacroix, MD, FRCPC, FAAP
Professor
Department of Pediatrics
Université de Montréal
Montréal, Québec, Canada

Satyan Lakshminrusimha, MD
Associate Professor of Pediatrics
Children's Hospital of Buffalo
Buffalo, New York

Joanne M. Langley, MD, MSc
Professor, Departments of Pediatrics and Community Health and Epidemiology
Division of Infectious Diseases
Dalhousie University;
Medical Director, Infection Prevention and Control Services
IWK Health Centre
Halifax, Nova Scotia, Canada

Peter C. Laussen, MBBS
Chief, Division Cardiovascular Critical Care
Department of Cardiology
DD Hansen Chair in Pediatric Anesthesia
Department of Anesthesia, Pain and Perioperative Medicine
Children's Hospital Boston;
Professor of Anaesthesia
Harvard Medical School
Boston, Massachusetts

Daniel L. Levin, MD
Attending Physician, Pediatric Intensive Care
Children's Hospital at Dartmouth
Professor of Pediatrics and Anesthesia
Dartmouth Medical School
Lebanon, New Hampshire

Mithya Lewis-Newby, MD, MPH
Assistant Professor
Pediatric Cardiac Intensive Care Unit
Division of Pediatric Critical Care Medicine
Department of Pediatrics
Seattle Children's Hospital
University of Washington School of Medicine
Seattle, Washington

Mary W. Lieh-Lai, MD
Associate Professor of Pediatrics
Director, ICU & Critical Care Medicine Fellowship Program
Children's Hospital of Michigan
Wayne State University School of Medicine
Detroit, Michigan

Daphne Lindsey, LCSW
Pediatric Intensive Care Unit Social Worker
Seattle Children's Hospital
Seattle, Washington

Catherine Litalien, MD, FRCPC
Associate Professor
Division of Pediatric Intensive Care
Department of Pediatrics
Director, Clinical Pharmacology Unit
CHU Sainte-Justine
Université de Montréal
Montreal, Quebec, Canada

Robert E. Lynch, MD, PhD
Director, Pediatric Critical Care
St. John's Children's Hospital
Creve Coeur, Missouri;
Adjunct Professor of Pediatrics
Department of Pediatrics
Saint Louis University Medical School
St. Louis, Missouri

Amy T. Makley, MD
Surgical Resident, University of Cincinnati College of Medicine
Cincinnati, Ohio

James P. Marcin, MD, MPH
Professor, Department of Pediatrics
University of California Davis Children's Hospital
University of California Davis School of Medicine
Sacramento, California

Mary Michele Mariscalco, MD
Associate Dean for Research
Professor of Pediatrics
KU School of Medicine Wichita
Office of Research
Wichita, Kansas

Barry Markovitz, MD, MPH
Director, Critical Care Medicine
Anesthesiology Critical Care Medicine
Children's Hospital Los Angeles;
Professor of Clinical Anesthesiology and Pediatrics
USC Keck School of Medicine
Los Angeles, California

Lynn D. Martin, MD, MBA
Professor
Department of Anesthesiology & Pain Medicine;
Adjunct Professor, Department of Pediatrics
University of Washington School of Medicine
Director, Department of Anesthesiology & Pain Medicine
Seattle Children's Hospital
Seattle, Washington

Norma J. Maxvold, MD
Helen DeVos Children's Hospital
Grand Rapids, Michigan

Paula M. Mazur, MD
Associate Professor of Clinical Pediatrics and Emergency Medicine
Child Abuse Pediatrician
State University at Buffalo School of Medicine and Biomedical Sciences
Women and Children's Hospital of Buffalo
Buffalo, New York

Jennifer A. McArthur, DO
Assistant Professor of Pediatrics
Pediatric Critical Care
Medical College of Wisconsin
Milwaukee, Wisconsin

Jerry McLaughlin, MD
Critical Care Medicine
Seattle Children's Hospital
Seattle, Washington

Gwenn E. McLaughlin, MD, MSPH
Professor of Clinical Pediatrics
University of Miami
Chief Quality and Safety Officer
Holtz Children's Hospital
Jackson Health System
Miami, Florida

Karen McNiece-Redwine, MD, MPH
Assistant Professor of Pediatrics
Section of Pediatric Nephrology
University of Arkansas for Medical Sciences/
Arkansas Children's Hospital
Little Rock, Arkansas

Nilesh M. Mehta, MD, DCH
Assistant Professor of Anesthesia
Harvard Medical School;
Associate in Critical Care
Division of Critical Care Medicine, Anesthesia
Children's Hospital Boston
Boston, Massachusetts

Renuka Mehta, MBBS, DCH, MRCP, FAAP
Associate Professor
Department of Pediatrics
Medical College of Georgia
Augusta, Georgia

Ann J. Melvin, MD, MPH
Associate Professor
Department of Pediatrics
University of Washington;
Division of Pediatric Infectious Disease
Seattle Children's Hospital
Seattle, Washington

Sharad Menon, MD
Department of Critical Care Medicine
Phoenix Children's Hospital
Phoenix, Arizona

Jean-Christophe Mercier, Prof
Service d'Accueil des Urgences Pédiatriques
Pôle de Pédiatrie Aiguë et de Médecine Interne de l'Enfant
Hôpital Robert Debré
Paris, France;
Assistance Publique, Hôpitaux de Paris et Université Paris
Colombes, France

Ayesa N. Mian, MD
Associate Professor
Department of Pediatrics
University of Rochester School of Medicine
Rochester, New York

Kelly Michelson, MD, MPH
Assistant Professor of Pediatrics
Division of Critical Care Medicine, Children's Memorial Hospital
Northwestern University Feinberg School of Medicine;
Associate Physician, Buehler Center on Aging, Health & Society
Chicago, Illinois

Kelly A. Michienzi, PharmD
Clinical Pharmacy Coordinator
Department of Pharmacy
Women & Children's Hospital of Buffalo;
Adjunct Clinical Instructor
The University at Buffalo School of Pharmacy and Pharmaceutical Sciences
Buffalo, New York

Patricia A. Moloney-Harmon, RN, MS, CCNS, FAAN
Advanced Practice Nurse/Clinical Nurse Specialist
Children's Services
Sinai Hospital of Baltimore
Baltimore, Maryland

Paul Monagle, MBBS, MSc, MD
Stevenson Professor of Paediatrics
Royal Children's Hospital
University of Melbourne;
Director, Department of Clinical Haematology
Royal Children's Hospital
Melbourne, Australia

Michele M. Moss, MD
Professor, College of Medicine
Department of Pediatrics
Vice Chair, Clinical Affairs
University of Arkansas for Medical Sciences
Little Rock, Arkansas

Steven S. Mou, MD, FAAP
Assistant Professor, Anesthesiology and Pediatrics
Department of Anesthesiology and Pediatrics
Section on Pediatric Critical Care Medicine
Wake Forest University School of Medicine
Winston-Salem, North Carolina

Jared T. Muenzer, MD
Assistant Professor of Pediatrics
Division of Pediatric Emergency Medicine
Washington University School of Medicine
St. Louis, Missouri

Vinay Nadkarni, MD, FAAP, FCCM, FAHA
Endowed Chair
Department of Anesthesia and Critical Care
Medical Director, Center for Simulation, Advanced Education, and Innovation
The Children's Hospital of Philadelphia;
Associate Director, Center for Resuscitation Science
University of Pennsylvania School of Medicine
Philadelphia, Pennsylvania

Thomas A. Nakagawa, MD, FAAP, FCCM
Professor, Department of Anesthesiology and Pediatrics
Section on Pediatric Critical Care Medicine
Wake Forest University School of Medicine;
Director, Pediatric Critical Care Medicine
Brenner Children's Hospital at Wake Forest University Baptist Medical Center
Winston-Salem, North Carolina

Navyn Naran, MD
Clinical Assistant Professor
Department of Pediatrics
University at Buffalo School of Medicine
Women & Children's Hospital of Buffalo
Buffalo, New York

Trung Nguyen, MD
Assistant Professor
Section of Critical Care Medicine
Department of Pediatrics
Section of Cardiovascular Research
Thrombosis Division
Department of Medicine
Baylor College of Medicine
Texas Children's Hospital
Houston, Texas

Carol E. Nicholson, MD, FAAP
Project Scientist
Collaborative Pediatric Critical Care Research Network (CPCCRN)
Program Director
Pediatric Critical Care and Rehabilitation Research
Eunice Kennedy Shriver National Institute for Child Health and Human Development
National Institutes of Health
Bethesda, Maryland

Katie R. Nielsen, MD
Pediatric Critical Care Fellow
Pediatric Critical Care Medicine
Seattle Children's Hospital
Seattle, Washington

Tracie Northway, BScN, MSN, CNCCP(C)
Quality & Safety Leader
Pediatric Critical Care
BC Children's Hospital
Vancouver, British Columbia, Canada

Victoria F. Norwood, MD
Robert J. Roberts Professor of Pediatrics
Chief, Pediatric Nephrology
Department of Pediatrics
University of Virginia
Charlottesville, Virginia

Daniel A. Notterman, MD
Professor, Pediatrics, Biochemistry and Molecular Biology
Vice Dean for Research and Graduate Studies
Penn State University College of Medicine
Hershey, Pennsylvania;
Associate Vice President for Health Sciences Research
Penn State University
University Park, Pennsylvania

Jeffrey E. Nowak, MD
Children's Respiratory and Critical Care Specialists
Children's Hospitals and Clinics of Minnesota
Minneapolis, Minnesota

Peter Oishi, MD
Assistant Professor of Pediatrics
Associate Investigator
Cardiovascular Research Institute
UCSF Benioff Children's Hospital
University of California, San Francisco
San Francisco, California

Richard A. Orr, MD, FCCM
Attending Physician, Cardiac Intensive Care
Children's Hospital of Pittsburgh;
Professor, Critical Care Medicine and Pediatrics
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Yves Ouellette, MD, PhD
Assistant Professor
Division Chair, Pediatric Intensive Care Medicine
Department of Pediatrics
Mayo Clinic
Rochester, Minnesota

Daiva Parakininkas, MD
Associate Professor
Department of Pediatrics
Medical College of Wisconsin;
Pediatric Intensivist/Pulmonologist
Assistant Medical Director
Pediatric Intensive Care Unit
Pulmonary/Critical Care Division
Children's Hospital of Wisconsin
Milwaukee, Wisconsin

Margaret M. Parker, MD
Professor of Pediatrics, Anesthesia, and Medicine
Stony Brook University
Stony Brook, New York

Tony Pearson-Shaver, MD, MHSA
Chief, Division of Pediatric Critical Care Medicine;
Department of Pediatrics
Medical College of Georgia;
Clinical Service Chief for Medicine
Children's Medical Center
Medical College of Georgia Health, Inc.
Augusta, Georgia

J. Julio Pérez Fontán, MD
Joel B. Steinberg, MD, Chair in Pediatrics
Associate Dean for Pediatric Services and Program Development
UT Southwestern Medical Center;
Executive Vice President of Medical Affairs
Children's Medical Center
Dallas, Texas

Mark Peters, MBChB, MRCP, FRCPCH, PhD
Senior Lecturer in Paediatric Intensive Care
Critical Care Group–Portex Unit
Institute of Child Health
University College
London, United Kingdom

Catherine Pihoker, MD
Professor of Pediatrics
University of Washington
Seattle, Washington

Maury N. Pinsk, MD, FRCPC
Associate Professor
Department of Pediatrics
Division of Pediatric Nephrology
University of Alberta
Edmonton, Alberta, Canada

Murray M. Pollack, MD, MBA
Chief Medical and Academic Officer
Phoenix Children's Hospital;
Professor of Pediatrics
University of Arizona School of Medicine
Phoenix, Arizona

Steven Pon, MD
Associate Professor
Department of Pediatrics
Weill Cornell Medical College;
Associate Director
Pediatric Critical Care Medicine
New York-Presbyterian Komansky Center for Children's Health
New York, New York

Michael Quasney, MD, PhD
Professor of Pediatrics
Pediatric Critical Care
Department of Pediatrics
Medical College of Wisconsin
Milwaukee, Wisconsin

Surender Rajasekaran, MD
Helen DeVos Children's Hospital
Grand Rapids, Michigan

Sally E. Rampersad, MB, FRCA
Attending Anesthesiologist
Department of Anesthesiology and Pain Medicine
Seattle Children's Hospital;
Associate Professor
Department of Anesthesiology and Pain Medicine
University of Washington School of Medicine
Seattle, Washington

Suchitra Ranjit, MD
Head, Pediatric Intensive Care and Emergency Services
Apollo Children's Hospital
Chennai, India

Erin P. Reade, MD, MPH
Assistant Professor of Pediatrics
University of Tennessee Medical College at Chattanooga;
Division of Pediatric Critical Care
TC Thompson Children's Hospital
Chattanooga, Tennessee

James J. Reese Jr., MD, MPH
Resident, Child Neurology
Department of Neurology
LSU Health Sciences Center
New Orleans, Louisiana

Monica Relvas, MD, FAAP
Pediatric Critical Care Medicine
Fellowship Director
Virginia Commonwealth University
Richmond, Virginia

Kenneth E. Remy, MD, FAAP, FACP
Fellow, Pediatric Critical Care Medicine
Children's Hospital of New York
Columbia University College of Physicians and Surgeons
New York, New York

Jean-Damien Ricard, MD, PhD
Institut National de la Santé et de la Recherche Médicale
UFR de Médecine, Université Paris Diderot
Paris, France;
Assistance Publique, Hôpitaux de Paris, Hôpital Louis Mourier
Service de Réanimation Médicale
Colombes, France

Tom B. Rice, MD, FAAP, FCCP
Professor and Chief
Pediatric Critical Care
Medical College of Wisconsin;
Director of Critical Care Services
Children's Hospital of Wisconsin
Milwaukee, Wisconsin

Debra Ann Ridling, RN, MS, CCRN
Director of Nursing Quality and Evidence Based Practice
Nursing Professional Development
Seattle Children's Hospital
Seattle, Washington

Joan S. Roberts, MD
Code Blue Chair
Co-Director Pediatric Critical Care Fellowship
Assistant Professor
University of Washington
Seattle Children's Hospital
Seattle, Washington

Ashley S. Ross, MD
Assistant Professor
Neonatal-Perinatal Fellowship Director
Co-Medical Director, UAMS NICU
Section of Neonatology
Department of Pediatrics
University of Arkansas for Medical Sciences
Arkansas Children's Hospital
Little Rock, Arkansas

Kimberly R. Roth, MD, MPH
Assistant Professor of Pediatrics
Division of Pediatric Emergency Medicine
Children's Hospital of Pittsburgh of UPMC
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Alexandre T. Rotta, MD, FCCM, FAAP
Director, Pediatric Cardiac Critical Care Program
Riley Hospital for Children at Indiana University
Associate Professor of Clinical Pediatrics
Indiana University School of Medicine
Indianapolis, Indiana

Mark E. Rowin, MD
Associate Professor of Pediatrics
Division of Pediatric Critical Care
TC Thompson Children's Hospital
University of Tennessee Medical College
Chattanooga, Tennessee

John Roy, MBBS
Department of Clinical Haematology
Royal Children's Hospital
Victoria, Australia

Christopher M. Rubino, PharmD, BCPS
Vice President, Pharmacometrics
Institute for Clinical Pharmacodynamics;
Adjunct Assistant Research Professor
The University at Buffalo School of Pharmacy and Pharmaceutical Sciences
Buffalo, New York

Randall A. Ruppel, MD
Pediatrician
Critical Care Physician
Saint Vincent Hospital
Indianapolis, Indiana

Cynda H. Rushton, RN, PhD, FAAN
Associate Professor
Department of Nursing and Pediatrics
Johns Hopkins University;
Faculty, Berman Institute of Bioethics
Johns Hopkins University;
Program Director, Harriet Lane Compassionate Care
The Johns Hopkins Children's Center
Baltimore, Maryland

Rita M. Ryan, MD
Professor of Pediatrics, Pathology and Anatomical Sciences, and Gynecology-Obstetrics
University at Buffalo
Women & Children's Hospital of Buffalo
Buffalo, New York

Rosanne Salonia, MD
Children's Hospital of Pittsburgh
Post-Doctoral Scholar; Clinical Instructor
Department of Critical Care Medicine
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Joshua Salvin, MD, MPH
Assistant in Cardiology
Department of Cardiology
Division of Cardiac Intensive Care
Children's Hospital Boston
Instructor in Pediatrics
Department of Pediatrics
Harvard Medical School
Boston, Massachusetts

Ronald C. Sanders Jr., MD
Associate Professor
Section of Critical Care
Department of Pediatrics
University of Arkansas College of Medicine
Arkansas Children's Hospital
Little Rock, Arkansas

Ajit A. Sarnaik, MD
Critical Care Medicine
Children's Hospital of Michigan;
Assistant Professor of Pediatrics
Wayne State University School of Medicine
Detroit, Michigan

Ashok P. Sarnaik, MD
Chief, Critical Care Medicine
Department of Pediatrics
Children's Hospital of Michigan;
Professor of Pediatrics
Wayne State University School of Medicine
Detroit, Michigan

Georges Saumon, MD
UFR de Médecine
Université Paris Diderot
Paris, France

Preface

On publishing this Fourth Edition of *Pediatric Critical Care,* we are struck by how much the milieu of pediatric critical care medicine and the content of this textbook have changed over the last 2 decades. The first edition of *Pediatric Critical Care* appeared in 1992, only 5 years after the first Pediatric Critical Care Medicine certification examination. In fact, the first table of contents for *Pediatric Critical Care* was constructed to encompass the American Board of Pediatrics' original content specifications for pediatric critical care medicine. Since then, most of the authors and editors of *Pediatric Critical Care* have survived recertification and are now actively engaged in "Maintenance of Certification." However, the value of a comprehensive textbook such as *Pediatric Critical Care* remains constant; it continues to provide a comprehensive overview of pediatric critical care medicine for those working in the field.

That noted, the content of *Pediatric Critical Care* has certainly evolved through these four editions. Cardiopulmonary physiology still represents comfort food for most intensivists. Those concepts remain as fundamental as ever. However, the virtual explosion of molecular biology has fueled the expectation of personalized medicine. When the first edition of *Pediatric Critical Care* appeared, the Human Genome Project was just getting underway. Today, whole genome mapping is common in research, and, in the near future, it will probably become an element of the medical record.

Reanimation was once a comic book fantasy. Today, extracorporeal life support has become an integral component of cardiopulmonary resuscitation in many hospitals. Since the first systemic pulmonary shunt was performed in 1943, the advances in pediatric cardiac surgery and postoperative care have been nothing less than spectacular, including the growth of pediatric cardiac intensive care as a new focused subspecialty. A parallel pattern of subspecialization seems to be appearing in pediatric neurocritical care. Similarly, pediatric critical care medicine has clearly played a role in improved survival of hematology/oncology and hematopoietic progenitor cell transplantation patients.

At the time of the first edition of *Pediatric Critical Care,* family-centered care was merely an interesting and controversial concept. Now parents routinely contribute information during rounds to help inform the daily care plan. Pulmonary artery catheters were once in common use, often placed by cut-down vascular access. Today, a pediatric critical care medicine fellow is more likely to encounter a pulmonary artery catheter in a simulation laboratory, yet is skilled in vascular ultrasonography and echocardiography, techniques that facilitate placement of vascular catheters on the first pass and provide three-dimensional visualization of complex cardiac anatomy. Before the new millennium, pediatric and adult patients with hypoxemic respiratory failure were commonly supported by using tidal volumes of 10 to 15 mL/kg. Chest tube insertion equipment and draining systems were typically ordered to the bedside on initiation of mechanical ventilation because pneumothorax was an anticipated and frequent complication. Similarly, catheter-associated bloodstream infections were a troublesome and not unexpected complication of central venous catheterization. Meanwhile, over the past 20 years, there has been a remarkable decline in deaths from sudden infant death syndrome, and infants of ever-greater prematurity have survived.

Two publications, "To Err is Human: Building a Safer System" and "Crossing the Quality Chasm" would not appear until the twenty-first century and have ushered in a new hospital paradigm of continuous quality improvement.

Although there have been huge advances in knowledge of the molecular pathophysiology of sepsis since the first edition of *Pediatric Critical Care,* basic critical care principles remain paramount: early detection; early, vigorous hemodynamic resuscitation; and early antibiotics—simple concepts that clearly save lives. Success in the field of pediatric critical care medicine has allowed a change in outcome focus of interventional clinical trials from death to long-term morbidity. Particularly over the last decade, pediatric critical care medicine has seen the emergence of clinical research networks that will continue to foster translation of important basic research into practice.

With the publication of the Fourth Edition of *Pediatric Critical Care,* the editors note that new challenges continue to emerge for practitioners, particularly in a field that is now overtly international in scope. Worldwide, roughly 25 children still die of sepsis every minute. Obesity now complicates the neurogenic-inflammatory-endocrine stress response to critical illness. A growing population of children with acquired immunodeficiency increasingly find their way into the pediatric intensive care unit, as do an increasing number of children with chronic complex conditions.

As in the past, although in debt to many, we remain particularity grateful to our families, friends, and colleagues who have been patiently supportive through three revisions of this textbook. We thank our new section editors as well as the hundreds of authors who have contributed to the success of this and former editions of the textbook. Lastly, we thank the members of the multidisciplinary teams who make pediatric critical care medicine work and the patients and families who allow us into their lives at a time when they are most vulnerable. Being a pediatric intensivist remains an amazing, challenging, rewarding, humbling, and privileged occupation.

We hope this Fourth Edition of *Pediatric Critical Care* will help nurture our evolving specialty.

Bradley P. Fuhrman

Jerry J. Zimmerman

Chapter 1

History of Pediatric Critical Care

Daniel L. Levin and I. David Todres†

"In critical care, it strikes one that the issues are three: realism, dignity, and love."

Jacob Javits, 1986 (United States Senator)

PEARLS

- There are many heroes in medicine and in pediatric critical care medicine, but most of the courage awards go to our patients and their parents.
- The evolution of pediatric critical care medicine has been a long process of progress in ventilation and resuscitation, physiology and anatomy, anesthesia, anesthesiology, neonatology, pediatric general and cardiac surgery, and pediatric cardiology.
- The role of nursing is absolutely central to the evolution of critical care units.
- Pediatric critical care physicians have made remarkable achievements in the understanding and treatment of critically ill children.
- Until the 1950s and 1960s, intensive care units were organized by grouping patients with similar diseases. In the 1960s, neonatal intensive care units began to group children according to age and severity of illness, and pediatric intensive care units followed this example.
- The development of sophisticated interhospital transfer services was significant in reducing mortality and morbidity of critically ill children, and "retrieval medicine" holds great promise for future improvements in care.
- We have seen great progress in the national and international organization of pediatric critical care medicine as well as in education and research in the field.
- Better and increased use of technology has advanced the care of critically ill children but has also created an environment with increasing errors, complications, and sequelae and a greater need for humane, caring environments for the patients and their families.

In his book *Retrospectroscope: Insights into Medical Discovery,*[1] Dr. Julius H. Comroe Jr, wrote about the courage to fail. He concluded there is no single definition of courage but that it comes in different sizes, each with its own definition. There are four sizes.

Courage, Size 1: "This, the largest size…..The person voluntarily involves himself in an action (or sometimes inaction) that places *himself* in grave peril such as loss of life, liberty, or pursuit of happiness. Courage, Size 1…also bars as a motive any possible gain, material or otherwise, to the individual should he fail or succeed, and postulates that if he succeeds, he wants the gain to be for someone else."

Examples of Courage, Size 1 awards go to James Carroll, William Dean, and Jesse Lazear (a former house officer of W. Osler),[2] who all volunteered to be bitten by yellow fever-infected mosquitoes to prove the mosquitoes were the human-to-human vector of the disease. They proved it and Lazear died. Also Werner Forssmann, who in 1929 introduced a catheter into his own right atrium in order to improve diagnosis for treatment of certain disorders, not knowing whether the tip would cause ventricular fibrillation.[2,3] He received little acclaim for this breakthrough until 1956, when he won the Nobel Prize.

Courage, Size 2: "Size 2…… differs from Size 1 in that the investigator… is not the one who takes the risk, in initial experiments the subject is usually a close member of his family, even one of his children…An example is Lady Montague who having survived an attack of smallpox in the early 1700s, long before Jenner (cowpox) had her children inoculated with pus from patients suffering from virulent smallpox. Another is Edward Jenner who vaccinated his first son Edward with cowpox and then injected him with pus from smallpox patients on five or six occasions to prove he was immune. He then vaccinated his second son Robert.

Courage, Size 3: "This is similar to size 1, in that the individual puts his own life at risk instead of that of another…, the risk is a grim one, and considerable benefits to mankind would surely accrue if his mission should be successful. It ranks below Sizes 1 and 2 because his act is motivated by assured fame and fortune if he succeeds. There are no examples of this in medicine, but Charles Lindbergh's 1927 transatlantic flight is an example in aviation.

Courage, Size 4: "Size 4 medals go to patients who, informed by specialists they have advanced disease and statistically have only weeks, months, or years to live, elect to undergo a previously untested operation or other form of therapy…It might benefit them or lead to earlier death." Examples are the first man (1925) to have bilateral sympathectomy for very high arterial blood pressure; Dr. James Gilmore (1933), the first patient to have one whole lung removed surgically at a single operation; the family of the first patient to receive insulin; the first patient to receive penicillin; and the family of the first "blue baby" operated on by Blalock.

†Deceased.

Some physicians may get Courage, Size 4 awards when they face intense professional criticism and loss of professional esteem for their efforts, such as Dr. Ludwig Rehn, a German surgeon, who in 1896 repaired a 1.5 cm stab wound of the right ventricle of a young man, saving his life. He did this despite a pronouncement in 1883 by the dean of European surgery, Billroth, who warned others not to try. Some patients (or parents) get Courage, Size 4, awards for the willingness to try a procedure or treatment despite knowing this has met with repeated failure. For example, in 1948 Claire Ward, a 24-year-old woman, was the fifth patient to be operated on by Dr. Charles Bailey in Philadelphia for mitral stenosis. This operation had previously been reviewed and proclaimed unsuccessful, and, when Bailey revived it, his first four patients died. Mrs. Ward traveled to Chicago by train 10 days after the operation, went on to live for 23 more years, and gave birth to two children.

Some physicians may have nothing to lose but may get a Perseverance, Size 1 award for continued effort. For example, there are Zoll's attempts at converting ventricular fibrillation by the closed-chest technique; the first three patients died before his first success. Others include Smythe and Bull, who pioneered neonatal ventilation (see below).

Although we in pediatric critical care have plenty of physician "heroes" we admire and appreciate, none get Courage Size 1, 2, or 3 awards. Rarely, we encounter those worthy of Size 4 awards for having risked their professional standing. By far and away, more of our Courage, Size 4 awards go to patients and parents who have had the courage to fail when presented with bleak prognoses and offered only untested or previously unsuccessful procedures or therapies.

Definitions

An important early principle of pediatric critical care medicine (PCCM) is centralization of resources and expertise. Currently, we have highly trained individuals and sophisticated technology in specialized physical spaces. In the future, we may see these highly trained individuals extending their services into additional sites to address the problems of sick children earlier in their illness.

Definition of a Pediatric Intensive Care Unit

In the 1983, Guidelines for Pediatric Intensive Care Units (PICUs)[4] (updated 1993[5] and 2004[6]) the committee defined a PICU as "…a hospital unit which provides treatment to children with a wide variety of illnesses of life-threatening nature including children with highly unstable conditions and those requiring sophisticated medical and surgical treatment." Randolph et al.[7] have expanded this definition, stating, "A PICU is a separate physical facility or unit specifically designated for the treatment of pediatric patients who, because of shock, trauma, or other life-threatening conditions, require intensive, comprehensive observations and care."

Definition of Pediatric Intensivist

Randolph et al.[7] define a pediatric intensivist (in the United States) as "…any one of the following: (a) a pediatrician with subspecialty training in PCCM and subspecialty certification from the American Board of Pediatrics (ABP); (b) a pediatric anesthesiologist with special competency in critical care with subspecialty certification from the American Board of Anesthesiology; (c) a pediatric surgeon with special competency in critical care with subspecialty certification from the American Board of Surgery; or (d) a physician (as above) eligible for subspecialty certification by their respective board." Similar requirements for training exist or are in development elsewhere in the world.

History of Critical Care

Resuscitation and Ventilation

The key to understanding the present practice of intensive care for children lies in knowing the history of scientific study of cardiorespiratory anatomy and physiology and of the discovery of techniques to support ill patients. Although one could think our current practice suddenly emerged with the late twentieth-century technical discoveries, Downes and Todres have skillfully reminded us[3,8] that accomplishments in the development of resuscitation and ventilation that we take for granted today date back to the Bible, and numerous events and contributions led to our current practice. In a biblical story,[9] Elisha resurrected a young boy who was dead when, " …he climbed onto the bed and stretched himself on top of the child, putting his mouth to his mouth, his eyes to his eyes, and his hands to his hands, and as he lowered himself onto him the child's flesh grew warm….Then the child sneezed and opened his eyes." In 117 CE, Antyllus performed tracheotomies for patients with upper airway obstruction.[10] Paracelsus, a sixteenth-century Swiss alchemist and physician, first provided artificial ventilation to both animals and dead humans using a bellows,[10] and Andreas Vesalius, a Flemish professor of anatomy, in *De Humani Corporis Fabrica* reported ventilating open-chest dogs and pigs using a fireplace bellows in 1543.[11-13]

The French obstetrician Desault, in 1801, described how to successfully resuscitate apneic or limp newborns by digital orotracheal intubation with a lacquered fabric tube and then blowing into the tube.[3] In 1832, Dr. John Dalziel in Scotland developed a bellows-operated intermittent negative-pressure device to assist ventilation,[14] In 1864, Alfred F. Jones, of Lexington, Kentucky, built a body-enclosing tank ventilator, and in the 1880s, Alexander Graham Bell developed a "vacuum jacket" driven by hand-operated bellows.[14] In 1876, Woillez, in Paris, built what was probably the first workable iron lung, which was strikingly similar to the respirator introduced by Emerson in 1931.[14] Braun developed an infant resuscitator, as described by Doe in 1889, which was used successfully in 50 consecutive patients. A respirator developed by Steuart in Cape Town, South Africa, in 1918 apparently successfully treated a series of polio patients, but he did not report it.[14]

In 1888, Joseph O'Dwyer, a physician working at the New York Foundling Hospital who was concerned about the severe death rate in croup and laryngeal diphtheria, instituted the manual method of blind laryngeal intubation. *Despite severe criticism from associates and the other practitioners, he persisted in the use of this technique.* He assembled a series of sized tubes for the palliation of adult and pediatric laryngeal stenosis and, with George Fell, devised a method of ventilation with a foot-operated bellows connected by rubber tubing to the endotracheal tube (Figure 1-1).[12] O'Dwyer may deserve a Courage, Size 4 award for his work.

In 1898, Rudolph Matas of New Orleans adapted the Fell-O'Dwyer technique to perform chest wall surgery and, in the early 1900s, George Morris Dorrance of Philadelphia used the technique to perform resuscitations.[12] In 1910, at the Trendelenburg Clinic in Leipzig, two thoracic surgeons, A. Lawen and R. Sievers, developed a preset, electrically powered piston-cylinder ventilator with a draw-over humidifier. It was used with a tracheotomy tube during and after surgery and for a variety of diseases.[3] Over a long career, Chevalier Jackson (1858-1955), a surgeon at Temple University in Philadelphia, developed the techniques for laryngoscopy, bronchoscopy, and tracheotomy.[3]

In 1958, Peter Safar published work in which he showed the longstanding resuscitation technique of chest-pressure arm-lift was virtually worthless and, in effect, went back to Elisha and proved jaw thrust and mouth-to-mouth resuscitation superior.[15] Soon after, W.B. Kouwenhoven and James Jude at Johns Hopkins published work on the effectiveness of closed-chest cardiac massage.[16] Beck and his team, in 1946, had demonstrated open-chest electrical defibrillation, and, in 1952, Zoll and his team proved the efficacy of external defibrillation and, in 1956, the effectiveness of external cardiac pacing.[17]

Anesthesia

The evolution of PCCM is tightly linked with the demand for postoperative care for infants and children with conditions needing complex surgery. The evolution of anesthesia allowed surgeons to develop the techniques to address the problems of these patients.

In 1842, Crawford W. Long, a University of Pennsylvania Medical School graduate practicing medicine in rural Georgia, observed that bruises encountered by participants during "ether frolics" caused no pain when they occurred during the "exhilatory" effects induced by inhalation of vapor. This also occurred when nitrous oxide was inhaled. Both of these agents, at the time, were inhaled for their hallucinatory effects in the United States. Long utilized this serendipitous observation to provide ether to James Venable and incise a cyst from his neck, without pain. This was 4 years before Morton's demonstration of the use of ether at Massachusetts General Hospital in 1846. In 1849, Long reported his experience with his third patient, an 8-year-old boy who had a diseased toe, which was amputated without pain in 1842.[18]

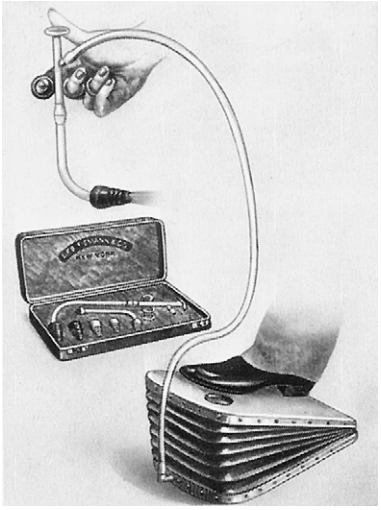

Figure 1–1. The Fell-O'Dwyer Respiratory Apparatus. *(Reproduced with permission, Blackwell Scientific Publications, Oxford.)*

The widely publicized public demonstration of the use of ether by the dentist William T.G. Morton took place at the Massachusetts General Hospital on October 16, 1846. Dr. John Collins Warren removed a mandibular tumor, without the patient experiencing pain. This great success was quickly picked up and used by John Snow in London and later by Friedrich Trendelenburg in Leipzig, who first used anesthesia via an endotracheal tube in 1869.[19]

Anatomy and Physiology

What seems simple and obvious today took a great deal of time, effort, and insight to understand. Downes[3] has provided a thorough review of this topic, and we briefly note here some of the contributions that advanced medicine and enabled the development of cardiorespiratory support and, eventually, intensive care. Andreas Vesalius (1514-1564), the Flemish anatomist, corrected many previous mistakes in anatomy and provided positive-pressure ventilation via a tracheotomy tube to asphyxiated fetal lambs. Michael Servetus of Spain (1511-1553) correctly described the pumping action of the heart's ventricles and the circulation of the blood from the right heart through the lungs to the left heart. *He was burned at the stake for his views* and thus deserves a Courage, Size 1 award. Matteo Realdo Columbo (1515?-1559) described the pulmonary circulation and the concept that the lungs added a *spirituous* element to the blood by the admixture of air. William Harvey (1578-1657), with his genius and *perseverance,* published *De Motu Cordis* (On the Motion of the Heart)[20] in 1678. Since he did not yet have the microscope available, he could not see the capillaries and thus could not include the mechanism for transfer of blood from the arterial to the venous system of the pulmonary circulation. Capillaries were described by Marcello Malpighi (1628-1694, Italian) in *De Pulmonibus* (On the Lungs) in 1661. Thomas Willis (1611-1675) and, eventually, William Cullan (1710-1790) led the way to understanding the role of the nervous system as the site for consciousness and the regulation of vital phenomena. Richard Cower (1631-1641) proved it was the passage of blood through the lungs, ventilation of the lungs, and gas exchange with blood that vivified the blood and turned it red. Stephen Hales (1677-1761) measured blood pressure with a brass tube connected to a 9-foot glass tube in a horse. Joseph Black (1728-1799) identified carbon dioxide as a gas expired from human lungs. Karl Wilhelm Scheele (1742-1785) isolated oxygen, as did Joseph Priestley (1733-1804), who named it *dephlogisticated air* and determined its vital role in supporting combustion. Antoine Laurent Lavoisier (1743-1794) identified oxygen as the vital element taken up by the lungs that maintains life and gave it its name, but its essential role in physiology and biochemistry was clarified much later. Joseph Lister (1817-1916), one of the founders of modern histology, reasoned that bacteria were the source of pus in rotten organic material and used carbolic acid in surgical fields to eliminate bacteria. This technique improved patient outcomes for wounds and after surgery. Along with the discovery of antibiotics, antiseptic technique was an important step in patient care. Nonetheless, imperfect antiseptic technique, sepsis, inflammation, and the consequences of multiorgan failure are still a major portion of what pediatric intensivists deal with today. Felix Hoppe-Seyler (1825-1895) described the transportation of oxygen in blood by hemoglobin. Robert

Koch (1843-1910) developed his postulates in 1882. William Konrad von Röntgen (1845-1923) discovered x-rays. Scipione Riva-Rocci (1863-1937), in 1846, measured blood pressure using the sphygmomanometer, and Nikolai Korotkoff, in 1905, introduced his auscultation method.[3] In the present day, cardiac catheterization, echocardiography, computerized tomography, and magnetic resonance imaging have enabled clinicians to delve into anatomy and physiology in the living patient with relative ease.

History of Pediatric Critical Care

Pediatric Anesthesiology

The development of PCCM rests on the efforts of pediatric anesthesiologists, as well as pediatric general and cardiac surgeons, and neonatologists. In fact, most of the original PICUs were founded by pediatric anesthesiologists (Table 1-1).[3,8,21-28] Much depends on the definition of a PICU, very much a moving target in the early days, with units eventually evolving from separate areas within recovery rooms and adult units to separate freestanding PICUs. In addition to those noted in Table 1-1, there were probably others which are not as well documented.

Pediatric General and Cardiac Surgery

The pioneering efforts of Dr. William E. Ladd (1880-1967) at Boston Children's Hospital (BCH) in developing many of the techniques to operate on noncardiac congenital malformations and Dr. Robert Gross, also at BCH, to operate on congenital cardiac lesions (7-year-old Lorraine, coarctation of the aorta, August 23, 1938) were instrumental in developing their surgical fields and demonstrating the need for good postoperative care. Dr. C. Everett Koop trained there for 6 months and then returned to Children's Hospital of Philadelphia (CHOP) where he, with the help of nursing staff, developed the first neonatal surgical intensive care unit in 1956. This was staffed by Dr. Leonard Bachman (anesthesiology) and his colleagues. Dr. Bachman's young associate, John J. Downes, subsequently set up the PICU in the hospital in 1967. Dr. C. Crawfoord in Sweden repaired a coarctation of the aorta in 1945, and Drs. Alfred Blalock (surgeon) and Helen Taussig (cardiologist) with Mr. Vivien Thomas (laboratory assistant) at Johns Hopkins created the subclavian-to-pulmonary artery shunt for tetralogy of Fallot, also in 1945. Dr. John Gibbon at Jefferson Medical College Hospital in Philadelphia performed the first successful open-heart surgery (for atrial septal defect) using cardiopulmonary bypass in 1953.[3] As the surgical procedures became more invasive, the need for improved postoperative support of all organ systems advanced rapidly. Although some surgeons believed the success or failure of treatment was solely determined in the operating room, others credited improved survival to better postoperative care.

Neonatology

Pediatric critical care owes a great debt to fellow neonatal pediatricians.[3,8,29] In the 1880s and 1890s special care nurseries were developed in Paris, and in 1914, the first premature infant center in the United States was opened at Michael Reese Hospital in Chicago by Dr. Julius Hess (1876-1955). In Canada, Dr. Alfred Hart performed exchange transfusions in 1928, and in 1932, Drs. Louis Diamond, Kenneth Blackfan, and James Batey at BCH described the pathophysiology of hemolytic anemia and jaundice of erythroblastosis fetalis; in 1948, the same team performed exchange transfusions using a feeding tube inserted in the umbilical vein. In the 1950s and 1960s, Dr. Geoffrey Dawes at the Nuffield Institute for Medical Research at Oxford University began work, using fetal and newborn lambs, to describe the circulation of mammalian neonates. This work was continued, and the fetal transitional circulation further elucidated, by Dr. Abraham Rudolph and colleagues at the Cardiovascular Research Institute (CVRI) of the University of California, San Francisco (UCSF).

Dr. Clement Smith at Boston Lying-In Hospital published his textbook of neonatal physiology in 1945, and in 1959, a research fellow at Harvard, Dr. Mary Ellen Avery (with mentor Dr. Jere Mead) discovered the deficiency of alveolar surfactant in lungs of newborns dying from respiratory distress syndrome (RDS). Dr. L. Stanley James from New Zealand was recruited to Columbia in New York by Dr. Virginia Apgar (anesthesiology) in the 1960s and helped confirm the work of Dr. Dawes. In the 1960s, neonatologists altered the practice used in adult ICUs of cohorting patients with similar diseases by establishing units with infants with a variety of life-threatening conditions and shifted from supportive care to more invasive measures to treat organ failure.

In 1959, Drs. Peter Smythe (pediatrician) and Arthur Bull (anesthesiologist) had the first real success in long-term mechanical ventilation of neonates, treating infants with neonatal tetanus for 4 to 14 days using tracheotomy and a modified Radcliff adult ventilator.[30] Up until that time, infants were not given ventilatory support for more than a few hours using manual ventilation. There were no pediatric ventilators, humidifiers, or blood gas analysis. Dr. Smythe had to overcome these obstacles by innovation. On July 13, 1957, he began intermittent positive-pressure ventilation on a baby with neonatal tetanus at Groote Schuur Hospital, with the assistance of anesthesiologist Bull. This was truly a landmark event in the evolution of PCCM. There are three interesting points to be made about their work. First, although considered a success story in that it was the first time infants survived long-term positive-pressure mechanical ventilation, the first 7 of 9 patients died. Eventually their survival rate reached 80% to 90%. Surely Smythe and Bull deserve Perseverance, Size 1 awards. Second, they commented that, "No praise can be too high for the nursing staff, who were all student nurses and without any special training." And third, Dr. David Todres, a medical student at the time, administered intramuscular curare to these patients. Dr. Smythe moved to Red Cross Children's Hospital when it opened in 1958, and established a 6-bed neonatal tetanus unit.

In 1963–1964 in Toronto, Drs. Paul Swyer, Maria Delivoria-Papadopoulos and Henry Levison were the first to successfully treat premature infants with RDS with positive-pressure mechanical ventilation and supportive care.[31] They emphasized the importance of a full-time team, *including dedicated nurses and therapists* as well as physicians. In 1968, Dr. George Gregory and colleagues demonstrated greatly improved survival with the addition of continuous positive airway pressure (CPAP) and positive end-expiratory pressure (PEEP) to the mechanical ventilation regimen.[32] However, as always, progress in treating a disorder leads to unforeseen complications and new disorders, and successful treatment of RDS led to

Table 1–1 Early Pediatric Intensive Care Units and Programs

Year	Institution/Location	Medical Director(s)	Director(s) Specialty
1955	Children's Hospital, Goteborg, Sweden	G. Haglund	Pediatric Anesthesiology

survivors with chronic lung disease, retinopathy of prematurity, and hypoxic brain injury. When Morriss and Levin were first working in Dallas they complained that the beds were taken up by chronic patients. One of the pediatricians commented, "Before you started doing this, we didn't have chronic patients." This was an early observation still relevant today: Pediatric intensive care allows successful treatment of disorders previously considered hopeless, but may also result in a population of children with long-term problems that also require study and clinical attention.

Pediatric Cardiology

As previously indicated, the vision of Dr. Taussig in devising a method to treat "blue babies," in cooperation with pediatric cardiac surgeons, led to infants and children who survived surgery and then needed postoperative care. This sequence has been well documented by Dr. Jacqueline Noonan.[33] She notes that, "Much success of the surgery can be attributed to a group of pediatric intensivists, pediatric intensive care units, improved ventilatory support, and trained respiratory therapists." Advances in technology, especially for imaging, have allowed clinicians to "see" into living patients with astounding accuracy. Increased understanding of anatomy and physiology has led to improved surgical care for children with very complex problems. Perhaps ironically, some recent developments in cardiac catheterization and interventional radiology have enabled clinicians to treat many lesions without surgery, improving outcomes without the need for open-heart surgery and potentially difficult postoperative intensive care. The burgeoning growth of techniques, both interventional and surgical, has resulted in many centers creating specific cardiac intensive care units often run by pediatric cardiac intensivists, although not without some controversy in the world of PCCM.

Poliomyelitis

The interwoven history of resuscitation and ventilation, anesthesia, anatomy and physiology, pediatric anesthesiology, pediatric general and cardiac surgery, neonatology, and pediatric cardiology all come together in an astounding story of the treatment of paralytic polio and respiratory failure ("bulbar polio"). The confluence of great scientific and clinical minds and the organizational efforts of physicians, nurses, and technicians addressing the needs of polio patients rapidly led to the creation of PICUs. In 1929, Philip Drinker, an engineer, Dr. Louis Shaw, and Dr. Charles F. McKhann published their experience with a mechanical ventilator which was an electrically powered negative-pressure body tank, eventually termed the "iron lung" by a now unknown journalist (Figure 1-2).[34] On October 12, 1928, an 8-year-old girl with polio and difficulty breathing was admitted to BCH. On October 13, her respiration was failing and she was placed in the respirator at low pressure. She improved and was taken off the device, but on October 14, she was comatose and cyanotic and was placed back in the respirator at high pressures. She regained consciousness and a little later asked for ice cream. "Most of the people who witnessed the scene were in tears."[14] Even though this patient died on October 19, with necropsy findings of poliomyelitis and bronchopneumonia, the device subsequently saved the lives of a student nurse at Bellevue Hospital in New York and a Harvard College student at Peter Bent Brigham Hospital.

As dramatic as this was, it seems to be overshadowed by the remarkable polio epidemics in Los Angeles in the early 1950s and in Copenhagen in 1952.[14] Writing in 1953,[35] H.C.A. Lassen, Chief Epidemiologist of the Department of Communicable Disease, Blegdam Hospital, Copenhagen, describes treating 2772 patients for polio between July 24 and December 3, 1952. Of these, 866 patients had paralysis and 316 of these were in respiratory failure. Of the 316, 250 eventually underwent tracheotomy. Previously, starting in 1948, such patients underwent tracheotomy and suctioning for secretions without ventilatory support, but all died. Of the 15 patients treated with a mechanical respirator without tracheostomy, five patients, one adult and four children, survived. During the first month of the 1952 epidemic, of the 31 patients with respiratory paralysis, 27 died, for a mortality rate of 85% to 90%. Thereafter they consulted Dr. Bjorn Ibsen, an anesthesiologist, who suggested tracheotomy, rubber-cuff tubes, and manual positive-pressure ventilation ("iron lungs" were not commonly available in Europe at the time) using a rubber bag. From August 28 to September 3, 1958, they were admitting 50 patients a day, 12 of whom had respiratory failure and were admitted *to a special unit for respiratory care.* In this unit they had as many as 70 cases at once in respiratory failure. There were 200 patients admitted to the unit who underwent tracheotomy, manual positive-pressure ventilation with 50% oxygen, and suctioning. They employed 200 extra nursing

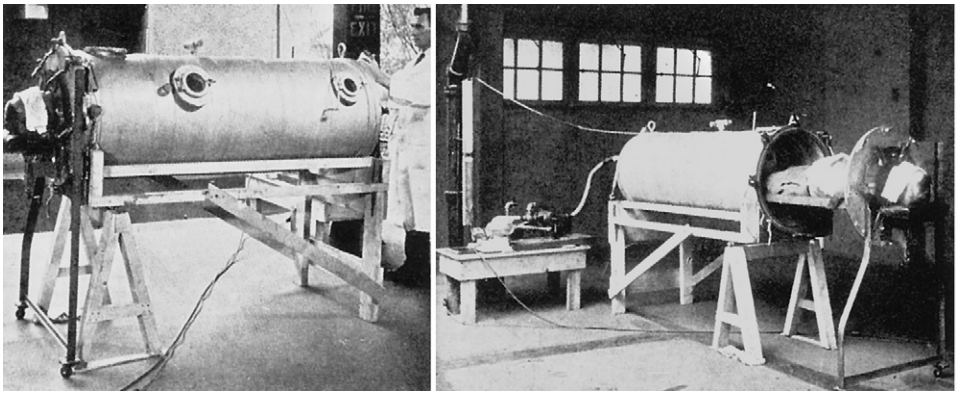

Figure 1–2. The Drinker negative-pressure mechanical ventilator. *(Reproduced with permission, Blackwell Scientific Publications, Oxford.)*

auxiliaries (students and aides), 200 medical students at a time each working 8-hour shifts to provide manual ventilation (1000 in all), and 27 technicians per day to care for the patients.[35-37] The mortality decreased from 90% to 40%. Ibsen adds that the first patient was a 12-year-old girl with paralysis of all four extremities and atelectasis of the left lung, who was gasping for air and drowning in her own secretions. She had a temperature of 40.7° C and was cyanotic and sweating. The tracheotomy was done under local anesthetic and a cuffed endotracheal tube was inserted. During the procedure she became unconscious. They connected her to the ventilator but could not ventilate her. He then gave 100 mg of pentothal IV and she collapsed, her own respirations stopped, and he could then provide manual ventilation. She then developed signs of carbon dioxide retention even with full oxygenation (rise in blood pressure, skin clammy, and sweating), and she again started her own respirations with gagging and bucking. Secretions began to pour out of her mouth and nose. This was relieved in a few moments with increased ventilation but then her blood pressure dropped and she appeared to be in shock. He gave a blood transfusion and her condition improved, with her skin becoming warm, dry, and pink, "Which always makes an anesthesiologist happy." A chest radiograph showed atelectasis of the left lung and she was placed on a mechanical positive-pressure ventilator, after which all the signs of underventilation recurred, along with cyanosis. She was given supplemental oxygen and her color improved, but she still showed signs of carbon dioxide retention. Manual ventilation was started and she improved.[36]

He concluded that tracheotomy with local anesthetic without an endotracheal tube in place was too difficult. The patients were anxious, vomited, aspirated, and had airway spasms. Few survived, so they started doing the tracheotomies earlier with endotracheal intubation and anesthesia and had great success.[36,37] Another change in strategy was that patients from outlying areas were being sent in ambulances without sufficient attendants and airway care and arrived moribund. They started to send teams in ambulances out to the pick up the patients in the countryside, with marked improvement ("retrieval teams"). This was the beginning of an important aspect of PCCM that many believe still has great potential for improving care in the future and which remains far from fully implemented. They also started passing stomach tubes for nutrition and the rubber-cuffed tubes were replaced with a silver cannula. Even with all the improvements he concludes, "Naturally we ran into a lot of complications."[37]

They also received help from other bright people who were focusing their efforts on treating polio. The clinical biochemist Poul Astrup developed a method to measure carbon dioxide, and C.G. Engstrom constructed a volume-preset positive-pressure mechanical ventilator. This spectacular and thrilling story resulted in a cohort of patients in respiratory failure in a single geographical area being cared for by full-time physicians, nurses, and technicians.

Although these units tended to disband after the summer-fall polio season, they led to the creation of full-time units, the first of which was described by Dr. Goran Haglund in 1955, at the Children's Hospital of Goteberg, Sweden.[23] He called the unit a Pediatric Emergency Ward. The patient who inspired Dr. Haglund to organize the unit was a 4-year-old boy who was operated on in 1951 for a ruptured appendix. Postoperatively, he lapsed into a coma and the surgeon declared they had done all they could and he would die of "bacteriotoxic coma." The anesthesiologist offered to help and the boy was intubated, given manual positive-pressure respiration with generous oxygen, tracheostomized, and given a large blood transfusion. After about 8 hours, the bowels started to move, and 4 hours later he was out of coma. After 20 hours, he had spontaneous respiration and had been successfully treated for respiratory insufficiency and shock. The unit had 7 acute care beds, 6 full-time nurses and 15 nursing assistants, with 24-hour coverage. In the first 5 years, the team treated 1183 infants and children, with a mortality rate of 13.6%. Haglund goes on to state, "But what we did was something else. It was the application of the basic physiology to clinical practice. Our main purpose was not to heal any disease, it was to forestall the death of the patient. The idea was—and is—to gain time, time so that the special medical and/or surgical therapy can have desired effects."[23] (Morriss and Levin[38] took this approach in organizing the first edition of their textbook in 1979.) He was also careful to point out that, "There are few jobs more exacting, demanding, and taxing than emergency nursing. Our nurses and nurse assistants are tremendous. They must be!"[23]

Nursing

As has been shown, the dissemination of the knowledge and skills that the anesthesiologists had developed in the operating room to postoperative recovery rooms, surgical and medical wards, and eventually to geographically defined units, permitted improved treatment of patients with a variety of disorders, only some of which required surgical intervention. Among the diseases treated were polio in the 1920s to 1950s, tetanus in the 1950s and 1960s, and Reye syndrome in the 1970s and 1980s.[3] These epidemics, along with developments in neonatology, pediatric general and cardiac surgery, and pediatric cardiology created a demand for greater services for more unstable patients. The events paralleled those in the world of adult critical care, with early intensive care units opened in 1923 at Johns Hopkins in Baltimore, a three-bed unit for postoperative neurosurgical patients directed by Dr. W.D. Dandy,[10,39,40] in 1953 at North Carolina Memorial Hospital in Chapel Hill, North Carolina, in 1954 at Chestnut Hill Hospital, Philadelphia, in 1955 at the Hospital of the University of Pennsylvania in Philadelphia,[41] and 1958 at Baltimore City Hospital (Dr. Peter Safar) and Toronto General Hospital (Dr. Barrie Fairley).[3]

Although many sources emphasize the role of advanced technology in the creation of adult, neonatal, and pediatric ICUs,[3,24] it is interesting to consider the important role of nursing in this evolving process. Porter,[42] as well as others, reminds us of the vital role of nursing in triage and organization of care for patients by degree of illness. Long before the organizational efforts just described, Florence Nightingale (1820-1920) organized the military hospital at Scutari in 1854, during the Crimean War, to provide more care to the most severely injured soldiers by grouping them together. Although the care consisted mostly of better hygiene and nutrition, the mortality rate dropped from 40% to 2%.[43] These efforts were continued in the United States by Dorothea Dix (1802-1887) and Clara Barton (1821-1912), the "Angel of the Battlefield," during the American Civil War, and when Barton brought the Red Cross to America in 1882. It was Nightingale who provided the definition of nursing as "helping the patient to live."[42,43] Fairman and Kagan[41] conducted an interesting study looking

at the creation and evolution of an adult intensive care unit by researching the historical records and interviewing the people involved at the Hospital of the University of Pennsylvania from 1950 to 1965. They emphasize that there really was no new equipment, only the migration of existing equipment from the operating room to the wards. In fact, some nurses remembered that they did not really have much in the way of equipment at all, even monitors. Certain social factors and the need for nurses were much more influential in forming geographically defined units away from the operating room or recovery room. Most patients at that time were operated on for gallbladder disease, appendectomies, and tonsillectomies. Poor patients were admitted to the ward postoperatively and wealthier patients were admitted to private or semi-private rooms and hired, at their own expense, private-duty nurses to care for them. This resulted in a two-tier system, with poorer patients having little postoperative care. Then a shortage of private-duty nurses occurred; many private-duty nurses refused to work nights, weekends, and holidays, and nurses with less training worked "off-shifts." Surgeons and families complained they could not get care, and of course the poorer patients did not receive adequate care at all. The hospital, to save money, (the average cost per patient per day for recovery room care in 1960, at Baltimore City Hospital, was $50 to $80)[44] demanded more from existing hospital nurses, tried to hire more private-duty nurses at family expense, and failing that, shifted some semiprivate patients to the ward. This resulted in complaints of noise (from patients) on the ward and understaffing to the point of safety concerns. One of the patients became disconnected from a ventilator and died unnoticed.

There was a move by nurses for better training, improved safety, and better staffing, as well as for more specialized rooms to organize the care of the sickest surgical and medical patients in architecturally distinct areas at no extra cost to the patients. This resulted in the creation of the Fifth Special Unit, closure of obsolete wards, and a more egalitarian admission policy to the special unit. There developed a shared sense of adventure between nurses and physicians in the ICUs, which seemed like experimental laboratories. Similar development was mirrored in PICUs, and the camaraderie and spirit were evident. The ICU nurse in adult, neonatal, and pediatric units rose to the top of the ladder in the hospital hierarchy. As one graduating Dartmouth Medical School student said in his class address, "When I started on clinical rotations I needed to learn how to function in the hospital. In order to do this I needed to understand the hierarchy in the institution. It quickly became apparent to me that the ICU nurse was at the very top of the pecking order."[45]

Several other references to the central importance of nursing in creating and enabling intensive care to develop have been cited.[3,8,23,30,31,42] As Fairman and Kagan[41] conclude, "…powerful social contextual forces, such as workforce and economics, architectural changes, and an increasingly complex hospital population—rather than new technology—supported the development of critical care."

Pediatric Critical Care

Getting Started

As we have seen, geographically defined PICUs, directed by specific medical and nursing personnel, emerged in the 1950s and 1960s and gathered momentum in the 1970s. These early units were heavily influenced by pediatric anesthesiologists (Table 1-1). But even in the 1970s, the future of these units and the role of pediatricians in them were far from certain.

We all owe a great deal to the efforts and leadership of Drs. Downes, Todres, Shannon, and Conn. The first physician-directed multidisciplinary PICU in North America was established at Children's Hospital of Philadelphia (CHOP) in January, 1967, as an outgrowth of a hospital-wide respiratory intensive care service.[3] The unit consisted of an open ward of six beds equipped with bedside electronic monitoring (electrocardiography, impedance pneumographic respiratory rate, and two direct blood pressure channels) and respiratory support capabilities. An adjacent procedure room could serve as an isolated seventh bed. An intensive care chemistry laboratory, manned 24 hours per day by a technician, was located next to the unit with a pass-through window for handing blood samples and receiving written reports. The nurses were assigned full-time to the unit, and most had previously served in the recovery room or the infant ICU for patients on the cardiac surgery or respiratory intensive care services. Dr. Downes was the medical director and worked closely with two other anesthesiologists, Dr. Leonard Bachman, Chief of Anesthesiology, and Dr. Charles Richards, an allergist/pulmonologist, Dr. David Wood also shared duties and call. One of four pediatric anesthesiology/critical care fellows was in or immediately available to the PICU on a 24-hour basis. Rounds with the nurses, fellows, and anesthesiology staff physician on service were conducted each morning and late afternoon. They were most fortunate to have close relationships with Dr. C. Everett Koop (Chief of Surgery and strong supporter of critical care), Dr. William Rashkind (the father of interventional pediatric cardiology), Dr. John Waldhausen (one of the nation's few full-time pediatric cardiac surgeons and a creative thinker), and Dr. Sylvan Stool (a pioneer in pediatric otolaryngology), as well as the support of numerous pediatric and surgical consulting staff and house officers. In 1971, at the Hospital for Sick Children in Toronto, Dr. Alan Conn resigned as director of the department of anesthesiology to become director of a new multidisciplinary 20-bed PICU, by far the largest and most sophisticated unit in North America. The establishment of this unit and a critical care service culminated a decade of efforts by Dr. Conn and his associates. They were able to cohort critically ill older infants and children in one geographic area that was not a postanesthesia recovery area. This advanced complex was the forerunner of units developed in major pediatric centers throughout North America over the following decade.[3] Also in 1971, Dr. David Todres, an anesthesiologist, and Dr. Daniel Shannon, a pediatric pulmonologist, founded a 16-bed multidisciplinary unit for pediatric patients of all ages at the Massachusetts General Hospital.[3,8] Each of these units also established vibrant training programs in critical care medicine and conducted clinical research. Among their numerous accomplishments, Dr. Conn became a noted authority on the management of near-drowning victims, and Dr. Todres pioneered long-term mechanical ventilation for children at home with chronic respiratory failure. These early PICUs and their training programs had a favorable impact on mortality and morbidity rates—particularly those associated with acute respiratory failure—and led to the development of similar units and programs in most major pediatric centers in North America and Western Europe during the 1970s and early 1980s.

In 1966, after internship, Dr. Max Klein joined Drs. H. de V. Heese and Vincent Harrison in a two-bed neonatal research unit at the Groote Shuur Hospital in Cape Town. Over the course of the next 2 years and more, their research resulted in many significant papers, not the least of which was "The Significance of Grunting in Hyaline Membrane Disease,"[46] demonstrating that oxygen tensions fell when infants were not allowed to grunt. This provided the rationale for the application of CPAP, an artificial grunt, to these patients. By 1969, pediatric patients at Red Cross War Memorial Children's Hospital with respiratory failure (e.g., Guillain-Barré) were ventilated on the wards and deaths were common. There was no centralized facility for older children. He encouraged Dr. Malcolm Bowie (consultant) to start a six-bed ICU, or "high-care ward," originally in collaboration with the anesthesiology staff. In 1971, Dr. Klein did a year of adult pulmonary fellowship with Professor M.A. de Kock at the University of Stellenbosch and then 2 years at the CVRI, UCSF. When he returned to Cape Town in 1974, he combined the neonatal tetanus ward of Dr. Smythe and the six-bed ICU of Dr. Bowie into the first full-time PICU in South Africa. An important aspect of the effort was that, at the time, the hospital was racially segregated. It took Dr. Klein *25 years of persistent effort* to create a nonsegregated PICU. He is truly deserving of a Perseverance, Size 1 award.[47]

The path to providing care for the sickest patients on a full-time basis remained unclear for an extended period. Subsequent early leaders in the field each carved out his own path. Dr. Daniel Levin completed pediatric cardiology and neonatology fellowships to learn how to take care of sick children, but found few chairmen interested in hiring an "intensivist." Dr. Nicholas Nelson, Chairman of Pediatrics at Penn State University Medical School in Hershey, would permit him to work at developing a PICU on the side, but he did not think it would work. A few years later he hand wrote a letter to Levin, actually apologizing and indicating that he now believed that in the near future, children's hospitals would be nothing but ICUs and most other patients would be cared for as outpatients. In 1974, Dr. Abraham Rudolph, one of Dr. Levin's mentors, inscribed his new book, *Congenital Diseases of the Heart,* "Wishing you the best in your chosen career as an 'intensivist" (quotes his). A career as a pediatric intensivist was far from a sure thing. In 1975, Drs. Levin and Frances Morriss (pediatrics and pediatric anesthesia) were recruited to Dallas by Dr. Theodore Votteler, Chief of Surgery and a former trainee of Dr. Koop, and by Heinz Eichenwald, Chairman of Pediatrics, to start a PICU at Children's Medical Center of Dallas.

In 1970, when Dr. Peter Holbrook finished medical school, he had been exposed as a student to the work of Dr. John Downes at CHOP. He also knew he wanted to work full-time taking care of the sickest children, but during his residency at Johns Hopkins he was discouraged by prominent pediatricians and told by some of the earliest leaders in the field that he needed to become an anesthesiologist. Dr. Peter Safar at Pittsburgh, however, welcomed him as a fellow in critical medicine in a personalized program to prepare him for PCCM. Dr. Safar told him, "We've been waiting for you."[27] In 1975, Dr. Holbrook and pediatrician Dr. Alan Fields, who also trained in Pittsburgh, went to Children's Hospital National Medical Center, as pediatricians in the Department of Anesthesia, to run their PICU.

Dr. Bradley Fuhrman finished his residency in 1973 and did both pediatric cardiology and neonatology fellowships to master both cardiovascular and pulmonary life support. In his words, "it seemed like the best route at the time."[48] After finishing the fellowships, he started the first PICU at the University of Minnesota Hospital in 1979.

Dr. Mark Rogers recognized the lack of senior supervision of interns during his pediatric residency in Harvard-affiliated hospitals. Like many of the early intensivists he was discouraged that junior people were left in charge of the sickest children. He subsequently studied pediatric cardiology and then chose to complete an anesthesiology residency. He was appointed director of Pediatric Intensive Care at Johns Hopkins after his residency. There were so few of this new breed of "intensivist" that many became directors right after completion of residency or fellowship. At the beginning, no one wanted to be responsible for pediatric intensive care.[28]

Dr. Bradley Peterson[49] went into the military service after his pediatric and neonatology training and then took an anesthesiology residency at Stanford. Upon completion of the latter, he opened the PICU at Children's Hospital of San Diego in 1977. Dr. George Lister[50] had many of the same experiences and thoughts as a resident at Yale. He found sicker older children scattered around the hospital without an organized approach to their care. He studied cardiorespiratory physiology and improvised a training program at the CVRI to gain the background and knowledge to take care of critically ill children. Post-cardiac surgery infants were cared for in the NICU and older children in the adult ICU, at Moffett Hospital. He started his attending career there in 1977 in the combined adult-pediatric ICU and, due to the director's illness, quickly found himself as the co-director of the unit.[51]

Eventually more and more pediatricians decided to devote their careers to being members of a multidisciplinary team taking care of the sickest children in hospitals on a full-time basis. In 1975, the CHOP program started to accept PCCM trainees who were pediatricians without anesthesia residency. The field grew rapidly in the late 1970s and 1980s.

During this time period, Calvin[39] indicated there was a struggle for authority in adult units, with some clinicians trying to change the culture of intensive care from one in which each different service cared for its "part" of the patient to one in which a full-time service was consistently available, and cared for the whole patient, with the help of consulting specialties. Although this conflict was probably worse in units for adults, it was certainly a prominent issue in PICUs as well.[27]

The Present

Although the field of PCCM was undergoing a period of rapid growth, it faced several problems. These were: (1) the need for a common "home" or national structure in which to meet and communicate; (2) acceptance or validation of pediatric critical care as a subspecialty; (3) education within the field; and (4) academic credibility with meaningful research.

A small group of interested people met at the Society of Critical Care Medicine (SCCM) National Education Forum in San Francisco in 1979 to discuss structure and a home.[27,52] There were about 15 people present, and memories have faded, but Drs. Holbrook, Gregory, Downes, Raphaely, Vidayasagar, and Levin were among them. It was decided to petition the SCCM to form a section of pediatrics. The society had no

subsections, but the petition was successful, and the pediatric section was formed in 1981.[3] In 1981, Dr. James Orlowski, with the support of others, petitioned The American Academy of Pediatrics (AAP) to form a section of Pediatric Critical Care or Intensive Care Medicine within the AAP. Although there was some controversy and some within the AAP wanted the new section to be housed within in an existing section (such as Anesthesiology, Emergency Medicine, or Diseases of the Chest), the petition was successful and the section began in 1984.[52] These organizations provided structure, places to meet, and opportunities to discuss common goals and concerns. Increasing international investment in pediatric intensive care was recognized with the first World Congress of Pediatric Intensive Care in Baltimore in 1992 and foundation of the World Federation of Pediatric Intensive Critical Care Societies (WFPICCS) in Paris in 1997 by Dr. Geoffrey Barker and others, providing a global platform for the field.[28]

Acceptance and legitimization were reflected in, and enhanced by, establishment of a new sub-board of Pediatric Critical Care Medicine of the American Board of Pediatrics in 1985, and the first certifying examination occurred in 1987.[53] Certification provided clear guidelines for hospital credentialing of PCCM physicians[54] and in 1989, special requirements for training in PCCM were developed by the American College of Graduate Medical Education (ACGME) with formally accredited programs first recognized in 1990.[53] In 1983, a committee of the SCCM developed guidelines for PICUs,[4] which have been regularly updated.[5,6]

In 1979, Ross Planning Associates indentified 150 PICUs of four or more beds, and another 42 were thought to exist (total 194).[3] Only 40% had a pediatric intensivist available at all times. Forty percent had fewer than seven beds and only one half had transport systems. By 1995, there were 306 general PICUs and in 2001 there were 349. Of these, 94% had a pediatric intensivist on staff. Pediatrics ward beds decreased by 22.4% between 1980 and 1989, by 10.8% between 1990 and 1994, and by 15.7% between 1995 and 2000. During the same three time periods, PICU beds increased by 26.2%, 19.0% and 12.9%, respectively.[7] The first subboard examination in 1987 certified 182 PCCM subspecialists. By 2006, there were 1454. In 1983-1984 there were 32 PCCM training programs, and the ACGME accredited 28 of them in 1990. By 2008, there were 62 PCCM training programs.[53] The number of fellows enrolled in PCCM has increased by 40.8% since 1997 (2006 figure) and the percent of women fellows increased from 39.6% to 44.6% from 1997 to 2006, peaking at 45.4% in 2000-2001. Eighty-five percent of applicants intended to work exclusively as intensivists.[54]

Education within the field has progressed rapidly. Educational programs at the annual SCCM, AAP, Pediatric Academic Societies, and American Thoracic Society meetings have been supplemented by a unique volunteer effort, started in 1983 by Dr. Hector James, a pediatric neurosurgeon from San Diego, and continued by Dr. Peter Holbrook in 1984, called the Pediatric Critical Care Colloquium (PCCC). National and regional organizations around the world conduct many other specialty-specific meetings. There have been many textbooks in the field in many languages including texts specifically for PCC nurses (Table 1-2). Through the efforts of members of the SCCM, that society's journal, *Critical Care Medicine*, and WFPICCS, a new journal, Pediatric Critical Care Medicine, began in 2000, edited by Patrick Kochanek.[81]

Academic credibility that results from meaningful scientific research has come slowly. In the early days, intensivists were mostly consumed by clinical and administrative responsibilities, but high-quality science, addressing a broad range of problems, has gradually emerged. Huge amounts of effort and money in PCCM have gone into clinical trials in attempts to improve therapy, but have failed to deliver on some promises[24] such as liquid ventilation,[82,83] recombinant bacterial/permeability–increasing protein ($rBPI_{21}$),[84] and activated protein C.[85] This may have as much to do with the incredibly difficult task of performing large clinical trials on very sick children as the validity of the concept or experimental design.

In the early 1990s, the Pediatric Critical Care study group was formed and led by Dr. Gregory Stidham of LeBonheur Children's Hospital.[24] In 1998, Dr. Adrienne Randolph initiated a clinical trials group with early assistance from Drs. Jacques Lacroix and Douglas Willson, that was initially formed to assist each other with oversight and conductance of three multicenter trials[86-88] and which subsequently evolved into the Pediatric Acute Lung Injury and Sepsis Investigators (PALISI). By directly applying the already successful programmatic model of research developed by the Canadian Critical Care Trials Group (CCCTG),[89,90] PALISI has grown and prospered due to the cooperative volunteer spirit of the more than 70 North American member units, with[91] many publications in high-quality journals, ongoing funded clinical trials and observational studies, and active new protocol development. The Virtual PICU started in 2000, and Drs. Randall Wetzel of Children's Hospital of Los Angeles and Thomas Rice of The Children's Hospital of Wisconsin have created a massive database for research and quality control.[24] In Canada, the "Pediatric Interest Group" was created in the year 2000 within the CCCTG by Drs. Jacques Lacroix, James Hutchison, and Haresh Kirpalani, with the help of the Canadian Institutes of Health Research.[92]

In April 2004, the National Institute for Child Health and Human Development established funding (renewed in 2009) for the first network supporting pediatric critical care research, the Collaborative Pediatric Critical Care Research Network (CPCCRN), "To initiate a multicentered program designed to investigate the safety and efficacy of treatment and management strategies to care for critically ill children, as well as the pathophysiologic basis of critical illness and injury in childhood."[93] In the first 5 years, a number of landmark studies including observational studies on bereavement, opioid tolerance, and pertussis were initiated as well as several interventional trials, including a randomized controlled trial of immune prophylaxis and a study developing and testing a functional status outcomes scale. The NIH has also supported research in PCCM through the Pediatric Critical Care Scientist Development Program (PCCSDP), a K-12 program funded by the Eunice Kennedy Shriver National Institute of Child Health Development to support the development of young physician scientists in pediatric critical care. The PCCSDP entered its second project period in 2009, under the continuing direction of Dr Michael Dean at the University of Utah.[94]

The growth of education and research in PCCM has coincided with better care for children. In addition to the examples of diseases such as polio, tetanus, and Reye Syndrome that were stimuli for forming the subspecialty, examples such as the decrease in mortality from septic shock help demonstrate the improvement. During the period from 1958 to 1966, the

mortality of gram-negative bacteremia in patients less than 16 years of age at the University of Minnesota was 60% in medical and 40% in surgical patients.[95] The mortality in septic shock was 95%. Now is it less than 10% and continues to be a major focus of clinical and research attention.

Drs. Murray Pollack and Timothy Yeh have shown us how to study severity-adjusted mortality in pediatrics and demonstrated that patients do better[96] when cared for by pediatric intensivists. Dr. Debra Fiser's group[97] has shown us there is improvement in mortality in patients with respiratory disease. Although many would attribute the improvements to technology and scientific advances, Dr. Yeh and others remind us it is possible that the presence of a full-time team and attention to a few basic principles rather than great investment in exotic high-technology solutions improves outcomes.[98] This is echoed by Dr. Frank Shann, who has two rules of PCCM: Rule 1 is "the most important thing is to get the basics exactly right all of the time"; Rule 2 is "organizational issues are crucially important.[28] Yeh as well as Ibsen[37] and Richard Orr have emphasized the important contributions of regionalization and the quality of PCCM transport teams in improving outcomes.[99,100]

The Cost of Success

Everything comes at a cost. In the field of PCCM, as in many others, advances have lead to increased cost, chronic disease, medical errors, and dehumanization of patients. The spiraling cost of medicine in general and intensive care in particular are well known and have been well presented by Dr. Downes[3] so will not be discussed further here.

As mentioned earlier, most intensivists are fully aware of and are distressed by the increased population of chronic patients who have prolonged PICU stays and frequent readmissions. Most of these patients did not exist previously; they died. Although we return many sick children to complete health, many children who would have died previously now live with chronic neurologic, respiratory, cardiac, and renal disease and residual problems from surgery, oncologic disease, and other causes.

Medical errors come in many forms. In addition to the well-publicized problems with staff fatigue, the tremendous complexity of the patients and environment makes individual errors a frequent occurrence. In addition, many systemic errors occur, not due to individual staff members' mistakes or fatigue but due to overarching issues such as equipment design and use, treatment regimens, communications, inherent problems with medications, and others. These have been well documented in neonatology by Drs. Silverman[101] and Robertson.[102-104] Well-intentioned, but in some cases not well-designed or reasoned, interventions have caused a great deal of morbidity and mortality. Many approaches that for long years were thought to be correct are now thought to be harmful, useless, or incorrect (e.g., normalizing $PaCO_2$ and PaO_2,[105] and transfusing patients from hemoglobins of <10 g/dL to >12 or 13 g/dL[87]).

In an extremely technical, frenetic environment, dehumanization of patients is always a danger. The story of intensive care for children has moved from triumph to triumph. However, in the process, the public has perceived that although medicine has succeeded on the technical level, it has lost much of its human touch, becoming more impersonal and forbidding. Some have stated that medicine has lost its way, although clinicians have started to reclaim this lost heritage of caring and compassion. This has been particularly true in end-of-life care, with the combined expertise of both intensivists and palliative care-givers. Pediatric intensivists have come to the realization that caring for critically ill children requires the simultaneous gathering of information in two areas. One is the disease itself, which includes the symptoms, signs, investigations, and clinical management. The other is the context of illness, which is the patient's and family's agenda of concerns, expectations, feelings, and thoughts that are unique to each individual and family. An intensivist acts to bring about a positive good or benefit to the patient; however, experience in the PICU has shown that conflicts arise when the presumption to save life (a good) requires interventions that may cause undue suffering. The more aggressive are the efforts to reverse illness, often the more suffering is inflicted on the patient. This leads to a situation where the physician begins to question how far to pursue these procedures. These ethical dilemmas are increasingly receiving the attention of intensivists. Ethics committees have been helpful in providing the health care team with important perspectives in approaching these difficult issues. Early on we asked, "How to do procedures," then we asked "When to do procedures," and increasingly we have asked, "Should we do procedures?"

In many units an increasingly diverse patient population has sensitized intensivists to the need to understand and respect individual cultural differences. Stereotyping a particular culture fails to respect individual differences. Increasingly, care is centered on the patient and family in recognition of the effects of personal spiritual/religious, cultural, and family values on patients' illness and recovery and in coping with the end of life. In many PICUs, chaplains are brought to the bedside and become part of the intensive care team.

The addition of child psychiatrists and social workers to the PICU consulting team has helped families and children cope with the severe and devastating effects of critical care illness. For the health care team, the long hours of stressful work and the occasional feelings of despair and frustration that all the hard work is not making a difference lead to emotional distress and a sense of loss of fulfillment in their professional lives. Understanding this problem and helping the team to realize they are making an important difference and are valued will reduce burnout and enhance staff morale. To illustrate the importance of knowing that one's effort does make a difference in people's lives, the following letter received by one of the nursing staff after a visit to the family at home stated,

"In the almost 3 weeks that we were in the pediatric ICU (PICU), we witnessed two deaths besides our son's….We know that death is part of your job and therefore must be dealt with as each sees fit….it seems funny that we'd be so happy to see people we barely know but your visit and the effort you took to come signifies a great deal. It meant that you DID care about our baby. And the solace received from your caring was—and is—immense. Special thanks for that….Please do not feel that your encouragement helped to give us false hope. Hope is what got us through those 3 weeks. Despair could wait."

One way we have attempted to support patients and families is to include families as members of the team by having them present at rounds with their child.[106] This effort allows the family, and often the patient, to hear what the team has to say and to ask questions, both of which empower the family and build trust.

Around the World

We have alluded to the many contributions of people around the world to the evolution of PCCM, both through innovative treatment of specific diseases (e.g., polio[3,14,35,36] and tetanus[30]), and in organizing and creating PICUs (see Table 1-1), and education (see Table 1-2).[107] What follows below are the varied contributions from many places, using a geographical approach.[8]

Canada

At the Hospital for Sick Children in Toronto, Dr. Alan Conn, anesthetist-in-chief, had the vision of developing an ICU utilizing his anesthesiology skills. In 1971, he took on the position of full-time director of critical care and initiated a flourishing clinical and research program. Dr. Conn was followed by Dr. Geoffrey Barker, who continued to promote the unit as one of the leading PICUs in the world. Dr. Barker's vision of the need to bring together intensive care from many parts of the world led to his directorship of the WFPICCS, which has done much to foster the development of pediatric critical care in countries around the world and to bring the skills and experience so vital in this practice to the benefit of multiple countries. In Montreal, the first patient was mechanically ventilated outside the postoperative recovery room in 1965, in what would later be named the PICU. This unit was first run by Dr. Paul Stanley, a pediatric cardiac surgeon. A medical PICU was created in 1972 by a pediatrician, Dr. Michel Weber, and pulmonologist Dr. André Lamarre. The units were merged in 1982. Drs. Marie Gauthier and Jacques Lacroix (Université de Montreal) and John Gordon (McGill University) were very active in the development and implementation in 1992 of a fellowship program in PCCM supervised by the Royal College of Physicians and Surgeons of Canada.[92]

Africa

Dr. Pat Smythe, a pediatrician working with Dr. Arthur Bull, an anesthesiologist at the Red Cross Children's War Memorial Hospital in Cape Town, South Africa, conceived a brilliant

therapeutic plan to treat infants afflicted with tetanus from infected umbilical cord stumps. This was the first successful long-term mechanical ventilation of sick infants. A dedicated group of nursing aides caring for these infants played a crucial role in their survival. Monitoring these infants depended on close observation of chest movement and visualization of cyanosis. Routine blood gas analyses had not yet entered the scene. The Severinghaus electrode (Pco_2) appeared in 1959 and the Clark electrode (Po_2) in 1961. However, using the Van Slyke method on a sample of end-tidal gas provided a measure of Pco_2. This labor-intensive method, which was performed by the pediatric resident, was applied somewhat infrequently! In combination with the efforts of Dr. Christiaan Barnard (cardiac surgery) and Dr. Jannie Louw (general surgeon) during the 1950s and 1960s, this experience led to the logical step of applying these principles of ventilator-supported care to the other critically ill infants and children, which followed later with the designation of a special unit for critically ill children in 1974 with full time intensivists. Dr. Max Klein with Drs. Louis Reynolds, Jan Vermeulen, Paul Roux, Cass Matola, and later Andrew Argent assumed this role with distinction. Dr. Klein's commitment to psychosocial issues in the care of patients was exemplary. His vision went beyond the PICU. In an excellent home-care tracheostomy program of 60 to 70 children, he, with nurse Jane Booth, were successful in ensuring the care of these children despite dreadful home conditions. In talking with him about the program, Dr. Todres recalled his enthusiasm for the need to have these children nurtured away from the hospital, and his staff provided these children with visits to the public gardens![47,108]

Asia: Japan

In the 1960s, Dr. Seizo Iwai, Chief of Anesthesia at the National Children's Hospital in Tokyo, was the first Japanese physician to introduce long-term mechanical ventilation and arterial blood gas analysis of critically ill infants, fostering a tradition of anesthesiologists taking care of every critically ill child outside of the operating room if a child should need their expertise. He was a strong force in developing a close relationship with other Asian countries and invited trainees from those countries to promote the teaching and development of pediatric critical care. His close working relationship with Drs. Conn and Barker in Toronto, Canada, paved the way for Dr. Katsuyuki Miyasaka to study in Philadelphia with Dr. Downes. Dr. Miyasaka returned to Japan in 1977 and, in October 1994, opened the first geographically distinct PICU in Japan at the National Children's Hospital and founded the Japanese Society of Pediatric Intensive Care. He continues to foster the development of a new generation of pediatric intensivists and to play a major role in facilitating this process.[109]

India

Development of neonatal and pediatric critical care in India has been described in detail before.[110] As in the developed countries, the discipline of neonatology and neonatal critical care preceded the development of the discipline of pediatric critical care in India. NICUs in India were established in 1960s, first at All India Institute, Delhi, and subsequently at teaching hospitals in major cities.

Today almost all major cities in India have NICUs providing different levels of intensive care. The well-established NICUs provide care on a par with NICUs in the Western countries. They are equipped to provide inhaled nitric oxide therapy and to manage complex cases including extremely low birth weight, surgical, and cardiac surgical cases. The outcome results are very encouraging.[111]

The first PICUs were established at major postgraduate centers (Delhi, Chennai, Chandigarh, Mumbai, and Lucknow) nearly two decades after the development of NICUs.[112] A special interest group of the Indian Academy of Pediatrics (IAP) working in PICUs was formed in 1997, and the Section of Pediatric Intensive Care was formed in the Indian Society of Critical Care Medicine (ISCCM) in 1998.[113] The Pediatric Critical Care Council (PCCC), a joint body of the Intensive Care chapter of the IAP and the Pediatric Section of the ISCCM,[114] provides the professional practice guidelines for pediatric critical care for the practitioners and the hospitals, and has initiated fellowship training programs in recognized units.[115] Today, PCCM is the fastest growing pediatric subspecialty in India. The growth of PICUs had been mainly in the private sector, although major government teaching hospitals are also improving the PICUs in their hospitals.

Prompt access to the available critical services is critical for pediatric patients. A study at a Children's Hospital in Hyderabad, Andhra Pradesh, India has shown that patients travel long distances (up to 500 km) to seek pediatric critical care, with survival inversely proportional to the distance traveled.[116] To overcome these difficulties, a bold and innovative statewide patient transport program, the Emergency Management and Research Institute (EMRI), was started in 2005 with a fleet of 70 ambulances deployed in the state of Andhra Pradesh, India.[117] The public-private collaborative organization has 2500 staff including EMTs, support staff, and associates, and a call center in the capital city of Hyderabad. A call using number 108 from any phone in the state gives access to ambulance service in the remote parts of the state. After 5 years, EMRI has a fleet of 652 ambulances and covers 23 districts and attends to over 4500 emergency calls per day. The EMRI center is linked to 331 private and public hospitals throughout the state and because of its success, the model is being adopted in other states of the country.[118]

Replicating this success elsewhere in India and the developing world will have an immense impact on resource needs. In view of the high birth rates (annual births of 25 million) and large pediatric population (35% of total or approximately 300 million) the required number of NICU and PICU beds will be enormous. It would therefore be prudent that all District hospitals (750 in the country) be upgraded to provide good level II services to meet the needs of rural communities.[119]

Although the development of PICUs is essential for overall improvement in child survival of the developing countries, the high cost of intensive care limits patients' access to PICU services. A recent study in Papua New Guinea demonstrated that the use of pulse oximetry in addition to clinical signs before initiating antibiotics, according to a World Health Organization (WHO) protocol, decreased mortality by 30%.[120] Similar low-cost innovative approaches may meet the demands of critical care in the developing world. It is therefore important to train health care personnel in early detection of infants at risk, for example, for respiratory distress, and in early initiation of treatment that would reduce the need for admissions to PICUs.

Australia and New Zealand

As in the United States and Canada, Australian PICUs started forming in the early 1960s, arising out of postoperative recovery wards with congenital heart surgery. In 1963, Drs. John Stocks and Ian McDonald in Melbourne introduced postoperative respiratory support with prolonged nasal intubation. Other units followed in Adelaide, Perth, Sydney, and Brisbane. An important contribution to the development of intensive care was the use of plastic endotracheal tubes for prolonged intubation and ventilation. Dr. Bernard Brandstater, an Australian working in Lebanon, reported prolonged intubation as an alternate to the tracheostomy at the First European Congress in Anesthesia in 1962. The first report of prolonged intubation in 50 patients was described in the *British Journal of Anesthesia* in 1965 by Drs. McDonald and Stocks.[121] Australian pediatric critical care is highly regionalized in tertiary university services supported by sophisticated retrieval services. Until 1991, all critically ill children in New Zealand received care in adult ICUs. The first PICU opened in December 1991 at the Starship Children's Hospital in Auckland.

Since 1996, all units have contributed outcome and other data to the Australian and New Zealand Pediatric Intensive Care Registry. The registry has evolved into a multicenter trials research group, affiliated with the Australian and New Zealand Intensive Care Society Clinical Trials Group. Recent evidence utilizing various scoring systems including the registry-developed PIM (Pediatric Index of Mortality) score reveal that outcomes in the region are better than predicted.[122] A formalized training scheme evolved during the 1990s and a separate College of Intensive Care Medicine will control all training in intensive care for the region from 2010 onwards.[123,124]

Europe

In Europe, pediatric intensive care followed shortly after the poliomyelitis epidemic in Denmark in 1952. Even in the early years, it was recognized that children had a higher mortality than adults in these poliomyelitis respiratory units; thus separate PICUs were developed in Uppsala and Stockholm in the 1950s. In 1955, Dr. Goran Haglund, an anesthesiologist, established the first PICU for infants and children at the Children's Hospital in Goteborg in Sweden. In 1961 Dr. Hans Feychting, a pediatric anesthesiologist, established the first PICU in Stockholm, Sweden, and became recognized as a pioneer in the development of pediatric intensive care in Europe. He introduced many of the skills that had been developed for the operating room and were later applied to pediatric intensive care.

In France, in July 1963, a newborn presented with tetanus and was admitted to l'Hôpital des Enfants Malades of Paris. Shortly afterward, Dr. Gilbert Huault opened the first multidisciplinary PICU, in Saint Vincent de Paul Hospital. This unit was the first pediatrician-directed PICU in Europe; it soon became a major influence on the development of ICUs, and in it, Drs. Francois Beaufils and Denis Devictor were to play an important role in the further development of critical care practice in pediatrics.

In Britain, in 1964, the first PICU was opened by Dr. G. Jackson Rees, an anesthesiologist, at the Alder Hey Children's Hospital in Liverpool. Other units soon followed, essentially serving as areas allowing prolonged postoperative support. Dr. Todres worked in such a unit at the Hospital for Sick Children, Great Ormond Street, London, in 1966. Although not designated "a pediatric ICU," in essence it was a unit that operated in this manner. This experience formed the foundation of intensive care practice that followed, with primary attention to conditions that led to failure of ventilation and circulation. Here Dr. David Hatch was instrumental in developing a PICU that provided outstanding clinical care and research.[125,126]

In Spain, a pediatrician, Dr. Francisco Ruza, had started working in neonatal surgical intensive care in 1969. By 1976, he opened a multidisciplinary medical-surgical PICU for older infants and children at the "Hospital Infantil La Paz" in Madrid. This center, directed by Dr. Ruza, has served as a major training center for pediatric intensivists not only from Spain but from South America as well.[127]

The first PICUs in The Netherlands were established in the late 1970s and early 1980s at the Sophia Children's Hospital in Rotterdam, the Wilhelmina Children's Hospital in Utrecht, and the Emma Children's Hospital at the Academic Medical Center in Amsterdam. In 1995, a section on Pediatric Intensive Care Medicine was founded by the Dutch Pediatric Association, which certifies the training of nearly all Dutch pediatric intensivists in fellowship programs. The PICUs are multidisciplinary, and all are part of university teaching hospitals. A nationwide transport system to connect this centralized care system of pediatric critical care was developed. Dr. Albert Bos in Amsterdam and Dr. Edwin van der Voort in Rotterdam continue to foster the highest standards of pediatric critical care. Units were opened in Germany[128] and Slovakia[129] as well as in many other places at that time.

Israel

Although located in the Middle East, Israel has traditionally been part of the European scientific organizations. The first PICU in Israel was established in 1977 by Dr. Zohar Barzilay as a five-bed facility located within the Children's Hospital at Sheba. Now, 32 years later, Israel has 12 PICUs and two cardiac PICUs. Extracorporeal membrane oxygenation services as well as cardiac transplantation are provided nationwide as part of the national health insurance program. A special chapter in Israel pediatric critical care medicine belongs to the Palestinian pediatric population. About 30% of the patients in many of the PICUs in Israel come from the Palestinian Authority. Palestinian physicians trained in PCCM in Israel established the first PICU in Gaza.[130,131]

Latin America

In Argentina, the first PICU was established in Dr. Ricardo Gutierrez Children's Hospital in Buenos Aires in 1969 as part of a general surgery ward. In 1972, Dr. Jorge Sasbon became the first staff director of the PICU. In 1972, a PICU was set up in Pedro de Elizalde Children's Hospital under the guidance of Dr. Clara Bonno, and the unit has been a pillar of the specialty in Argentina.

Critical care progressed steadily, and the first liver transplant in a pediatric patient was performed in 1987. With the introduction of international fellowships, physicians were able to travel abroad for further training in units in Toronto, Pittsburgh, Madrid, and London. The J.P. Garrahan National Pediatric Hospital was inaugurated as a tertiary center in 1987, and has developed a sophisticated PICU under the direction of Dr. Jorge Sasbon.

In Brazil in the 1970s, epidemics of polio and meningococcal disease with high mortality led to the creation of small units for the care of these patients, attended to by personnel with skills and technical resources (although they were scarce). These units were the precursors of PICUs later established at Hospital das Clínicas São Paolo by Dr. Anthony Wong (1977), at Hospital São Lucas in Porto Alegre by Dr. Pedro Celiny (1978), and in Rio de Janeiro. At the same time, neonatal intensive care was developing, and the model of the NICU was transferred to the care of critically ill children in the 1980s. In 1982, Dr. Jefferson Piva opened a 13-bed PICU at Hospital da Criança Santo Antonio in Porto Alegre.[132]

In 1984, the first Brazilian Pediatric Intensive Care Congress in São Paolo took place. These congresses continue annually. At the three major tertiary centers in São Paolo, Rio de Janeiro, and Porto Alegre, government agencies actively support research programs. Pediatric intensivists in the Brazilian Pediatric Society and the Brazilian Critical Care Society worked together to establish the subspecialty, with examination certification commencing in 1990. Brazil's intensivists also are active in cooperative efforts with other Latin American intensive care societies. One of the pioneers of development of pediatric critical care in Latin America was Dr. Mauricio Gajer, a dedicated physician from Uruguay. Dr. Gajer, with the stimulus of Professor Ramon Guerra, created the first PICU in Uruguay in 1975. He traveled to France, where he worked with Professors Huault and Beaufils. After returning to Uruguay he created the first private ICU in Uruguay. With his enthusiasm to bring all Latin American pediatricians together in the cause of critical care, he organized the first Latin American Pediatric Intensive Care Congress in Uruguay in 1993, which led to development of the Pediatric Intensive Care Society. In Colombia, Pediatric Intensive Care started in the early 1960s, with postoperative care of cardiovascular patients in the Clínica Shaio of Bogotá, with adult cardiologists in charge. In the 1970s the cardiovascular patients were taken care of by Dr. Merizalde, a pediatrician with training in pediatric cardiology. In 2007, the first pediatric critical training started in Bogotá, and 2 years later there are five programs in three cities.

In 1956, in the Luis Calvo Mackenna Children's Hospital in Santiago, Chile, a single-bed postoperative care unit was started by Drs. Helmut Jager (cardiac surgeon) and Fernando Eimbecke (cardiology). In 1968 this evolved into a five-bed PICU started by Dr. Eduardo Bancalari who was later joined by Drs. Patricio Olivo and Jaime Cordero (pediatricians). In the 1970s, Dr. Carlos Casar started a PICU at the Roberto del Rio Children's Hospital in Santiago, Chile and was later joined by Dr. Bettina von Dessauer (pediatrician).[133] There was no formal training in PCCM and these pediatricians devised individual programs to prepare themselves for taking care of sick children. Intensivists there have devoted great effort toward developing transport systems to overcome the impact of Chile's difficult geography.

In a similar fashion, the first intensive care unit in San Jose, Costa Rica was opened in 1969 as a postoperative cardiac care unit. It was initially a nine-bed unit run by anesthesiologists and surgeons. Eventually pediatricians, without special PCCM training, became involved. Dr. Aristides Baltodano was the first formally trained (Toronto) pediatrician to work in intensive care in Costa Rica, joining the staff in 1982. They now have a 22-bed multidisciplinary unit with more than 1000 admissions per year.[134]

Our Heroes

As previously noted, there are people in medicine who deserve Courage, Size 1 awards. These include, but certainly are not limited to, Dr. Jesse Lazear (yellow fever), Michael Servetes (pumping action of the heart), and a Guatemalan physician, Dr. Juan Francisco Pratesaba, who refused to stop treating wounded guerilla soldiers who presented themselves to his clinic during the civil war. He disappeared shortly thereafter, and was tortured and killed.[135] There are no Courage, Size 1 awards in PCCM. There are Courage, Size 4 awards (e.g., O'Dwyer) and probably many Perseverance, Size 1 awards (e.g., Smythe and Bull, and Klein). Certainly our most prominent awards are Courage, Size 4 to our patients and their families.

But we do have "heroes" by other measures, who have been recognized for their contributions to the field by their peers and organizations. These include the international pioneer awards of the WFPICCS (Box 1-1), the distinguished career awards of the Section on Critical Care of the AAP (Box 1-2), the chairs of the PCCM sub-board (Box 1-3), pediatric intensivist presidents of SCCM (Box 1-4), chairs of the

Chapter 2

The Intensivist in the New Hospital Environment: Patient Care and Stewardship of Hospital Resources

Margaret M. Parker

PEARLS

- Effective teamwork is essential for optimal care of the critically ill child in the setting of limited resources.
- Communication and collaboration among members of the health care team improve the quality and efficiency of patient care.
- The intensivist, as "captain of the ship," must manage the clinical care of the critically ill child and the organization of the intensive care unit to make optimal use of limited resources.

Intensive care units (ICUs) create an environment in which critically ill patients can be supported and many lives can be saved. By their very nature, ICUs are resource intensive with respect to both technology and the need for skilled health care providers. A large percentage of hospital costs are attributed to the ICU. As the cost of health care increases, the need to manage the resources of the ICU as efficiently and effectively as possible increases in importance as well.

Many studies in the literature have reported that management of the ICU and critically ill patients by intensivists increases survival rates and decreases resource utilization.[1-4] In addition to improvement in resource utilization, Gajic et al.[3] reported that the presence of a critical care specialist was associated with improved staff satisfaction, an important consideration when considering the increasing staffing limitations. Not all studies have reported a benefit in outcome, however. In sharp contrast to the many studies showing improved outcomes associated with intensivist staffing, Levy et al.[5] reported that patients managed by intensivists had a higher risk of death than did those who were not managed by them. It is not clear why this study had such disparate results from previous studies, but one likely reason is that the study design was very different from that of previous studies, as were the definitions used.[6] The systematic review by Pronovost et al.[1] defined high-intensity staffing as the ICU policy requiring that the intensivist have responsibility for care for all of the patients in the ICU (closed ICUs) or that there be a mandatory consultation by an intensivist. In the study by Levy et al.,[5] the involvement of the intensivist was elective (i.e., not decided at the unit level but by the choice of the attending physician). According to the definition by Pronovost et al.,[1] ICUs that allow the choice of whether to involve an intensivist are low-intensity staffing models. The effect of intensivists in low-intensity–staffed ICUs has not been studied adequately. Levy et al.[5] did a separate analysis of no-choice ICUs versus choice ICUs and reported that the mortality rate was higher in the no-choice ICUs, raising the question again as to whether intensivist staffing may increase mortality rates, although a mechanism by which this outcome might occur is not apparent. The preponderance of available studies continues to show a benefit of management by an intensivist.

Unlike adult critical care units, nearly all pediatric ICUs have trained pediatric intensivists who manage most (if not all) of the patients. In the United States, only about 30% of the adult ICUs are staffed by trained intensivists. Regionalization of trauma services for adults has improved outcomes of trauma patients.[7] Regionalization has been recommended as a way to improve the care of critically ill or injured adults and children, although the barriers to regionalization are far greater for adults than for children.[8,9] Regionalization effectively puts limited resources together to maximize the effectiveness and availability of these resources to a greater number of patients, although at the expense of travel for many patients and their families.

Organization and Quality Issues

During the past 2 decades, the cost of health care in the United States has increased dramatically, with hospital costs increasing more rapidly than other cost indexes. Controlling critical care medicine costs will be an important issue as health care reform is discussed. Critical care consumes an increasing proportion of hospital beds as the acuity of hospital inpatients increases. Although the cost of critical care is rising, the proportion of national health expenses used in critical care medicine has decreased over time.[10,11] Different methods for calculating critical care medicine costs create some discrepancies in the estimates of these costs, making it difficult to ensure that efforts to control costs are really effective.

The ICU provides support to a variety of services that could not be offered without ICU care, such as cardiac surgery and transplantation. Defining the ICU as the cost center gives a very different picture of the expense of ICU care than would attributing the costs of such patients to the services that use the ICU. Similarly, attributing some of the revenue that such services generate to the ICU and critical care physicians rather than solely to the surgical service per se provides a different view of the value of the ICU to the institution. Different strategies for controlling costs have potential benefit but often have unintended consequences. Shifting costs from the ICU to the supporting hospital services further complicates efforts to account for accurate ICU costs. True critical care medicine cost containment is extremely difficult, if not impossible.[12]

Today's intensivist must be knowledgeable about the economic aspects of managing the ICU and balance economic realities with the needs of the critically ill patient. Controlling costs of care without compromising the care of the patient requires a multitude of administrative and clinical skills. Close attention to both clinical details and financial considerations is necessary to meet these dual challenges. The intensivist needs to demonstrate flexibility and adaptability in order to navigate the business aspects of critical care while providing the best possible care for the patient.

Effective multidisciplinary care requires developing a teamwork model in the ICU. True teamwork recognizes the importance of the role of each member of the team and requires respect and trust for the other professions represented on the team. Effective communication between all members of the health care team and the patient/family cannot be overemphasized. A collaborative partnership with shared responsibility for maintaining communication and accountability for patient care includes the recognition that no one provider can perform all parts of patient care; the whole team is much more effective than each member of the team alone. True teamwork is a complementary relationship of interdependence.[13]

An effective team is critical to both the clinical and financial health of the ICU.[14] Good teamwork requires a number of skills. A team performance framework for the ICU requires communication, leadership, coordination, and team decision making. Effective team leadership is crucial for guiding effective team interactions and coordination. Leadership performance can be measured; the leadership performance of attending intensivists is associated with accomplishment of daily patient goals.[15] Important leadership characteristics include communication skills, conflict management, time management, acknowledging others' concerns and one's own limitations, focus on results, setting high standards, and showing appreciation for the work of the team.

Quality improvement is an important part of ICU management. The intensivist must be responsible for leading and ensuring quality improvement efforts. The Institute of Medicine's "six aims for improvement" are safety, effectiveness, equity, timeliness, patient centeredness, and efficiency.[16] These aims are certainly relevant to pediatric critical care practice and can provide a framework for improving quality in the pediatric ICU (PICU). Acuity scores have been used as tools for measuring quality in the ICU. It is important for the intensivist to understand the various available scoring systems and how they can be used to ensure appropriate use of these tools.[17]

The use of clinical pathways has been shown to improve efficiency of care and decrease resource utilization.[18] The intensivist, as leader of the team, must ensure that these guidelines are developed with input from all members of the ICU team to optimize acceptance and smooth implementation of such guidelines. Standardization of care increases the likelihood that every patient will get the appropriate treatments at the right time. A common objection to standardization is that ICU patients are too complex or too different to be able to standardize their care. However, some aspects of care should be provided to most, if not all, patients and can be overlooked easily if they are not standardized. One example is insertion of central venous catheters using full-barrier precautions to prevent line-associated bloodstream infections. Checklists are helpful to remind all members of the team to carry out the "routine" steps every time. In the case of a patient who has a contraindication to "standard" care, the contraindication should be documented. In an environment that is increasingly complex, ensuring reliability in processes of care is exceedingly difficult. Standardizing the processes means that everyone on the team knows what to expect. Empowering every member of the team to speak up if he or she observes an unsafe condition further increases the safety of the patient and the reliability of care.

A systematic review by Carmel and Rowan[19] described eight organizational categories that may contribute to patient outcome in the ICU. These factors include staffing, teamwork, patient volume and pressure of work, protocols, admission to intensive care, technology, structure, and error. Pollack and Koch[20] demonstrated that organizational factors and management characteristics can influence health outcomes in the neonatal ICU. The intensivist, as captain of the ship, is responsible for ensuring that these important organizational factors are optimized in the ICU.

Manpower Issues

By its very nature, critical care is an intense and stressful field. Optimal clinical care and management in the ICU depends first and foremost on the availability of sufficient numbers of trained critical care professionals. Shortages of all types of critical care providers are an increasing concern. The Society of Critical Care Medicine, the American College of Chest Physicians, and the American Thoracic Society performed a manpower analysis of critical care specialists in 1997 and projected an increasing shortage of intensivists during the next 2 decades.[21] These three professional societies, along with the American Association of Critical-Care Nurses, further reviewed the available literature to identify causes of the shortage of critical care professionals and possible approaches to redesigning critical care practice.[22] These groups recommended common standards across the critical care field to promote uniformity and quality, use of information technology to promote standardization and improve efficiency, government incentives to attract health care professionals to critical care, and sponsorship of research defining the optimum role for intensive care professionals in the delivery of critical care. In an interesting study that looked at intensivist/bed ratio, Dara and Afessa[23] reported that differences in intensivist/bed ratios from 1:7.5 to 1:15 were not associated with differences in mortality rates, but a ratio of 1:15 was associated with increased ICU length of stay. Shortages of intensivists, which lead to higher numbers of patients per intensivist, may further limit the availability of ICU beds by increasing the

length of stay. Although these projects and the resulting documents were primarily aimed at critical care services for adults, the need for which will unquestionably increase markedly as the population ages, there are similar and equally pressing shortages of well-trained pediatric critical care professionals.[24] The pediatric intensivist needs to be aware of the importance of the health care professional as one of the most important resources of the PICU.

A matter that is at least as concerning as the physician shortage in the ICU is the increasing shortage of critical care nurses. As the supply of nurses decreases, the nurse/patient ratio in many ICUs increases. Increasing the number of critically ill patients a nurse must care for has negative effects on both patient care and on nursing morale and job satisfaction.[25,26] Decreased morale leads to increased turnover and the loss of experienced and highly skilled nurses. This situation, in turn, places patients at increased risk.

The presence of a pharmacist on rounds in the ICU has been shown to reduce drug errors and improve patient safety. Pharmacists are another group of critical care professionals who are in increasingly short supply.[27]

With the increasing shortage of intensivists has come consideration of other ways to provide adequate numbers of practitioners to care for critically ill patients. Hospitalists provide a substantial amount of critical care in the United States. One study reported that after-hours care in the PICU by hospitalists was associated with improved survival rates and shorter length of stay compared with care by residents.[28] Numerous studies have looked at the role of nurse practitioners and physician assistants as physician extenders in the PICU.[29-31] These practitioners can effectively complement the physician staff in the ICU, especially as resident work hours decrease.

Summary

Health care costs continue to increase and will likely do so until there is meaningful health care reform in the United States. Critical care consumes a large, although not increasing, share of health care costs. With the increasing complexity of management of the critically ill patient, careful management of the very limited resources available to promote optimal outcomes is increasingly important. The pediatric intensivist must be skilled in the management not only of the critically ill child, but also in the administration of the PICU and the appropriate use of all of its resources. Effective teamwork will be the key to ensuring optimal care in the face of limited resources.

Chapter 3

The Nurse in Pediatric Critical Care

Patricia A. Moloney-Harmon and Martha A.Q. Curley

PEARLS

- Nursing's unique contribution to patients within the health care environment is that nurses create safe passage for patients and families.
- Nurses coordinate the patient's and family's experiences by their continuous attention to the person who exists underneath all the advanced technology that is being employed.
- Building a humanistic environment that endorses parents as unique individuals capable of providing essential elements of care to their children lays the foundation for family-centered care.
- Caring practices are a constellation of nursing activities that are responsive to the uniqueness of the patient/family and create a compassionate and therapeutic environment with the aim of promoting comfort and preventing suffering.
- Excellence in a pediatric critical care unit is achieved through a combination of many factors and is highly dependent on a healthy work environment.
- Studies have demonstrated that a stable, established, and proficient nursing workforce improves patient outcomes.
- A successful critical care professional advancement program recognizes varying levels of staff nurse knowledge and expertise and fosters advancement through a wide range of clinical learning and professional development experiences.
- Technical training alone is insufficient in meeting patient and family needs in the critical care environment.

Pediatric critical care nursing has evolved tremendously over the years. The nurse is the singular person in the pediatric critical care unit who creates an environment in which critically unstable, highly vulnerable infants and children benefit from vigilant care and who coordinates the actions of a highly skilled team of patient-focused health care professionals. Pediatric critical care nursing practice encompasses staff nurses who provide direct patient care, nursing leaders who facilitate an environment of excellence, and professional staff development that ensures continued nursing competence and professional growth. This chapter discusses the essential components of pediatric critical care nursing practice.

Describing What Nurses Do: The Synergy Model

The synergy model describes nursing practice based on the needs and characteristics of patients and their families.[1] The fundamental premise of this model is that patient characteristics drive required nurse competencies. When patient characteristics and nurse competencies match and synergize, optimal patient outcomes result. The major components of the synergy model encompass patient characteristics of concern to nurses, nurse competencies important to the patient, and patient outcomes that result when patient characteristics and nurse competencies are in synergy.

Patient Characteristics of Concern to Nurses

Every patient and family member brings unique characteristics to the pediatric intensive care experience. These characteristics—stability, complexity, predictability, resiliency, vulnerability, participation in decision making, participation in care, and resource availability—span the continuum of health and illness. Each characteristic is operationally defined as follows.

Stability refers to the person's ability to maintain a steady state. Complexity is the intricate entanglement of two or more systems (e.g., physiologic, family, and therapeutic). Predictability is a summative patient characteristic that allows the nurse to expect a certain trajectory of illness. Resiliency is the patient's capacity to return to a restorative level of functioning using compensatory and coping mechanisms. Vulnerability refers to an individual's susceptibility to actual or potential stressors that may adversely affect outcomes. Participation in decision making and participation in care are the extents to which the patient and family engage in decision making and in aspects of care, respectively. Resource availability refers to resources that the patient/family/community bring to a care situation and include personal, psychological, social, technical, and fiscal resources.

These eight characteristics apply to patients in all health care settings. This classification allows nursing to have a common language to describe patients that is meaningful to all care areas. For example, a critically ill infant in multisystem organ failure might be described as an individual who is

unstable, highly complex, unpredictable, highly resilient, and vulnerable, whose family is able to become involved in decision making and care but has inadequate resource availability.

Each of these eight characteristics forms a continuum, and individuals fluctuate at different points along each continuum. For example, in the case of the critically ill infant in multisystem organ failure, stability can range from high to low, complexity from atypical to typical, predictability from uncertain to certain, resiliency from minimal reserves to strong reserves, vulnerability from susceptible to safe, family participation in decision making and care from no capacity to full capacity, and resource availability from minimal to extensive. Compared with existing patient classification systems, these eight dimensions better describe the needs of patients that are of concern to nurses.

Nurse Competencies Important to Patients and Families

Nursing competencies, which are derived from the needs of patients, also are described in terms of essential continua: clinical judgment, clinical inquiry, caring practices, response to diversity, advocacy/moral agency, facilitation of learning, collaboration, and systems thinking.

Clinical judgment is clinical reasoning that includes clinical decision making, critical thinking, and a global grasp of the situation coupled with nursing skills acquired through a process of integrating formal and experiential knowledge. Clinical inquiry is the ongoing process of questioning and evaluating practice, providing informed practice on the basis of available data, and innovating through research and experiential learning. The nurse engages in clinical knowledge development to promote the best patient outcomes. Caring practices are a constellation of nursing activities that are responsive to the uniqueness of the patient/family and create a compassionate and therapeutic environment with the aim of promoting comfort and preventing suffering. Caring behaviors include, but are not limited to, vigilance, engagement, and responsiveness. Response to diversity is the sensitivity to recognize, appreciate, and incorporate differences into the provision of care. Differences may include, but are not limited to, individuality, cultural practices, spiritual beliefs, gender, race, ethnicity, disability, family configuration, lifestyle, socioeconomic status, age, values, and alternative care practices involving patients/families and members of the health care team. Advocacy/moral agency is defined as working on another's behalf and representing the concerns of the patient/family/community. The nurse serves as a moral agent when assuming a leadership role in identifying and helping to resolve ethical and clinical concerns within the clinical setting. Facilitation of learning is the ability to use the process of providing care as an opportunity to enhance the patient's and family's understanding of the disease process, its treatment, and its likely impact on the child and family. Collaboration is working with others (i.e., patients, families, and health care providers) in a way that promotes and encourages each person's contributions toward achieving optimal and realistic patient goals. Collaboration involves intradisciplinary and interdisciplinary work with colleagues. Systems thinking is appreciating the care environment from a perspective that recognizes the holistic interrelationships that exist within and across health care systems.

These competencies illustrate a dynamic integration of knowledge, skills, experience, and attitudes needed to meet patients' needs and optimize patient outcomes. Nurses require competence within each domain at a level that meets the needs of their patient population. Logically, more compromised patients have more severe or complex needs; this in turn requires the nurse to possess a higher level of knowledge and skill in an associated continuum. For example, if a patient is stable but unpredictable, minimally resilient, and vulnerable, primary competencies of the nurse center on clinical judgment and caring practices (which include vigilance). If a patient is vulnerable, unable to participate in decision making and care, and has inadequate resource availability, the primary competencies of the nurse focus on advocacy/moral agency, collaboration, and systems thinking. Although all the eight competencies are essential for contemporary nursing practice, each assumes more or less importance depending on a patient's characteristics. Optimal care is most likely when there is a match between patient needs/characteristics and nurse competencies.

Clinical Judgment

Clinical judgment, that is, skilled clinical knowledge, use of discretionary judgment, and the ability to integrate complex multisystem data and understand the expected trajectory of illness and human response to critical illness defines competent nursing practice. In critical care, the novice nurse focuses on individual aspects of the patient and the environment. As expertise develops, the nurse develops a global understanding of the situation. The expert nurse anticipates the needs of patients, predicts the patient's trajectory of illness, and forecasts the patient's level of recovery. Evolving clinical expertise creates safe passage for patients. The very best nursing care often is invisible, as it should be, because untoward effects and complications are prevented. Nursing's unique contribution to patients within the health care environment, which encompasses all nursing's competencies, is that nurses create safe passage for patients and families. Safe passage may include helping the patient and family move toward a greater level of self-awareness, knowledge, or health; transition through the acute care environment or stressful events; and/or a peaceful death.

Clinical Inquiry

Clinical inquiry optimizes the delivery of evidence-based care. Studying the clinical effectiveness of care and how it affects patient outcomes provides information that helps balance cost and quality. Quality improvement methods include use of multidisciplinary teams that work together to help systems operate in a way that promotes the best interests of patient care. Collaborative practice groups working with clinical practice guidelines (CPGs) provide the opportunity to initiate evidence-based interventions.

CPGs—that is, patient-centered multidisciplinary and multidimensional plans of care—help the team provide evidence-based practice and improve the process of care delivery. CPGs ensure practitioner accountability, encourage coordinated care, decrease unnecessary variation in practice patterns, improve quality and cost-effective services, and provide a means to systematically evaluate the quality and effectiveness of practice in moving patients toward desired outcomes. Effective CPGs are driven by patient needs and help provide

evidence linking interventions to patient outcomes. CPGs help guide the appropriate use of resources, limiting interventions. Evidence-based guidelines can help to eliminate interventions that do not benefit patients but frequently are steeped in tradition and opinion.

Caring Practices

Caring practices bring clinical judgment to view. Caring practices are activities that are meaningful to the patient and family and enhance their feelings that the health care team cares about them. Families equate caring behaviors with competent behaviors. Families trust that nurses will be vigilant. Vigilance, which includes alert and constant watchfulness, attentiveness, and reassuring presence, is essential to limit the complications associated with a patient's vulnerabilities.[1]

Nurses coordinate the patient's and family's experiences by their continuous attention to the person who exists underneath all the advanced technology that is employed. This steady attention can make an important difference for patients by helping patients and their families better tolerate the experience of critical illness. This aspect of practice, our presence with patients, is unique to the profession of nursing.[1] For example, in working with patients with head injuries, caring nurses acknowledge the person by surrounding them with their possessions, such as family pictures and cards from friends, and their favorite music. Nurses talk with their unresponsive patients, orienting them and telling them what is going on, which preserves the patient's "humanness." Occasionally a patient responds as evidenced by as an increase in heart rate or blood pressure, a decrease in intracranial pressure, or the shedding of a tear. Nurses take this level of communication one step further by teaching this process to family members so they too can interact with their critically ill loved one.

Pediatric critical care nurses, more than any other intensive care unit (ICU) nursing subspecialty, have made significant progress in integrating family-centered care into the practice of critical care. Building a humanistic environment that endorses parents as unique individuals capable of providing essential elements of care to their children lays the foundation for family-centered care. Family-centered care is more than just providing parents with unlimited access to their children.[1]

Nursing research provides the foundation for this change in practice. Based on nursing research, we know that parents have the need for hope, information, and proximity; to believe that their loved one is receiving the best care possible; to be helpful; to be recognized as important; and to talk with other parents with similar issues. Pediatric critical care nurses have gone beyond the identification of family needs to illustrating interventions that patients and families find helpful.[1] We provide families with what they need to help their child. Parents believe the most important contribution pediatric critical care nurses make is to serve as the "interpreter" of their critically ill child's responses and of the pediatric ICU environment.

Response to Diversity

Response to diversity honors the differences that exist in the people we are and in the individuals we care for. At a minimum, it requires that care be delivered in a nonjudgmental, nondiscriminatory manner. Effective communication with patients and families at their level of understanding may require customizing the health care culture to meet the diverse needs and strengths of families. Skilled nurses foresee differences and beliefs within the team and negotiate consensus in the best interest of the patient and family.

Advocacy/Moral Agency

Moral agency acknowledges the particular trust inherent within nurse-patient relationships, a trust gained from nursing's long history of speaking on the patient's behalf in an effort to preserve a patient's "lifeworld" (Hooper, personal communication, 1996). The holistic view of the patient that nurses often possess is a reflection of moral awareness.

When a cure is no longer possible, nurses turn their focus to ensuring that death occurs with dignity and comfort. Nurses "orchestrate" death, supporting parents and family members through the death of their loved one. Nurses often coordinate the experience for patients and families when death is imminent. This most intimate aspect of nursing care is a profound contribution to humankind.[2]

Pediatric critical care nurses provide critical support of the practice of family presence during procedures and resuscitation. Including family members during pediatric resuscitation is not a universal practice. However, one study established that the parents who were able to be present during their child's resuscitation collectively believed that their presence provided comfort to their child and themselves.[3] Parents who were not able to stay regretted not being able to comfort their child in the final moments of his or her life. The study authors advocated that policies be developed to facilitate parental presence during resuscitation. A study of physicians ascertained that most respondents encouraged family members to be present during their child's resuscitation.[4] The majority of physicians believed that being there was helpful to parents and that physicians should be prepared for this practice. Nurses take on the essential accountability of preparing families to stay with their child.[5]

Facilitator of Learning

Nurses facilitate learning so that patients and their families become knowledgeable about the health care system and can make informed choices. Teaching is an almost continuous process that involves helping the patient and the family understand the critical care environment and therapies involved in critical care. Also essential is reinforcement of the patient's experience and how, most likely, the infant or child will cope with the ICU experience. This education provides patients with the capacity to help themselves and for parents to help their infants and children.

Collaboration

Collaboration requires commitment by the entire multidisciplinary team. A classic study done by Knaus et al.[6] found an inverse relationship between actual and predicted patient mortality and the degree of interaction and coordination of multidisciplinary intensive care teams. Hospitals with good collaboration and a lower mortality rate had a comprehensive nursing educational support program that included a clinical nurse specialist and clinical protocols that staff nurses can independently initiate. The American Association of Critical-Care Nurses Demonstration Project also documented a low mortality ratio, low complication rate, and high

patient satisfaction in a unit that had a high perceived level of nurse/physician collaboration, highly rated objective nursing performance, a positive organizational climate, and job satisfaction and morale.[7]

Systems Thinking

Nurses are constantly challenged to design, implement, and evaluate whole programs of care, manage units where programs of care are provided, and determine whether the health care system is meeting patient needs.[8] These vital components require a patient-centered culture that stresses strong leadership, coordination of activities, continuous multidisciplinary communication, open collaborative problem solving, and conflict management.[9] For many years nurses have learned to manipulate the system on behalf of their patients; however, systems thinking[10]—that is, the ability to understand and effectively manipulate the complicated relationships involved in complex problem solving—is a new but necessary skill in taking overall responsibility for the caregiving environment.

Managing complex systems is essential to creating a safe environment. Nurse-patient relationships commonly occur around transitional periods of instability brought about by the demands of the health care situation. Helping patients make transitions between elements of the health care system—for example, into and out of the community—requires systems knowledge and intradisciplinary collaboration.[11]

Optimal Patient Outcomes

According to the synergy model, optimal patient outcomes result when patient characteristics and nurse competencies synergize. The study of many patient outcome measures is appropriate, including physiologic, psychological, functional, and behavioral outcome measures, as well as symptom control, quality of life, family strain, goal attainment, utilization of services, safety, problem resolution, and patient satisfaction.[12] A "nurse-sensitive" outcome, a term first coined by Johnson and McCloskey,[13] defines a dynamic patient or family caregiver state, condition, or perception that is responsive to nursing interventions. Brooten and Naylor[14] note: "The current search for 'nurse-sensitive patient outcomes' should be tempered in the reality that nurses do not care for patients in isolation and patients do not exist in isolation." Outcomes have been described at three levels: patient, provider, and system.

Patient Level Outcomes

Major patient level outcomes of concern to pediatric critical care nurses include hemodynamic stability and the presence or absence of complications. Outcomes related to limiting iatrogenic injury and complications of therapy demonstrate the potential hazards present in illness and in the critical care environment. Patient/family satisfaction ratings are subjective measures of health and/or the quality of health services. Patient satisfaction measures involving nursing typically include technical/professional factors, trusting relationships, and education experiences.[15] Patient-perceived functional change and quality of life are multidisciplinary outcome measures. Linking patient satisfaction, functional status, and quality of life is important because the three factors often are related.

Provider Level Outcomes

Provider level outcomes include the extent to which care/treatment objectives are attained within the predicted time period. Nurses coordinate the day-to-day efforts of the entire multidisciplinary team. The nurse's role as the coordinator of numerous services is essential for optimal patient outcomes and shorter lengths of stay. As discussed, nurse–physician collaboration and positive interaction is associated with lower mortality rates, high patient satisfaction with care, and low nosocomial complications.[6,7]

System Level Outcomes

Critical care units must manage resources and maintain quality as collaboratively defined by both users and providers in the system. The goal is high-quality care at moderate cost for the greatest number of people. Important patient-system outcome data include recidivism and costs/resource utilization. Recidivism, that is, rehospitalization and readmission, is repeated work that adds to the personal and financial burden of providing care. In addition to patient and system factors, nurses can decrease the patient's length of stay through coordination of care, prevention of complications, timely discharge planning, and appropriate referral to community resources. Reducing length of stay and tracking emergency department visits and rehospitalization ensure that cost shifting is not occurring.

Nightingale Metrics

One population-specific approach to measurement of nurse-sensitive outcomes is the Nightingale Metrics.[16] This program was developed so that bedside nurses could be actively involved in identifying nurse-sensitive metrics important to their unique patient and family population. Nurses give care in an environment that supports the capacity of the patient and family to heal. Much of nursing is preventive care that often is not measured; thus care is often invisible. When measuring outcomes, it is important to measure the invisible aspects of nursing that have a tremendous impact on patients. For example, invisible are the large numbers pressure ulcers that never develop because of good nursing care. The Nightingale Metrics reflect current standards of care, are based on evidence, and are measurable (Box 3-1).

Box 3–1 Pediatric Intensive Care Unit—Nightingale Metrics

- Pain and sedation scores every 4 hours
- In patients with a central venous line, changing the dressing every 7 days
- Establishment of a nutrition plan within 24 hours of admission
- Pressure ulcer bundle: If patient is immobile, documentation of position change every 2 hours and positioning of heels off the bed; if not on bed rest, documentation of patient being out of bed or held in parent's or nurses' arms
- Ventilator-associated pneumonia bundle: Head of bed elevation at 30 to 45 degrees; documentation of oral hygiene twice in 24 hours; peptic ulcer prophylaxis (in patients not receiving tube feedings); discussion of extubation readiness test on rounds; daily holiday from sedation or chemical paralysis
- "Time to critical intervention": response to panic laboratory value, the time intervals from sending specimen to laboratory to first intervention to correct laboratory value

Leadership

Excellence in a pediatric critical care unit is achieved through a combination of many factors and is highly dependent on effective leadership.[17] Numerous studies have demonstrated the importance of leadership in creating an environment where both nurses and patients can flourish. Effective leaders help diverse groups work together in harmony.[18]

Specialized units such as pediatric critical care units require staff with the expert knowledge and skill required to meet the multifaceted needs of patients and families. A healthy work environment should improve retention and recruitment. A study was done to determine the incidence of ICU nurses' intention to leave their jobs because of working conditions and to identify factors predicting this phenomenon.[19] Nurses were divided into two groups: (1) those intending to leave because of working conditions, and (2) others (e.g., those not leaving or retirees). Work environment was measured by investigating seven subscales: professional practice, staffing/resource adequacy, nursing management, nursing process, nurse/physician collaboration, nurse competence, and a positive scheduling climate.

A total of 2323 nurses from 66 hospitals and 110 critical care units in the United States completed surveys. Seventeen percent (n = 391) reported that they intended to leave their position in the coming year. Of those, 52% (n = 202) stated that the reason for their planned departure was working conditions. The authors of the study determined that improving the professional practice environment and clinical competence of the nurses as well as sustaining new nurses may decrease turnover and help secure an established and proficient workforce.[19]

The literature validates that an established and proficient workforce improves patient outcomes. A study conducted by Aiken et al.[20] observed the effect of nurse staffing levels on patient outcomes and factors affecting nurse retention. A total of 10,184 nurses from 168 hospitals were surveyed. The results concluded that after adjusting for patient and hospital characteristics, each additional patient per nurse was associated with a 7% increase in the likelihood of dying within 30 days of admission and a 7% increase in the odds of failure to rescue (death subsequent to a complication that develops and was not present at admission). In addition, after adjusting for nurse and hospital characteristics, each additional patient per nurse was associated with a 23% increase in the odds of burnout and a 15% increase in the odds of job dissatisfaction.

Aiken and colleagues[21] have continued their work by assessing the net effects of work environments on nurse and patient outcomes. Using data from the 168 hospitals and 10,184 nurses, they investigated whether better work environments were related to lower patient mortality and better nurse outcomes independent of nurse staffing and the education of the RN workforce in hospitals.[21] Work environments were considered based on the practice environment scales of the Nursing Work Index. Three of the five subscales studied were nursing foundations for quality of care; nurse manager ability, leadership, and support; and collegial registered nurse/physician relationships. Outcomes studied included job satisfaction, burnout, intent to leave, quality of care, mortality, and failure to rescue. Aiken and colleagues found that a higher percentage of nurses working in hospitals with unsupportive care environments reported higher burnout levels and dissatisfaction with jobs. They also found that work environment had a significant effect on plans to leave their units. When all patient and nurse factors were taken into account, the likelihood of patients dying within 30 days of admission was 14% lower in hospitals with healthier care environments. These findings support the observation that nursing leaders have at least three major opportunities to boost nurse retention and patient outcomes. These opportunities include increasing nurse staffing; using a more highly educated nurse workforce; and enhancing the work environment.

One of the best examples of a work environment that champions the nurse at the bedside is Magnet Hospital designation. Data demonstrate that hospitals that use the structure for magnet designation achieve significant improvements in their work environments.[21] Hospitals that have even some of the magnet characteristics illustrate improved nurse and patient outcomes. Characteristics of magnet hospitals that have the most impact on nurse and patient outcomes are investments in staff development, superior management, frontline manager supervisory skill, and good nurse/physician collaboration.[21]

The importance of a healthy work environment cannot be stressed enough as the means to ensure a viable, competent, and caring workforce. Nurses look for a culture that respects the nurse's experience, skills, abilities, and unique contributions. The standards for a healthy work environment as established by the American Association of Critical-Care Nurses (AACN) are skilled communication, true collaboration, effective decision making, appropriate staffing, meaningful recognition, and authentic leadership.[9]

Beacon Award

The Beacon Award for Critical Care Excellence, created by AACN, distinguishes adult critical care, adult progressive care, and pediatric critical care units that attain high-quality outcomes. This prestigious Award provides the critical care community with a means of recognizing achievements in professional practice, patient outcomes, and the health of the work environment.

A pediatric critical care unit can achieve the Beacon Award by meeting several criteria in the areas of recruitment and retention; education/training/mentoring; evidence-based practice/research; patient outcomes; healing environment; and leadership/organizational ethics. All of these areas provide a comprehensive view of any given ICU. To date, 17 pediatric critical care units have received the Beacon Award for Critical Care Excellence (M. Herigstad, personal communication, 2010).

Professional Development

A critical aspect of development for the nurse is the ability to advance and be recognized professionally. A successful critical care professional advancement program recognizes varying levels of staff nurse knowledge and expertise and fosters advancement through a wide range of clinical learning and professional development experiences. Essential components of this program include an orientation program, a continuing education plan, in-service education, and an array of other opportunities for clinical and professional development. Unit-based advancement programs are most effective when they are

linked to the nursing department's professional advancement program.

A professional advancement program that recognizes and rewards evolving expertise contains elements of both clinical and professional development strategies. The synergy model's ability to describe a patient–nurse relationship that optimizes patient and family outcomes illuminates the various dimensions of critical care nursing practice that require attention from a development perspective.[1,22] The impact of these contributions can be measured based on the nurse's level of expertise, and professional development strategies can be focused to have an impact on patient care.

By combining the nurse competencies identified in the synergy model and the behaviors identified in Benner's levels of practice,[23] a continuum of expertise can be described that matches behavior with practice levels. It focuses recognition and reward on clinical practice. The impact of expert nurses on patient outcomes is presented in quantitative and financial parameters that can be understood throughout the health care system. The model links clinical competencies to patient outcomes.

Nurses require a broad body of knowledge to meet patient and organizational needs. This requirement necessitates a lifelong process of professional development targeted to specific levels of clinical practice. Nurses can choose from many learning options, such as academic education, continuing education, participation in research, collaborative learning, case studies, and simulations. Nurses view the presence of continuing education, both as learning in the unit and in-service education, as very important.[24]

Staff Development

The goal of nursing staff development programs is safe, competent practice. Comprehensive programs provide the critical resources to support and promote practice. In addition, professional nursing standards of practice, health care laws, regulations, and accreditation requirements focus on the components of competent patient care to protect the health care consumer. The establishment of a staff development program that is linked to clinical practice is key to the success of professional nurse development.

Critical care staff development programs can be designed to educate staff nurses within the competencies of the synergy model.[1] The program builds on the nurse's prior education and professional nursing experience, which facilitates attainment and maintenance of competence. Concepts intrinsic to the educational process and to critical care nursing are used as a framework around which professional development opportunities are organized. Once defined on the basis of a unit's patient population, the organizing framework serves as the structure within which all critical care nursing staff development programs are designed.

Technical training alone is no longer sufficient to meet the care delivery needs of the nurse in the critical care environment. Critical care nurses require broad knowledge and expertise in areas such as communication, critical thinking, and collaboration.[9] They need to attain the diverse skills necessary to meet the complex needs of their patients and families.

The theory and science required to meet the synergy competencies includes topics such as disease processes, nursing procedures, cultural differences, moral and ethical principles and reasoning, research principles, and educational learning theories. This information can be presented through a variety of methods, including lectures, written information, posters, self-studies, or computer-based technology. However, it is essential that the information be related to realistic clinical situations. Clinical scenarios, case studies, and simulations that represent the dynamic and ambiguous clinical situations nurses encounter daily are most effective.[25]

Bedside teaching is particularly helpful in the development of clinical judgment and caring practice skills. Expert nurses are role models for many of the competencies delineated by the synergy model. Novice nurses learn by watching these expert nurses and emulating their behaviors. Clinical teaching also enables the novice practitioner to gain experience with unfamiliar interventions in a safe and protected environment. Communicating and validating clinical knowledge focuses learning, positively affects patient outcomes, and adds to the total body of nursing knowledge.[25]

Information about research and research utilization builds clinical inquiry and system thinking skills. Demystifying research, outcome, and quality processes contributes to the development of these key skills. Use of journal club formats and supporting staff involvement in research develop clinical inquiry skills. Building knowledge in the areas of health care trends and political action expand system thinking skills. Development of critical thinking skills and problem solving skills also assists with development of system thinking.

Nurses acquire facilitation of learning skills by incorporating communication development into their professional development plan. Presenting clinical teaching strategies and helping staff to determine learner readiness and assess understanding are included in the development of facilitation of learning. The importance of developing patience, flexibility, and a nonconfrontational style is reinforced.

Negotiation, conflict resolution, time management, communication, and team building are components of collaboration skills. Role playing, role modeling, and clinical narratives are methodologies that have been used to develop collaboration skills.

Nurses learn technical skills and scientific knowledge in many ways, but caring practices and advocacy are developed only through relationships that evolve over time.[26] Nurturing professional relationships with experienced staff promotes the novice's integration into practice. Expert nurses who share their clinical knowledge and coach other nurses have a tremendous impact on novice nurses. Nurses who coach are in their roles because they are able to clinically persuade and guide situations. They demonstrate expert skills and expedite the ongoing clinical development of others.

A variety of staff development programs exist, but most fall into three general categories: orientation, in-service education, and continuing education programs.

Orientation

Orientation programs help acclimate new staff to unit-based policies, procedures, services, physical facilities, and role expectations in a work setting. A specific type of orientation program that has developed in response to the nursing

shortage is the critical care internship program. These programs have been developed as a mechanism to recruit and train entry-level nurses. They are designed to integrate nurses with little or no nursing experience into the complex critical care environment. They provide extended clinical support for novice nurses and introduce new knowledge more deliberately than do traditional orientation programs. Basic information and skill acquisition are the core features of these programs. This foundation builds on the knowledge and skills that these nurses previously acquired in their nursing school programs. Teaching usually is under the direction of a hospital educator and generally involves less senior staff as preceptors. Typically, the novice nurse starts with providing care to the least complex patients. The program establishes a foundation on which the novice can develop into a competent clinician.[25]

AACN has recently released the Essentials of Pediatric Critical Care Orientation program. This program provides a bridge for the knowledge gap between what nurses learn in their basic education program and what they need to develop clinical competence with critically ill pediatric patients. The program consists of an interactive eight-module course that provides case scenarios and practice activities that augment knowledge and lead to improved job satisfaction. This program provides flexibility because it is a self-paced didactic e-learning course that can be incorporated into a blended learning environment, combining traditional educational activities such as preceptorships, discussion groups, workshops, or simulation experiences.

In-Service Education

In-service education programs, which are the most frequent type of staff development activity, involve learning experiences that are provided in the workplace to assist staff in the performance of assigned functions and maintenance of competency.[27] These programs usually are informal and narrow in scope. They often are spontaneous sessions resulting from new situations on the unit in settings such as patient rounds or staff meetings. Examples of planned in-service sessions are demonstrations of new equipment, procedure reviews, and patient care conferences.

Continuing Education

Legislation, regulations, professional standards, and expectations of health care consumers help determine the need for continuing education. Continuing nursing education includes planned, organized learning experiences designed to expand knowledge and skills beyond the level of basic education.[27] The focus is on knowledge and skills that are not specific to one institution and that build upon previously acquired knowledge and skills. Examples of continuing education programs include formal conferences, seminars, workshops, and courses.

Certification in Pediatric Critical Care Nursing

In 1975, the AACN Certification Corporation was established to formally recognize the professional competence of critical care nurses. The mission of the AACN Certification Corporation is to certify and promote critical care nursing practice that optimally contributes to desired patient outcomes. The program establishes the body of knowledge necessary for Critical Care Registered Nurse (CCRN) certification, tests the common body of knowledge needed to function effectively within the critical care setting, recognizes professional competence by granting CCRN status to successful certification candidates, and assists and promotes the continual professional development of critical care nurses.

Before 1992, content and construct validity of the CCRN examination were established for critical care nurses who primarily care for adult patients. Pediatric critical care nurses who took the CCRN examination were tested on content that did not reflect their practice. In 1989, the AACN Certification Corporation conducted a new role delineation study. Major differences among neonatal, pediatric, and adult critical care nursing practice were identified in the types of patient care problems for which direct bedside care is provided and in the amount of time spent caring for patients with specific problems (Table 3-1). The results, for the first time, described the practice of pediatric critical care nursing and justified the need for separate pediatric, neonatal, and adult CCRN examinations.

In 1997, the unique competencies of pediatric, neonatal, and adult critical care nurses were rearticulated using the synergy model[1] as a conceptual framework. Recently, AACN published the new test plan (Table 3-2). To date 2610 pediatric critical care nurses hold CCRN–Pediatric certification (M. Herigstad, K. Harvery, C. Hartigan, personal communication, 2009).

Table 3–1 Percentage of Time Caring for Patients with Alterations in Body Systems

System Dysfunction	Pediatric Practice (%)	Neonatal Practice (%)	Adult Practice (%)
Pulmonary	18%	24%	18%
Cardiovascular	14%	10%	20%
Neurologic	14%	10%	12%
Multisystem	13%	10%	8%
Hematology/ immunology	5%	6%	2%
Renal	6%	5%	6%

Endocrine	3%	3%	5%
Behavioral/ psychosocial	3%	7%	4%

Effective for testing starting 2010, American Association of Critical-Care Nurses.

Summary

Pediatric critical care nursing has evolved into a specialty in its own right. Pediatric critical care nurses make significant and unique contributions to the health care of children. A pediatric critical care nurse requires knowledge and skills in both the art and science of nursing. A supportive, empowered environment and support for professional advancement are essential to the development of knowledge and skills.

Table 3–2 Pediatric CCRN Test Plan

I. Clinical judgment (80%)

A. Cardiovascular (14%)
1. Acute pulmonary edema
2. Cardiac surgery (e.g., Norwood, Blalock-Taussig shunt, tetralogy of Fallot repair, arterial switch)
3. Cardiogenic shock
4. Cardiomyopathies (e.g., hypertrophic, dilated, restrictive, idiopathic)
5. Dysrhythmias
6. Heart failure
7. Hypovolemic shock
8. Interventional cardiology (e.g., catheterization)
9. Myocardial conduction system defects
10. Structural heart defects (acquired and congenital, including valvular disease)

B. Pulmonary (18%)
1. Acute lung injury (e.g., acute respiratory distress syndrome)
2. Acute pulmonary embolus
3. Acute respiratory failure
4. Acute respiratory infections (e.g., acute pneumonia, croup, bronchiolitis)
5. Air leak syndromes (e.g., pneumothorax, pneumopericardium)
6. Aspiration (e.g., aspiration pneumonia, foreign body, meconium)
7. Asthma, chronic bronchitis
8. Bronchopulmonary dysplasia
9. Congenital anomalies (e.g., diaphragmatic hernia, tracheoesophageal fistula, choanal atresia, pulmonary hypoplasia, tracheal malacia, tracheal stenosis)
10. Pulmonary hypertension
11. Status asthmaticus
12. Thoracic surgery
13. Thoracic trauma (e.g., fractured ribs, lung contusions, tracheal perforation)

C. Endocrine (5%)
1. Acute hypoglycemia
2. Diabetes insipidus
3. Diabetic ketoacidosis
4. Inborn errors of metabolism
5. Syndrome of inappropriate secretion of antidiuretic hormone (SIADH)

D. Hematology/immunology (3%)
1. Coagulopathies (e.g., idiopathic thrombocytopenic purpura, disseminated intravascular coagulation, heparin-induced thrombocytopenia)
2. Oncologic complications

E. Neurology (14%)
1. Acute spinal cord injury
2. Brain death (irreversible cessation of whole brain function)
3. Congenital neurologic abnormalities (e.g., myelomeningocele, encephalocele, atrioventricular malformation)
4. Encephalopathy (e.g., anoxic, hypoxic-ischemic, metabolic, infectious)
5. Head trauma (e.g., blunt, penetrating, skull fractures)
6. Hydrocephalus
7. Intracranial hemorrhage/intraventricular hemorrhage (e.g., subarachnoid, epidural, subdural)
8. Neurologic infectious disease (e.g., congenital, viral, bacterial)
9. Neuromuscular disorders (e.g., muscular dystrophy, Guillain-Barré syndrome, myasthenia gravis)
10. Neurosurgery
11. Seizure disorders
12. Space-occupying lesions (e.g., brain tumors)
13. Spinal fusion
14. Stroke (e.g., ischemic, hemorrhagic)

F. Gastrointestinal (6%)
1. Acute abdominal trauma
2. Acute gastrointestinal hemorrhage
3. Bowel infarction/obstruction/perforation (e.g., necrotizing enterocolitis, mesenteric ischemia, adhesions)
4. Gastroesophageal reflux
5. Gastrointestinal abnormalities (e.g., omphalocele, gastrochisis, volvulus, Hirshsprung's disease, malrotation, intussusception)
6. Gastrointestinal surgeries
7. Hepatic failure/coma (e.g., portal hypertension, cirrhosis, esophageal varices, biliary atresia)
8. Malnutrition and malabsorption

G. Renal (6%)
1. Acute renal failure
2. Chronic renal failure
3. Life-threatening electrolyte imbalances

H. Multisystem (11%)
1. Asphyxia
2. Distributive shock (e.g., anaphylaxis)
3. Hemolytic uremic syndrome
4. Multiorgan dysfunction syndrome (MODS)
5. Multisystem trauma
6. Near drowning
7. Sepsis/septic shock
8. Systemic inflammatory response syndrome (SIRS)
9. Toxic ingestions/inhalations (e.g., drug/alcohol overdose)
10. Toxin/drug exposure

I. Behavioral/psychosocial (3%)
1. Abuse/neglect
2. Developmental delays
3. Failure to thrive

II. Professional caring and ethical practice (20%)

A. Advocacy/moral agency (3%)

B. Caring practices (4%)

C. Collaboration (4%)

D. Systems thinking (2%)

E. Response to diversity (2%)

F. Clinical inquiry (2%)

G. Facilitation of learning (3%)

Chapter 4

Research in Pediatric Critical Care

Randall C. Wetzel and Carol E. Nicholson

"A fool is a man who never tried an experiment in his life."
Erasmus Darwin, 1792

PEARLS

- Research is the right thing to do for critically ill children, their families, and our profession. Whether or not it is supported at your institution does not alter this fact, nor does it relieve you of your scholarly responsibilities as a physician.
- Make inquiry, comparison, and analysis a permanent part of your critical care practice. Keep a follow-up card as a lifelong habit in the practice of medicine. Go to postmortems, and keep looking through the microscope.
- Before you accept dogmatic teaching from anyone, make a habit of analyzing its basis. Keep a "reading" section on your follow-up card.

Among the factors that define a medical specialty is the recognition of a clearly defined body of knowledge that is intrinsic and unique to that specialty. This body of knowledge is determined by the disease processes that the specialists treat, comprehensive understanding of those disease processes, and, most importantly, the academic and intellectual constructs that allow the advancement of medical knowledge, not only narrowly in the specialty but also in general. Endeavors directed at increasing the specialty's knowledge base are the research interests of that specialty. Thus a recognized medical specialty has a clearly defined patient population, clearly defined disease processes, and clearly defined research interests. Medical specialties frequently have associated societies, professional organizations, and national institutes, all of which facilitate research funding, sharing of research information, and advancing knowledge in the specialty.

Because organ system classification of specialties is fairly obvious, it is a common basis for specialization. The specialists who treat diseases of the lungs are familiar with the wide spectrum of pulmonary diseases, their pathogenesis, and their treatment. There exists a large body of research-derived knowledge and a great deal of ongoing related research activity. This activity is presented at national meetings, such as the annual American Thoracic Society meeting. There is a network of extensive funding sources available to this specialty, such as the American Lung Association; the American Heart Association; and the National Heart, Lung, and Blood Institute (NHLBI). Taken together, these form the clearly defined specialty of pulmonary medicine. Not all specialties are organ specific; for example, infectious disease and immunology are specialties that are concerned with diseases that affect the entire patient. These specialties have managed to clearly define a body of knowledge that is both intrinsic and unique, as well as crucial, to the specialty.

How does critical care medicine measure up to this standard? Have we succeeded in defining disease processes, patient populations, and research efforts that are unique to critical care medicine? What are these areas? Is it necessary for intensivists to participate in some area other than critical care medicine for their academic and research involvement? Commonly, physicians whose clinical practice is critical care are involved in research integrated into multiple other specialty areas. To define critical care medicine as a medical specialty able to stand on its own, not only must the clinical practice and the pathophysiology of the unique disease entities be defined, but also critical care researchers must make a unique contribution to understanding and treating the pathophysiologic conditions that affect critically ill children. Without a body of research that is unique to critical care medicine, the certainty of the specialty's future will be in question.

Research Areas

There are clearly pathophysiologic processes that appear to be unique to critical care medicine. Probably the most clear-cut of these processes is acute respiratory distress syndrome (ARDS),[1,2] although this is only one manifestation of a systemic process. The syndrome appears to develop in critically ill patients whose initial injury arises from a wide variety of organ-specific insults. Although the lungs appear to be the primary target organ, all organs are affected by the same complex underlying pathophysiologic process. This process causes widespread endothelial injury involving many organ systems.[3] This results in tissue edema, decreased organ perfusion, ischemia, and multiple organ failure. This pansystemic disease is familiar to the intensivist and is one of the most extensive areas of unique research interest in critical care today. Understanding this systemic inflammatory response is central to understanding critical care.

Another major disease process that clearly interests critical care physicians is shock. Shock, whether it be hypovolemic, septic, or of some other etiology, by its very nature is a multisystem, non–organ-specific, acute, life-threatening process.[4,5] Another natural area for critical care research would

be specifically aimed at preventing and/or ameliorating the multisystem insults that occur because of the body-wide activation of potentially lethal mediators triggered by episodes of shock. The spectrum of research opportunities in this area ranges from molecular biologic to large-scale clinical trials and has grown exponentially in the past few years.[6]

Organ system interaction also provides an area of primary interest in critical care. In particular, cardiorespiratory interaction has immediate, everyday application in ventilatory management, cardiopulmonary resuscitation, and cardiac support. The physiology of how changes in the pleural pressure affect cardiac function during either spontaneous or positive pressure ventilation is an area of constant relevance to the intensivist.[7] In a broader sense, cardiorespiratory interaction extends beyond this arena. How changes in cardiac function alter ventilation, airway resistance, and lung compliance is an integral part of critical care. The pulmonary endothelial synthesis, release, and degradation of multiple mediators, ranging from myocardial depressant factors to systemic vasoactive substances, that alter cardiovascular function can be considered cardiorespiratory interaction and are of unique interest to the intensivist.[7] This area also encompasses a broad spectrum of possible approaches from molecular biology to cell physiology to integrated physiology. An area of research that is particularly important to critical care medicine is cell biology. All organ system failure can be described in terms of cellular failure. For example, the general effects of superoxide radicals produced by leukocytes on other cell functions are legion and clearly of interest to intensivists.[4,8] Extending the argument of cellular specialization is possible for other cell types. An argument could be made to consider the endothelium the specialty organ of intensivists.[9] All organs that fail in critically ill children contain large areas of biochemically active endothelium. This endothelium is important because it elaborates hormones and autacoids that have systemic and local effects. These effects include alteration of coagulation and blood viscosity, superoxide generation and tissue damage, smooth muscle regulation, metabolism of circulating vasoactive substances, and interaction with the immunologic system.[10,11] All generalized stressors (e.g., sepsis, hypoxia, hypovolemia) alter endothelial cell function. One way of looking at multiple organ system failure is to view it as an "endotheliopathy." This endotheliopathy gives rise to widespread organ-specific damage, such as renal failure, ARDS, myocardial depression, and alterations in the blood-brain barrier, with subsequent cerebral edema. Endothelial cell function changes over time as the child develops and may be specifically affected by disease processes particularly prevalent in children, such as the infectious vasculitides.[12] This sort of theoretical construct could serve as an organizational basis for research efforts in pediatric critical care and offer new insights into our understanding of critical illness in children.

Because of the astonishing success of the human genome project, the development of gene chips, and the increasingly realized potential of proteomics, understanding the genetic nature of critical illness no longer seems beyond our reach.[13] Understanding the genotype of individuals who physiotypically display fatal responses to meningococcal disease while their classmates remain asymptomatic, albeit colonized by the same serotype organism, holds the promise of prospectively tailoring therapy to each patient individually. The many genomic and proteomic projects developing within pediatric critical care will help our understanding of the genetic bases of critical illness and holds out hope for understanding systemic inflammatory response syndrome (SIRS) and sepsis.[13-15]

An area unique to pediatric critical care is that of caring for children and their families who must cope with acute critical and sometimes fatal illness. No other physicians deal with death and dying more frequently than intensivists. This role is especially important in the care of children. Supporting the family facing the acute, unexpected, critical illness and death of a child requires masterly physician interpersonal skills that may attenuate family problems long after the child's death. The psychosocial impact of critical illness and palliative care has been explored very little, and we need to know more. Such issues are intrinsic to critical care medicine, and it is imperative that intensivists become responsible for the research in this area. Potential avenues for the intensivist-investigator include epidemiologic study, such as family and sibling bereavement patterns, and randomized therapeutic interventions, such as the effect of frequent postmortem follow-up on the high incidence of divorce among couples who have lost a child.

Finally, and perhaps most importantly, the burgeoning area of medical informatics holds the promise of enabling us to understand complex, critical, but rare disease processes previously impossible to study.[16-19] Understanding knowledge discovery in databases and building national and international collaborative partnerships to understand the scope of pediatric critical care have come within our reach.[20] Informatics research with national funding may provide real-time guidance for management of the rarest critical illnesses. In addition participation in national databases to support quality improvement and multisite research studies provide a new and fertile area for critical care research.[21,22]

These examples indicate part of the wide spectrum of research opportunities in pediatric critical care medicine. There are many more, including the now well-established multicenter National Collaborative Pediatric Critical Care Research Network, now in its second 5-year epoch of funding by the National Institute of Child Health and Human Development (NICHD), one of the National Institutes of Health. Networked research is necessary in critical care and the Pediatric Lung Injury and Sepsis Investigators (PALISI; http://pedsccm.org/PALISI_network.php) is an important example of a national research network focused on pediatric critical care. Constant sensitivity to identifying the questions (incorrectly answered, unanswered, and unasked) is the character trait required in the academic intensivist if our specialty is to continue to grow. Identifying areas unique to critical care medicine provides the knowledge base for the specialty necessary for its growth and for our patients' well-being. Given the many unique areas of interest in critical care, how do we uncover them and encourage research in the subspecialty?

Wellsprings of Research

Collective Needs

Why must critical care collectively, as a specialty, support research in pediatric critical care? The arguments mentioned previously suggest that without the academic, intellectual, and scientific pursuit of areas that are specifically unique and relevant to critical care, we have no specialty. In this broad sense,

research establishes a collegial respect for physicians who practice critical care and engenders academic support for the specialty. If all we do is provide clinical care for desperately ill or dying children, and clinical care that other physicians do not understand by virtue of their not being dedicated to it, the challenge of "what do intensivists do?" should only in part be answered by "spend long hours with children who are critically ill and their families." This question addresses a deeper issue: Are intensivists contributing to the further understanding of critical illness? Are intensivists contributing to the intellectual advancement of medicine and the rich intellectual and academic milieu in the universities in which they find themselves? Are intensivists obtaining extramural funding for university-wide interactive and collaborative research efforts? Are intensivists training future generations of physician-scientists? Unless we can affirmatively answer these questions from a uniquely critical care point of view, it should not be surprising that physicians in other subspecialties do not understand or reliably value our labors. This justification—to ensure the viability and respectability of a specialty whose primary concern is treating the critically ill—is a major reason we must encourage and support research. Failure to do so is a failure to critically ill children.

A further reason for the commitment to research by the critical care medicine community is to allow young investigators ample introduction to research. They must be able to discover what research is, be provided with the tools to answer the outstanding questions in the field, and eventually make contributions both scientifically and educationally. These contributions will occur only if sufficient foresight is exercised to ensure that the facilities and resources are available. One of the chief rewards of developing this integrated structure will be the advancement of a specialty that truly is able to improve patient care. There are other rewards from this organized research endeavor and the education it provides. If the young investigator returns to clinical medicine, never to enter a basic science laboratory again or to organize even one clinical trial, this physician will at least be sensitive to the critical questions in patient care and be able to read and apply the literature with a better understanding. Many otherwise perfectly adequate young physicians are unable to critically evaluate the medical literature as a tool to improve management of their patients until they have been involved in contributing to it. Didactic methods are inadequate for teaching the rigorous effort required to write an article published in a first-class journal. It requires practical and challenging mentoring and arduous doing; however, once done, the emerging clinician is better able to understand and critically review the contributions of her/his colleagues and their relevance to critically ill children.

There is a further benefit from encouraging our fellows to research. The research effort provides excellent opportunities to observe how modulation of biochemistry, biology, and physiology alters the status of living beings. The practical knowledge gained in learning how to accurately measure the aortic/systemic and pulmonary artery pressures in animal models, determining the growth requirements of endothelial cells, maintaining sterile tissue cultures, and measuring pharmacokinetics provides insights into daily clinical practice unobtainable in any other way and practical for the care of every critically ill child. For this reason, it is nearly impossible to become a well-rounded clinician without having learned the basics involved in, and completed the exercise of, addressing a research question. The spinoffs of how to do cutdowns, insert catheters, start arterial lines, measure tidal volumes and pressures, manipulate ventilators, care for cultures, bioassay eicosanoids, perform chromatographic separation of bioactive lipids, and sequence the messenger RNA for endothelin immediately improve the bedside care of children, both intellectually and practically.

Individual Motivation

Beyond the learning relevant to clinical practice, individual motivation to answer questions and change the field is essential. Research is difficult, expensive, and time consuming. It removes the clinician from patient care, it is frequently thankless, often difficult to plan and organize, and hard to execute. Even when excellently done, it may be challenging to present and possibly not well received. Why then should any physician dedicated to the critical care of children be even slightly interested in becoming involved in research? Surely the desire to be promoted in the academic setting, see your name in prestigious journals, and impress your family, friends, and colleagues is insufficient motivation to contribute vast amounts of time, exhaust your intellectual and physical energy, and reduce your availability for patient care and family life. Although these may be some of the benefits of a research career, they are merely some of the lesser fruits of research. They are inadequate to provide the primary motivation for being involved in research. Personal motivations for research are many, and there are numerous rewards.

One of the most obvious is that being an attending physician in a pediatric intensive care unit 12 months of the year is not something that either can or should be done, no matter how much physical and emotional stamina one may have (or think he or she has). Diversion from clinical and administrative responsibilities and refreshment and renewal are obvious rewards of research. This benefit, prevention of burnout, is not achieved merely by avoiding clinical work. Rather, the invigoration that comes from involvement in, and a commitment to, improving patient care and advancing the specialty are the source of the benefits. Active involvement in research provides reciprocal inspiration from the daily questions in clinical work and the value of the research endeavor. It helps the clinician intensivist see the long hours of clinical care in a broader perspective. Of course, research can (and should) be fun. If it is not fun, if the investigator does not look forward to being involved in the understanding, development, design, execution, analysis, preparation, and presentation of the research, then it is not worthwhile for that individual investigator to remain involved. You must like what you are doing, or the dedication and commitment required for Edison's "99% perspiration for each 1% inspiration" will be lacking.

Personal motivation is the necessary starting point for research invovlement. No amount of external pressure can produce a successful researcher. Where does this personal motivation spring from? The noble goal of adding to the knowledge base of the field is excellent; however, it is unlikely that many clinicians wake up in the morning and say, "Aha! I will add to the knowledge base of critical care today." In the practice setting clinicians are continually challenged by questions that arise from providing critical care for children, by questions about patient management, and by uncertainties and confusion in providing patient care. It must be very rare

indeed for a young clinician not to wonder about, be curious about, or be interested in answering these questions. It is the role of all preceptors in critical care to make certain that the trainee is aware of these questions and that they are asked. To teach critical care as if it were dogma is destructive to these goals. To constantly point out and demonstrate where there are failures and conflicts in our understanding and where matters of style, rather than matters of substance, determine our clinical practice is to uncover fertile areas for research. Unless the young intensivist senses these exciting challenges, the personal enthusiasm toward research will not be discovered.

Another motivating factor is the simple desire to know what research is. The great shibboleth of research has been held up before medical students and pediatric residents for years. Nevertheless, most young physicians have no idea what research is. They may have seen a fragment of a clinical trial, but they likely did not participate in a basic research experience. All too frequently they have little understanding of the real application of the scientific method or statistical analysis. Curiosity for what research is should be recognized, fanned, and fed. The inquisitive clinician must not be lost because of a poor understanding of research or a feeling that it is an elitist club. For this reason, our fellowship programs must provide valid scientific research experiences guided by seasoned investigators. Not until junior physicians realize that they can acquire the skills to answer the questions that arise clinically, in a rigorous and scientific fashion, can we expect them to do so.

The previously mentioned personally motivating factors, which include personal aggrandizement such as fame, fortune, job security, avoidance of burnout, fun, ability, education, and training, still are not, however, sufficient. All of these possible motivations do not provide the major essential driving force. Individual curiosity, a tireless need to question, and the restless search for answers must be the source of the entire endeavor. Curiosity? Is this the crucial concept? Sir Peter Medawar calls it a "nursery word"—a motive too inadequate.[23] Everyone possesses curiosity, and yet not everyone makes a commitment to seek solutions, occasionally at great personal cost. So it must be more than mere curiosity. Medawar calls this driving compulsion the "exploratory impulsion"; Kant called it "restless endeavor."[23] It is not merely curiosity but a surrender to the urge, often sacrificially, to seek the answer that motivates the investigator. This urge must be strong because it will require a great deal of time and energy before the question that originally piqued the clinician's curiosity can be addressed. This innate, compelling motivation of the individual is the main driving force of medical investigation.

Where the collective needs of the specialty and the individual's needs come together is that both have a genuine, deep-rooted desire to understand better how to help critically ill patients. This symbiosis of specialty needs and individual motivation forms the essential chemistry of discovery. In a fascinating address to the American Society for Clinical Investigation, J.L. Goldstein[24] presented the formula:

Clinical stimulus + Basic scientific training = Fundamental discovery

The individual, when clinically stimulated, can make a fundamental contribution only with appropriate training. The specialty can meet the needs mentioned previously by providing that training. The collective combination of financial and intellectual resources and the individual's blood, sweat, and tears is critical. Resources will be provided only if the physicians involved in critical care are committed to providing, for individual intensivists who have the curiosity and desire, the means to find answers to their individual questions. No matter how well organized, the specialty organizations can encourage individuals to labor toward solutions only for the problems that interest them. Selection of these trainees is critical. Erasmus Darwin said in 1792, "A fool is a man who never tried an experiment in his life."

Let us not train too many fools. Constantly striving to recruit the seeker, doubter, questioner—and when they are recruited, to support them—is the responsibility of all physicians involved in critical care. Without them, critical care research will be nonexistent. Significant advances in our specialty can grow only from accepting this responsibility. Without this commitment to encourage and train, critical care medicine will lose promising young clinician-scientists to other specialty areas, because it will be only there that they will be able to seek answers to their questions. This crucial issue and its centrality to the growth of our specialty cannot be overemphasized. The training also must be thorough. This takes time, but without the commitment to train young investigators to think like basic scientists, they will be unable to apply the tools of basic science and will end up paralyzed and lost to the specialty of pediatric critical care.[24]

Doing Research

"Gentlemen, do not think! Try and be patient. Have you performed the experiment?"

John Hunter

Variations in study populations, techniques of data gathering, study designs, questions asked, answers required, types of analyses, and whether the question should be addressed clinically or by a basic science approach (and, if basic science, whether by molecular, cellular, physiologic, biochemical, or biophysical experiments) can be very confusing. Then there are statistics. To understand how to address a given question, familiarity with the basic process of research is necessary. For example, the simple question, "Should I give my septic, acidotic patients sodium bicarbonate?" could be addressed in many ways (and indeed has been!). The options range from experiments to discern the subcellular effect of changes in pH on mitochondrial function to prospective, randomized, double-blind, multicenter clinical trials to determine whether bicarbonate therapy improves survival in septic shock. All of these factors have a part in answering what may first appear to be a simple question. Many factors influence how the researcher goes about answering any question, not the least of which are the researcher's background and training. The availability of resources in the researcher's institution and previous research relevant to the question being asked are also important.

So, what is research? Research is scientific investigation. If the motivation to do research can be matched by the commitment of the specialty to support research, is that sufficient? How is the bedside problem answered? If a keen investigator with a good question has a willing pediatric intensive care unit director with money, or at least one who is willing to help find resources, what next? How is research done? What is the scientific process?

Over the past 200 years, the scientific method has been developed by learning how to test our guesses about the universe.[25,26] The key factors involved are the following:

- Observation
- Intuition
- Formulation of hypotheses
- Experimentation
- Development of scientific laws, theories, or axioms
- Testing these new theories

Sir Francis Bacon provided one of the first common-sense answers to the question, "How is research done?" The answer was "by observation and experimentation." Which observations and data should be collected may seem fairly obvious at first, but deciding what should be observed and recorded are the crucial research questions. Approaches that may be useful in determining whether bicarbonate helps a critically ill child include observing and recording every physiologic parameter and every biochemical response, as well as measuring every enzyme's activity and looking at urinary metabolic products. It is evident that these are not necessarily the best, most direct ways to answer the underlying question. Merely compiling a mountain of data without scientific reasons behind each observation (fishing) is risky, time-consuming, inefficient, and often futile. One of the main tasks of the investigator is to decide which observations in the whole set of possible observations are crucial. Lack of critical thinking may result in missing important observations and fruitless experimentation. Similarly, determination of what type of experiment should be performed is crucial.

What is an experiment? The original meaning of the term experiment was "a test made to demonstrate a known truth." It served as a means of proof for an already "known" truth. This sort of experiment was not designed to generate new knowledge. This Aristotelian concept of experimentation, involving classical deductive logic, has limited application in modern medicine, other than perhaps that of pedantry and teaching high school chemistry. The essential concept of experimentation that has a more contemporary meaning entails an uncertain or unknown outcome. To the present-day researcher, the purpose of performing an experiment is to discriminate between possibilities. How experiments are designed to discriminate between possibilities depends on the underlying assumptions. Understanding the logic that underlies how an experiment is performed is useful in avoiding multiple traps, not only in reviewing the data but also in applying experimental results to real patients. Bacon[27] noted: "If a man begins with certainties, he shall end in doubts, but if he will be content to begin with doubts, he shall end in certainties." Many experiments are still designed—contrived may be a better word—to demonstrate the validity of preconceived ideas (sometimes called an 'hypothesis'). This reasoning from preconceived ideas or premises to the specific situation is known as the process of deductive logic. Deductive logic is reasoning from the general to the specific. A clinical example of such deductive logic is the following syllogism:

Major premise: Penicillin is an effective treatment for pneumococcal pneumonia.
Minor premise: My patient has pneumococcal pneumonia.
Inference: I will treat my patient with penicillin.

The experiment performed in this case, treating a patient with penicillin, will have a certain outcome only inasmuch as the deductive logic is correct and the underlying primary assumption (major premise) and diagnostic result (minor premise) are true. In a general way, all specific conclusions that rest on authoritative statements of truth are deductive in origin. By their very nature, although they guide our clinical activity, they do not expand our medical knowledge. The hallmark of deductive logic is complete reliance on the certainty of known or revealed facts. Some 300 years after the modern scientific revolution and the birth of true scientific method, modern experimental medicine remains beset with this type of logic. Aristotelian experimentation is the process of clinical practice. We reason from general principles and accepted facts to specific interventions and treatments. The entire evidence-based practice movement is based on deducing therapy from sound premises.

The difficulty comes when the dogmatic assumptions that underlie our clinical practice, and deductively lead to our therapies, are incorrect. Aristotelian experimentation provides no way to approach outcomes in medicine that are exceptional, yet these are the very occurrences that may be enlightening. Charles Darwin has exhorted us never to allow these exceptions to go unnoticed.[28] Deductive logic is unable to assist in the discovery of new knowledge and therefore general principles. This was clearly noted by Bacon,[29] who stated in 1620:

"The syllogism consists of propositions, propositions consist of words, words are symbols of notions. Therefore if the notions themselves (which is the root of the matter) are confused and overhastily abstracted from the facts, there can be no firmness in the superstructure. Our only hope therefore lies in a true induction."

The great revolution in scientific and philosophic writing in the 1600s was typified by Bacon's absolute refutation of the concept that any new truths could be discovered merely by a deductive act of the mind[4]:

"The discoveries which have hitherto been made in the sciences are such as lie close to vulgar notions, scarcely beneath the surface. In order to penetrate into the inner and further recesses of nature, it is necessary that both notions and axioms be derived from things by a more sure and guarded way; and that a method of intellectual operation be introduced altogether better and more certain."

The Baconian revolution in scientific thought was dependent on observation and experimentation. The underlying premise was that the general could be determined, inferred, and understood from observing the specific. This led to the realization that by the use of thoughtful inductive logic, linked to observation and understanding, specific discovery of new generalized truths was possible.

A clinical example of this sort of contribution to modern medicine is the well-known example of vaccination. Jenner's recurrent observation of the specific immunity to smallpox of patients who had been infected by cowpox led to experimentation with observation and a series of inductive steps that ultimately led not only to the eradication of smallpox in the world but also to generalization of the concept of vaccination to other infectious processes and vast discoveries in the area of immunology. It is impossible to conceive how Aristotelian deductive logic could have led to these discoveries. Bacon's contribution was to realize that observations of the specifics in nature would lead, through application of the intellect,

through inductive logic, to the discovery of new truths. Bacon did realize that we were unable to rely on "the casual felicity of particular events"[23] to provide us with all the specific information required to discover scientific truths, even if we spent an entire lifetime observing nature. He thus realized the necessity to devise experiences and contrive occurrences to collect factual information by which we would understand the natural world. This is Baconian experimentation. However, this still was not experimentation as practiced in medicine today.

Current medical experimentation is more accurately described as Galilean experimentation.[23,28] The Galilean experiment discriminates between possibilities and, in so doing, confirms a preconceived notion by supplying facts that support the inductive process and lead to a sound conclusion. The essence of an experiment as proposed by Galileo was a true test, a trial, or an ordeal of an hypothesis. This constructive experimentation more accurately reflects what we think of today when we want to further our understanding of critical illness. As Stephen Hawking[26] put it in *A Brief History of Time*:

"Our present ideas about the motion of bodies date back to Galileo and Newton. Before them people believed Aristotle, who said that the natural state of a body was to be at rest and that it moved only if driven by a force or impulse. It followed that a heavy body should fall faster than a light one, because it would have a greater pull toward earth."

The Aristotelian tradition also held that you could work out all the laws governing the universe by pure thought: it was not necessary to check by observation. As incredible as it may seem, no one, until Galileo, bothered to see whether bodies of different weight did, in fact, fall at different speeds. Mythology reports that Galileo demonstrated that Aristotle's belief was false by dropping weights from the leaning tower of Pisa. The story almost certainly is untrue, but Galileo did do something equivalent: he rolled balls of different weights down a smooth slope. The situation is similar to that of heavy bodies falling vertically, but it is easier to observe because the speeds are smaller. Galileo's measurements indicated that each body increased its speed at the same rate, no matter what its weight. A scientific revolution ensued.

In Galileo's experiment, the hypothesis tested was that objects of different mass fall at different velocities. The "control" group could have been a group of spheres with mass = X. The experimental group (or groups) would have been X × 1 kg (or X × 1 kg, X × 2 kg, and so forth). Because the null hypothesis: that all objects (regardless of mass) fall at the same velocity could be falsified or disproven, the hypothesis could be tested. His data failed to support the hypothesis (supported the null hypothesis, failed to reject the null hypothesis), and the hypothesis was irrevocably disproved and destroyed, instantly. The old system was dead. The deductively logical syllogism of Aristotle's day was as follows:

Major: The velocity of a falling object is determined by the object's mass.
Minor: These two objects are of different mass.
Inference: They will fall at different rates.

This syllogism was disproved by a single observation. Therefore the conclusion was incorrect and therefore if the minor premise was true, the major premise had to be false. A new intellectual universe became possible. Every preconceived notion was testable by experiment. All that is required is a testable hypothesis. The routine function of medical experimentation, the purpose of all medical science and the major modus vivendi of all the national institutes, is the testing of hypotheses. Although gathering facts and cataloging their relationships as in Aristotelian and Baconian experimentation remains of some value, testing hypotheses is our strongest research tool. Galilean experimentation provided the capability of constantly revising our hypotheses and avoiding unnecessary persistence in theoretical structures based on hypothetical errors that lead to no more than a house of cards.The generation of scientific hypotheses that can be critically tested is the basis of scientific discovery. Discovery has its beginnings in imaginative preconception, which is the creative act of mind that gives rise to a hypothesis.[28] Asking the question or conceiving the question is only the beginning of the scientific process. Casting the question in the form of testable, verifiable, scientific hypotheses is where the creative work of research really begins. The brilliant guess, the eureka moment—these scientific insights are the sources of these hypotheses. The hypothesis is a mark to be attained, a suggestion of the probable, a provisional proposal of an underlying truth, or some specific facet of it. The hypothesis has but one purpose, to be tested. But this approach means that an hypothesis, no matter how interesting, can never be proven. Absolute proof of a hypothesis is not, by the very nature of inductive logic and Galilean experimentation, ever possible because all possibilities cannot possibly ever be tested. Again, according to Stephen Hawking[26]:

"Any physical theory is always provisional, in the sense that it is only a hypothesis: you can never prove it. No matter how many times the results of experiments agree with some theory, you can never be sure that the next time the result will not contradict the theory. On the other hand, you can disprove a theory by finding even a single observation that disagrees with the predictions of the theory. As philosopher of science Karl Popper has emphasized, a good theory is characterized by the fact that it makes a number of predictions that could in principle be disproved or falsified by observation. Each time new experiments are observed to agree with the predictions the theory survives, and our confidence in it is increased; but if ever a new observation is found to disagree, we have to abandon or modify the theory."

Whereas a theory is an organized system of knowledge used to analyze or explain nature or behavior, a hypothesis has no such value. Theories may be built up from facts learned by testing hypotheses and may even contain partially substantiated hypotheses that are useful in predicting events, but hypotheses are useful only insofar as their testing acts as a focus for the discovery of truths. Without a doubt, hypotheses are the most important instruments in research. Developing a hypothesis is the initial phase of research and scientific investigation. It generates the plan for the research. Nevertheless, it is "a means, not an end," as Thomas Huxley cautioned.[28] The ultimate goal of research is not to hunt blindly for unrelated facts but to test related hypotheses.

If we accept the fact that the purpose of experimentation is to test hypotheses, then it is clear that a necessity for research is to formulate appropriate hypotheses. The hypothesis must be focused, with a limited number of possible outcomes and limited number of implications that lead logically to further investigational steps. This minimizes futile activity.

A hypothesis that accommodates all possible phenomena or outcomes is totally uninformative. The more restrictive it is, the more focused it is, the more instructive it is. One final warning about hypotheses: although they are the driving force of research, they must be kept in their place. Accepting unproved hypotheses can clearly lead you down a rabbit hole, often a time-consuming, expensive, and disastrous one. Failure to give up unsubstantiated or disproven hypotheses can lead (and has led) to a futile cycle of experimentation. Although scientists require hypotheses, find them attractive, and may not be able to live without them, they must not fall in love with them.[23,28] The basic fact of science, that hypotheses are never proven and that they are only as good as the results they generate, must never be forgotten. Likewise, the physician-scientist as observer of nature must be encouraged to use quantitative and qualitative descriptive tools to develop the platform for meaningful hypothesis generation and testing.

The Null Hypothesis

Galileo's revolutionary experiment proved nothing! Rather, it disproved the accepted dogma by a single observation. When deductive logic is correctly performed and the major and minor premises are correct, the inference is absolutely, positively true. This is not true in the other direction. Reasoning from the inferences is unreliable. The arrival of two objects at the ground at different times does not assure us that the objects are of different mass or that objects of different mass fall at different rates. In the penicillin case, the fact that our patient improved with penicillin proves neither that he had pneumococcal infection nor that penicillin is effective against pneumococcus. He could have just had erysipelas. Then again, if the objects of different mass arrive simultaneously—that is, the inference is wrong—then something also is very wrong with one or both of the premises. If penicillin does not reliably, reproducibly treat pneumococcal pneumonia, then something is wrong with the diagnosis or with the efficacy of penicillin against pneumococcus. Yes, an astute clinician sees all sorts of problems in this statement, but the problems only emphasize the importance of rigid control of nuisance variables (discussed later). Nevertheless, the fact that inference is asymmetrical demonstrates that falsification—the disproving of a hypothesis—is logically a stronger, surer process than the so-called (and impossible) proving of a hypothesis. As Hawking explained, absolute proof is not possible. Instead, to support scientific hypothesis we generally attempt to disprove the opposite hypothesis, that is, we try to "refute the null hypothesis." For example, Galileo said: "All objects, irrespective of mass, fall at the same velocity." The null hypothesis would be that objects of different mass fall at different velocities or, as previously asserted, mass determines velocity. Galileo absolutely refuted this null hypothesis; thus his data were consistent with his own hypothesis. Even so, they did not prove it; he merely disproved the null hypothesis.

As a clinical example, if the hypothesis is "steroids improve morbidity in shock," then the null hypothesis is that they do not. To refute this null hypothesis, the investigator has to demonstrate a difference between steroid-treated and nontreated patients in an adequately randomized and powered trial. If so, the null hypothesis is rejected and the hypothesis survives this test—this time. Statistics are applied to determine the certainty of the rejection of the null hypothesis and actually are performed to demonstrate that the null hypothesis has been rejected with a degree of certainty. For example, if $P = .05$, then it is 95% certain that the null hypothesis is incorrect and that the results are consistent with the scientific hypothesis.

It is this asymmetry of inference that allows us to disprove major premises by demonstrating the untenability of the inference. This is how we support scientific hypotheses. This refutation of the null hypothesis is generally taken to affirm that the very opposite is true. This is done because falsification of the inference and/or minor premises proving the falseness of the major premise is such a potent tool. Proving the major premise true is, in fact, impossible. Thus the basic tool used to demonstrate that a hypothesis is true is that of proving that the null hypothesis is false. The scientist's experimental goal is to reject the null hypothesis rather than to prove the actual scientific hypothesis. Because refuting the null hypothesis is such a potent tool, good scientific hypotheses must be of such a nature that their null hypothesis (or, indeed, many of their null hypotheses, because several may stem from one hypothesis) can be tested. This test is virtually always a statistical one.

Medical Research

"It is incident to physicians, I am afraid, to mistake subsequence for consequence."

Samuel Johnson

The first great divide in medical research is between clinical and laboratory research. Many consider such a division arbitrary, and the bench to bedside to bench translational models that have enabled modern physician-scientists to bring breakthrough understanding to the care of critical illness mandate that effective pediatric critical care researchers have "feet" in both domains. Still, in this classical distinction, clinical research is carried out in patients. It is an extension of previous experience in patients or of results obtained from laboratory research. Clinical research can occur in any medical arena. Laboratory research clearly does not involve patients; rather, it relies on the results in animals or tissue-derived "subjects."

Clinical research can be either retrospective or prospective. Retrospectively, epidemiologic studies, demographic studies, and studies of disease processes and outcomes of management regimens can provide useful information in directing future therapy. Certainly the great wealth of data now available in patient records can continue to provide worthwhile insights to aid our patients. Unfortunately, retrospective trials cannot convincingly answer therapeutic questions; rather, their utility is in hypothesis generation. Their solution requires true Galilean experimentation. Baconian studies such as these prospective trials require as much planning as possible before the patient actually is observed for the results of a therapeutic intervention, but this has started to change. Learning from reliable observations is the basis of physical science, and applying these research principles to data obtained from human subjects is useful in reliably suggesting a general theory if large enough numbers of observations are collected and analyzed. In medical informatics, this is the basis for knowledge discovery in databases. Thus with a sufficient number of observations (controlled, defined, verified data) we may learn how to manage our patients by applying analytical techniques to retrospective events. The information revolution may be driving knowledge discovery once again toward some reliance on deductive logic.[18]

The principles that guide all medical research, including clinical trials, are in place to minimize the possibility of an incorrect conclusion. A major cause of error is bias, either by the observer or the subject. A further cause of incorrect conclusions results from inadequate study design that may prevent accurate statistical analysis of the information obtained.

The other overwhelming principle that guides clinical research is to preserve the rights, autonomy, and safety of the individual subject.[30-32] This is of particular importance in clinical research involving children. The issues of risk, informed consent, and the potential to benefit the patient are particularly finely focused in pediatrics. The spectrum of opinion runs from believing that research in children is not allowable to believing that child subjects should be treated exactly the same as adult experimental subjects. Any researcher who proposes doing clinical research in critically ill children must be familiar with all aspects of these arguments and realize the sensitivity of the issues involved in this area.[33,35]

Research Design

In the simplest of all experiments, two observable populations, the experimental and the control, are observed for discrete occurrences. The results of the experiment are that the two observable sets of data from these populations are or are not different. Performance of a critical Galilean experiment that is clearly designed and meticulously executed will unambiguously answer this question. Any experiment that does not contain a control is not truly Galilean. The control group contains subjects as identical as possible to the experimental group. The observations made are the same before and after the introduction of the independent variable.

Designing an experiment involves attention to three separate areas: independent variables, subject selection, and dependent variables. Essentially, an experiment involves controlling or altering independent variables while observing in the subject changes in dependent variables. In short, the scientific method can be reduced to "if I do A, then what happens to B?" An example in early pediatric experimentation is provided by the first demonstration of adrenaline. Sir Henry Dale injected ground-up cow adrenal gland (independent variable) into his small son (subject) and determined the effect on his son's blood pressure (dependent variable). The closer study designs are to this simple algorithm, the more likely they will yield clearly understandable, unambiguous, and true results. Unfortunately, this is rarely possible except in highly controlled settings.

The independent variable is that which is under the control of the experimenter. The dependent variable is that which reflects the effects associated with altering the independent variable.

Independent Variable

The selection of the independent variable in any experimental design is crucial. Not only can this be a treatment variable but also the level at which treatment is delivered (dose). The independent variable must be one that can be manipulated and rigidly controlled. For example, to determine the effect of light on bilirubin in jaundiced babies, the independent variable is light. This variable can be fluorescent, incandescent, or solar. The duration of exposure and the efficacy of various light wavelengths could be—and indeed have been—experimentally determined by changing the independent variable and measuring the effect on the dependent variable (bilirubin concentration). In most therapeutic trials, the independent variables are either treatment or no treatment. For example, you test the therapeutic efficacy of a drug or the comparison of two or more treatment interventions for a disease, such as acyclovir versus cyclosporine for treatment of herpes encephalitis. A recurrent trial design relevant to critical care is provided by multiple studies on the use of one of many steroids in septic shock. These include steroid versus no steroids as the independent variable or, alternatively, multiple dosing levels of steroids.

The definition of the independent variable must be as precise as possible. Independent variables can be qualitative or quantitative. From the phototherapy example, a qualitative independent variable applies to the type of radiation. The radiation could be solar or incandescent light, and there will be a difference in the response of the dependent variable. There are many different kinds of treatment. Quantitative differences in the independent variable, by contrast, result from the same treatment given at different levels. The simplest of these is comparison of zero (no therapy) to a known dose of therapy, for example, 0 mg of steroids versus 30 mg/kg steroids. In addition, multiple doses can be given for a comparison of dose ranges. The exact selection of the independent variable and the quantitative nature of it ideally should be dictated by the specific hypothesis being tested.

Dependent Variable

Both practical and theoretical considerations are necessary in determining which dependent variables to observe. Clearly, the dependent variables will be determined by the expected outcome, as indicated by the hypotheses. In large-scale clinical trials, the dependent variable can be as simple as mortality or as complex as altered hemodynamic function described by a broad spectrum of hemodynamic parameters. The potential for dependent variables is enormous; however, some rules guide selection.

Most statistical analyses limit themselves to assessment of one dependent variable at a time. Selection of the dependent variable is determined by its distribution within the population, how reliably it can be measured, how sensitive and specific it will be to the independent variable, and how practical it is to measure. Clearly, maximum sensitivity and reliability are preferable. The more sensitive and reliable the selected dependent variables, the more likely the time and effort invested, number of subjects required, and cost of investigating the hypothesis will be minimized. Variables may be either quantitative or categorical—nonnumeric and discontinuous. With regard to distribution, it is generally assumed that dependent quantitative variables in the study population will undergo a normal (gaussian, bell-shaped curve) distribution. When abnormal distribution occurs, it must be specifically addressed statistically. It also is possible, in some instances, to transform an abnormal distribution to a normal distribution for the purposes of analysis. Disease states are often not normally distributed and parameters may be skewed (asymmetric) or demonstrate kurtosis (distribution of values near the mean) both of which alter how the population variance relates to the mean and therefore the validity of statistical

inferences. Unfortunately, a single dependent variable rarely approximates the clinical situation, where a single independent variable intervention may have a series of effects on a host of dependent variables. Therefore it is frequently necessary to evaluate two or more dependent variables at any given time. This process requires advanced study design and analysis that takes requirement into account; for example, multivariant analysis may be required.

Nuisance Variables

Anyone who has ever attempted any form of scientific experimentation is familiar with nuisance variables. Nuisance variables are best defined as undesired causes of variation in the observed or dependent variable. These variables are of no interest to the investigator but may significantly alter the outcome of the experiment. For example, nuisance variables may include factors such as patient age, gender, disease process, previous therapy, socioeconomic background, nutritional status, and presence or absence of infectious disease processes. The list is long, even infinitely so, and this is a problem for scientists. Unless these nuisance variables are controlled, outcome is uncertain. For example, an epidemiologic experiment to determine whether fatality is more common in lower socioeconomic groups following road traffic accidents could miss the effects of underlying nutritional status, distance from the hospital, and previous disease process and thus arrive at an erroneous conclusion.

One way to control nuisance variables is to ensure that they are both constant and equivalent for all subjects for the entire duration of the experiment. For example, male sheep exactly 6 months old, weighing 30 pounds, and of a specific breed and diet would provide better control for nuisance variables than a population of sheep of any age, weight, gender, size, or breed. In clinical trials it is generally impossible to obtain ideally matched controls. It must be assumed that some nuisance variables will always escape control.

The second broad approach to controlling nuisance variables is to assign subjects to experimental groups *randomly*. The principle of randomization rests on the supposition that the study population contains normally distributed nuisance variables and that these nuisance variables will be equally and normally distributed in the experimental subgroups (discussed later). This assumption can be true only if the experimental groups are of sufficient size to assure normal distribution. This is one of the major factors determining sample size. Randomization is the most powerful and most commonly used tool for controlling nuisance variables.

A third method for eliminating the effect of nuisance variables is merely to include them in the experimental design and thus study their effect on dependent variables. A final, nonexperimental method of controlling nuisance variables is statistical control. Analysis of covariance is a method of statistical control that removes the effects of nuisance variables through the use of multiple regression analysis. This is a complex statistical manipulation that should be prospectively designed into any trial when eliminating anticipated (or even reveal unanticipated) effects of nuisance variables is necessary.

Both independent and nuisance variables can be caused by the subject's innate characteristics, such as gender, weight, age, and previous illness, or by external environmental influences. These environmental influences may include temperature, humidity, presence or absence of other caregivers, a variety of pharmacologic interventions, socioeconomic group, diet, and various other factors. Task-related variables also may affect the dependent variable. These factors may be inadvertently introduced into the experiment study design, and they must be rigorously sought and avoided. For example, the experimental design or the particular sequence of observations made may alter the dependent variable in such a fashion as to confound the effects of the independent variable.

Design Efficacy

The problem facing the investigator who wishes to address a medically related question is to design a study (or a series of experiments) that can answer the question as validly and efficiently as possible while taking into consideration the research situation available to the investigator. Efficiency of research design can be accounted for in several ways. Cost can be one of these determinants, and the cost per observation or the cost per experiment can be compared to the amount of information obtained. Alternatively, time can determine efficiency: the maximum useful data in the shortest period of time. In fact, careful stewardship of resources for biomedical research is an underappreciated principle. Every emerging researcher in pediatric critical care must commit herself/himself to incorporating such stewardship as an underlying value. These factors are inherently determined by the amount of variance in the dependent variable that can be attributed to extraneous or nuisance variables.

This situation gives rise to the concept of experimental error variance. A major source of this error is the variability inherent to subjects. A further cause is the lack of precise uniformity in experimental conduct. When comparing two groups it is important to ensure that observations are made at the point where differences between the groups are the greatest. It is possible that the effects of two drugs are equal at higher doses, but significant differences could exist at a lower dose range. Observations at the former point would yield negative results but at the latter point reveal a beneficial effect with less drug. Clearly, information about efficacy (dose response) is necessary before a comparison trial. Federer[27] formulated a method for evaluating the efficiency of experimental design that takes into account the number of subjects at each treatment level, the cost of collecting data per subject, the degrees of freedom, and an estimate of error variance per observation. These are factors the investigator must consider when designing any experiment.

The basic technique of experimental design is that of replication of observations in two or more subjects under identical experimental conditions. The number of replications or the sample size depends on the following five factors[36]:

1. Number of treatment levels
2. Minimum treatment effects to be detected
3. Error variance of the study population
4. Necessary power (probability of rejecting the null hypothesis)
5. Probability of making a type I error

There are two common ways of increasing the power of an experimental design. The first method is to design experiments that provide precise estimates of the desired treatment effects while minimizing error effects. The second method is to increase sample size.

Randomization

All statistical theory is based on the supposition that at some stage during the experiment, a process of random selection is performed. Conclusions based on these statistical studies are valid only inasmuch as the randomization process is understood and observed. A random procedure has at least two possible outcomes, and the probabilities of all possible outcomes are specified prior to the randomization procedure.[37] It is important to note the frequent errors practiced in the name of randomization. First among these is the naive belief that the number of subjects in an experiment is related to randomness. Although the principle of safety in numbers may be reassuring, it is unwarranted. Experiments usually are performed in only a small sample of a normally distributed population. If this sample is truly representative, then the size of the population sample does not matter. By contrast, if the sample of the population is not representative (e.g., it is drawn from patients at one end of the normal distribution), then no matter how large the sample, randomness will not be possible. For example, to determine the case fatality ratio in children with meningitis, it would be just as useless to study 10,000 as 10 autopsies.

It is important to note the difference between a random sample and a haphazard sample. A haphazard sample indicates the investigator has no idea of whether the sample is representative of the whole population and hence the value of the data. The more a given sample can be constructed wherein as many biases as possible are appreciated, the more likely the results will be truly randomized and known as opposed to haphazard. It is crucial to know that the investigator's ignorance of the characteristics of the sample population is not the same as randomization. Similarly, ignorance of associations within a sample population does not make the sample random and provides another serious source for potential bias. Simple inability to show any clear biases in selection does not assure randomization. Another error made in randomization is to confuse the source of bias by mixing populations of unknown bias. Finally, the absence of a clear plan for randomization does not ensure randomization; rather, haphazard sampling leads to haphazard results.

So how do we ensure that randomization takes place? Obviously, with an adequate sample of the best-designed and most homogenous population, randomization can be optimized. In any experiment requiring randomization, the study population must be as explicitly defined as possible before randomization occurs. This is relatively simple if all subjects are prospectively chosen (e.g., 10 patients with sickle cell disease). It is less clear when the subjects can be drawn from a large population (e.g., the next 10 children with ARDS). Second, the system for selection must be prospectively described. Steps should be taken to ensure equal numbers of, for example, boys and girls, age distribution, race, and operative procedure. Once the subjects have been defined and selected, a means of randomizing them, with a representation in the randomization procedure for each subject, must be made (e.g., even or odd numbers, a randomization table, or something as simple as drawing names out of a hat).[37] This process is only as useful as the prerandomization population is homogeneous. Of course, with human experimentation, subjects frequently differ. It also is necessary to describe the action to be taken following randomization; for example, all odd numbers get no therapy, and all even numbers get steroids or prostacyclin. Finally, the subjects are randomized, and nothing is allowed to alter the outcome. A large host of confounding factors in randomization will occur. Other randomizations, such as randomized block design and Latin square design, are potential approaches for solving these problems.[36]

Validity

Evaluating an experimental design requires taking into account those factors that ensure the validity of the results. First of all, the overall field of research must be known so that experimental observations can be made that provide the opportunity for comparison of findings with other investigators. In addition, accepted practices and procedures in the research area should be followed wherever possible. Next, it is necessary to decide if the data collection method produces reliable results and that the data obtained are accurate. It is also necessary that the design of the experiment permits the experimenter to determine which effects are caused by experimental error and which results are caused by manipulation of the independent variable. In addition, some attention is necessary to optimizing the efficiency of the experiment and understanding the experimental constraints. Finally, to justify doing any experiments at all, the design should be of sufficient power to be certain that an adequate test of the statistical hypothesis will result.[36]

It is essential to ensure that valid conclusions concerning the effects of the independent variable on the dependent variable can be drawn from the experiment.[38] In general, this is satisfied by statistical analysis. In addition, in the medical setting, generalizations of these results to populations and settings of medical interest are necessary. This requires probability theory.[37] It is important to realize that statistical theory and probability theory are not the same. The purpose of ensuring the validity of the statistical conclusion is to ensure that incorrect data resulting from errors in randomization and inappropriate statistical analyses are not made.[36] There are several threats to the validity of inference from the data.[38] Clearly, the statistical analysis must be correct, but in addition it is necessary to assess the internal validity of the experiment. "Internal validity" deals with the assumption that the relationship between observed variations in the dependent variable is resulting from variations in the independent variable. "Construct validity" of causes or effects deals with the potential that alterations in the independent variable and observations in the dependent variable result from and are construed in terms of other variables. Finally, "external validity" of the results indicates the extent to which the results of a particular experiment can be generalized to populations and subjects. This concerns comparison with existing results and the probability of extending the results of a given experiment to a wider population and ultimately to treatment decisions.[37]

Statistics: A Word

This section is not intended to be a primer on statistics or to serve as a catalog of how to do a *t* test or analysis of variance. Numerous textbooks and computer programs exist for those purposes. Rather, this section emphasizes the common—and most frequently violated—principles that

underlie the statistical analysis of experimental data. They are the source of rejection of articles and of grant applications and a great deal of wasted effort—not to mention the potential for misguided therapy. Every study, every paper, every grant, and ultimately the validity of every therapy rests on these principles. Statistical analysis of the data yields the likelihood of certainty from the experiment at hand.[36] Probability theory deals with the predictive statements based on the outcomes of an experiment.[37] In medicine, both diagnosis and prognosis rely heavily on probability theory. When analyzing experimental data, we generally think in statistical terms. Although statistical analysis of data frequently is used to apply results to the clinical situation, it really is valid only for testing hypotheses and estimating outcomes. Statistical approaches are concerned with the concept of a scientific hypothesis, not with medical treatment. Scientific experimentation is based on testing formulated hypotheses. Therefore a scientific hypothesis must be testable and requires, by its mere formulation, verification. Hypotheses should be reasonable, informed, and intelligent guesses about the phenomena observed in nature. They should be stated as far as possible in the "if A occurs, then B occurs" format. They should be testable. The common technique for assessing the plausibility of a scientific hypothesis is by constructing the hypothesis that manipulation of the independent variable (a treatment) has no effect. This is the so-called *null hypothesis* (as discussed previously). The objective of the experimental scientist is to demonstrate that the null hypothesis is untenable and therefore the hypothesis is supported by default (i.e., variation of the independent variable has some effect on the dependent variable).

For this purpose, the scientific hypothesis must be formulated as a statistical hypothesis by deductive inference, which then can be tested by random sampling and estimation from a population and subjected to a specific statistical test (Fig. 4-1). The statistical test will determine whether the null hypothesis is tenable or untenable, and this result, by inductive inference, will be applied to the scientific hypothesis under question. This sequence of demonstrating a scientific hypothesis is the basis of experimental medicine. One should not, however, infer that each scientific hypothesis has a specific and pertinent null hypothesis. Multiple null hypotheses may be compatible with the scientific hypothesis tested, and several may need to be tested to give a broad basis of acceptance to the scientific hypothesis. For example, if the scientific theory is "Mortality can be decreased by steroid use in septic shock," a potentially testable statistical hypothesis might be: "Steroids do not alter pH within 24 hours in patients in septic shock." Although the theory would be statistically difficult to demonstrate (and indeed has been) in a patient population by prospective controlled experiment with all other independent variables held constant, this particular null hypothesis could be tested. There are obviously assumptions between the relationship of pH and outcome. A more useful null hypothesis is that survival at 72 hours is not improved by steroids. This is a testable hypothesis, and with the appropriate study design and statistics it can be tested. Obviously, many other statistical hypotheses bearing on the scientific hypothesis can be designed. It is up to the investigator (and the evaluator of the investigation) to understand the relationship between the statistical hypothesis being presented and the scientific hypothesis being tested.

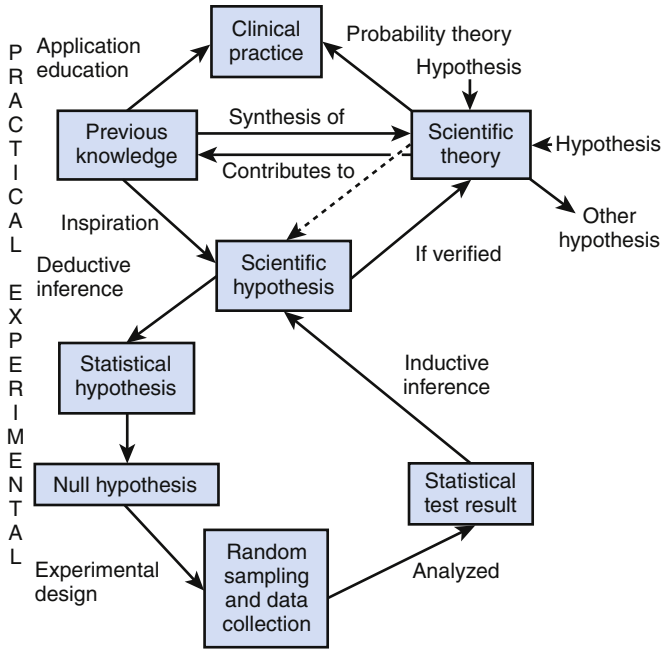

Figure 4–1. General schema of the relationship between clinical practice and medical research. Note the central position of the scientific hypothesis and the steps necessary for verifying it. Also note that the statistical analysis of experimental data does not apply to the application of medical scientific theory (built up of multiple hypotheses) to clinical practice.

Type I and Type II Errors

The aim of testing the null hypothesis is to either accept or reject it and thus to refute or support the hypothesis. This decision will be either correct or incorrect. An incorrect decision that leads to invalid conclusions can be made in two different ways. The first is rejection of a null hypothesis that is, in fact, true. This is a type I error. Second, a false null hypothesis may not be rejected when in fact it ought to be rejected. This is a type II error. The difference between these two arises, in part, from the asymmetry of proof described previously. Support for a null hypothesis does not necessarily disprove the hypothesis. There are also two choices of how a correct decision can be made. If there is a true null hypothesis and the experimenter does not reject it, this is correct acceptance of the null hypothesis. If there is a false null hypothesis that is rejected, then a correct rejection has also been made. These choices are summarized in Figure 4-2.

In general, the likelihood of making a type I error is determined when the level of significance is specified. The probability of making a type I error is .05, when α equals .05. This is the probability of rejecting a true null hypothesis. The determination of α also determines the likelihood of the correct acceptance of a true null hypothesis $(1 - \alpha)$.

The probability of making a type II error is symbolized by β. Thus the probability of correctly rejecting a false null hypothesis equals $1 - \beta$. Alternative terms for these errors are α errors (type I) and β errors (type II) for obvious reasons. β is determined by a number of factors, including sample size, standard deviation of the population in general, difference between the mean of the sample and the mean of the overall population, whether a one- or a two-tailed test is used, and level of significance selected. The power of a statistical test is defined as the probability of making a correct rejection $(1 - \beta)$. Because the

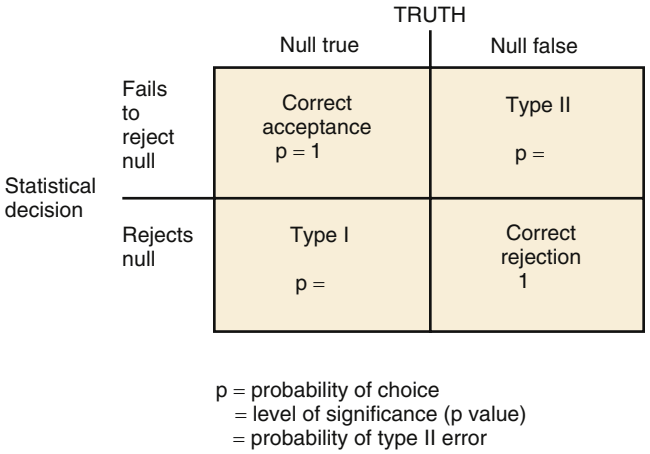

Figure 4–2. Difference between type I and type II errors in statistical analysis. Null refers to the null hypothesis derived from the scientific hypotheses. Note that the likelihood of a type I error, rejection of a true null hypothesis and therefore acceptance of the statistical/scientific hypothesis, is generally equal to the p value of the analysis. Thus when $P = .01$, there is only a 1% chance of a type I error. A type II error is more subtle and requires determination of β (see text) to understand the likelihood of falsely rejecting a true hypothesis.

mean of the overall population from which the study population is selected is generally unknown, an estimate of it must be made or a value selected that would be of interest. Statistical techniques are available that determine the sample size and population characteristics necessary for the experimental circumstances.[36]

The investigator must determine whether a type I or type II error is more costly. As an example, with regard to steroids and shock research, experiments are generally designed to test the null hypothesis that steroids are not effective as a therapy for shock. A type I error (rejection of the null hypothesis, when it is in fact true) could result in confirming the effectiveness of steroids and lead to their use. The consequences of this decision would be steroid therapy for septic shock. As long as this did not supplant another useful therapy or carry with it complications of its own, the consequences of this error would not be so severe. In contrast, falsely deciding that steroids were not effective, a type II error, would prevent the use of steroids in septic shock. However, further research might be stimulated that ultimately leads to an effective steroid regimen or alternate therapy. In this case, the long-term consequences of a type II error would be less than those of a type I error. A detailed understanding of the importance of accepting or rejecting the null hypothesis for each scientific hypothesis determines at what level type I and type II errors are acceptable. This is necessary information before designing an experiment. In general, making a type I error is more serious than making a type II error. For this reason, α frequently is set at .05 or .01. If a type I error could be very serious, then $P = .001$ may be necessary. Unfortunately, as α decreases, β tends to increase.

There are multiple threats to the statistical validity of experimental design. Some of the threats that increase the likelihood of type II errors are:

- Unreliability in measurement of the dependent variable that inflates the error variance
- Unreliable treatment, administration, and implementation
- Heterogeneity in the sample population because of idiosyncratic characteristics of subjects that inflates the estimate of error variance
- Presence of nuisance variables

To avoid making invalid conclusions or inferences from the data, one must realize that there are certain assumptions in statistical testing. For example, whenever multiple comparisons are made, there is the possibility of an error rate problem. That is, the likelihood of making an erroneous conclusion increases as the number of comparisons on the same set of data increases. To avoid these major errors in statistical design, multiple comparison tests and the definition of which tests are essential will determine which statistical tests are valid.

This introduction to statistical theory forms the essential basis of all experimental statistical testing. Although simple statistics and analysis of variance are by far the most commonly used statistical tests in medicine, the frequency with which they are inappropriately applied is staggering.[39] Study design must be simplified, and the statistical analysis that is to be used should be determined before the experiments are performed. Haphazardly searching for a statistical test to make the data significant is an all too common error that can be seriously misleading. Thus *a priori* decisions are necessary to ensure the validity of the inferences made from statistical tests. This point cannot be too strongly emphasized. It is the reason the experimental scientist must be familiar with statistics. Employing a mathematical statistician who does not understand the experimental and medical implications of the study to give some magical statistical analysis is inappropriate, especially if attempted *post hoc*. The more the statistician understands the medical setting of the experiment and the more the experimenter understands statistical theory, the more likely the results will be applicable to the children initially intended to benefit from the research.[40,41]

Neoempiricism, Data Mining, and Knowledge Discovery in Databases

The modern knowledge base of medicine has been vastly enhanced by inductive research (see above). The medical literature and the National Institutes of Health (NIH) depend on the hypothesis-driven research. The gold standard for medical therapy rests on hypothesis-driven, double-blind, randomized, rigidly controlled clinical trials analyzing specific data determined *a priori* by statistical means also determined *a priori*. In contrast, physicians practice empirically or perhaps rather, anecdotally, attempting to remember their experience and education, and hoping to apply it intuitively to the next patient. The persistence of anecdotal medical practice demonstrates our human comfort with this approach. The respected senior clinician who approaches a difficult patient with the words: "I once saw a patient like this…" is not lauded for his grasp of the literature but rather his clinical expertise built on experience and reason. This is empirical medical practice, almost the antithesis of evidence-based medicine. Or is it? The evidence of what the clinician remembers, what she has seen, experienced, the results of all of these natural experiments with thousands of patients and what the experienced clinician 'knows' to guide the next patient's therapy is based on personally gleaned evidence. Unfortunately, this depends on the

human grasp of the seven or so variables a mind can track at one time,[42] and the brilliance and frailty of human memory. We are all too familiar with errors in health care (from leeches to steroids) based on this sort of deductive reasoning (from known, 'true' generalities to specific facts).

But times have changed. Health care is an information business. We have vast quantities of data, which increasingly are becomingly digital in nature and thus available for sharing, analyzing, and learning and teaching from. This, at times overwhelming, amount of data, when managed by appropriate computational techniques, offers the opportunity to assist health care providers' memory and grasp of the data. Using computational techniques and modern data management as a cognitive prosthesis, it may be possible to support a new era of empirical research—a neoempiricism built on validated observations in thousands of patients detailing what has actually happened. We are in the situation now of having done the experiments but having failed to capture, keep, analyze, and learn from the data which could guide the therapy of the next patient.

Health care is now involved in collecting large amounts of data about patient care for purposes of quality improvement, oversight, and improving efficiency. There are also vast collections of clinical data potentially available for further analysis. VPS, LLC currently links over 85 hospitals' PICUs with data on over 300,000 patient admissions (https://portal.myvps.org/). It is possible to capture highly granular (detailed) data from electronic medical records capturing every blood pressure, heartbeat, and saturation plus much more from every critically ill child. This is a rich data source. Can all of these mountains of digital clinical observations be converted from mere data to information and knowledge to guide treating the next patient? Can we learn from what we have done, from the myriad experiments involving thousands of patients? To waste the potential knowledge available from managing these patients, or to continue to use it merely to inform clinicians one at a time, would be unethical. Failing to learn from each patient and share that knowledge is denial of the very ethos of medicine.[22] Fortunately, there are increasingly sophisticated techniques to do just that—learn from every single patient encounter, make the data and knowledge derived from it available and apply it to the next patient. To know how the last 300 children with asthma were treated in the last 6 months would paint a picture of the standard of care, provide real-life comparisons of approaches, and detail therapeutic responses. The summed experience of multiple practitioners would be available for the next child admitted with asthma—not relying on the clinician's memory but on valid data from hundreds of therapeutic trials. Learning from observations, i.e., data, is what science is about. In recent years, there has been tremendous growth in medical data mining—the process of analyzing data to discover patterns and associations. Associations, clusters, and linear sequences, often for the purposes of forecasting or predicting what may happen in the next patient.

Knowledge discovery in databases goes beyond data mining to extract unknown, implicit, and potentially new and useful information/knowledge. Using artificial intelligence methods such as machine learning, neural networks, and other sophisticated techniques to learn about and manage our next patient offers a challenging opportunity for bringing information to the bedside in near real time. There remain enormous challenges to make learning from clinical data possible. These challenges provide a valid research opportunity. How is medical data best mined, are routine business data-mining algorithms applicable to health care data? How can data validity be assured? What about the security and HIPAA issues involved with patient level data? The NIH, Agency for Healthcare Research and Quality (AHRQ), and the Department of Health and Human Services (DHHS) have recognized the importance of this field with related funding opportunity announcements.

Research Funding

Obtaining Financial Support

Research takes time and costs money. Investigators must have financial support for personnel and research materials. It is generally incumbent on the investigator with the idea and the enthusiasm for performing the research to acquire financial support, but senior investigators should provide advice and encouragement to less experienced scientists, and never convey the impression that their ideas are not of sufficient value to deserve consideration. It is necessary for any investigator with extramural funding to support the broader research effort, especially on behalf of young investigators. Without this commitment, the resources necessary for research will never be available. All investigators are aware of the difficulty of obtaining—and the increased competitiveness for—extramural research support. Despite the prophecies of doom and gloom, myriad funding sources remain available.

Since World War II, the prosperity of the United States has enabled the NIH to become preeminent as a resource supplier for medical research by conscious governmental effort. Although this system has funded the tremendous surge in medical research that contributed to the growth of medical schools, university faculties, and hospitals and a research effort second to none in the world, it also has rendered this establishment dependent on federal dollars. This dependence has made the politicization of medical research difficult to avoid.[43] Some in the research community may express the opinion that these national funding programs have become less supportive of the ideas of individual investigators and more directive of national medical research priorities. Nevertheless, approximately 80% of overall NIH funding still supports investigator-initiated research. The experienced or emerging investigator needs to become familiar with diverse sources of funding and how to access them, and the experienced investigator has a responsibility to help.

Sources of Research Funding

From the perspective of the investigator, sources of research funding can be broadly divided into intramural and extramural sources. Intramural funding is that available from within the investigator's institution. The source of funds for this research is private endowments, grants, donations and gifts to the university, and clinical funds directed to research support via individual clinical departments. In addition, universities may receive training grants from federal organizations or other granting agencies to facilitate training, education, and research endeavors by their faculty, fellows, and staff.

Box 4–1 Funding Resources

Many of these resources can be found online or in university offices for sponsored research or research administrators, deans' offices, or medical school and university libraries.

Box 4–2 Guidelines for Grant Writing

- Read and study the instructions.
- Present a well-organized, precise, lucid explanation of all points.
- Never assume the reviewers will know what you mean.
- Explicitly and clearly, state the rationale of the proposed investigation.
- Refer thoroughly to, and demonstrate thoughtful familiarity with, the literature.
- Use well-designed tables and figures; a picture is worth a thousand words.

Intramural Funding

The first line of funding for the junior investigator generally is intramural funding; however, securing it should not delay the investigator's exploration of extramural funding possibilities. Scientific productivity is the first concern for the new investigator, but being productive financially is always an asset. Intramural funds are developed and administered by individual research directors, division and department chiefs, institutions, and dean's offices. Donations from patients, private individuals, and corporations, and funds generated by the clinical activity of individual faculty members support innovative entrepreneurial "start-up" research projects that serve as pilot and preliminary studies to ultimately obtain extramural funding. Junior faculty should not hesitate to seek such support from hospital auxiliaries, private foundations, or individual donors.

Providing access to funds for junior investigators is the responsibility of senior physicians with long-term commitments to critical care medicine. Frequently, the fundraising foundations of hospitals or the research offices can help the investigator find resources from these sources. Without this "seed" money, new ideas may never get far enough to generate extramural funding and bear the fruit of complete investigation and experimentation. A commitment to research as a vital part of clinical practice, as well as seeking and dispersing gifts and donations, is crucial to ensure vital funding for the research endeavor in critical care medicine. The percentage of research funded from clinical resources, external donations, and extramural research funding varies widely. Young investigators should understand that this seed money usually is for a limited time. Once they have been given an opportunity to initiate their work, most institutions expect them to find extramural funding, so that other young investigators can be supported.

Extramural Funding

Extramural funding comes from numerous private and public sources to which the investigator can apply either independently or through the sponsorship and direction of the institution. Federal funding accounts for a large proportion of available extramural support in U.S. universities performing biomedical research. Much of this funding comes from the NIH, and valuable insight into the agency and the process of obtaining funding can be obtained from the NIH Web site http://www.nih.gov/. In this section, we discuss some of the funding opportunities available through the NIH. A subsequent section discusses the NIH structure and operation as a major part of the "research landscape" in the United States.

Extramural support sources include private philanthropy, industrial/pharmaceutical research support, private grants and contracts, and government grants and contracts. Exhaustive lists of granting organizations should be available in the deans' offices and offices of sponsored research and research administration at any academic instituton (Box 4-1). The staffs in these offices may be an underutilized resource at many institutions, and critical care investigators should identify and contact them. Another obvious source of funding opportunities comes from within the specialty's collegial network. Conversations with colleagues within the university, professional organizations such as the Society for Critical Care Medicine and the American Academy of Pediatrics, and personal research contacts frequently provide useful information on the current funding available from various sources. In addition, numerous research publications in this field may be found in the medical school or university library or at the dean's office (Box 4-2).

These publications provide a useful, but not exhaustive, list of potential resources for research allocation and an excellent starting point. Additionally, most universities have career development awards and institutional granting organizations that can provide interim, emergency, and seed support for

research projects with the promise of obtaining extramural funding. Again, reference to the local university offices is suggested.

Between 1994 and 2006 the NIH budget was aggressively increased by Congress, but such increases have not continued and this has led to significant tightening of funds. The largest segment of the NIH budget still goes to funding extramural (that is, the research is conducted outside the NIH campus) investigator-initiated projects, as summarized in Figure 4-3. Because of the more competitive budget situation, it is crucial that those with ongoing research interests maintain a detailed understanding of the NIH, our federal government's principal agency for supporting biomedical research.

Although obtaining funding through the NIH can seem daunting, it is best to begin any such endeavor by understanding some of the basic funding mechanisms because this may ultimately assure successful choices. Funding may take several forms. The most common form is direct grants, which are reasonably unrestrictive and awarded to institutions in response to specific applications by investigators. These grants provide the major basis of federal funding. Under most circumstances, institutions receive substantial indirect funds from NIH-funded research: an additional 50% to 70% is added to the grant amount, supplying the institution with substantial support for facilities and administration (also known as "F and A" or indirect costs). There are many types of NIH grants: the investigator should peruse all of them on the Internet (http://grants1.nih.gov/grants/index.cfm). The following brief discussion of a few of these mechanisms is introductory only.

- **Research Project Grants (R01s)** are awarded to an institution on behalf of a principal investigator who has requested support for a specific research project in an area in which he/she is competent and interested. This funding mechanism is widely considered to be the vehicle for successful scientific support and the goal of the investigator with serious research aspirations.
- Most NIH funding goes to investigator-initiated proposals, and the R01 is the most commonly used mechanism. The research plan focuses on a specific set of research aims, and the plan to achieve these aims typically is hypothesis-driven. The level of support varies; the budget (direct costs) of an R01 typically is $250,000 to $350,000 per year, with 3 to 5 years of support requested. The award is renewable, in a competitive renewal process. The specific policies and scope of the R01 can be reviewed on the NIH Web site, http://grants.nih.gov/grants/guide/pa-files/PA-10-067.html.
- **Small Grants and Exploratory/Developmental Grants:** The R03 is a small grant mechanism that offers up to $50,000 (direct costs) as a level of support for 2 years. Although not all institutes offer this funding mechanism, it is often used as a first independent funding mechanism by new or emerging investigators. It may be especially useful for obtaining pilot data to answer scientific questions or provide direction for future larger studies. The R21 or exploratory/developmental grant provides 2 years of support for planning research or for exploration of scientific questions, particularly innovative approaches. This mechanism provides up to $275,000 direct costs during the 2 years. These two funding mechanisms are significantly less difficult to obtain for newer investigators than the R01, because requirements for substantial pilot data are less.

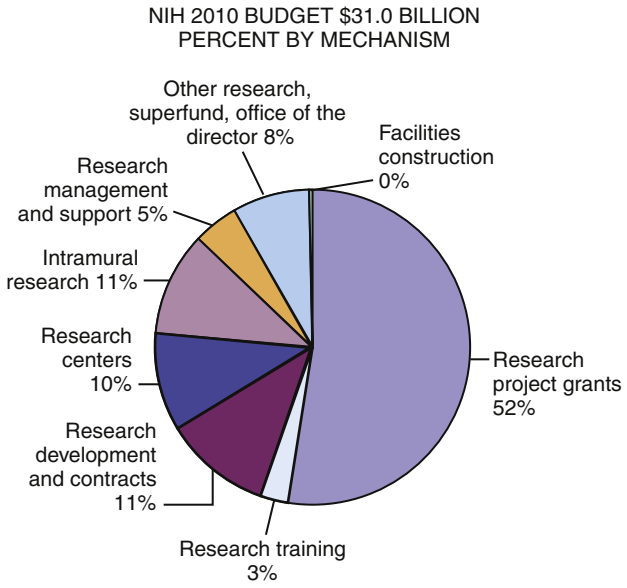

Figure 4–3. National Institutes of Health (NIH) budget for fiscal year 2010. Approximately 75% to 80% of NIH funds support investigator-initiated science outside of the NIH.

- **Program Project Grants** are awarded to the institution and are provided to support broad-based, long-term research programs involving multiple investigators, multiple projects, and a common objective. Often, the objective is announced in a scientific initiative, such as a Request for Applications (RFA), or a Program Announcement, published by one of the government agencies or one of the NIH institutes.
- **Research Career Development (K series) and Training Grant Awards (F and T series)** are given to institutions to develop the research capabilities of emerging investigators (F and T series) and to develop research careers with mentoring (K series). In our emerging specialty, these merit further discussion (see below). The NIH Web site provides an overview of the commitment to early stage investigators (http://grants.nih.gov/grants/new_investigators/index.htm). At the junior faculty level, career development awards are available for those wishing to enhance their early research careers through work with an experienced mentor. Every junior faculty member with research as a substantial interest should consider the K mechanism. These are salary support grants that provide mentored research time for individual emerging investigators. Typically, 75% salary support is provided. This NIH award series has been expanded in recent years. Some of the specific career development and fellowship awards of significance to critical care investigators are listed below.
- **The K series** (K01, K08, K23, and several others) provide mentored investigator funding opportunities from the NIH and are often used as a first funding mechanism. Choice of mentors is crucial, and this choice should be made with the nascent investigator's interests foremost. It is nearly essential that the mentor have established extramural funding from the NIH; mentors should not be young investigators with their own K awards. An exciting recent development for emerging scientists in pediatric critical care (at the junior faculty level) is the Pediatric Critical Care Scientist

Development Program established in 2004. This program had 15 Scholars in its first 4 years, and the application deadline is October 1 of each fall. Information can be obtained from http://www.pccsdp.org/, or interested applicants may contact the program director, who will provide assistance to applicants in the strategy of obtaining funding, and who has a list of potential mentors.

- **Institutional Training Grants (T32):** These awards are made to institutions for support of graduate research training, postdoctoral research training, and research fellowships in clinical and basic science investigation.
- **Cooperative agreements ("U series" funding mechanisms)** are becoming increasingly important, especially in research networks. The government agency enters into an agreement with the investigator(s) to manage the project cooperatively, for example, the National Collaborative Pediatric Critical Care Research Network (CPCCRN) established in 2005. These awards are made after application for specific funding opportunities published by the NIH. The specific collaborative terms are spelled out between the investigator and the funding organization. Industry is providing a greater portion of research resources.

In 1980, 30% of health research was funded by industry compared with 59% by the federal government. By 1990, industry was funding 45% of U.S. biomedical research efforts. Economic fluctuations make it difficult to predict future trends, but such support will likely continue. Industry supports research in two ways: first, by funding foundations that support research, and second, by contracting with researchers to perform specific, directed product development, such as drug trials, clinical studies, and product evaluation. Information about these programs is available from the sources listed earlier and from the Food and Drug Administration (FDA).

Contracts provide another funding source. These formal agreements are made either with the federal government (often the NIH but many other federal agencies also issue research contracts), industry, or with private foundations for specific research projects designed by the grantor of the contract. Research contracts can be divided broadly into contracts that provide reimbursement for the cost of investigations and experiments, and fixed-price contracts that basically are awarded to achieve a specific goal at a fixed cost to the grantor of the research contract.

Awareness that industry (pharmaceutical agencies, insurance companies, medical equipment companies) has the money to fund its research priorities and wants to carry out such studies should motivate all in pediatric critical care to explore contact possibilities and increase awareness of these opportunities. In addition to direct business contacts, the critical care investigator should become familiar with the Small Business Innovation Research and Technology Transfer (SBIR/STTR) Programs, which are an important source of research funding. Companies seeking professional research consulting are listed on the SBIR/STTR website.

Foundations may be merely philanthropic (funding good ideas) or they may be directive (addressing issues of specific interest to the foundation).[44] They can bring investigators together, fund research, and disseminate ideas. Foundations are a source of research "venture capital" and as such often take greater risks than federal funding agencies.[44] Accepting research support from industry (whether through a foundation or more direct corporate source) has ethical implications.[45] Research and clinical decisions should be guided by data, not funding sources. Private funding for research, especially if lavish, may raise questions regarding the integrity of the researcher; for this reason, prospective ethical guidelines are essential. Clear declaration of all potential conflicts of interest must be made, including those that may have only the appearance of conflict.[46] Although absolute ethical integrity is the cornerstone of research (see below), it is nowhere more critical or more readily corrupted than when dealing with profit-motivated industry.

National Institutes of Health

The NIH is an agency of the DHHS. The DHHS has overall responsibility for many other agencies, including the Centers for Disease Control and Prevention (CDC), FDA, Substance Abuse and Mental Health Services Administration (SAMHSA), Health Resources and Services Administration (HRSA), and the AHRQ. Many of these agencies (and other federal agencies) have research funding programs in addition to that of the NIH.

The NIH is made up of 27 institutes and centers. Its structure is summarized in Figure 4-4.

Most of these individual NIH institutes (called "ICs" at the NIH) and centers have programs that provide both intramural (internal to the NIH) and extramural (outside the NIH) funding support for research. The institutes with only extramural funding programs are shown in black in Figure 4-4. Some of the NIH institutes that may be supportive of critical care research and therefore are most familiar to intensivists are:

- National Institute of Child Health and Human Development
- National Heart, Lung, and Blood Institute
- National Cancer Institute
- National Institute of Diabetes and Digestive and Kidney Diseases
- National Institute of General Medical Sciences

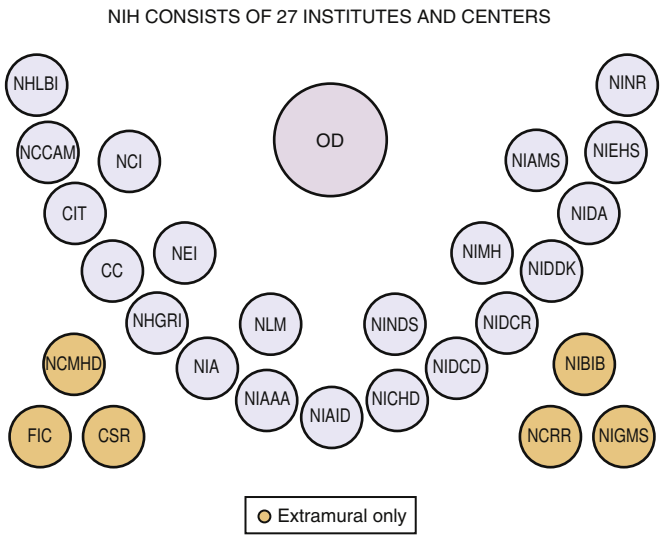

Figure 4–4. The 27 institutes and centers at the National Institutes of Health (NIH). Those shown in white support both intramural (at the NIH) and extramural science. Those with gray backgrounds support only extramural science.

Each NIH institute is accessible through the NIH Web site at: http://www.nih.gov/. By visiting the Web site of the specific IC, one can review the funding priorities and programs, and find scientific contact personnel who are of great assistance to investigators. Both NICHD and NIGMS have formal programs that are specifically supportive of critical care research. Both institutes offer career development, institutional and individual training awards, and investigator-initiated awards. Program staff generally make themselves available for questions and guidance.

The NIH extramural programs are divided into grants, contracts, and cooperative agreements. The role of the NIH in each of these programs is, respectively: patron, as granting agency (grants), to provide assistance and encouragement; purchaser (contracts), to provide procurement of necessary resources; and partner (cooperative agreements), an assistance mechanism (rather than an "acquisition" mechanism) in which substantial NIH scientific and/or programmatic involvement with the awardee is anticipated during performance of the activity. The NIH publishes the weekly NIH Guide for Grants and Contracts, which announces NIH scientific initiatives and provides NIH policy and administrative information. The guide publishes notices, program announcements (PAs), requests for applications (RFAs), and requests for proposals (RFPs). It is important for investigators to understand the basic differences in these scientific initiatives. Checking the guide weekly (subscribe at http://grants1.nih.gov/grants/guide/listserv.htm) provides access to the latest funding initiatives at the NIH as soon as they are published. PAs have no specific funds set aside but indicate broad areas of ongoing research interest within the NIH. FOAs (funding opportunity announcements) are formal announcements describing an institute's initiative in a specified scientific area. Requests for Applications are announcements that indicate that funds have been set aside to make awards in the area requested. They serve as invitations to investigators in the field to submit research grant applications for a one-time competitive assessment.

The following is a general scheme of how an NIH grant application is processed. This scheme serves as the model for grant applications discussed in the following section (Figure 4-5). The investigator initiates a research idea and, in conjunction with the school or other research center, electronically submits an application to the NIH. Applications initially go to the NIH Office of the Center for Scientific Review (CSR), where the application is assigned to the appropriate study section and institute.

The study section, as the peer review groups are widely known, evaluates the study for scientific and technical merit and assigns a priority score. The grant application is evaluated for programmatic relevance by the NIH staff of the individual institutes and submitted to the Advisory Council, which officially recommends funding action to the director of the NIH institute. The responsibility of each component of this review system for grant applications is outlined in Figure 4-6. The first-level peer review provides the initial scientific review of grant applications for scientific merit and assigns them a competitive score, using published criteria available on the NIH Web sites. The instructions to reviewers are reproduced here for investigator convenience but can be downloaded from the Center for Scientific Review Web site (http://cms.csr.nih.gov/PeerReviewMeetings/ReviewerGuidelines/). It is important to be aware that different funding mechanisms may have different review criteria. As well, the review process and reviewer selection process are explained at the CSR home page (http://cms.csr.nih.gov/). The criteria for each funding mechanism are available online at http://www.csr.nih.gov/guidelines/guidelines.htm.

This first-level review, known as peer review (study section is often used to describe the first-level review group), does not set program priorities or make funding decisions. Study sections elect not to discuss noncompetitive applications (those proposals in the bottom 50% of those being reviewed at a given session) submissions.[47] Nevertheless a complete review is done and a written critique provided to the investigator. Scoring is provided by section of the grant, but an overall

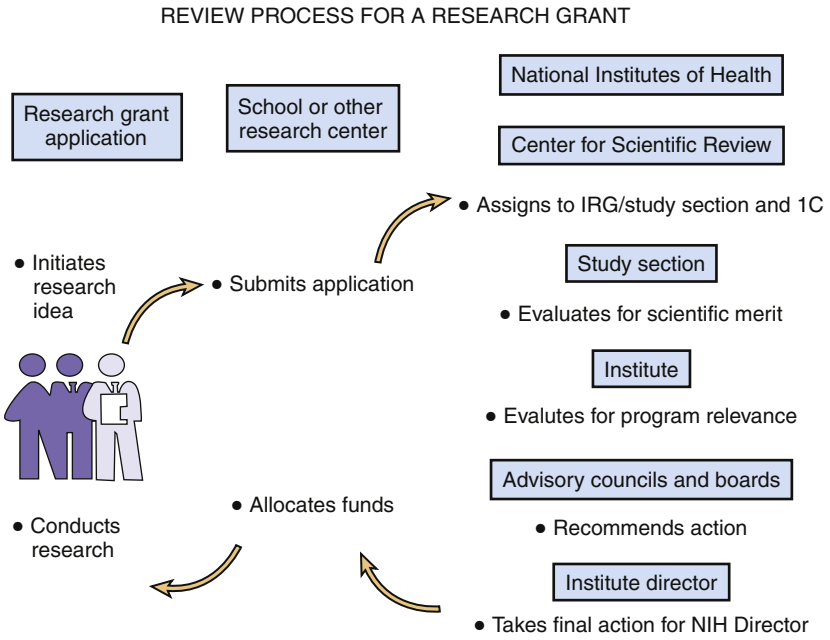

Figure 4–5. Schematic representation of the course a National Institutes of Health grant application follows in the review process. *(Courtesy the Office of Extramural Research, Office of the Director, National Institutes of Health, Bethesda, MD.)*

score is not provided. The reasoning is that these proposals are not presently fundable, and what is really needed is a thorough critique that conveys to the applicant-investigator the level of overall enthusiasm among the reviewers for the proposed research and specific, helpful feedback to the investigators. Sometimes, specific actions required to make the proposal more competitive are suggested. All proposals, scored and unscored, receive this feedback.

After scientific merit review in the study section, the scored proposals go to the second level of review, which is the Advisory Council. The Advisory Council is a national-level group composed of distinguished scientists and community members who advise the director of the institute on policy and funding decisions. Here, the quality of the study review group's assessment of the grant application is evaluated, and the council makes recommendations for funding to the institute's director after considering the recommendations of program staff of the institute. At this second level of review, the council evaluates program priorities and relevance by recommending funding and advises on policy. The institute's director takes final action to allocate funds. When funds are allocated, the individual researcher conducts the research using the allocated funds granted to the investigator's institution. This dual level of review is summarized in Figure 4-6.

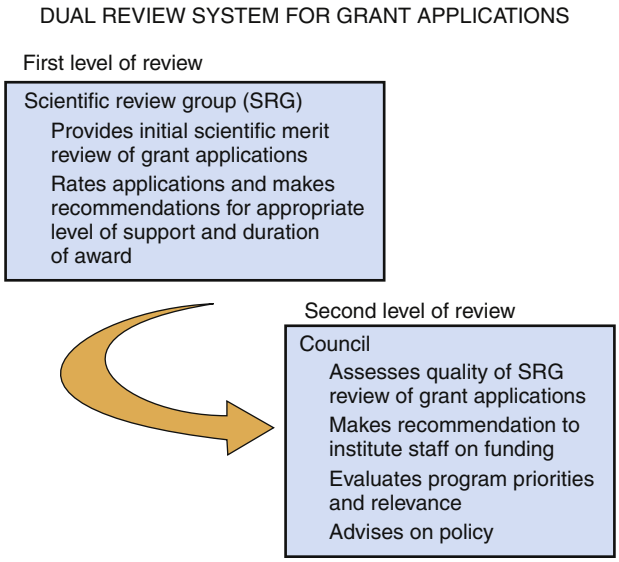

Figure 4–6. All National Institutes of Health grant applications undergo two levels of review. Of note is that the study group does not make funding decisions. It can, however, review and advise on the appropriateness of the proposal budget. *(Courtesy the Office of Extramural Research, Office of the Director, National Institutes of Health, Bethesda, MD.)*

Writing the Grant Application

In making grant applications, particular attention should be paid to the due dates and instructions for application, as well as page number limitations. Although the following guidelines are specifically intended for NIH grant applications, they serve as general guidelines for any granting organization. It seems superfluous to say that no matter how brilliant the idea, it must be presented to the granting organization in a readily accessible, understandable, clear, and concise fashion. Proposals that are clear and concise, with a precise approach and research plan are more likely to gain reviewer enthusiasm.

In general, investigators reviewing the grants are at the top of the scientific community pyramid (Figure 4-7). They are active and productive researchers who have been through the process themselves. They are both sympathetic and critical. There are no guarantees that they are interested in the individual investigator's area of expertise, that they are uniformly knowledgeable about it, or that they are committed to funding it. As a matter of fact, NIH reviewers are specifically admonished to make no evaluation or recommendation about funding. Rather, the reviewers' judgment of scientific merit is to be precise and thorough. Most reviewers want to act as advocates for individual research proposals; it is the investigator's

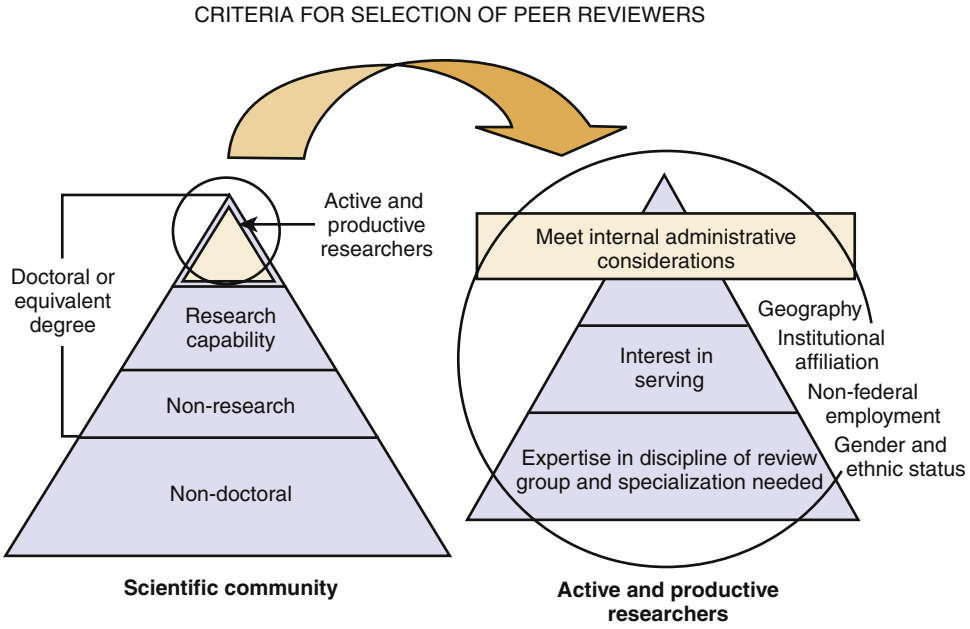

Figure 4–7. Reviewers are chosen from the peak of the scientific community's active researchers. *(Courtesy the Office of Extramural Research, Office of the Director, National Institutes of Health, Bethesda, MD.)*

responsibility to provide the reviewer with the ammunition necessary to support the research proposal accurately and effectively to the study section as a whole.

When writing a grant, it is essential that the same care and consideration, if not more, for the development of ideas and presentation of concepts be used as in the final publication of the research. The review process of a research grant application will be every bit as critical and rigorous as the review for publication of articles. To allow an ongoing contribution to the research effort in the field, success with grant applications is always a necessary step. The following section serves only as a quick overview of how successful grants are written. Basic concepts that underlie all successful grant applications are that they present a good idea backed up with good science and presented in a well-written format. The applicant should be particularly attentive to the detailed instructions that are provided for each mechanism. Periodically there are significant changes to the format and length of NIH grants, but the general outline remains similar. Four questions must be approached:

1. What do the investigators intend to do? (specific aims)
2. Why is it important? (significance)
3. What has already been done? (preliminary studies, other investigations)
4. How are the aims to be accomplished? (experimental plan)

Writing a grant proposal can be intimidating and confusing; however, lucidly presenting these simple points not only makes a grant easier to present but also easier to award. All investigators must realize that they are assessed on the quality of the grant and not just on their track record[46]:

"If you are a beginning investigator submitting your first application and worried because you do not have a professional reputation, remember that you will have already impressed the reviewers in the literature section by your familiarity with the field, and your capability for keen and wise discrimination between the significant and the banal, the valid and the presumed…"

The research grant application provides numerous opportunities to demonstrate qualifications and scholarly attributes; however, it also readily reveals faulty thinking, hasty preparation, superficiality, and inexperience.

Hypothesis-Driven Research-Specific Aims

This section is restricted to a single page, and forms the "good idea" portion of the application in which the investigator should document the creative, valuable, and exciting research questions that need to be answered. It justifies the rest of the proposal. There should be two to three specific aims, generally with individual statements of hypothesis. In general, the hypothesis should be aimed at delineating, explaining, understanding, or defining mechanisms of action. This is in distinction to those where the goals are merely observational, empirical, or data-gathering exercises. Frequently this is a matter of correctly stating the research endeavor. For example, an investigation to determine whether there are gender differences in hypoxic pulmonary vasoreactivity (HPV) could be justified on a descriptive basis, or it could be justified as the means of examining a hypothesized, specific research question delineating using the differences between male and female responses to injury in an animal model, with the specific aim of reaching a significant conclusion about how gender and/or the presence of estrogen modulates endothelial prostacyclin release, and providing a mechanistic answer.[9,49,50]

The research proposal should have specific, achievable, well-defined goals that are neither overly ambitious nor superficial. During development of NIH proposals, these research aims should be conveyed, via e-mail, to the program staff of the institute that is the contemplated recipient of the proposals. These program staff are committed to assisting potential grant applicants to improve their applications and help them be competitive. Criticism, tightening, and delineation of hypotheses should be completed and reconveyed to the investigator. Then, biostatistical assistance, including power analysis, can be obtained and a detailed research plan generated.

It is emphasized that the Specific Aims page may be the most important page in the entire grant proposal. Reviewers are very busy individuals, and this page forms the "bait" to make the reviewer excited about reading the remainder of the proposal with a positive attitude. Experienced grant writers indicate that they spend up to 75% of their entire writing effort on this single page.

Although the specific proposal should have specific aims, it also is important to present how these research aims fit the broader picture. This is accomplished by relating the research aims and hypotheses of the grant to long-term scientific objectives and integrating them into the overall field relevant to the proposal. The summary paragraph at the end of this page should help the reviewer understand the importance of the project in the broad picture. All of the problems in an area of research cannot be solved by one research proposal.[51,52]

Significance

Although the literature supports the significance of the proposed study, the grant applicant should present a thorough familiarity with the literature, its deficiencies, contradictions, and pitfalls. It should be clear to the reviewer how the hypothesis (or data mining or descriptive project) was generated from the current field of knowledge and exactly how the present proposal fits into that area readily and concisely. A thorough review of all available literature on the subject must be carried out on a continuous basis. Investigators should search the NIH Reporter *system (http://projectreporter.nih.gov/reporter.cfm)*—this system has replaced the older CRISP database of federally funded studies—so that they can present their own work as innovative and an important new development of the science in the field. This site is also particularly useful for trying to identify potential mentors and collaborators.

Preliminary Studies

Pilot studies with preliminary results should be included to demonstrate that the hypothesis is testable and supportable, or the descriptive project practicable, and that the investigator has the capabilities of pursuing the research goals. Reference to abstracts and papers previously published by the investigator and preliminary studies with data presentation should provide a complete overview of the capabilities of the investigators. The investigator's scientific capabilities must be evident in the presentation of the proposal.[46,51]

Experimental Plan

The methodology should be appropriate, available, well worked out, and well supported. In addition, it should be specifically targeted and precisely capable of addressing the questions raised in the specific aims. Methodology must be described so that the reviewers can be assured that valid results will be achieved. If new methodology is being proposed, detail is necessary to assure the reviewers of the applicability of new methodology, as is inclusion of preliminary results demonstrating the likelihood of success of the experiments.[48,51,52]

As clear a statement as possible of the underlying assumptions and their validity and of the limitations and applicability of the proposed research plan should be presented. Investigators applying for career development awards (K awards) should be aware that although the science they propose will be reviewed, the most rigorous analysis will be applied by the reviewers to the career development plan as outlined. The mentor's commitment to the emerging investigator must be specific, and the mentor must be well qualified for the task. Specific discussion must be provided as to how the requested support will result in the development of the scientist who is capable of achieving the aims of the proposal. Formal course work and specifically mentored laboratory work are two crucial elements in this plan.

Specific attention must be paid to how the data will be evaluated, analyzed, and statistically approached. An expert statistician's input before submission of the proposal is essential, and the analytic plan (including power analysis) must be included. At the end of reading the method section of the proposal, the reviewer should be confident that the investigator understands and intends to use good scientific method to address specific aims in a logical, clear, focused, and precise manner.

Presentation

The final necessity for a research proposal is that it be well presented. Overall, the number of grant applications at the NIH has increased, and the competition for support has become greater. Visually attractive, well-presented, easy-to-follow, clearly delineated research proposals will clearly stand out from the herd. Although showmanship will not make up for poor substance, sloppy applications may obscure good science. The first rule is strict adherence to the guidelines in the research application with regard to page number, layout, content, and other details. A clear, simple, lucid, grammatically correct, and typographically perfect presentation is essential; leave nothing to assumption and guesswork. Seeking help from many sources with different skills and perspectives is tremendously valuable. Senior department members, deans, review offices, research administrations, English teachers, spouses, lay people, and other investigators all may have valuable contributions to make to the clarity of a research proposal. Frequently, it is worthwhile to have a grant proposal read by an outside, independent, unbiased assessor before it is submitted to the NIH. Review by a successful investigator who is neither familiar with nor involved in the specific research area can be invaluable.

Familiarity with and commitment to the guidelines and recommendations for both human and animal experimentation is essential. Obtaining institutional review board (IRB) approval of research proposals before submission to the NIH is not mandatory. Be aware, however, that the proposal will not be funded until this clearance is officially verified. The internal review process of the institution may be of benefit in establishing and clarifying research proposals. Finally, budget preparation must be meticulous. As a general rule, everything should be justified briefly and concisely.

Although excessive financial support should not be sought, the investigator must request sufficient resources to achieve the specific aims. Availability of other resources, such as capital equipment, research space, and collaborative resources, to complete the work should be demonstrated. Frequently, preparation of the budget for the proposal is a very time-consuming process. The investigator should not be intimidated by this process but should not underestimate its importance. The investigator should first determine precisely what is needed to perform the experiments and what the technical and personnel needs are, and then, in conjunction with the university, determine fair costs for these items, supported with documentation where necessary. Reviewers are most concerned with completeness of budgetary considerations. A grant that has insufficient resources to achieve its goals is a waste of time, money, and effort for both of the NIH and the investigator.

Page Limitations

New, stringent, page limitations add an additional challenge to successful application. Writing must be concise, yet not obscure the excitement and clarity of the science. The critical importance of the Specific Aims page is increased by the shortening of the remainder of the application. Material that relates to the investigator's particular skills relating to the grant are now included in the NIH Biosketch, and should not be in the main scientific narrative. The resources section of the grant should include institutional support, equipment, and commitment to young investigators. These topics are important components of K applications. Perhaps most important, the smaller grant format should allow the writer more time to polish and enhance the grant, using feedback from colleagues. This will, of course, occur at competitor institutions as well. Thus, the shorter format both enhances the opportunity and importance of writing a tight, concise, and exciting proposal. A "seven steps" guide presented in Appendix 4B (available online at http://www.expertconsult.com) has been helpful to many applicants.

Your Chances: Money

Anyone who is in the remotest way connected with the biomedical research effort in the United States is aware that there is never sufficient money to fund all of the worthy ideas.[52] Regardless of whether this money crunch arises from the ambitious, laudable scientific goals, budget deficits, or shifting priorities, a competitive system will be necessary for the foreseeable future. The concern for the continued existence of medical research has led to some fairly horrific statements. It is simply not true that "… nothing is getting funded these days…" —the NIH budget is more than double its budget in 1994. More dollars go to research than at any previous time, and more awards are made. However, the recent leveling of funds has resulted in a shortage of funding compared to the number of applications being received, since the first years of the new millennium. This results in a lower percentage of grants receiving funding. What is certain is this: *You will not receive funding from an NIH grant if you do not apply.*

With all of the available resources for American pediatric critical care researchers, we all wonder "how we can look so rich and feel so poor?" Up through 2002 the NIH budget was doubled. Such expansions are unlikely in the foreseeable future. Nevertheless, Congress has made its intentions quite clear: the desire is for an expanded, rather than contracted, biomedical research effort. More people are submitting grants; that is, the competition is getting tougher. In 1993, 4121 of 19,072 R01s (22%) were funded. From 1999 through 2001, the percent funded increased to 32%, but has declined since then, and in 2009 was down to 22% again. The total number of applications increased to a peak of 29,097 applications in 2006, and has decreased since, perhaps reflecting discouraged investigators, but was still 26,675 in 2009. Of these 5924 were funded, an increase in numbers of over 40%. The percentage of applications funded varies by institute, budgetary availability, and national priorities. Research project grants also undergo a substantial budget cut after award. About 17% to 20% is not uncommon. All of these factors have sustained major changes in recent times, and it is likely that considerable variation will continue over time.

Despite the challenges, more people are involved in medical research now than at any previous time in our history, and more funding is going toward it. Priorities for biomedical research shift with national priorities, economic change, technologic and business developments, and political interest. Total reliance on funding from the federal government is unjustified and risky. We need to be aware of other available sources of extramural funding and encourage industrial and private support for research endeavors in pediatric critical care, as well as provide evidence of our own commitment to the research endeavor by continuing to contribute support from clinical income. Since the previous edition of this textbook, the number of pediatric critical care physicians with NIH funding has dramatically increased; this is due to focused efforts by leaders in the field and at the NIH to encourage young investigators to apply for funding. The perception of "tight funding" should not discourage pursuing the data upon which future grant applications will depend and from which future improvements in pediatric critical care will come. The future of our young patients is dependent on continuing our efforts to secure funding for research in our field.[53]

Your Chances: Cultures in Conflict

By training, philosophy, motivation, and research style, doctors and scientists might as well be from different phyla.

***New York Times,* April 24, 1992**

The competition is not merely other pediatric intensivists. Researchers in pediatric critical care must be involved with, collaborate with, and be familiar with the work of investigators from other areas of medicine who may not be clinical researchers at all,but rather basic and translational scientists.

A *Journal of the American Medical Association* editorial titled "The Two Cultures of Biomedicine: Can There Be a Consensus?" crystallizes the problem.[54] A researcher-developer stated, "For medicine to advance, you have to be willing to have your patient die on the operating table," whereas a typical clinician said, "The more important thing when you are starting, is to finish with a live patient." These two approaches must be made compatible, and both are essential for our patients' well-being. The practical, patient-concerned physician must apply the results of biomedical science and work in close collaboration with the basic researcher to maintain the appropriate focus. Pure scientists are concerned with studying the underlying mechanisms of diseases, which, to them, may be abstract entities. That is, they seek to describe pathways and phenomena without a direct link to human health and disease.[55] They need to understand the clinical and human significance and impact of the questions asked and results obtained. This difference is expressed in the *New York Times* by a research director: "I go through medically-oriented publications and see they don't have enough controls and they ignore relevant interpretations of their data. You can get the idea that doctors are too free and easy with science."[55]

The fact that two cultures in biomedical research exist is clear. This is recognized not only by teaching hospitals, where they tend to exist side by side, but also by the community and, clearly, by the NIH. This division cannot be allowed to develop as a polarized dichotomy. The two sides need each other. Physician-researchers are classically viewed as the pinnacle of academic success, but only inasmuch as they are true researchers who understand patients' needs. The fact that they are so well-respected supports the notion that they also are quite rare. Cooperation between these two cultures of biomedical research is the only hope for clinical and basic biomedical science, and neither can exist without the other, contrary to what either may wish. As Tom Stossel, director of the Translational Medicine Division at the Brigham and Women's Hospital in Boston, said[56]:

"Modern medicine is an increasingly complex and troubled profession, but most will agree that science is at its heart. People know this and demand technical and scientific excellence as well as caring from their physicians. Consumers' wishes aside, the constant evaluation and reevaluation of the knowledge base in medicine—pathogenesis, diagnosis and therapy—is a medical categorical imperative. Physical, biologic, and behavioral sciences underpin medicine, but the science that is unique to medicine is clinical investigation."

Competition for limited resources will remain intense. There should, however, be no competition over turf. There need be no competition over areas of interest, and indeed there can be no competition from nonphysicians in the unique science of medicine/clinical investigation. Allocation of resources will be in the direction where collaboration, cooperation, and cross-fertilization between the two cultures of biomedical science are the most fertile. There is no need for competition for ideas. As Stossel concluded: "All kinds of research are needed. The fund of medical knowledge seems vast indeed, but the reservoir of ignorance is even greater."[56]

Research Ethics

"There is no vice that doth so cover a man with shame as to be found false and perfidious."[57]

Francis Bacon, 1578

A comprehensive presentation of the ethical issues for investigators is beyond the scope of this chapter. Each clinical investigator must be thoroughly aware of the ethics of human

investigation before committing children to the necessary uncertainties of research.[56] Issues of information, understanding and consent, risk to patient and investigator, privacy concerns, and the welfare of patients participating in research have been thoroughly discussed in many publications. All of these issues require the investigator's attention. There is, however, more. It cannot be too strongly stressed that intrinsic to these issues is the necessity for well-designed studies that are likely to yield useful results and to be of future benefit either to the patients enrolled in a given trial or to future patients. As Nelson[59] has stated:

"The prospective, randomized, double-blind, controlled, multicenter clinical trial requires a pre-contract among investigator, physician and informed patient that the rigorous rules of statistical mathematics will be enforced."

Performing shoddy or slipshod science is among the most unethical actions possible for any investigator, experienced or naive, to commit. For those investigators involved in animal research, rigid adherence to standards of ethical animal treatment is necessary.[60,61] These standards should be as stringently maintained as in human trials. The sacrifice of animals in poorly designed studies that yield useless results is unacceptable. Such experiments lend credence to the animal rightist's bumper sticker: "Animal research = Scientific fraud." All investigators should adhere to the rules and procedures of their local institution, their state governments, and the NIH when dealing with animals in a humane fashion.[62] Constantly reviewing how subjects—whether animals or children—are treated and the value of any trial or experiment is a mandatory part of professional scientific practice.

Nothing is more important in the practice of medical investigation than absolutely rigid, scrupulous adherence to the truth. The goal of research is to discover true results upon which to base sound conclusions. This goal is threatened in two major ways. The first is poor science, sloppy techniques, and "honest errors." The second is fraud. Both must be avoided. As CP Snow[63] has said:

"The only ethical principle which has made science possible is that the truth shall be told all the time. If we do not penalize false statements made in error, we open up the way, don't you see, for false statements by intention. And, of course, a false statement of fact, made deliberately, is the most serious crime a scientist can commit."

False statements made intentionally or in error cannot be tolerated. This is important not only during the final summation and reporting of results but also at every step along the way. The least suggestion of fudging or poor study design, the least bit of misrepresentation of results at any stage, is merely the first step on the slippery slope that ultimately leads to out-and-out fraud. Advice given by Samuel Johnson[64] in 1778 is valuable for all of us who are concerned with scientific observation and reporting, whether supervising or performing research at any level:

"Accustom your children constantly to this: If a thing happened at one window and they, when relating it, say that it happened in another window, do not let it pass, but instantly check them; you do not know where deviation from the truth will end."

Several threats to the truth occur during the course of medical research. As in all things, recognizing the potential errors is the first step in preventing them. From the very conceptualization of the hypothesis, when there is a risk for plagiarism, through the indifference of senior investigators, to the final analysis of data, the truth is challenged. Charles Babbage, the nineteenth-century mathematical genius remembered as the prophet of the electronic computer, gave us three interesting definitions of data misrepresentation nearly 150 years ago[65]:

"Trimming: the smoothing of irregularities to make the data look extremely accurate and precise.

Cooking: analyzing only those results that fit the theory and disregarding others.

Forging: inventing some or all the research data reported, or reporting experiments to obtain those data which were not performed."

Every investigator at every level must incessantly resist these temptations. Meticulously resisting overzealous curve fitting, data smoothing, data elimination, and data insertion is necessary. All forms of unacceptable behavior stem from one or more of these three cases, or from carelessness or plagiarism. Although we may not be certain where the slightest "deviation from the truth will end,"[64] we can be certain that, in time, these deviations will be discovered. As Shakespeare said[66]:

"Time's glory is to calm contending kings,
To unmask falsehood and bring truth to light."

Scientific fraud will be discovered in the long run. An interesting, if extreme, example is that involving the Nobel prize-winning physicist Robert A. Millikan. Not until 1978 was research he published in 1913 discovered to be based on cooked data.[67] Millikan represented his results as being from an unselected, consecutive group of drops, which he examined for electrical charge. As it turns out, the group was highly selected. Although 65 years elapsed before the truth emerged, the certainty of Shakespeare's dictum was supported. Generally, the discovery of fraud is not so protracted. This is a good thing; otherwise, the errors resulting from subsequent work based on false data could be quite serious. Adding fraudulent bricks to the edifice of medical knowledge undermines the entire structure and may add to suffering of critically ill children and their families.

In addition to the certainty of discovery aspect of Millikan's error, another lesson is evident. This particular case demonstrates that even the great are not immune to the temptations of dishonestly interfering with results. Perhaps our conviction and love for our hypotheses, which may lead to "honest errors," also occasionally lead to serious and unacceptable overenthusiasm. A.J. Balfour,[68] in a letter to a friend in 1918, was well aware of this risk of enthusiasm: "It is unfortunate considering that enthusiasm moves the world, that so few enthusiasts can be trusted to tell the truth."

Perhaps this particular skepticism is what we all must have, most importantly for our own work and not only for the work of others. Although tremendous energy and enthusiasm are necessary to do research, skepticism is necessary to

present it. Biased enthusiasm leading to nondeliberate alterations of results and frank dishonesty clutters the history of science.[69] Such alterations not only lead to the dishonor of individuals involved but also contribute to a lack of faith in the entire enterprise, no matter how well intentioned. Perhaps even worse than this, fraud in medical science misleads one's colleague and can lead to years of fruitless investigation and dangerous therapies.[14] Straightforward honesty is the basis of honor in science.

It's unfortunate to need to focus on this topic so strongly; however, it has become increasingly clear that we cannot be too cautious.[69,70] Anything less opens the door for the sort of embarrassment that Braunwald and American medicine suffered at the hands of Darsee and continue to suffer by finding research based upon that fraudulent data.[70] Science is a cooperative enterprise. Continual questioning of oneself and each colleague and continuous sifting and analysis are necessary. This provides the excellence referred to in an editorial in *Nature*[71]:

"A research laboratory jealous of its reputation has to develop less formal, more intimate ways of forming a corporate judgment of the work its people do. The best laboratories in university departments are well known for their searching, mutual questioning."

Scrupulous attention to honesty is crucially important because of an inherent characteristic of the scientific method. As discussed earlier, we can support theories only by disproving the null hypotheses. We can never absolutely prove them. Because we can never prove a theory, science is inherently based on uncertainties. The risk of basing our knowledge on uncertainties is obvious. When uncertainties become dishonesties, the entire structure and process of scientific thought are distorted.[71] Fraudulent data, as in the cases described above, or "in service" to controversial theories serves only to inflame passions and obscure the needed answers to pressing issues. Examples that have affected broad swaths of society include the impact of the fake "Piltdown man" on the discussion of evolution and that of the questionable data from the University of East Anglia on the climate change debate (see below).

Add to our communal necessity for rigorous truthfulness and accuracy the fact that many of us are unable to thoroughly and completely understand data generated in areas even closely related to our own, and the situation is even more concerning. We frequently are asked to accept on faith the statistics, results, research techniques, and conclusions based on theories and hypotheses with which we are unfamiliar and certainly unable to test ourselves. In addition, ideas spring into our minds; whether the sources are a paper recently refereed, a research grant recently reviewed, or an idea that occurred to us from our own data is sometimes difficult to ascertain. The potential for chaos and error is great.[71] In this milieu, the presence of police officers, watchdogs, and whistle blowers is too rare and, for the sake of productive research, somewhat undesirable. Journal reviewers should determine whether the results are of sufficient importance to justify publication. Reviewers cannot reliably "police the data." The best source of check and countercheck is at the bench level, where researchers work together.[71,72] The price to be paid by failure and/or fraud at this personal level is far too great. The words of Jacob Bronowski[73] in *Science and Human Values* again demonstrate the overwhelming imperative of honesty:

"All our knowledge has been built communally; there would be no astrophysics, there would be no history, there would not even be language, if man were a solitary animal. What follows? It follows that we must be able to rely on other people; we must be able to trust their word. That is, it follows that there is a principle, which binds society together because without it the individual would be helpless to tell the truth from the false. This principle is truthfulness."

Perhaps no story is more illustrative of the consequences of unethical scientific behaviour than the recent revelation of massive, repeated, pervasive fraud committed by climate researchers at the University of East Anglia's Climate Research Unit.[74-76] Not only does it appear that every form of data manipulation and outright falsification, including data destruction, cooking, fudging, cherry-picking, trimming, and forging has occurred, but also that there was blatant subversion of the peer review and funding processes. Investigators at the top of the climate research world, by bullying other investigators, blocking publication of conflicting studies, and refusing to release and even destroying data have cast doubt on all of climate research and the validity of global warming.

If true, global warming has consequences for the survival of life on Earth. Few scientific theories could be more important. To cast doubt on this potentially vital theory by shoddy research, fraud, and manipulation, is beyond despicable. If climate change is false, then the waste of huge financial resources for research, mitigation, and global economic impact to the tune of trillions of dollars, when they are necessary in other important areas is criminal. The politics of global warming, based on what may be false and fraudulent data present the huge possibility of global confusion over such a vitally important concern. Although this is disastrous enough, the devastation of 'climategate' goes beyond climate research. The entire edifice of scientific endeavor, largely funded by the public, with its promise of hope, has been seriously tarnished by the act of a few, careless at best and dishonest at worst, investigators in what has been called: "the greatest scientific scandal of our age."[77] Climategate undermines science, as stated in the *Wall Street Journal* article "Climategate: Science is Dying"[78]:

"Everyone working in science, no matter their politics, has a stake in cleaning up the mess revealed by the East Anglia emails. Science is on the credibility bubble. If it pops, centuries of what we understand to be the role of science go with it."

The authority of science is gravely damaged by this fraud and the public may conclude that science is merely another 'faction' – nothing but opinion. The consequences of this profound ethical breach for medicine are obvious.

Chapter 5

Proving the Point: Evidence-Based Medicine in Pediatric Critical Care

R. Scott Watson, Mary E. Hartman, and Derek C. Angus

"Not all clinicians need to appraise evidence from scratch, but all need some skills."[1]

PEARLS

- All physicians have an ethical and clinical obligation to use the best available evidence whenever applicable.
- The evidence base for critical care is growing rapidly.
- Practicing evidence-based medicine is straightforward, and keeping up with relevant evidence is becoming easier and less time consuming.
- PubMed now includes research methodology filters (found under the "Clinical Queries" heading) that enhance the efficiency of searching the literature.
- Multiple evidence-based medicine–related resources also can be found on the Internet.

What is evidence-based medicine (EBM)? How is it different from what we have always done? EBM is simply the integration of the best available evidence with individual clinical expertise and patient preferences.[2] The definition is not complicated, and one could easily make the incorrect assumption that its practice is, and always has been, ubiquitous. However, proven interventions are often misapplied, and striking variations in clinical practice (not attributable to patient differences) occur even when high-quality evidence is available.[3-8] Practicing EBM in critical care in general and pediatric critical care in particular poses unique challenges. Decisions that can have profound implications for a child and his or her family must be made quickly and, until recently, with little good external evidence. However, pediatric critical care and EBM both have matured to the point that EBM is an indispensable and realistic component of optimal practice.

Despite decades of international support and growth, the practice of EBM continues to be hindered by misconceptions. It is not "cookbook medicine" that suppresses the individual freedom of practitioners.[9] (To the contrary, EBM relies on individual clinicians to accurately identify clinical situations to which external evidence can be applied.) It is not a cost-cutting tool. Treatments found to be effective may be more expensive than the previous standard of care. It is not unrealistic to think that physicians in the "real world" can practice it. Criticisms that EBM is too difficult and time consuming may have been valid in the past, but advances in literature search engines and the increasing availability of EBM resources make it accessible and applicable for busy clinicians.

This chapter provides an overview of the steps in practicing EBM, including a summary of common study types, information about many excellent EBM-related resources, and definitions of selected terms used in EBM (Appendix 5A, available online at http://www.expertconsult.com). EBM is here to stay, and the field of critical care is in the midst of a groundswell of outstanding clinical research that is improving the outcome of critically ill patients. Our goal is to demystify the process of EBM so that pediatric intensivists can keep up with these changes, understand EBM, and incorporate it as a fundamental element in their practice.

The Evidence-Based Medicine Process

The steps in the EBM process are straightforward: (1) define the problem, (2) search for relevant evidence, (3) evaluate the evidence, and (4) apply the evidence.

1. Define the problem

   EBM starts with a well-built clinical question that is constructed to facilitate an efficient literature search (see http://www.cebm.net).[10] The question needs to clearly state the patient population; the intervention(s), event(s), or exposure(s); and the outcome of interest. These steps were codified by Doig and Simpson[10] in the simple mnemonic PICO: ***p***opulation, ***i***ntervention, ***c***omparison, and ***o***utcome. Focusing the question is key because it enables identification of relevant search terms (described below).

2. Search for relevant evidence

   Keeping up with the basic pediatric literature alone would require reading at least five articles per day, 365 days per year.[11] The objective of searching the literature is to find the answer to the clinical question as quickly and efficiently as possible amidst the 20,000 medical journals and more than 2 million articles published annually.[12] To hone in on relevant articles, a search strategy should take advantage of Medical Subject Headings (MeSH) and incorporate new and useful filters that have been developed. Taking advantage of specific combinations of MeSH terms has been found to increase the speed and effectiveness of searches.[13]

MeSH are descriptive terms assigned to each bibliographic reference in Medline by the National Library of Medicine. There are 25,186 terms organized into a hierarchical structure (http://www.nlm.nih.gov/mesh/meshhome.html). At the most general level are very broad headings such as "Diseases" or "Organisms." More specific headings are found at more narrow levels of the 11-level hierarchy, such as "Sepsis" and "*Neisseria meningitidis*." Thousands of cross-references also exist that assist in finding the most appropriate MeSH (e.g., "MODS, see Multiple Organ Failure").

So that clinicians need not memorize complicated combinations of search terms, search engines have incorporated many of these terms into easy-to-use research methodology filters for clinicians. These filters are combinations of search terms that can increase searching efficiency. PubMed, for example, allows searchers to select filters for studies of etiology, diagnosis, therapy, and prognosis. Similar filters can be found in Ovid Technologies' search engine, in addition to filters on clinical prediction guides, qualitative studies, costs, and economics. In both, the choices are presented under the "Clinical Queries" heading. Searchers can choose among highly sensitive searches to produce comprehensive retrievals (particularly useful for subjects in which little work has been done), highly specific searches to retrieve only the most rigorous studies and little nonrelevant material (for subjects in which much work has been published), or optimized searches to maximize the tradeoff between sensitivity and specificity.

In addition to Medline, multiple other specialized databases and Internet-based resources are available that can yield relevant results quickly. Table 5-1 lists a sample of these resources. One of the best known is the Cochrane Library, which contains a large collection of peer-reviewed systematic reviews on a wide variety of health care interventions.[14] It is thoroughly indexed and easily searched. ACP (American College of Physicians) Journal Club and Evidence-Based Medicine are EBM-related journals that are linked for searching through Evidence-Based Medicine Reviews (EBMR) from Ovid Technologies. The British Medical Journal publishes *Clinical Evidence*, an annual compilation in book and CD-ROM format of the best available evidence on the effects of common medical interventions. In addition, the PedsCCM Evidence-Based Journal Club posts critical reviews of studies related to pediatric critical care.

3. Evaluate the evidence

After a search yields potentially useful evidence, the clinician must evaluate the evidence and determine its scientific validity and clinical utility. For a piece of evidence to be useful, it must be valid, have clinically important findings, and be applicable to the particular patient. Guides for assessment of validity, such as those shown in Box 5-1, exist for different types of studies. Worksheets to determine whether a study is valid are available from a number of sources, including the Centre for Evidence-Based Medicine and a number of the Web sites listed in Table 5-1.

Study Types

The type of clinical question determines what kinds of studies are most relevant. For example, questions about therapy usually are best answered with a randomized controlled trial (RCT) or systematic review. On the other hand, to determine the prevalence of a disease or risk factors for its development, observational studies are needed.

Interventional Studies

Interventional studies are clinical experiments, the strongest of which is the RCT. RCTs are the gold standard in the assessment of the efficacy of an intervention.[15,16] Randomization minimizes the risk of an unequal distribution of known and unknown factors (confounders) that may influence patient outcome. The presence of a control group helps distinguish changes in outcome that result from the therapy in question from changes that otherwise would have occurred. Because of their high cost, RCTs usually are designed to maximize the likelihood of finding a positive effect. Therefore they tend to be efficacy studies, with highly selected patient populations treated by experienced providers. The effectiveness of a therapy as used in general practice often requires additional study, usually through subsequent observational studies.[17] In addition, many questions cannot be answered, either ethically or practically, by an RCT, such as the effect of intensivists on patient outcomes.

Observational Studies

The principal alternative to interventional studies involves observation rather than experimentation. Observational studies are powerful tools for addressing many questions that RCTs cannot and for generating hypotheses that can be tested in interventional trials. For example, they can elucidate epidemiologic characteristics and prognosis of diseases or effects of organizational characteristics on outcome. They can provide information on a treatment's effectiveness (as opposed to efficacy) and determine cost effectiveness. They have become increasingly sophisticated in design and execution, but, as with all study types, they have limitations. Confounding may be difficult to control, and even if known confounders are well controlled, unknown or unmeasured confounders may influence study results. Selection of an appropriate control group is crucial but can be difficult. If conducted retrospectively, observational studies are subject to recall and selection bias.

Different kinds of observational studies are designed to address different types of questions. These kinds of studies include case-control studies, cross-sectional surveys, and cohort studies. In case-control studies, researchers compare subjects with a particular outcome (the cases) to subjects who do not have the outcome (control subjects). Ideally, the case subjects and control subjects are identical except for (1) the outcome of interest and (2) the risk factor or exposure that leads to the outcome of interest. With such a study, risk factors or exposures that are responsible for the outcome (e.g., smoking as a risk factor for lung cancer) can be identified. Of course, finding groups of patients that are so nearly identical is impossible. However, well-done case-control studies that include rigorously selected case subjects and control subjects can be extremely informative. They often are the only feasible study method for uncommon outcomes or when the lag time between an exposure and outcome is very long.

Cross-sectional studies provide a snapshot of a population at one point in time. They can identify the prevalence, or frequency, of a condition, such as the frequency of sepsis among patients in an intensive care unit. They are relatively inexpensive and can be conducted in a short time. Cross-sectional studies usually establish only association, not causality.

In cohort studies, researchers follow a group of subjects through time, recording exposures and outcomes. Cohort studies have a number of strengths, including the ability to establish the timing and sequence of events and provide population-based results. The best cohort studies measure exposures and outcomes in a blinded, objective manner, have long and complete follow-up, and identify known confounders. One of the most famous and successful cohort studies in the United States is the Framingham Heart Study, which fashioned the current medical view of atherosclerotic disease.

Case reports may be the only available information in support of a therapeutic strategy, especially for extremely rare or fatal conditions. In addition, some therapies evolved into the standard of care based on case reports and anecdotes prior to

Box 5–1 Critical Appraisal of a Study of Therapy

Are the results of the study valid?

- Were patients effectively randomized?
- Were all the patients accounted for?
- Was follow-up complete?
- Were patients analyzed according to how they were randomized (i.e., intention to treat)?
- Were all people involved in the study blinded?
- Were the groups similar at the start?
- Were the groups treated equally apart from the experimental intervention?

Are the results clinically useful?

- How large was the treatment effect?
- How precise was the estimate of the treatment effect?
- Are the patients similar to the "norm"?
- Were all clinically important outcomes considered?
- Was a cost-to-benefit analysis performed?

Adapted from Sackett DL, Straus SE, Richardson WS, et al: *Evidence-based medicine: how to practice and teach EBM*, ed 2, London, 2000, Harcourt.

the use of randomized trials. The difficulty generalizing from case reports makes them among the weakest forms of clinical evidence.

Research Summaries

Research summaries that provide a standardized, thorough critique of studies are particularly valuable for busy clinicians. Formal summaries of research are becoming increasingly well done and common. Single studies can be presented in a format called a *critically appraised topic*, which addresses issues of validity and clinical utility in a standardized manner.[18]

Multiple studies of a single topic can be summarized in several different ways. Narrative reviews include traditional review articles and textbooks. A knowledgeable author reviews the literature, formulates an opinion, and disseminates this opinion along with references to support it. Narrative reviews provide a detailed qualitative discussion that usually is easy to comprehend. Unfortunately, the literature is rarely searched and evaluated in an organized, reproducible manner. Textbooks are well organized and synthesize tremendous amounts of information. However, because of the inherent lag in publishing times, they can be an unreliable source of current information. There is no way to ensure that the evidence is complete or that it receives an unbiased critique. For example, in 1988, pooled data from nearly 9000 patients in 15 studies on the use of prophylactic lidocaine in patients with acute myocardial infarction showed that the practice was useless at best. Nonetheless, in 1990, narrative review articles and textbooks still contained more recommendations for the use of prophylactic lidocaine than against it.[19]

A systematic review combines the results of multiple studies through the systematic search, assembly, and appraisal of primary research. Systematic reviews are an exhaustive effort to find all related information in a given area. Criteria for reviews to be systematic, as opposed to narrative, are explicit. Search criteria, including the inclusion and exclusion criteria for individual studies, are predefined. The methods section provides search terms and key words to establish reproducibility. They can provide an excellent summary of the literature up to the date of the review. The main disadvantage of systematic reviews is that they are only as good as the studies they include. However, even when the studies are weak, systematic reviews can be an important means by which to identify gaps in evidence and thus outline a research agenda.

In a meta-analysis, data are combined from multiple studies to yield a quantitative summary. If the combined studies use similar methodology and are of high quality, meta-analyses can increase the power to find an effect. However, difficulties in interpretation of summary statistics arise when meta-analyses combine studies that vary in quality, population, or intervention.

Levels of Evidence

One of the most widely used taxonomies for classifying evidence and clinical recommendations comes from the Oxford Centre for Evidence-Based Medicine (Appendix 5B, available online at http://www.expertconsult.com). Each study can be assigned a level of evidence based on its design and quality. For a given topic, the quality of the entire body of evidence forms the basis for the strength (or grade) of a clinical recommendation. The best studies are level 1a evidence (systematic reviews of studies using similar methods), and the worst studies are level 5 evidence (expert opinion). Clinical recommendations then are graded from A (consistent level 1 evidence) to D (level 5 evidence or troublingly inconsistent or inconclusive studies).

Apply the Evidence

The strongest evidence is useless unless it is effectively applied. Bedside decision making has been the traditional focus of EBM. Clinicians must use their knowledge and experience to understand how the results of studies can be applied to individual patients. With evidence in hand, a clinician practicing EBM will place it in the context of the specific clinical circumstances and the patient's (or guardian's) preferences.[20] Patient characteristics or preferences may be sufficiently unique to render even good evidence inapplicable.

EBM can be implemented on a larger scale through clinical practice guidelines and clinical pathways, which can disseminate and promote best practice at institutional, regional, or national levels. They are especially useful for common illnesses and procedures, and they allow implementation of EBM even when individual physicians are unable to incorporate evidence by themselves because of a lack of either time or expertise. The most compelling guidelines contain a summary of the evidence both for and against the guideline and how to apply the recommendations to specific clinical situations.[18] Recently, the Centers for Medicare and Medicaid Services have begun to link reimbursement for the treatment of some conditions with the provision of elements of care thought to be essential based on extensive bodies of evidence (such as the timely administration of antibiotics for pneumonia).

Challenges to Evidence-Based Medicine

It is impossible to practice EBM without evidence. Until recently, a paucity of strong evidence existed in support of particular care paradigms in the critically ill, with even less evidence related to critically ill children. A growing number of studies now offer guidance on a wide set of critical

care problems.[21] However, much of our care remains largely empiric. A basic tenet of EBM is that a lack of evidence that an intervention is effective is not proof that an intervention is ineffective (i.e., "Absence of evidence is not evidence of absence"). This issue is particularly relevant to pediatric critical care, in which numerous therapies are used without proven efficacy, and the evidence base for many other therapies is from studies of adults. Whether unproven therapies should be used depends on (1) whether proven alternatives are available, (2) the likelihood and magnitude of potential harm from the therapy, (3) the natural history of the disease or condition being treated, (4) in the case of prophylaxis, the risk of developing disease, and (5) the cost of treatment (as well as the cost of not treating the patient).

Even for therapies proven to be effective, clinicians must weigh the potential risks and benefits for a given patient. Evidence-based guidelines can be useful in helping clinicians and patients make these decisions, but they cannot take the place of clinical judgment. Treatments that are proven to be useless or harmful should be avoided, of course. However, restrictions on existing therapy solely on the grounds that the therapy is unproven are generally inappropriate.

In the absence of practice guidelines and clinical pathways, EBM relies on individual clinician skill and initiative. Unfortunately, each step of EBM practice can be challenging, particularly for clinicians with little EBM experience. Generating specific, patient-centered questions is difficult. Because of the relative paucity of available evidence, searching for the right article can be akin to searching for a needle in a haystack. Fortunately, electronic databases are increasingly user friendly and efficient. The culture of medicine and the methodology of EBM are changing to put applicable, understandable evidence at the fingertips of clinicians.

Conclusion

The practice of critical care is changing constantly, but studies documenting remarkable practice variation suggest that the change is much too inconsistent. Intensivists tend to be resourceful, creative, efficient, and comfortable with applying clinical skills to desperate circumstances amidst a paucity of evidence. Although critical care physicians often have both the predilection and facility for making important decisions quickly and independently, that same temperament may impede the acquisition and application of a growing body of evidence related to critical illness and critical care.

All physicians have an ethical responsibility to apply EBM. Meticulously designed and executed clinical research is expensive and difficult to perform. Society expends scarce resources on it. Subjects in clinical trials face significant personal risks in hopes of a better outcome and for the advancement of knowledge. Our responsibility extends beyond individual patients, for whom the benefits of using the best available treatment usually are clear. We owe it to subjects of prior trials, researchers who carried out the trials, and the society that supported them to use and build on the knowledge gained. The unique vulnerability of critically ill patients, with their significant risk of death or long-term morbidity, creates perhaps a stronger ethical imperative for intensivists to use evidence whenever it is available. When evidence is inadequate, we are left to do our best with our clinical expertise for our current patient and to generate the evidence needed for future patients.

Chapter 6

Outcomes in Pediatric Critical Care Medicine: Implications for Health Services Research and Patient Care

Anthony D. Slonim, James P. Marcin, and Murray M. Pollack

PEARLS

- Quality improvement seeks to improve care while health services research seeks to advance knowledge and identify best practices.
- Ensuring quality is an important aspect of delivering critical care services to children, and clinical outcomes are an important measure of the quality, safety, and effectiveness of care.
- A framework that integrates pediatric intensive care into "Systems of Care" is helpful for organizing and improving the delivery of services to patients and assuring that they receive the best possible care.

Quality in health care has received increasing attention over the last several decades. This focus has been particularly apparent over the last 10 to 15 years and has captured the attention of clinicians, managers, executives, insurers, and policy makers.[1,2] Unfortunately, much of the discourse has been vague, and clinicians, in particular, may not fully understand how quality is defined, what it means to their patients, and how it can be incorporated into their daily practice.

Pediatric critical care medicine (PCCM) has experienced challenges similar to those of other disciplines in attempting to quantify clinical outcomes. As physicians, we are biased in our assessments by our knowledge and experience. Physicians rarely have sufficient objective and quantifiable data to make decisions about outcomes, except perhaps at the extremes of illness severity. Often, there is insufficient time for understanding how clinical decisions are made, how care is delivered, and how to evaluate the achieved outcomes. Without the evaluative step, we fall short in identifying opportunities to improve our care. While physicians certainly do influence the ultimate outcomes of the critically ill child, the system of care includes important contributions by other clinical team members and non-human factors that can also influence quality and outcomes.[3]

This chapter provides a framework for understanding outcomes from critical illness for the acutely ill or injured child and considers mechanisms for contributing to new knowledge through health services research (HSR) methods.

What Is Health Services Research?

Health services research (HSR) is a field of inquiry that is concerned with the creation of new knowledge related to the organization and delivery of health care services and their outcomes.[4,5] A number of formal definitions have been provided by leading organizations over the last several decades and demonstrate how the conceptualization of HSR has evolved with time and become more comprehensive (Table 6-1).[6-8]

The discipline of HSR has relevance for social science fields like health policy and economics as well as for clinical disciplines like PCCM. This section will focus on how pediatric critical care is organized and how bedside care can be used to explore differences in treatments and outcomes within and across pediatric intensive care units (PICUs), hospitals, regions, and populations, so that new knowledge is generated, shared with colleagues, and applied. The results of HSR can also inform policy decisions that can influence the organization, financing, and structure of health care delivery for critically ill children.[4]

A System of Care

An organized and methodical system of care is necessary to ensure that critically ill children receive care that is of the highest quality.[9] This begins prior to the time when the services are actually needed and relies upon a primary care structure that ensures children can benefit from preventive strategies designed to keep them healthy. There are important strategies that are necessary for assuring childhood health including adequate nutrition, appropriate vaccinations, and easy access to clinicians for acute minor illnesses and injuries,

necessary medications, and follow-up care for chronic conditions. Unfortunately, in some settings, the capacity to manage pediatric health prior to acute illness is lacking. The result is that timely delivery of services cannot be ensured and an unnecessary burden is placed upon emergency department (ED) services.[10]

The provision of health care is complex and requires appropriate organization. The study and evaluation of the organization of care, as is accomplished using HSR methods, provides some of the most fertile ground for generating new knowledge and identifying opportunities to improve outcomes for critically ill children.[4,5] Some believe that this organization, particularly for high-end pediatric clinical services like pediatric critical care, should be highly regionalized (Figure 6-1). There are a number of good reasons to favor regionalizing care, including the need to reduce unnecessary variation and improve outcomes and resource use, both from a structural (e.g., ICUs, bed numbers) and a human perspective (e.g., manpower issues). However the term 'regionalization' does not convey one of the most important aspects of PICU care related to outcomes—integration of care. Regionalizing care will prove to be insufficient for generating good outcomes if care from the child's immediate environment to the tertiary or quaternary hospital is not integrated, and if there is not shared accountability for outcomes at the population level.

Most states have coordinated systems for supporting the care of the acutely ill or injured patient on a regional basis.[11] This is good news, but unless the regional care structures are integrated into a hierarchically arranged system of care based upon increasing patient complexity, outcomes may fall short. In an integrated model, children with acute illness can gain access to the health care system through a number of different access points and be cared for by appropriately trained personnel at each level of care.[10] For those children whose condition deteriorates or whose care needs become more complex with time, the system's integrated components can assure that the child's and family's needs are met in a timely and seamless manner by progression through the integrated system with established measures of performance.[12] The investigation of how the health care system is organized, how the system's components operate, how it is funded, and what alternatives may work better are fundamental HSR analyses.

Organizing Health Systems

Systems represent a concept of an "integrated whole" that is dependent upon components and the relationships of those components to one another both inside and outside of the system for the successful delivery of outputs (or outcomes if the system under investigation is health care).[13-15] Systems have structure, and this structure provides a framework to organize the components into a hierarchical arrangement, known as *microsystems* and *macrosystems*, that helps to provide an understanding of the components' relationships to one another.[13-15]

While these terms might imply two different levels of functioning, there are multiple levels of embedded hierarchy that can be described between the microsystem and macrosystem levels.[13-15] This approach is useful for describing the complex care required by the critically ill child in the PICU; it provides important opportunities to consider, study, and improve care more broadly for pediatric patient populations, as would be performed in HSR.[4-5] To succeed with this approach, the interdependent components of systems need to be considered and criteria-based quality measurement and improvement need to be operationalized within and between the levels of the system's hierarchy.[16] These relationships among and between the system's components have important implications for addressing both the quality of care and HSR questions.

Microsystems and Macrosystems

Microsystems

A system's hierarchy can be collapsed to the frame of reference of a single critically ill child and the respective system components that affect that child (Figures 6-2, *A* and *B*). The system components are termed 'microsystems' and, when integrated and functioning appropriately, provide for consistent performance.[13,15] At the unit level, there is a nursing microsystem; a physician microsystem, often with attendings, residents,

Table 6–1 Contemporary Definitions of Health Services Research

Source	Year	Definition
Agency for Healthcare Research and Quality	2002	Health services research examines how people get access to health care, how much care costs, and what happens to patients as a result of this care. The main goals of health services research are to identify the most effective ways to organize, manage, finance, and deliver high quality care; reduce medical errors; and improve patient safety.
Academy for Health Services Research and Health Policy	2000	Health services research is the multidisciplinary field of scientific investigation that studies how social factors, financing systems, organizational structures and processes, health technologies, and personal behaviors affect access to health care, the quality and cost of health care, and ultimately our health and well-being. Its research domains are individuals, families, organizations, institutions, communities, and populations.
Institute of Medicine	1995	Health services research is a multidisciplinary field of inquiry, both basic and applied, that examines the use, costs, quality, accessibility, delivery, organization, financing, and outcomes of health care services to increase knowledge and understanding of the structure, processes, and effects of health services for individuals and populations.
Institute of Medicine	1979	Health services research is inquiry to produce knowledge about the structure, processes, or effects of personal health services. A study is classified as health services research if it satisfies two criteria: it deals with some features of the structure, processes, or effects of personal health services. At least one of the features is related to a conceptual framework other than that of contemporary applied biomedical science.

and fellows; and microsystems for providing respiratory care, social work, radiology, and laboratory services.[13,15] Each of these microsystems operates within a broader framework for providing care across hospital units, or even across hospitals or the population (Figure 6-2, *A* to *C*). When components within these systems fail, the child and family may experience adverse events, safety problems, errors, excessively long lengths of stay (LOS), or even unnecessary death, and the family's perception of the experience is suboptimal.[17,18] Normally, these systems function quite well, given their complexity and interdependence; the child achieves a good outcome, and the family is satisfied.

Macrosystems

Variability in performance within microsystems creates problems with performance at the macrosystem level, as care across the different dimensions of quality is aggregated.[18] An analytic approach that capitalizes on the contextual elements of individual microsystems while addressing the broader concerns of the macrosystem's performance is important for understanding and improving the care for the population (Figure 6-2, *B* and *C*).[13-15] Hierarchical modeling and cluster analysis are some of the available analytic tools to improve our understanding of the interaction of system elements that are parallel or at multiple levels of hierarchy.[19] For example, to achieve appropriate estimates of ICU care at the state level (macrosystem), analytic approaches that account for similarities in practice patterns at multiple ICUs within a given hospital (microsystem #1) or within a given city (microsystem #2) because of geographic proximity need to be used. These methods are globally termed hierarchical or multilevel models, because they help to account for biases at multiple levels of the macrosytem.

The six dimensions of quality as described by the Institute of Medicine are operative at both the macrosystem and microsystem levels (Table 6-2).[1-2] While the prior section was focused on improving the clinicians' understanding of how new knowledge can be generated through HSR methods, the intent of the following section is to provide an improved understanding of important patient level outcomes in PCCM for quality improvement. The distinction is a bit artificial in that the study of outcomes in the PICU can also be used to generate new knowledge about delivering care at the bedside.

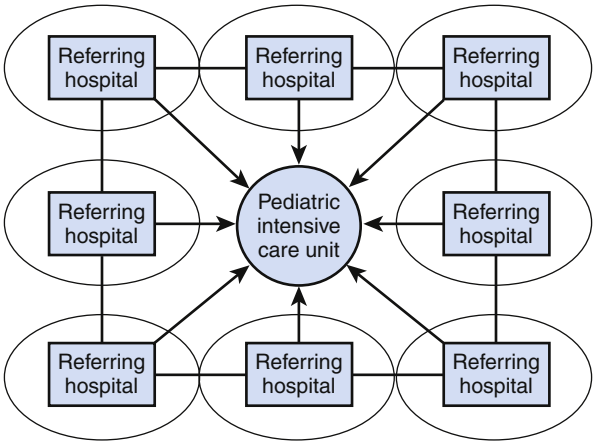

Figure 6–1. Hub and spoke model for regionalizing pediatric critical care services that assures integration for children within and across communities served by local hospitals.

The Macrosystem: Pediatric Critical Care

The three major focus areas of interest for considering pediatric critical care at the macrosystem level are access, quality, and cost. These areas also provide an important framework for considering the organization and delivery of care for the critically ill child at the macrosystem level. Figure 6-3 provides a schematic overview of how the critically ill or injured child

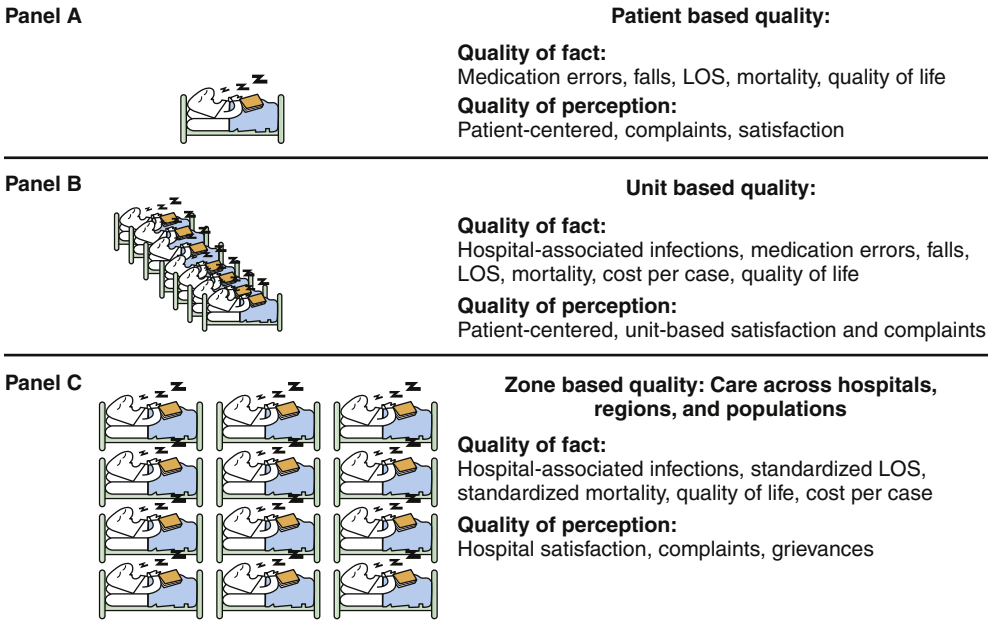

Figure 6–2. A depiction of three levels of organizing care at the microsystem level for pediatric critical care, and examples of outcomes in fact and perception associated with each level. A represents the outcomes focused on the patient level. B represents the outcomes focused on the unit level. C represents the outcomes beyond the intensive care unit.

experiences the health care system. While this figure represents a somewhat linear depiction of these care experiences, the reader is reminded that there is considerable overlap and interaction between the different elements of the system.

Access

Access represents the entry point into the health care system for those seeking care. For children, access represents the availability of appropriate services and financing to ensure that children are able to see providers with the knowledge, skills, and abilities to deliver care appropriately.[4] Care needs for children are different from those of adults and require specific considerations for the acutely ill or injured child.

Access to pediatric expertise for anticipatory care and acute care is important. At the policy level, access depends on an adequate number of pediatric providers distributed in a way that assures appropriate primary care. The medical home is one model that attempts to anchor children with primary care providers who act on behalf of the child to organize and coordinate their care.[20-22] With this model, age-appropriate anticipatory guidance for health concerns is provided, and vulnerabilities such as underimmunization, obesity, and risk-taking behaviors can be addressed proactively. When a child becomes ill, it is important to have access to providers and services for timely intervention and referral without the need to use other system structures (e.g., EDs). This ensures that care be provided at the most appropriate entry level, thereby saving higher-level resources for those most likely to benefit. This has important implications for the critically ill child.

Acutely ill children can decompensate quickly. Resources to care for these children also must be organized in a way that allows the child to receive lifesaving and resuscitative care immediately (see Figure 6-3). Considerable improvements in prehospital emergency care of children have been undertaken over the last several decades.[11] These improvements have been aimed at assuring that community-based prehospital providers have the pediatric training and equipment to deliver appropriate care and safely deliver the child to appropriate ED resources.[11]

While access points like EDs are readily available in many communities, they may not be staffed or equipped to provide specialty care for acutely ill or injured children.[10] Emergency care for children is an example of one 'specialized care area' that is notable for considerable variation in ED readiness and provider training for pediatric emergencies.[10] Of the more than 30 million pediatric ED encounters annually in the US, only 18% are provided at pediatric EDs.[10] Children have important differences in their anatomy, metabolic demands, and disease processes that make the expertise and equipment for their diagnosis and treatment different than those for adults. Unfortunately, only 6% of all EDs nationally had the necessary supplies for pediatric emergencies.[10] In addition, there are unique emotional and developmental considerations that need to be accounted for when caring for acutely

Table 6–2 The Institute of Medicine's Aims of Quality

Quality Aim	Definition
Safety	To limit the unintentional harm associated with the delivery of health care
Effectiveness	To use evidence-based practices, the best scientific evidence, clinical expertise, and patient values to achieve the best outcomes for patients
Efficiency	To provide care that is done well and with limited waste
Equity	To provide care that is free from bias related to personal demographics like gender, race, ethnicity, insurance status, or income
Timeliness	To provide care without unnecessary wait and to assure that patients have access to the care they need
Patient-centeredness	To provide care that reflects a focus on the patient's needs, including empathy, compassion, and respect

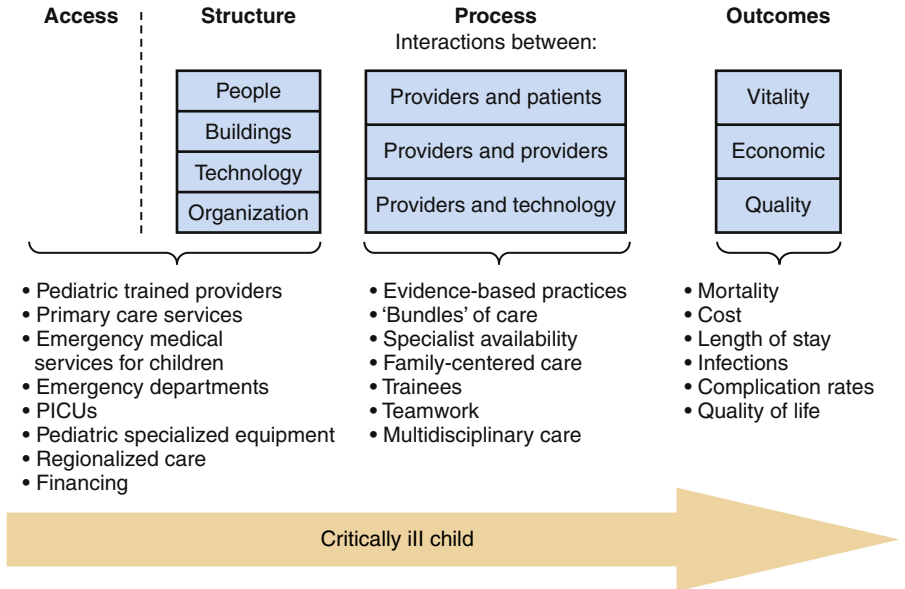

Figure 6–3. The macrosystem of care for the critically ill child, demonstrating the major components of access, structure, process, and outcome.

ill children and their families in the ED, and this expertise may not be present in all EDs. Hence, when confronted with acute, severe, complex, and infrequently encountered pediatric emergencies, long delays may be experienced before definitive critical care services and expertise are available and provided to the child. Given a child's limited ability to compensate during a physiologic crisis, these delays in care lead can potentially lead to worse outcomes.

Quality

Quality is defined as the degree to which health care services for individuals and populations increase the likelihood of desired outcomes and are consistent with current professional knowledge. Donabedian's seminal work described three major components of quality structure, which were first applied to health care in the mid 1970s and continue to provide a useful framework for quality improvement and health services research.[23-24]

Structure

Structure represents the organization of health care services, including the "bricks and mortar," personnel, and technology required to deliver care (Figure 6-3).[23] The modern PICU is staffed with a multidisciplinary team of providers with the availability of specialized expertise and technology to care for the critically ill child. The organization of pediatric critical care services is important to consider, given how they function as access points to personnel with the expertise to use advanced lifesaving technologies for critically ill children. There are several examples from our colleagues in other disciplines where systems of care have emerged and been organized at the macrosystem level for the benefit of patients, with improved outcomes. Specialized cancer centers and trauma centers are two notable examples, but even within the discipline of critical care medicine, pediatric critical care and neonatal critical care have operated, almost since their inception, with an organized and systematic approach.

A similar system of hierarchically arranging critical care for the pediatric patient, based upon increasing complexity and documented guidelines for critical care services and personnel at each level of care, can be envisioned at the macrosystem level. The provision of multidisciplinary critical care has improved the safety, quality, and efficiency of care in the ICU. However, despite these efforts, several challenges remain. First, in-house critical care attending physicians at regional centers improve the quality of care and patient and physician satisfaction in ways that are simply unavailable at smaller facilities. However, there is a disparity between the number of ICU beds and the supply of qualified intensivists, which is likely to become even more apparent as hospitals attempt to meet staffing recommendations of groups such as Leapfrog.[25] Second, critical illness represents a spectrum of disease severity that by its nature introduces variability at both the provider and institution levels. What is really needed to overcome the problems of a fragmented system is a solution that is designed and integrated in a way that allows national standards of care to get to the bedside at the local level in the near future. A system that is structured to provide highly integrated, well-coordinated care, of the highest quality based upon current scientific knowledge, and the most cost effective, should be the goal of any macrosystem.

While PICUs are neither distributed uniformly nor provide the same level of care, one approach for expanding the scope of services to communities without PICUs, while maintaining a central core of specialized expertise is the "hub and spoke" model (see Figure 6-1). This model depends upon a regional referral base that has the appropriate structures, including appropriately trained personnel, equipment, and knowledge, to identify, resuscitate, stabilize, and perhaps even care for, moderate degrees of pediatric illness. When the child's care needs outstrip the capabilities of these referring institutions, organized interhospital transportation services are available from a central hub to provide immediate access to care for those children who need it. This approach accomplishes several things. First, it improves access to specialized care for moderate-severity pediatric conditions for children in the communities in which they live. Second, it provides an organized and readily accessible access point for children who may become severely ill and require services and technologies unavailable on a widespread basis because of the cost of maintaining them. Third, this approach ensures the expertise of the core PICU because large volumes of patients with severe illness are needed to maintain specialized expertise. Finally, system level efficiencies allow the appropriate care to be delivered in a cost-effective manner in locations that are equipped to deal with them (see Figure 6-1).

Process

Donabedian described processes of care as the interactions between providers and patients that effectuate the delivery of care (see Figure 6-3).[23-24] Of importance, PCCM is highly dependent both on personnel and technology, but neither one of these structural components alone will assure the delivery of appropriate care. Only when trained personnel are provided with technology that is working appropriately and in adequate supply can quality be ensured.[18] For example, the most highly trained intensive care team including an intensivist, nurses, pharmacists, respiratory therapists, and social workers will be unable to sufficiently care for a critically ill child with respiratory failure if they do not have access to appropriate ventilators. Similarly, a ventilator, without appropriately trained personnel will also be insufficient for delivering care.

While Donabedian was primarily interested in the care processes that involved provider-patient interactions, with the evolution of PCCM there is now recognition that the provider-technology processes and the provider-provider processes represented by teamwork are also essential elements of this care delivery.

Pediatric critical care services are heavily dependent upon technologies for the delivery of care. A large component of critical care training is focused on the ability to assess, diagnose, and treat the critically ill or injured child. The training consists of significant experience in using life-sustaining technologies that are aimed at supporting the child's failed organ systems until they are once again able to compensate on their own. Critical care clinicians need to know how to initiate and discontinue these supports for the benefit of their patients as well as investigate problems that occur during their use.[18] The interactions between the clinician and the equipment are important to understand if there is to be success in achieving desired outcomes. For example, a clinician caring for a critically ill child with respiratory failure who is unable to troubleshoot the alarms or address malfunctions in the equipment

will be providing a substandard approach to care. Even simple devices like intravenous infusion pumps require the clinician to be trained and educated to more fully understand the opportunities for error.

The multidisciplinary clinical team that integrates with the family in shared decision making is essential to ensure quality for the child.[18] A team consists of two or more individuals with specialized knowledge and skills who are assigned to interdependent roles and tasks allowing them to accomplish a specific goal. When functioning well, teams can improve safety, and compensate for faulty system design and process failures. The care of a critically ill patient depends heavily on the assurance of good system design, knowledge, skills, and teamwork. In the ICU setting, Pronovost and colleagues identified teamwork and communication between nurses and doctors as critical 'nontechnical skills' for preventing harm to ICU patients.[26] However, there are limited data regarding teamwork and its effect on safety in the pediatric intensive care unit.

The PICU has historically been a place where the necessary knowledge and skills to care for critically ill children are present. Improvements in PICU design have fostered safer and more family-centered care. However, empirical evidence regarding the importance of teamwork and communication on patient care in the PICU is limited. Some foundational work that seeks to understand the attitudes of pediatric critical care providers towards teamwork have been performed.[27] In addition, there are some important examples that highlight how team performance can help to compensate for inadequacies in clinical performance in the care of pediatric patients, particularly in those team members that are less familiar in caring for children.[28]

Outcomes

The end result of the health care experience is reflected by health outcomes, which are usually considered in three major categories: vitality outcomes, economic outcomes, and quality outcomes (see Figure 6-3). Regardless of the category, outcomes should be objective and clearly defined. Quantitative estimates of clinical status must be used to assist with the evaluation of outcomes across different patient populations or ICUs. For critical care, this has been accomplished through the use of scoring systems that account for variability in patient case mix.

Survival and death have been the primary vitality outcome measures used in neonatal, pediatric, and adult ICUs. They occur with sufficient frequency in ICU settings, are well-defined, and are clearly important. Physiology-based estimates of mortality exist for each of these three ICU patient populations.

Neonatal Intensive Care Unit Mortality Scores. The Clinical Risk Index for Babies (CRIB) and the Score for Neonatal Acute Physiology (SNAP)[29] are two physiology-based mortality scores for neonates. CRIB was developed in the United Kingdom, before the widespread use of antenatal steroids and surfactant, for infants weighing less than 1500 g.[30,31] Six commonly measured variables, some of which are subject to physician practices, are collected within the first 12 hours of birth. SNAP II is a physiology-based score for neonatal severity of illness developed from large samples from United States and Canada. SNAP II has also been modified for use as a mortality prediction model (SNAPPE II) by the addition of variables including birth weight, small-for-gestational-age, and low Apgar scores.[32]

Pediatric Intensive Care Unit Mortality Scores. The two most commonly used severity-of-illness scores in pediatrics are PRISM and the Pediatric Index of Mortality (PIM). PRISM is now a third-generation score (PRISM III) developed from more than 11,000 patients in 32 PICUs, with the most recent recalibration being performed on more than 19,000 patients.[33,34] Mortality predictions can be made using the first 12 hours (PRISM III-12) or 24 hours (PRISM III-24) of physiologic variables and laboratory and diagnostic data. It is unique in that it can predict both mortality and LOS.[35]

PIM was developed on 5695 patients from Australian PICUs and one British PICU. It was developed using physiologic and laboratory data available upon patient presentation.[36] This was intended to eliminate the theoretical concern of lead-time bias, the concept that therapies initiated prior to the stabilization of the patient would alter a severity score that used physiologic measures obtained within the first 12 or 24 hours.[37] Thus models such as PRISM III that use data collected over the first 12 or 24 hours after admission might be affected by the quality of the initial pre-PICU management and thus affect the predicted mortality. The PIM score uses data collected from the time the ICU team first contacts the patient (e.g., in the ED or in transport) and through the first hours of PICU care. PIM includes mechanical ventilation as a predictor variable and as a result introduces the biases associated with the use of mechanical ventilation throughout the health care system, including the prehospital and emergency department settings into the prediction models. Although PRISM has been externally validated by other national and international PICUs, PIM has not been extensively tested in the United States.

There has been concern by many that the focus on death may miss other important outcome measures, such as disability. Measurement of serious disability has been a difficult problem in pediatrics because it is difficult to define, and there is wide variability in physician estimates of disability. The Pediatric Overall Performance Category (POPC) and Pediatric Cerebral Performance Category (PCPC) scores are global assessments that can quantify overall morbidity and cognitive impairment specifically for children.[38-40] Differences between baseline and discharge POPC and PCPC scores have been associated with morbidity, length of PICU stay, total hospital charges, discharge care needs, and summary measures of severity of illness. These scores do correlate with neuropsychological tests at hospital discharge, the Stanford-Binet Intelligence Scale IV, and the Vineland Adaptive Behavior Scales at 1 and 6 months postdischarge follow-up. Unfortunately, these scores depend upon the providers' estimates of the disability, which is typically not a core competency of PICU staff, and try to assess children for functional status at a time when the child is heavily dependent on others for their care. Finally, these tests (POPC and PCPC) are not sufficiently precise for use in individual patients. Individuals with the same neuropsychological measure might fall into very different POPC and PCPC groups based on the qualitative assessment of the caregiver's assessment of functioning. However, it appears that other outcomes, such as morbidity and disability, correlate well with the changes that affect mortality.

A new outcome measure, the Functional Status Scale (FSS), was recently developed and validated.[41] This scale is intended for use in large outcome studies of patients across the pediatric age spectrum, from term newborn to adolescents, in a wide range of inpatient environments. It comprises six domains, including mental status, sensory functioning, communication, motor functioning, feeding, and respiratory status, and correlates with adaptive behavior scales that require more time and specific expertise. Scoring in the FSS does not require expertise outside the realm of ICU physicians or nurses, is not subjective, and can be done rapidly. It is likely that this scale will enhance ICU outcome studies, providing significantly richer data related to morbidity and disability.

Economic outcome indicators are increasingly available and useful when evaluating expensive or resource intensive therapies. Several resource outcomes are commonly measured including length of stay, costs, and the use of critical care therapies, such as mechanical ventilation or vasoactive infusions.

Outcomes that relate to the performance or process of care are referred to as quality outcomes. These outcomes include adverse events such as nosocomial infection, surgical complications, and outcomes regarding functionality and health status, including disability as described above.[30]

The Microsystem: Pediatric Intensive Care Unit

The PICU can be considered as either a macrosystem or a microsystem depending upon the components of the system under study, the context, and the questions under consideration. Quality efforts are directed at improving care and outcomes.

Patient Level

An understanding of the fundamental work involved with caring for the acutely ill or injured child is important for advancing a discussion on clinical outcomes at the patient level. Figure 6-4 portrays the direct interactions between the expanded care team and the child and family needing PCCM services prior to and after their arrival in the PICU. A systematic model of outreach that allows appropriate care to be delivered to children where and when it is needed is an important part of this approach. For many locales, this is organized as a "hub and spoke" model (see Figure 6-1) where a PICU supports and integrates the care from a number of regional referring hospitals, assuring timely and efficient access to tertiary or quaternary pediatric services when the child's needs dictate.

Mechanisms for assuring outreach include information for referral hospitals, so that they will know what is available in their region to assist with caring for the child and family. Many hospitals use critical care transportation systems to bring needed services to the child in the community with skilled and experienced guidance from the region's PICU. Patient care dialogues and relationships are fostered in these episodes of care. The result is that referring centers gain valuable backup and expertise, tertiary PICUs are supported through these outreach efforts by an important referral base, and important services are provided to the children, families, and communities being served.

Once the child and family gain access to the PICU, they need to be welcomed, assessed, and triaged to an appropriate level of care (see Figure 6-4). Conditions can change during transport and the child may appear better or worse than the initial reports. The child and family then enter an important series of steps that include introductions to the care team, an assessment and plan of care, the establishment of whether advanced technologies are required, and the planning and delivery of treatment by members of the PICU team (see Figure 6-4). These steps are second nature to many who work in the PICU because they are performed repetitively. However, identifying each of the process steps not only provides an important framework describing the work of bedside care, it also represents the first step in understanding outcomes from critical illness.

At the bedside, the individual child or family experiences these steps in a way that is up close and personal. What may be a rote process for providers is an emotionally charged experience for the child and family. Figure 6-2, *A*, provides an important framework for understanding outcomes at the patient level. Each care episode can be evaluated using a standard quality improvement methodology that allows the care

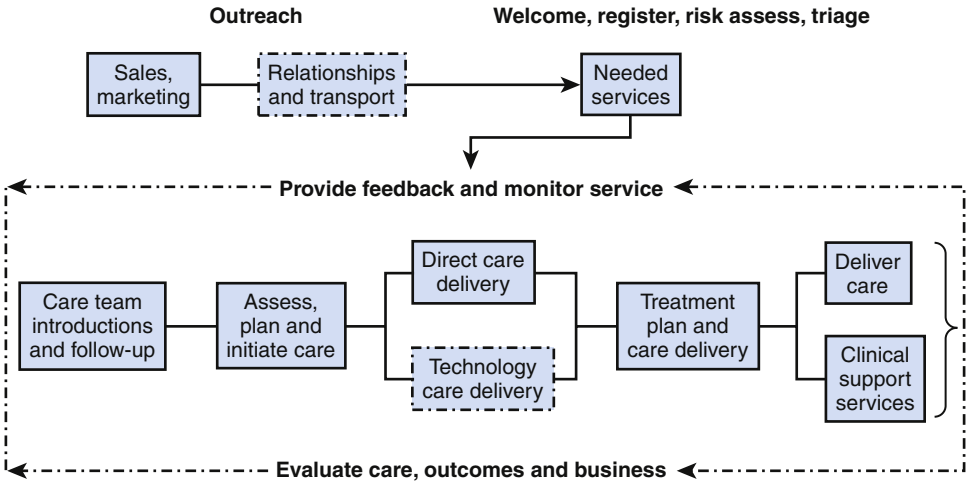

Figure 6–4. The microsystem of care for the critically ill child, demonstrating the major components of outreach, assessing, triaging, delivering, and monitoring care along with the evaluative components of outcomes.

to be measured and improved so that the care experience for the next family might be better.

There are two specific categories of care that can be evaluated at this time (Figure 6-2, *A*). The first category is referred to as *Quality of Perception* and allows the providers to have an improved understanding of how the family experienced the care. Taking the time to elicit feedback about the steps that were difficult, scary, or burdensome is an important opportunity for the family to provide feedback to members of the team. The second category is concerned with Quality of Fact, which is an evaluation of whether or not the child and family's clinical care needs were met. Reflecting on the care and its outcome are important for the team's learning. Did the child die? If so, why? If the child lived, is he or she left with disabilities or chronic conditions affecting quality of life that might have been averted? Were procedures performed appropriately and when needed? Was the referral timely? If yes, did the transport team arrive in a timely manner and provide the necessary services? If not, how can referral hospitals be assisted in knowing when to call for transport? While clinicians tend to be concerned with evaluating the elements of the clinical work, there are important operational components that can affect the delivery of clinical care and which also need to be addressed, including how long the child waited, whether the records and diagnostic studies were immediately available, and how long it took for clinical interventions to occur.

Because the patient is the focal point of these experiences, the measurement tools that are used include straightforward counting statistics. A medication error, a central line infection, a fall, or a complaint can be numerically tallied to provide the team with an understanding of their performance. Considerable practice-based learning can take place in these "n of 1" cycles that allow clinicians to see how their work succeeded or where it perhaps can be improved. The use of both factual and experiential aspects of care is the first step in understanding outcomes at the patient level.

Intensive Care Unit Level

While individual providers and managers are certainly interested in individual outcomes occurring one patient and one bed-space at a time, managers and directors can add value by assisting their teams in understanding aggregate outcomes across individual patients in the same PICU. Figure 6-2, *B* demonstrates how the individual outcomes can be incorporated at the unit or macrosystem level. Both Quality of Perception and Quality of Fact are also operative at the unit level. However, rather than using "counting" statistics to understand performance, "percentage statistics" are used. At the unit level, rates and proportions are used to monitor care over time. For example, medication errors per 1000 doses dispensed, ventilator-associated pneumonias (VAP) per 1000 ventilator days, and the percentage of families rating the care as "excellent" are all commonly used measures to monitor the care in the PICU.

Management and leadership can make a difference in improving PICU care, and the use of data is fundamental to being able to demonstrate improvements over time within a given PICU or in comparison to other PICUs. Whatever outcome measures are considered, they should be objective, clearly defined, reproducible, and account for differences in case mix and severity. While managers may evolve a level of comfort with percentage statistics and macrosystem thinking, individual clinicians may not. One reason for this is that individuals can have difficulty processing these complex rates and understanding how rates can lead to changes in their behavior that improves outcomes. Hence, it becomes important for managers to provide appropriate context for their staff. If the ventilator-associated pneumonia rate is 10 per 1000 vent days and this year's goal is to reduce it to 5 per 1000 vent days, the manager can convert the rate into the number of patients affected. Bedside clinicians can more easily remember the personal connection they had with the child or family who experienced a VAP under their care and are more likely to work to prevent the occurrence of VAP than if the numbers are represented as percentage statistics.

Beyond the Pediatric Intensive Care Unit

Figure 6-2, *C,* provides the next level of comparison for understanding outcomes. Whether the macrosystem analysis is focused at the hospital level, the regional level, or the population level makes little difference, the fundamental constructs of Quality of Fact and Quality of Perception are still operative. The strategy for measurement includes both counting and percentage statistics, as well as a few additional advanced epidemiologic and statistical tools to assist with understanding the delivery of health care across broader geographic regions, populations, or conditions. The use of these statistical tools does little to assist with distinguishing between quality improvement and research. Rather it is the intention of the analyses that helps to distinguish between the two types of work.

Conclusion

Understanding the organization of health care services has important implications for generating new knowledge through the use of HSR methods and actually improving care for critically ill pediatric patients. The quantitative and qualitative approaches used in research and quality improvement are complementary between the two disciplines. However, the clinician needs to have a clear understanding of the intent of the analytic approach and what he or she will do with the findings.

Chapter 7

Safety and Quality Assessment in the Pediatric Intensive Care Unit

Matthew C. Scanlon and Martin K. Wakeham

PEARLS

- The six domains of quality in the pediatric intensive care unit are safety, effectiveness, patient centeredness, timeliness, efficiency, and equity.
- Research demonstrates that errors in health care are often caused by poorly designed systems of care.
- Three essential activities of a patient safety program include risk identification, risk analysis, and risk reduction.

Since the last edition of this book, the importance of quality improvement (QI) and patient safety to pediatric intensive care units (PICUs) has increased. At the same time, the science supporting improvements in QI and patient safety has evolved. Unfortunately, both QI and patient safety draw on knowledge and concepts that are neither part of traditional medical education nor are intuitive. Using real-world examples, this chapter explores important concepts of safety and quality, with an emphasis on pediatric critical care.

A Brief Consideration of the Relationship Between Safety and Quality

Many similarities exist between safety and QI. As a result, there is potential confusion between the two domains. Are they the same? Is safety really applied QI? The Institute of Medicine weighed in on this discussion by identifying safety as a component of quality in the report Crossing the Quality Chasm.[1] Based on this report, safety is a prerequisite to achieving quality. That is, it is impossible to achieve true quality without improving safety. Others who argue that attention to other aspects of quality beyond safety is critical have confirmed this observation.[2] For the pediatric critical care provider, the important point is that safety is a necessary prerequisite for quality, but improving safety is insufficient to achieve quality.

State of Safety and Quality in Pediatric Intensive Care Units

The Institute of Medicine's report, *To Err is Human,* was the first widely recognized publication to identify the scope of preventable medical harm.[3] In response, patient safety and quality was placed on the radar screen of consumers, policy makers, and providers. Perhaps the most visible response from these groups is the focus on measurement as an attempt to drive improvement. Inherent to this is the recognition that adoption and public reporting of performance measures is a necessary (though not sufficient) step to achieving a high-quality health care system.

In PICUs, the increased focus on safety and improvement is evident in three major developments. First, the National Quality Forum endorsed the adoption of and public reporting of six PICU-specific performance measures in May 2008 (Table 7-1).[4] These measures were created based on the recognition that performance measures designed for adult populations may not be appropriate for application to the pediatric populations and settings.[5,6] For many PICUs, measurement and reporting of these endorsed measures is voluntary. However, formal endorsement by the National Quality Forum makes these measures "fair game" for evaluation by payers and accrediting bodies such as The Joint Commission.

A second development illustrating the importance of QI and patient safety to PICUs is the national catheter-associated bloodstream infection (CA-BSI) team collaborative.[7] This national initiative is focused on applying bundle tools to reduce cather-associated bloodstream infections. Based on data from 29 teams, applying the bundle recommended by the collaborative prevents 22 CA-BSI infections and saves two lives and $750,000 each month.

A third manifestation of the increased importance of QI and patient safety in PICUs is the American Board of Pediatric's requirements for Maintenance of Certification. Intensivists interested in maintaining their credentialing must now demonstrate that they meet four conditions: professional standing, lifelong learning, cognitive expertise, and performance in practice.[8] A component of meeting these conditions is the active participation in an improvement project. Of note, active participation in the previously mentioned CA-BSI project will meet this condition.

Consistent with each of these three developments, multiple authors have concluded that physician leadership and participation are crucial to the success of QI and patient safety efforts.[9,10] Unfortunately, a 2003 survey among U.S. physicians showed that they infrequently participate in improvement efforts, they don't routinely use data for assessment of their performance, and are reluctant to share those data.[11]

Table 7–1 Endorsed Pediatric Intensive Care Unit Measures

Measure	Description
PICU standardized mortality ratio	The ratio of actual deaths over predicted deaths for PICU patients, adjusted using an accepted risk of mortality tool.
PICU severity-adjusted length of stay	The number of days between PICU admission and PICU discharge for PICU patients, adjusted using an accepted risk of mortality tool.
PICU rate of unplanned readmissions within 24 hours of PICU discharge	The total number of patients requiring unscheduled readmission to the ICU within 24 hours of discharge or transfer, over the number of discharges and transfers.
Review of PICU unplanned readmissions within 24 hours of PICU discharge	Periodic clinical review of unplanned readmissions to the PICU that occurred within 24 hours of discharge or transfer from the PICU.
PICU pain assessment on admission	Percentage of PICU patients receiving pain assessment on admission.
PICU periodic pain assessment	Percentage of PICU patients receiving periodic pain assessment while in the PICU.

Specific to the PICU environment, a more recent survey of pediatric critical care providers demonstrated that responders had poor knowledge of national quality and safety initiatives and similarly poor compliance with these national initiatives.[12] These data suggest that significant gaps in knowledge and practice of safety and quality activities by physicians caring for critically ill children persist.

Fundamentals of Quality Improvement and Patient Safety: Systems Thinking

To understand patient safety and quality in health care, one first must recognize the importance of systems to the way care is delivered. The Institute of Medicine, drawing from James Reason's studies of errors, defines a system as "a set of interdependent elements interacting to achieve a common aim." One model of systems in health care consists of five interaction components: people (1) use tools and technologies (2) to perform tasks (3) within an enviroment (4) in the context of an organization (5).[13] Each of these five components interacts with the others to yield the emergent properties (greater than the sum of the parts) of safety and quality.

Several essential implications follow from this model. First, no matter how safe any component is (ie, an intensivist who never makes mistakes), it is the five components and their interactions that determine if care is safe and of high quality. Second, if you change any of these components, it will have impact on the other components and their interactions. This is illustrated through the routine practice of cannulation for extracorporeal membrane oxygenation (ECMO) in the PICU. Merely changing the environment from the PICU to the hospital parking lot would have dramatic implications for the people, their tasks, the tools, and the organization's culture and liability. A third implication of this model is that changes to one or more of the five components will inevitably impact their emergent properties of safety and quality. This is illustrated by the growing literature that suggests that "safety technologies" may actually cause errors and harm.[14-19] Thus for critical care providers, understanding the role of systems in the work done in an intensive care unit (ICU) is crucial to improving quality or reducing harm.

Additional characteristics of systems that are important to intensivists are their complex adaptive nature[20] and the concept of tight coupling.[21] A complex adaptive system is one with several characteristics. First, complex adaptive systems have multiple similar agents that are autonomous entities that observe and act on their environment (such as PICU providers). More important, these multiple agents are adaptive, allowing for a high degree of resilience to system changes. The complex adaptive nature of the PICU is illustrated by sudden, unpredicted events such as codes, an unplanned extubation, or even multiple simultaneous admissions. In each of these scenarios, the future was unpredictable, the response was adaptive, and order is emergent rather than predetermined.

A tightly coupled system has events that must occur sequentially; it does not tolerate variation in supplies or inputs without creating delays and may tolerate failures less well than systems with slack designed into them. An example of tight coupling in the PICU is the common challenge of patient flow. An unplanned admission from the operating room (OR) requires a PICU bed postoperatively. The OR team is under pressure to transfer the patient to the PICU as soon as possible to free up the OR room and prevent delays in the surgical schedule. However, the patient who could leave the PICU can not be transferred because there is no floor bed. There are no floor beds because there is a delay in paper work and the need for a parent to drive the floor patient home. In this process, failure at any step leads to delay, the steps allow for little variation in process, and the majority of steps must occur sequentially. These features of complex, tightly coupled systems are endemic in health care settings.

Quality Improvement and Value

Quality has been defined as "the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge."[22] This definition, which comes from the Institute of Medicine, draws from the work of Donabedian.[23] In his work, quality was defined in the context of structure, process, and outcomes. In other words, to measure quality, you should consider the structure or capacities of health care, the process or interactions between patients and care providers, and the outcomes or evidence of changes in a patient's health condition. Ideally, considerations of quality should consider all three components.

The Institute of Medicine has identified six essential domains for achieving health care quality.[1] These areas include safety, effectiveness, patient-centeredness, timeliness, efficiency, and equity. Based on these and Donabedian's components of quality, efforts to improve quality should consider improvement of process, structure, and/or outcome focused on one of the six areas identified by the Institute of Medicine. The first of these domains, safety, is discussed in depth later in this chapter. These initiatives are intended to identify, analyze, and reduce risks that contribute to medical errors and

injuries.[24] The CA-BSI bundle project discussed previously is an example of QI leading to improved safety.[25]

The second domain, effectiveness, implies providing services based on the best available scientific knowledge in order to achieve the best outcome. Publication and implementation of clinical practice guidelines seek to decrease unwarranted variability in care resulting in improved outcomes. A practical example of the latter is the 2002 American College of Critical Care Medicine guidelines for hemodynamic support of pediatric and neonatal patients in septic shock. Studies have provided evidence that these guidelines are useful and effective, though evidence that clinical guidelines are often violated [26,27] indicates that promoting their use will remain an additional challenge.

Patient-centeredness describes the provision of care in a manner that is respectful of and responsive to individual patient preferences, needs, and values. In the PICU, many children may be unable to express their desires. Therefore, the experience of their parents is recognized as being fundamental to defining this aspect of quality. Applying this perspective, the principle of family-centered care mandates incorporation of parents in daily aspects of care. Measuring patient and family satisfaction may be invaluable to improving this aspect of PICU quality. One strategy shown to have a positive impact on satisfaction is the presence and involvement of parents on rounds.[28]

Timeliness, the fourth domain of health care quality, involves the reduction of waiting and potentially harmful delays for both those who give and receive care. The PICU provides multiple opportunities for improvement in this domain including but not limited to the timely administration of antibiotics, timely and goal-directed fluid resuscitation, and timely communication of significant radiology and critical laboratory findings.

Efficiency in the PICU could be measured by the ability to achieve adequate outcomes while keeping resource utilization appropriate, thus minimizing cost. Length of stay (LOS) is a common meaure of resource utilization in the PICU, and reduction is one potential method of reducing cost and improving efficiency. In adult ICUs, consistent identification of daily rounding goals during multidisciplinary patient care rounds leads to reduced LOS with improved staff understanding of what is needed to perform care.[29] It is important to note that improvement efforts targeted solely at efficiency may have unintended but foreseeable adverse effects on safety and satisfaction. This could be seen if efforts to reduce LOS lead to premature discharge with subsequent readmission. Thus, improvement efforts may need to view how they influence all six of the domains.

The final domain of quality is equity. Essentially, the quality of care provided in the PICU should be independent of characteristics such as gender, ethnicity, geographic location, and socioeconomic status.[30] Studies have documented disparities in the allocation of resources to critically ill adults related to race and insurance status.[31] In one multicenter study of three PICUs, the authors concluded that risk-adjusted mortality and resource utilization for critically ill children did not differ according to race, gender, or insurance status. However, uninsured children had significantly greater physiologic derangement at time of PICU admission.[32] More research into the issue of equity in pediatric critical care may be necessary before the community concludes there is no room for improvement. Even if admission criteria are free of inequity, are there comparable resources available for effective long-term care?

A discussion of the definition of quality should include potential shifts in thinking. Of note, there is literature suggesting that beyond quality, the issue of value is important to health care. In this context, value is defined as a measure of quality per unit cost.[33] This can be illustrated by considering what automobile the reader drives. Whether an entry-level compact car or a "loaded" luxury vehicle, for each consumer there is some determination of both the quality of the vehicle and whether that quality is worth the cost. Although robust measures of quality and true costs remain elusive in health care, critical care providers could improve value to patients by improving quality, reducing cost, or both.

Quality Improvement Methods

QI seeks to improve the quality of care. To improve care, you must first define the process of care that needs improvement. Ideally, a goal is set to define what is desired in terms of the outputs of the process. Then data are obtained to understand the process, and finally interventions are made with follow-up measurement to assess the change, positive or negative.[34]

Several important components are included in the last paragraph. First, you must define and understand a specific process or system. This is critical to making improvement feasible. For example, a hospital may identify that its LOS for patients with diabetic ketoacidosis is prolonged compared with peer organizations. However, efforts to improve all the elements involved in the hospital course simultaneously likely will fail because of the magnitude of the efforts. Instead, by identifying the components included in the hospitalization and contributing to the LOS, it may be possible to focus on manageable segments of the care process and make incremental change.

A second important concept is understanding variation in the data and the value of data over time (see the section on variation and display of data over time). As data are understood, goals can be set and interventions made. Continuing data acquisition allow assessment of the impact of the interventions. The establishment of goals provides a target for interventions and a context for measurement of data. To paraphrase a QI cliche, changing a process through an intervention is not the same as improving a process. Instead, measurement of data and comparison to set goals allow for assessment of improvement.

Ideally, these changes and reevaluations are done in an iterative manner. This method has been labeled as the "PDSA (Plan, Do, Study, Act) Cycle."[34] The Institute for Healthcare Improvement (www.IHI.org) has advocated use of a PDSA method over a short period to create what it calls "rapid cycle improvement." With either model, changes often are introduced quickly and sometimes multiple changes are introduced simultaneously. This method has evoked pushback from some physicians because of an apparent lack of scientific and statistical rigor. From a QI standpoint, many improvements are achieved without the need for meeting a given P value. Ironically, the resistance to QI methodology because of lack of statistical rigor is inconsistent with much clinical practice in the PICU. There does not exist a standard of care that every intervention performed in resuscitating a patient be accompanied by evaluation for statistical significance. In fact, resuscitations may involve multiple interventions

(endotracheal intubation, chest compressions, administration of medications) in a rapidly sequential or simultaneous manner. With a successful resuscitation, an intensivist may be unable to identify which of numerous interventions was responsible for the improvement. Arguably, if improvement occurred, neither the patient nor the family necessarily cares which intervention resulted in the positive change. Such is the QI mindset. If a given intervention can be identified and causation established for a specific improvement, this information may be applied to different settings. However, the goal is improvement, and improvement without clear identification of the causative factor remains an improvement.

Variation and Display of Data over Time

If an intensivist watches a physiologic monitor for any length of time, it is normal to view variability in heart rate and other vital signs. This reflects the dynamic nature of physiologic systems and processes. Similarly, health care processes vary within certain ranges under normal circumstances. Reacting to changes within normal variation may lead to interventions that increase variation rather than reducing it.[35] However, the range within which the variation is occurring may be outside the desired goal. Thus improvement may address the amount of variation associated with an existing system and/or fundamental redesign of the system.

Again, understanding the normal variation in a process is critical. The PICU provides physiologic illustrations of this concept. A patient who is doing reasonably well in the PICU has a normal range of heart rate variability, and loss of heart rate variability has been associated with increased risk of death in certain populations.[36] Similarly, a relatively well patient in the PICU who acutely develops either tachycardia or bradycardia merits evaluation for new or worsened pathology. In this case, the heart rate variation that normally occurs does so within certain parameters. This variation is called common cause variation in the QI literature. When the variation crosses either the upper parameter (tachycardia) or lower parameter (bradycardia), then something is amiss. The same holds true for processes and systems within health care. Variation that crosses certain thresholds or is an abnormal outlier is called special cause variation.

Plotting data over time allows for an understanding of this variation, normal or abnormal, in data. When data points (eg, LOS) are placed on a chart with time (eg, in days) plotted on the ordinate, this is called a run chart. Control charts, or statistical process control charts, also plot data over time. However, control limits are added that help define the limits of normal variation. Control limits, first described by Walter Shewart in the 1920s, are calculated in a variety of statistical manners, in part depending on the type of control chart. The type and distribution of data determine the choice of control charts[37]; methods for choosing a control chart are beyond the scope of this chapter. At the most basic limit, control levels are set at three times the standard deviation of the data, around the line of central tendency.

In general, when data exist within the control limits, a process is said to be in control. Data that either extend beyond the control limits or demonstrate one of several patterns suggest either an unstable process or a process that is responding to a change. This change may be an intentional effort to alter a process or may represent the effect of an unknown cause. Returning to the heart rate analogy, a patient who becomes bradycardic from hypoxia would demonstrate deviation of the normal heart rate variation in response to the special cause (hypoxia). Correction of the hypoxia ideally returns the heart rate (process) to its normal range of variation. An example of a control chart is displayed in Figure 7-1. Another example of process variation over time in the PICU is rates of CA-BSIs. For years, CA-BSIs were viewed as an unpreventable cost of PICU and adult ICU care. However, the systematic introduction of central line insertion bundles has resulted in transformative improvement in rates of CA-BSIs. With the addition of central line maintenance bundles, ICUs have reached sustained CA-BSI rates of zero. Analagous to the rate of codes outside an ICU with the introduction of a rapid respose team (see Figure 7-1), plots of CA-BSI rates over time in control charts similarly allow intensivists to understand the relationship between improvement efforts and infection rates.

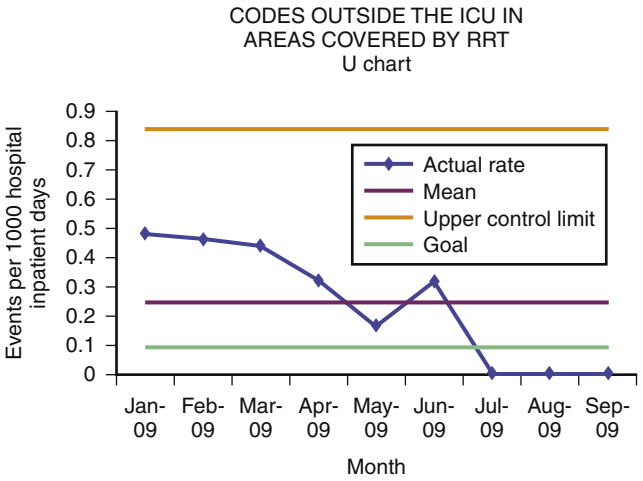

Figure 7–1. Control chart demonstrating codes outside the pediatric intensive care unit in areas covered by a rapid response team.

Other Quality Improvement Tools

Interested readers are directed to one of the numerous QI primers available for a thorough discussion of tools used in QI. However, several of these tools bear at least some mention. A Pareto chart is simply a histogram used to identify the major contributors to a problem or variation. For example, if PICU LOS is of concern, it may be beneficial to identify which, if any, diagnosis categories contribute to the prolonged LOS. By plotting LOS in days on the abscissa against diagnosis on the ordinate, those diagnoses that contribute to the greatest portion of the length of hospitalization might be identified.

Root cause analysis (RCA) is another tool used to attempt to identify the root cause for an event or problem. In its simplest form, RCA is performed by asking the question "why?" five times. Often used in conjunction with a cause-and-effect or Ishikawa diagram, the process of root cause investigation seeks to identify what caused a failure in a process (safety related or quality related) by defining the contributing factors (Figure 7-2). From each of the five categorical branches, smaller branches are added that answer the question "why?,"

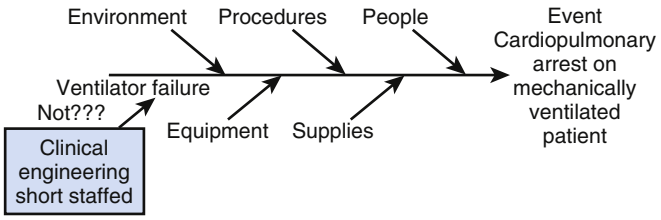

Figure 7–2. Sample cause-and-effect diagram with partial completion to demonstrate structure.

and in turn the same question of "why?" is asked again. The resultant diagram often is described as a fishbone, explaining the third name for this diagram: a fishbone diagram.

By asking the question "why?" repeatedly, the belief is that the root cause of a problem can be identified. This leads to three limitations of RCA. First, there is great danger of introducing hindsight bias. The investigators' beliefs of what happened may lead them to identify only those things on the cause-and-effect diagram.[38,39] A second, related limitation is that RCAs may restrict problem solving and brainstorming to only those factors that are known. Because you only know what you know and, similarly, you don't know what you don't know, there is the potential for missing important factors.[40] Finally, the most important limitation of RCA as a tool is the suggestion that there is a single root cause. This is a dangerous belief. Usually there are multiple causes of events. To limit thinking to one or two causes oversimplifies the situation and may preclude meaningful improvement. Use of RCA should be tempered with the knowledge of these limitations and the potential for drawing incorrect conclusions.

Fundamentals of Patient Safety

Patient safety is the freedom from preventable injury, an adaptation of the definition used by the Institute of Medicine.[3] For the sake of completeness, we offer two accepted defintions of error. The first definition of error draws from the work of James Reason,[39] who defines human error as consisting of two possible types of failure. First is an error of execution, in which a correct plan of action is not carried out correctly. An example is ordering intravenous morphine for a patient in pain, with the patient inadvertently receiving a tenfold overdose. A second failure is an error of planning. In this case, the action taken is incorrect. An example might be treating a patient with respiratory distress with beta-agonists when he or she has a pneumothorax. The execution of the action would have been correct, had the patient's problem been reactive airway disease.

The second definition of medical error considers an error any overuse, misuse, or underuse of medical care. In this setting, overusing radiographic imaging such as head computed tomography for every seizure in a known seizure patient, misuse of analgesics when sedatives are indicated, and underutilization of immunizations all are considered medical errors.

In addition to errors, there are adverse events. An adverse event is an undesired outcome of medical care. Adverse events, by definition, are unwanted. However, they are not necessarily the result of an error. Idiosyncratic drug reactions are an example of an undesirable event that is both unpredictable and unpreventable.

Errors, Injuries, Systems, and Risks

A central goal of all health care is to provide care without causing harm. Unfortunately, the identified harm in health care is often incorrectly attributed to a problem with errors, instead of understanding that both errors and harm are the result of poorly designed systems of care that either promote errors or allow harm to occur in the face of errors. This is manifested through such statements as: "We wouldn't have this safety problem if we could stop people from making so many errors." This, in turn, suggests that to achieve safety, we simply need to urge people to follow policies and be careful. However, people make errors; as long as there are people in PICUs, there will be errors. To that end, there are numerous safety improvement efforts that focus on people that can be seen by the following "solutions:" warning labels, signs and posters exhorting staff to "be careful" and to "do this" or "do not do that," repeated educational campaigns, and reliance on policies and procedures. None of these activities is bad per se, and in fact, they can be part of an effective safety effort. However, they are not sufficient to provide safety. In each of those "solutions," the goal is to error-proof the people, despite the inherent property of people to err. No amount of rules, education, or warnings will prevent errors from occurring.

In contrast, the science of Human Factors Engineering (HFE) supports the belief that efforts to improve patient safety that depend on requiring people to be infallible are misguided, wasteful, and potentially harmful. The previous section on systems thinking clearly identified patient safety and quality as emergent properties of systems. Not suprisingly, there is research that demonstrates that errors often are caused by poorly designed systems or "design-induced" errors.[41] Therefore, if an error occurs, one should not ask "why did the person make the mistake" but rather "what caused the mistake to occur?"

A clinical example that is relevant to PICU care is the restriction of the availability of high-risk medications. Sources of medication errors include the storage of look-alike vials or medications of the same name but differing concentrations in the same area for use in the PICU. An incorrect look-alike medication can be given in error, potentially resulting in harm. A safety program focused on "people" would solve this problem through educating staff to pay more attention to look-alike vials and to make the labels on the medications appear more distinct. In contrast, an HFE or system-based approach would involve removing the high-risk medications to another area, making it impossible to confuse medications or concentrations. In others words, by redesigning the systems for medication storage and access, the opportunity for error (and harm) decreases or even ceases. Central to this solution is the characteristic of using system redesign to reduce the risk of errors and harm. Consistent with epidemiological and public health models that attempt to identify, understand and reduce risk factors for disease or injury, the risk-reduction approach described here is a standard HFE and safety science approach.[42-44]

Improvement in the Pediatric Intensive Care Unit

The thought of improving safety in the PICU is daunting. The number and complexity of care processes seem overwhelming, and it is reasonable to wonder how to even begin. Building on the concepts of systems and risk reduction, a simple approach

to improving patient safety in the PICU involves three steps: risk identification, risk analysis, and risk reduction.[45]

The process of risk identification is relelatively straightforward. Drawing on reported events, chart reviews, concerns identified by staff, patients, and families, as well as issues identified in other units in a hospital, one can compile a list of potential risks that may be relevant to the patients cared for in the PICU. Of note, both errors and injuries inform the identification of risks. However, rather than focusing exclusively on trying to reconstruct prior events, the idea is to use past events to guide proactive improvement efforts to prevent future risks.

As the list of identified potential risks is generated, the next step is to systematically analyze the risks. This analysis involves three major steps. First, ask: "Is our PICU at risk for this happening?" If the identified risk was related to a published report of ECMO pump failure and ECMO is not performed in your PICU, then you can safely conclude that this risk does not apply. In contrast, if your PICU does perform ECMO, then the second step involves gathering more information to inform the risk assessment. This step might involve understanding what brand or type of pump was failing and whether this pump is in your center. Finally, after all available data are gathered (or perhaps new data are collected), the final step in risk analysis is to provide clinical interpretation by clinical experts familiar with the process. In the case of the ECMO pump scenario, a group of surgeons, intensivists, nurses, and perfusionists would weigh available data to determine the extent of risk for their PICU population.

The last step of improving safety would be performing risk reduction, which would involve pulling together a team to brainstorm improvements and the potential unintended consequences of each potential improvement. The latter portion of this step is critical. A simple but potentially hazardous solution to the ECMO scenario would be electing to cease all new ECMO support. Although this solution would surely prevent adverse events from ECMO pump failure, it might also result in preventable harm to patients who could be saved by ECMO. Similar to the step of risk analysis, risk reduction requires people knowledgeable about the processes to help guide improvements and prevent introducing unintended new risks.

Understandably, not every risk identified in the PICU is amenable to reduction by the PICU team alone. For risks that cross multiple units or may require significant resource investment, the identified and analyzed risks should be communicated to hospital leaders who then can weigh these risks with all others identified in the organization. However, this proactive and evidence-based approach can provide a standard framework for safety improvement. Additionally, this risk-based safety improvement approach lends itself readily to risk-based safety metrics.

Culture

As attention is shifted from individuals to systems, inevitably the issue of accountability is raised. Commonly expressed concerns center on whether focusing on systems rather than individuals somehow absolves health care providers from responsibility. In part, this concern arises from a well-intended (but misguided) effort to move from a punitive culture in health care to a "blame-free" environment. The intention was not to create systems deplete of individual accountability, but to avoid blaming individuals for situations beyond their control or that resulted from human error to which anyone would be vulnerable.

One solution that represents a system focus has been described as a "just culture."[46] Under this model, systems problems and human error are considered. The model promotes efforts to learn from errors without punishing individuals involved. Systems problems that create situations in which individuals are "set up" to make errors also are treated as learning opportunities. When individuals violate policies, often because of "normalization of deviance," the response again is not punitive but instead focused on making it easier to do the right thing. In the PICU, this can be seen when workload constraints make performing required double checks on pump programming unrealistic. The failure to perform double checks may occur daily by many staff members without event, and no action is taken to stop the behavior. When a neglected double check leads to an error or harm, the traditional mindset is to punish the involved parties, despite a systematic acceptance of this behavior. In a just culture model, rather than punish the individual, efforts are made to again make it easier or more desirable to "do the right thing."

Systems thinking and a just culture are consistent with punishment. This may occur in the face of willful or reckless behaviors that place patients at risk. A physician who provides patient care while intoxicated is an example of reckless behavior that would be unacceptable in a just culture. When behaviors show a pattern of violations that individually may not represent reckless behavior but collectively demonstrate a high-risk pattern, the just culture model proposes two considerations.[46] First, the person may work in a high-risk situation where such patterns are inevitable. Alternatively, the person involved may have individual characteristics, such as marital stress or deteriorating physical abilities, which would require removing the person from that situation in a nonpunitive manner. It should be noted that, on rare occasions, individuals may be viewed as "out of control" because of mental health problems, substance abuse, or even patterns of behavior. As mentioned previously, a just culture would require prompt intervention to help or remove these individuals to prevent harm to patients and other providers.

Teams and Teamwork

The need for improved teamwork is a recurring theme in patient safety. This is certainly true in the PICU environment. However, there are important differences in how critical care physicians and nurses perceive what is meant by teamwork and how well their team performs.[47] One conclusion by the authors is that these differences might be due to training, gender, or role-related culture. Another potential explanation may be poor understanding of the sciences of teams and team performance.[48-53]

In PICUs, there is a variety of teams. There is the patient's care team comprising the nurses, respiratory therapists, pharmacists, attending physicians, and perhaps trainees such as residents and fellows. There are also the within-discipline clinical teams, such as the nursing or physician team that cares for a given patient over shifts, days, and weeks. A nurse and his or her nursing assistant might also be a team, as might all of the nurses on a given shift in a given ICU. However, despite that fact that we might call each of these "teams," that does not mean that they identify themselves or perform as teams.

Teams are "two or more individuals with specialized roles and responsibilities who must interact dynamically and interdependently and are organized hierarchically to achieve common goals and objectives."[54] But more than that, according to HFE evidence, high-performing teams are those that have been trained to have, and have demonstrated proficiency in, specialized knowledge, skills, and attitudes that support teamwork.[55] For example, in high-performing teams, all team members have the following knowledge: they share the same mental model of what needs to get done, they all know the team mission, and they all know each others' roles and expectations. Similarly, in high-performing teams all team members have been trained and have demonstrated proficiency in the following skills: back-up behavior, team leadership, conflict resolution, and closed-loop communication, among others. However, few health care organizations train their staff to have that knowledge or those skills. Until that happens, HFE research suggests that there will not be high-functioning teams in health care (including PICUs).[56]

Technology

PICUs are full of technology. Not surprisingly, there is a perception that additional technologies may enhance safety. Specific technologies attributed with improving safety include electronic health records, clinical decision support, computer provider order entry (CPOE), bar-coded medication administration, and "smart" infusion pumps. These technologies have been linked to reduction in errors, even though little evidence exists that they reduce harm to patients. There is also evidence that these technologies can introduce new types of errors, violations, and harm.[57-62]

That technologies intended to improve safety may create added errors, rule violations, and risks may seem counterintuitive. However, the systems model described previously helps explain this seeming paradox. For instance, CPOE does not exist in a vacuum within the ICU. Instead, people (physicians, nurses, pharmacists) must use the CPOE system to perform tasks (ordering, modifying, and managing medications) within a busy and often distracting ICU environment. Independent of whether the CPOE system works as intended, the interactions between technology and people, tasks and environment, not to mention how the technology was implemented and supported, will ultimately determine whether the CPOE improves or sometimes worsens medication safety.[63] Health information technologies intended to improve safety may have usability problems[64-70] that increase the likelihood of user errors, provide misleading feedback, lead to high rates of false alarms, or difficulties interpreting data. Examples of usability problems include CPOE systems that preselect a patient, increasing the likelihood of entering orders on the incorrect patient, as well as defibrillators that have unclear displays resulting in failed attempts to cardiovert a patient. If such usability problems exist, it can lead to the previously mentioned "design-induced" errors.[41]

As with team training, there is a rich body of non-health care literature and a growing body of health care-specific literature that can guide the design, selection, and implementation of technologies to yield the best results.[63,70-74] Without leveraging this knowledge, PICU providers risk the unintended but foreseeable consequences of suboptimal technology adoption and potential harm to their patients.

Patient Safety in the Pediatric Intensive Care Unit: Past, Present, and Future

The body of health care safety science has grown dramatically since the last edition of this text.

Now, patient safety is the subject of its own textbooks, with numerous national and international meetings devoted to expanding knowledge and improving solutions (Table 7-2). With this in mind, it is impossible to provide a complete discussion of all topics for the PICU audience. It is important to know that there are many important topics worthy of additional consideration. These include fatigue and performance in the PICU, the potential for simulation, and the importance of leadership and culture of safety in the PICU.

There is an evolution in the approach to patient safety within a clinical environment, including the PICU. The most basic approach that still exists in health care is one of denial (ie the belief that a PICU has no safety issues). However, in the absence of concrete evidence that harm such as CA-BSIs or decubitus ulcers do not occur in that unit, this approach resembles that of the flat Earth society: unfounded disbelief.

Beyond denial is the reactive approach, characterized by error counting, blame finding, and people-based "solutions." Unfortunately, this approach may be well intended but harmful because of the impact on care providers and the culture of safety. Next is a proactive approach in which PICU teams seek to identify, understand, and reduce risks in their environment. However, nothing about this approach assures that variation will not undermine safety improvement efforts.

The desire to eliminate unwanted and harmful variation is central to the standardization-based approach to safety. In

Table 7–2 Sampling of Major Patient Safety Meetings and References

these aspiring "high reliability organizations," there is a focus on standardization of processes in the care environment. For processes such as preparing and dispensing a medication, handoff communications, or placing a central venous line, standardization will reduce unwanted variation and potentially reduce waste while improving quality and safety. At the same time, the practice of standardization can be overused. Standardizing the ordering, dispensing, and administration processes of aminoglycosides in septic PICU patients would be beneficial; standardizing to a single dose of aminoglycosides regardless of patient age, weight, or renal function would be potentially dangerous.

If standardization of a process will support the needs of ICU providers in all or nearly all cases, HFE supports its use, allowing exceptions for the few cases where a standard process does not apply. If, on the other hand, standardization will only support the needs of the providers some of the time, then standardization may be problematic. After all, if a standardized process does not fit many typical situations, then standardizing will simply create more "violators."

The potential goal of safety programs both in and out of the PICU is resilience. "Resilience is the ability of systems to mount a robust response to unforeseen, unpredicted, and unexpected demands and to resume or even continue normal operations."[75] Any PICU faced with a mass casualty or even simultaneous cardiac arrests in patients understands the challenge of unanticipated demands on the system of care delivery. What is less clear is whether the PICU team can rise to meet these demands while still providing care to the other patients in the PICU. Safety science has revealed that it is the people in the complex systems that provide resilience[76,77] or the ability of the system to function safely despite the inherent complexity and the risks. Thus, when PICUs are provided resources and designed such that they can meet these demands while providing care to the other patients and assure safe and high-quality outcomes, then the goal of resilience is met.

Conclusions

The issues of patient safety and quality have proven themselves to be more than a fad. Continued and better recognized harm to patients is drawing greater attention from patients, their families, payers, regulatory bodies, and a growing number of health care professionals. As is true with any complex system, there are no easy answers to improvement, and those improvements targeted at "fixing people" are destined to fail. Instead, by learning and applying quality and safety science, there is the opportunity to enhance the historically good outcomes achieved in the PICU.

Chapter 8

Information Technology in Critical Care

Steven Pon, Barry Markovitz, Carl Weigle, and Brian Jacobs

PEARLS

- Information technology promises many benefits but is not without limitations and pitfalls. Physicians must learn about these technologies to develop realistic expectations, maximize their benefit, ensure patient safety, and avoid potentially catastrophic perils.
- In most institutions, administrators and nurses drive the advancement of various information technologies. Physicians, especially intensivists, must become involved in the selection and development of these technologies if their needs and concerns are to be adequately addressed.
- Organizations must ensure the security and confidentiality of personally identifiable protected health information. They must understand the legislated privacy rules and safeguard the security and confidentiality of patient data.
- All computer users should understand the threats to security and privacy for themselves, their computer, and their network. Users should make informed decisions about the measures required to safeguard security and privacy that are commensurate with the task at hand.

By one analysis, medicine is an information service. Its practitioners tirelessly gather and assimilate information while sometimes adding to the collective body of knowledge. Clinical information is meticulously compiled and interpreted for each patient, the disorders that afflict them, and the therapies to treat them. Efforts to automate medicine do not place patients on conveyor belts to be serially and automatically poked and prodded. Automation efforts are directed at managing the flow of information. Medical information is wielded to protect life and to shepherd death. Compassion, judgment, and technical skill may distinguish excellence in the discipline, but information defines medicine.

The volume of medical information, expanding at fantastic rates, threatens to drown even the most conscientious practitioner who devotes every waking hour of every day to collecting, cataloguing, and assimilating it. Advances in information technology (IT) can both fuel the information explosion and contain it. Computers connected to one another and to large data repositories give practitioners immediate access to vast knowledge and data while streamlining the tedious chores of searching and collating that information. IT has changed the way we practice.

Demonstrations of the potential of IT typically inspire awe and admiration. However, when the technology migrates from demonstration to actual use, awe and admiration sometimes give way to disappointment and disgust. The novel features that users think they need are either impossible to achieve or require significant reengineering of the original product. The lure of the idealized technology suffers from its real limitations. Knowing the limitations helps users to avoid falling victim to them. This understanding can help the clinician focus on what can be accomplished readily while awaiting "the next upgrade."

The Electronic Health Record

The computer-based patient record (CPR) or electronic health record (EHR) is defined as a comprehensive database of personal, health-related information that is accessed and updated across a health care network.[1] Its potential and real benefits include the following:

- Improved quality of care through more timely, more complete, and better organized information delivery to the health care provider, with decision support and clinical pathways
- Cost savings through elimination of duplicate testing, shorter lengths of stay, and more efficient data collection and review
- Higher productivity by structuring patient care tasks to improve continuity of care and reduce practice variation by facilitating the creation of more consistent and more comprehensive content, and by making the medical records more readily accessible to more users simultaneously
- Facilitate research, education, quality improvement, outcomes assessment, and strategic planning.

The three principal functions of such a database, like any database, are data acquisition, data access, and data storage.

Data Acquisition

The complete EHR acquires data from a variety of sources, including hospital registration, nursing and physician input, laboratory services, radiology and other test interpretations,

therapist and nutrition services, monitoring devices, and physicians' orders. The most important system that feeds the database is the "enterprise-wide master patient index," which ensures that each patient is identified properly and uniquely. All other systems must have the correct identifier in order to deliver their data to the correct patient record. A multimedia database can include images such as radiographs, electrocardiograms, fetal monitoring, sonography, magnetic resonance images, computerized tomograms, and even paper-based documents such as consent forms, questionnaires, and, sometimes, handwritten notes and hand-drawn diagrams. Data acquisition is organized in a manner that minimizes duplicative effort and maximizes data consistency.[2]

One of the significant challenges to any implementation of an EHR is engineering the various interfaces between it and the host of systems that feed it data. Some of the feeder systems, such as laboratory services, have their own established validation protocols that are applied before transmission to the EHR.

Data originating from bedside devices such as cardiopulmonary monitors, pulse oximeters, ventilators, and intravenous infusion pumps represent critical elements of the patient care record. Manual capture and entry of these data into the EHR by nurses and other healthcare practitioners is associated with inefficiency and transcription errors. Technology is currently available to connect devices to the EHR through bedside medical device interfaces (BMDI). BMDI allows properly formatted data from a medical device to flow into and update the patient's EHR. One of the challenges in BMDI relates to the diversity of medical devices and EHRs, which makes it impractical for most vendors to directly connect. Often, biomedical device integration systems are required to extract, read, interpret, and forward data to the EHR in order for it to be useful. Basic physiologic data including heart rate, blood pressure, and respiratory rate are generally the first to be targeted for EHR integration. Other types of monitoring data that can be integrated with the EHR include temperature, pulse oximetry, end-tidal CO_2, and cardiac output measurements. Other types of devices that can be utilized for BMDI connectivity include intravenous infusion pumps, ventilators, dialysis, hemofiltration systems, cerebral oxygenation monitors, and extracorporeal membrane oxygenation systems.

One of the clear benefits associated with BMDI is the improved efficiency associated with not having to manually retrieve and record the data. The increased efficiency therefore allows the nurse to spend more time at the patient's bedside or in other important activities. Though this time saving is minimal for any one piece of patient data, when the aggregated data for each patient and for the entire facility is considered, the opportunity for cost saving likely exceeds the cost of the initial investment. Another potential benefit concerns the completeness and accuracy of the data in the EHR. BMDI increases data-sampling frequency possibilities, which is particularly important in a dynamic patient situation where data may be changing rapidly. Caretakers may request higher data sampling frequencies without impacting the need for additional patient care resources. In addition, reading and manually recording data into an EHR is often associated with transcription errors. BMDI reduces the likelihood of these transcription errors.

Considering that a data element passes from one of several feeder systems through different computers, with possible transformations of that data element along the way, and considering the possibilities of lost transmissions, computer down-times, and network interruptions, consistent error-free data feeding would seem a virtual miracle. In a high-volume environment, a centralized interface engine that routes and converts transaction messages from disparate feeder systems can solve many of the interface issues efficiently and in a timely fashion.

The capture of textual information, such as progress notes, nursing assessments, or even radiology reports, presents particular challenges for several reasons. For the most part, text is entered via a keyboard, but alternatives include voice recognition, handwriting recognition, or handheld and wireless devices. Many other technologies have failed in practice to date. Semiautomated text entry with menu systems feeding structured and unstructured forms have met with some success. Although these solutions do not have the same expressivity of free text, they lend themselves to the capture of text as data. Collecting data better allows for future analysis, but despite this significant advantage over collecting bland text, it tends to be rigid, can make documenting the unusual impossible, generally requires more time to collect, and may be a significant source of frustration for the clinician. An as-yet-untested strategy is to allow free text entries but to apply natural language processing to extract data from it for analysis. The decision to pursue data rather than text requires an institutional commitment to the philosophy that data are more valuable and are worth the difficulties they can present.

Data Access

The computerized patient record serves as the focal point for most health care professionals. It might be accessed at inpatient sites, but also in emergency departments, nursing facilities, continuing care centers, physician offices, clinics, laboratory facilities, treatment centers, and, in the case of home health services, the patient's home. An ideal computerized patient record should be available when and where it is needed. However, databases with sensitive information must be controlled to prevent unauthorized use or alteration. These systems must satisfy five requirements:

1. Access control: Only authorized persons are allowed access for authorized uses.
2. Authentication: Some confirmation that a person granted access is, in fact, who he or she purports to be.
3. Confidentiality: No unauthorized disclosure of information is allowed.
4. Integrity: Information content is unalterable except under authorized circumstances.
5. Attribution/nonrepudiation: Actions taken (access, data entry, and data modification) are reliably traceable.

The interface through which most health care providers interact with the EHR should be user-friendly and intuitive. Most clinicians have little time or patience to sit through tedious training sessions, and, once trained, few clinicians will recall more than a minimum required to complete their immediate, routine tasks.

The system should be capable of providing a full, seamless view of the patient over time and across points of care. Views should be configurable so that a given user's information needs and workflow can be accommodated. Both detailed and summary views that juxtapose relevant data allow the clinician

to acquire the information required to optimize expedient decision making. Displays should be configured to highlight key information while suppressing clutter but making all pertinent data readily accessible. Dynamic linkages should exist between the computerized patient record and supporting functions such as expert systems, clinical pathways, protocols, policies, reference material, and the medical literature.

Response times must be sufficiently speedy and workstations should be conveniently accessible to the point of care. Mobile connections are a bonus. Access to patient data via wireless connections with portable devices is an attractive alternative for users but must overcome usability and security hurdles before it can be fully implemented (see section on Security & Privacy: Wireless Networks).

The patient database also supports many areas of research, education, decision support, and external reporting. Thus, data in aggregate can be accessed by administration, finance, quality assurance, and research areas.

Data Storage

The multimedia data of the comprehensive EHR are stored on media that allow for long-term storage while allowing searches and rapid retrieval of enormous volumes of data. The database must be updated in a way that ensures that it is current, complete, and consistent. Data, once entered, should be modifiable only in accordance with strict rules that assure data integrity.

The architecture of the database can be centralized or distributed, replicated or not. A centralized database is stored at a single site, whereas a distributed database is a single logical database with segments that are spread across multiple locations connected by a network. A replicated database has the advantage over a nonreplicated database by having at least one copy of all records in case the primary copy is inaccessible because of computer or network failure. The challenge of replication is maintaining consistency among all the copies, requiring timely, automatic synchronization of the original database and its replicas.

Even replicated databases must be backed up periodically to ensure against data loss. It is essential for an EHR to have a strategy for doing so as seamlessly as possible and for establishing a clear and workable recovery.

Once stored, the data should have a time stamp. Although the data can be modified, both the original and the revised versions should be maintained with appropriate time stamping. Appropriate safeguards must ensure database integrity so that its pieces do not lose their links and that the data are not subject to unauthorized modification. Supplanting the paper record with the EHR as the official medical record requires thoughtful consideration of the limitations of paper copies to reflect accurately the electronic record. Sanctioned hard copies of the patient record will be necessary for sharing with other health care institutions or with the legal system.

Whereas a clinical data repository is a database optimized to retrieve data on individual patients, a data warehouse is a database designed to support data analysis across individuals. This function can be distinguished from a simple archival function. The warehouse structure is designed to support a variety of analyses, including elaborate queries on large amounts of data. The data are generally static and updated intermittently in batches rather than continuously.

Hospitals can use data warehouses to perform financial analyses or quality assessments. With decision support tools, they can be useful in negotiating managed care contracts or distributing resources to clinical or ancillary services. Subsets of a data warehouse that are structured to support a single department or function are "data marts." These subsets are designed to perform periodic analyses or to produce standard reports run repeatedly, such as monthly financial statements or quality measures. Online analytical processing (OLAP) is decision support on databases that are partially digested for analysis and thus are more rapidly accessed. In finance and administration, they can assist in strategic planning by predicting the impact of decisions before they are made. In medicine, it can take the form of a clinical database to support evidence-based decisions. Data mining applications can sift through mountains of data in the warehouse and run complex algorithms to find obscure patterns. However, as with any database, the questions must be defined as precisely as possible and the database designed accordingly if meaningful results are to be expected.

Clinical Decision Support

Decision support systems are an integrated set of programs and databases that provide users with the ability to interrogate those databases and analyze information, retrieving data from external sources, if necessary, to assist in decision making.[3]

Most medical decision support systems are designed to improve the process and the outcome of clinical decision making. They can yield most of the benefit of clinical information systems; for example, they can shorten inpatient length of stay, decrease adverse drug interactions, improve the consistency and content of medical records, improve continuity of care and follow-up, and reduce practice variation.

Retrospective decision support tools can be applied to aggregate patient data to find historical patterns. Real-time decision support systems can be passive or active. Passive systems are activated when clinicians request help. Such assistance can come as reference material, automated calculations, or data review. Active systems include alerts and reminders that are triggered by preprogrammed rules governing specific circumstances. For example, an order for penicillin in a patient who is allergic to it can cause a warning to display.

An effective decision support system must have accurate data, a user-friendly interface, a reliable knowledge base, and a good inferencing mechanism. The knowledge base can include information regarding risks, costs, disease states, clinical and laboratory findings, and clinical guidelines. The inference engine determines how and when to apply the appropriate knowledge while carefully minimizing disruptions of workflow.[4,5]

Patient Safety

Patient safety concerns remain paramount in any hospital system, including clinical information systems.[6,7]

To the extent possible, redundant systems should be in place to minimize the effect of the failure of a single component. Robust down-time contingency plans must be developed should the clinical information systems cease normal function in either planned or unplanned situations. These contingency plans must account for continued data acquisition

and retrieval and provide for mechanisms for communication among health care providers and services. Users should be informed about recovery procedures and what they mean to the clinical database. Do backlogged data generated during the down time ever enter the system? How are they timed? Or is there a gap in the clinical information that the clinicians must fill in for themselves if they want the whole picture?

Many anomalous circumstances related to the EHR can threaten patient safety. Data, such as a laboratory value or a physician order, can be entered into the wrong patient record and prompt the clinician to respond appropriately but on the wrong patient. Similarly, data can be displayed in ways that are so confusing that they are interpreted incorrectly.

Default behaviors of portions of the computerized patient record should be designed carefully, because busy or distracted clinicians may accept the default without understanding what they are accepting or without considering the consequences.

Automated Adverse Event Detection

Children are at significant risk for adverse drug events, and recent studies have begun to describe the frequency and epidemiology of medication errors and adverse events in pediatric inpatients.[8-10] In 2006, The Institute of Medicine released guidelines urging improved surveillance systems to detect adverse events.[11] Traditional methods used to detect adverse events in children included manual chart review and voluntary incident reporting. These detection systems are inefficient and significantly underestimate the number and prevalence of adverse events.[12,13]

Another manual detection strategy relies on trigger methodology where an occurrence, found on manual chart review, triggers further investigation to determine the presence of an adverse event.[11,14] For example, the administration of flumazenil may trigger the detection of benzodiazepine-induced respiratory depression. Automated adverse-event detection relies on the generation of a trigger report from the EHR, which indicates the possibility that an adverse event has occurred requiring further investigation. This methodology has been proven an efficient and cost effective way to detect adverse events.[15-19]

Promises and Limitations

Information technology in the form of an EHR promises improved patient care.[20,21] Potential benefits of information technology include providing rapid access to integrated clinical data and extant medical knowledge, eliminating illegibility, improving communication, and issuing applicable reminders and checks for appropriate medical actions.[22]

A number of studies show that information technology can provide various benefits, including increasing adherence to guidelines (particularly in the outpatient arena) and decreasing some medication errors.[23,24] However, the majority of these studies come from a very small number of institutions with homegrown clinical information systems that were developed by devoted groups of clinicians.[25] Very few studies show that the commercially available systems confer similar benefits, and even if they do, it is unclear that their success can be migrated from one implementation to another.[26-28] In fact, any benefit may be outweighed by new problems introduced by the systems themselves. In effect, one set of problems may be traded for another.[29,30]

Despite considerable progress, the sentiment expressed by G. Octo Barnett in 1966 is often echoed today, "It is frustrating to meet with repeated disappointments when the objectives are superficially so simple."[31] The medical information space is vastly more complicated than it seems at first. EHR software programs are enormously complex, are built by large teams of programmers with input by numerous clinicians, demand high-speed processors and high-bandwidth networks, and rely on often fragile interfaces with other hospital systems. Implementation currently requires tremendous effort by both clinicians and technical specialists to configure these systems according to the specific needs of an institution and in ways that will enhance care rather than impede it. An often unappreciated complicating factor is that the technology does not simply replace paper; it also reengineers care—deliberately or not. (See Unfavorable Alteration of Workflow.)

Errors can and do occur in programming or configuration. Many programming deficiencies can be detected and corrected with thorough testing, preferably in a development environment that does not affect real patients; however, some of these problems will only become apparent under unique circumstances that are presented by patient care. Indefatigable vigilance for these errors is essential.

Numerous other unintended consequences result from implementing an EHR, including the creation of new kinds of errors, an increase in work for clinicians, an untoward alteration of workflow and change in communication patterns, an increase in system demands, a continuation of the persistence of paper use, and the fostering of potential overdependence on the technology.[32-34]

New Kinds of Errors

While some errors can be avoided by using an EHR with computerized physician order entry (CPOE), other errors may be created or propagated.[35,36] Many "new" errors are a result of poorly designed interfaces. For example, clinicians can easily make "juxtaposition errors," intending to select one item but selecting another close to it on a long, dense pick list in a small font. A similar kind of error is mistaking an open chart of one patient to be that belonging to another or picking the wrong patient from a long list of patients.

Interfaces between electronic systems are particularly vulnerable and can cause various new kinds of errors. Patients who have been physically transferred but remain, disembodied, in their previous electronic location may have all of their care suspended pending completion of the electronic transfer. Worse, should electronic transfers be delayed, medications may be delivered to a patient's former room and administered to a different patient admitted to that room. Allergies may be entered in the bedside system, but interface problems can prevent that information from reaching the pharmacy or nutrition systems. Occasionally, laboratory results can be inserted into the wrong medical record because of interface issues.

Rigid interpretation of policies and procedures can be configured into the EHR but may lead to difficulties in clinical practice when dealing with ambiguous circumstances and exceptions. Sometimes the process of care is incompletely understood and codification can be disastrous. Policies at most institutions include automatic stop orders that require rewriting medication orders in a specified time frame. Compliance to this rule can be forced with programming, but

implementing this rule without safeguards could lead to automatic discontinuation of medications and missed doses.

The benefit of legibility in electronically written notes can be outweighed by novel problems. Overuse of copy-paste functions can result in repetitive, monotonous, and loquacious notes punctuated by the sin of propagating erroneous text verbatim. Automatic transcription of data such as laboratory results or vital signs often bypasses cognition, something that does not happen when data are transcribed by hand.

Increased Work for Clinicians

While transcription errors can be eliminated by computerized order entry, it often falls to clinicians to shoulder the added burden of what might otherwise be considered clerical functions. Documentation in a structured format rather than as free text can enhance completeness and facilitate later data retrieval; however, it can also increase work by forcing the clinician to find ways to fit round pegs into square holes. Similarly, rigidly structured order input can force clinicians to waste time trying different ways to order nonstandard tests or therapies—with little guarantee that these orders will actually be executed if they are routed to electronic limbo.

Clinical alerts can help clinicians make decisions, e.g., when penicillin is mistakenly ordered for an allergic patient, but persistent interruptions of work by alerts can increase the workload of the clinician who must decipher their meaning and assess the risk in each specific circumstance. The frequency of these alerts can become intolerable when they are not delivered to the right clinician with the right information and at the right time and place. When these alerts become too frequent and too predictable, clinicians often adapt by "response chaining": dismissing the alerts with rote keystrokes much as a pianist plays a familiar tune. Alerts that evoke this response cannot be effective and may be counterproductive.[37]

Poorly integrated clinical information systems cause clinicians to access many different sources for information to solve a clinical problem, thereby increasing work. Similarly, users should not be required to input the same bit of data in multiple locations in different systems.

Another time-consuming feature of the EHR, and perhaps the most exasperating, is the loss of data, particularly when busy clinicians lose long notes they have just meticulously written. Workstation or interface crashes, network collisions, inopportune time-outs, or system failures of other types can be the culprit. System delays from a wide variety of causes also waste valuable time, as does having to hunt for an available workstation because those installed are insufficient in number or inconveniently placed.

Unfavorable Alteration of Workflow

The introduction of an EHR system significantly alters the sociotechnological milieu. Previously well-functioning medical practices may become entirely dysfunctional. Implementation of an EHR requires modeling of work processes but can sometimes result in ossifying those processes into something too inflexible for efficient and effective patient care.

Patients expected to be emergently admitted to the pediatric intensive care unit (PICU) but still in transit often have medications and urgent therapies ordered and prepared before arrival. A CPOE system may prohibit ordering or dispensing medications for patients who have not yet been admitted. In a paper environment, nurses frequently arrange dosing schedules based on the ordered frequency, the frequency of other ordered medications, and the availability of intravenous access. However, in many CPOE systems, medication orders go direct to the pharmacy and bypass the bedside nurse. Physicians are then saddled with picking the specific times of administration, only to have that schedule revised later by the nurse.

Sometimes, well-defined manual processes can be implemented in more than one way electronically. Without clear delineation of an institutionally sanctioned method, confusion and catastrophe can result. Transferring patients from one unit to another or to the operating room typically requires the discontinuation and reinitiation of all orders, including medications. With implementation of CPOE, clinicians without proper direction could suspend rather than discontinue the old orders. Reactivation of suspended orders could result in duplication and double dosing of medications ordered on transfer.

Redundant orders are sometimes facilitated by CPOE. The gate-keeping function of clerical personnel processing orders for routine radiographs or laboratories is bypassed. Remote access by multiple physicians acting on the same bit of new information can also generate duplicate orders.

Untoward Changes in Communication Patterns

Many care providers blame clinical information systems for unsatisfactory reductions in face-to-face communication. Some users complain that the EHR creates an "illusion of communication,"[38] where users believe that information entered into the system will be somehow communicated to the relevant personnel. This assumption can result in missed or delayed execution of orders or failure to appreciate the recommendations of a consultant. Users may erroneously assume that allergies entered into the system will adequately protect patients from receiving offending food or drugs.

Because of the time-consuming nature of CPOE and because workstations are not always available at the bedside, orders are often written after work rounds. In teaching hospitals, order writing is often delegated to the least experienced individual, such as the first-year resident. Residents may not readily appreciate the nuances of an order until they are confronted with an order screen that demands input he or she had not previously considered. By that time, the other members of the care team have disbanded, and clarification of the order requires tracking down and reconsulting the relevant personnel.

High System Demands and Frequent Changes

No installed EHR can remain static for long. Maintenance, revisions, and upgrades of both software and hardware contribute to constant flux. Consequences should be expected with every change, and many changes require testing that can become onerous. While minor changes can occur without supplemental training of personnel, failure to provide training for some changes can cause significant user frustration and errors. Some configuration changes requested by one group may also adversely affect other users in unexpected ways. Mechanisms must be developed to resolve conflicts of this nature. As clinicians become increasingly dependent on the system, pressure to keep the system operational mounts, requiring around-the-clock technical support. One analogy likened system maintenance to "repairing a jet engine in flight."[38]

Persistence of Paper

Anecdotally, installation of an EHR is associated with an increase in consumption of paper towels: clinicians often jot vital signs and other data on any scrap of paper to be entered into the EHR at a later, more convenient time. While "going paperless" is an often-stated goal, the total elimination of this most versatile recording device is unlikely. An EHR changes the pattern of paper consumption: a higher proportion of pulp is sent to the shredder rather than to medical records. Reports are printed in the process of caring for patients and are often discarded at the end of a shift. Some institutions also regularly print worksheets as backup in the event that the system experiences unscheduled downtime.

A more insidious problem of persisting paper can arise when the patient chart is divided between paper and an electronic version, particularly when one medical service writes notes in one medium and another service uses the other. Splitting physician documentation can result in breakdowns in communication, with serious consequences. Delineation of the exact constituents of the legal medical record is also a necessary exercise, one that must be repeated as the systems change.

Overdependence on Technology

As the EHR becomes more integrated into clinical practice, downtime becomes more onerous on the users. Prolonged failures can even cripple an organization by causing delays, diminishing capacity, and limiting capabilities. Although backup systems can never quite replace the fully functioning system, contingencies for downtime must be developed, and users must be adequately trained to execute these plans efficiently.

Clinical decision-support systems (DSS) can enhance the educational value of interactions with the EHR. They can also increase reliance on the information presented, without providing significant learning, thereby precipitating uncertainty and paralysis of practitioners who encounter situations in which decision support is not available. The danger also exists that clinicians will accept advice rendered by clinical DSS in circumstances when they should not. Furthermore, the clinician who expects to be protected by a system of alerts may be less vigilant than he or she would have been in the absence of alerts and can ultimately be betrayed by an inconsistent system.

Human Factors Engineering

Cognitive science, computer science, and human factors engineering are among many disciplines that can facilitate development of a successful EHR system. Human factors engineering investigates human capabilities and limitations and applies that knowledge in the design of systems, software, environments, training, and personnel management. Application of human factors considerations in developing an EHR, particularly regarding CPOE, can maximize successful design and implementation of these systems. Some human factors principles may seem self-evident but can be overlooked when not approached systematically. Developers must understand the users, undertake detailed task analyses, and assess computer-supported cooperative work—the study of how people work within organizations and how technology affects them and their work. Three principles that may improve clinical information systems are accounting for incentive structures, understanding workflow, and promoting awareness of the activities of other group members. Institutional and personal incentives for using an EHR differ, but only the latter will effectively influence use. Awareness of the roles played by other team members enhances collaboration. Improving collaboration may decrease the incidence of medical errors.[39,40]

Another important area of human factors engineering relates to interface design. Interfaces should be simple and consistent, with important data highlighted, such as the patient name or weight. "Progressive disclosure" means that commonly used and important functions should be presented first and in a logical order, whereas infrequently used functions should be hidden but available. Minimizing "human memory load" can be accomplished by displaying all relevant information together on one screen rather than relying on the user to remember critical bits of data from different parts of the chart. Potential user errors should be anticipated, and easy error recovery should be designed into the system. Error messages should be informative and could include advice about error recovery. Other feedback should be provided to acknowledge user actions, particularly when the system appears frozen. Given the chaotic healthcare environment, the interface should also be designed to forgive interruptions, allowing work to be saved and facilitating task resumption.

User satisfaction is an important predictor of system success. Satisfaction is enhanced when the systems are designed with the users' needs and preferences in mind. Peers who serve as advocates for their groups during development and subsequently teach other users generally increase acceptance of the systems. Ease of use, rapid response times, flexibility and customizability, mobile workstations, implementation of effective decision support tools, access to reference information, and adequate training and support are all important factors in enhancing both user satisfaction and system success.[41]

Continued Promise

The Institute of Medicine, in its report, "Crossing the quality chasm: a new health system for the 21st century,"[2] stated that health care should be safe, effective, patient-centered, timely, efficient, and equitable. The Institute further noted that these goals could be more easily reached through judicious application of IT. Automated order entry systems can improve safety. The use of automated reminders based on clinical practice guidelines, computer-assisted diagnosis or management, and evidence-based medicine (EBM) can improve the effectiveness of medical care. IT can enhance patient-centered care that is respectful of and responsive to patient preferences, needs, and values by recording them and appropriately reminding the health care professional. It can facilitate access to clinical knowledge through web sites and online support groups. Clinical decision-support systems can be used to tailor information and disease management messages based on the patient's individual needs. Timeliness can be improved by e-mail, telemedicine, and direct and immediate access to diagnostic test results and other clinical information. IT can improve efficiency by using clinical decision-support systems to reduce redundant and unnecessary tests and procedures, by improving communication among multiple providers of care to individual patients, and by supplying data for performance and outcome measures. Enhancing equity among patients and across socioeconomic, geographic, race, and ethnic lines can be achieved if IT can improve access to clinicians and clinical

knowledge, although it would depend upon equitable access to the technology infrastructure. IT is playing the starring role in the drive to improve the quality of health care today, and the Institute called for a national commitment to build the information infrastructure to support health care.

Design and Implementation

Implementation of an EHR system requires an investment of additional staff, hardware, software, and an expanded communications infrastructure or network. For large hospital networks, the costs can be exorbitant.[42]

Developing an EHR requires careful planning and phased implementation. The specific needs of the institution must be examined, particularly with regard to the existing technology and practices. The process should be viewed as an opportunity to enhance care, rather than simply to replace the paper, and requires reassessment of existing practices and re-engineering of healthcare delivery. As each incremental phase of implementation is approached, the focus should be on overcoming specific barriers to care rather than on the nebulous goal of "creating a paperless process."[43]

The first phase generally provides a patient-centric repository of clinical test results, including laboratory, radiology, pathology, and other textual data. A subsequent phase can include capture of paper document images, radiology images, and other nontextual data. A key phase is the capture of clinical data at the point of care, including vital signs, intake and output, nursing documentation, and physician notes. Implementation of a physician order-entry system is another key phase that requires careful coordination among services and interdigitating systems.[44-46]

Ensuring that the EHR satisfies every need involves considerable planning, designing, and testing. Even well-designed, off-the-shelf EHR systems can satisfy only 80% of the complex requirements of any multipractitioner organization. The remainder must be either adapted from other content or created from scratch. Substantial "expert" direction from teams of physicians, nurses, other allied healthcare providers, and medical records and financial staff is required to assist in developing the design and implementation of all EHRs.[47] If clinicians abdicate their responsibility in participating in this tedious process, they are virtually ensuring that the resulting system will fail to satisfy their needs. Physician acceptance and participation can be enhanced by acknowledging the importance of physicians in the process, training them early and often, frequently and routinely eliciting their feedback, and demonstrating responsiveness to their needs and concerns.

Clinical information technology specialists generally interpret the requests from clinicians for configuration. A dedicated technical staff must also ensure instantaneous access to, and constant availability of, patient information. As the size and variety of information systems increase, enterprises will find it necessary to implement a "help desk" service.

Health Information Exchange

The electronic exchange of clinical data among applications internally within single organizations has a relatively long and successful history, in contrast with such exchange externally among multiple organizations. Both are essential for the best possible practice of critical care medicine.

Data Exchange Within a Single Health Care Organization

Norman Maclean might have been describing clinical data in the PICU when he wrote: "It is hard to know what to do with all the detail that rises out of a fire. It rises out of a fire as thick as smoke and threatens to blot out everything—some of it is true but doesn't make any difference, some of it is just plain wrong, and some doesn't even exist, except in your mind, as you slowly discover long afterwards. Some of it, though, is true—and makes all the difference."[48] The detail that rises out of critically ill children reaches their physician's mind in part directly through the five senses, as it has for millennia; and in part through a series of transfers and transformations in various computer applications. Done well, those transfers and transformations clear the smoke, reveal the truth, and make a difference.

The initial transformation typically involves transduction of physical information (pressure, temperature, absorption of electromagnetic radiation, etc.) into an analog electrical signal. That transduced signal is then, in a bedside monitor, amplified and converted from analog to digital form. In that form, the information can be displayed as a real-time wave form, or converted to a snapshot or moving average for numeric display, or stored in a series of snapshots for display of trends. These functions are supported and enhanced by a network of monitors, central servers, and displays. Confined by the boundaries of the monitoring network, the information is, by definition, of limited value.

Those limits are lifted when the information moves across an interface into subsequent information systems. In the good old days, that interface was a nurse, who transcribed information from the monitor onto a paper flow sheet the size of a small tablecloth. Now the interface is mostly electronic, and the "tablecloth" is an electronic database allowing a flexible re-display of the information. The electronic interface is possible because monitor vendors and EHR vendors employ a standard method for data exchange in the form of "messages" sent from system to system. That messaging standard has been developed since the late 1980s by the standards development organization named Health Level Seven (HL7).

HL7 messages convey information among a variety of clinical information systems in a typical children's hospital—demographics, laboratory test results, transcribed documents, radiology test results, medication doses, vital signs, and so forth. The number of HL7 message interfaces in a given institution is in inverse relation to the degree of integration of the core EHR, and the degree of end-user adoption of that EHR. An institution with physicians, nurses, and pharmacists using a single integrated EHR for all medication management, documentation, and order entry will need far fewer interfaces than one with a separate system for each function, or with multiple documentation systems.

Data Exchange Among Multiple Health Care Organizations

Compared with the 20 successful years of intraorganizational data exchange, the interorganizational exchange of data has a history more brief, and successes that are less widespread. In the early 1990s, Community Health Information Networks (CHINs) (e.g. the Wisconsin Health Information Network, http://www.whin.net/clinical) had limited local successes in

sharing clinical data using a central repository subscription model. In the 2000s, Regional Health Information Organizations (RHIOs) began to form. By 2009, 57 of 193 identified RHIOs were found to be actively exchanging data.[49]

With the establishment of the Office of the National Coordinator for Health Information Technology (ONC) in 2004, attention was directed to the need for a national health information network (NHIN). The ONC and the importance of health information exchange (HIE) were given a boost by the Health Information Technology for Economic and Clinical Health Act (HITECH Act) of 2009, a part of the American Recovery and Reinvestment Act (ARRA) of 2009. In the HITECH Act, economic stimulus funds for provider organizations were tied to meaningful use of certified health care information technology (HIT). While the specific mechanics of determining "meaningful use" are yet to be finalized, it is clear that HIE will be an essential element.

The importance of HIE to critical care may be found in handoffs in care between organizations (i.e., interfacility transport) and in multicenter patient registries, such as Virtual PICU Systems. In the former case, the HL7 standard Continuity of Care Document (CCD), which is based on the HL7 Clinical Document Architecture (CDA) standard,[50] provides structure that EHR vendors can use to pass patient-specific summary data between disparate EHR systems. In the latter case, the Quality Reporting Document Architecture (QRDA) is an HL7 Draft Standard for Trial Use (DSTU) developed to support the exchange of quality data from clinical rather than administrative systems.[51] For ICUs with fully implemented EHRs, the QRDA offers the promise of automated data uploads for registries and for mandated regulatory reporting, without the need for costly and fallible manual transcription, and without the dubious relevance of administrative data.

Protected Health Information

Ensuring the privacy of personal health information has always been a concern, but the availability of this information in electronic form raises new concerns because securing it is not a simple matter of putting it under lock and key. In legislating the Health Insurance Portability and Accountability Act (HIPAA) to protect health insurance coverage for workers and their families when they change or lose their jobs, Congress also sought to alleviate some of the administrative burdens on health care providers by mandating standards for electronic data interchange (EDI). Because electronic transactions between providers and insurers would become easier, and more personal health information would become available in electronic form, privacy and security rules were incorporated into the legislation. These rules apply specifically to protected health information (PHI), which is any health information that can be linked to an individual (Box 8-1).

The Privacy Rule applies to protected health information whether it is stored in electronic form or not. The Rule limits the nonconsensual use or release of protected health information, gives patients new rights to access their medical records and to know who accessed them, restricts most disclosures of health information to the minimum needed for the intended purpose, establishes penalties for improper use or disclosure, and establishes new requirements for access to records by researchers and others. The impact of HIPAA on research relates to consent paperwork that safeguards the privacy of patients participating in research, simplified guidelines regarding the limited circumstances where patient health information can be used for research purposes without authorization by the research subject, and clarifying methods by which protected patient health information can be de-identified so that such information can be disclosed freely.[52]

The Security Rule attempts to provide a uniform level of protection of all protected health information that is housed or transmitted electronically. These standards mandate safeguards for physical storage and maintenance of equipment that contains patient data. Network closets and servers should be locked up and data must be backed up. The displays of computers in public areas should be turned away from open view, and screens installed to limit the viewing angle. Storing protected health information on computers in unlocked offices, on laptops, or on removable media such as flash drives is prohibited unless the data are encrypted. Users should log out of applications that access PHI when those applications are no longer needed. Access to data must be limited to authorized personnel on an as-needed basis with clear administrative policies for granting and revoking those privileges. There must also be technical safeguards to prevent unauthorized intrusion into networks or interception of transmissions over open networks. Firewalls should protect hospital networks, particularly if there are wireless access points. PHI should never be sent by email without encryption because standard email is inherently insecure.

The implementation of the Security and Privacy Rules varies with the circumstances of each organization. Regardless of the specifics, institutional policies must be established and followed. In the past, violations of such policies, including

Box 8–1 Elements Considered Protected Health Information

- Names
- All elements of dates (except year) for dates directly related to an individual, including:
  - Birth date
  - Admission date
  - Date of procedure
  - Discharge date
  - Date of death
- Telephone numbers, fax numbers
- Electronic mail addresses
- Social security numbers
- Medical record numbers
- Health plan beneficiary numbers
- Account numbers
- Certificate/license numbers
- Vehicle identifiers and serial numbers
- Device identifiers and serial numbers
- Web URLs
- IP address numbers
- Biometric identifiers, including finger and voice prints
- Full face photographic images and any comparable images
- All geographic subdivisions smaller than a state, including:
  - Street address
  - City
  - County
  - Zip code, and their equivalent geocodes
- Any other unique identifying number, characteristic, or code

sharing personal passwords or accessing information to which employees had no right to access, were punishable by official reprimand or, at worst, dismissal. With the new rules, violators may face criminal or civil penalties as well.

Clinical Tools

Information technology has clearly changed our world. The typewriter has disappeared from the office milieu, conspicuously replaced by computers with word processors. Presentation programs and digital light projectors have supplanted slides and overhead projectors in the lecture room. Appointment books and Rolodexes have given way to personal portable electronics. Computationally intensive activities such as statistical analysis no longer reside in the realm of mainframes and punch cards.

In clinical areas, ritualized calculations have become easier and less prone to error with the development of computer applications developed for a variety of platforms from cellphones to networked computers. Some of these programs now can be found in a variety of devices not traditionally considered computers but which operate on integrated circuit computer chips, such as intravenous infusion pumps.

Smart Infusion Pumps

Errors related to intravenous infusions are often associated with significant harm in the PICU. A 2001 study involving pediatric inpatients noted that intravenous infusions were associated with 54% of potential adverse drug events (ADEs).[8] Furthermore, ADEs associated with intravenous infusion devices generally result from incorrect programming. Smart infusion pumps represent a new generation of intravenous infusion pumps and have been associated with a reduction in medication administration errors.[53]

Most intravenous infusion pumps in use today have the flexibility and capacity to deliver a wide range of infusion rates and volumes. In an effort to standardize pump systems throughout an organization, the same device may be used to deliver medications to an infant or an adolescent. Therefore significant dosing errors can be easily programmed by a bedside provider if there are no double checks or electronic decision-support systems in place. Smart infusion pumps contain sophisticated software that allows for programming medication safety libraries within each pump. In addition, these devices may be queried to allow aggregation and analysis of data regarding infusion practices for quality improvement purposes. Furthermore, some pump vendors offer the ability to connect the device via a wireless network to allow bidirectional flow of information to and from the pumps.

Smart infusion pump medication libraries include drug name, usual concentrations, and dose range checking to avoid high or low dosing for both infusion and bolus dosing. Generally these libraries are created for a given patient care unit, patient population, or provider group. Providers who attempt to program the pump beyond the limits set in the library will encounter an alert that may either be overridden (soft alert) or not overridden (hard alert). The impact of smart infusion pump technology on patient safety is not completely clear at this time. Rothschild et al. noted no measurable impact on the serious medication error rate using this technology in a controlled trial in the ICU.[54] These devices must be paired with optimal design and process change in order to achieve meaningful outcomes.

Bar Coding in Health Care

In 2004, the FDA published a "Bar Code Rule" mandating manufacturers and repackagers to have a bar code of the National Drug Code on the immediate drug containers label by April 2006.[55] An integrated system that includes bar coding of medications focuses on preventing errors in drug administration, which may represent up to 38% of medication errors.[56] The essential components for safe medication administration utilizing bar code technology revolve around the "five rights": the right patient, right drug, right dose, right route, and right time. In bar code medication administration, the nurse uses a bedside scanning device to scan the medication, the patient's wristband, and the nurse's identification. A query is then sent to the EHR to the patient's medication orders. A match on the five rights then signals the nurse that the medication may be administered. Though bar code medication administration systems have been associated with error prevention, they have also been associated with new errors.[57] Proper implementation is key to achieving value with these systems.

Virtual Care and Telemedicine

Telemedicine typically refers to remote patient care for diagnosis, treatment, or consultation using some form of information transfer technology. Primary and subspecialty care can be brought to underserved areas of the world, from rural regions to prisons.[58]

Pediatric subspecialties, including critical care, have experimented in telemedicine for decades, and evidence suggests that such care is both effective and cost-effective. While many technical, legal (licensing and credentialing), and financial hurdles remain, telemedicine is emerging as a viable and valuable care delivery model for critical care, either as a consultation service or as a remote "e-ICU."[59,60]

Creative twists on traditional telemedicine in the PICU are also being explored. A recent pilot PICU telemedicine project created individualized, password-protected web sites for PICU patients—their beds equipped with webcams—allowing families remote access to their children's clinical status, complete with nursing notes and patient images. In addition, each child's web site had a messaging area, where nurses and family members could exchange comments and questions. Preconfigured laptop computers were even available for loan to families in need. A separate web site for each child with physician notes and radiographic images was made available to the patients' community physicians. Clearly, there is merit to keeping the referring physician informed of his or her patient's progress. However, the promise of information technology may be greatest as a means of empowering children and their families during their hospitalization.[61]

Medical Knowledge Bases

The vast amount of medical information that clinicians need to practice evidence-based medicine can only reasonably be managed today by networked, searchable, and linked medical knowledge bases. Online search engines, accessible with

Box 8–2 Top-Ten List of Web Sites Relevant to Pediatric Critical Care Medicine

1. PedsCCM: Pediatric Critical Care Medicine web site (PedsCCM.org)
   Still the number one "hit" on Google when entering "Pediatric Critical Care Medicine," this is the headquarters for pediatric critical care medicine on the web. It represents a multidisciplinary educational and practical resource, with announcements, reports, opportunities (including fellowship listings and physician and nursing jobs databases), organized links to original educational material and research reports, and the PedsCCM Evidence-based Journal Club.
2. American Academy of Pediatrics (www.aap.org)
   The Section on Critical Care of the American Academy of Pediatrics (AAP) is very active in promoting the interests of critically ill children and pediatric intensivists within the Academy. The Academy is the prime advocate for children's health care in the United States. For AAP members, the Members Only channel contains timely announcements relevant to all pediatricians. The AAP Policy Statements and Practice Guidelines are available on this site. In addition, the AAP publishes a monthly review of pediatric critical care in its PREP series; PREP ICU is a Critical Care Subspecialty Self-Assessment Program, approved for use as part of the American Board of Pediatrics' Maintenance of Certification for pediatric intensivists.
3. Society of Critical Care Medicine (www.sccm.org)
   As a prime supporter of the intensivist-directed multidisciplinary critical care team, the Society of Critical Care Medicine (SCCM) plays an important role in education and advocacy. The SCCM's educational and research programs, including the American College of Critical Care's guidelines and practice parameters, are on this site. The organization has launched an online "digital community workplace" with chat rooms, threaded discussion groups, file sharing, and calendar functions. There are designated "e-rooms" for every section, chapter, and committee of the SCCM.
4. Diagnostic Decision Support
   Isabel (www.isabelhealthcare.com) Although now only available via subscription, the natural language decision support reminder system, Isabel, was developed by a pediatric intensivist.
5. Journals:
   Pediatric Critical Care Medicine (www.pccmjournal.org)
   Critical Care Medicine (www.ccmjournal.com)
   Intensive Care Medicine (www.springer.com/medicine/journal/134)
   American Journal of Respiratory and Critical Care Medicine (ajrccm.atsjournals.org/)
   Chest (chestjournal.chestpubs.org/)
   These are the major journals in our specialty, all available online.
6. General Medical References
   UpToDate (www.uptodate.com)
   This resource is probably the preeminent regularly updated and reliable reference source online.
7. Calculators on the web and downloadable applications
   Cornell's Dr. Steve Pon maintains multifunction medical calculators (http://cornellpicu.org/). ICU scoring systems are available for the Société Française d'Anesthésie et de Réanimation (http://www.safer.org/article/315/scores). PICUTools is a downloadable suite of such tools for your Palm OS PDA (Dr. Michael Verive at www. mverive.com). Medical "apps" for the Apple iPhone probably number in the hundreds as of this writing via the iTunes Store (www.iTunes.com/Downloads). Finally, the revered Harriet Lane Handbook is now available in multiple handheld formats (www.skyscape.com).
8. Networking
   The Virtual PICU (www.picu.net) joins nearly 100 PICUs learning how to track outcomes, measure quality, and engage in benchmarking. The VPS (VPICU Performance System) is available through the VPICU, as is information on distance learning, pediatric critical care telemedicine, and more. The VPICU also hosts our specialty's premier discussion forum (email and/or web-based), the PICU list.
9. Drug References
   Few resources benefit more from the rapid accessibility and searching capability than drug databases and references. Many exist, from the venerable Physicians Drug Reference (www.pdr.net) to the well-established Drug Information Handbook from Lexi-Comp (www.lexi.com/). Versions of several drug databases for handheld devices also are available and are rapidly becoming indispensable to junior and experienced clinicians.
10. World Federation of Pediatric Intensive and Critical Care Societies (WFPICCS)
    An organization of member societies of pediatric intensive and critical care from around the globe.

natural language queries unfettered by complex rule-based search terminology requirements, have revolutionized access to multiple types of medical knowledge bases (Box 8-2).

Nearly anyone who has used a web browser is familiar with the power of natural language queries posed to a highly intelligent search engine. Indeed, the power of one such engine has turned searching the web with this tool into a verb: to Google. Google and Google Scholar (searches limited to scholarly databases), have become quite useful even for professional medical knowledge searches. Some clinicians have even taken to searching Google with a list of signs and symptoms as a diagnostic decision-support tool.

Resources available for free access online include classical original medical literature citations, such as via the National Library of Medicine's PubMed site (http://www.ncbi.nlm.nih.gov/pubmed). Powerful and focused results are now possible without understanding the difference between MeSH (Medical Subject Heading) terms and keywords. Abstracts are presented, and if the full-text paper is online anywhere, PubMed provides a direct link. More and more publishers and journals are opening (at least) their archived editions older than 6 to12 months to free access on the Internet. PubMed itself is a large repository of freely available manuscripts from a wide range of journals.

Also online are pharmaceutical databases, medical calculators, textbooks, image libraries, evidence-based reviews and guidelines, though not all are necessarily freely available. For physicians in academic medical centers, however, contractual arrangements between universities or hospitals and publishing cooperatives can enable apparently free access to the end user if the resource is accessed from within the institution's

network. Many publishers also allow free access to users in developing countries, potentially revolutionizing education and communication even in remote corners of the world.

The accompanying CD for this chapter includes several computer-generated animations, demonstrating a unique teaching capability of technology. Pediatric critical care medicine is in the forefront of using this technology for teaching purposes, as Tegtmeyer et al. published the *New England Journal of Medicine*'s first computerized instructional video on arterial catheter insertion.[62,63]

The Internet and the Patient

Though beyond the scope of this text, health care providers should be aware of the extent to which Internet access is empowering patients and families. Consumers are becoming increasingly savvy in their ability to access reliable medical information from the web, including the same research papers and guidelines that providers rely upon. In addition to access to medical information, the Internet provides patients and families access to each other. Social networking sites, some disease-specific, enable virtual support groups to share experiences worldwide. So we should not be surprised if a parent enters the PICU and asks why, given the evidence and recommendations, is their child's head of the bed not elevated 30 degrees as a preventative strategy for ventilator-associated pneumonia. Another family may relate how different the treatment for their child's condition is elsewhere, or ask why they can't be enrolled in a clinical trial they located on Clinicaltrials.gov.

Research Databases

There are few areas of clinical or laboratory research that do not generate volumes of information that require analysis. All but the simplest studies involve entry of data into an electronic database. Perhaps the most common types of databases involve single flat tables of variables and measured values. In fact, many researchers use spreadsheet programs, not database programs, to perform most of their analyses. As data are acquired and complex relationships among the data are built into the data models, their structure becomes more intricate and better suited to true database programs. Most of these are relational database programs that run on personal computers or on mainframes. Both the characteristics of the data and the nature of the desired output affect the design of the data models and database structure.

There are areas of research where the sheer volume of information can overwhelm any single program or computer system. The solution to which more researchers are turning has met enormous success in fields such as astronomy, astrophysics, and genetics. That solution is "internetworking."

Integrating data from multiple, disparate databases to form public repositories open for new discovery is a difficult problem. The separate databases could be consolidated into one large database, but both the data and the data model can easily become asynchronous with the contributing databases. The other approach is federation, where the original databases exist on their own but are linked together and bound by data standards. These include standard, regulated vocabularies, and a standard syntax to govern the form of the data. Rather than adopting a particular platform (Unix or Windows) and a particular program, eXtensible Markup Language (XML) has emerged as the standard syntax because of its flexibility. It also allows these databases to be freely available on the Internet and open to query by researchers worldwide. Specialized data that require further characterization are governed by additional specifications such as Biopolymer Markup Language (BIOML) and MicroArray Markup Language (MAML) for microarray data.

The field of bioinformatics occupies the intersection between biogenetics and IT.[64] The volume of biologic data being collected cannot be digested without some way of processing it. The data include not only DNA sequencing, but also polymorphisms, cross-species comparisons, levels of mRNA expression, protein-protein interactions and enzyme kinetics, location of gene products within the cell, and the three-dimensional structure of the macromolecular gene products and their ligands. The Human Genome Project owes a great portion of its success to advances in bioinformatics. Linking these databases with clinical databases represents additional challenges, but ones that are being met. The Online Mendelian Inheritance in Man (http://www.ncbi.nlm.nih.gov/omim) database of inherited human disorders is a successful example. Linking genetic variation and clinical response to drugs with the goal of adjusting therapeutic regimens according to genetic profiles represents the challenge of pharmacogenomics.[65]

Given the direction of this evolving technology, it is conceivable that clinical data from multiple institutions could be linked in similar ways. Detailed analysis for patterns in large volumes of clinical data can serve as a springboard to novel clinical studies. This kind of analysis is known as data mining in some disciplines but is referred derogatorily as data torturing by some. The true value of this approach cannot yet be predicted, but there can be no argument that the limitation of most studies in pediatric critical care is currently the paucity of data from individual institutions. In aggregate, who knows what we may learn?

Ethics and patient privacy and confidentiality represent key issues for some of these research efforts. Simply removing patient identifiers is not adequate because it is still possible to bring together information from a variety of sources to reconstruct, either exactly or probabilistically, the identity of patients. Fortunately, there are means for adequately protecting confidentiality, including mediation and scrubbing. Mediation programs on a database limit the kinds of queries and responses based on specified rules and requester privilege. Scrubbing blurs the data by decreasing precision or reporting ranks rather than actual values. It also limits queries to those resulting in more than a specified "bin" size. Queries that violate preset rules would not yield results. Although the privacy and confidentiality issues may be soluble with judicious application of technology, the ethical issues may be more intractable and will require careful study and action.

Virtual Pediatric Intensive Care Unit Systems

In collaboration with the National Association of Children's Hospitals and Related Institutions (NACHRI), and the National Outcomes Center located at Milwaukee Children's Hospital and Medical System, the Virtual PICU (funded by the Childrens Hospital Los Angeles and the L.K. Whittier Foundation) developed a data collection tool specifically designed to understand pediatric critical care, the distribution of demographics, diagnoses, and outcomes, and to form a basis for clinical research, quality improvement and, ultimately,

comparative data analysis. Over the years, there was significant "scope creep" and the minimal database evolved in to a comprehensive tool for understanding pediatric critical care and exploring outcomes in a comparative fashion.

As of 2009, there are 85 PICUs participating in the Virtual PICU Systems (VPS), which includes over 250,000 patient admissions in the database and is growing at a rate of over 70,000 cases per year. Participating institutions participate in an advisory committee, a users' group organization with annual meetings, and a research committee, and receive periodic comparative quality reports detailing the performance of their ICUs along multiple axes, modeled on the Institute of Medicine's "Six Dimensions of Quality."

The VPS database has been used extensively to inform pediatric critical care research. Merely providing demographics and descriptions and diagnostic patterns in critical care has aided the design of multiple national research projects and National Institutes of Health funded projects. However, the core purpose of the prospective data collection is quality improvement, allowing comparative data reporting against comparable but unidentified institutions. These reports enable intensivists to objectively demonstrate the quality of the care they provide.[66]

Security

The security of a networked system involves at least three components: physical security, prevention of unauthorized access, and protection from malicious software.

Physical access to sensitive portions of the system must be secure. Servers should be in locked rooms with controlled access. Networking closets with wiring and hubs should be locked. Sensitive equipment must be protected from extreme temperatures, fire, and water damage. Backup power sources are required. Workstations, wherever possible, should be in open areas where their use can be monitored, but not so open that unauthorized persons can peer over a user's shoulder to steal a user name and password or to see sensitive information. Physical security also involves ensuring that the data are backed up and readily accessible whenever they are needed.

Preventing unauthorized electronic access involves blocking attacks from the outside and authenticating legitimate users before allowing them access. Wireless networks must be configured to minimize the risk of intruders tapping into the system. Systems can be attacked by malicious software, loosely labeled as viruses. Securing systems from these threats is becoming increasingly challenging.

Firewalls

Any computer or network with connections to the outside world, such as the Internet, is vulnerable to attack. These attacks can come in the form of a hacker gaining access to confidential data or another causing data loss or corruption. The first measure of security against such threats is a firewall. In the parlance of architects and builders, a firewall prevents fire from spreading across sections of a building while allowing traffic through specially constructed doors. A network firewall protects the resources of a network from unauthorized access while allowing its users access to external resources such as the Internet. Personal firewalls can protect an individual computer from certain kinds of network traffic.

The simplest firewalls are packet filters. Information is sent across a network in packets wrapped in layers of protocols with a header that includes IP addresses and port numbers. Packet filters examine the headers and, based on a set of rules configured into them, allow or deny passage of each packet. Routers can be configured as packet filters, becoming screening routers. However, not all packets are what they appear to be, and packet filters do not examine their contents. Readily available hacking tools can create normal-appearing packets that can take advantage of well-known security flaws in network applications.

Proxy servers provide the next level of firewall protection. They intercept requests for data from network users and forward them using the proxy address (hiding the requester's internal network address). The reply from the Internet returns to the proxy server, which evaluates it to ensure that the contents contain an expected response. If the commands or data are suspicious, the packet is discarded. Legitimate packets are forwarded to the requester but only after they are repacked in a new packet. No packets ever cross directly from the network to the Internet or from the Internet to the network. The proxy server is always between them, evaluating each packet trying to make its way through.

Software on the user's computer or on a computer that serves as a gateway to other networks can function as a firewall. In fact, home computers constantly connected to the Internet via a broadband connection (e.g., cable modem, digital subscriber line [DSL], or integrated services digital network [ISDN]) should have personal firewall software to protect them from attack. A "firewall appliance," a hardware device dedicated to this task can also do the job.

Even with a firewall to protect the perimeter of a networked environment, much vulnerability remains. For example, any computer on the network connected via modem to any outside system effectively bypasses network firewalls. This security flaw can be plugged with properly configured firewall software. Effective security solutions include network and Internet gateway monitoring, intrusion detection, firewall software for vulnerable nodes, antivirus software, and periodic penetration testing. Firewalls are only one bulwark against attack.

Wireless Networks

Wireless networking allows freedom from the tether of network wiring. In a large intensive care unit with multiple patient rooms and shifting isolation precautions, an untethered workstation allows efficient access to information systems during rounds, making it an integral part of the information exchange.

Most hospital networks do not provide for wireless technology, citing the security risk. In fact, many wireless implementations allow the equivalent of leaving the wiring closet completely open for intruders to enter and plug directly into the network. The Institute of Electrical and Electronics Engineers (IEEE) 802.11 standard on which these networks are based includes a provision for encryption called wired equivalent privacy (WEP) that was eventually superceded by the more secure Wi-Fi Protected Access (WPA or WPA2). Surprisingly, most implementations of wireless networks do not use any encryption method. Many network administrators do not even bother changing the factory default security settings, including passwords.

It is possible to sufficiently secure wireless technology, even for the most sensitive applications. WPA2 and all other security features must be configured appropriately. The access points can be positioned to minimize inadvertent transmission beyond the desired boundaries of the building. The connections can also be limited in number and by media access control (MAC) address, which identifies each node on a network. The most effective strategy is to place the wireless access points behind a firewall and have wireless users gain access to the network by using a virtual private network (VPN).

Virtual Private Network

A VPN is a private network set up within a larger public network. It can provide a secure private connection from a home or remote office, over the Internet or other unsecured network (e.g., wireless), to the hospital's local area network for access to the clinical information system and other sensitive applications. With a combination of secure authentication, encryption, and "tunneling," the remote user can have access to the same applications as if he or she were on site. Authentication ensures that only authorized persons gain access to the VPN. Encryption prevents the data from being read if intercepted. Tunneling allows the data to traverse the Internet and get past the firewalls and gain access to the network (Figure 8-1).

Remote access to patient data is one of the major issues where physicians and IT administrators clash. Physicians demand it, but the administrators are reluctant to implement it, especially in view of the HIPAA security regulations. The security of a VPN is a function of how tightly authentication, encryption, and access controls are connected. A VPN with a desktop firewall solution and appropriate audit trails is a compromise that is workable in many institutions.

Authentication

Authentication is the process of establishing the identity of a user to a computer or system with some degree of certainty. Most often, it is used to grant access. The most common method of authentication uses passwords. "Smart cards" with magnetic strips or barcodes are another method of authentication. Their problems relate to loss or theft, if not duplication or forgery. Biometrics identifies individuals by fingerprints, faces, voices, irises, retinas, signatures, or other physical attributes using some combination of hardware and software. Although the specifics vary, the general process includes collection of the biometric information by a scanner (fingerprints), a camera (face), a microphone (voice), or some other modality. This information is converted by some algorithm to a mathematical template that can be compared with a database of authorized users. The data often are encrypted to prevent intercepted information from being used as keys. Biometric devices are not bulletproof and can be fooled or bypassed. However, as the technology matures, the problems may diminish.

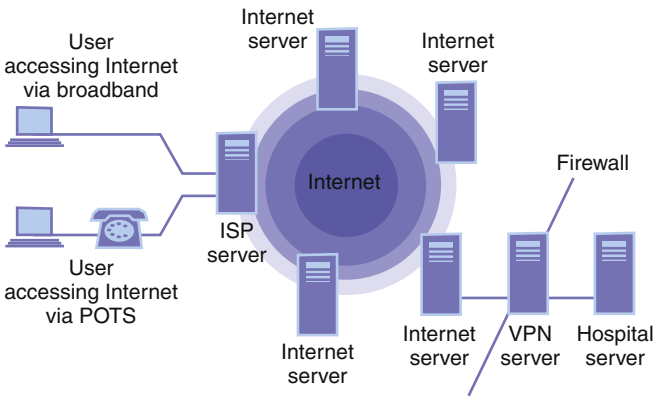

Figure 8–1. Virtual private network connection. The user gains access to the Internet through any means, usually an Internet service provider (ISP), while running VPN software. Data are directed at the hospital VPN Server by "tunneling" through the public Internet by encryption and special packaging. Once the data stream reaches the hospital's VPN server, it is unencrypted and sent through the firewall to the hospital server that receives the data, the latter oblivious to the fact that the data came from outside the hospital network. The reply to the user follows the same path through the VPN server that encrypts and packages it to traverse the public Internet.

Most security experts agree that the best way to effectively protect any computer system is to layer complementary technologies, hence the adage, "Something you know. Something you carry. Something you are." Items known to the user include passwords and other personal information. Items carried by the user can include keys or identification cards with barcodes or magnetic strips designed to make forgery difficult. Authentication based on an individual's physical characteristics using biometrics composes the last category. A multilayered approach may be necessary to protect super-secret government agencies, but the requirements for most medical information are less stringent. Although some zealous individuals may equate patient privacy with national security, multilayered security systems may be difficult to implement, particularly in an environment where slow or unreliable access may compromise a patient's well-being.

The authentication system widely used remains the combination of user ID and password. These systems are only as secure as the least compliant user. Although there are recommendations regarding choosing and maintaining passwords (Box 8-3), many users ignore these guidelines, making the entire system vulnerable to unauthorized access.

Poorly designed passwords are vulnerable to cracking by any of a number of commercial software programs or by any enterprising programmer. In general, passwords should not be single words. They should be some combination of small

Box 8–3 Guidelines for Creating Passwords

1. Passwords should be at least six to eight characters in length, the longer the better.
2. Passwords should include uppercase letters, lowercase letters, and numbers. Non-alphanumeric symbols (e.g., #, @, !, &) can often be used, depending on the system.
3. Passwords should be easy to remember and easy to type.
4. Do not use any readily accessible information as any part of a password. This includes your user name, full name, address, birth date, or Social Security number.
5. Do not use single words or simple word combinations. Dictionary attacks can test millions of words or word combinations per second, including foreign words.
6. Do not record passwords on any unsecured medium, such as notes beside the computer, on an identification badge, or in a book.
7. Change your password every 4 to 6 weeks.
8. Do not recycle old passwords or use the same password for several different applications.

words and numbers, and they should be changed with some frequency. They should never be written down, let alone posted on the side of the monitor. Passwords should never be shared. Most hospitals have policies that forbid sharing or borrowing user names and passwords. Dismissal is generally the penalty for such infractions.

Users should always log out of all systems before stepping away from a workstation to prevent giving others unauthorized access on their login. Because users do not always remember to do so, there should be a mechanism for automatic logout or lockdown if there is no activity over a specified period. Workstations that have "timed out" should still be available for use after the user has been reauthenticated or when another user is authenticated.

Viruses or Malware

Malicious software, or "malware," is designed to damage or infiltrate computer systems of unsuspecting users. Knowing how malware works is an important step in preventing an attack. The taxonomy of malware includes viruses, worms, Trojan horses, and "blended threats" that have features of more than one type.

Computer viruses are malicious programs attached to executable files or programs. They technically require human intervention to spread from machine to machine, as when users share files on transportable media, across a network, or via e-mail. Once on a system, the damage occurs only when the file is opened and the program executed by the user. Worms differ from viruses by the method they are transmitted from system to system. No longer limited by human intervention, worms can replicate and spread wildly within a system and across networks, sometimes by hijacking an e-mail program and using the stored email addresses to distribute themselves. The damage occurs when the program is executed by the user, initiating unchecked replication and using up the computer's resources. Trojan horse programs are disguised as, or are embedded in, programs that appear legitimate but perform some illicit activity when they are run. They typically do not replicate themselves or infect other files. Some Trojans are written to cause the loss or theft of data such as password information. Others make the system vulnerable to takeover by another computer. Still others simply destroy programs or data on the hard disk. The increasingly common and dangerous blended threats combine features of different kinds of traditional malware while attempting to exploit multiple vulnerabilities on both single-user computers and network servers. By using several different techniques targeting different weaknesses, blended threats can spread rapidly and cause widespread damage before they can be detected and neutralized. Combating blended threats requires an integrated solution at all levels of a network, including web servers, e-mail servers, and client computers, to protect every vulnerability.

At one time, document files were considered safe because they did not contain any executable programming. Modern word processors, spreadsheet programs, and other applications can create document files that contain macros. Macros are programs that allow a certain degree of automation in the creation or modification of that document and are embedded in the document file. Although these macros allow for additional functionality, they can be co-opted for malicious purposes. Obviously, not all macros are viruses, but if a file contains a macro, it would be wise to consult the author as to its legitimacy and whether it can be disabled without compromising the document. Other types of document files, including Joint Photographic Experts Group (JPG) graphic files, have been shown in laboratories to be capable of carrying viruses, but none have yet surfaced "in the wild."

Early web documents contained only textual information, graphics, and rudimentary formatting. The wish for enhanced functionality to augment the modern web experience led to the creation of new programming languages. ActiveX and Java programs embedded in a web page can generate eye-popping special effects and can greatly increase the interactive nature of web encounters, but they also can be used as means to attack computer systems. Web browsers configured with "high" security settings prevent ActiveX and Java programs from executing. Unfortunately, this configuration can significantly degrade the web experience, and it is a difficult task to selectively block malicious programs while allowing others to run.

Hoaxes or phantom viruses, although not technically malware, prey on the naïveté of most computer users. Although they generally amount to no more than an e-mail chain letter, they sometimes advise users to delete a needed file, adding that the "virus" cannot be detected by any antivirus software. Most of these false warnings urge users to "forward this to everyone you know" in an effort to perpetuate the hoax. If there is ever any question regarding a legitimate threat or a hoax, users should consult the web pages of any of the antivirus program distributors or perform a simple web search.

Safe computing practices should be used at all times and by all users within a system (Box 8-4). Antivirus software programs should be installed on every computer and the virus definitions should be kept up to date. The virus definitions are strings of bits that uniquely identify each virus from any other file, much like a DNA fingerprint. Out-of-date definitions cannot protect users from the most recently identified threats. Although some viruses can be intercepted by network administrators who protect their mail servers with antivirus software, there are other means by which malware can infiltrate a system. Sharing files through instant messaging or downloading files via web sites, newsgroups, or file transfers (file transfer protocol [FTP]) are among the many sources of security breaches. Carelessly and indiscriminately running received executable programs, opening received documents, or allowing ActiveX or Java programs from questionable web sites to run are high-risk behaviors.

Some experts view the current reactive paradigm of malware protection insufficient to secure legitimate users from the threat of increasingly sophisticated, malicious, and destructive attacks we likely will see in the future. Some security developers are turning to more proactive approaches to detect and neutralize yet unknown threats. One approach has distributed attack sensors on servers throughout the Internet to provide early warning. Another approach is heuristic analysis, where abnormal behaviors propagated by files identify and isolate potential threats.

User Privacy

The Privacy and Security Rules outlined by HIPAA regulate access to patient information. However, the privacy of the computer user, whether related to patient information or not, is vulnerable on many other fronts.

Box 8–4 Safe Computing Practices

- **Back up your data.** Safe computing practices can decrease the risk to your data but cannot eliminate it altogether.
- **Use antivirus software.** Use real-time virus protection at all times. Scan all files obtained across network or Internet connections, including from e-mail, web sites, instant messaging, or other sources. Scan all flash drives, CDs, or other removable media that are given to you. Scan all software before you install it. (There are verified reports of brand-new, shrink-wrapped retail software that contained viruses.) Periodically scan all hard drives on your computer. Maintain the most up-to-date virus definitions.
- **Beware of e-mail attachments.** Be suspicious of all e-mails, but especially those that are unexpected or out of character. Do not leave infected e-mail attachments or any unwanted attachments on your system. Do not set the e-mail program to automatically open attachments. If the e-mail program can render HTML messages, set it to disallow all executables (ActiveX, Java, and JavaScript).
- **Do not share.** File sharing and printer sharing should be disabled if these functions are not needed. If they are needed, limit access to your network. Never allow anonymous sharing of your system. Turn off unneeded services, such as hypertext transfer protocol (HTTP), FTP, Telnet, and personal web servers. Be wary of any files given to you, particularly those with the file extensions .exe, .com, .bat, .pif, and .vbs.
- **Use a firewall**. Use a hardware or software firewall. Files attempting access to the Internet or Internet servers attempting to access your computer should be investigated before they are granted access in the firewall configuration. Know the range of IP addresses used in your network so that intruders can be more easily detected.
- **Protect passwords**. Follow accepted guidelines for creating strong passwords. Do not record passwords in any unsecure documents. Disable password management in the web browser.
- **Keep security updated**. Obtain and install all software security updates, particularly for operating systems, e-mail clients, and web browsers.
- **Keep browser security updated**. Consider setting the browser security setting on "high" to prevent ActiveX or Java programs from running. This configuration may degrade your web experience, depending on the web sites that are frequented. Consider obtaining and using software to manage cookies and to warn you of web bugs.
- **Use macro virus protection**. Offered by some programs, notably Microsoft Office, macro virus protection identifies files that contain any macro before they are opened. It cannot determine whether these macros are viruses or legitimate macros.

The amount of personal information disclosed over the web intentionally or inadvertently can be disturbing to persons concerned about privacy, but every web surfer can take certain precautions. Primarily, users should not disclose any information they do not want to share. If personal information is required, as in a financial transaction, make sure the information is transmitted over a secure connection. Avoid answering questions such as your annual income, your mother's maiden name, or your Social Security number. If some information is "required," you should feel free to make up an answer. In addition, unless you are fond of junk e-mail, you should opt out of getting "special offers."

Your web browser can reveal volumes about you, including your computer's IP address, the web sites recently visited, and the contents of your browser memory cache. Users should routinely purge their browser cache, their browsing history, and the location bar memory. Cookies should be reviewed periodically with one of the available utilities. Those that contain sensitive information or belong to undesirable sites should be deleted. Some advertising networks allow users to opt out of their systems by going to the http://www.networkadvertising.org web site. Special applications or services can be used to block web bugs or to surf anonymously through a web proxy server.

For many of the threats to security and privacy in the electronic world there are software solutions with varying degrees of effectiveness. Some e-mail services can make the sender anonymous; others provide secure, encrypted mail, saving only one copy to be retrieved by the user. Other software can filter out spam—unsolicited e-mail advertisements—although many standard e-mail agents can perform similar filter functions. Several antispam software packages include antivirus scanning of all incoming mail and some firewall capabilities. It is possible to prevent your IP address from being discovered, even by web bugs, and to encrypt all web page requests. Still other products can block, sort, or clean up cookies. Advertisements can be blocked, as can any site with potentially objectionable material.

It takes a fair amount of effort to protect your privacy. Cookie sorting can take as much as a half-hour per week, but even sporadic use of online commerce requires cookies. Constructing an impervious wall of privacy is not a practical goal. There will be tradeoffs between the services provided by web sites and the personal information you are willing to surrender, but there are abundant wares available that can help keep your business your own.

Spyware

Various technologies to spy on computer users exist, and new classes continue to be developed. Spying software can log every keystroke, raise flags when key phrases are typed, capture and store periodic screen shots, record e-mail and chat sessions, and report suspicious activities by e-mail. Use of this kind of software in the workplace is becoming more commonplace as employers seek to recoup lost productivity from their workers engaging in non–work-related activities. Some computer viruses or other malicious software (see Viruses or Malware) include spyware that can snoop on and even commandeer the victim's computer. Other spyware attempts to capture passwords or credit card information and forward them via e-mail or Internet relay chat.

Hardware key loggers are inconspicuous devices that can capture every keystroke typed on a keyboard en route to the computer. Hidden in the keyboard or the computer case and completely undetectable by software, they can capture more than a year's worth of typing.

Network sniffers can effectively perform a wiretap on a network or over the Internet by intercepting and recording packets of raw data to and from the victim's computer. Most of the data, particularly e-mail, that traverses networks is not encrypted and therefore is highly vulnerable. Wireless networks (802.11 protocol) are even more accessible (see section on wireless networks).

A computer stores a wide range of backup data and cache information to speed performance and help recovery in the event of system crashes. Even files that you thought you had deleted may continue to exist on your hard drive and may be recoverable by forensic software. Web browsers also store a history, cookies, and cache that usually enhance a user's experience on the web, but can also be a font of information to an investigator. Furthermore, as some White House staffers discovered to their dismay, e-mail deleted from their own computers was not necessarily removed from their e-mail host server.

Countermeasures require that users be aware of the potential threats. Installing and frequently updating antivirus software is only the beginning. Spying software can take up significant disk space, cause unexpected disk activity, or produce unusual network traffic. Personal firewall software can warn the user that his or her computer is sending information without authorization.

Cookies

Web pages are considered "stateless," that is, they have no way to know what items are in the electronic shopping cart or to even remember anything about the user or where on the web site the user had been. In order to improve the experience, cookies were developed. Cookies are data created by a web server, stored on the user's computer, and later read by the originating web server. A cookie includes the address of the web site that sent it. Web browsers will allow a web site to read only those cookies originating from that site and no others. Cookies also include a date after which that cookie is set to expire and to be removed from the user's computer. They can track where on the site the user has been and how often. They can remember user IDs and passwords, and they can remember user preferences so that content can be tailored to the user's interests. Although they can "improve your experience," they also can offer a wealth of information for marketers and others.

Cookies are stored in a file on the hard disk. The web browser can be set to accept all cookies, reject all cookies, or notify you if a cookie is being set. The ubiquity and importance of cookies make the latter two choices virtually untenable; however, newer versions of popular browsers provide some ability to selectively reject cookies and to allow editing of cookies to eliminate any information you would not want sent back to web sites on future visits. Most reputable web sites mention the use of cookies in their privacy policies. These policies often go unread, they are not binding and often are subject to change without notice.

Web Bugs

Information about web traffic and about the persons who visit certain web sites is extremely valuable to commercial web sites, advertisers, and others. Web bugs exploit the way browsers handle web pages to surreptitiously collect limited but important information. These "bugs" (as in clandestine listening devices, not insects or programming errors) also are known by euphemisms such as "web beacons," "clear GIFs," "1-by-1 GIFs," "invisible GIFs," and "beacon GIFs."

A web bug is a graphic on a web page designed to feed information back to the owner. The size of these images typically is 1×1 pixel; some are not just small but also are invisible. They often are in the graphical interchange format (GIF) file format (Figure 8-2).

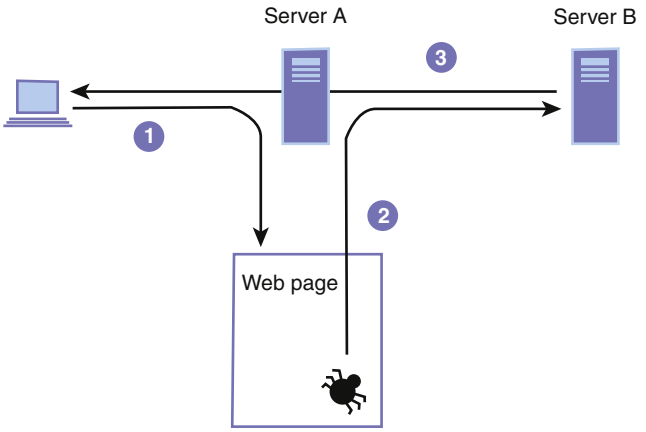

Figure 8–2. Web bugs. (1) A user requests a web page from Server A. (2) A web bug on the requested page points to an image on Server B. That server can record the information that is relayed to it, including the IP address of the requesting computer and the URL of the web page containing the web bug. (3) Server B can send a cookie directly to the requesting computer. If the user visits another site with a Server B web bug, that cookie will tell it where else this user had been.

The information that can be sent back to the server includes the IP address of the user's computer, the URL of the web page, the URL of the web bug image, the time the web bug was viewed, the kind of web browser used, and any cookies previously set for that server. It can provide an independent accounting of the number of persons visiting a particular web site or the popularity of a particular web browser. Furthermore, anything entered on a web page, whether a zip code, birth date, or even search strings, can be shared among web sites. Advertising networks can generate a detailed personal profile by piecing together all these data and other publicly available data. This profile can be used to specify the banner ads displayed, and the web bugs can correlate the display frequency of a particular banner ad with what was purchased.

Software is available that serves as bug repellant, but its use can make it difficult to navigate certain sites without a barrage of warnings. Most web sites make their privacy policies available. The reputable sites mention the use of web bugs, although they often use one of the euphemisms listed.

Profiles and Privacy Policies

Reading privacy policies posted on Internet sites can be fairly revealing and can precipitate significant paranoia. These disclosures often admit to using a variety of methods of tracking user patterns, although they are nonbinding and subject to change without notification. The methods of user tracking are not limited to those outlined here. For example, one popular drug-information personal device software company admits to tracking the number of times a drug is looked up and the screens viewed. These data are sent back during synchronization and are stored in aggregate and as personally identifiable information. Furthermore, the profiles are supplemented by public information about users from sources such as the American Medical Association.

Although much of these data are collected to "improve customer satisfaction," we should not assume that the intentions

of all collectors are to benefit the users. Some may have nefarious intent. Regardless of their intent, creators of certain software or web sites leave few alternatives to these invasions of privacy besides total abstinence.

Electronic Mail

E-mail has been likened to sending a postcard written in pencil. Just like a postcard that passes through many hands between writer and reader, e-mail can be read by anyone who can view the message as it passes by their electronic eyes either on a mail transfer agent (MTA) or on the network. Not only can the message be read, but it also can be "revised."

E-mail originally was developed to deliver only plain text (American Standard Code for Information Interchange [ASCII]). Sending anything other than plain text required that the data be "attached" to an e-mail message. Attaching files requires that they be coded for transmission and decoded once received. The most common method in use today is multipurpose Internet mail extensions (MIME). Sending files as attachments to e-mail allows users to share documents, photographs, and computer programs, but also viruses.

Although standard e-mail messages are pure text, some e-mail software can view messages that are composed like a web page in hypertext markup language (HTML). This web browsing feature requests images and other components to be downloaded and renders the HTML with fancy text, tables, images, and hyperlinks. Although this capability improves the user experience, it also opens new vulnerabilities, particularly the web bug method (see section on web bugs). The most readily accessible information by this method is the user's IP address. Reading this kind of e-mail can synchronize the IP address to an e-mail address, a threat to anonymity that exposes users to an explosion of junk e-mail.

HTML mail opens additional vulnerabilities through exploits of programming languages such as ActiveX, Java, and JavaScript. Users should configure their e-mail client software to disallow the execution of these programs.

The bane of most e-mail users is "spam" or unsolicited advertisements. They are the junk mail and the telemarketers of the Internet. The authors of spam usually purchase your name and e-mail address from a marketing agency or directly from web sites you visited. Other than limiting yourself to web sites that do not collect your e-mail address and refusing to disclose your e-mail address altogether, there are some things you can do to reduce spam. Some spammers offer opportunities for users to "unsubscribe" from their mailing list. Although these offers sometimes are legitimate, a response often only serves to identify the user's e-mail address as "live" or valid. Addresses that are known to be valid often are subjected to more vigorous spam campaigns. Some users prefer to maintain more than one e-mail address, reserving one for work, one for personal use, and yet another for use in public areas such as web sites that require an e-mail address. Most e-mail software programs offer methods of filtering messages and applying a variety of automatic actions. Users can create filters to automatically delete messages from senders of spam. These messages should be deleted from both the user's computer and the mail server.

If these measures fail to adequately control spam, some software packages are designed specifically for this purpose. This software filters content for common phrases used by spammers. Content filtering can be expanded to eliminate other inappropriate messages, such as sexually explicit language or racial epithets. Many corporations use content filtering on their mail servers, blocking or tracking inappropriate language, corporate secrets, and even viruses.

Conclusion

Medicine is an information service and critical care is perhaps the most information-intensive medical subspecialty. It is no accident that many intensivists have a particular interest in IT, but every practitioner will be more effective if he or she obtains the skills to better manage the flow of information. Furthermore, as physician leaders focusing on IT, intensivists can lead the way in creating a safer environment for all patients. Understanding the limitations and pitfalls of the technology and exercising caution as it is implemented is of paramount importance for success.

As everyday users of IT, all users should understand the threats to privacy and security, not only for our patients but also for ourselves. Networked systems are as vulnerable as their weakest link. Sustained vigilance and safe computing practices are essential to avoid calamitous data loss or exposure to exploitation.

With these caveats, IT greatly enhances our lives and our work. It profoundly augments what we know and the speed with which we know it. We and our patients are both better because of it.

Chapter 9

Family-Centered Care in the Pediatric Intensive Care Unit

Debra Ann Ridling, Mithya Lewis-Newby, and Daphne Lindsey

PEARLS

- Using family-centered care principles to establish the parents as partners with the health care team encourages trust and cooperation, reduces fear and anxiety in both the patient and family, and creates an environment of mutual respect.
- Access to their critically ill child is reported by parents to be a high priority. Benefits have been clearly demonstrated when pediatric intensive care unit policies support parent presence in the unit at all times, including periods that traditionally have been closed to them, such as change of shift, during admissions, and during emergencies.
- Access to information provides parents with tools to better collaborate with the health care team. Participation in rounds, access to their child's medical chart, and daily communication with a care provider result in more accurate exchange of data and fewer errors in communication and improves the patient's and family's experience.
- Pediatric intensive care unit staff can facilitate parents' participation in the daily care of their child, thereby supporting the parental role, preserving the parent-child bond, and reducing the impact of traumatic events, such as procedures and resuscitation, on both the patient and family.

Admission to the pediatric intensive care unit (PICU) constitutes a crisis for both the patient and family. This crisis is amplified by the stress felt by the parents in the ICU environment. (In this chapter, the term "parents" is used for the primary caregivers of the child, whether they are biologic, adoptive, legal, or other.) The main contributors to the stress are the child's uncertain outcome as well as the disruption of the parents' role and their separation from the child. In addition, the environment, appearance of the child, procedures performed on the child, and staff interactions all contribute to stress.[1-9] A crisis is an emotionally destabilizing change that occurs when a person's normal and usual methods of coping and problem solving are not effective.[10] Reestablishing the parental role in partnership with health care providers as early as possible mitigates the fear and frustration experienced by most families. Establishing this partnership is the core of the family-centered care philosophy, and it requires respectful attention at every level.

Caring and Compassion

In 2009 the Institute of Medicine[11] reported on its model for improvement, which included six quality aims: safety, effectiveness, equity, timeliness, efficiency, and patient-centeredness.

The Institute of Healthcare Improvement[12] adapted these into their "Idealized Design of the ICU." PICU leaders,[13] in collaboration with Agency for Health Care Research and Quality, took this model and adapted it to the PICU setting. Patient-centeredness is weighted as having importance equal to the other core components of the model, including safety and effectiveness. Core components of patient-centeredness were defined as empathy, compassion, and respect. This patient-centeredness should be extended to the parents. In many cases, the admission of a child to an ICU may be the most stressful, frightening event a parent has ever experienced. Providing empathy and compassion to patients is central to the work of critical care providers, but this care must be extended to the parents and is just as important as providing exceptional clinical care. Actions that can demonstrate care for parents include skilled communication, education, emotional support, and promotion of family participation in care.[13]

Humanitarianism and Defining the Family

Care teams can spend a great deal of time determining who is "the family" or "the immediate family." Traditionally, parameters pertaining to visiting and involvement in care have been defined and limited by the preferences of the health care team. Extended family and important friends often have been excluded. For many years the definition of *family* used by health care teams was based on the 1950s model of two biologic parents being the primary care givers and the main support being the grandparents.[9,14,15] These assumptions are no longer valid. The team should ask the parents to define their family so that caregivers are clear on who can receive information, be present, and be integrated into the care team. It is important to understand both the legal and informal arrangements of the family so that information is communicated to the appropriate members and requirements pertaining to consent and other legal issues are maintained.

Although these logistical arrangements are necessary, humanitarianism should be demonstrated toward the entire

family. One must recall that individual members of the family may have different fears, dreams, and expectations for their child. Providers are providing care not only for the child and parents, but for siblings, relatives, and an extended network of friends, teachers, and classmates. As noted by Kissoon,[16] "Whatever the composition of the family, the humanistic leader recognize[s that] paternalistic physician-patient/family interactions are outdated and should be replaced by partnership." Listening to parents and supporting them is respectful and fosters a collaborative relationship.

Family-Centered Care Core Concepts

Family-centered care is based on the assumption that the family is a child's primary source of strength and support. Family-centered care is characterized by four principles:

- **Dignity and respect.** Health care practitioners listen to and honor patient and family perspectives and choices. Patient and family knowledge, values, beliefs, and cultural backgrounds are incorporated into the planning and delivery of care.
- **Information sharing.** Health care practitioners communicate and share complete and unbiased information with patients and families in ways that are affirming and useful. Patients and families receive timely, complete, and accurate information in order to effectively participate in care and decision making.
- **Participation.** Patients and families are encouraged and supported in the decision to participate in care and decision making at the level they choose.
- **Collaboration.** Patients and families also are included on an institution-wide basis. Health care leaders collaborate with patients and families in policy and program development, implementation, evaluation, health care facility design, professional education, and delivery of care.[17]

Some general considerations described by the Institute for Family-Centered Care include a shift in attitudes and the development of new language. Some themes to be considered when developing guidelines around principles of family-centered care should include these concepts (Table 9-1).[17-23]

Challenges for the Team and Family

For families, critical care means fear, imbalance, turmoil, crisis, and a host of other sudden, deep emotions.[24] Both physical and psychological demands are placed on the family.[25]

Although the majority of families are able to adjust during this crisis, some are overwhelmed to the point of dysfunction. Like any other traumatic situation, for a small percentage of families, the crisis is sufficient to collapse an already overloaded family system.[9] Family functioning, adaptability, and resilience are affected by many factors, including the family's baseline functioning before their child's critical illness.[25] The family that lacks the financial, physical, emotional, or psychological resources to cope with the crisis of a hospitalized child deserves special consideration. All available resources should be directed to the family to assist them in their ability to support their ill child. A multidisciplinary team, including a social worker, child life specialist, pastoral care provider, and psychiatric care provider, when appropriate, may assist the family in resolving the concerns distracting them and enhance their coping skills, allowing them to focus on their child. It is helpful to designate one health care provider as the spokesperson with whom the family can speak daily for medical updates, which reduces the opportunity for confusion or contradiction among caregivers. If the family is still unable to provide a calm, nurturing atmosphere for their child after provision of these additional practical, psychological, and spiritual supports, it may become necessary to structure or limit the family's participation.

Culturally Sensitive Care

Culture is a pattern of learned beliefs, shared values, and behavior that includes language, styles of communication, practices, customs, and views on roles and relationships. It goes beyond race, ethnic background, and country of origin.[26]

Because individual clinicians cannot be knowledgeable about all cultures or even the major groups of organized religions, the unit should develop principles of cultural competency.[27-29] Many hospitals are creating Centers of Diversity and Health Equity to assist in developing and implementing policies that create and maintain a culturally competent environment. Providers can be trained in interpersonal interpretation—that is, to look beneath the surface when communicating with someone from another culture, to listen actively, and to seek out the real meaning underlying a family member's statement.[26] Many hospitals are creating Patient Navigator Programs to build trust with families in their own language and ensure that families understand the care that is being provided. Patient navigators are trained, culturally sensitive health care workers who provide support and help families navigate through the various components of the health care system. Additionally, patient navigators help providers understand families' particular needs.

Taking into account the diversity and uniqueness of each patient and family is important if one is to provide respectful care and services that are responsive to their language, race, gender, culture, spiritual values, family configuration, education, and other attributes. One of the most effective ways to understand the needs of an individual family is to ask. Often the spokesperson for the family can provide the team with the necessary information that will assist in the care of the critically ill child.

Professional Boundaries

Although family-centered care principles require a shift in professional practices and a change of culture within the hospital, professional roles still must be clearly defined and respectfully maintained. When entering the child's room, clinicians should introduce themselves to the family and explain their role on the care team. Respect toward other members of the health care team should be demonstrated at all times. It is crucial to maintain good working relationships when caring for a critically ill child whose clinical condition may change quickly and whose outcome may depend on continuous collaboration between persons of many disciplines.[16] Stable, trusting relationships between a patient, family members, and providers is critical in treating and managing a patient's illness. However, developing and maintaining stable, trusting relationships in the PICU can be challenging. Developing a

Table 9–1 Family-Centered Care Concepts

Traditional	Contemporary	Concepts
Deficit	Strength	Highly involved parents who require detailed information and continual presence with their child have often been considered a distraction to the delivery of care because of the time and energy required by the health care team to attend to these parents. Sometimes, the parents have been thought of as a nuisance. The paternalistic model of desiring parents to be passive observers of care is now called into question. A family-centered care approach considers involved parents to be a strength to the child and multidisciplinary team. Appropriately incorporated into the delivery of care to the child, the parents can be an important asset.
Control	Collaboration	Traditionally, the health care team has controlled the degree of involvement parents had in their child's care. This control has included all aspects of care, including access to the child, information, and even the care being delivered. The contemporary approach of collaboration incorporates the parents in all aspects of care and supports the parents as an equal team member for the optimal delivery of care to their ill child.[59]
Expert	Partnership	In the oldest and outdated model of critical care, the delivery of care was driven by the medical physician without input from other disciplines. As critical care has become more complex and progressed over the years, most intensivists value the contributions of a number of experts from a variety of disciplines, such as nursing, respiratory care, social work, and pharmacy. Partnerships have been established with a variety of experts to deliver comprehensive critical care. Partnering with parents places value on what the parents bring to the team, such as continuity, history, and how the child responds to illness and treatment.
Information gatekeeper	Information sharing	Health care team members and institutions have desired to control information. This control of information has been considered to be related to the parents' lack of ability to understand medical concepts and/or health care providers' fears of litigation. Information sharing actually decreases the risk of litigation and gives parents the necessary tools to make complex, informed decisions.
Rules	Guidelines	Historically, administrators and managers have set rules for how family members should behave while in the hospital. The connotation of the word "rule" is considered harsh and not congruent with the approaches of family-centered care. The use of *guidelines* for behavior is more respectful and demonstrates an attitude of flexibility and collegiality.
Visitors	Parents	In some of the older models of critical care, parents had strict restrictions on how much time they were permitted to stay with their child. For example, in some settings, only weekly visits were allowed. More recently, visitation has been liberalized, but some units still limit visitors to certain hours of the day or specific time increments. Parents should be exempt from most rules of visitation. Parents should be considered an extension of the child and should have full access. The most respectful language is not to call the parents visitors at all but to reserve that term for casual acquaintances of the child or family, such as a school friend or teacher.
Rigid	Flexible	Some units still approach unit standards by rigid rules, setting policy in the strictest sense. In this traditional model of strict adherence to policy, the individual needs of the patient and family are not respected. Some units set policy based on experience with the worst circumstances. Families ask that policies be created to meet most families' needs with room for flexibility and regard for the needs of the child.

clear understanding of the concept of boundaries and therapeutic relationships and a skill set in these areas is crucial.[30] A therapeutic relationship is defined as "an interactive relationship with a patient and family that is caring, clear, boundaried, positive, and professional."[30] Therapeutic relationships involve ensuring that patients' and families' needs are met while maintaining personal and professional boundaries. Providing services beyond the scope of your professional role undermines the health care team partnership, no matter how well intended your actions. It is the professional's responsibility to maintain boundaries and help parents and families maintain theirs.

Personalizing Care

The environment of care has a growing impact on families.[26] Creating an opportunity for the individual characteristics of the child to be expressed when the child is unconscious promotes humanitarianism in the PICU setting. Individualizing the environment to include photos, favorite toys and blankets, music, and audio recordings of siblings and family members is an effective technique. The creation of a collage or poster about the child and family is an activity that often is well received by families and clinicians alike and can be therapeutic for the family. Mementos from home draw providers to the bedside and promote conversations that provide a glimpse of the child when he or she was well,[30] assist the care team in getting to know the family, and help the team see child and family as people, not just diagnoses.

Communication

The highly technical nature of the PICU environment and its multiple caregivers, paired with parental stress, creates a complex situation with a great potential for miscommunication. It is important to establish clear lines of communication both among the various members of the health care team and between the team and the family.[26] Because the stressed family is less able to take in, comprehend, and retain information,[21,31-33] explanations must be clear, concise, and repeated.

Special attention must be focused on avoiding medical jargon and abbreviations. Routine care conferences should be held because they are an important avenue to provide information, share opinions, and reach consensus. These care conferences may be held to provide medical updates or make treatment decisions.[26] It may be helpful to advise parents to maintain a bedside journal or log in which they can note information given and list questions to be addressed later. Placing a board in the child's room that lists the names of the care providers, the daily plan, and goals and that is updated daily is helpful to families. Collaborative care planning will help reduce stress for all persons involved in the care of the patient and may resolve or defuse conflicts between the family and the medical team or within the team itself.[26]

Daily Communication

To reduce confusion or contradiction among the caregivers' messages, it is helpful to designate one health care provider as a spokesperson with whom the family can speak daily. Ideally, this person should be the attending physician.[27,34] The content of the communication should include the status of the child, the results of any tests, procedures, or consultations, and the plan of care. Different families prefer different communication styles; the best practice is to ask them how they like to give and receive information. One helpful mnemonic that has been shown to improve communication in the ICU is VALUE (***v***alue, ***a***cknowledge, ***l***isten, ***u***nderstand, and ***e***licit).[35]

Daily contact should allow sufficient time for questions and support and should occur in a quiet environment. The decision to talk at the bedside versus at a remote space depends upon the level of consciousness and developmental level of the child, the type of information to be communicated, and the desires of the family. Generally, in the case of a conscious adolescent or an older, mature school-aged child, it may be most appropriate and respectful to include the patient in the conversations rather than exclude him or her. Alternatively, initial conversations may be conducted away from the bedside and then duplicated at the bedside of the awake, more mature child. Ideally the health care provider should sit down with the family and allow the conversation to include a period of silence to ensure that the family has ample time to voice questions and concerns. Listening is one of the most highly rated traits of health care providers by family members and leads to greater family satisfaction with care.[36]

Consultants should communicate directly with the attending physician who is coordinating the care before talking with the family. Parents can become confused and overwhelmed when they receive different portions of information from a variety of providers. If care is complicated or if the ICU stay extends beyond a week, arranging a family care conference that can include more family members and all important members of the care team is strongly encouraged. Care conferences can provide the opportunity for more in-depth discussion and more time for family questions and comments and should be considered a critical aspect of ICU family-centered care.

Respectful Language

All written and verbal communication should be respectful in tone and content; it also should be concise and consistent. Effective and understandable communication between parents and the medical team benefits the child, decreases parental stress and anxiety levels, and is the basis for trust.[37] It is helpful to communicate information in a variety of formats.[4] Information should include an explanation for why some restrictions are necessary (e.g., safety, a sterile environment, and isolation) and why some behaviors are prohibited (e.g., consumption of food in the patient's room and cell phone use). Table 9-2 provides examples of ways to communicate ICU restrictions without being perceived as being unnecessarily controlling or demeaning. Most families respond positively to guidelines that protect their child, especially when the guidelines are presented with a rationale. Staff should be reminded that most parents have never had experience in an ICU and do not arrive understanding expected behaviors. Questions should be answered honestly in terms families can understand.[26] Patients and parents need to be treated as equal partners as much as possible and be allowed dignity and control to the extent that is practical.[16] Respectful language between staff members is important, especially in the presence of family members. Family members who are sleep deprived and stressed may misunderstand conversations that are not respectful. This situation may lead to increased worry or lack of trust in their care providers' ability to work together as a team or even in their overall competency. Additionally, family members, who often seek information, may listen for inconsistencies by observing disagreements. Its important for the entire team to understand how conversations and language that is not collaborative can be misunderstood.[38] Table 9-3 provides examples of ways that problems may be communicated among staff that are less likely to add to patient and family distress.

Table 9–2 Examples of Traditional and Respectful Language Used with Visitors

Traditional Language	Respectful Language
SIGNAGE	
Parents only after 8 PM	Visitors are welcome from 10 AM to 8 PM. Parents are always welcome.
No smoking	A site for smoking is provided on the first floor outside the entrance.
SPOKEN	
You are not allowed to eat here.	Let me show you where you can eat.
You need to clean your hands.	Let me place that gel where you can reach it.
You can't use your cell phone here.	Let me show you where you can use your cell phone.

When English Is not the Primary Family Language

Families who do not speak the primary language of the medical team have considerable additional stress. Expecting them to be able to conduct conversations without a professional interpreter for either in-depth discussions or short updates or questions during the day is an unreasonable expectation. Even families who speak "pretty good English" will have more

Table 9–3 Communication Among Staff Promoting Patient and Family Trust

	Not Respectful (Does not Promote Trust of Parents)	Respectful (Demonstrates Collaboration)
RN to MD	You ordered that test wrong.	I was notified that we need to change how the test was ordered; I can show you how.
RN to MD	You ordered a 10 times overdose of morphine.	Can you please change this order? Our typical dose of morphine would be 1 mg for a patient of this size.
RN to MD	You just contaminated your gloves.	Let me grab you a new pair of gloves.
RN to resident	You'd better not wake up that baby; he just got to sleep.	He just fell asleep—would it be possible to examine him later? I can call you.
RN to resident	Why don't you know how to order this medication?	Do you want to grab your fellow to help you order this medication?
MD to RN	Why didn't you call me with this result last night?	Please feel free to call me anytime; I would appreciate hearing these results, even if it is in the middle of the night.
MD to RN	Why did you give him so much sedation? He is too sleepy.	How much sedation has he had?
MD to RN	Why did you lose that arterial line?	What happened to the arterial line?
RN to RT	You did not clean your hands before touching the patient.	Let me grab you some hand gel.
MD to family	The nurses should have called me about this; how long has this been going on?	Can you tell me how long this has been going on?

MD, Physician; *RN,* registered nurse; *RT,* respiratory therapist.

difficulty than native English speakers in processing new information during this time of crisis. Interpreters are essential in situations in which a language barrier exists.

Care should be taken in choosing an interpreter. The complex medical issues that arise in the PICU require a trained interpreter for effective communication to occur.[26] Using another family member as an interpreter is not advisable because it puts undue pressure on that person. In addition, the interpersonal dynamics of their relationships can influence communication and compromise the patient's confidentiality or may even lead to inaccuracies.[26,39] When an interpreter is not readily available onsite, use of interpretation services by telephone is preferable to use of a family member. It should be the standard of care to provide professional in-person interpreter services at least daily.

Access to Information

Second only to their need to be with their child, parents need easy access to information.[32,40-44] In addition to conversations with the health care team, parents should be supported with regard to access to their child's medical record. Access to the same information available to the other health care team members in the same format encourages trust and cooperation. Having a health care professional available for clarification as needed may be helpful but is not mandatory. Requiring parents to go through administrative or legal protocols to gain access to this information is destructive to the partnership of care. In that environment, ultimately, no matter how conscientiously it is delivered, the care of the child suffers.[45]

Technology

As the public becomes more technologically sophisticated, they expect the same sophistication in the ICU, including Internet access at the bedside. Traditionally, families may have been discouraged from using the Internet to obtain information, but most care providers realize that a large portion of the public uses the Internet as their first source of information. Providers must find a way to partner with parents and, rather than discouraging use of the Internet, work with them to explain what they are finding and provide appropriate sites that include accurate information and are sanctioned by the hospital and/or subspeciality.

In addition, as the public has become more e-mail savvy, they expect rapid communication and a timely response to their questions, regardless of whether an individual provider is present. Some units could allow families to e-mail the attending physician, with time allocated for the physician to respond daily. Furthermore, a growing number of ambulatory care centers provide patients with access to their electronic medical record. This same system could be used for critically ill patients. Although one can imagine challenges that might occur with any given system, providing access to laboratory results, diagnostic studies, and even surgical reports could facilitate knowledge and understanding of particular conditions.[25,46]

Rounds

Family-centered care can be effectively enhanced by inviting parents to attend and participate in daily multidisciplinary rounds. To ask parents to leave when the multidisciplinary team is focused on their child fosters mistrust and decreases efficiency. Traditionally, parents have been intentionally excluded from rounds, or they have been allowed to stay but not encouraged to contribute. Clinicians have feared that parents may misinterpret information, become concerned about staff competence, delay rounds by asking too many questions, or unintentionally inhibit necessary open and honest communication between health care providers about the patient's care. Contrary to these concerns, parents' participation in

rounds works well, improving parental satisfaction, patient care, and teamwork.[47]

Family participation in rounds provides an opportunity for open communication for families, patients, and the entire health care team. All team members should be encouraged to contribute information and ask questions. Parents often are excellent historians and keen observers of their child. Parents should be recognized as their child's expert, having a unique perspective on how their child responds to illness and treatment. Parents also can provide needed continuity with large and constantly changing care teams.[32] It is important to orient the parents to the purpose and system for rounds upon admission to the hospital. If rounds are to be the primary contact with health care providers for the day, the parents need to be informed of this so they are prepared to ask questions and to ensure they understand the care being delivered. The team should provide adequate time to conduct rounds if this is the model that is developed. If the model does not provide time for questions from parents, this situation should be communicated to the parents early on so they understand their role and do not become disappointed or frustrated by incomplete communication during rounds. In this case, the attending physician needs to ensure that he or she has time later in the day to meet with the parents.

Shift Report

Traditionally, parents have been asked to leave when nurses make their shift report. The same concerns and benefits related to rounds are applicable here. When concerns about confidentiality or legal issues exist, staff can accommodate the parents by making their report elsewhere. Other than factors relating to legal issues of abuse or neglect, parents have a right to know the details of their child's care, so information communicated through the report should already be available to the parents, including unplanned events.[9]

Depending on the unit design, concerns may exist about privacy and confidentiality of information when patients are in a shared space (e.g., double rooms and wards). Providers should be sensitive to issues of confidentiality but also should be reminded that parents, who often are present continuously through the day, may be very knowledgeable about the condition of their child's roommate, just by virtue of being present and overhearing routine conversations of care. Parents also are responsible for protecting the privacy of all patients and for being respectful. Most hospital brochures and parent handbooks speak to this point.

Disclosing Medical Errors

Disclosing errors or unplanned events demonstrates the principle of communicating complete and unbiased information in ways that are affirming and useful. As Levinson[48] comments, "Building a relationship in which the patient (and family) feels respected, supported, and trusting is critical to patient and family satisfaction and malpractice risk reduction." The person delivering these messages needs to follow the same principles that one does when conveying any other difficult news: Tell the parents as soon as feasible in a private setting. Communicate without blame how the error occurred, let them know what to expect, and help them to understand the implication of the error and its effect on their child. Elicit and acknowledge their responses. Parents should be reassured that everything will be done to prevent the incident from recurring. Clearly communicate any plans for follow-up, which includes identifying a contact person. All medical errors, even those that have minor or no effects on the child, should be reported.

Multidisciplinary Team

A variety of disciplines are needed in the care of any critically ill child. The components of the team are dependent on the needs of the child, although a physician and nurse are always included. The assignment of a consistent physician and nurse has been shown to decrease parental stress.[33] This assignment may be difficult to accomplish, particularly during an extended ICU stay; however, every effort should be made to ensure health care provider continuity. In the course of a child's stay in the PICU, the family will meet many team members. It is important for everyone to understand that any of these team members can become the family's primary source of support. In complex situations, the multidisciplinary team may become quite large and may contribute to family stress. The family should be encouraged to keep a written record of health care providers for clarity. In certain complex situations, establishing a continuity attending physician may be helpful. Regular care conferences also may be helpful in these circumstances.

Social Worker

Social workers are integral members of the health care team, and all parents should have access to a social worker.[28] This individual may be a member of the PICU team or part of a continuity team based on a specialty, such as cardiology, oncology, or organ transplantation. Often PICU admission, critical illness, and trauma are not anticipated and parents are unprepared for the turmoil they are thrown into. Having a social worker available who can provide crisis intervention and assist families in understanding the implications and complexities of the medical situation and the PICU is extremely important. Feelings of helplessness and an overall feeling of being out of control are common among parents,[49] and the social worker's ongoing supportive care, grief/bereavement counseling, and provision of concrete needs are critical in alleviating some of their stress. The social worker can be available consistently, can educate the family regarding how the PICU works, and often serves an important role as a liaison between families and the medical team. Social workers can be advocates for parents as they help them address the special needs of their child and family with the team.

The social worker's initial and ongoing psychosocial assessment of the family can help the medical team provide culturally appropriate and family-centered care. The social worker also provides a liaison with community resources, child protective agencies, and law enforcement when necessary.

Chaplain/Spiritual Care

The chaplaincy service carries an important role in providing respectful spiritual care and emotional support to patients, families and staff. This may take place through conversation and listening, rituals, prayer, help in ethical decision making, and bereavement support. They can offer Interfaith opportunities for worship, celebration, reflection, and spiritual exploration. They can also provide assistance with contacting a local

or hometown faith community or minister, priest, rabbi, or other spiritual leader.

Child Life Specialist

A child life specialist (CLS) should be available to all critically ill children.[28] Factors associated with the highest stress for parents include disruption of normal interactions with their child, changes in their child's behavior or emotions, parents' inability to comfort their child, and having a child undergo painful procedures.[26] The CLSs are members of the health care team who work directly with patients and families to help reduce anxiety and adjust to the hospital experience. A CLS can provide support and create a coping plan with patients to use during a medical test or procedure. They utilize therapeutic and medical play to help patients understand medical procedures and provide ways to express feelings and help maintain a sense of control. A CLS can teach coping techniques, such as distraction, guided imagery, and story telling, as a means to reduce pain and anxiety.[50] Bedside activities can be provided to support a child's need to play. A CLS can work with community resources, schools, and in-home care personnel to assist with the child's transition after discharge from the hospital.

Pet Therapist

Pets are considered by many persons to be part of the family. They provide emotional support for many people, particularly in times of stress or illness. There is growing support of animal-assisted therapy in many areas of health care, including critical care, as a complementary therapy.[51] Benefits for patients include an increase in positive outlook, stress reduction, normalization of the hospital environment, and overall feelings of comfort and happiness.

In general, there are two main approaches to pet therapy in the ICU. The first incorporates the family pet, and the second makes use of a professional or therapy dog. Incorporating the family pet into the child's hospital stay meshes well with the concept of family-centered care. Pets have a significant effect on humans by lowering stress, stabilizing the heart rate, and improving mood. Pets have been shown to prevent depression.[52-55] Many cases have been reported of critically ill patients responding to pets in a positive way, such as by becoming more interactive and willing to participate in their own care and recovery.

It may not always be feasible for a child's pet to visit because of distance, the animal's temperament, or other logistical realities. An alternative to having the patient's own pet visit is the presence of a professional or therapeutic animal. Although the emotional tie to the therapeutic animal will not be present, benefits similar to those seen with the patient's personal pet can be observed.

Parent Advisory Council/Family as Consultant

One of the principles of family-centered care is the collaboration of providers with patients and families.[17] As expert "consumers," families bring an experiential perspective and creative solutions that help advance the best possible care.[22,56] Many hospitals have created Family Advisory Councils composed of parents who have had a wide variety of health care experiences. They advise the hospital on how it can more effectively meet the needs of children and their families. Additionally, they can provide recommendations and feedback on policy, programs, and organizational changes that affect the family experience. Family "consultants" can be used at the unit level for a variety of activities (Box 9-1).

Box 9–1 Family Consultant Activities

- Teacher/orienter of new nursing or medical staff by sharing stories and answering questions about the experience as a parent in the PICU
- Author and analyst of satisfaction surveys
- Member of focus groups that are considering changes in service delivery
- Co-leader of a parent support group
- Consultant on orientation materials for families
- Consultant for PICU remodel or redesign team
- Committee member for relevant topics, such as ethics or quality improvement

Parent Support Group

While their child is in the PICU, parents naturally seek the understanding of other parents in similar circumstances. Availability of parent support groups can meet this need.[20,57,58] These groups may be led by a trained parent volunteer and/or a professional. Participation can help to normalize the hospital experience by providing an opportunity to share stories in a supportive environment. Other more structured parent support groups and sibling groups meet regularly and usually are convened around a specific population, such as organ transplant, cancer, or bereavement.

Volunteers

Volunteers play an important role in providing normal activities for ill children. They can engage in distraction and quiet play, such as reading or watching a movie, or more active play, such as games and crafts.[31] Volunteers also can be trained to perform more advanced tasks. For example, volunteers who receive training in crisis intervention can staff the waiting room. Another example of the use of volunteers can be found at Children's Hospital in Seattle, Washington, where volunteers in an "Aunties/Uncles" program develop and maintain an emotional, nurturing bond with a specific hospitalized infant or child when the parents are unable to provide that time at the bedside. These specialized volunteers commit to spending 5 to 6 days per week at the hospital for a minimum of 6 months. Parents give their permission for this surrogate to be with their child.

Financial Services

Although paying the bill usually is not the concern of the health care team, it may be a serious stressor for a parent in the PICU. This added stress can affect the parent's ability to make careful decisions. In some cases, parents may worry that their child will not receive the best care because of their limited financial resources. Recognition of socioeconomic constraints such as the inability to pay for care or to be away from work and trying to alleviate these hardships are important aspects of family-centered care.[16] Providing a financial counselor who can coordinate care with insurance carriers and identify alternative sources for payment can greatly reduce the anxiety of the parents.

Ethicist

Ethical dilemmas are inherent in modern medical practice and are frequently identified in the PICU. That said, a large proportion of what appear to be ethical dilemmas are frequently

failures in communication, both between staff and between staff and the family. Improving communication at all levels and at all times will greatly help to prevent and reduce disagreement and the need for ethical intervention. For true ethical dilemmas, training staff in ethical principles and having an ethicist as part of the core multidisciplinary team can foster open discussion and resolution of difficult issues for the entire team, which includes the family.[59] Whenever possible, it is most beneficial to have an ethicist present on a regular basis rather than only during a crisis. Because ethical concerns are recurrent, having a familiar person with whom to consult is a way to be supportive of staff and families.

Palliative Care

Pediatric palliative care services complement other health care goals and should be widely available in the PICU. Palliative care teams care for a wide variety of patients and ideally become involved at the time of a life-threatening diagnosis.[33,60] Palliative care resources are not limited to end-of-life issues and hospice care. In fact, palliative care complements cure-directed therapies. Because of the misconception that palliative care is limited to end-of-life issues, many pediatric palliative care teams around the country are changing their names to Pediatric Advanced Care Teams. The trained palliative care expert can facilitate discussions between the medical team and the family that takes into consideration the preferences and values of the family, medical indications (benefits and risks), quality of life, and contextual issues such as cultural, spiritual, and community supports. This discussion is coordinated with health providers and family members, resulting in the completion of a comprehensive decision-making tool. This tool sets the care plan, which follows the patient through his or her illness to the return home.[61] This document, which is revised as needed, allows for earlier coordination in the hospital and within the community, resulting in more consistent and compassionate care on all levels. In complex situations, the palliative care team member can provide excellent continuity of care, both within the PICU and beyond.

Access Concepts

Access to their child is probably the single most important issue for a family with a hospitalized child.[1,3,5,9,32,41,62] For the child, the family provides a reassuring constant in the unfamiliar PICU environment. To mitigate the anxiety experienced by families in crisis and the displacement of parental roles, access should be supported 24 hours per day, with clear communication related to the importance of parental involvement. Parents should be viewed as partners in care rather than visitors. Additionally, to the extent possible within the constraints of the medical care, parents should be given every opportunity and encouragement to have physical contact with their child. Parents can be leery of medical technology, and staff should help them overcome this uneasiness.

Admission Process

The admission process can be frightening for the parents and child, especially in cases of emergent or unplanned admissions.[63] Every effort should be extended to help the parents acclimate to the new environment with compassion, courtesy, and time. Parents report a loss of control, which can be unbearable when they are separated from their ill child. To support the child and the parents, caregivers should invite the parents to be part of the admission process and support them in their desire to remain with their child.[1,21,32,63-65]

If parents cannot be directly at the child's bedside because of space limitations or caregiving tasks, a space should be provided for the parents where they can see their child. They usually understand the need to be away from the bedside in this instance and, upon being given a brief explanation and a dedicated space near their child, they usually are tolerant of the separation. As soon as feasible, a caregiver should provide the parents with some initial brief information. Because anxiety greatly affects short-term memory, it often is difficult for stressed parents to take in detailed information early on. Once the child is stabilized and caregivers have more time to devote to the parents, caregivers can sit down with the parent, either at the bedside or in another confidential space, to provide more information.

The initial information given to parents should include the condition of the child, what has been done so far, and the plan of care. Parents often request a prognosis as well. When done well, this discussion is a predictor of later comprehension of what is communicated by the health care team.[27] Once the child is stabilized and the parents have spoken with the physician, cues can be taken as to when the parents are ready for a general orientation to the unit (Box 9-2). For a scheduled stay in the PICU, this orientation can most effectively be done prior to the admission.[66]

Sibling Participation

Siblings are an important but often overlooked part of the process of adjustment for patients and families to hospitalization. Sibling presence at the bedside should be supported based on the needs of the patient, parents, and sibling.[9,67-71] Siblings have not always been welcome in the PICU, although the concern that young siblings pose a greater infectious risk to the patient than do adults was disproved in the 1980s. Some persons fear that siblings will become frightened by what they see. However, siblings often appear to accept the environment better than do some adults. Often the sibling's imagination about the condition of an ill brother or sister is much worse than the reality. During an initial visit by siblings, time should be spent preparing them, the parents, and the patient for the hospital experience.[67] Any trained team member can prepare

Box 9–2 General Orientation to the Unit

- Access to the unit
- Communications within the unit (telephone, pager, computer)[56,81]
- Bedside accommodation of family members
- Handwashing protocols
- Isolation protocols
- Sibling visitation guidelines
- Sleep accommodations
- Eating/drinking possibilities at the bedside and within the hospital
- Clinical team member identification and roles
- Multidisciplinary rounds orientation
- Registration paperwork

the family, but the preparation might be most effectively done by a social worker or CLS. The patient's condition should be explained to the sibling so the interpretation is not left up to the child's imagination. It often is helpful to show the siblings a photo of the patient and the room and discuss what will be seen. This step helps prepare siblings for what they will see. Siblings should be allowed and prepared to visit, but they always should be asked if they want to change their mind, and their decision to decline a face-to-face contact should be respected. During the visit, a clinician should be available to support the siblings and answer questions. Following a visit, a short debriefing is helpful to answer additional questions and support siblings in expressing their feelings. Providing materials for the child to prepare a memento, such as a card or drawing, to be left at the bedside can be therapeutic for the entire family.

Family Space

Family-centered care principles can be demonstrated by the physical setting.[33,43,72,73] The patient's bedside should include dedicated space for families. The space should include an area where parents can sleep so they can stay overnight if they wish, storage, individualized lighting, and a phone with voice mail and computer access. Additional support space can include sleeping facilities in close proximity to the PICU. Parents should have access to shower and laundry facilities, a cafeteria, and transportation.[20]

Participation in Care

Parents are better able to cope when their role as caregiver is maintained.[1,6,7,21,43,64,69,74,75] Staff are accustomed to providing all the care for their patients, and they often feel that parents expect this care. Yet for many parents, the provision of such care can be alienating because they may feel incompetent to care for their own child. Staff can help parents provide care for their child, thus promoting the parent-child bond and improving the self-esteem of the stressed parent.[7] Staff, especially nurses, can collaborate with parents in defining the kind of care both parents and caregivers are comfortable in providing. Parents may feel frightened by their child's appearance or overwhelmed by the technology, and they require assistance in developing their new role as parents of a critically ill child. Part of routine care in the PICU should include the education of parents on the technology attached to their child, such as monitors. Traditionally, some nurses have encouraged parents to ignore the monitor or not pay attention to it, trying to get the parent to focus on their child and not be concerned about every beep and alarm. It is very difficult for parents to disregard these devices that are attached to their children, and not educating families has been shown to increase their stress level.[76] The clinician can be most effective by clearly communicating safe and appropriate care for the individual patient and modeling the behavior. This modeling may be as simple as holding the child's hand and helping the parent to do the same. Parents can participate more actively as well. They can be given options, such as assisting with bathing, positioning, or massage.

Procedures

Clinicians may have concerns about parents' presence during procedures, but a growing body of evidence demonstrates that parents want to be present, and this approach generally works well.[77-85] In academic hospitals where junior staff are learning how to perform procedures on patients, clinicians may feel uncomfortable with parents observing. Because the teaching process will occur whether or not the parents are present, it is honest to support the parents' presence if that is their preference.[9,82] As with any event, the parents should be prepared for what to expect. In addition, parents should be told who will be performing the procedure, any teaching that will take place, how the parent can support the child, and where in the room they can safely remain.

When the parents choose not to stay or cannot be present, they should be provided a comfortable place to wait that is close to the PICU. There should be a plan for communicating with the parents during the procedure and at its conclusion. If the child will be sedated for the procedure, the parents should be allowed to stay with the child until he or she has been sedated and then brought back to the bedside at the conclusion of the intervention.

Resuscitation

Clinicians have expressed a number of concerns related to parental presence during their child's resuscitation (Box 9-3). However, increasing evidence and a wealth of clinical experience supports the parents' presence.[14,82-95] Parents may wish to be present even during resuscitation. Preparing them for what they will see is an important aspect of supporting them so they can be at the bedside. One of the primary benefits is that the parents can see that every effort was made to save their child. Often when parents are not allowed to be present, their imagination of what is happening behind closed doors is worse than the reality. They may come to mistrust the team and begin to question what really happened in their absence. Additionally, parents may believe their presence gives their child strength and that it is important that they be with them spiritually. Parents come to trust the health care team more because they witness the team working together in a common effort to save their child. Even in cases in which resuscitation fails, the partnership developed between the parents and health care providers previous to and during the resuscitation can be helpful for the parent's acceptance of the child's death.[96,97]

It is important that parents be given a choice of whether to be present. In all cases, a staff member should be assigned to the parents to explain the care being given to their child. Ideally the parents should be familiar with this caregiver, but this scenario may not be possible, nor is it essential. The caregiver should give brief explanations of what is occurring, answer questions, and act as a liaison between the resuscitation team and the parents. This individual should be focused on the parents and not

Box 9–3 Clinicians' Cited Concerns/Fears Regarding Parents' Presence During Resuscitations

- Interference with the resuscitation
- Misinterpretation of the team's performance
- Liability risk
- Team competence questions
- Familial emotional injury
- Staff uncomfortable with grieving family members present
- Distraction, lack of concentration by medical team

be directly involved in the resuscitation. Because most units have preassigned roles for resuscitations, one should be designated for parental support. Finally, families should be offered the opportunity to be alone should they feel the need.

In some units, the parents of other patients are asked to leave the area when a resuscitation is occurring. This practice should not be routine unless space is extremely limited and the parents would interfere with the ability of the team to deliver the care. Parents should stay with their own child so that they can comfort them in the midst of what is happening around them. It can be frightening when a child is separated from a parent and is left behind, unsupported, during a crisis. Parents can be helpful by staying with their child if staff are pulled to another bedside to assist with an emergency. Parents also can share in the experience with their child and provide ongoing and future support related to the event.

Transferring out of the Pediatric Intensive Care Unit

Transfer from the PICU can be a time of anxiety and uncertainty. Families experience loss when they leave caregivers with whom they have developed relationships during crises. Among the fears reported by patients and families is not knowing what to expect from unknown caregivers. Additionally, they report anxiety related to the higher patient-to-nurse ratios and leaving an area where every patient physiologic event is closely monitored. The family can benefit from a variety of approaches to allay their anxiety, all geared toward providing encouragement, information, and inclusion in the process.[98-101]

If the child has been in the PICU for an extended period or the parents are particularly anxious, a care conference can be arranged with staff from the receiving unit to delineate who will be caring for the child when the child is transferred, discuss the goals of care, and answer any questions the parents may have. PICU staff should be careful to speak positively about staff in other areas of the hospital and reassure families about their competence in handling emergencies.[100] Written information about the transfer has been shown to significantly reduce parental anxiety about imminent transfer from the PICU.[98] Other potential interventions for improving the transition for families, especially those with long ICU stays, are noted in Box 9-4.

Compassion Fatigue

The very nature of the work in the PICU puts care providers at increased risk of burnout and compassion fatigue (also known as *vicarious traumatization*). These two syndromes can affect the care provider's mental and physical health, contribute to impaired job performance and lower team moral, and even lead to suboptimal quality of care, medical errors, and lower patient and family satisfaction.[102] To cope with the difficult nature of this work, many care providers distance themselves emotionally from their work. Care providers can develop detached responses to families and their experiences and suffering because of the perception that detachment protects against burnout and compassion fatigue.[103] Contrary to this belief, a recent study found that a practice called *exquisite empathy*, described as "highly present, sensitively attuned, well-boundaried, heartfelt empathic engagement,"[104] actually was protective against burnout and compassion fatigue.[102] To provide optimal family-centered care in the PICU, it is imperative to learn about these syndromes, educate staff, employ organizational changes, and encourage staff self-care practices to mitigate symptoms.

Box 9–4 Activities to Prepare for Transfer

- Initiate transfer process early
- Remove monitor well before transfer if the patient will be off a monitor in the receiving unit
- Identify a primary nurse prior to transfer who will meet with the family to help them plan their involvement in the patient's care
- Conduct a tour of the receiving unit
- Provide written information prior to transfer, including descriptions about the receiving unit and its staff
- Assign a PICU liaison check-in with the family after the transfer

Chapter 10

Ethics in Pediatric Intensive Care

Joel E. Frader and Kelly Michelson

PEARLS

Major Principles of Medical Ethics

- Beneficence: Provide care that benefits patients
- Nonmaleficence: Avoid harming patients
- Autonomy: Individuals should decide what constitutes their own best interests
- Justice: Provide service fairly, without bias from factors irrelevant to the medical situation

Informed Consent

- Patients or surrogates must have adequate decision-making capacity (competency, in legal terms)
- Patients or surrogates must have the ability to understand and communicate about the medical situation
- Patients or surrogates must have the ability to manipulate information and deliberate about the nature and consequences of alternatives
- Patients or surrogates must have the ability to make a choice among alternatives based on relevant values
- Decision makers should have adequate, comprehensible information
- Professionals should assess the decision maker's understanding of the situation and alternatives
- Valid choices require freedom from undue pressure

Decision Standards

- Substituted judgment: Surrogates decide based on knowledge of the patient's views of the situation or, if that knowledge is unavailable, on the patient's general beliefs and lifestyle
- Best interests: Surrogates decide based on information about the patient's situation, alternatives, and overall judgment about which course best serves the patient

Intensivists struggle with value questions all the time, regardless of whether they explicitly label the process "ethical decision making." This chapter addresses some of the common and more important moral questions arising in pediatric intensive care units (PICUs). It aims to clarify how the values of patients, families, health care professionals, and those of the wider society do and should influence the practice of pediatric intensive care. Although the goal of the chapter—helping intensivists to help patients and families better—is practical, it is best served if the reader appreciates a small amount of the theory that supports much of contemporary medical ethics.

Moral Theory

Medical ethics does not constitute a completely independent field. Most persons think of medical ethics as an applied discipline of the wider branch of philosophy that is ethics. Like most other intellectual pursuits, ethics has developed according to several theoretical traditions. In Western ethics, two particular ways of thinking have dominated for some time. Because these approaches may yield rather different perspectives on some questions, they deserve mention.

Consequentialism

One tradition, known as *consequentialism,* examines the correctness of an action according to what effects the act will likely have on the real world. Good actions produce the most favorable ratio of happiness, pleasure, or some similar value to unhappiness or a similarly disvalued result. The utilitarian philosophers Bentham and Mill enjoined us to seek the greatest happiness for the greatest number of individuals possible. These theories emphasize the social nature of human moral action, requiring calculation of the consequences of an act. Only after determining the impact of an action for those directly and remotely involved can a person pronounce ethical judgment.

Deontology

The other main approach to moral theory proceeds from different premises. Deontology (from the Greek word for duty) holds that some actions have intrinsic moral worth. Many religious moral rules conform to this view. Hence the Ten Commandments pronounce that we should not kill. Other approaches, such as Kant's categorical imperative, also proclaim universal truths and rules that persons should honor irrespective of the consequences.

A consequentialist might claim that removal of organs from persons in a persistent vegetative state does not harm the individuals because they can no longer experience meaningful life, or even hunger or thirst. The consequentialist also might assert that harvesting the organs best serves the class of patients in a persistent vegetative state because, overall, transplantation fosters the well-being (and by implication, happiness) of humans who can actually benefit from continued treatment. Some deontologists, however, surely would argue that the killing that necessarily results from the removal of vital organs, no matter what the intent, undermines human dignity and is morally impermissible.

Prevailing Principles

Despite the "opposing" traditions of ethics, most persons in medical ethics agree on a small number of important principles that should guide medical behavior. The reader should note, however, that narrow adherence to these notions encourages an oversimplified approach. Medical ethics neither begins with nor ends with the principles named here. A more nuanced view includes many more considerations and a clear sense of how different ideas interact, especially how some moral duties conflict with others. Nevertheless, a few guideposts may help intensivists understand that medical ethics, like clinical medicine, uses formal logic and has a recognizable structure.

Beneficence

The first principle, beneficence, demands that physicians provide care that benefits the patient. This principle may seem self-evident until you remember that many potential conflicts of interest can influence medical decisions. For example, parents of children may face tragic choices about the support of a sick child whose survival could endanger the economic or psychological integrity of the rest of their family. Other conflicts may involve doctors, especially those in a fee-for-service system, who benefit financially from providing services that promise only marginal, if any, additional benefit.

Nonmaleficence

Beneficence contrasts with nonmaleficence. According to this notion, doctors have a duty to avoid harming patients. Again, the idea may seem obvious, but the practical application involves considerable complexity. For example, when deciding whether to use extracorporeal membrane oxygenation for a desperately ill infant with a diaphragmatic hernia, you must consider the possibility that the technology will extend the life of the baby only by several days but may cause discomfort to implement and maintain; that is, no long-term benefit will accrue to balance the burden of the procedure. Similar reasoning might apply to cases of malignancy for which chemotherapy and other treatments have no or little likelihood of producing a cure or substantial life prolongation, whereas the treatments impose burdens, such as nausea, itching, extreme fatigue, and high risk of infection. The principle of nonmaleficence reminds us to take potential pain and suffering seriously before recommending no-holds-barred medical intervention.

Autonomy

When considering which medical treatments will best help a patient and what harms to avoid, a natural question arises: whose perspective should we use? The principle of autonomy suggests that we must respect individual human differences. To the extent possible, persons should decide for themselves what is in their own best interests. In pediatrics, respecting autonomy can present difficult questions about when children develop the capacity and independence to accept or refuse recommended treatment. The autonomy principle reminds us that individuals or their families often have different values and goals from those of their physicians. Medical decisions usually should be in accordance with the patient's or family's perspective.

Justice

The fourth principle, justice, provides some of the most pressing and challenging dilemmas for modern medical care. Put simply, this principle exhorts us to use our services fairly, that is, to avoid decisions that accept or reject candidates for treatment based on factors that are irrelevant to their medical situation, such as poverty. The application of the justice principle runs into two major obstacles today. First, members of our society seem to have a great deal of difficulty agreeing on what constitutes just or fair allocation of medical resources. Second, we have not yet decided exactly how considerations of justice should affect the medical care system.

Medical goods can be distributed, assuming not everyone can have everything, according to a number of different schemes: based on the likelihood of success; by some definition of need (urgency, desperation); as a reward (for past achievement, for waiting the longest, for future contribution); by equal shares; by random assignment until the goods run out; or, as we often do in our society, by ability to pay. Different philosophical and political traditions support each of these approaches, and we seem far from agreeing on which is best.

With respect to the second issue, some persons urge physicians to ignore financial constraints to do everything "medically indicated" for patients, regardless of the economic consequences.[1] The argument is that, at least for decisions about individual patients, physicians discharge their fiduciary responsibility only by advocating the best, even if most expensive, care. Macroeconomic concerns, regional and institutional issues, and microeconomics challenge this view.

From a macroeconomic perspective, our society resists increasing medical spending as an ever-increasing proportion of total social expenditure (such as percent of gross domestic product). Most Western industrial countries spend on average 9% of gross domestic product on health care. Does the United States get incrementally better outcomes for its 15% or larger outlay?[2] By many measures of public health (e.g., infant mortality and longevity), the well-being of the U.S. population does not reflect our high medical expenses.[2] Similarly, does the way we spend our health care dollar make the most sense? Should we spend great sums of money on expensive intensive care at the end of life for patients with little likelihood of benefit? In pediatrics, we have reason to believe that preventive measures (e.g., immunization and accident prevention) reduce morbidity and mortality rates[3-5] and, in some cases, save money.[3,4]

Regional and institutional economic questions involve matters such as consolidation of care to increase economic efficiency and medical efficacy. However, political and psychosocial factors often lead to duplication of services and diffusion of experience. Certain programs may even create conflicts of interest. For instance, a hospital could offer a particularly scarce and expensive service (e.g., extracorporeal membrane oxygenation or pediatric organ transplantation). The costs of the service might be so high that just a few patients treated "free," that is, without charge to the family, might threaten the economic stability of the enterprise. Such fiscal concerns surely help shape what services institutions offer and the way those services become available (are "marketed") to those in need.

With respect to microallocation, intensivists frequently engage in decisions about the distribution of specific services

to particular patients, sometimes with clear awareness that competition exists under conditions of scarcity. With a nearly full ICU and a large demand for postoperative care for the cases on the next day's operating room schedule, intensivists often must negotiate and juggle, trying to meet varying claims about who should occupy scarce beds and receive nursing attention. Even the decision to use one vasoactive drug or antibiotic instead of a far more or less expensive agent requires an attempt to balance expected benefit against drains on resources. It seems inappropriate to demand that physicians ignore such actual conflicts. Intensivists, like other practitioners, rarely enjoy the luxury of having a single duty to a single patient with an unlimited ability to pay for services. Although doctors might prefer to leave economic considerations to policymakers and the marketplace, justice issues do find their way into ICU routines.

The challenge for the pediatric intensivist involves applying the various ethical principles and perspectives to individual cases and to policies that affect how the unit operates. The following sections focus on a few topics where ethical concerns arise frequently.

Health Care Decision Making: Consent

A major shift in doctor–patient–family relations occurred in the last half of the twentieth century. Doctors now have less freedom to make paternalistic decisions about how to treat patients according to their own beliefs and feelings than they did in the 1950s. With a wider range of technical options, social trends emphasizing individual liberty and consumer preferences, and the weakening of traditional authority and trust in professionals, legal and moral arguments at the beginning of the twenty-first century emphasize patient/personal choice in directing medical decisions.

These trends have become embodied in the doctrine of informed consent. Backed by philosophical arguments concerning the importance of individual and family autonomy, ethicists, legal scholars, and judges have advanced the notion that patients or their valid surrogates have the right to or should, if they wish, determine which of the available medical alternatives to follow.

In most circumstances, minors are legally incompetent; that is, state statutes determine the age at which children become legally entitled to make binding decisions, including those about medical care. In general, children have limited legal rights to make medical decisions for themselves until age 18 years. As a consequence, like other legally incompetent patients, surrogates must authorize medical treatment for children. Usually, parents serve as the valid surrogates for their children. Moreover, informed consent, per se, has limited direct application in pediatrics. Valid consent requires adequate information and understanding, involves judgments about a proposed intervention, and reflects personal values bearing on the situation; thus consent can only be given by a patient with decisional capacity.[6] Strictly speaking, parents or guardians give informed permission, a concept supported by the American Academy of Pediatrics.[7]

When parents or another surrogate provide informed permission for older children and adolescents, clinicians should seek the child's assent when possible. By obtaining the child's assent, clinicians empower children to the extent of their capacity and foster trust in and improve patient-physician relationships. According to the American Academy of Pediatrics, assent should include: "(1) Helping the patient achieve a developmentally appropriate awareness of the nature of his or her conditions; (2) telling the patient what he or she can expect with tests and treatment(s); (3) making a clinical assessment of the patient's understanding of the situation and the factors influencing how he or she is responding (including whether there is inappropriate pressure to accept testing or therapy); and (4) soliciting an expression of the patient's willingness to accept the proposed care."[7] In certain situations, U.S. federal regulations require respecting the child's wishes, such as in proposed participation of a minor in research that provides no substantive potential for individual benefit. In the clinical arena, when treatment refusal is not life-threatening, physicians should make an effort to understand the patient's reasons for refusal and help him or her understand the consequences of such a decision.[6]

Certain legal and ethical exceptions exist where a "child" has decision-making authority for himself or herself. Almost all states have statutory provisions for children to obtain treatment for sexually transmitted diseases without parental or other surrogate consent. In many states, similar laws apply to children seeking contraception, care for pregnancy-related matters (sometimes including abortion), and mental health care, including care for substance abuse. Children may achieve legal status to make their own medical decisions when emancipated. Depending on the jurisdiction, emancipation may mean graduation from high school, joining the armed forces, living separately from and economically independent of parents, or being pregnant or being a parent. Thus under some circumstances a critically ill minor may be legally entitled to consent to or refuse treatment, even over and against parental wishes.

In addition to specific legislative rights for some children to consent for themselves, another legal notion may apply. Courts have used the theory of the "mature minor" in judging whether a child has the capacity and maturity to decide what is best for herself or himself. Such cases typically involve chronic or long-standing medical conditions where the minor has had an opportunity to observe the implications of the disorder; to experience the effects of the disease; and to reflect on the religious, moral, and factual matters relevant to medical decisions. Examples of such situations include adolescents with cystic fibrosis, end-stage renal disease, and muscular dystrophies. The mature minor doctrine allows that, in selected cases, the child may accept or decline life-sustaining treatment, such as dialysis, mechanical ventilation, and transplantation, with or without agreement from the family. Other situations might include those where long-standing and well-thought-out beliefs, such as those held by adolescent Jehovah's Witnesses, would lead the child to refuse blood transfusions that otherwise might be essential for appropriate medical care. These cases require careful individual determinations about the actual capacities of the patient and the issues involved, and prudence may suggest judicial review. (This discussion does not imply that legal entitlement equals the best moral solution to dilemmas or disputes. However, the law recognizes that some children have legitimate independent claims regarding their medical care that may differ from the expressed wishes of their parents or guardians. This legal recognition suggests that, at times, professionals should support admittedly divisive stances that minor patients take.)

The right, in the law, of a "reasonable person" to accept or refuse offered medical treatment, however, involves some important qualifications. The legal reasonable person standard assumes a competent patient or surrogate. To make a valid choice, the patient or surrogate needs comprehensible information about the medical situation so that any choice reflects the range of alternatives and their consequences. Simply having the information does not suffice; the decision maker must actually exhibit an understanding of what he or she has learned. Finally, choices of individuals or surrogates should occur voluntarily, that is, free of any undue pressure, especially from health care providers.

Competency

Legal entitlement does not mean the proposed decision maker actually is competent, whether referring to the child, a parent, or other guardian. More accurately, we should regard competency as a legal determination, and physicians must assess the decision-making capacity of the patient or surrogate. This capacity has several features and elements. First, capacity to make medical decisions involves specific determinations for each "significant" decision. A patient or surrogate may have appropriate capacity to accept, in general, medical efforts to prevent death from fulminant hepatic failure. However, the patient's agreement to accept intensive care does not provide a warrant for the doctors to proceed directly to liver transplantation. The proposal of the latter treatment should trigger a separate exploration of the decision-maker's capacity to agree to transplant surgery. Similarly, decisional capacity refers to specific kinds of decisions. If a parent cannot balance his or her checkbook or pay medical bills on time (because of a lack of understanding of what is involved, rather than a lack of funds), it does not follow that such a parent cannot rationally refuse mechanical ventilation for a son or daughter with a degenerative neuromuscular disease. Further, disagreement with a medical opinion does not, in and of itself, constitute grounds for declaring a patient or surrogate incapable of making sound choices. Rejection of medical recommendations may trigger concern about mental abilities, but such disagreement does not establish the case that the decision maker lacks decision-making capacity.

Although not everyone agrees on how to define medical decisional capacity, most persons accept the notion that it involves (1) an ability to understand and communicate about the medical situation at hand, (2) an ability to manipulate information about the situation and deliberate about the nature and consequences of alternatives, and (3) an ability to make a choice among the alternatives, preferably based on relevant values.

Information

Assuming a patient or surrogate has appropriate decision-making capacity, the decision-maker needs information about the patient's condition, prognosis, and alternative treatments. Clinicians should provide details without jargon and abbreviations. Frightened and dependent patients or surrogates may nod or respond as if they understand, but some empirical evidence and common sense suggest otherwise.[8,9] Ethical and legal considerations require that the information be understandable to the decision-maker.

In addition to the actual content of any information provided, doctors must consider the timing of decisions and the state of mind of the decision-maker. Even the best prepared patients or surrogates may need complex material presented repeatedly (hence the value of written or audiovisual aids) and may need time to absorb and reflect on what he or she has learned. A common problem is the assumption by health care professionals that consent (or refusal) occurs at some magic instant in time, usually associated with a signature on a form. Lidz, Appelbaum, and Meisel[8] suggested a superior conception of consent as a process that occurs over time in the context of a relationship among doctors, patients, and surrogates. Although intensivists may object that the nature of their patients' problems and the hectic critical care environment make evolving, deliberative, and relational consent unrealistic, truly emergent treatment decisions remain relatively rare and, in any case, are exempt from legal consent requirements. Most important decisions can occur with adequate time for reflection and with time for relationships to develop. Also, physicians should not consider decisions immutable. Just as medical situations change and require reconsideration, so may the goals of treatment and the acceptable means of reaching those ends remain fluid. The concept of "time-limited trials" may help health care professionals and patients or surrogates remember the value of periodically reassessing courses of action.[10,11]

Understanding

For the capacitated decision-maker who has received sufficient understandable information, the clinician can and should determine if the decider actually comprehends the facts and issues. Experts disagree on what criteria to use in assessing understanding. Some persons accept having the decision-makers repeat a summary of the facts and concerns (which demonstrates recall rather than understanding), whereas others have health care providers ask detailed questions in which they probe the matter. Still others permit the assumption of understanding in the absence of questions from the decision maker. Clearly, a "yes" answer to the question "Do you understand what I have just said to you?" demonstrates very little. Research suggests that physicians routinely overestimate what patients and family members understand.[9] Some persons might say that life-and-death treatment in the ICU is so complicated that parents cannot possibly understand it anyway. Although we should perhaps seriously consider this challenge to the value and importance of informed consent and patient or surrogate autonomy, these concepts remain the legal standard of care and deserve attention on that account.

Voluntariness

The final aspect of informed consent that requires discussion involves whether the patient or surrogate has given permission for treatment or diagnostic tests freely or voluntarily. Permission obtained under duress generally cannot be considered valid consent. Here, as with other aspects of consent, we may encounter difficulty agreeing on how to determine what constitutes freely given acceptance of medical plans or recommendations.

The usual model of informed consent applies most directly to situations in which all parties have considerable time to

reflect on the available options. Although in some cases we need not invoke the notion of emergency, patients or parents may not have many hours or days to consider alternatives. Do time limitations themselves constitute so coercive an influence as to invalidate full consent? Surely the nature of the patient's situation can prevent ideal, deliberative decision making. Having to make decisions that may affect life and death may leave parents feeling, "If we don't accept this doctor's plan, we may be harming our child." Undoubtedly, telling parents faced with a life-and-death matter that they must accept their doctor's favored approach when several valid medical alternatives exist cannot be tolerated.

Shared Decision Making

Although the shift in decision making has been toward patient autonomy, the general approach to medical decision making is also changing. The emerging interest in shared decision making focuses on the process and places less emphasis on the specific endpoint chosen. The concept of shared decision making was first introduced by the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research in 1982. In that report, shared decision making was described as a process based on mutual respect and partnership between the patient and clinician.[12,13] Although a variety of definitions for shared decision making exist, a literature review describes common characteristics, including deliberation/negotiation; flexibility/individualized approach; information exchange; multiple individuals; compromise; mutual respect; partnership; and patient education and participation.[14] Shared decision making involves a process of clinicians, patients, and, where appropriate, loved ones considering together all options, accounting for patient values or best interests, and finally arriving at an appropriate choice for the patient in the particular situation. Shared decision making allows physicians to take an active role in decision making; indeed, in some circumstances patients may ask the physician to assume the entire decision-making responsibility.[14]

Surrogate Decision Making: Parental Rights and Obligations

Theorists and courts have agreed that autonomous individuals can accept or reject medical treatment for almost any reason.[15] Doctors have had to defer to adult patients' whims, isolated false beliefs, and strongly held opinions about medical matters to satisfy society's insistence on respecting individual liberty. (The need, in the end, to accept reluctantly that what a person believes to be an inappropriate course of action does not relieve the physician from the burden of trying to dissuade the patient from his or her view.) Parents and others with responsibility for surrogate decision making, however, must adhere to different standards. In the cases of individuals who have had an opportunity to express beliefs about desired or unwanted medical care, surrogates usually must use a standard known as "substituted judgment." In these situations, surrogates attempt to decide what the particular patient would want under the specific circumstances based on their knowledge of the patient's views. Written documents (such as "living wills"), oral discussions of particulars (such as the patient's feelings about long-term mechanical ventilation after severe head injury), or a general understanding of the patient's preferences and lifestyle all may form the basis of legally valid surrogate decisions.[16] To the degree that young patients with sufficient decision-making capacity, such as adolescents with sickle cell disease at risk for cerebral vascular accident or those with muscular dystrophy at risk for cardiac or respiratory failure, have expressed views about possible treatments before becoming unable to express their wishes, the notion of substituted judgment also should prevail in pediatrics.

Far more commonly, however, substituted judgment makes no sense in pediatrics. It only can be a flight of the most fanciful imagination: just how might a toddler with a high spinal cord transection from a motor vehicle accident "think" about what he or she would want (death or a life on a ventilator)? Accordingly, most scholars in ethics and most courts have attempted to apply a different standard for making decisions for children, that of "best interests." The standard enjoins the surrogate to take into account all relevant information about the patient's condition and the alternative treatments (including, presumably, the resources available to obtain and maintain care) and decide, all things considered, on what course to follow.[17]

One term used by many persons, "quality of life," has received considerable attention in these decisions. The phrase has been used to convey two substantially different concepts. Some persons reject quality-of-life considerations because they believe that parents, doctors, or others use it to make judgments about the social worth of the patient; that is, for some persons, quality of life implies something about the potential of the patient to contribute to the general social welfare (e.g., hold a job, pay taxes, or simply consume resources). Those who fear that social worth will equal quality of life strongly oppose taking quality-of-life evaluations into account in surrogate decisions. Most commentators mean something different. For them, quality-of-life considerations involve overall prognosis, including pain and/or suffering associated with the patient's condition(s) and treatment(s); the practical likelihood of overcoming barriers to effective treatment, including the financial, social, and psychological resources available to the patient and family; and other nontechnical matters.

Aside from confusion about what meaning to assign to the phrase "quality of life," it seems quite reasonable to weigh factors beyond simply what technical approaches can affect the child's medical condition(s). Although fears about inappropriate discrimination against the handicapped have a legitimate basis, history raises at least equivalent, if not overriding, concerns about excessive and inhumane treatment, whether in obeisance to the technologic imperative or in pursuit of a vitalist belief.[18] Examples include overzealous neonatal intensive life support in the face of increasing complications and parental objections, such as that detailed in *The Long Dying of Baby Andrew*,[19] or the use of artificial hydration and nutrition over surrogate objection, which took place in the highly publicized Terri Schiavo legal battle.

Arriving at an adequate, practically useful definition of "best interest" has eluded the efforts of many in the pediatrics, social work, legal, and ethics communities. Without a clear notion of what constitutes the best interests of the child, it has been difficult to establish readily applicable limits on surrogate decision making. A lively debate continues about the acceptability of including "third party" or parent/family considerations in decisions for or about children, especially life-and-death decisions.

The difficulty for the pediatric intensivist lies in knowing when parental or other surrogate decisions fall outside some socially or morally adequate range. These difficulties involve medical uncertainty about diagnosis and prognosis, varying community standards regarding many different practices (especially the existence of state laws on religious exemptions from child abuse and neglect laws), and changing social attitudes about lifestyle. Concrete examples of these problems illustrate the dilemmas.

Consider a critically ill child with intestinal failure. During the past few years, several treatments have been offered to children with short bowel syndrome and some severe motility disorders who approach exhaustion of their options for total parenteral nutrition. Controversy exists about the effectiveness of enteral feeding,[20,21] operations for improving intestinal function,[22] and small bowel transplantation.[23]

For each of these approaches, we know little about the long-term outcomes. No one has attempted a straight-on comparative trial of these radically divergent treatment methods, in part because of strong beliefs about which intervention works best. Unfortunately, these convictions have little or no basis in scientifically valid research. Some intensivists caring for a patient with short bowel syndrome believe that because neither the surgical approach nor intensive medical treatment has proven long-term benefit, parents should remain free to accept or reject each intervention and accept palliative/hospice care. Others believe it necessary to challenge parental refusal in court.

Resolving such a dilemma requires consideration of the general question of how much physicians need to know about any therapy, especially of the therapies they recommend, before justifiably attempting to impose treatment, through judicial means, on reluctant patients and families. A helpful question might be the following: what would the doctor choose for her or his own family? A study of neonatologists, pediatric cardiologists, and pediatric cardiac surgeons noted considerable discrepancy between what the physicians recommended to parents of newborns with hypoplastic left heart syndrome (HLHS) and what they would want for their own child. A significantly greater proportion of the physicians accepted nonsurgery—and the inevitability of death—for themselves compared with what they recommended to families.[24]

With regard to community standards of care, the majority of states have laws limiting the application of child abuse and neglect standards in cases in which parents invoked religious practices as the reason for delays in, or refusal of, medical care for their children. The manner in which religious exemption laws have been used, either in decisions not to intervene (i.e., order treatment or prosecute criminal cases when a child has been harmed) or as a primary defense in court, has varied greatly across jurisdictions. Most persons agree that parental religious beliefs should not prevent children from receiving clearly beneficial treatment that would permit the children to accept or reject their parents' faith when the children become more mature.[25] The difficulty comes in deciding what conditions warrant intervention and what treatments confer obvious benefits.

Criminal prosecutions in California, Massachusetts, Arizona, Florida, and elsewhere remind the pediatric community that certain religious convictions, in these cases Christian Science convictions, favor prayer over antibiotics for meningitis, surgery for bowel obstruction, and other standard medical treatments.[26] Assuming timely diagnosis and intervention, deaths of children could have been prevented, and the likely medical outcome would have been excellent. Yet in some cases that may involve pediatric intensive care, the need for treatment and its benefits leave room for doubt.

Some pediatric cardiothoracic surgeons have taken on the challenge of correcting congenital heart defects by using cardiopulmonary bypass without supplemental blood. At the request of families who are Jehovah's Witnesses, these surgeons agree to operate by using saline solution in the bypass circuitry. Documentation of their success has long been available in the peer-reviewed medical literature.[27] Witnesses believe that doctors can frequently provide adequate treatment without using the blood or blood products that their faith cannot accept. In other circumstances, pediatricians may request and receive court permission to treat sick children with blood transfusions when routine use of blood relies on tradition and not scientifically established need. For example, a child with an acute lung injury may receive packed red blood cells to maintain the hemoglobin above 10 mg/dL. Few data support a clear medical need for this intervention, and emerging data would refute the need for empiric transfusion.[28] In that and other circumstances involving the children of Jehovah's Witnesses, clinicians ought to think twice before seeking court orders to perform blood transfusions.

Although understandable, psychosocial factors that lead physicians, anxious to protect their patients, to assert professional control do not constitute an ethical justification for action. In light of the importance of religious freedom in the history and political system of the United States, intensive care professionals should consider giving great deference to personal beliefs, especially in medically marginal or uncertain circumstances.

If there is debate about the proper role of parental religious views in determining medical care for children, we have utter confusion about the role of so-called third-party considerations, such as the impact of a child's disease and treatment on the parents and other family members. Some authors have suggested that when substantial uncertainty exists about the benefits of treatment, when the burdens of treatment seem weighty (e.g., multiple operations, long-term hospitalization, or toxic drugs), or when the ability of the patient to experience human pleasures will be seriously compromised, parents can and should consider the impact of the child's treatment on the family as a whole.[29] Such concerns might include temporal, fiscal, and psychological resources that the sick child will consume and that might otherwise be available to siblings or other dependents.

These matters can become quite confusing, as the following case suggests. A 6-month-old child was referred to a distant center for consideration of organ transplantation. The message to the family at the referring hospital had been heard by the parents as ambivalent; that is, the parents believed the doctors in their hometown were not entirely convinced of the value or likelihood of the success of transplantation. The transplantation physicians believed the child was an excellent candidate for the procedure and had a favorable prognosis (65% or better 1-year survival, at the time). The parents hesitated to accept treatment, stating that transplantation would mean that the mother's recent reentry into her career would be derailed, that they did not want the (considerable) expense of chronic immunosuppressive medication, and that, all things

considered, transplantation seemed more of a burden to the family than they thought they could tolerate.

The situation caused considerable distress among the staff at the referral center. Had the parents said, "No, thank you, we'd rather take the money we'll have to spend on antirejection drugs and buy a sailboat," the staff would not have hesitated to challenge their decision-making authority. However, the parents stated coherent and serious concerns. Given the nontrivial risk of complications and the actual burdens of treatment (e.g., lifelong immunosuppression with possible serious infection, malignancy, and toxic injury from medications), their refusal of the "standard of care" (not experimental treatment) seemed difficult to accept but sufficient to prevent an attempt to obtain court intervention. No doubt some other centers would have reacted differently.

With regard to unorthodox parental preferences concerning treatment, courts have not always acted to support mainstream physicians. In one older but still important New York State case, the "Matter of Hofbauer," the courts supported the parents' choice of a licensed physician who agreed to treat the child's Hodgkin's disease with "nutritional or metabolic therapy, including injections of Laetrile."[30] The Court of Appeals of New York decided it could not and should not choose among treatments, each of which was supported by physicians legally practicing within the state. Following that view, parents only need to find a licensed practitioner to endorse their preferred approach to prevail in court. Doubtless the limits on parental or other surrogate decisions will continue to be debated by those concerned with pediatric ethics, laws, and medicine. For the time being, only a rough consensus exists that the best interests of the child should remain the guiding principle in most cases. When doctors and parents experience serious difficulty in defining or predicting what action will best serve the child's interests, other considerations become more important. Other legitimate concerns include the family's religious views or moral commitments, the family's resources, and the ordinary and reasonable plans and projects of family members.[31] Adherence only to narrow technical goals of treatment has little place in the provision of advanced pediatric intensive care.

Conscientious Objection to Participation in Proposed Interventions

The shift in medical authority from physicians to patients/family members has prompted some concern about loss of professionals' moral agency. Some physicians, nurses, and others have responded by claiming a "right" to refuse participation in some proposed or offered medical interventions, calling this "conscientious objection" based on religious or other strongly held personal beliefs. Curlin and colleagues[32] have articulated these concerns most clearly. Although many of the targeted practices concern reproduction, such as the provision of contraceptives or performing abortions, some interventions reach into the PICU, including offering nonsurgical palliative care for infants with hypoplastic left heart syndrome, procuring solid organs for transplantation after death declared by cardiac criteria, and use of palliative sedation at the end of life. In each of these situations some intensivists believe that participation violates their moral codes, and they invoke conscientious objection.

Some persons have pointed out problematic features of these claims of conscientious objection. Frader and Bosk[33] noted the historical development of professional codes and their link to social status and an ethic of dutiful subservience of the professional's personal well-being to that of the patient's best interests. In many contemporary claims of conscientious refusal to provide care, the professionals assert the importance of not participating in any aspect of the behavior they see as wrong, including discussing options with the patient or providing referrals to those who might engage in discussion or provide the service. Given the relative paucity of knowledge and skill patients possess, Frader and Bosk see this extended form of conscientious objection as abandoning the professionals' responsibility to fulfill the ethical and legal responsibilities encompassed by the doctrine of informed consent.[33]

May and Aulisio[34] note the importance of distinguishing between the formal complicity of acts, for example, taking the patient to die in the operating room to facilitate rapid removal of organs after death, and morally weaker material complicity in which one's behavior may lead to the undesirable outcome. May and Aulisio suggest that one cannot avoid material complicity in a world with social interaction and that material complicity, although real, is not strong enough to avoid the basic professional duty of telling the family of a dying patient about the possibility of organ donation after cardiac death.[34]

In controversial matters in which substantial numbers of professional colleagues and patients/family members consider a legally available option reasonable, such as nonoperative care of a child with HLHS, conscientious refusal appears to return to medical paternalism and may place undue burdens on patients and families to seek out professionals willing to talk about all the alternatives within the scope of standards of care.[35]

Pediatric Intensive Care and "Experimentation"

Experimentation has two rather common meanings. In the first sense of the term, experimentation refers to research; that is, the scholarly pursuit of generalizable knowledge. Many children receiving intensive care become "subjects" of research when their care follows protocols designed to assess the value of some element of the treatment. Sometimes the research element of the child's care is incidental, possibly even trivial, such as whether one brand of monitoring equipment speeds the jobs of the health care professionals more than another. To the extent that the research determines essential aspects of patient care and may affect outcome, however, doctors must approach such experimentation somewhat differently from their usual practice; that is, experimental treatments (or diagnostic procedures) require greater attention to parental authorization. As noted previously, children may receive treatment by court approval, over and against parental wishes, when the therapy constitutes the standard of care. By contrast, parents may, under regulations governing the use of federal research funds, refuse to enter children into research protocols and may withdraw their children from such projects at any time.[36]

The other meaning of experimentation concerns the "use" of the patient for the learning and practice of trainees. When and under what circumstances the subjection of critically ill children to additional risk or discomfort related to education

can be justified poses a number of difficult questions. First, the patients and their families represent a captive population. The majority of pediatric intensive care takes place in training institutions. Only rarely do parents have an opportunity to express a meaningful preference about which PICU should provide care for their child, given the relative scarcity of units, the relationship of any particular unit to other persons or facilities that parents have chosen (e.g., surgeon, oncologist, or hospital setting), and emergency situations in which legal, bureaucratic, triage, or other considerations leave little room for parental wishes. Unlike the wider "health care market," parents have few substantive choices about their child's ICU.

Second, training must occur. New generations of pediatricians, pediatric nurses, pediatric intensivists, and other specialists need to accrue experience so that they learn to care competently for subsequent critically ill children. Even with use of modern instructional aids, including realistic artificial models, animal laboratory experience, and intellectual preparation, the novice medical professional must perform her or his first intubation, central line placement, and other relatively risky procedures on actual patients.

The intensivist faces an uncomfortable dilemma: parental choice is severely constrained, yet the education must continue. Whether parental permission, even in the somewhat unlikely event of full disclosure and understanding, could be given freely can easily be questioned.

The institutions of medicine (i.e., the practitioners and the organizations that provide the care and the training) must do a better job of telling patients and surrogates that we continually need to teach people how to provide lifesaving care. Greater efforts at public education would at least help convince many persons of the long-term benefits of medical education. More importantly, the profession and the organizations need to promise and actually provide adequate supervision of trainee practice. It is one thing for a new ICU fellow to accomplish her or his first rapid sequence intubation in a trauma victim with a faculty mentor at her or his side, ready to advise or take over as needed, and quite another for the trainee to be thrown into the thick of the action with only telephone connection, if any, to an experienced consultant. The dual responsibilities of better education of patients and families and sufficient supervision need more attention from the intensive care community.

What should happen if parents know about and refuse involvement of trainees, despite realistic assurances of adequate supervision? Administrators may suggest holding fast to prevent the establishment of undesirable precedents. Although the worry is legitimate, one wonders if expending the time and energy involved in such a battle results in unreasonable delays in needed patient care, alienates the parties, and undermines the trust needed to facilitate treatment. Flexibility and interpersonal skill might accomplish more than rigid bureaucratic responses. Moreover, parental protest of this sort may reflect underlying anxiety about what is happening to their child or their role in whatever troubles have afflicted the patient. Direct inquiry regarding the parents' fears and guilt may provide greater benefit for all concerned than a confrontation over the educational mission of the unit.

Finally, the matter of practice on insensate or (newly) dead patients deserves mention, if not resolution. In these situations, doctors legitimately claim that the patient or former patient cannot "appreciate" any harm, and substantial benefit may derive from such "harmless" practice. Two problems arise, however. First, in our society we generally hold that dying patients, permanently unconscious individuals, or even dead bodies have interests. Religious and secular laws specify, often in great detail, what constitutes dignified treatment of bodies. In addition, formerly competent individuals have the legal right to specify how they wish to be treated should they become incompetent or die (e.g., via living wills, donor cards, and declarations about funeral arrangements, such as the desire to be buried or cremated). Thus how one construes harm to the body may vary, depending on perspective, and there is no guarantee that the patient or family will see things in the same way as do the doctors. The second problem derives from the first. Because most people hold that former persons and bodies have interests, one needs to determine those interests and obtain permission for the proposed action (assuming a coincidence of interests). Most doctors and other health care professionals do not want to ask permission to use bodies for practice. They fear a premorbid request will trigger unwarranted concern that the physicians will not do everything possible to prevent death and that a postmortem request will only add to family grief, not to mention the guilt and discomfort of the staff. Although this discussion may seem abstract or even absurd, picture a scene in which a resident is attempting a difficult intubation on a recently dead patient and a parent unknowingly slips into the room or through the closed curtain. Without proper prior authorization, it seems likely the discovery would produce an unwelcome response.

Chapter 11

Ethical Issues in Death and Dying

Norman Fost

PEARLS

- It is not only permissible to discontinue treatments that are not serving the patient's interest, it is obligatory.
- Claims of medical futility are rarely sufficient to justify unilaterally withholding or withdrawing life-sustaining treatment over the family's objection.
- The empiric fact is that, in the United States, it is difficult to find a case of physician liability for unilateral withholding or withdrawing of life-sustaining tretament unless the conduct was "outrageous."
- The Baby Doe regulations do not regulate physicians or hospitals. They regulate state health departments, all of which have been found to be in compliance.

Critical care, perhaps more than any other medical specialty, is devoted to saving lives. The intensive care unit (ICU) epitomizes the successes of medical technology in averting or delaying death. But it also is the focal point of claims that sometimes technology goes too far and that we should not always do all that we can do. This chapter summarizes the ethical and legal issues involved in death and dying in the pediatric intensive care unit (PICU) and identifies areas of consensus.

Withholding and Withdrawing Life Support

There is a general ethical and legal presumption in the United States that life is preferable to death. The medical profession is generally expected to preserve life and to maximize the patient's opportunities to experience and enjoy the benefits of life. Nonetheless, there comes a point in every life when continued existence does not serve the interests of the patient, usually because the burdens outweigh the benefits. This point is most clear when the patient has no apparent interests, such as an infant with anencephaly, who is incapable of experiencing any of the pleasures of biologic existence. Similarly, patients in perpetual coma seem to have no interests. Even the conservative "Baby Doe" regulations, supported by many groups with a strong "right to life" orientation, concede that medically beneficial treatment need not be provided to a patient who is irreversibly comatose. The debate is not about whether medically beneficial treatment can be withheld. The challenge is to define acceptable principles that can help identify those patients who should no longer be treated and determine who should decide.

There is strong consensus in ethics and law that there is no meaningful distinction between withholding and withdrawing life-sustaining treatment. The President's Commission on Ethical Problems in Medicine concluded that contrary to widespread feelings on the matter, withdrawing treatment was preferable to withholding for two reasons.[1] First, withdrawing treatment implies that there has been more time for assessment of prognosis and the likelihood of a successful outcome. It comes after a clinical trial. Good ethics starts with good facts, and a decision to withhold treatment generally is made with less data than the decision to withdraw after treatment has been tried. Second, a tradition of reluctance to withdraw treatment often led to inappropriate withholding of support from patients who, in retrospect, may have had a good chance for meaningful long-term survival. One common setting was the delivery room, where high-risk infants sometimes were not resuscitated because of the fear that treatment would succeed in the medical sense, but that the infant's prognosis for meaningful survival would vanish without any means of reversing the decision to treat. Allowing treatment to be stopped allows all patients to enjoy the potential benefits of initial intervention and the possibility of success. The central ethical issue is whether treatment serves the interests of the patient. If it does not, whether it is being considered or has already been tried is irrelevant.

Two types of errors can occur. A type I error is one in which a patient lives who, in retrospect, would have been better off had he or she died much earlier. A type II error is one in which a patient dies who, in retrospect, probably would have enjoyed life. There is consensus that the latter is generally more serious than the former for two reasons: first, because life is valued so highly and most people would prefer even a handicapped life or existence with suffering over death; and second, because a type I error usually is reversible whereas a type II error by definition is not. Particularly in the intensive care setting, prolonged survivors who are better off dead usually are dependent on some technology that can be discontinued to allow a natural death to occur. The increasing ethical and legal acceptance of discontinuing nutrition and hydration makes it theoretically possible to reverse any decision that, in retrospect, was not in the patient's interest.

A corollary of these observations is that uncertainty generally should be resolved by maintaining the patient's life, because resuscitation that on reflection may not have been indicated usually can be reversed, whereas failure to keep the patient alive cannot be corrected.

Active Versus Passive Euthanasia

Once a decision has been made that treatment is no longer serving the patient's interest, it would seem to follow that a quick and painless death would be preferred to a long dying process, with associated discomfort for the patient or his or her family. Active euthanasia can be defined as a physical act that causes the death of a patient and was intended to be in the patient's interest. Passive euthanasia is generally understood to include withholding or withdrawing treatment, with the intent and expectation that death will occur sooner rather than later, based on the belief that an early death is in the patient's interest. Both practices have the intent and usually the consequence that death will occur sooner rather than later. Active euthanasia is nearly universally prohibited, and passive euthanasia is widely tolerated. The major reason for the distinction is based primarily on concern for future patients, not the patient at hand. Indeed, active euthanasia often seems more merciful from the patient's perspective, precisely because the suffering is reduced. This concern is less relevant when suffering can be relieved with sedation and analgesia.

Some have claimed that terminal sedation constitutes active euthanasia, but there is broad consensus, in ethics and in law, that if the intent is to relieve suffering, the fact that death may be accelerated does not constitute active euthanasia.[2,3]

The major objection to active euthanasia is based on the concern that physicians and others will slide down a "slippery slope," meaning that they will become progressively less sensitive and careful about who is a suitable candidate for euthanasia. The claim is made that if the traditional barrier against killing is lowered, doctors will give in to pressures and temptations to end suffering, including the suffering of family, nurses, and the physician, by taking advantage of the quick release that killing provides.

There is some evidence for this view in studies of the two modern societies in which active euthanasia has been widely practiced and tolerated by the state. Lifton's interviews with physicians who worked in Germany in the 1930s and 1940s demonstrate a progression from killing patients with terminal or severely disabling conditions to the slaughter of healthy people in the death camps.[4] Physicians who were directly involved and responsible for the executions reported that they believed at the time that there was no moral distinction between the two types of killings. They justified and defended their involvement in the death camps primarily as an example of their duty as physicians to relieve suffering.

In contemporary Holland, active euthanasia is widely practiced and tolerated by state policy. Public policy limits the practice to clearly competent patients, but cases of children incapable of consenting who were killed at parental request have been reported.[5]

The prohibition of active euthanasia based on "slippery slope" concerns implies that present patients' interests may be sacrificed to those of future patients. However, if suffering can be eliminated with medications, there should be few, if any, patients whose interests will be harmed by prohibiting active killing. In fact, the vast majority of patients in the contemporary ICU depend on technologies whose discontinuation usually will not result in a long dying process. The major exception is patients who depend only on nutrition and hydration, whose deaths can take 1 week or longer but for whom sedation can reduce suffering.

Withholding Food and Water

Once the judgment has been made that continued existence no longer serves the patient's interest, it should not matter, from the patient's perspective, what treatment is being used to keep him or her alive. The only exception would be treatments that serve to keep the patient comfortable during the dying process. However, if the patient is incapable of experiencing discomfort, whether because of his or her condition or treatments that render him or her unconscious, then any treatment that keeps the patient alive contrary to his or her interests not only may be discontinued but also should be discontinued. It is not only permissible to discontinue treatments that are not serving the patient's interest, it is obligatory.

For these reasons, treatments that provide nutrition and hydration have come to be seen as analogous to other treatments that keep patients alive. In addition to the President's Commission,[2] the American Medical Association, numerous state courts, and the United States Supreme Court have ruled that food and water can be discontinued when other requirements for withdrawing life-sustaining treatment have been met.

It is understandable that discontinuing food and water is psychologically more distressing, particularly to nursing personnel, than withdrawing other forms of treatment, in part because feeding is such an innate human instinct, unlike transfusing, resuscitating, or providing oxygen. Therefore decisions to discontinue food and water often require more discussion and staff support.

One aspect of withholding or withdrawing food and water that distinguishes it from withholding other medical treatments is the extent of the opportunity for abuse. Because every patient requires nutrition and hydration, the power to withhold it gives the physician a power that is almost indistinguishable from active euthanasia.[6] This is not to say opportunities to discontinue other forms of technology, such as mechanical ventilators or surgery, are not subject to abuse. The concern about abuse arises not so much in the ICU, where almost all patients are utterly dependent on some technology, but elsewhere in or out of the hospital where food and water may be the only "treatment" keeping a seriously ill or handicapped patient alive.

Competence, Incompetence, and Baby Doe

Autonomy is a central principle in American medical ethics. It implies that a competent person has a nearly absolute right to decide what shall be done to his or her body. Courts have consistently upheld the right of competent patients to refuse lifesaving treatment, even if it appears foolish or unwise to others, whether for religious or secular reasons or for no reason at all.

The definition of competence is itself controversial,[7] but many adolescent patients meet the standard. The most common definition relies on the ability of the patient to understand the consequences of his or her decision. Physicians therefore should be sensitive to distinctions between the wants and the interests of pediatric patients.

The vast majority of PICU patients, regardless of age, are incompetent because of developmental status, disease, or medication. Traditionally, parents had nearly complete discretion to make decisions on behalf of their children. This

practice came under intense criticism in the 1970s and 1980s upon disclosure of many cases in which handicapped and critically ill infants who appeared to have good prospects for long, meaningful life were allowed to die.[8] These cases most commonly involved infants with Down syndrome or spina bifida. In some instances, infants with Down syndrome and duodenal atresia were allowed to die of dehydration. In one center, more than 50% of infants with spina bifida had standard treatment withheld with the intention that they would die.[9] This pattern of inappropriate undertreatment has been called the Baby Doe problem, named after a celebrated case involving a newborn with Down syndrome and esophageal atresia who was allowed to die without surgery.[10]

The response of pediatricians and state courts was generally to respect the wishes of parents, even when decisions appeared to be contrary to the interests of the child.[11,12] In 1982, the federal government promulgated regulations requiring reports to a hotline and investigations by "Baby Doe squads" of alleged withholding of medically beneficial treatment based on handicap. These regulations were found unconstitutional but were reinstated pursuant to amendments to a child abuse statute that provided funds to the states for implementation of child abuse and neglect programs.[12a] The most controversial aspect of these regulations is their apparent prohibition of withholding or withdrawing medically beneficial treatment from any infant based on handicap or prognosis for quality of life. The three exceptions allowed are (1) if the infant is permanently comatose, (2) if the infant is imminently dying, or (3) if the treatment would be "inhumane." The legal significance of these regulations and the role of the law in these cases in general have been the sources of continuing confusion and controversy.

Legal Implications of Withholding or Withdrawing Life Support

Involvement of state and federal legislatures and courts in decisions involving treatment of dying patients is rapidly evolving, and varies among jurisdictions.[13] Generalizations are difficult, and the law varies among states. Nonetheless, some legal aspects are reasonably clear.

The most widespread source of confusion is the failure to recognize the difference between the law in theory and the law in practice. Although a variety of statutes, court decisions, and regulations have been interpreted, in many cases, as prohibiting discontinuation of treatment, the empiric fact is that, in the United States, it is uncertain whether any physician has ever been found to have civil or criminal liability for withholding or withdrawing life-sustaining treatment from any patient unless the physician's conduct was "outrageous." The law in practice has been remarkably deferential to physician discretion.[14]

Even on theoretical grounds, there are reasons to believe that the Baby Doe regulations do not regulate decisions by physicians, parents, or hospitals. Although the substantive standards appear very restrictive, the implementation standards and sanctions defer to the states. All that is necessary for states to be in compliance with the law is to provide assurances to the federal government that reports of alleged medical neglect will be handled in a prescribed way. States are not required to initiate investigations but are permitted to rely on reports, in accordance with traditional regulations involving child abuse and neglect. A study by the U.S. Office of the Inspector General found all states were in compliance with the Baby Doe regulations, although the federal Civil Rights Commission argued that more restrictive legislation is needed.[15]

In 1990, the U.S. Supreme Court issued its first opinion on the specific issue of discontinuing treatment of an incompetent patient. The case involved Nancy Cruzan, a young adult who had been in a persistent vegetative state for 8 years and was being kept alive with nasogastric feedings. Her parents had requested that the feeding be discontinued and that she be allowed to die. The Court upheld a Missouri statute that required "clear and convincing" evidence that a patient had expressed her wish that she would want to die in that specific circumstance. It is unclear whether the decision has any relevance for children, even in Missouri, and it is important to realize that the decision has little or no relevance for decisions in the majority of states that do not have statutes as restrictive as those in Missouri. The central finding in the Court's opinion was that states are free to make their own laws in this area. The majority of states at present defer to physician judgment in theory and virtually all defer in practice. Even in Wisconsin, where an appellate court decision held that parents may never consent to withholding of lifesaving treatment of a child unless he/she is in a persistent vegetative state,[16,17] physicians and hospitals routinely ignore the decision, and there have been no prosecutions.

The difficulty of sustaining a legal challenge against decisions to discontinue treatment was dramatized in an Illinois case involving a 2-year-old child, Sammy Linares, who was in a persistent vegetative state and ventilator dependent for 8 months. The hospital refused the parents' request to discontinue the ventilator, based on the hospital attorney's claim that to do so would be illegal. The father held the medical staff at gunpoint while he discontinued the ventilator until his son died. Despite committing at least two prima facie felonies involving illegal possession and use of a deadly weapon, the district attorney could not convince a grand jury to indict the father. Despite the clear illegality of his action in theory, in practice the legal system was typically sympathetic and supportive of the decision because it appeared to violate no interests of the child.[18] In a similar case, a federal appellate court upheld the right of a hospital to discontinue life support, over parental objection, for a child with profound brain injury.[19]

Despite the nearly universal legal deference to physician judgment, many physicians overtreat infants because they either misunderstand the law or have an exaggerated fear of liability. A survey of neonatologists found that 30% to 50% would continue treatment even when they thought it was not indicated, based on their belief that the Baby Doe regulations required such treatment.[20] Another survey of a group of California neonatologists before and after the Baby Doe regulations also found a trend toward overtreatment.[21]

In a Virginia case, an anencephalic infant known as Baby K was kept alive for 2.5 years, including intermittent ventilator support, at the request of the mother. A federal court ruled that resuscitation was required under a federal statute known as the EMTALA Act, a law that was intended to prevent dumping of patients from emergency rooms. That ruling is generally not followed in other courts, and the Center for Medicaid and Medicare Services has ruled that EMTALA does not apply to inpatients.[22] It is also important to note that the courts generally rule only when asked. Nor does the ruling prove that there would have been liability if the doctors had refused to treat the

infant. In a related case, a jury acquitted a doctor at the Massachusetts General Hospital who discontinued life-sustaining treatment for a woman in a persistent vegetative state, over the objection of the family.[23] The contrast with the Baby K case is that court opinion was not sought.

Futility

The increasing success of technology in maintaining vital functions has led to an increase in survival of patients with little prospects for long or meaningful life, resulting in conflict between parents who want "everything" done, and medical staff, who believe continued treatment is not in the interests of the child. The debate over withholding or withdrawing treatment against family objection frequently focuses on the claim that treatment is futile, and therefore need not be offered. When treatment is truly medically ineffective—such as mechanical ventilation in a child with extreme pulmonary hypoplasia—a claim of medical futility is warranted. More commonly, however, those who wish to make a unilateral decision to limit treatment, over family objection, are relying on a social notion of futility; that is, a claim that even if the treatment is medically effective, it will not result in a life worth living, or is not worth the cost. These judgments may be defensible, but they are not medical judgments, and physicians have little basis for assuming authority to make such judgments unilaterally. These difficult cases usually need to be resolved through negotiation and persuasion, with the help of institutional ethics committees.[24,25]

Hospital Ethics Committees

With the difficulty in reaching a consensus on substantive standards for decisions to discontinue life support, interest grew in procedural guidelines. The conceptual basis for the guidelines is the general notion that because one can never know whether a decision actually is right, the question of whether or not a decision is morally defensible depends on the process by which the decision is made. The process is similar to other areas of decision making, including the judicial process, in which the legal correctness of a decision resides almost completely in the process by which it is made; in the scientific method, which concedes the impossibility of ultimately knowing the truth but accepts successive approximations if they withstand scrutiny of the process by which they are made; and judgments about the quality of medical care, which ultimately depend less on outcomes than on process.

One procedural theory of ethical decision making that influenced the formation of ethics committees is called ideal observer theory.[26] The theory argued that a decision is morally right if it could receive approval from an ideal ethical observer with the following characteristics: 1) omniscient, meaning access to the relevant and available facts; 2) omnipercipient, meaning the ability to empathize, to vividly imagine how others feel, or to put one's self in another's shoes; 3) disinterested, having no vested interest in the outcome; 4) dispassionate, not being overwhelmed with emotion at the time critical decisions must be made; and 5) consistent, meaning that similar cases will be decided similarly.

In retrospect, decisions that appeared to be indefensible could be analyzed in this framework. In most cases, the failure to appreciate readily available facts appeared to be at the center of controversial decisions. Erroneous assumptions about prognosis, the availability of alternative care arrangements, or misunderstandings about the law are common examples. Because no single person can have the godlike qualities of an ideal ethical observer, interest arose in a process that might better emulate the model than traditional doctor–parent decisions. The federal Baby Doe regulations recommended but did not require such committees, which they referred to as "Infant Care Review Committees." Since 1994, the Joint Commission on Accreditation of Hospitals has required ethics committees or some other mechanism for resolving disputes about terminal care, and they have become a standard method for resolving controversial decisions.[27] These committees typically are interdisciplinary groups of 10 to 20 people, including hospital-based professionals and community members, which advise and recommend but do not typically decide on treatment plans.[28] Some hospitals have ethics consultants who work independently of an institutional ethics committee. Studies of their activities are limited,[29] but their growth has been accompanied by an apparent disappearance of the problem of undertreatment. That problem has been replaced by an apparent growth in overtreatment, which may be aggravated by the influence of hospital attorneys or risk managers on committees.[30] Consultation with committees usually is voluntary, though some hospitals require consultation for specified complex cases, such as "futility" cases.

Ethics committees often serve other functions besides ethical consensus development. They have been used to protect decision makers from liability. Malpractice charges require a finding of negligence, which means the physician failed to take adequate care in how a decision was made. Review and approval by an ethics committee may not only be helpful in defending against such a charge but may deter initiation of a suit. Similarly, a district attorney or judge considering legal charges may be less likely to pursue a case in which there was a special effort to obtain consultation and in which there was broad consensus beyond the family and attending physician. Committees have also served a therapeutic role, helping to manage tensions among medical staff, particularly nurses, when they do not necessarily disagree with a decision but appreciate the opportunity to review it in a broader forum than can be found within the ICU.

Caring for the Terminally Ill

Once a decision has been made that continued treatment is no longer in the patient's interest, attention can turn to implementing the decision in a way that minimizes suffering for the patient, family, medical staff, and other patients.

Decisions to terminate care should be well documented in the chart and in the orders. With regard to legal liability, inadequate documentation is more likely to create vulnerability than the opposite. Because the decision to terminate care should have the support of all involved, there should be no reason to conceal the decision or the reasons for it. Consultation with an ethics committee should be documented, either by the attending physician or by a representative of the committee.

If a judgment has been made that the patient would be better off dead, there is rarely a reason to continue some treatments while stopping others. The common practice of discontinuing one life-prolonging measure—resuscitation—while

maintaining other life-supporting treatments may be illogical. These seemingly contradictory measures are sometimes motivated by concerns for the feelings of family or staff.[31] As long as the patient is not suffering from continued treatment, this practice may be justified for a brief period, but prolonged treatment while waiting and hoping that a patient will die despite the treatment at some point becomes a misuse of limited resources, whether of personnel or an ICU bed.

Similarly, "limited codes" or "partial codes" generally should not be tolerated if their only purpose is to treat the sensitivities of medical and nursing staff. One hazard of partial resuscitation is that it may succeed in keeping the patient alive but result in additional damage to the patient because of inadequate oxygenation or perfusion. In summary, if a decision has been properly made that a patient is better off dead, it usually is best to effect that decision as soon as possible by discontinuing all measures that might prolong the patient's life.

Definition of Death and Organ Retrieval

Determining that a patient is dead is of special interest because of its implications for organ retrieval (see Chapter 13). Death traditionally has been considered a necessary condition for organ retrieval from critically ill patients, although there are increasing challenges to this assumption.[32]

Brain Death

All states now support brain death as a legal standard for determination of death, although there is growing controversy about the moral and clinical relevance of the concept. This standard requires irreversible cessation of all brain activity, including the brainstem. The criteria for determining that brain death has occurred are medical criteria not established by statutes or court cases. They change as new technology and research evolves; therefore it is incumbent on the physician to keep abreast of developments in this area. One study showed considerable ignorance and confusion on the subject.[32] The clinical criteria promulgated by a Harvard committee 20 years ago have come under increasing criticism, as it is clear that many patients declared to be brain dead by standard criteria have not lost all brain function, particularly the hypothalamus, evidenced by normal regulation of antidiuretic hormone activity.[33] Guidelines have been developed for applying clinical standards to children, including neonates.[34] Infants born alive with anencephaly typically have brainstem function and therefore do not meet any current definition of brain death.[35]

Organ Retrieval

There is a wide gap between the number of patients who could benefit from organ transplantation and the supply of organs. There also is a gap between the number of people who say they are willing to donate their own organs or those of family members when death has occurred and the number who actually do donate. These observations led to a national "required request" law, which requires hospitals to inform relatives in appropriate cases that organ donation is an option. The law has not resulted in the anticipated increase in organ supply, for a variety of reasons. Nonetheless, the ICU staff not only has a legal duty to ask but also should realize that organ donation is generally perceived as a benefit to those who consent to it, not as a burden.

Questions may arise regarding who should ask and when. It is a longstanding principle that those involved with the care of potential recipients, such as members of the transplant team, should not be in contact with the family of the potential source of the organ because of the obvious conflicts of interest. It is important to coordinate such decisions to maximize the efficiency and effectiveness of the transplantation; therefore it is appropriate that those caring for the "donor" communicate with the transplant team. It also may be appropriate for members of the transplant team to meet with the family of the "donor" after the decision has been made, to answer questions.

The shortage of organs has also stimulated new efforts to remove organs more efficiently from patients who are not brain dead and who die by traditional criteria of cessation of heart and lung function. Protocols have been established for discontinuing ventilator support in the operating room so that organs can be removed promptly after death is declared—donation after cardiac death and before organ viability is threatened by warm ischemia (see Chapter 13).[36]

Chapter 12

Palliative Care

Jeffrey Burns and Cynda H. Rushton

PEARLS

- "Palliative care begins when illness is diagnosed, and continues irrespective of whether or not a child receives disease-directed treatment…providers should evaluate and alleviate a child's physical, psychological, and social distress; effective palliative care requires a broad multidisciplinary approach that includes the family and makes use of available community resources; it can be successfully implemented even if resources are limited…it can be provided in tertiary-care facilities, community health centres, and at home." (World Health Organization definition of pediatric palliative care)
- During the past 25 years, an ethical and legal consensus has emerged in the United States that supports proportionate palliative sedation and analgesia; that is, administration of the minimum amount of medication to relieve refractory physical symptoms is not only a defensible practice but the desired practice. More controversial are such practices as administering medication to dying patients with the intended end point of hastening death.
- Effective communication is consistently reported to be one of the most important determinants of parent's satisfaction with the care of their dying child in the pediatric intensive care unit. Studies in this area support the importance of relational skills such as physician availability, attentive listening, and expressions of empathy, and indicate that these skills are more important than the precise words spoken to parents.
- Prior to the withdrawal of mechanical ventilation in particular, it is important for clinicians to hold a team meeting to anticipate the abrupt and unpredictable change in patient symptoms with the cessation of assisted ventilation and to have in place a flexible and effective plan of care to address changes as they arise.

What Is Pediatric Palliative Care?

Pediatric palliative care aims to improve the quality of life of patients (and their families) facing life-threatening illnesses through the prevention and relief of suffering by early identification and treatment of pain and other problems, whether physical, psychosocial, or spiritual.[1] It is comprehensive care provided throughout the child's illness, not solely at the very end of life. The World Health Organization[2] says of pediatric palliative care:

- "Palliative care for children is the active total care of the child's body, mind, and spirit, and also involves giving support to the family."
- "Palliative care begins when illness is diagnosed, and continues irrespective of whether or not a child receives disease-directed treatment."
- "Health providers should evaluate and alleviate a child's physical, psychological, and social distress."
- "Effective palliative care requires a broad multidisciplinary approach that includes the family and makes use of available community resources; it can be successfully implemented even if resources are limited."
- "Palliative care can be provided in tertiary care facilities, community health centers, and at home."

Palliative care is broadly viewed as a model for the relief of suffering and the improvement of quality of life across the spectrum of illness. The National Consensus Project for Quality Palliative Care has released Practice Guidelines intended to serve as a blueprint from which to build optimal palliative care.[1] The guidelines outline several domains of palliative care, including communication, ethical decision making, management of pain and suffering, and psychological and spiritual well-being (National Consensus Project for Quality Palliative Care, *Clinical Practice Guidelines for Quality Palliative Care, Second Edition,* 2009; available at http://www.nationalconsensusproject.org/guideline.pdf).

Issues of Concern in Palliative Care

From the time of the patient's admission to the critical care unit, a mindful awareness of the potential for death or altered life span and quality of life is paramount. Given the enormous uncertainty that surrounds the care of critically ill children, palliative care principles are relevant to their care regardless of the ultimate outcome, providing clinicians with a "road map" for working with families and colleagues. Communication, decision making, pain and symptom relief, and clinician support are highlighted here.

Communication

Communicating with patients and families who face a serious progressive disease is extraordinarily difficult because of the associated issues of prognostic uncertainty, the potential for

death and dying, and the loss of hope. Embedded in these situations is the existential pain of witnessing the suffering of children and their families; discomfort about speaking truthfully with children, especially older adolescents; and reluctance to fully share decision making with parents because of the magnitude and lifelong burden of the decisions and concerns about abandonment of patients or families when values or decisions conflict.[3] The quality of communication with physicians and nurses is consistently reported as one of the most long-remembered and important determinants of parent's satisfaction with the care of their dying child in the pediatric intensive care unit.[4,5] Most clinicians recognize from experience that parents are not uniform in their preferences about communication. Nevertheless, repeated findings from the literature document a deficit in physician empathy and availability in establishing adequate communication patterns with parents. Meert and colleagues[6] examined the audio recordings from semi-structured telephone interviews of 56 parents of 48 children who had died 3 to 12 months earlier at six children's hospitals in the National Institute of Child Health and Human Development Collaborative Pediatric Critical Care Research Network. Of the 56 parents interviewed, 40 (71%) wanted to provide feedback on the way information about their child's terminal illness and death was communicated by pediatric intensive care unit (PICU) physicians. The most common communication issue identified by parents was the physicians' availability and attentiveness to their need for information. These investigators concluded that parents want physicians to be accessible and to provide honest and complete information with a caring affect, using lay language, and at a pace in accordance with their ability to comprehend. They also concluded that withholding prognostic information from parents often leads to false hopes and feelings of anger, betrayal, and distrust.

As with other skills that are important in the intensive care unit, the quality of clinician communication can be improved. Just as there is now a strong emphasis on identifying the communication skills that can contribute to, or protect against, preventable medical errors, so too a developing body of literature describes approaches and tools that may have a positive impact on the perceived quality of end-of-life communication. Interventions that teach critical care practitioners how to speak less and listen more would be likely to improve the experience of the parents of dying children. For example, Meyer[7] audiotaped 51 family meetings in Seattle hospitals during which discussions about withdrawing life support were likely to occur. They found that clinicians did more than two thirds of all the talking over an average family meeting lasting nearly 30 minutes. Meyer also found that an increased proportion of family speech was significantly associated with increased family satisfaction with the physician's communication and with decreased family ratings of conflict with the physician. Interestingly, in this study the families' opportunity to talk and knowledge that they were being attentively listened to by the clinicians was more important to their overall satisfaction with communication from the physician than even the total duration of the conference.[7]

Most clinicians recognize that ineffective communication can compound a family's suffering or unleash emotional responses that only add to a painful experience, yet few receive any formal or informal training on optimal practice for a difficult conversation in this context. Expressing the "right words" and avoiding words that unintentionally provoke harm is a source of anxiety for most clinicians in the PICU, especially when a child is dying. An educational program for pediatric critical care physicians and nurses recently has been developed to address this gap in training. Meyer and colleagues[20] describe the philosophy and pedagogical approach of an innovative educational program that is grounded in principles of relational learning and designed to improve the preparedness of health care professionals for engaging in challenging conversations with patients and families. Some examples of effective and ineffective communication styles suggested by the investigators who developed this course are outlined in Table 12-1.

Palliation of Symptoms or Relief of Suffering?

Few issues are as difficult and contentious for clinicians as the effective and ethical management of distressing patient symptoms and the suffering that often accompanies them. Witnessing the suffering of patients and their families is a source of concern for clinicians, and when interventions aimed at relieving the patient's distress, pain, or suffering are ineffective, clinicians often feel helpless or morally distressed.[9-13] The conceptual foundation of palliative care is that there is more to improving the quality of life for a child with a life-threatening illness than treatment with medications such as opiates. Rather, all of the child's physical, emotional, psychological, and spiritual needs must be continually assessed and managed comprehensively and not in isolation. Many reviews of comprehensive pediatric palliative care management have been reported in the literature in the past several years.[1,14-16]

Yet no other issue in palliative care is as contentious as determining how much is too much sedation and analgesia for a dying patient.[17-21] Clinicians struggle with the obligation to relieve suffering versus intentionally ending life. Such issues raise the full spectrum of ethical and legal concerns for which there is not universal agreement. Despite this situation, during the past 25 years an ethical and legal consensus has emerged in the United States that proportionate palliative sedation and analgesia, that is, administering the minimum amount of medication to relieve refractory physical symptoms, is not only a defensible practice but the desired practice.[22] More controversial are such practices as administering medication to dying patients with the intended end point of hastening death. To address these concerns, the Society of Critical Care Medicine has published a consensus recommendations intended to provide information and advice for clinicians who deliver end-of-life care in intensive care units.[23] A practical guide to end-of-life care, based on these guidelines, is provided in this chapter.

The provision of medical nutrition and hydration to a child at the end of life raises equally contentious issues.[24,25] Must it be continued because it is ethically required or provides symptom relief benefits, or may it be withheld or withdrawn because it may induce unwanted symptoms and is not ethically obligatory? There is broad consensus that withholding or withdrawing medical interventions is morally permissible when requested by competent patients or, in the case of patients without decision-making capacity, when the interventions no longer confer a benefit to the patient or when the burdens associated with the interventions outweigh the

Table 12–1 Communication with Families at Clinically Significant Times

Clinical Context	Suggested Explanation	Potential Pitfalls
Uncertain neurologic prognosis	"Lindy has had a very serious head injury and we are worried about her. Right now, we are doing everything to support her and to treat her head injury. Lindy's prognosis—our estimate of how she will do—is uncertain at this time. We expect that her clinical situation will become clearer over the next 24 to 48 hours. We can talk with you often to keep you updated as best we can."	Being overly optimistic or pessimistic in prognostication; setting an unrealistic time frame regarding clinical course; avoiding or not answering the family's difficult questions
Patient not responding to treatment, prognosis grim, need for brain death examination	"We are concerned that, despite our best treatment efforts, we have not seen the improvement in Lindy that we were all hoping for. Lindy is not waking up, and there are signs that the injury to her brain has gotten worse. Patients may be declared dead when either their heart or their brain ceases to function. Unfortunately, we are at the point now where we need to do an examination to see if Lindy's brain is still functioning. We will keep you informed of the results of our tests and what they will mean for Lindy."	Provision of conflicting information by different staff members; being vague and indirect in communication with the family
Providing results of first brain death examination	"Our preliminary testing indicates that Lindy's brain has ceased to function. We need to confirm this testing again in several hours. Unfortunately, if the testing is confirmed, it will mean that Lindy has died."	Being unprepared for families to raise questions about organ donation even before the diagnosis of brain death has been established
Waiting period between brain death examinations	"We will hold Lindy's second brain death examination at 10 AM tomorrow morning. Following that examination, we would like to sit down with you and let you know the results of the examination and what it means for Lindy. In the meantime, we will provide the best care for Lindy and be here for you, too."	Avoiding the family and contributing to the family's experience of feeling abandoned or under-informed; "hovering over" patient and family, providing too little privacy and special time between child and family
Brain death confirmation and withdrawal of life support	"We are sorry to say that, based on the results of Lindy's two examinations, we are now certain that your daughter has no brain function, and has died." The death certificate should be completed at this point, indicating the time the second examination was completed as the time of death.	Using language that suggests the child is dying, not dead; do not say, "Your child is being kept alive until you decide if you want to donate organs," or "Now we need to decide whether to withdraw life support"
Potential organ donation	"I would like to introduce you to some colleagues of mine who can help explain to you the options that are available at this point and who can assist you in making the best decisions for Lindy and your family."	Going beyond your limits of expertise regarding explanation about organ donation; hesitancy or reluctance to refer to the Organ Procurement Organization in a timely manner; not conveying trust or confidence when referring to the organ donor representative

From Truog RD, Christ G, Browning DM et al: Sudden traumatic death in children: "we did everything, but your child didn't survive," *JAMA* 295:2646–2654, 2006.

benefits received. The withdrawal or withholding of measures such as attempted resuscitation, ventilators, and critical care medications is common in the care of terminally ill adults and children. The American Academy of Pediatrics also has recently endorsed a position that the withdrawal of medically administered fluids and nutrition for pediatric patients is ethically acceptable in limited circumstances and preferably with an ethics consultation.[26]

Spiritual and Environmental Needs

A child's death is undoubtedly one of the most stressful experiences a human being can endure, and parents' views of longstanding relationships and beliefs can be shaken, if not in effect shattered, and their spiritual needs can be intense. Meert and colleagues[27] interviewed 32 parents of 26 children after their child's death in the PICU and reported that the main spiritual need described by parents was that of maintaining connection with their child. Parents maintained connection at the time of death by physical presence and after the death through memories, mementos, memorials, and altruistic acts such as organ donation, volunteer work, charitable fundraising, support group development, and adoption. Using a similar methodology, Robinson and colleagues[28] examined the experience of 56 parents whose children had died in three Boston PICUs after the withdrawal of life-sustaining therapies. These investigators found that four explicitly spiritual/religious themes emerged (prayer, faith, access to and care from clergy, and belief in the transcendent quality of the parent-child relationship that endures beyond death) in three quarters of the respondents and concluded that staff members should be explicit in their hospitality to parents' spirituality and religious faith to foster a culture of acceptance and integration of spiritual perspectives. Recent guidelines that have been promulgated for addressing the spiritual aspects of care for people facing life-threatening illness call for greater awareness and emphasis for patients across the life span and spectrum of disease.[29]

Support of Clinicians

Caring for critically ill children is uniquely rewarding and uniquely stressful. Clinicians who listen to and witness the pain and suffering of children and their families also may experience pain and suffering because they care.[9] The moral, emotional, and physical distress of clinicians caring for critically ill children, and their grieving process, has recently received more thorough examination. Clinicians—nurses, physicians, respiratory therapists, social workers, chaplains, child life specialists, and others—have unique needs for support. Hamric and Blackhall[30] and Rushton[31] have noted that nurses shoulder a large proportion of the stress in caring for dying children by the very nature of their proximity and sustained involvement with patients and families and are especially vulnerable to moral distress. Moral distress arises in situations where the clinicians are "unable to translate their moral choices into moral action…the costs of unrelieved moral distress are high; ultimately, as with all unresolved professional conflicts, the quality of patient care suffers."[31] Despite the predominance of literature focusing on moral distress in nursing, there is increasing recognition that moral distress and burnout affect the entire interdisciplinary team.

Programs that train clinicians to cope with the psychosocial and spiritual aspects of caring for dying children, including the high levels of moral distress, grief, and professional exhaustion, have been lacking until recently.[28,32] The American Association of Critical Care Nurses (AACN) has developed a program to address the issues of persons experiencing moral distress in the ICU entitled "Rise Above Moral Distress." This program describes four "A's": ask, affirm, assess, and act.[33] The AACN also calls for the implementation of interdisciplinary strategies to recognize and name the experience of moral distress; the establishment of mechanisms to monitor the clinical and organizational climate to identify recurring situations that result in moral distress; and taking corrective action, including the development of employee assistance programs, protocols for end-of-life care, critical stress debriefings, and grief counseling. Similarly, forums where troubling questions can be deliberated upon openly and intentionally among the interdisciplinary team members are essential for the well-being of each of the team members.[34] Unquestionably, physicians and respiratory therapists experience all of the same concerns as nursing professionals, and all clinicians need a variety of strategies to enhance their resilience and personal well-being, including stress reduction strategies, mindfulness, mind-body interventions, end-of-life care training, and a sense of community.[31,35-38]

Practical Aspects of Care at the End of Life

Optimal palliative care begins with the patient's admission to the PICU and continues without disruption through discharge from the hospital, regardless of whether the child lives or dies. All of the rapidly evolving clinical and ethical decisions underlying this care surface most dramatically when the issue arises of whether to withdraw life-sustaining treatment with the intention of allowing the child to die—in particular, discontinuation of mechanical ventilation.

Failure of the clinical team to anticipate the abrupt and unpredictable change in patient symptoms with the cessation of assisted ventilation and have in place a flexible and effective plan of care to address changes as they arise can lead to hasty decisions, and this situation can leave both the patient's parents and clinicians with lasting emotional distress that optimal and ethical end-of-life care was not provided.[39] How can clinicians provide care within an ethical framework consistent with the values of the medical profession and our society and yet still respond effectively to the evolving physiologic, emotional, and spiritual needs of the patient and their family members in a timely manner? A practical guideline, such as the one provided in the following section of this chapter (adapted with permission from the protocol used at the Division of Critical Care Medicine at Children's Hospital Boston and based on the Society of Critical Care Guidelines[23]), outlines the steps that should be taken.

The Anticipatory Clinical Team Meeting

Effective and cohesive end-of-life care must be led and supervised by the attending physician at all times. This begins with a brief meeting of all clinicians who will be providing end-of-life care prior to the withdrawal of life-sustaining treatments.[16] Among the questions that should be briefly addressed in this ad hoc meeting are the following:

What Treatments May Be Withheld or Withdrawn?

- We never withdraw care, only treatments and interventions.
- It is ethical and legal to withhold or withdraw any medical treatment when the patient's legal surrogate, as informed by a recommendation from the clinical team, determines that the burdens of such treatments outweigh the benefits.[40,41]
- Any medical intervention, from extracorporeal membrane oxygenation and pacemakers to the use of physiologic monitors, may be withheld or withdrawn from the dying patient in the ICU.
- A guiding concept in determining what treatments to continue and what treatments to withhold or withdraw is that any intervention that appears to promote the patient's comfort or dignity (as well as ameliorate emotional, psychological, or spiritual concerns) should be continued. Those that do not appear to promote the patient's comfort or dignity should be withdrawn.

Where and When Will Mechanical Ventilation Be Withdrawn?

- Will mechanical ventilation be withdrawn in the ICU, or in a private but appropriate area in another part of the hospital? Is it feasible to offer to transport the patient home for withdrawal of the ventilator?

How Should Mechanical Ventilation Be Withdrawn?

- An artificial airway may be removed (extubation), or the patient may have supplemental oxygen and/or positive pressure ventilation gradually reduced (i.e., a terminal wean with no plan for extubation). The method of withdrawal should be guided by the specific circumstances of the patient.
- How will mechanical ventilation be withdrawn—by terminal wean or extubation? Consider a terminal wean if the patient is likely to have pulmonary edema/hemorrhage or severe gasping from a low lung compliance or high airway resistance process.

- A terminal wean is performed by the gradual reduction in fraction of inspired oxygen and/or ventilator rate at a pace not faster than pharmacologic sedation is administered to treat objective signs of distress from the effects of hypoventilation and hypoxia.
- Studies suggest that the most rapid descent into unconsciousness with the least agitation occurs when hypoxia is allowed to progress in the face of normocarbia.
- Many parents will request that mechanical ventilation be withdrawn by having their child extubated. In this case, the abrupt removal of respiratory support will likely lead to the abrupt escalation in symptoms of respiratory distress. In this case the patient generally should receive sedation or analgesia prior to extubation in anticipation of respiratory distress, with subsequent doses titrated to the patient's level of discomfort.

Preparation and Support of the Family

- After the clinician meeting, preferably the senior physician and bedside nurse should meet with the family to provide clear and explicit explanations about the process of withdrawal of life-sustaining treatments and assurance that symptoms of patient suffering will be treated. Meeting with the family is essential to prepare them for what to expect and may alleviate some of their anxiety around the process.
- It is best to avoid making firm predictions about the patient's clinical course after withdrawal of mechanical ventilation or other forms of life-sustaining treatment, because often they are inaccurate. Substantial loss of credibility may result when predictions about death or the timing of death are inaccurate.
- When predictions are incorrect, clinicians and families frequently get very anxious as if something has gone "wrong," and this situation can lead to hastily made and poor decisions. The mindset of everyone in the room should be that the patient's trajectory after the withdrawal of mechanical ventilation can be different from what was expected and that any outcome will be treated calmly and compassionately for as long as necessary.
- When answering questions about what will happen, it is better to say, for example, "We think it is unlikely that your child will survive after the ventilator is withdrawn, but whether he/she breathes only for a short time or for a very long time, we can assure you that we will treat any symptoms that appear to be causing her/him discomfort."
- At times it will be necessary for the clinicians to anticipate, ask, and answer questions that the family appears to be afraid or unable to verbalize. For example, a clinician might say, "Sometimes after the ventilator is withdrawn patients experience a change in skin color, or unusual breathing noises, and this is to be expected. Our job is make sure that your child does not experience symptoms of suffering or discomfort. If we see signs of discomfort, we will treat them."
- Families should have the opportunity to be helpful and be invited to participate in activities to relieve discomfort, such as mouth care, bathing, and repositioning. They should be encouraged to participate in assessment of the patient's pain and suffering. The family also may be encouraged to provide other means of comfort to the patient that had been important to them in the past, such as holding or rocking their child, wrapping the child in a special blanket, or giving their child a massage.

Determining Who Will Care for the Patient at This Time

- Care of the dying patient is a solemn professional responsibility too important to delegate to one individual. It requires the presence of an experienced physician who can be immediately available at the bedside to work in collaboration with the nurse in guiding appropriate and timely therapies.

Determining How Signs of Apparent Discomfort Will Be Treated

- Pharmacologic and nonpharmacologic strategies to treat apparent discomfort should be discussed, and one person should be assigned to be the "circulator," that is, someone who is free to get additional supplies without leaving the patient alone.
- Palliative measures should be comprehensive and not rely solely on sedation and analgesia. For example, simple positioning or massage may be effective alone or in conjunction with pharmacologic agents.
- Assessment of breathing patterns can be complicated in dying patients. Irregular breathing patterns are a natural part of dying and may not be uncomfortable for the patient. Unfortunately, the irregular pattern that accompanies dying is often referred to as "agonal," which may imply to the family and other clinicians that the patient is in "agony."
- Gasping is a medullary reflex and can occur in the absence of consciousness. Similarly, noisy respirations from airway secretions (the "death rattle") are more likely to be distressing to the family and other observers than they are to the patient. Not all gasping need be treated with escalating doses of sedatives or narcotics. Ideally the decision to treat should be made based on consensus between the family and clinicians at the bedside regarding whether the breathing pattern appears to be causing, or is a manifestation of, suffering.
- In general, the clinician's obligation is to treat objective signs of discomfort as experienced by the patient. The distress of the family should be addressed by continued reassurance and emotional support.

Neuromuscular Blockade and the Withdrawal of Mechanical Ventilation

- Neuromuscular blocking drugs have no sedative or analgesic properties and may mask symptoms of suffering at the end of life. As a general rule, therefore, pharmacologic paralysis should be avoided at the end of life.[23,42]
- In most cases, the effect of these agents can be reversed or allowed to wear off within a short period, allowing for the withdrawal of mechanical ventilation in the absence of the confounding effects of paralysis. Patients who have been receiving neuromuscular blockades chronically for

management of their ventilatory failure occasionally can present a more difficult ethical dilemma. In some situations, restoration of neuromuscular function may not be possible for several days or even weeks. When faced with this problem, the clinician must choose between withdrawal of the ventilator while the patient is paralyzed versus continuation of life support well beyond the point at which the patient and family have determined that the burdens of such treatments outweigh the probable benefits. In this circumstance, it may be preferable to proceed with withdrawal of life support despite the continued presence of neuromuscular blockade.

Consideration of the Level of Sedation and Analgesia to Be Used

- Current ethical and legal guidelines place importance on the intentions of clinicians in administering analgesics and sedatives at the end of life. Specifically, clinicians should administer doses that *are intended to relieve pain and suffering but not intended to directly cause death.* We cannot, however, give more sedation than what the patient needs to be comfortable (thus, one should be prepared for the request, "Please, can't we just get this over with?").
- The goal is to ensure that objective signs of apparent discomfort are treated as needed. The goal of treatment is not to ensure that the patient's death is intentionally hastened or to avoid giving any treatment for fear of hastening death.[18,20,43-45]
- Because intentions are essentially subjective and private, the only ways to infer the nature of a clinician's intentions are through self-report and by an analysis of his or her actions.[46]
- Accordingly, documentation of one's intentions in the patient's chart is an important part of providing end-of-life care. When "prn" orders are written for analgesics and sedatives, the indication for administration should be stated clearly (e.g., pain, severe upper airway obstruction). This step reduces the likelihood of misinterpretation or abuse.
- With regard to actions, when a clinician titrates morphine in doses of 1, 5, or 10 mg every10 or 20 minutes, it is plausible to conclude that the clinician intends to make the patient comfortable and not to directly cause the patient's death. On the other hand, when a clinician administers 2000 mg of morphine acutely to a patient who is not profoundly tolerant, it raises the concern that the clinician may have primarily intended the death of the patient.
- Sedation and/or analgesia should be titrated to effect, and the dose should not be limited solely on the basis of "recommended" or "suggested" maximal doses. In most cases, patients who do not respond to a given dose of an opioid or benzodiazepine will respond if the dose is increased—there is no theoretical or practical maximal dose.
- The concept of "anticipatory dosing" (as opposed to reactive dosing) also should guide clinicians in the use of sedation and analgesia at the end of life. The rapid withdrawal of mechanical ventilation is an example of the need for anticipatory dosing. At the time of ventilator withdrawal, the clinician can anticipate that there will be a sudden increase in dyspnea. It is not sufficient simply to respond to this distress with titrated doses of an opioid (reactive dosing). Rather, clinicians should anticipate that the abrupt withdrawal of assisted breathing will trigger increased respiratory distress, and therefore they should provide adequate sedation or analgesia beforehand (anticipatory dosing). As a general rule, the doses of medication that the patient has been receiving hourly should be increased by twofold or threefold and administered acutely before withdrawing mechanical ventilation.

The Goal of Using Sedatives and Analgesics in This Context

- The goal of titrating sedatives and analgesics after withdrawal of mechanical ventilation is only to treat objective signs of discomfort that evolve; it is not to bring about a certain outcome. Stated another way, the target is to make the patient comfortable; the target is not some arbitrary maximum dose, and the target is not the death of the patient.
- If there are no objective signs of discomfort and the patient breathes effectively after extubation, despite the prediction that death would immediately follow withdrawal of ventilation, there should be no panic among the clinicians that something is wrong and further sedatives or analgesics must be administered. If the patient is unexpectedly breathing comfortably after extubation, all other non-medication measures of palliative care should be continued and ongoing and comprehensive support should be provided for the family.
- On the other hand, multiple boluses of escalating doses of sedatives and analgesics may be required to treat clear signs of discomfort after extubation in order to keep the patient comfortable.
- Either way, the team's frame of mind before the withdrawal of life-sustaining treatments must be that the patient will proceed to die at his or her own time and pace. Clinicians need to respond to what evolves, but it is not their intention in administering sedatives and analgesics to ensure that a certain outcome evolves.
- The sole focus is that a patient for whom life-sustaining treatments have been withheld or withdrawn will not experience suffering that is untreated.

Issues After Death

- In most jurisdictions, after a patient dies, physicians are required to notify other caregivers not in attendance, such as the pediatrician and consultants, along with the local organ procurement organization (if not prior to death for consultation about organ donation questions), because every cadaver is potentially a tissue donor of corneas, skin, heart valves, and bone. In some cases the medical examiner or coroner will need to be notified.
- Seeking permission for an autopsy raises special issues.[47] First, a child's death is an unparalleled time of stress for parents, and the physician who approaches a family for permission to perform an autopsy should have "earned the right" by virtue of his or her prior clinical relationship with the patient and family.

- Second, physicians involved in obtaining consent to perform an autopsy must be fully knowledgeable on (1) the autopsy procedure; (2) limitations to the procedure; and (3) the storage, use, and disposition of organs. Not only are physicians who are poorly educated about autopsies likely to misinform families and potentially generate subsequent medicolegal issues, but they are also more likely not to request an autopsy.
- A follow-up telephone call within 4 weeks of the patient's death to assess the family's grief status and to screen for problems and provide resources for continued support in the community should be provided by a bereavement support program.

Essential Basic Documentation

- A brief description should be placed in the patient's medical record of the decision-making process that led to the withholding or withdrawal of life-sustaining treatment and the palliative care provided.
- In describing the palliative care measures provided, it is important to briefly document the rationale used to titrate sedation and analgesia, if administered. For example, "Signs of suffering were noted with the onset of gasping respirations and increased work of breathing after the patient was extubated. Morphine and Versed were ordered by Dr. Burns and administered by C. Rushton, RN, and titrated to treat these signs of patient suffering. The patient's signs of suffering were relieved after three boluses over 20 minutes. The patient died at 3:45 PM."

Support of the Caregivers

- Caregivers should be provided opportunities for informal debriefing immediately after the death, and programmatic formal debriefing for other staff members not present should be provided at some reasonably close future date.[1,39,48]

Chapter 13

The Process of Organ Donation and Pediatric Donor Management

Thomas A. Nakagawa and Steven S. Mou

PEARLS

- Involvement of critical care specialists, specifically in pediatrics, where there are a limited and decreasing number of donors, has improved the quality and number of organs recovered.
- Donor management is crucial to the successful recovery of organs for transplantation. Management of the potential pediatric organ donor requires knowledge of the physiologic derangements associated with this specific patient population.
- It is imperative to involve the organ procurement organization coordinators in a timely manner for any impending death. Best practices have allowed organ procurement organization coordinators and medical professionals to dialogue and improve consent rates while assisting families with end-of-life care issues.
- The diagnosis of brain death in children is based on clinical criteria that are consistent across the age spectrum.
- Donation after circulatory determination of death allows patients with a catastrophic brain injury who do not progress to meet brain death criteria to donate organs. Success with organs transplanted from this type of donor is occurring in many centers.

Overall, the demand for organs continues to increase at a rapid pace, far exceeding the number of organs available for transplantation. Approximately 2% of the patients on the national transplant wait list are children 18 years of age or younger.[1] However, in contrast to the increasing number of adults on the wait list, the number of children has decreased during the past several years. The reason for this decrease in large part is because more organ transplants are occurring in children.[1] Additionally, patients in need of a transplant who in the past would have died from organ failure while waiting are now living longer lives as a result of improved pharmacologic and medical management. Some of these patients may not require a transplant at all, further reducing the number of children on the national wait list. Nonetheless, children continue to die while waiting for a life-saving transplant, with the highest death rate observed in children younger than 1 year.[1] Additionally, another 40 to 50 children are removed from the pediatric wait list annually because their condition has deteriorated to a degree where transplantation is no longer an option.[1] The need for more organs is clear in this patient population.

The number of adult donors has continued to increase during the past 10 years, while the number of pediatric donors has decreased.[1] This decline in pediatric donors has occurred for many reasons, including improved medical and surgical treatments, vaccinations that have reduced deaths associated with childhood infectious diseases, safety restraints, education and awareness regarding health hazards affecting children, and pediatric critical care specialists who have reduced morbidity and mortality for children who are critically ill or injured.

Missed opportunities for organ donation occur in many medical institutions nationally.[2] Frequently these losses occur when families decline the option of donation, but in some cases families are not even being given the opportunity for donation. Organs available for transplantation may be lost because of caregivers' lack of familiarity with appropriate donor management, or opportunities for donation may be denied by medical examiners who fear losing evidence and the ability to successfully prosecute homicide cases in situations where abusive trauma has claimed the life of a child.

Unique issues are associated with the process of organ donation and transplantation in children. Parents and guardians must act as surrogate decision makers without benefit of being guided by the donor's wishes, as is often possible with adults. Size and weight constraints can limit acquisition and use of organs recovered from children. Technical challenges related to surgical procedures in smaller children and infants and age-related variation in the timing associated with declaration of brain death can result in organ deterioration and affect viability of organs for transplantation. Specialized care required for the management of critically ill children and pediatric organ donors may be lacking at institutions that have limited expertise and support for children. This includes expertise from nursing and critical care specialists, as well as support from pediatric neurologists, neurosurgeons, general surgeons, and other pediatric specialists.

The process of donation begins when a critically ill or injured child is identified as a potential donor with a timely referral to the organ procurement organization (OPO). Early involvement of the OPO enhances chances of recovering viable organs for transplantation while allowing coordination

of the donation process. Medical management of the potential pediatric organ donor requires knowledge of the physiologic derangements associated with this patient population. Hemodynamic instability, alterations in oxygenation and ventilation, metabolic and endocrine abnormalities, and coagulation disturbances are common. Support and care of the family provided by a team of physicians, nurses, social workers, chaplains, and other support staff trained in the unique aspects of pediatric medicine are integral to the care of these children and their families.[3,4] Each of these elements is essential to ensure successful recovery of organs from this select group of patients.

Role of the Pediatric Intensivist and Critical Care Team in the Process of Organ Donation

Effective donor management is crucial to the successful recovery of organs for transplantation. The integral involvement of pediatric critical care specialists in the management of critically ill and injured children has been a foundation of the clinical practice of critical care in many successful pediatric centers. Caring for the critically ill child and his or her family through all phases of illness, including end-of-life issues, should be a seamless transition. The continuum of care for the dying patient who progresses to death and becomes a donor requires the expertise of the pediatric intensivist and critical care team to manage and prevent deterioration of organ systems and loss of transplantable organs. Involvement of critical care specialists, especially in pediatrics, where there is a limited and decreasing number of donors,[1] improves the quality and number of organs recovered.

It is federally mandated to inform the OPO of any impending death in a timely manner. Suitability of the potential donor needs to be determined and issues regarding donation need to be discussed with the medical team and the family. The model utilizing OPO coordinators and designated requestors to obtain consent from families has been successful in the adult arena; however, we continue to learn that the situation with children and their families is different. One study found that parents seem to prefer discussions regarding donation with the pediatric intensivist or a member of the health care team they have come to trust, rather than the OPO coordinator.[5] Timing of the first request relative to discussions of brain death did not influence the decision to donate organs, but consent for donation was more likely when parents had sufficient time to discuss this issue.[5] These concepts are vastly different from the traditional approach in which the OPO coordinator requests consent and decouples the death and consent process. Improved communication between the health care team and the OPO remains important, however. A team approach has been adopted by many institutions for discussing donation with families. This practice is encouraged in the United States Department of Health and Human Services Organ Donation Collaborative's final report on best practices.[6] Best practices promote coordinated efforts between OPO coordinators and medical professionals to improve consent rates while assisting families with end-of-life care issues. Involvement of palliative care teams also has been identified as another resource to assist the intensive care unit (ICU) team, parents, and families facing end-of-life issues with their child.

Determination of Brain Death

The "dead donor rule" states that patients must be declared dead before removal of vital organs for transplantation can occur.[7] Therefore, accurate determination of brain death is essential before efforts at organ recovery proceed. Determination of brain death must occur in a timely and efficient manner for several reasons: it allows the family to begin the grieving process as they prepare for the loss of a loved one; it allows the process of organ preservation and preparation for recovery to begin; and if donation is not planned, medical therapies can be stopped, allowing redistribution of scarce ICU resources to other critically ill and injured patients.

Good donor management is imperative for recovery of viable organs for transplantation. Hemodynamic instability and organ dysfunction account for a loss of up to 25% of potential donors when donor management is not optimized.[8] Furthermore, the institution of hormonal replacement therapy (HRT) early in the donation process may assist with stabilization of the donor, improve the quality of organs recovered, and enhance posttransplant graft function.[9-13]

The determination of brain death in children is a clinical process based on clinical criteria that are consistent across the age spectrum. No unique legal issues differentiating declaration of brain death exist for children. However, age-related issues can make determination of irreversible injury and declaration of brain death more difficult in younger patients, resulting in age-based recommendations.[14] The clinical history, cause of coma, and brain injury must be determined to ensure that an irreversible condition has occurred. Physical examination criteria rely upon the coexistence of coma and apnea in a child who is neither hypothermic nor hypotensive for age and whose examination is not affected by sedatives or neuromuscular blocking agents. Neurologic criteria to determine brain death in infants and children are listed in Box 13-1. Absence of neurologic function is defined by the

Box 13–1 Neurologic Examination Criteria for Brain Death in Children

1. Coma. The patient must exhibit complete loss of consciousness, vocalization, and volitional activity.
2. Apnea. The patient must have the complete absence of documented respiratory effort (if feasible) by formal apnea testing demonstrating a $Paco_2$ ≥60 mm Hg.
3. Loss of all brain stem reflexes, including:
   - Midposition or fully dilated pupils that do not respond to light
   - Absence of movement of bulbar musculature including facial and oropharyngeal muscles
   - Absent gag, cough, sucking, and rooting reflexes
   - Absent corneal reflexes
   - Absent oculocephalic and oculovestibular reflexes
4. Flaccid tone and absence of spontaneous or induced movements, excluding spinal cord events such as reflex withdrawal or spinal myoclonus.
5. Reversible conditions or conditions that can interfere with the neurologic examination must be excluded prior to brain death testing.

Data from American Academy of Pediatrics Task Force on Brain Death in Children: Report of Special Task Force: guidelines for the determination of brain death in children, *Pediatrics* 80:298-300, 1987.

following features on physical examination: mid-position and fully dilated nonreactive pupils, absence of spontaneous eye movements induced by oculocephalic or oculovestibular testing, absence of bulbar function, cough, corneal, gag, and rooting reflexes, and absence of respiratory effort when challenged with elevated carbon dioxide levels that otherwise would induce respiratory effort in such a patient. Serial neurologic examinations are necessary to establish the diagnosis of brain death. The duration of observation between examinations and the need for ancillary studies is based on age, history, and clinical examination. The examination results must remain consistent with brain death throughout the observation and testing period.

Determination of brain death for any infant or child requires establishing and maintaining normal physiologic parameters. Before neurologic examination or neurodiagnostic testing for brain death can be meaningful, correction of hypotension and hypothermia must occur. The 1987 guidelines for determination of brain death in children provided no definition of hypothermia.[14] Current adult and Canadian guidelines use a core body temperature of >35° C (95° F).[15,16] Conditions that can interfere with the neurologic examination or factors capable of imitating brain death must be excluded. Conditions such as severe hepatic or renal dysfunction, inborn errors of metabolism, or metabolic disturbances may play a role in the clinical presentation of the comatose infant or child. These conditions should be considered and, if identified, appropriate treatment should be instituted to correct the derangements resulting in coma. Instances may occur in which these conditions cannot be corrected and additional ancillary testing may be required to confirm brain death. Testing for drug intoxications including barbiturates, opiates, and alcohol should be performed as indicated. The half-life of sedative agents must be considered when determining the appropriate timing of the clinical examination. Longer acting or continuous infusion of sedative agents and recent administration of neuromuscular blocking agents can interfere with the neurologic examination. These agents should be discontinued for a reasonable amount of time to allow adequate clearance of the drug(s) prior to initiating electroencephalogram (EEG) testing and clinical examination for brain death testing. Barbiturates reduce cerebral blood flow (CBF); however, no evidence exists that high-dose barbiturate therapy completely arrests CBF. Evidence suggests that radionuclide CBF study or cerebral arteriography can be utilized in patients who have undergone high-dose barbiturate therapy to demonstrate absence of CBF.[17,18] Clearance of neuromuscular blockers can be confirmed by use of a nerve stimulator.

The apnea test is a critical and essential component of the clinical examination to determine brain death. Testing for apnea must allow adequate time for the partial pressure of carbon dioxide, arterial ($Paco_2$) to increase to levels that would normally stimulate respiration. Apnea testing must be performed while maintaining normal oxygenation and stable hemodynamics. Patients should be preoxygenated with 100% oxygen to prevent hypoxia. Mechanical ventilatory support should be adjusted to eliminate ventilation, allowing the carbon dioxide tension (Pco_2) to rise while observing the patient for spontaneous respiratory effort. False reports of spontaneous ventilation have been reported while patients were maintained on continuous positive airway pressure for apnea testing despite having sensitivity of the mechanical ventilator reduced to minimum levels.[19] Attaching a self-inflating bag valve system, such as a Mapleson circuit, to the endotracheal tube or tracheal insufflation of oxygen using a catheter inserted through the endotracheal tube also has been used to provide supplemental oxygen. High gas flow rates with tracheal insufflation may promote carbon dioxide washout, preventing adequate $Paco_2$ rise during apnea testing. Additionally, adequate gas outflow must be ensured to prevent barotrauma. The $Paco_2$ should be measured and allowed to rise to 60 mm Hg or greater while continually observing the patient for any spontaneous respiratory movements over a 5- to 10-minute period. If no respiratory effort is observed during this time, the apnea test is consistent with brain death. The patient is reconnected to mechanical ventilator support until death is confirmed with either a repeat clinical examination or an ancillary study. If the apnea test cannot be completed because of hemodynamic instability, desaturation, or an inability to reach a $Paco_2$ of 60 mm Hg, an ancillary study should be pursued to make the diagnosis of brain death. Infants and children with chronic respiratory disease or insufficiency may only breathe in response to supranormal $Paco_2$ levels. In this instance, the $Paco_2$ level should rise to ≥20 mm Hg above their baseline $Paco_2$ level. If there is any concern regarding the validity of the apnea test, an ancillary study should be pursued.

Recommended clinical observation periods between examinations in children differ from those for adults, with a greater duration suggested for younger children. Box 13-2 lists the recommended observation periods based on the age of the infant or child from the Task Force Guidelines for Brain Death in Children.[14] Observation periods have never been validated. Many authors have argued that except in very immature, preterm newborns, the same criteria to declare brain death can be applied to full-term newborns, infants older than 7 days of age, children, and adults.[20-27] Despite this controversy, the only published guideline to determine brain death in children recommends observation periods based on the age of

Box 13–2 Recommended Observation Period to Determine Brain Death in Infants and Children

7 Days to 2 Months

- Two examinations and EEGs separated by at least 48 hours

2 Months to 1 Year

- Two examinations and EEGs separated by at least 24 hours
- A repeat EEG is not necessary if a cerebral radionuclide scan or cerebral angiography demonstrates no flow or visualization of the cerebral arteries

Older than 1 Year

- When an irreversible cause exists, ancillary testing is not required and an observation period of 12 hours is recommended
- The observation period may be decreased if the EEG demonstrates electrocerebral silence or the cerebral radionuclide or cerebral angiography study demonstrates no flow or visualization of the cerebral vessels

EEG, Electroencephalogram.
Data from American Academy of Pediatrics Task Force on Brain Death in Children: Report of Special Task Force: guidelines for the determination of brain death in children, *Pediatrics* 80:298-299, 1987.

the child.[14] The Special Task Force for the determination of brain death provided no guidelines to diagnose brain death in infants younger than 7 days of age.[14] Guidelines for this age group were not defined because of limited clinical experience, lack of sufficient data, and concerns about the ability to reliably confirm irreversibility of brain injury in this patient population.[25,26] This situation does not imply that brain death does not occur in this patient population, only that it can be more difficult to diagnose. Diagnosing brain death can occur in the term infant, even in those younger than 7 days of age; however, an observation period of 48 hours has been recommended to confirm the diagnosis. It has been suggested that the observation period can be reduced to 24 hours if ancillary studies demonstrate no CBF or an isoelectric EEG.[26,27] The younger the child, the more cautious one should be in determining brain death.

Ancillary studies can provide additional supportive information to assist in declaring brain death. These studies are useful when the clinical examination or apnea testing cannot be safely completed because of the underlying medical condition of the patient, if there is uncertainty about the findings of the neurologic examination, or if a confounding medication effect may be present. Ancillary studies are not necessary if determination of brain death can be made based on clinical examination criteria in the older child. They are, however, recommended by the Task Force for children younger than 1 year.[14] Ancillary studies may be utilized to expedite the diagnosis of brain death by reducing the clinical observation period, potentially increasing the viability of transplant tissue. However, in the circumstance that an ancillary study is equivocal, the observation period can actually be increased until another study or clinical examination is performed to confirm brain death. Ancillary studies can be helpful for social and medical reasons. These studies may allow family members to better comprehend the diagnosis of brain death and may be important in situations where death is the result of homicide. Ancillary studies are not a substitute for a complete physical examination.

Four-vessel cerebral angiography evaluating anterior and posterior cerebral circulation remains the gold standard to determine blood flow for brain death testing; however, this test is difficult to perform in small children and requires technical expertise that may not be available in every facility. Furthermore, transporting a potentially unstable patient to the angiography suite carries additional risk that can complicate this process. For these reasons, cerebral angiography is rarely performed. EEG documentation of electrocerebral silence and absence of CBF using radionuclide CBF study remain the most widely available and useful ancillary studies to assist with the diagnosis of brain death in infants and children. These studies are more easily accomplished at the bedside, without the need for extraordinary technical expertise. Radionuclide CBF studies have been used extensively with good experience.[28] Use of the portable gamma camera for radionuclide angiography has made CBF studies more accessible, allowing for the study to be undertaken at the bedside.[28,29] This study is becoming a standard in many institutions, replacing EEG as an ancillary study to assist with the determination of brain death in infants and children.[30] EEG and radionuclide CBF studies are both accepted ancillary studies used to assist the clinician in determining brain death in children. EEG may be more specific, although less sensitive, than the radionuclide CBF study. EEG testing evaluates cortical and cellular function, while radionuclide CBF testing evaluates flow and uptake into brain tissue. Each of these tests requires the expertise of appropriately trained and qualified individuals who understand the limitations of these studies to avoid misinterpretation. Transcranial Doppler sonography and brain stem audio-evoked potentials have been utilized[29,31] but have not been studied extensively or validated in children.[25,32,33] These studies, along with computed tomography angiography, perfusion magnetic resonance imaging, and magnetic resonance angiography-magnetic resonance imaging cannot be relied upon as dependable ancillary studies at this time.[32,33]

Ancillary studies are least sensitive in the neonatal age group.[26,34] Limited experience with ancillary studies performed in the newborn younger than 30 days of age indicates that EEG is less sensitive than CBF in confirming the diagnosis of brain death. Sensitivity remains quite low, however, even with CBF, for this age group.[25,27,34,35] Diagnosing brain death in the neonate can be more difficult; therefore, serial examinations are essential to ensure that the clinical examination remains consistent throughout the observation and testing period. The younger the child, the more cautious one should be in diagnosing brain death. If there is any uncertainty about the examination or the ancillary study, continued observation and clinical examination or a repeat ancillary study should be performed to make the diagnosis of brain death.

Diagnosing brain death has great implications with profound consequences. The clinical diagnosis of brain death is highly reliable when made by experienced examiners using established criteria.[36,37] There are no reports of children recovering neurologic function who met adult brain death criteria upon neurologic examination.[35] Diagnosis must never be rushed or take priority over the needs of the patient or the family. Appropriate emotional support for the family should be provided, including adequate time to grieve with their child after death has occurred. Each state has laws or regulations for determination of death that have, in most cases, been modeled after the Uniform Determination of Death Act.[38] The Uniform Determination of Death Act states that a person who has sustained either (1) irreversible cessation of circulatory and respiratory functions or (2) irreversible cessation of all functions of the entire brain, including the brain stem, is dead. A determination of death must be made in accordance with accepted medical standards. The reader is encouraged to become familiar with guidelines in his or her institution. At the time this chapter was being written, guidelines for the determination of brain death in infants and children were being reviewed and revised by a committee formed by the Society of Critical Care Medicine and The American Academy of Pediatrics.

Brain Death Physiology

As the patient with severe intracranial pathology progresses to brain death, neuroendocrine dysfunction often requires specific interventions. These physiologic derangements reflect the powerful neuroendocrine changes that occur during progression to brain death. Efforts to control cerebral perfusion pressure, hemodynamic manifestations of herniation, and loss of central nervous system function all contribute to the instability that routinely occurs during and after progression to brain death. These physiologic changes clearly affect end-organ viability in the prospective organ donor. Understanding

the physiologic changes and anticipating associated complications with brain death therefore is critical for organ recovery.

Loss of central nervous system function causes diffuse vascular regulatory and cellular metabolic injury.[39] Brain death and cerebral ischemia increase circulating cytokines,[40] reduce cortisol production,[41] and precipitate massive catecholamine release. The combination of these factors results in physiologic deterioration and ultimately end organ failure if left untreated.

CBF is approximately 50 mL/100 g/min and consumes 15% of the cardiac output.[42] Without consumption by the brain, glucose needs are reduced and the patient is prone to hyperglycemia. Furthermore, with this reduction in cerebral metabolism, carbon dioxide production falls, resulting in a reduction in $Paco_2$. Hypothermia should be anticipated as a result of hypothalamic failure and loss of thermoregulation. Additionally, impaired adrenergic stimulation results in loss of vascular tone with systemic vasodilation and increased heat loss. Neuroendocrine dysfunction occurs because of inhibition or loss of hormonal stimulation from the hypothalamus, resulting in fluid and electrolyte disturbances and eventually cardiovascular collapse if left untreated.

Hemodynamic deterioration that occurs with brain death is initiated by a massive release of catecholamines, commonly referred to as sympathetic or autonomic storm, associated with cerebral ischemia and intracranial hypertension. This deterioration manifests clinically with systemic hypertension and tachycardia.[39,43] During this autonomic storm, organs are exposed to extreme sympathetic stimulation from direct neural stimulation or from significant increases in endogenous catecholamines. The local effects of such sympathetic stimulation include increased vascular tone, effectively reducing blood flow and potentially causing ischemia to these organs.

This autonomic storm also has direct effects on the myocardium as the surge of catecholamines increases systemic vascular resistance, myocardial work, and oxygen consumption.[44] This imbalance between myocardial oxygen supply and demand[39,45] can cause ischemic changes. Myocardial injury can impair cardiac output and lead to dysfunction of other organs. Left ventricular end diastolic pressure rises, causing pulmonary edema. This condition may be exacerbated by displacement of systemic arterial blood into venous and pulmonary circulations as a result of catecholamine-mediated systemic vasoconstriction. Increased pulmonary vascular resistance and right heart volume overload may displace the ventricular septum into the left ventricle, further impairing cardiac output by impeding left ventricular filling.[46]

Following determination of brain death, and once a decision has been made by the family to proceed with organ donation, the focus of care shifts toward the preservation of vital organs. Subsequent care may differ from management before death. Efforts to reduce intracranial pressure are abandoned and care shifts toward providing ample blood flow and oxygen delivery to transplantable organs. Hemodynamic management goals are directed at maintaining normal peripheral perfusion and blood pressure for age. Decreased intravascular volume, caused by efforts to reduce CBF and control intracranial pressure (e.g., volume restriction and diuretic agents), must be corrected. Attention to volume loss from derangements such as diabetes insipidus (DI), must be anticipated and addressed. Additional donor management goals include the normalization of Pco_2, normalization of temperature, and correction of metabolic disturbances. Donor management goals are listed in Box 13-3. Progression from brain death to somatic death and loss of transplantable organs can result if appropriate care is not instituted.[8,46] Aggressive donor management optimizes organ function and affects the quality of organs recovered.[11,46] This scenario can result in more transplantable organs and improved graft function,[9-12] potentially reducing the length of the hospital stay and decreasing the incidence of morbidity and mortality for the transplant recipient.

Box 13–3 Pediatric Donor Management Goals

Hemodynamic Support

1. Normalization of blood pressure
2. Systolic blood pressure appropriate for age
   NOTE: Lower systolic blood pressures may be acceptable if biomarkers such as lactate and Svo_2 are normal
3. CVP <12 mm Hg (if measured)
4. Dopamine <10 μg/kg/min
5. Normal serum lactate

Oxygenation and Ventilation

1. Maintain Pao_2 >100 mm Hg
2. Fio_2 0.40
3. Normalize $Paco_2$ 35-45 mm Hg
4. Arterial pH 7.30-7.45
5. Tidal volumes 8-10 mL/kg
6. PEEP 5 cm H_2O

Thermal Regulation

1. Core body temperature 36°-38° C

Blood Pressure

	Systolic (mm Hg)	Diastolic (mm Hg)
Neonate	60-90	35-60
Infant (6 mo)	80-95	50-65
Toddler (2 y)	85-100	50-65
School age (7 y)	90-115	60-70
Adolescent (15 y)	110-130	65-80

Fluids and Electrolytes

1. Serum Na^+ (mEq/L)	130-150
2. Serum K^+ (mEq/L)	3-5.0
3. Serum glucose (mg/dL)	60-150
4. Ionized Ca^{++} (μmol/L)	0.8-1.2

CVP, Central venous pressure; Fio_2, fraction of inspired oxygen; *PEEP,* positive end-expiratory pressure; Svo_2, venous oxygen saturation.
Data from: Nakagawa TA: *North American Transplant Coordinators Organization (NATCO) updated donor management and dosing guidelines*, Lenexa, KS, 2008, North American Transplant Coordinators Organization.

Treatment of Hemodynamic Instability

Cardiac instability is the greatest limiting factor to successful organ recovery. Of all the physiologic abnormalities encountered in the prospective organ donor, the cardiovascular system is fraught with the greatest complexity and variation. The tremendous physiologic derangements associated with neuroendocrine dysfunction require specific interventions to restore normal physiology.

The sympathetic storm associated with cerebral ischemia and intracranial hypertension is a predictably transient phenomenon. Although end-organ ischemia can occur transiently, treatment with antihypertensive agents may not be warranted and indeed can create additional problems with perfusion when this phase of sympathetic outflow has passed. If hypertension is severe and treatment is believed to be indicated, a single intravenous dose or continuous infusion of a short-acting antihypertensive agent such as hydralazine, sodium nitroprusside, esmolol, or labetalol can be administered and titrated to effect.

Once brain death occurs, there is an associated drop of sympathetic outflow, leading to loss of sympathetic tone and vasodilation. This situation results in profound and abrupt hypotension. Management goals during this phase of patient care are directed at aggressive restoration of circulating volume, optimizing cardiac output and oxygen delivery to the tissues, and maintaining normal blood pressure for age (see Box 13-3). Aggressive restoration of circulating volume and utilization of catecholamines to support blood pressure are mainstays of treatment.[47] The use of artificial plasma expanders such as Hespan or dextran for volume resuscitation should be avoided because large volumes of these agents can promote coagulation disturbances.[48,49] Inotropic agents such as dopamine, dobutamine, and epinephrine can be titrated to effect. Catecholamines and dopamine appear to have immunomodulating effects that may help blunt the inflammatory response associated with brain death and improve kidney graft function.[50,51] Although sometimes necessary, the administration of high-dose vasoactive agents can be associated with reduced perfusion to donor organs, potentially jeopardizing their viability prior to recovery and transplantation. The use of HRT with agents such as thyroid hormone, steroids, vasopressin, and insulin is commonly used during donor management, especially in situations in which significant inotropic support is required.[10-12,47,52] Clinical characteristics such as blood pressure and central venous pressure (CVP) and biomarkers such as mixed venous oxygen saturation and serum lactate levels serve as guides to adequate cardiac performance and tissue oxygen delivery. Some clinical indicators may not be reliable once brain death has occurred. Urine output may not be a good clinical indicator of intravascular volume if DI is present. After death of the brain stem, heart rate may not be a reliable sign of intravascular volume status because there is loss of beat-to-beat variation and lack of vagal tone and a fixed heart rate. Perfusion also may be affected because temperature instability and hypothermia can result in delayed capillary refill time. Biomarkers such as mixed venous oxygen saturation and serum lactate levels may usefully guide cardiac management and manipulation of oxygen delivery to tissues. Elevations in serum lactate and the development of a metabolic acidosis provide evidence of tissue ischemia and should prompt immediate attention.

Arrhythmias can occur during the progression to brain death or following brain death. The catecholamine storm triggered by adrenergic stimulation can promote rhythm disturbances and myocardial ischemia. Hypotension from hypovolemia and vasodilation causes poor cardiac output and metabolic acidosis. Other factors that contribute to arrhythmias include hypoxemia, hypothermia, cardiac trauma, and the pro-arrhythmic properties of inotropes. Electrolyte and metabolic disturbances—specifically hypomagnesemia, hypocalcemia, and hypokalemia that occur with DI—also may precipitate rhythm disturbances. Identification and correction of the underlying cause of the arrhythmia is essential to address rhythm disturbances.

Hormonal Replacement Therapy

Significant volume resuscitation and inotropic support are commonly required to correct severe cardiovascular derangements following brain death. Thyroid and cortisol depletion may contribute to the hemodynamic instability encountered in patients who have progressed to brain death. Common strategies used to support this patient population are the initiation of HRT to augment blood volume and inotropic support to optimize cardiac output. The use of HRT has allowed a management strategy in which blood pressure and normovolemia are maintained using a minimum amount of vasoactive agents.

HRT in adult donors is controversial because the correlations of hormone use, cardiac function, and clinical outcome are variable.[9-12,53-57] However, in one adult series HRT has been shown to reduce the need for vasoactive infusions in 100% of unstable donors and to abolish the need in 53% of such donors.[57] Decreased inotropic requirements also have been noted in children who received levothyroxine and vasopressin as part of management following brain death.[58,59] Although limited studies are available, HRT seems to be a reasonable consideration in situations in which the hemodynamic status of the child is refractory to conventional therapy with fluid and inotropic administration. HRT has been associated with an increased number of organs recovered from donors.[8,10-12,60] No published studies are available in children; however, one unpublished abstract retrospectively reviewed 1903 pediatric donors.[61] HRT was associated with significantly increased odds of having the liver and at least one kidney and lung transplanted. There was no significant increase in the odds of the heart being transplanted. The greatest benefit of HRT in donor management may in fact be improved graft function following transplantation.[9,60,62-64] Given these observations, many OPOs have adopted the use of HRT as a routine part of donor management. Commonly used agents and doses for hormonal resuscitation in pediatric donors are listed in Table 13-1.

Impaired cardiac performance following brain death is due to vascular injury associated with the catecholamine storm. Additionally, reduced free triiodothyronine (T_3) levels may impair mitochondrial function and deplete energy stores. Animal studies have shown that diminished circulating levels of T_3 and thyroxine[39] impair oxygen utilization. The effects of thyroid hormone on myocardial contractility are complex and can be immediate or delayed. The acute inotropic properties of T_3 may occur as a result of β-adrenoreceptor sensitization or may be completely independent of β-adrenergic

Table 13–1 Pharmacologic Agents Used for Hormonal Resuscitation in Children

Drug	Dose	Route	Comments
Desmopressin (DDAVP)	0.5 μg/h	IV	Terminal half-life = 75 min (range, 0.4-4 h) Titrate to effect to control urine output (2-4 mL/kg/h) May be beneficial in patients with an ongoing coagulopathy
Vasopressin (Pitressin)	0.5 mU/kg/h	IV	Half-life = 10-35 min Titrate to effect to control urine output (2-4 mL/kg/h) Hypertension can occur
Levothyroxine (Synthroid)	0.8-1.4 μg/kg/h	IV	Titrate to effect Bolus dose 1-5 μg/kg can be administered; smaller infants and children require a higher bolus and infusion dose
Triiodothyronine (T_3)	0.05-0.2 μg/kg/h	IV	Titrate to effect
Methylprednisolone (Solu-Medrol)	20-30 mg/kg	IV	Dose may be repeated in 8-12 h; fluid retention and glucose intolerance can occur
Insulin	0.05-0.1 U/kg/h	IV	Titrate to effect to control blood glucose levels; monitor for hypoglycemia

IV, Intravenous.
Data from Nakagawa TA: *North American Transplant Coordinators Organization (NATCO) updated donor management and dosing guidelines*, Lenexa, KS, 2008, North American Transplant Coordinators Organization.

receptors.[62,65,66] Furthermore, T_3 administration may play an important role in maintaining aerobic metabolism at the tissue level after brain death has occurred.[67] Beneficial hemodynamic effects in brain-dead patients receiving T_3 administration have been variable.[62,64] Levothyroxine (Synthroid) and T_3 are the two intravenous thyroid agents available for administration. T_3 is used in some centers for HRT; however, the cost of this medication may be prohibitive. Dosing of thyroid hormone for the pediatric organ donor is not well established. Thyroid hormone dosing is based upon weight. One retrospective study in which younger children received larger bolus and infusion doses than did older children demonstrated enhanced weaning of inotropic support in children who progressed to brain death.[58]

Steroids such as hydrocortisone are another pharmacologic agent routinely used by many centers for HRT to assist with hemodynamic support. Few data exist to show that hydrocortisone provides hemodynamic benefit in the potential pediatric organ donor.[47] The potential benefit of hydrocortisone and other steroids may lie in their ability to alter adrenergic receptors and regulate vascular tone by increasing sensitivity to catecholamines.[68,69] Steroids also have been shown to stabilize pulmonary function, reduce lung water accumulation, and increase lung recovery from donors.[70-73]

The combination of thyroid hormone and steroids may be used to reduce vasoactive agent dose requirements in children. Additionally, vasopressin for control of DI can reduce the need for inotropic support.

Management of Pulmonary Issues for the Potential Pediatric Organ Donor

Increasing success with lung transplantation for the treatment of patients with end-stage lung and pulmonary vascular disease has placed a premium on the acquisition of lungs from the donor pool. Children waiting for a lung transplant comprise less than 10% of the national pediatric wait list.[1] However, the demand far exceeds availability. Experience has shown that lungs are the organs most likely to be found unsuitable for transplantation. Recovery of lungs for transplantation accounts for 7% to 22% of the multi-organ donor pool.[74,75] The low percentage of lung recovery for transplantation reflects stringent donor selection criteria and lack of suitable organs for transplantation. Lung protective strategies have the potential to salvage marginal lungs for transplantation; however, in many instances these strategies are not implemented, resulting in the loss of potential lung donors.[75]

Many factors contribute to the limitations associated with acquisition of lungs for transplantation. Blunt trauma in children resulting in pulmonary contusion/hemorrhage accounts for a large portion of injuries to the thoracic cavity. Inhalational or thermal injury can injure the lungs and airway structures. Infectious etiologies can compound the effects of existing lung disease or injury. Often these injuries are the reason the patient has become an organ donor. Furthermore, the lungs are particularly vulnerable in the face of critical illness, leaving them susceptible to complications such as fat emboli, pulmonary emboli, aspiration pneumonia, ventilator-associated pneumonia, and atelectasis.[71] Each of these disorders is associated with lung injury and impaired ventilation and oxygenation that diminishes lung suitability for transplantation.

The physiologic aberrations that accompany brain death also can result in end organ damage, rendering lungs unsuitable for transplantation. Management of pulmonary physiology is often complicated by the development of pulmonary edema from the progression of brain injury.[46] The sympathetic storm associated with brain death causes systemic and pulmonary vasoconstriction. Neurogenic pulmonary edema occurs as pulmonary venous pressure rises, causing pulmonary capillary wall disruption and evolution of pulmonary edema.[76] This predictable deterioration of pulmonary function increases the vulnerability of the lungs to injury in the brain-dead donor.[75,77] Massive brain injury may in fact act as a preconditioning factor that renders the graft more susceptible to subsequent lung damage and increases the risk of post-transplant graft failure.[77]

Lung protective management strategies have been developed as a result of the complex physiology and vulnerability of the lungs following brain death. Measures to protect donor

lungs have resulted in improved recovery and successful transplantation of these organs.[78,79] Management strategies include measures such as diligent pulmonary toilet with frequent suctioning, patient turning, clearance of mucous plugs, and airway evaluation with flexible bronchoscopy.[71,80] Ventilator management with attention to recruitment maneuvers such as sustained inflations and positive end-expiratory pressure (PEEP) have been advocated to avoid the development of atelectasis and to treat the pulmonary edema associated with the catecholamine storm that occurs with brain death.[79,80] The benefit associated with the use of inflation maneuvers and PEEP must be balanced against the risk of barotrauma and effects on preload that can potentially adversely affect cardiac output in the donor with myocardial dysfunction. Volume administration and inotropic support may be required if blood pressure is affected by this maneuver. These cardiovascular effects can be minimized if adequate preload is provided prior to escalation of PEEP. Colloid solutions have been recommended to minimize accumulation of pulmonary edema.[80] Additionally, albuterol has been shown to enhance clearance of pulmonary edema in an animal model[53] and to improve mucociliary clearance.[71] Steroids are frequently utilized in the donor and have been shown to reduce lung water accumulation and stabilize pulmonary function.[70-73] Another novel therapy involves the use of naloxone to improve gas exchange in donor lungs.[81]

Ventilatory requirements may become minimal in the donor as brain death occurs. Respiratory alkalosis is common as metabolic production of carbon dioxide from the brain ceases and compliance of the chest wall changes. Restoring normocarbia with a goal of 35 to 40 mm Hg in the child who has progressed to brain death is ideal given the effects of pH on unloading characteristics of oxygen from hemoglobin. Avoiding overdistention of the lungs during mechanical and manual ventilation is crucial to reduce the risk of barotrauma or further pulmonary injury.[71,79] Donor management goals include achieving a Pao_2 of greater than 100 mm Hg, oxygen saturation of greater than 95% using the least amount of oxygen necessary, tidal volume of 10 mL/kg, and PEEP of 5 to 10 cm/H_2O to ensure adequate alveolar recruitment. Elevation of the head of the bed and use of a cuffed endotracheal tube with high cuff pressures to reduce aspiration risk also are advocated.[70] Donor management guidelines for oxygenation and ventilation are summarized in Box 13-3.

An oxygen challenge test is routinely performed to determine the suitability of the lungs for transplantation. A Pao_2/fraction of inspired oxygen (Fio_2) higher than 300 on an Fio_2 of 1.0 and a relatively clear chest radiograph are preferred by transplant surgeons. Early flexible bronchoscopic evaluation of the lungs is advocated by many OPOs to address correctable issues and maximize ventilation strategies to improve lung function.

Fluid and Electrolyte Disturbances

Fluid and electrolyte disturbances in the pediatric donor are the result of physiologic abnormalities, as well as consequences of earlier medical management. Commonly encountered derangements include dehydration, hyperglycemia, and sodium, potassium, and calcium disturbances. Metabolic fluctuations associated with progression toward brain death require meticulous management of fluids and electrolytes. If left untreated, these abnormalities can adversely affect organ viability.

Intravascular volume depletion is frequently encountered in the child with traumatic brain injury who has progressed to brain death. Fluid restriction, along with hypertonic solutions and osmotic diuretics, are commonly used in the management of cerebral edema. Another contributor to intravascular volume depletion is osmotic diuresis from hyperglycemia resulting from steroid and catecholamine use and increased availability of glucose from loss of cerebral metabolism. Furthermore, DI compounds sodium and water imbalance if not ideally treated. The intravascular volume of the potential donor must be adequately resuscitated, as guided by CVP, perfusion, serum electrolyte concentrations, and serial lactate measurements. Restoring intravascular volume is crucial to maintaining organ viability.

Diabetes Insipidus

DI occurs in many brain-dead patients, and if left untreated, it can have profound effects on the donor. Uncontrolled free water losses result in severe hypernatremia and significant dehydration with eventual cardiovascular collapse. Hypernatremia can affect organ suitability for transplantation and has been associated with graft failure following liver transplantation.[82]

In addition to hourly maintenance intravenous fluids, one quarter or half normal saline solution can be used to replace urine output in excess of 3 to 4 mL/kg until pharmacologic replacement therapy is implemented. The use of glucose in renal replacement fluids should be avoided to prevent further exacerbation of hyperglycemia and osmotic diuresis. Enteral free water supplementation administered through a nasogastric tube can be used for correction of severe hypernatremia. Rapid osmolar shifts during correction of hypernatremia are inconsequential because brain death has already occurred. DI frequently requires pharmacologic treatment with antidiuretic hormone to reduce ongoing free water loss. Pharmacologic agents such as vasopressin or desmopressin (DDAVP) are routinely utilized in HRT protocols to control urine output. These pharmacologic agents have specific indications and adverse effects that must be considered when contemplating their use to treat DI.[83] Donor management goals for treating DI include maintaining a normal serum sodium level and reducing excessive urine output. Pharmacologic treatment is not intended to completely stop urine output.

Vasopressin is a polypeptide hormone secreted by the hypothalamus and stored in the posterior pituitary. Vasopressin acts on V_1 and V_2 vasopressin receptors to stimulate contraction of vascular smooth muscle with resultant vasoconstriction. It has a short half-life of 10 to 20 minutes, and unlike desmopressin, it has no effect on platelets.[84] Vasopressin can be administered by bolus or continuous intravenous infusion. The most desirable features of this agent derive from its ease of titration to control urine output. When discontinued, its effects are short lived. Vasopressin is administered at doses of 0.5 mU/kg/h and can be titrated to control urine output to 2 to 4 mL/kg/h.[83,84] By titrating in this way, one preserves renal function and avoids volume overload and metabolic abnormalities such as hyponatremia and hyperkalemia. Vasopressin infusions commonly require rapid titration to control

excessive urine output, then avert complete loss of urine output[85] during rapid swings in renal output. High doses of vasopressin may potentially reduce splanchnic perfusion, including hepatic and pancreatic blood flow. Additionally, vasoconstriction and increased smooth muscle contractility may affect coronary and pulmonary blood flow.[45] Excessive dosing of vasopressin should be avoided to preserve end organ function.

Desmopressin acetate is a more potent synthetic polypeptide structurally related to vasopressin. This agent lacks smooth muscle contractile properties and is more specific for the V_2-vasopressin receptor. Desmopressin enhances platelet aggregation and has a longer half-life of 6 to 20 hours when administered as a single intravenous dose.[86] Desmopressin may be a preferred agent for the correction of hypernatremia given its lack of hemodynamic effects. Desmopressin can be administered by continuous infusion at 0.5 μg/h and titrated to control urine output.[83,88] Intramuscular and intranasal administration can result in erratic absorption and should be avoided. The terminal half-life of desmopressin administered by continuous intravenous infusion is 75 minutes, with a range of 0.4 to 4 hours.[88] The longer half-life of desmopressin may be less desirable than the shorter half-life of vasopressin in potential kidney donors. Desmopressin therapy may be discontinued 3 to 4 hours prior to organ recovery.[83] Fluid replacement for excessive urine output can be administered as needed for the short period prior to organ recovery.

Oliguria

Oliguria can be seen with volume depletion, acute renal insufficiency or failure, and overly aggressive pharmacologic management of DI. If urine output falls to less than 1 mL/kg/h and does not improve after decreasing or discontinuing vasopressin, intravascular volume status must be evaluated and appropriately treated. If urine output is not improved following volume expansion, initiation of inotropic or vasopressor support may improve urine output. Furosemide (Lasix) or mannitol can be used to stimulate urine output in the patient with adequate intravascular volume status. A selective dopamine agonist such as fenoldopam can be used to enhance urine output and may provide renal protection in the normotensive or hypertensive patient.[89]

Glucose, Potassium, and Calcium Derangements

Hyperglycemia as a result of steroid and catecholamine use and increased availability of glucose as a result of the loss of cerebral metabolism can lead to an osmotic diuresis, exacerbating an already depleted volume status in the donor. Hyperglycemia can be avoided by frequently assessing blood glucose concentration and making appropriate adjustments in the dextrose concentration in intravenous fluids. If these simple maneuvers are unsuccessful in controlling blood glucose levels, an insulin infusion should be instituted to maintain glucose levels between 60 to 150 mg/dL. Serum glucose levels should be closely followed to avoid hypoglycemia.

Potassium derangements can result from diuresis, renal insufficiency, steroid administration, and acid-base disturbances. Potassium can be supplemented if hypokalemia is significant. The adverse effects of hyperkalemia are clearly more hazardous than those of hypokalemia. The adverse effects of hypokalemia most likely to affect the potential donor are dysrhythmias.

Hypocalcemia occurs commonly as a result of large volume replacement with colloids such as albumin; massive blood transfusions, which result in large amounts of citrate-reducing free calcium concentrations; and sepsis. The use of calcium supplementation should be guided by ionized calcium levels.

Coagulation Abnormalities and Thermoregulatory Instability

Coagulation abnormalities can arise as a result of the release of tissue thromboplastin and cerebral gangliosides from injured brain.[45] Additionally, the catecholamine surge associated with traumatic brain injury may contribute to coagulation disturbances.[90] Thrombocytopenia and platelet dysfunction can be induced by common drugs such as heparin, antibiotics, β-blockers, calcium channel blockers, histamine H_2 receptor antagonists, tromethamine, and hespan.[91] Patients with liver disease have reduced synthesis of vitamin K–dependent clotting factors. A dilutional coagulopathy can occur from massive transfusions if coagulation factors are not replenished. Coagulation abnormalities also can be exacerbated by hypothermia. Correction of the coagulopathy can be treated using fresh frozen plasma, platelets, and cryoprecipitate, and by restoring and maintaining normothermia. The goal of blood product replacement for coagulopathy should be tailored accordingly based on the abnormalities encountered.

Coagulation abnormalities should be addressed prior to transport of the donor to the operating suite for organ recovery. A minimum platelet count of 75,000/mm^3 should be obtained prior to recovery of organs in the operating suite. The use of aminocaproic acid (Amicar), an antifibrinolytic agent, and other similar hemostatic agents are not recommended for treatment of bleeding because microvascular thrombosis may be induced in donor organs.[45]

Hypothermia commonly occurs following brain death. Vasodilation with an inability to compensate for heat loss by shivering or vasoconstriction is a common cause of thermoregulatory instability in this patient population. Additionally, the infusion of large volumes of room-temperature intravenous fluids to treat DI and volume depletion contributes to hypothermia. Hypothermia can promote cardiac dysfunction, arrhythmias, coagulopathy, a cold-induced diuresis resulting from decreased renal tubular concentration gradient, and a leftward shift of the oxyhemoglobin dissociation curve, resulting in decreased oxygen delivery to the tissues.[92] Radiant warmers, warm blankets, thermal mattresses, warm intravenous fluids or a blood warmer for infusion of blood products, and environmental warming will help maintain body temperature. Additionally, heating inspired gases can assist in controlling body temperature. Prevention of hypothermia is essential to prevent deterioration of the potential organ donor.

Medical Examiner/Coroner Issues and Organ Donation for Children

Many children who die from head injuries are victims of nonaccidental trauma. When nonaccidental trauma has resulted in the death of a child, great sensitivity is required to preserve

the integrity of the criminal investigation. Successful recovery of organs from these patients can still occur in most cases with close cooperation between forensic investigators, treating physicians, the transplant team, and the OPO.[93-97] Protocols to facilitate organ recovery in child abuse victims can decrease denials for organ donation by medical examiners/coroners.[96-99] Involvement of the district attorney during protocol development also should be a consideration. Efforts to reduce the number of medical examiner denials for donation are occurring at a national level and supported by the National Association of Medical Examiners.[100] Despite these national efforts, many potential pediatric donors continue to be lost because of medical examiner/coroner denials.[2]

Donation After Circulatory Determination of Death

Whereas the vast majority of recovered organs will be recovered from brain-dead donors, donation after circulatory determination of death (DCD)—that is, the organ donor without a beating heart—provides another source of valuable organs for transplantation.

DCD allows donation to occur from patients with catastrophic brain injury who do not progress to brain death. The discussions and decision to donate organs can only occur after the decision to withdraw life support has been made. This step avoids the perceived ethical conflict that we are allowing the patient to die to recover organs. Routine end-of-life care, including comfort measures, are provided for these patients just as they would be for any patient in whom withdrawal of medical support occurs.

Criteria must be met for organs to be recovered by this method. Circulatory arrest must occur within 60 minutes of withdrawing support. The time constraint is important because longer periods to achieve circulatory arrest will result in organ ischemia, rendering potential transplant tissue useless. Following loss of cardiac electrical activity (electrical asystole) or pulse pressure (mechanical asystole), the patient is observed for 2 to 5 minutes before recovery of organs can occur. This 2- to 5-minute observation period is crucial to ensure that auto resuscitation of the heart with restoration of circulation does not occur. If electrical or mechanical asystole is consistent with circulatory death following the observation period, organs are recovered for transplantation. Families must be prepared for the possibility that death may not occur within the specified time period. If this situation occurs, continued comfort measures are provided for the patient and family support continues.

DCD is not a new method of organ recovery. In fact, DCD is the foundation of modern transplant medicine. Organs were routinely recovered by this method prior to institution of brain death guidelines. The reevaluation of this method of donation was prompted by the increasing need to meet the demands of a growing national transplant wait list.[101,102] Between 2005 and 2006, there was almost a 100% increase in the number of pediatric DCD donors nationally. This sustained practice during the past few years is reflected by an average of 72 pediatric DCD donors per year, accounting for approximately 10% of all DCD donors during this period.[1] DCD has the potential to increase organ donation in children.[103-105] Individual numbers of DCD donors may be small at any one pediatric center, but the collective impact from all pediatric centers actively recovering organs from this type of donor has the potential to significantly increase the number of organs available for transplantation.[101-106]

DCD focuses on recovery of the two most commonly needed organs for children, the liver and kidney. Success with transplantation of DCD organs, primarily the kidney and liver, is occurring in many centers. Rates of graft survival for these organs appear to be similar to those of organs recovered from brain-dead donors.[107-111] Although experience is limited, lung transplants from DCD donors have occurred in several institutions.[112,113] Additionally, the successful transplantation of three hearts recovered from neonatal DCD donors, under an established research protocol, has occurred[114]; however, ethical concerns about when circulatory death occurs have been raised and continue to be debated.

Although some controversy exists over this mode of donation, the Society of Critical Care Medicine, the Institute of Medicine, the American Medical Association, and the American Academy of Pediatrics support DCD as an acceptable means to recover organs for transplantation.[93,115-118] Education regarding this mode of donation is crucial so that all health care personnel can successfully identify and recover organs from this population of children.[119,120]

Summary

The process of organ donation begins when a critically ill or injured child is identified as a potential donor with a timely referral to the OPO. Identifying and caring for the organ donor requires a skilled team of specialists who deal not only with the deceased child, but also the family. Early involvement of the OPO allows coordination with physicians, social workers, chaplains, and family support services, enhancing the chance for the family to understand and agree to organ donation. Timely and accurate determination of brain death allows the focus of medical management to transition toward care and preservation of organs for transplantation once consent is obtained. Management of the pediatric organ donor is a natural extension of care for a critically ill or injured child. Meticulous care of the potential donor can result in more transplantable organs with improved graft function. The option for organ donation should be made available to every family. It should be the expectation that the family will be approached in a professional, compassionate manner that allows for open discussion during the most difficult, agonizing time in their lives. Pediatric critical care specialists working together with other dedicated professionals to provide specialized care to the donor can affect the lives not only of the donor family, but also of many potential recipients and their families through the effects of a life-saving and life-changing transplant.

Chapter 14

Pediatric Transport: Shifting the Paradigm to Improve Patient Outcome

Kate Felmet, Richard A. Orr, Yong Y. Han, and Kimberly R. Roth

PEARLS

- In transport, patients are subjected to a high-risk moving environment with limited resources and few monitoring capabilities. The goal during transport should be to provide the same or better quality care than the patient received before transport.
- A retrieval system has a responsibility to the referral community to make tertiary care accessible. The components include a communication center, administrative staff, appropriately trained team members, reliable equipment, and education and safety programs.
- A hospital should not transfer a patient until (1) the patient has been stabilized within the ability of the transferring hospital, (2) the patient consents to transfer having been informed of the risks of transfer, and (3) the referring physician certifies that the medical benefits expected from the transfer outweigh the risks. The transferring hospital has responsibility for providing copies of the medical records and imaging studies to accompany the patient. The receiving facility must have available space and qualified personnel and agree to accept the patient. The transport must be made by qualified personnel.
- The pathophysiology of acute respiratory and hemodynamic embarrassment in children differs from adults in ways that may impact care during transport.
- Underutilization of acquired procedural or assessment skills often leads to decrement in skill level. It is a major challenge for multidisciplinary teams to acquire and maintain the knowledge and skills to provide competent care for critically ill children and adults.
- Evidence that early resuscitation of pediatric shock improves outcome is mounting. The paradigm of transport in which speed of transport takes precedence over quality of care must be abandoned if we are to realize improved outcomes in the critically ill child who requires transport to a critical care center. Goal-directed therapy should begin in the prehospital arena and continue throughout the critical care continuum.

Along with the regionalization of pediatric emergency and critical care centers has come the growth of interfacility transport programs, allowing geographic expansion of tertiary medical care. Eighty-nine percent of pediatric emergency department (ED) visits occur in nonpediatric EDs, where the extent of illness or injury is assessed and initial stabilization is provided.[1] Most community hospitals do not have the personnel, space, or facilities to provide critical care to infants or children beyond the period of initial stabilization, necessitating transfer to a tertiary facility. In transport, children are subjected to a high-risk environment with limited resources and monitoring capabilities. The goal during transport should be to provide care commensurate with the degree of illness severity in a safe and effective manner, minimizing the risk of deterioration and unplanned events before transport and en route. Little research exists to support the choices about mode of travel or makeup of the transferring team that are made every time a child is transferred to a tertiary facility.

Improvements in critical care are incremental: There are no miracle drugs or technologies. The major improvements in care in the last decade involve early, aggressive administration of simple therapies: timely initiation of resuscitation fluids, inotropes via peripheral intravenous line, and antibiotic therapy can improve outcomes.[2,3] If appropriate resuscitation waits until the child arrives in the pediatric intensive care unit (PICU), the benefits of early, aggressive action are likely to be lost. Goal-directed therapy must begin before and continue during transport for the benefits noted in these studies to occur. Significant barriers to realizing this ideal exist.

In this chapter we will briefly discuss the barriers that have stifled progress. Information about appropriate vehicles, medication, and equipment for transport is summarized elsewhere, in the American Academy of Pediatrics (AAP) Guidelines for Air and Ground Transport of Neonatal and Pediatric Patients.[4] This chapter is designed to challenge the pediatric intensivist, whose patient population is largely derived from transport, with the important concept that a well designed and staffed pediatric critical care transport system can have a dramatic impact on patient outcomes, and deserves great attention from pediatric intensivists.

The Problem: An Adult-Oriented Retrieval System Focused on Rapid Movement

Emergency medical services (EMS) and regional flight teams are focused on the major causes of mortality in the adult population, such as myocardial infarction and trauma, for which rapid transfer to a center that can provide definitive care is an important determinant of outcome.[5] Adult-oriented ED and EMS services do not provide ideal care for children. Still, multidisciplinary teams transport the majority of critically ill children. Many argue that pediatric specialized transport systems are not necessary, for the reasons given in Box 14-1.

With the support of other interested bodies, the American Academy of Pediatrics recently issued a policy statement detailing the recommended pediatric equipment for ambulances.[2] It is not known what percentage of ambulances are adequately equipped, but two independent studies reported that as recently as 2003, only 6% of emergency rooms were appropriately equipped to care for children. Items frequently not available included laryngeal mask airways and infant and neonatal equipment.[6]

Limited pediatric training coupled with limited exposure to pediatric patients may hamper the ability of EMS providers to respond appropriately to pediatric emergencies. In 2000, nationally registered paramedics received a median 358 total hours of instruction, less than 5% of which were dedicated to pediatrics. Moreover, most paramedics in this study were not required to take pediatric continuing medical education (CME) training.[7] Without repeated reinforcement, cognitive and interventional skills deteriorate over time. Fewer than 10% of all EMS runs nationwide are for infants and children, and a small percentage of these involve advanced life support (ALS) or critical care.[8,9] Babl et al.[10] demonstrated that in a program with 50 active ALS providers, each provider is expected to have one pediatric bag-valve-mask (BVM) case every 1.7 years, one pediatric intubation every 3.3 years, and one intraosseus cannulation every 6.7 years. Su et al.[11] demonstrated that the knowledge acquired in didactic sessions deteriorates rapidly over a 6-month period. Henderson[12] also demonstrated that the ability of a provider to intubate or provide BVM ventilation for a child deteriorates significantly over the course of 6 months.

Underutilization of an acquired skill can lead to a decrement in skill level and a fear-related aversion to performing the procedure. With any given scenario in the EMS setting, adult patients are more likely to receive an appropriate intervention compared with a child having the same problem.[13,14] Prehospital care providers are reluctant to attempt intubation, even when it is clearly indicated. Aijian et al. examined a population of pediatric patients who had suffered a prehospital cardiopulmonary arrest and determined that endotracheal intubation was attempted only 68% of the time, with a success rate of only 64%.[15] In patients younger than 1 year, endotracheal intubation was attempted only 38% of the time, with a success rate of only 50%.[15] Multiple investigators have documented a decrease in the percent of successful intubations in children compared with adult patients, both in ground EMS systems and air ambulance systems.[16-19]

Studies of pediatric trauma victims make it clear that prehospital providers could do a better job with children. Children were twice as likely to die of trauma in the field compared with adults, which was attributed to the lack of pediatric training.[5,8,20] Ramenofsky et al. determined that 53 of 100 deceased pediatric trauma victims in their study could have been salvaged given an optimally functioning emergency medical system and that in 79% of the potentially salvageable cases, mortality was associated with prehospital iatrogenic or secondary insults.[9]

Referring hospitals that lack pediatric expertise may create suboptimal situations prior to transport. Esposito et al. found that frequent errors occur in ED management of pediatric trauma, leading to preventable mortality of approximately 9%.[21] In addition, they reported a 64% error rate in the management of children, including gross violations of basic trauma care.[21] Han et al.[22] found that resuscitation practice in a community ED was consistent with American College of Critical Care Medicine-Pediatric Advanced Life Support (ACCM-PALS) guidelines in only 30% of children who presented with septic shock. Athey et al.[23] found that nearly 10% of all U.S. hospitals without pediatric intensive care facilities admit critically ill and injured children, and that 7% of these hospitals routinely admit these children to adult intensive care units rather than transferring the children to a more appropriate facility. Of the facilities that keep children, few have protocols for obtaining pediatric consultation for emergencies, and most did not have appropriate-sized equipment to care for children.[23] Those referring hospitals that do transport children to pediatric facilities are often inadequately equipped to care for children or unfamiliar with established guidelines and protocols and, as a result, may be in a rush to send children, sacrificing stabilization and eschewing transport by a more experienced team in the interests of saving time. When facilities and physicians lack

Box 14–1 Arguments Against and for Use of Specialized Pediatric Transport Teams

Arguments against	Arguments for
• Expensive and resource-intensive	• Resource use may be justified by improved outcomes
• The patient is already packaged to go—what else is there to do?	• A specialized team brings goal-directed ICU care to the patient and continues attentive resuscitation as the patient changes en route
• Limitations of the transport environment—what more can a specialist do?	• For most transports, the critical time is time to initiation of appropriate therapy, NOT time to arrival at the tertiary care center
• Specialized teams spend too much time on the scene; no appreciation for what is time-critical	• Nonspecialized teams lack experience with children and have difficulty maintaining learned skills
• Requires two-way transport; takes longer to get to the critical care center	• Improved outcome may justify development of specialized teams
• ABCs (airway, breathing, circulation) are no different for children	
• Not available in many settings	

insight about their ability to care for children, requests for transfer may come too late, after irreparable organ damage has already occurred.

Critical Pediatric Physiology Relevant to Transport Medicine

There are some critical differences between the respiratory mechanics and cardiovascular physiology in adults and children that lead to a need for earlier, more aggressive intervention in children with common pediatric problems. Failure to understand these differences can lead to a potentially injurious delay in advanced airway management and shock resuscitation. Airway interventions should be planned carefully and performed early in the course of respiratory failure to avoid having to deal with a respiratory crisis while en route.

Peripheral airway resistance in children younger than 5 years is approximately four times higher than in adults or older children, in whom the upper airway is the major contributor to airflow resistance.[24] Because of this, young children are more likely to have lower airway obstructive disease and less likely to respond to airway positioning, an intervention which is commonly used by paramedics to defer intubation in adults.

Infants and small children have more compliant chest walls with low elastic recoil compared with older children and adults, increasing the risk of lung collapse.[25] In infants and small children, muscular effort is required to stabilize the chest wall, and a portion of the force of contraction of the diaphragm is wasted in distorting the rib cage.[26] This mechanical disadvantage leads to increased energy expenditure, and increases the likelihood that infants with lung disease may fatigue and stop breathing.[27] Gastric distension can further decrease the efficiency of the diaphragm in children and should be prevented or treated with a nasogastric tube. Positive pressure breathing applied early in the disease process can stop the progression of atelectasis and respiratory failure.

Functional residual capacity is only slightly higher than critical closing volume in infants and small children, leading to alveolar collapse much earlier in the course of respiratory failure. Lung growth appears to involve both an increase in the number of alveoli and an increase in the size of alveolar spaces,[28] which may also predispose the infant lung, with its smaller alveoli, to collapse. In addition, the adult lung contains anatomic channels that allow ventilation distal to an obstructed airway, also known as collateral ventilation; the absence of these pathways in young children further increases the risk for atelectasis.[29] The diffusing capacity across the alveolar-capillary membrane in a child is only about one third that of an adult, making gas exchange less efficient.[30]

The delivery of goal-directed therapy may be hampered by the inability of practitioners to recognize shock. Infants and children have a greater capacity to increase systemic vascular resistance in shock states and tend to preserve blood pressure until very late in the evolution of shock.[31] Pediatric shock resuscitation protocols developed by the consensus of experts in the field call for treatment of shock using clinical signs, including age-specific targets for heart rate and blood pressure, and relatively subtle indicators of perfusion as therapeutic endpoints.[32]

Rapid Transfer, Goal-Directed Therapy, and the Golden Hour

EMS and regional flight teams focused on adult experience work under the assumption that the time between the moment of injury and arrival at a center capable of delivering definitive care is among the most important determinants of survival. This "golden hour" is the driving force for clinical decision-making and usually translates into providing minimal care and moving quickly (Figure 14-1). The concept of the "golden hour" often is described as having its origin in a surgical commentary by Cowley et al.[33] on the success of implementing a helicopter-based program for trauma, during an era when prehospital care consisted of providing supplemental oxygen and a fast-moving vehicle. "Scoop and run" and the "golden hour" remain the prevailing philosophies in the transport of infants and children, few of whom benefit from the speed of transport alone.

There are a few disease processes, such as aneurysms requiring neurosurgical intervention or complete transposition of the great arteries requiring urgent atrial septostomy, in which rapid transport to a center that can provide definitive care is the most pressing issue. These are rarities. Respiratory insufficiency and shock are common reasons for referral of pediatric patients. A recent study identified shock in 37% of children transferred to tertiary centers *regardless of the reason for referral.*[34] It is increasingly recognized that rapid resuscitation is critical to the management of pediatric shock.[32] In adults and children, protocolized, aggressive, early therapy of septic shock has proven vastly more effective than any pharmacological intervention.[2,22,34,35] Aggressive fluid resuscitation and initiation of inotropes and antibiotics should be accomplished within the first hour after presentation. In adults with septic shock, a delay in antibiotic therapy is associated with worse survival, with mortality increasing by 7% for every 30 minutes that passes without delivery of appropriate antibiotic therapy.[3]

The American College of Critical Care Medicine (ACCM) clinical practice parameters for hemodynamic support of pediatric and neonatal septic shock are divided into specific

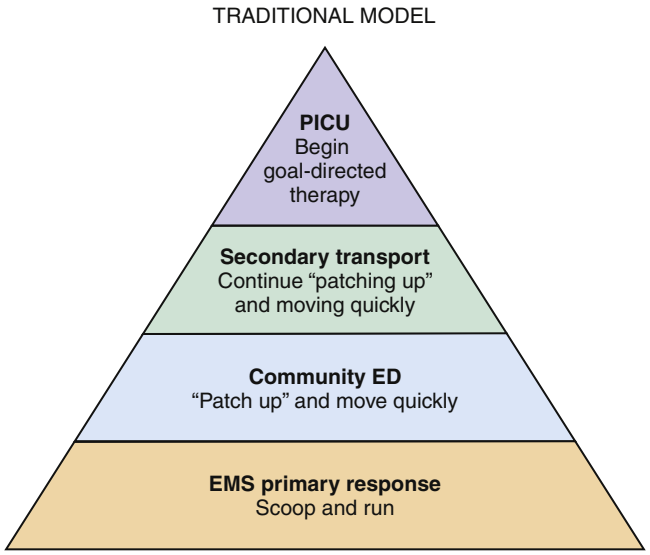

Figure 14–1. Traditional model of emergency care based on the concept of the "golden hour." *ED,* Emergency department; *EMS,* emergency medical services; *PICU,* pediatric intensive care unit.

tasks to be accomplished in the first 5 minutes, the first 15 minutes, and the first hour. The recommended treatments are simple interventions that can be initiated in community EDs and continued and refined in transport, provided that the treating physician and transferring team appreciate the urgent need and are sensitive to the subtle signs of shock in children. Han et al. reported that when community physicians aggressively resuscitated and successfully reversed shock before a transport team arrived, patients had a ninefold increase in their odds of survival.[22] These studies defy the popular notion that out-of-hospital stabilization "wastes time" and "delays" definitive therapy that should be rendered at the receiving facility. Initiating treatment in the referring facility to the best of the institution's ability and bringing skilled transport personnel to the child rather than transporting the child with inadequately skilled personnel may markedly decrease the time to effective treatment.

Specialized Teams Improve Outcome

In 1978, Chance et al.[36] demonstrated reduced mortality and more stable physiology in neonates weighing less than 1.5 kg who were transported by a specialized team. Improved acid-base balance and hemodynamic stability on arrival to tertiary care centers has also been noted in pediatric patients transported by specialty teams.[37] Macnab[38] found fewer preventable insults occurred in children transported by a pediatric intensive care team. Edge et al.[39] demonstrated that patients who were transported by nonspecialized teams had a tenfold increase in transport-related adverse events (such as loss of an endotracheal tube) compared with specialized teams, after adjusting for severity of illness (Pediatric Risk of Mortality [PRISM]) and number of interventions (Therapeutic Intervention Scoring System [TISS]). In a prospective risk assessment of 1085 children transported to a children's hospital, Orr et al.[40] found that patients who were transported by nonspecialized transport teams were more likely to suffer from an unplanned event (odds ratio, 22.2) and in-hospital death (odds ratio, 2.4) compared with children transported by a specialized team, after adjusting for severity of illness, age, and diagnosis. Mobilization time, scene time, and total transport time did not predict unplanned events or death. In a case-control study of head-injured children, Macnab et al.[41] found more preventable insults among the patients transported by untrained escorts compared with trained escorts. The authors determined that the additional cost of care resulting from secondary adverse events occurring during transport by untrained escorts was $135,952.

In a prospective cohort study in which allocation of teams depended on team availability, not severity of illness, Orr et al.[42] showed that use of a specialized team resulted in fewer unplanned adverse events and lower mortality compared with use of a nonspecialized team. Most importantly, mortality was high in children transported by nonspecialized teams compared with specialized teams (23% vs. 9%) a difference that remained significant when controlling for pre-ICU PRISM score.

The Solution: A Retrieval System Focused on Improving Outcome

Pediatric transport is part of a critical care continuum that includes EMS, the referring ED, secondary transfer, and the receiving critical care facility (Figure 14-2). In our experience, the continuum is often fragmented, primarily by territorial issues, resulting in poor communication, isolation, lack of continuity of care, and inadequate quality assessment (Figure 14-3). The most effective system provides excellent communication between the referring hospital and the tertiary center with clear advice to support the referring staff's care, brings critical care and goal-directed therapy to the patient at the referring institution, and continues optimal care through transport and into the PICU (Figure 14-4). Bringing evidence-based recommendations and then skilled transport personnel to the child rather than transporting the child with inadequately skilled personnel may markedly decrease the time to effective treatment. Ideally, if optimal care is to be provided,

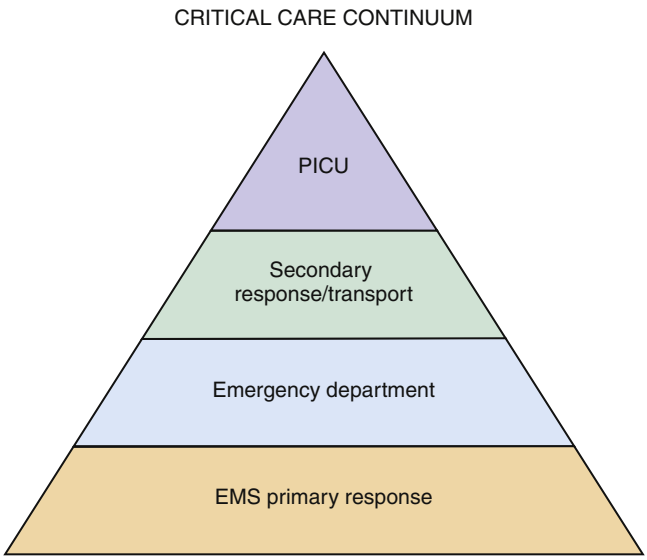

Figure 14–2. Pediatric transport as part of the critical care continuum. *EMS,* Emergency medical services; *PICU,* pediatric intensive care unit.

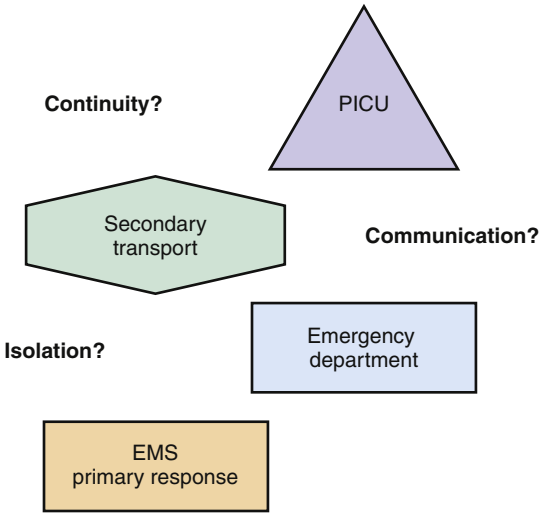

Figure 14–3. Authors' depiction of fragmented critical care continuum within a disjointed system. *EMS,* Emergency medical services; *PICU,* pediatric intensive care unit.

physicians and other caregivers from emergency medicine, neonatology, surgery, and intensive care all take an active role in designing each segment of the continuum and maintaining quality assurance. The critically ill child ultimately will be the responsibility of the pediatric intensivist, so it behooves him or her to have significant input into system design and protocols.

Responsibility of the Retrieval System

The retrieval system has a responsibility to the referral community to make tertiary care accessible, including transport. The referring community's expectations of the regional center's response to transport requests vary according to the standard of care and topography for that region. Regardless of its origin, a retrieval system should include a communications center, administrative staff, appropriately trained team members, reliable equipment, and a safety program.

Communications

The communications center for the retrieval system should be easily accessible to both the referring physician and the transport team.[43,44] It should be staffed round-the-clock by full-time communication specialists who are trained in handling emergency calls and who have no other distracting duties that would delay a response. The communication specialist should follow a prescribed protocol to minimize the number of calls necessary to organize efforts, notify the appropriate personnel, and arrange all aspects of the transport so that the referring physician can direct his or her attention to patient care. A detailed log of transport requests, including time, demographic data, diagnosis, and vehicle availability, should be kept for both administrative review and medical-legal documentation. Equipment for direct communication with the center should be available in every transport vehicle. The receiving physician who is responsible for the transport maintains contact with the communications center and with the referring physician.

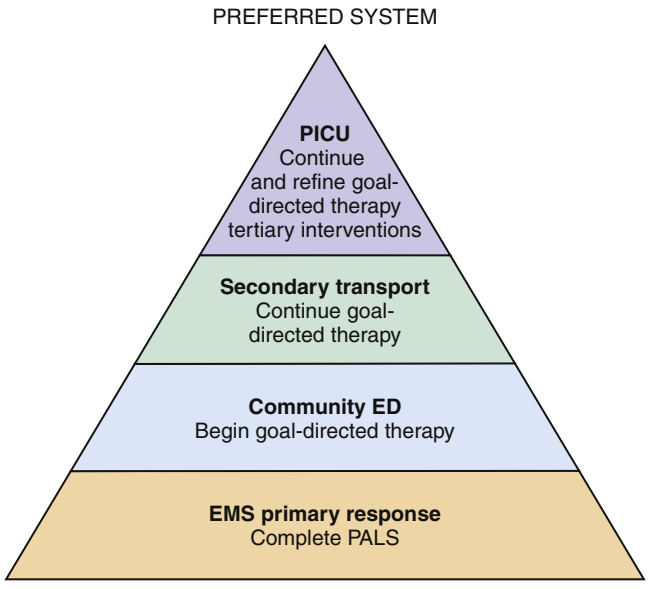

Figure 14–4. Authors' depiction of preferred system of goal-directed care model. *ED,* Emergency department; *EMS,* emergency medical services; *PALS,* pediatric advanced life support; *PICU,* pediatric intensive care unit.

The receiving physician should obtain a brief history of the patient's present illness and a summary of initial interventions and should give recommendations tailored to the capabilities of the referring hospital and pertinent to the current problem. This information should be documented on a log that remains a part of the patient's medical record.

Staffing

The administrative staff of a retrieval system should include, at a minimum, a program director, medical director, transport coordinator, and medical command.[43,44] The program director is responsible for the structure, activities, and organization of the transport system and assumes overall program responsibilities; acts as a liaison between the team and hospital administration; and develops and implements quality management.

The medical director should be a specialist in critical care or emergency medicine. He or she might have training in a surgical subspecialty (trauma) or in pediatrics (neonatology). He or she is a licensed physician who is responsible for supervising and evaluating the quality of medical care provided by the transport team, and must have educational experience in the areas of medicine that are commensurate with the mission of the retrieval service. The medical director should be experienced in both air and ground transport (as appropriate to his or her specific system), should understand patient care capabilities and limitations in the transport environment, and should be educated in infection control, stress recognition and management, altitude physiology,[45] and stressors in the transport and flight environments. The medical director must be actively involved in quality management, administrative decisions affecting medical care, and the hiring, training, and continuing education of all transport personnel. He or she must orient those physicians who provide online medical direction to the policies, procedures, and patient care protocols and should act as a liaison to the referral community for teaching and outreach.[43,44]

The transport coordinator, usually a nurse or paramedic, collaborates with the medical director with regard to training, protocols, scheduling, data collection, quality management, and marketing. The medical director and transport coordinator should participate in patient transport, whenever possible, to maintain skills and perspective. A command physician should oversee every transport and provide advice to the referring physician and transport team as necessary.

The command physician must be experienced in handling transport calls and offering management suggestions for the period before arrival of the transport team. He or she should be knowledgeable about the availability of resources and have the authority to accept transferred patients without further consultation, to perform triage, and to activate backup systems when necessary. Medical control is usually accomplished in one of two ways: online or offline.[46] Online medical control is direct real-time voice communication (radio, telephone, cellular telephone, or satellite phone) between the medical control physician and the transport team. The transport team must always know who the command physician is throughout the transport process. Responsibility for medical control varies based on local practices and the policies of the transport service. Medical control physicians must be experienced in critical care transports to ensure that the crews provide appropriate care. For specialized transports, the transport service

should have a mechanism in place for medical control physicians to have timely consultation with subspecialists or the receiving physician. Alternatively, the critical care transport team should have the ability to consult with the receiving physician and to provide updates to the receiving facility. Offline medical control consists of written protocols or standing orders for patient management by the transport team. There is no direct communication between the team and the medical control physician. The medical director is responsible for developing and renewing transport protocols and procedures used for offline medical control.

Team composition and training strategies vary considerably among transport programs. The choice of personnel usually depends on the availability of professionals in the sponsoring facility, the anticipated patient population, financial support for the program, and other practical considerations. Selection of team members is critical to the success of a transport program. Members should be selected based on their experience and competence in the care of children in the inpatient setting. Techniques for training personnel depend on the team members' anticipated role in the care of transported patients, their experience providing care for neonates and older children, and their familiarity with the transport environment.

Although the specific requirements of training depend on the professional background of the team members, their experience, and their roles in inpatient care, the goals and general content of training are the same for nurse, respiratory therapist, physician, and paramedic. Transport crew members should be experienced in the care of critically ill patients and be able to deal with complex environments and limited resources. They must be highly skilled in airway management, resuscitation, and vascular access. They should have a fundamental knowledge of field priorities and be able to make decisions independently. All team members should have specific training in transport medicine, which includes methods of functioning in a moving environment, aeromedical physiology, and troubleshooting for equipment-related problems.

The team transporting a critically ill pediatric patient should include a team leader who is experienced in diagnosing and managing life-threatening illnesses or injuries in neonates and children. This caregiver must (1) understand pathophysiology and the usual clinical course and complications of common pediatric illnesses, (2) understand how to use appropriate laboratory and radiographic tests as diagnostic aids, and (3) have experience in managing neonates and children who require intensive pharmacologic intervention. The team should be capable of performing all standard emergency procedures required in the care of critically ill neonates and children. A very high level of expertise in performing these procedures is necessary, because they often are performed under adverse conditions.

The team leader role is commonly filled by either an experienced nurse or physician. Many dedicated pediatric transport teams include a physician, although little objective evidence indicates this configuration results in improved outcome compared with nonphysician teams. Physician attendance is particularly controversial when the role is filled by physicians-in-training, since all but the most advanced trainees lack the knowledge and experience needed in the transport environment.

A transport program should define the cognitive knowledge and technical skills required for each professional group and should include a method to document the acquisition of these skills. Procedure performance proficiency should be approved by the base facility and, where appropriate, by state regulatory agencies that govern the activities of each professional group. Instruction typically includes didactic sessions designed to assist personnel to acquire cognitive knowledge, a skill development and maintenance program, and a supervised orientation period. Simulation has been shown to improve adherence to protocols in the training of crisis-response teams and may be a useful adjunct to team member training.[47] The supervised orientation period should end only when the training program director and the trainee are confident in the trainee's abilities. A continuing education program must follow and include transport case conferences and review and ongoing competency-based training.

Equipment

Equipment taken on transport should be complete and adequate to provide continuing intensive care throughout the trip. Oxygen reserve should be calculated for each patient transported and should be at least twice the amount needed for the expected duration of the trip, in case of delays or equipment malfunction. Portable, compartmentalized equipment packs must be designed for easy access and must be able to withstand the stress of the transport environment. For air medical transport, weight and space restrictions must be considered when selecting equipment and range of medications. Transport monitors should have battery power that will last beyond the expected duration of transport, because of the possibility of unexpected delays or vehicle breakdowns, and should be free of movement artifact. Most important, the transport team should be self-sufficient and not dependent on the referring hospital for supplies. All equipment should be routinely checked and maintained after transport by a team member dedicated to that task.

Safety

Safety should be a high priority in any transport program. Emergency vehicle operation carries substantial risks, not only to the crew and the patient but also to others in its vicinity. The medical director is responsible for thoroughly researching vendors of air or ground transport services in the areas of maintenance, safety records, experience of drivers and pilots, and reliability of equipment. Written contracts between the institution and the vendor should include specific insurance details. Ambulance drivers should be discouraged from exceeding the speed limit because no evidence indicates that use of lights and sirens has any positive effect on patient outcome.

Aeromedical transport involves a unique set of safety issues. The four leading causes of accidents are weather, engine failure, collision with an obstacle, and loss of control. Pressure on pilots to fly, competition among aeromedical services within a region, and failure to observe minimal weather standards are among the components contributing to these accidents. In order for pilots to make sound decisions based on the flight conditions, they must be isolated from patient care issues. In regions with competing aeromedical services, the services should act jointly to establish regional safety guidelines, minimum weather standards, and a quality assurance program that examines compliance.

Transport team members must have a good understanding of aviation medicine and of how the aeromedical environment

affects both them and the patient. Barometric pressure changes that occur with increasing cabin altitude lower alveolar oxygen tension and increase the volume of any entrapped gas (e.g., in the bowel, sinuses, pneumothorax, and endotracheal tube cuffs)[48] and may affect intravenous infusion rates. The results of poor eating habits (hypoglycemia), sleep deprivation, and drugs (e.g., alcohol, marijuana, antihistamines) are potentiated by increasing altitude. Vibration can produce fatigue, and accelerating and decelerating forces can produce vertigo. Night vision is decreased at cabin altitudes above 5000 feet. The transport team should be adept at survival techniques for their region and should always be prepared to deal with an off-airport landing. Regular sessions to review safety and emergency procedures for each transport mode should be provided for the transport team members.

Referring Hospital Responsibilities

Transfer of patients from one institution to another is regulated by federal statute. The legislation that created the patient stabilization and transfer requirements for hospitals and physicians was the Consolidated Omnibus Budget Reconciliation Act (COBRA) of 1986, also known as the "antidumping law," and its amendment, the Omnibus Reconciliation Act of 1989.[49,50] This is the current legal standard. One of the main objectives of this resolution was to guarantee equal access to emergency treatment to all citizens regardless of their ability to pay. COBRA attributes responsibility for the patient's transfer to the referring hospital and physician. Violations can result in a number of penalties, including termination of Medicare privileges for the physician and hospital. A hospital can be fined between $25,000 and $50,000 per violation, and a physician can be fined $50,000 per violation. A patient can sue the hospital for personal injury in civil court. The Emergency Medical Treatment and Labor Act (EMTALA) established by the COBRA legislation governs how patients can be transferred from one hospital to another. Hospitals cannot transfer patients unless the transfer is "appropriate," the patient consents to transfer after being informed of the risks of transfer, and the referring physician certifies that the medical benefits expected from the transfer outweigh the risks. Appropriate transfers must meet the following criteria: 1) the transferring hospital must provide care and stabilization within its ability; 2) copies of medical records and imaging studies must accompany the patient; 3) the receiving facility must have available space and qualified personnel and agree to accept the transfer; and 4) the interfacility transport must be made by qualified personnel with the necessary equipment.

Emergent interfacility transport should occur after initial stabilization and determination by the referring facility that the patient's needs for definite care are beyond the scope of local capabilities. Transfer of the critically ill patient occurs with the expectation that appropriate care will continue en route to the receiving facility and that complications will be identified and treated. These goals frequently require specialized personnel and equipment. Coordination between referring and receiving institutions and medical direction during transport are fundamental to guarantee continuation of care and optimal utilization of resources. Interfacility transport can be performed by a transport team from the referring facility, by the receiving facility, or by a third party. It is the responsibility of the referring physician in consultation with the receiving physician to decide the best mode of transportation (air vs. ground) and to ensure that the transporting personnel have the necessary expertise and equipment to deal with the patient's condition and possible complications.

Complete copies of all patient care records must be sent. This documentation includes results of all therapeutic and diagnostic interventions, copies of all imaging studies performed, and patient consent for transfer. Teleradiology has a role in allowing receiving centers to review a patient's studies prior to arrival. It is essential that the transport team establish direct communication with both referring and accepting physicians. Communication with the referring physician must detail the following information: 1) identification of the patient and medical history; 2) interventions performed during initial stabilization and patient's response; 3) pertinent physical examination findings; 4) ongoing therapy; and 5) potential complications that may occur during transport.

Summary

The limited pediatric training and exposure of EMS personnel, coupled with the differences in size, anatomy, physiology, and psychosocial aspects unique to children, will continually challenge the EMS provider. The approach that prioritizes rapidity of transport over stabilization and initiation of care, a pattern that is commonly accepted for adult patients, will not result in the best outcomes for most children. Children transported by nonspecialized teams are at higher risk of transport-related adverse events and mortality.

As the evidence mounts that earlier initiation of aggressive therapy for shock improves outcomes, we must realize that the need for pediatric-specific intensive care begins long before the patient arrives in the tertiary care center. The primary goals in the vast majority of pediatric transports should be anticipatory management of respiratory insufficiency and early and attentive application of the principles of goal-directed shock resuscitation. Most pediatric patients with septic shock survive their acute illnesses, and emergency providers rarely witness development of organ dysfunction from seeds sown in the first few hours of the shock state. The unique perspective of the pediatric intensivist is valuable and could help to change practice in the referring community. The goal of the pediatric intensivist should be to extend his or her sphere of influence in order to make this happen.

Chapter 15

Pediatric Vascular Access and Centeses

Stephen M. Schexnayder, Elizabeth A. Storm, Michael H. Stroud, Michele M. Moss, Ashley S. Ross, Richard T. Fiser, Muayyad Tailounie, and Xiomara Garcia-Casal

PEARLS

- Intraosseous infusion is a convenient means of emergency vascular access with new mechanical devices available. Vigilant observation of the needle insertion site is necessary to recognize extravasation and prevent serious complications.
- Pericardiocentesis may be required for both diagnostic and therapeutic purposes. Ultrasound imaging improves success and reduces complications, and should be performed in all cases except with life-threatening tamponade.
- Umbilical arterial and venous access may be useful in neonates up to 2 weeks of age.

Intraosseous Infusion

Venous access in critically ill infants and children can be one of the most challenging aspects of their care. Peripheral veins in infants can be quite difficult to cannulate, particularly in the event of shock with shunting of blood away from the periphery and collapse of small veins. Because of these challenges, intraosseous (IO) infusion has become widely accepted as a quick, reliable means to establish short-term emergency venous access.

IO infusion was first described in 1922 and became widely used in the 1930s and 1940s.[1] With the development of disposable needles and catheters, use of IO infusion fell out of favor. It was not commonly used again until the mid-1980s, when a series of publications demonstrated the utility of the technique for rapid venous access in critically ill children.[2,3]

The marrow space provides a noncollapsible access point to the vascular system. Marrow sinusoids drain into medullary venous channels that empty into the systemic circulatory system. Because of the noncollapsible nature of the marrow space and the direct connection to the venous circulation, fluids and medications infused into the marrow space are distributed rapidly through the venous circulation.

Indications

IO infusion is indicated in situations requiring the rapid acquisition of intravenous (IV) access in which the establishment of conventional peripheral access is difficult or impossible. The situations in which it is most often used include cardiopulmonary arrest, shock, burns, and status epilepticus. In these situations, one or two attempts at standard peripheral access are usually made prior to placing an IO needle. In cardiopulmonary arrest, one should immediately gain vascular access via the IO procedure. In addition to its use in the hospital, IO access has been successful in the prehospital setting as well as in critical care transport.[4,5]

The success rate with the technique is high, greater than 95% with experienced practitioners.[6] Equal success using the new mechanical intraosseous devices has also been demonstrated.[7] Most fluids and medications that can be given through a conventional IV line can be given via an IO infusion with comparable results. In the event of cardiac arrest or severe shock, IO access is at least as effective as peripheral venous access in providing fluids and medications to the central circulation. Studies have shown that commonly used resuscitation, antiepileptic, and antibiotic drugs all can be given effectively through an IO line. Three antibiotics produce subtherapeutic levels when given via an intraosseus line at standard IV doses: chloramphenicol, vancomycin, and tobramycin.[8]

In addition to the administration of fluids and medications, IO access can be used for certain clinical laboratory studies. No significant differences were found when comparing electrolytes, chemistries, pH, PCO_2, or hemoglobin from IO marrow specimen with either arterial or venous blood samples.[9] A marrow specimen can be cultured in lieu of a blood culture.[10] Finally, the marrow can be used for blood type and crossmatching.

Contraindications

IO infusion has few absolute contraindications. A fractured or previously punctured bone should not be used because infused fluid will extravasate and possibly cause compartment syndrome. Alternate sites in other bones can be used in such situations. Bone diseases such as osteogenesis imperfecta and osteopetrosis have been suggested as contraindications to intraosseous infusion,[11] but a case of successful IO access in a patient with osteogenesis imperfecta has been reported.[6] Placing the needle into an area of cellulitis or burn could cause osteomyelitis or other infectious complications and is a relative contraindication although if limited sites are available, placing the IO needle through burned skin is acceptable.

Supplies and Equipment

Access to the bone marrow space is accomplished with one of several different types of needles. Conventional bone marrow needles (e.g., Jamshidi needle, CareFusion, San Diego, Calif.) work well. Needles made specifically for IO infusion use are available, including a straight needle or a needle with a threaded screw device (e.g., Sur-Fast, Cook Medical, Bloomington, Ind.). Usually a 15- or 18-gauge needle is chosen. The smaller 18-gauge should be used in infants. Studies have shown no significant differences in time required to insert the needle, success rate, or extravasation rates between standard and threaded IO needles.[12,13] If bone marrow or IO needles are not available, standard lumbar puncture needles can be used,[6,14] although they are prone to bend. In neonates, even a 19- or 21-gauge butterfly needle can be used.[14] Needles with a stylet are preferred to prevent clogging of the needle by bone.

Two new mechanical devices appropriate for the pediatric population have been introduced: the Bone Injection Gun (B.I.G., Waismed Ltd., Herzliya, Israel) and the EZ-IO (Vidacare Corporation, San Antonio, Tex; see Figures 15-1 and 15-2). The B.I.G. is a spring-loaded device, while the EZ-IO is a small battery-powered drill; both of these penetrate the bone marrow more quickly as compared to the manual method.

Other equipment required for IO placement includes a towel or sandbag, syringes with saline or heparinized saline flush solution, IV fluid and tubing, a T-connector or stopcock, and antiseptic prep solution (iodine). Optional supplies include a pressure bag and materials for local anesthesia (syringe with 25-gauge needle and 1% lidocaine).

Technique

The IO needle can be placed into the bone marrow at one of several sites, including the proximal tibia, distal femur, distal tibia, iliac crest, and sternum. The proximal tibia is the site most commonly chosen. The sternum has been used in adults but should be avoided in children because of the possibility of perforating the smaller chest cavity.[15] In addition, placing the needle in the sternum can interfere with airway and circulatory resuscitative efforts. When the needle is placed in the proximal tibia, the insertion site is located by palpation on the flat anterior tibial surface 1 to 3 cm (two fingers breadth) distal to the tibial tuberosity (Figure 15-3). This site is chosen to avoid the proximal growth plate. The midshaft should not be used because of increased risk for fracture. Placing a towel or sandbag under the child's leg helps stabilize the leg and makes insertion easier. The skin overlying the area should be prepped with antiseptic solution. Because IO lines are usually placed in obtunded patients, local anesthetic is not always necessary. Local anesthesia by infiltration with 1% lidocaine can be performed if the patient is awake. If a needle with a plastic sheath is being used, adjust the sheath so that an adequate length of needle protrudes beyond the sheath. Some authors have suggested inserting the needle at a 60- to 75-degree angle away from the tibial growth plate, but others recommend using a perpendicular or 90-degree angle. The perpendicular angle helps prevent the needle from sliding along the bone. The needle is advanced using firm pressure and a twisting or rotary motion until a "give" or loss of resistance is felt, indicating entry into the marrow space. The force needed to penetrate the bony cortex is considerable; the twisting motion helps significantly in needle insertion. One disadvantage of using a threaded needle is that the "give" or loss of resistance that occurs when the needle enters the marrow space may not be felt; however, the needle may be more secure in the bone once the needle is placed.[25] The stylet is removed and a syringe is attached to the needle to attempt to aspirate marrow. Correct placement of the needle should be confirmed to avoid extravasation. Aspiration of bloody fluid into the syringe confirms that the needle is correctly placed.

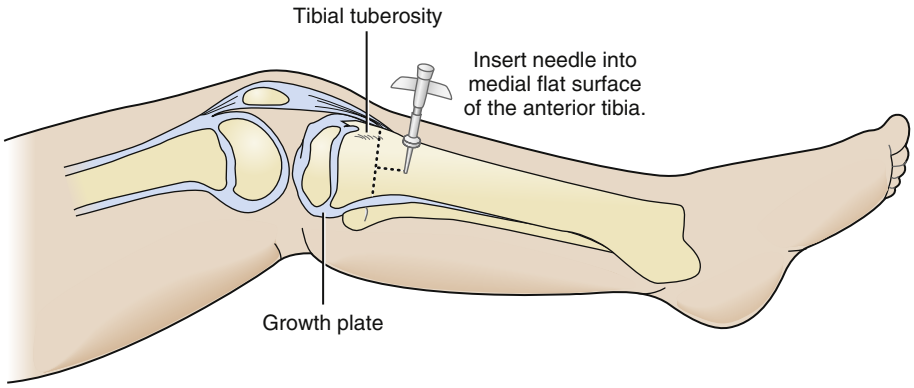

Figure 15–3. Insertion of the intraosseous needle into the anterior tibia.

Additional evidence of correct needle placement includes the observation that the needle stands upright in the bone without support and lack of resistance when flush solution is infused into the needle with the syringe. Sometimes, marrow cannot be aspirated even if the needle is correctly placed. If the "give" is felt on insertion and the needle stands alone in the bone but marrow cannot be aspirated, infusion of a small amount of fluid with the syringe can be attempted. Fluid should infuse easily with little pressure and without noticeable swelling of the soft tissues or extravasation of fluid.

In small studies, placement of IO needles with the new mechanical devices have success rates equal to or higher than traditional manual methods, with the added benefit of easy use and less risk to the user.[7] However, the high cost of this equipment may be a major limitation for use. In children, prehospital providers preferred the IO drill over the spring-loaded injection gun.[16,17]

When using the spring-loaded injection gun, after choosing the desired needle depth of penetration by dialing to the patient's age, the B.I.G. is positioned over the desired site with one hand while the other squeezes and pulls out the safety latch. The free hand is then used to activate the device at a 90-degree angle to the surface. The device is removed by pulling upward with a slight side movement to clear the needle. The stylet trocar is pulled out, then the safety latch should be slid over the needle and the apparatus taped as necessary for stabilization.

When using the IO drill, first ensure that driver and needle set are securely seated. After removing and discarding the needle set safety cap from the IO needle, position the driver at the insertion site with the needle set at a 90-degree angle to the bone and gently power or press the needle set until the needle set tip touches bone. Ensure that at least 5 mm of the catheter is visible. The bone cortex is penetrated by squeezing the driver's trigger and applying gentle, steady downward pressure. The trigger should be released when a sudden "give" or "pop" is felt upon entry into the medullary space and a desired depth is obtained. If excessive force is used, the driver may stall and not penetrate the bone. Gentle pressure and the catheter tip rotation will provide the necessary penetrating action. After placement, remove the power driver and stylet and confirm catheter stability. A primed extension set is then attached to the catheter hub's Luer lock and the apparatus is flushed. The manufacturer does not recommend attaching a syringe directly to the IO needle hub, to reduce the risk of needle dislocation.

The possible insertion sites are the same whether using the manual or mechanical needles. When the needle is placed in the distal femur, it should be placed approximately 2 to 3 cm proximal to the patella in the midline. In the distal tibia, the needle is placed 1 cm proximal to the medial malleolus in the midline, posterior to the saphenous vein. The proximal tibia is usually selected in children younger than 4 years, but the distal tibia has been recommended in older children in whom the proximal tibial cortex is thicker. The proximal humerus may be used for adolescents.

Maintenance

Once correct placement of the needle is confirmed, fluids and medication can be administered with a syringe via a stopcock or T-connector, or a standard IV infusion set can be connected to the needle. The needle is secured using gauze pads and tape. Some have suggested taping a clear plastic cup over the needle to help prevent dislodgment.[6] The site should be observed carefully visually and by palpation for signs of extravasation, both immediately after placement and frequently (every 5 to 10 minutes) during use. If evidence of extravasation is seen, the needle should be removed to avoid compartment syndrome. If needle placement is attempted at one site and the cortex is penetrated but the line cannot be used because of extravasation, another bone must be chosen for subsequent attempts.

IO access is intended only for short-term use in emergency resuscitative situations; long-term use increases the risk of extravasation, compartment syndrome, and infection.[38,43] Therefore, once IO access is secured, efforts should be directed toward obtaining conventional IV access. Once alternate access is obtained, the IO needle should be removed, manual pressure applied for 5 minutes, and a dressing applied to the site.

Complications

Significant complications of IO infusion are rare. The most common complication is extravasation of fluid. The causes of extravasation include incomplete penetration of the bony cortex, movement of the needle such that the hole is larger than the needle, dislodgment of the needle, penetration of the posterior cortex, and leakage of fluid through another hole in the bone, such as a previous IO site or fracture. Extravasation of a small

amount of fluid is usually not problematic, but compartment syndrome may result after extravasation.[18] One report documented a compartment syndrome after infusion of only 35 mL of fluid via the IO line.[19] Use of the IO line for prolonged periods and use of the IO line with pressure infusion appear to be risk factors for compartment syndrome. Compartment syndrome associated with IO infusion can result in the need for fasciotomy and amputation. Careful frequent observation of the IO site is necessary to detect extravasation and to prevent compartment syndrome. If extravasation occurs, the needle should be removed and the extremity observed for signs of compartment syndrome. Initial experience suggests the complications of the new mechanical devices are similar to the traditional IO needle.

Other rare complications include infection and bone fracture. Osteomyelitis, cellulitis, and sepsis have been reported in conjunction with IO infusion.[20] Risk for infection is increased when IO access is used in a bacteremic patient and when the line is used for a prolonged period. The risk of osteomyelitis is low. Although IO access is usually obtained in emergency situations, precautions to prevent infection should be taken, including use of sterile gloves and equipment and preparation of the skin with antiseptic solution (iodine or alcohol). Fracture of the bone has been reported.[21] One report of fracture associated with IO infusion is the case of a 3-month-old in whom a 15-gauge needle was used; a smaller needle size (18-gauge) should be used in small infants.

There are some theoretical complications that are probably not significant in clinical practice. Fat embolism occurs with infusion into the bone marrow space. An animal study found fat emboli in the lung with IO infusion, but no changes were seen in oxygen saturation or intrapulmonary shunt.[35] There are no reports of clinical fat embolization associated with IO infusion in humans in the English literature. However, intravascular air was discovered on postmortem studies in two patients.[22] Because of the risk of fat embolization, children with a right-to-left shunt may be at increased risk for cerebral emboli with IO infusion.[6]

The physical effects of infusion on the growing bone seem to be self-limited. Both animal studies and human follow-up studies of the bone and bone marrow show only short-term, minor changes and no long-term changes in bone structure, growth, or bone marrow.[23,24]

Summary

IO infusion is a valuable means of obtaining temporary, emergency vascular access in the critically ill infant or child. It has a high success rate and is associated with rare complications. Complications can usually be prevented by using appropriate technique and vigilantly monitoring the site for extravasation.

Arterial Catheter Placement

Frequent access to arterial blood is essential for complete and thorough assessment of acid-base status, oxygenation, and ventilation in the critically ill patient. Because of the dynamic, often rapidly evolving nature of critical illness in children, including the potential for rapidly changing hemodynamic status, continuous measurement of blood pressure can be invaluable in planning timely interventions aimed at improving systemic oxygen delivery. For these reasons, use of indwelling arterial catheters became routine in the 1970s, and now arterial catheters are an indispensable tool in the care of critically ill children. Placement of an arterial catheter allows continuous measurement of systolic, diastolic, and mean blood pressure, and provides a visible pressure waveform that may contribute additional diagnostic information. An arterial catheter also provides direct access to arterial blood for frequent, painless sampling. Hence the ability to place an arterial catheter is a fundamental skill in pediatric critical care medicine.

Indications

Indications for an arterial catheter include the following:

1. Need for frequent measurement of blood pressure to assess the patient's hemodynamic status and to allow for timely assessment of interventions aimed at improving hemodynamic status, such as fluid administration and titration of vasoactive infusions. Consider placement of an arterial catheter in any patient supported with vasoactive infusions.
2. Need for frequent sampling of arterial blood for laboratory analysis. Access to arterial blood through an indwelling catheter increases the ease of painlessly obtaining blood samples for analysis. Obtaining arterial samples through a catheter also eliminates skewing of results by physiologic changes related to the stress of arterial puncture or venipuncture, such as increased respirations with crying or localized poor perfusion or tourniquet use. Most notably, an indwelling arterial catheter allows for frequent assessment of arterial blood gas measurements, thereby providing the most accurate information on a patient's acid-base status, as well as measurement of Pa_{O_2}. Other laboratory tests may be obtained from an arterial catheter as well, thereby conserving peripheral veins.
3. Need for continuous monitoring of cerebral perfusion pressure (CPP) in patients with traumatic brain injury or other causes of increased intracranial pressure (ICP). Cerebral perfusion pressure is equal to mean arterial pressure minus intracranial pressure.
4. Need for arterial access to facilitate therapeutic procedures, such as exchange transfusions and continuous arteriovenous hemodiafiltration.

Contraindications

Very few absolute contraindications for placement of an arterial catheter exist. The skin at the site of arterial access must be intact prior to insertion of a catheter. Any evidence of infection of the skin or underlying structures is a contraindication to catheter placement at this site. Other disruptions in skin integrity, such as burns, are a relative contraindication. Severe coagulopathy and systemic anticoagulation increase the risk of hemorrhage from unsuccessful arterial punctures associated with attempted arterial catheter placement, as well as the risks of bleeding at the site of arterial catheter insertion. These risks must be weighed against the potential benefits of improved monitoring when deciding to place an arterial catheter in a coagulopathic or anticoagulated patient.

A catheter should not be placed in an extremity with compromised perfusion. Evidence of adequate collateral

Box 15–1 Supplies and Equipment for Arterial Catheterization

1. Appropriate size catheter (24 gauge for infants, 22 gauge for toddlers and older)
2. Sterile gloves
3. 10% povidone-iodine or chlorhexidine solution
4. Sterile towels
5. Syringe with 1% lidocaine and 25-gauge needle for local infiltration
6. Topical anesthetic cream
7. Luer-Lok connector with heparinized flush
8. 3-0 silk suture
9. Instrument tray with needle holder and scissors
10. Cloth tape
11. Plastic, nonocclusive dressing
12. Connecting tubing
13. Transducer
14. Fluids containing heparin (1 U/mL) and papaverine

circulation is desirable prior to placement of an arterial catheter. The traditional means of assessing collateral circulation to the hand is the Allen test. The radial and ulnar arteries are compressed until the distal extremity is blanched. Pressure over one artery then is released. Capillary refill should return to the distal extremity in less than 5 seconds. The test then is repeated by unblocking the other contributing artery after the distal extremity becomes blanched. Some practitioners question the utility of the Allen test because a normal test result does not guarantee adequate collateral circulation, nor does an abnormal test necessarily indicate possible complications.[25] The Allen test is considered less reliable for patients in shock. Additionally, an arterial catheter is often placed without assessing collateral circulation in emergent circumstances.

Procedure

Box 15-1 lists the supplies and equipment required for arterial catheterization.

Technique

The initial step in placing an arterial catheter is site selection. The radial, posterior tibial, and dorsalis pedis arteries are usually optimal sites, due both to the ease of access to these sites and to the typically good collateral circulation. Placement of the catheter in distal arteries of the extremities also allows for ease of site observation and hemorrhage control with direct pressure. Preductal placement in the right radial artery is preferred in infants with ductal-dependent heart lesions.

Catheters also can be placed in the axillary or femoral arteries if no peripheral sites are suitable. Insertion of a catheter into the axillary artery is technically more difficult than the other sites mentioned and is associated with a risk of brachial plexus injury due to hematoma compressing the neurovascular bundle.[26] Traditionally, many physicians have been reluctant to place arterial catheters for long-term use into the femoral artery, particularly in infants and young children, for fear of complications, most notably severe ischemia of the limb. A recent review of 745 femoral artery catheterizations in critically ill pediatric burn patients revealed a 1.1% rate of loss of distal pulse. In this retrospective study, limb ischemia was associated with younger age, smaller patient size, and increased severity of the burn injury. Patients who suffered limb ischemia were managed, for the most part, with immediate catheter removal and systemic heparinization. Three underwent thrombectomy. All patients in this series showed complete recovery of limb perfusion, except for one who required amputation of the fifth toe on the ipsilateral side.

Traditional teaching has held that the brachial arteries should not be used for arterial catheters because of the lack of collateral blood flow and risk of distal extremity ischemia. In a review of arterial catheter placements performed at a pediatric cardiac surgical center, the authors reported on the use of 386 brachial artery catheters in infants weighing 20 kg or less. None of these catheterizations were reportedly associated with permanent ischemic damage, and only three were associated with what was described as temporary loss of distal perfusion.[28] Despite these encouraging results, the complete lack of collateral circulation at the brachial artery requires careful consideration of risks and benefits before placement of a brachial artery catheter. Additionally, the superficial temporal arteries also should not be used because of poor collateral flow as well as the fact that retrograde flow from a catheter placed in this artery could result in showering of emboli into the cerebral circulation.

The selected site must be properly immobilized prior to placement of the indwelling catheter. If placing a radial artery catheter, the wrist is hyperextended 30 degrees to develop a straighter course and to bring the radial artery into a more superficial position. Typically, the radial pulse can best be palpated and catheter insertion should first be attempted in a position just proximal to the proximal crease, or usually about 1 to 2 cm from the wrist. Recently, the technique for placement of a radial arterial catheter has been expertly summarized in the "Videos in Clinical Medicine" series in the *New England Journal of Medicine*.[29] The following discussion of insertion technique can be applied to catheter placement at any of the sites discussed above. First, the site is prepared with a chlorhexidine solution and draped with sterile towels. Lidocaine (1% without epinephrine) is infiltrated locally. Alternatively, lidocaine/prilocaine (EMLA) cream can be used as a local anesthetic. Systemic narcotics and/or anxiolytics can be administered as well, although they should be used cautiously in a patient who is not being ventilated. Percutaneous placement of the catheter can be accomplished using one of several techniques. The first method uses a catheter over a needle, very similar to placement of a peripheral IV catheter. The needle is inserted through the skin at a 30-degree angle (bevel up or down). When a flashback of blood is obtained in the hub, the catheter is advanced another 1 to 2 mm. While holding the needle stable, the catheter is advanced over the needle into the lumen of the vessel. Blood should be flowing continuously into the catheter hub prior to attempting to advance the catheter. Once the catheter is inserted through the skin to the hub, a flushed Luer-Lok connector is attached to the hub while pressure is applied over the cannulated artery. Correct placement of the catheter is verified by aspirating arterial blood into a syringe attached to the connector. The catheter is then flushed and securely sutured or taped into position. A transparent dressing is placed over the catheter as a protective

barrier. Before the final dressing is placed, many centers use a chlorhexidine-impregnated patch at the site of catheter insertion to decrease catheter-associated bloodstream infections.[30]

Transfixation, the second percutaneous technique, involves inserting a catheter over a needle as described earlier. However, when a flashback of blood is seen in the hub, the needle and catheter are further advanced until the needle and catheter pierce the posterior wall of the artery and transfix this wall to the underlying structures. The needle is pulled out, leaving the catheter in place. The catheter is then slowly withdrawn until the tip is again intraluminal, with blood flowing back into the hub. The catheter is then advanced into the artery up to the hub. Catheter advancement can be facilitated by attaching a syringe filled with flush to a connecter and gently flushing as the catheter is advanced. The position of the catheter is confirmed, and the catheter secured as described earlier.

The final percutaneous method for catheter placement involves use of the Seldinger technique. A needle is used to pierce the anterior wall of the artery. When return of arterial blood is seen through the introducer needle, a guidewire is placed through the needle and advanced into the lumen of the artery. The needle is then removed, and a catheter is advanced over the guidewire into the lumen of the vessel. This method also can be used with a catheter over a needle. Confirmation of correct positioning and securing the catheter completes the procedure. A recent study in adults undergoing general anesthesia found no difference in the success rate or time to insertion when arterial catheters were placed using wire guides or without wire guides.[31] Placement using the Seldinger technique is the preferred method when placing a catheter into larger vessels such as the femoral artery. When placing a catheter into a central artery using Seldinger technique, a longer catheter (e.g., 2.5 to 3 Fr, 5 to 8 cm) should be used. Such catheters are available in commercially made kits.

Recently, interest has grown in ultrasound-assisted placement of arterial catheters. A study of adult patients requiring arterial catheter placement in an emergency department setting demonstrated decreased time to insertion and decreased number of attempts at catheter placement using ultrasound-guided technique compared to traditional pulse palpation technique.[32] A pilot study in pediatric patients undergoing surgery found that ultrasound-guided placement of radial arterial catheters had a higher success rate and required fewer attempts compared to traditional techniques.[33] However, a larger pediatric study that randomized patients receiving radial arterial catheters to placement via ultrasound-guided versus traditional techniques by pediatric subspecialty trainees or anesthesiologists found no difference in success rate at the first cannulation site, total number of attempts, or time to successful cannulation.[34]

If attempts at percutaneous cannulation of an artery are unsuccessful, a cutdown approach is an alternative means of obtaining arterial access. A superficial incision is made perpendicular to the artery through the skin. The subcutaneous tissues are bluntly dissected parallel to the vessel using hemostats. When the artery is identified, the posterior wall is gently dissected away from the adjacent structures. Two loops are placed around the vessel: one proximal and one distal. These loops are used to elevate the artery during the cannulation process; they should never be used to tie off the vessel. After dissection is completed and the loops are in place, the artery is cannulated under direct visualization using the needle over the catheter method. The catheter is secured with a suture through the skin, and the wound is closed with interrupted stitches. If excessive bleeding persists, the proximal loop can have gentle traction applied in an attempt to control the hemorrhage.

Maintenance of an Arterial Catheter

To prolong patency of an arterial catheter, heparinized fluid is most commonly infused through the catheter. A common practice is to infuse 0.9% sodium chloride containing heparin 1 U/mL at 3 mL/hr, although slower infusion rates may occasionally be used in small infants with a need for fluid restriction. Studies of perioperative arterial catheters in adults have found no difference in the rate of catheter patency using heparinized or nonheparinized solutions,[35] but this does not take into account the smaller vessel size in children or the need for more prolonged catheter patency common to the care of the critically ill child. A meta-analysis of randomized controlled trials of heparin use to maintain either peripheral venous catheter or peripheral arterial catheter patency demonstrated a positive effect of heparinized fluid on duration of arterial catheter patency and the risk of clot formation.[36] Comparison of normal saline to 5% dextrose in water, both with heparin, revealed that infusion of saline resulted in longer catheter life.[37] Papaverine is a smooth-muscle relaxant that can decrease vasospasm when used in arterial catheter maintenance fluids. A randomized, controlled trial of the addition of papaverine (60 mg/500 mL) to routine arterial catheter fluids demonstrated a significantly lower rate of catheter failure and longer catheter life in the papaverine group.[38] This study evaluated patients from 3 weeks to 18 years of age and recommended avoiding the use of papaverine in neonates due to a perceived increased risk of intraventricular hemorrhage (IVH). More recently, the use of papaverine-containing arterial catheter fluid in neonates from 25 to 36 weeks' gestational age was shown to prolong catheter life without an increased risk of IVH.[39] Despite these results, many institutions routinely avoid the use of papaverine in arterial catheter fluids in preterm neonates and in patients with traumatic brain injury or other preexisting intracranial hemorrhage for fear of causing or worsening an IVH.

The arterial catheter should always be visible so that any bleeding around the catheter site or caused by inadvertent disconnection of the tubing from the catheter, which can quickly result in significant hemorrhage, can be immediately observed. Securing the catheter with suture and using a Luer-Lok connector to connect the catheter to the tubing help to decrease the possibility of accidental detachment. The site of catheter insertion should be closely monitored for any signs of infection or compromised perfusion. Mottling of the skin proximal and/or distal to the catheter may be indicative of intraarterial thrombus formation, and discoloration of fingers or toes distal to a catheter may result from emboli. The catheter must be removed if any of these complications are observed.

For accurate direct measurement of blood pressure with an arterial catheter, one important consideration is the positioning of the transducer in relation to the catheter and the patient's position. Standard practice for hemodynamic monitoring involves having the transducer zeroed to atmospheric pressure for accurate pressure measurement. The transducer is often maintained as close as possible to the level of the right

atrium for accurate blood pressure measurements, particularly when the patient is in the supine position.[40] Studies in animal models have demonstrated that positioning the transducer level with the aortic root results in accurate measurement of mean arterial pressure regardless of patient position or catheter site, while placement of the transducer level with the catheter tip resulted in significant error in mean arterial pressure measurement when the patient was in positions such as reverse Trendelenburg.[41] It is common practice at present to change the fluids and tubing every 72 hours. A study that investigated increasing the interval for changing arterial catheter fluids and tubing from 48 to 72 hours showed no increased risk for catheter-associated infection.[42] The overlying dressing also is changed on a scheduled basis.

Inability to draw blood from a catheter or flattening of the waveform on the monitor is suggestive of either a kinked catheter or thrombus formation at the end of the catheter. If evidence of compromised perfusion distal to the catheter is present, the catheter should be removed. If no evidence of compromised perfusion is present, changing the catheter over a guidewire may be considered. However, strong consideration should be given to removing the existing catheter and placing a fresh arterial catheter in a new position, as changing a catheter over a guidewire has been associated with an increased risk of catheter-associated bloodstream infection (CABSI), at least in central venous catheters.[43]

Complications

Complications related to arterial catheters include hemorrhage, thrombus formation, emboli, distal ischemia, and infection. Permanent ischemic complications related to radial artery catheters in adult patients are a very rare event.[25] A recent study used ICD-9 codes to define arterial catheter complications in a large multi-institutional administrative database in an effort to examine the prevalence of and risk factors for arterial catheter complications in critically ill children.[44] This study found a complication of some sort in 10.3% of patients with arterial catheters, most often infection/inflammation, and found a rate of thrombotic or embolic complications of 7.5%. Complications were more common in younger children and tended to be associated with longer hospital courses. Arterial catheter complications were independently associated with cardiac surgery, bone marrow transplantation, and dialysis, probably reflecting an effect of the severity of illness. In addition to bleeding, infection, and distal limb ischemia, an uncommon but well-recognized complication of arterial catheter placement is growth arrest due to physeal injury from extravasation, aneurysm formation, or ischemia.[45] Such injury can occur to the femur, tibia, radius, or ulna.

Catheter-related infections can be local or the focus for systemic sepsis. The risk of catheter-related infection has previously been thought to be lower for arterial catheters than for central venous catheters. Recent studies, however, have found very comparable rates of catheter-related infection in critically ill patients having both types of catheters.[46] The risk of arterial catheter infection has been related to the duration of catheter use and to placement of a catheter in the femoral artery. [46-48] In one recent study of catheter-related infections in children, the presence of an arterial catheter was noted to be a risk factor for any type of catheter-related infection, but in this study the arterial catheter most likely represents a surrogate marker for greater severity of illness.[49] Regardless, however, the arterial catheter should be considered a possible source of sepsis, as is the central venous catheter, and strong consideration should be given to removing an arterial catheter when it is no longer absolutely necessary for optimal care.

Summary

Arterial catheters are a routine part of the monitoring of many critically ill children, and the ability to place an arterial catheter is a necessary skill for the pediatric intensivist. As with any procedure, the potential risks and benefits of arterial catheter placement should be carefully weighed prior to the procedure. Recent publications demonstrate that the rates of and risk factors for complications of arterial catheterization in critically ill children need further study.[44]

Pericardiocentesis

Pericardiocentesis is the aspiration of fluid or air from the pericardial space. The most compelling indication for the procedure is relief of cardiac tamponade, but it also can be performed to diagnose the cause of a pericardial effusion. Pericardiocentesis can be performed emergently without imaging guidance techniques; however, this should only be undertaken in dire circumstances because of the risk of the procedure and the higher failure rate when no guidance is used.

Indications

Drainage of a pericardial effusion of any cause is absolutely indicated when cardiac tamponade is present. Often drainage is recommended if the effusion is large, even in the absence of tamponade, for diagnosis and fluid removal.[50] For small effusions, pericardiocentesis may be indicated for diagnosis alone. In pediatric patients, pericardial effusions most commonly occur with postviral or idiopathic pericarditis, but they are also seen with postpericardiotomy syndrome, collagen vascular disease, oncologic disease, and, rarely, uremia. Purulent pericarditis resulting from *Staphylococcus aureus* or *Streptococcus pneumoniae* infection can be seen in cases of concomitant pneumonia with empyema. Although rare in developed countries, tuberculous pericarditis can occur. Drainage of purulent pericarditis is indicated for relief of tamponade, prevention of constrictive pericarditis, diagnosis, and drainage of infection. With purulent pericarditis, open drainage may be more effective because of the difficulty in draining thick pus.[51] If using a tube pericardiocentesis and drainage, instillation of a thrombolytic such as alteplase (recombinant tissue plasminogen factor) or urokinase may be considered with purulent effusions.[52] Traumatic pericardial effusions secondary to penetrating trauma often require surgical drainage of the blood, because tamponade is common. Pneumopericardium secondary to pulmonary air leaks in mechanically ventilated patients is usually well tolerated hemodynamically but may require drainage, especially in small infants, because of the development of tamponade.

Contraindications

When acute tamponade is present, pericardiocentesis is unequivocally indicated. However, when elective or diagnostic pericardiocentesis is to be performed, the presence

of a bleeding diathesis is considered a contraindication. The presence of aortic dissection is considered a major contraindication.[50] Lack of experience with the procedure is a relative contraindication for elective pericardiocentesis. Open drainage is preferred to closed drainage when the patient has traumatic tamponade and is in cardiac arrest.[53] When the effusion is loculated in a location not easily reached using the subxiphoid approach, needle pericardiocentesis is contraindicated because the risk of complications increases and the possibility of successful drainage becomes remote.

Procedure

Drainage of a pericardial effusion can be performed either by simple needle aspiration or by insertion of a drainage catheter. If the procedure is for diagnosis only and the effusion is small, then needle drainage is adequate. However, if tamponade is present, the effusion is sizable, or effusion likely will continue, insertion of a catheter for continuous drainage is indicated.

Equipment

1. **Needle for drainage.** The size of the needle ranges from 14 to 20 gauge, depending on the type of fluid and the size of the patient. For thicker fluids, such as pus or blood, a larger-bore needle is used. A steel needle, such as a vascular introducer needle or a spinal needle, can be used, but often an IV catheter is more effective because once the fluid is reached, the steel inner needle can be removed from the IV catheter, leaving the softer, needleless catheter in place while the fluid is aspirated. This process decreases the risk of cardiac puncture.
2. **Syringes, three-way stopcock, and short extension tubing** are assembled for aspiration. A 5- or 10-mL slip-tip syringe is used when accessing the pericardium for easier manipulation. A larger 20- to 30-mL syringe may be needed for fluid drainage, depending on the predicted volume. The stopcock and short tubing are useful when draining large amounts of fluid.
3. **Equipment for insertion** includes 2% chlorhexidine solution, sterile gloves and drapes, and 1% lidocaine for local anesthesia.
4. Appropriate **sterile sample tubes** should be available for collection of fluid for chemical, cellular, and microbiologic analysis.
5. **Cardiac monitor** is essential for determination of arrhythmias during the procedure.
6. **Catheter, dilator, and flexible J-wire** are necessary when the catheter will be left in place. Placement in the pericardial sac of a 5 to 8 Fr pigtail catheter with multiple side holes is recommended. The size of the catheter is determined by the size of the patient and the viscosity of the fluid. If the fluid is fibrinous in appearance by echocardiography, then a larger-bore catheter should be placed. Several pigtail catheters are manufactured specifically for fluid drainage, often available as kits that also contain an appropriate-size dilator and J-wire guide. If a kit is not available, then a venous dilator of appropriate size with a separate J-wire can be used. A J-wire is used to prevent another puncture of the pericardium or heart using a straight wire. Before the needle is inserted, the wire, dilator, and catheter must be checked to ensure their sizes are compatible.

Technique

Needle aspiration can be performed blindly in the event of a true emergency such as traumatic tamponade; however, the technique has higher complication and failure rates. Fluoroscopy has been useful but is cumbersome because it requires patient transport to a radiologic or catheterization suite in the absence of portable fluoroscopy.

Echocardiographic guidance is recommended for most pericardiocenteses because it can be done at the bedside and is logistically less complex. The most common technique uses transthoracic scanning, which can easily visualize the effusion. Echocardiographic scanning is indicated prior to needle drainage or catheter insertion for any reason except tamponade with cardiac arrest. Pericardial fluid can be identified by computed tomography or magnetic resonance imaging. Because these techniques are cumbersome and time consuming, they should not be used in acute tamponade because echocardiography is more readily available at the bedside and is usually fast in skilled hands. The echocardiogram can show the size of the effusion, its distribution around the heart including any loculations, the presence of fibrin or clots, and evidence of tamponade.[54] Tamponade can be diagnosed using two-dimensional imaging when the right atrium collapses during late diastole. Normally the right atrial free wall is concave throughout the cardiac cycle. With tamponade, the pericardial pressure exceeds the right atrial pressure at end-diastole and causes the right atrial free wall to collapse toward the center of the right atrium. The worse the tamponade, the longer into systole the collapse occurs.[55] Echocardiographic guidance in patients with tamponade has been shown in adults to have a 99% success rate in relieving the tamponade.[56] After the fluid has been echocardiographically evaluated, the patient is placed supine with the head elevated approximately 30 degrees. The subxiphoid approach is the safest and most common approach, although other approaches have been described. The approach is extrapleural and, in patients with normal anatomy, avoids major vessels such as the internal mammary, coronary, and pericardial arteries.[50] The subxiphoid and lower costal margin are prepared with 2% chlorhexidine. The area is draped in sterile fashion. Lidocaine local anesthesia is infiltrated at the junction of the xiphoid and the left costal margin. The needle is inserted at a 30- to 45-degree angle with the needle directed toward the left clavicle (Figure 15-4). The slip-tip syringe is attached and is aspirated continually while the needle is inserted (Figure 15-5). Needle advancement is halted when air or fluid is aspirated. If blood is obtained, analysis is necessary to determine whether the blood is of pericardial or intracardiac origin. Several techniques are helpful for this determination. The hematocrit of pericardial fluid will be lower than that of intracardiac blood, which will be equal to the patient's hematocrit. Dropping a few milliliters of the fluid on gauze sponges determines whether the fluid will clot. Fluid that does not clot is pericardial; fluid that does clot is most likely intracardiac blood.[57] Another technique involves injection of small amounts of saline microbubble contrast (saline in a syringe that has been agitated) through the introducer needle while imaging with echocardiography.[58] If contrast bubbles are seen in the heart, then the tip of the needle is intracardiac. If bubbles appear in the pericardial sac, then the needle is appropriately placed in the pericardium.

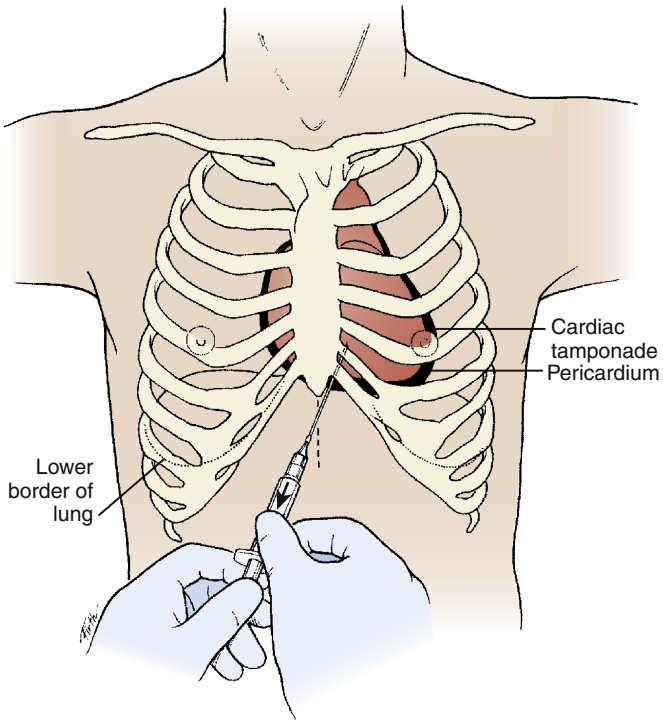

Figure 15–4. Insertion of needle for pericardiocentesis at the junction of the xiphoid and the left costal margin, aiming toward the left shoulder. *(From Brundage SI, Scott BG, Karmy-Jones R et al: Pericardiocentesis and pericardial window. In Shoemaker WC, Velmahos GC, Demetriades D, editors:* Procedures and monitoring for the critically ill, *Philadelphia, 2002, Saunders Elsevier.)*

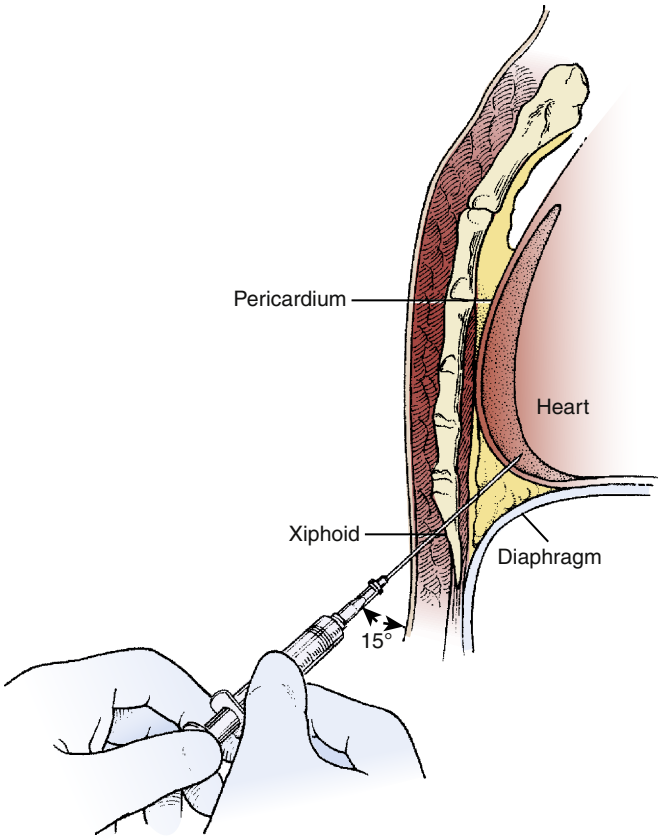

Figure 15–5. In pericardiocentesis, the needle is inserted slowly, under continuous aspiration, toward the heart at a 15-degree angle to the skin. *(From Brundage SI, Scott BG, Karmy-Jones R et al: Pericardiocentesis and pericardial window. In Shoemaker WC, Velmahos GC, Demetriades D, editors:* Procedures and monitoring for the critically ill, *Philadelphia, 2002, Saunders Elsevier.)*

During insertion the needle is guided using two-dimensional echocardiography. The echocardiographic probe is placed on the chest where the fluid is best seen. The needle tip is identified by ultrasound and followed as the needle is advanced.[59] Another technique involves mounting the needle on the echocardiographic probe, which has been placed in a sterile sleeve. The needle is advanced while the operator also handles the probe. This technique allows the use of locations other than the subxiphoid approach for insertion of the introducer needle, with the potential for better fluid visualization.[60]

Previously, the most common guidance technique used electrocardiography to guide the needle. Alligator clamps were placed on the steel insertion needle and connected to an electrocardiogram monitor. The ECG complexes were visualized while the needle was inserted. If an injury pattern was noted in the ST segment, then the heart presumably had been touched by the needle. The needle was pulled back into the pericardial sac, and the ECG trace would return to normal. Although this technique is simple to perform, echocardiographic guidance offers more specific information about needle position and fluid location, allowing for a safer and more successful procedure.

Once the needle is determined to be well-positioned in the pericardial sac, if a catheter is to be inserted, then the J-wire can be passed through the needle as with standard Seldinger technique. The needle is removed, and the dilator is passed over the wire to open the tissues outside the pericardium and enlarge the puncture in the pericardium. The dilator is removed, taking care to leave the J-wire in good position. The catheter is passed over the wire into the pericardial sac. Its position can be confirmed echocardiographically. The wire is removed. The connecting tubing and three-way stopcock are connected and the fluid is aspirated. The tubing can be connected to a drainage bag for removal of fluid that continues to accumulate. A sterile sample of the aspirated fluid should be sent to the laboratory for appropriate analysis. The catheter is secured with suture and covered with an occlusive dressing. A chest radiogram should be taken at the end of the procedure, and daily to confirm the catheter position.

Maintenance

The catheter is simple to maintain. The dressing should be changed according to the ICU protocol for central venous lines. The fluid in the drainage bag should be measured and the amount recorded on a regular schedule. If fluid is no longer draining, then a small amount (1 to 2 mL) of heparinized saline can be infused into the pericardium through the stopcock after preparation with antiseptic solution. This process can release any fibrinous material occluding the catheter. If no fluid is forthcoming, then echocardiography can be performed to determine if residual pericardial fluid remains. If more fluid is present, flush the catheter again in an attempt to open up the catheter. If the fluid had originally been purulent, then instillation of a fibrinolytic agent may allow better drainage. If no fluid remains, the catheter can be removed, depending on the patient's condition and the underlying cause of fluid development.

Complications

Cardiac puncture is not an uncommon complication of the procedure. If the ventricle is entered and the needle quickly withdrawn, then the injury is minor and of no clinical consequence. Coronary laceration occurs rarely, resulting in acute ischemia, and has been associated with death from the procedure.[61] The pleural space can be entered with the insertion needle or the catheter, resulting in a hemothorax or pneumothorax. Hemoperitoneum and pneumoperitoneum can occur. Injury to the diaphragm, intestines, and stomach have been reported. Infection of the indwelling catheter can occur, but is rare because the catheter usually is not in place for more than 3 to 4 days. Cardiac arrest and death have been reported during pericardiocentesis.[62, 63] In a retrospective study of pericardial drainage catheters in pediatric patients, Zahn et al.[64] noted only five complications in a total of 43 procedures. Four of the complications were considered minor and included myocardial perforation with no hemodynamic alteration, pneumopericardium, and ST-segment elevation. One critically ill neonate who had suffered a myocardial perforation during cardiac catheterization died. The results of the study indicated that pericardial catheter placement in pediatric patients is a relatively safe procedure. Most complications of pericardiocentesis with or without catheter placement can be prevented by careful guidance of the needle with echocardiography and greater experience of the practitioner.

Interpretation

Laboratory analysis of pericardial fluid includes cell count and differential, microbiologic evaluation, cytology, and blood chemistry workup, which may include protein, glucose, pH, lactate dehydrogenase (LDH) and triglycerides. Normally, pericardial fluid is clear and straw-colored. Cloudiness may indicate purulence resulting from infection, or chyle if the patient has undergone recent chest or cardiac surgery. Serosanguinous fluid can be seen with multiple diagnoses, including trauma, postpericardiotomy syndrome, collagen vascular disease, infection, and neoplastic disease.

The presence of white blood cells with a predominance of polymorphonuclear cells greater than 1000 per milliliter is indicative of bacterial infection. When the predominant cell type is lymphocytic, then tuberculous pericarditis should be suspected. In idiopathic or postviral pericarditis, the fluid contains fewer than 1000 cells per milliliter, and the cells are mostly monocytic or lymphocytic. Occasionally, the fluid is hemorrhagic with a preponderance of red blood cells. Neoplastic effusions may contain neoplastic cells, which may be missed on routine cell count but will be visible on cytologic examination. With purulent pericarditis, the protein level is high and the glucose level and pH are low. LDH is elevated with neoplastic effusions. With purulent effusions, the ratio of LDH in the fluid to LDH in the blood is increased to greater than 0.6. With chylous effusions, the fluid has an increased triglyceride level.

With acute nonpurulent pericarditis the fluid should be evaluated for viruses; Coxsackie viruses are the most common causes of viral pericarditis. Viral culture can be performed, although the yield is generally low. Polymerase chain reaction has been used successfully to diagnose viral and bacterial etiologies.[65] For purulent pericarditis, Gram stains and acid-fast bacilli stains should be performed, as should appropriate bacterial (both aerobic and anaerobic) and fungal cultures, as well as bacterial PCR analysis. If tuberculous pericarditis is suspected, adenosine deaminase (ADA) and PCR for mycobacteria are indicated.[50]

Summary

Pericardiocentesis, with or without catheter placement, is a straightforward procedure that is indicated for relief of cardiac tamponade and for diagnosis of certain pericardial effusions. It is a lifesaving technique for patients with tamponade. Used in conjunction with guidance techniques such as echocardiography or electrocardiography, pericardiocentesis can be performed safely in patients of all ages.

Umbilical Arterial Catheter and Umbilical Venous Catheter Placement

When a baby is born, regardless of the gestational age, the umbilical vessels are readily accessible for catheterization. However, catheterization of umbilical vessels should not be taken without due consideration. The decision to place umbilical catheters should be based on the patient's gestational age, the expected duration and severity of illness, and underlying disease processes. The risk and benefits should be weighed carefully against peripheral venous catheterization. Umbilical catheters can be an avenue to rapid venous and arterial access in neonates up to age 1 week, and in some up to 2 weeks.

Umbilical Artery Cannulation

Indications for umbilical artery cannulation (UAC) placement include the need for frequent monitoring of acid-base balance, continuous measurement of blood pressure, angiography, resuscitation, and exchange transfusions. Infusions of medications or fluids may be warranted when a UAC is present, but placement of a UAC is not indicated for infusions alone. UAC placement is contraindicated in patients with omphalitis, peritonitis, necrotizing enterocolitis, omphalocele, hypercoagulable states, or known ischemia of the perineum, or lower extremities.[66,67]

Supplies and Equipment

A bed with adequate lighting and a heat source are essential. Prepackaged UAC trays are commercially available and contain different sizes and types of catheters. Umbilical catheters should be radiopaque with rounded tips and single holes. A Luer-Lok system is available on some catheters and has some advantages; others need trimming and attachment of a blunt needle to connect them to a three-way stopcock. Babies weighing less than 1500 g need a 3.5 Fr catheter; infants weighing more than 1500 g require a 5 Fr catheter.[68] Other supplies needed include povidone-iodine or chlorhexidine solution; umbilical tie; sterile drapes; gloves; scalpel; scissors; iris forceps; pick-ups; gauze pads; 3-0 silk suture; 3-mL, 5-mL, or 10-mL syringes; tape; and heparin flush (1 unit heparin per milliliter of normal saline).[69]

Technique

Prior to UAC placement, gently restrain the baby and determine the catheter insertion distance. Restrain the infant in a supine position by using soft restraints of the arm and legs. Alternatively, restrain the baby by swaddling technique.

High or low placement of the catheter is based on the vertebral level at which the catheter resides in the aorta. Complications have been reported with both low and high UACs.[70-72] A low UAC should lie at or below the third lumbar vertebra (caudal to the origins of the renal arteries).[73] A high UAC should have its tip between the sixth and ninth thoracic vertebrae. A high UAC position is the preferred position and a low UAC should only be used if a high UAC is not attainable.[74] The calculation for insertion length can be determined using various methods, such as birth weight, shoulder-to-umbilicus length, and total body length.[75-77] A simple method for calculating insertion depth for high placement is as follows: for babies weighing more than 1500 g (3 × birth weight [in kg]) + 9 = centimeters of catheter to insert to the umbilical ring; for babies less than 1500 g, use the formula (4 × birth weight [in kg]) + 7 = centimeters of catheter to insert to the umbilical ring.[78,79]

Next, attach the UAC to a three-way stopcock, and also attach to the stopcock a 3- or 5-mL syringe filled with heparin flush. Fill the stopcock and UAC with heparin flush solution. Turn the stopcock off to the catheter prior to insertion. Prepare the cord with antiseptic solution and drape the baby, sparing the head and chest to allow for patient monitoring during the procedure. Place an umbilical tie snugly around the epithelialized portion of the umbilical cord using a one-looped tie. The umbilical tape should be able to apply pressure to the cord in the event of acute hemorrhage, but should not be so tight as to hamper introduction of the catheter. Use a scalpel to cut the cord horizontally approximately 1 to 2 cm above the umbilical ring. The larger thin-walled umbilical vein is typically in the 12 o'clock position (cephalad) and two small thick-walled umbilical arteries can be identified at the 5 and 7 o'clock positions. Grasp the cord securely with a hemostat (or forceps) near one of the umbilical arteries. Use the iris forceps to dilate an arterial lumen by first inserting the forceps in the closed position, finally allowing both prongs to spring open and dilate the lumen. Holding the catheter with the iris forceps, introduce the catheter into the dilated artery, taking care to ensure that the catheter is in the lumen of the vessel. Insert the catheter approximately 0.5 cm and pull the umbilical cord toward the infant's head before attempting to advance the catheter. Aspirate blood and flush the catheter once it has been advanced to the desired length. Ensure air bubbles are cleared prior to flushing the catheter. If the catheter meets resistance, apply gentle steady pressure for approximately 30 seconds to determine if the catheter will advance. Do not force the catheter. If the catheter will not advance or no blood return is seen, a false passage may have been created. A double-catheter technique can be attempted in this situation.[80] Leave the catheter that is meeting resistance in place and carefully advance a second catheter beside it to the appropriate distance. If the double-catheter technique fails, the second umbilical artery can be cannulated. Suture the catheter in place, using a pursestring stitch cinched tightly to provide hemostasis and wrapping both ends of the suture around the UAC before tying a square knot. Secure the line using a tape bridge or other available securing device. Finally, loosen the umbilical tie and keep it in place for any needed hemostasis. A transducer may be attached for continuous blood pressure monitoring while still allowing for blood sampling. Anteroposterior and lateral x-ray films of the abdomen are needed to confirm proper positioning of the catheter. A malpositioned catheter should be adjusted promptly. If it is too high, it should be pulled back; if it is too low or in a vessel other than the aorta, the catheter should be removed and replaced.[67] Never advance a UAC once the sterile field has been broken.

Maintenance

A continuous infusion is needed to keep the lumen of the catheter clear, and catheters should be flushed after blood draws to keep the catheters free of clot. An infusion containing heparin should be used containing 1 U heparin per milliliter at 0.5 mL/hr for a 3.5 Fr catheter or at 1 mL/hr in a 5 Fr catheter. As little as 0.25 U/mL of heparin can be used successfully without increased risk of catheter occlusion.[81] The composition of the heparin-containing fluid varies by institution and may be influenced by gestational age and electrolyte status. A typical solution includes 38 or 77 mEq/L sodium chloride or sodium acetate, or an isotonic amino acid solution with heparin 1 U/mL running as a continuous infusion.[82] Infants can be placed in the supine position or on their sides; prone positioning is usually not used. A dressing should not be applied to the umbilicus so that the catheter insertion site and cord can be easily inspected. The UAC should be removed when the original indication for placement no longer exists or continuous blood pressure monitoring and frequent blood gases are no longer needed. It is generally recommended, while using a UAC, to avoid or limit enteral feeds. To remove the UAC, withdraw it slowly in increments of 1 cm/min. This process should allow the artery to spasm and provide hemostasis. If bleeding occurs, apply pressure to the cord.[69,83] The sutures should be removed at the time of catheter removal.

Complications

A variety of complications are associated with UACs. Malpositioned catheters, vascular-related complications, infections, and hemorrhage are common categories of complications related to UACs. Intimal injury almost universally occurs to some degree with UAC placement. With malpositioned UACs, especially in the branches of the iliac artery, gross disfigurement can result.[71,84] Unusual complications related to vascular injury include acquired coarctation of the aorta and umbilical arterial rupture.[85,86] Blanching of the legs or buttocks secondary to vasospasm may occur in the ipsilateral leg to the UAC. If blanching does not improve, catheter removal is warranted to prevent severe ischemic complication. Thrombotic and embolic complications resulting from fibrin deposition on the catheter are not clinically significant in most patients, but thrombosis of the aorta or its major branches can be devastating.[71,87] Infectious complications are similar to those associated with other central vascular lines. Acute hemorrhage is an infrequent complication that can result in significant morbidity and mortality. Significant blood loss can occur with accidental withdrawal of the catheter or disconnection from the blunt needle. Close monitoring and proper securing of the catheter can prevent most of these problems. Hypertension secondary to UAC placement has been frequently reported.[88] Catheter-related sepsis occurs in neonates possessing UACs, with coagulase-negative *Staphylococcus* the most commonly identified pathogen. Some complications infrequently associated with UACs are development of aneurysmal dilatation of the aorta, peritoneal perforation, bladder injury, breaks or transection of catheters, intravascular knots

of catheters, a catheter looping back on itself, umbilical artery rupture, and others.[67]

Summary

UACs are commonly used in the care of severely ill neonates. Often overlooked by the pediatric intensivist, they can be extremely valuable tools for infants up to 2 weeks of age for assessment and management, but their use is not without problems. Because of the clinical significance of complications associated with UACs, alternative noninvasive tools for patient monitoring have been developed.

Umbilical Vein Cannulation

The umbilical vein is catheterized for emergency fluid or medication administration. In the first few hours of life, the umbilical vein is much easier to cannulate for central access than the umbilical arteries but can become more difficult as the ductus venosus constricts. In addition to resuscitation, the umbilical vein can be catheterized for prolonged central venous access in severely ill neonates. Other indications include exchange transfusion and monitoring of central venous pressure.

Equipment

The materials required for umbilical venous catheter (UVC) placement are identical to the materials required for UAC placement. Double-lumen UVCs are commercially available and are preferred unless the catheter is being placed for exchange transfusion. Typically, a 3.5 Fr catheter is used for neonates weighing less than 1000 g, 5 Fr for neonates weighing 1000 g to 3500 g, and 8 Fr for those weighing more than 3500 g.

Technique

UVC placement requires the same preparation and aseptic technique as described for umbilical artery cannulation. The umbilical vein is located at the 12 o'clock position when the umbilical cord is cut 1 to 2 cm above the umbilical ring. Apply a hemostat or forceps to the cord near the umbilical vein. The umbilical vein is not constricted when compared with the umbilical arteries and does not routinely require dilation prior to introduction of the catheter. The umbilical cord should be gently pulled toward the feet during placement to straighten the course of the vein and reduce resistance during insertion of the UVC.[66,67,83]

The length of catheter insertion is determined by the size of the infant and by the indication for placement. In emergency situations (resuscitation) and exchange transfusion, the catheter should be placed only to a depth where rapid blood return is achieved, which is 3 to 5 cm in most infants. A long-term UVC should reside at the junction of the inferior vena cava and right atrium. The formula ([3(weight in kg) + 9]/2) + 1 or the shoulder-to-umbilicus distance can be used to estimate depth of UVC insertion in centimeters from the umbilical ring.[67,78] A malpositioned UVC in the portal vein is indicated by resistance and bouncing at an insertion depth of 4 to 5 cm. If this type of resistance is encountered, a new catheter can be gently inserted (with a 50% success rate) using a side-by-side technique.[89] Remove the misdirected catheter after successful insertion of the second catheter. A catheter should never be forcefully advanced when resistance is met. Catheter position must be confirmed radiographically with both anteroposterior and lateral radiographs of the abdomen and chest. A malpositioned UVC may be missed if both views are not evaluated after placement of the line. The catheter should be sutured using a pursestring stitch and secured with a tape bridge, as described for the UAC. A malpositioned catheter should not be used for infusion of fluids. Never advance a UVC once the sterile field has been broken.

Maintenance

The UVC should be maintained as part of a closed system to prevent air embolism. Normally, infants are not placed prone while the UVC is in place, and careful observation of the umbilicus for signs of infection is warranted. Sterile technique should be used to minimize the risk of infection. A malpositioned catheter should never be advanced, and low catheters should only be used in extenuating circumstances. If placed for exchange transfusion, the catheter should be removed immediately after the procedure. If the UVC was placed for central venous access, it should be removed when it is no longer needed. Generally, UVCs should be discontinued within 10 days to 2 weeks after placement to decrease the likelihood of complications, although in babies weighing less than 1250 g it may be safe to leave a UVC in place for up to 28 days.[90,91] UVCs should be removed in the manner described for UACs.

Complications

Infection is the most common complication associated with UVC placement, with increased risk when the catheter is left in place for prolonged periods of time.[71,90] Thrombosis is another reported complication of UVC placement and can lead to late portal hypertension when it occurs in the portal venous system.[92,93] Associated hepatic necrosis, liver abscess, cardiac infections, arrhythmias, cardiac tamponade, cardiac perforation, necrotizing enterocolitis, and peritoneal perforation or peritoneal fluid extravasation have been described in the literature, with some being life-threatening.[67,71,92,94-96]

Summary

UVCs provide emergency access during resuscitation of a severely ill neonate. In low-birth-weight infants, UVCs can be the initial route for providing valuable high-calorie nutrition. Appropriate catheter placement should be confirmed with two-view radiographs. Complications from UVCs are more likely if the catheters are left in place for prolonged periods or are incorrectly positioned. Ideally, UVCs should be removed within 7 days due to increased risk of infection.

Central Venous Line Placement

Intensivists must be expert in central venous line (CVL) placement and use. The need for central access should be anticipated so that circumstances surrounding the procedure, such as sterile technique and the patient's safety and comfort, can be optimized.

Indications and Contraindications

Indications for CVLs include:

- The need for reliable and durable venous access:
  - In the face of lack of or inadequate peripheral venous access.
  - For administration of vasoactive infusions, TPN, and other medications that require central vascular access.

- Frequent blood sampling.
- Monitoring of central venous pressure and central venous oxygen saturation.
- Providing access for certain extracorporeal support modalities such as continuous renal replacement therapy and apheresis.

Contraindications to central access are not absolute and are primarily related to catheter placement at specific sites. In the presence of increased bleeding risk, sites where bleeding may be difficult to control, such as the subclavian, should be avoided if possible. In patients with significant intraabdominal or pelvic trauma, femoral catheters may pose increased risk. Bacteremia present at the time of catheter placement likely will colonize to central venous catheters. Catheters should not be inserted through obviously infected skin. The relative risk and benefit of catheter placement should be carefully considered before each procedure.[97]

Technique

Critically ill pediatric patients vary greatly in size, and the pediatric intensivist should have an awareness regarding the dimensions of the vein that is being accessed and the proximity and anatomical relation of the respective artery to the vein. The diameters of the central veins vary across the pediatric age groups (Table 15-1), and those veins and their respective arteries can be very vulnerable to damage during the cannulation process due to variations of the anatomical relationship that exist among patients.

Appropriate-sized catheters for CVL placement in pediatric patients should be readily available. In acutely ill patients requiring central access for a relatively short period (days to weeks), plastic polymer catheters are commonly used. These catheters are available in a variety of diameters, lumen numbers, and lengths. They can be packaged with appropriate-sized introducer needles, guidewires, and tissue dilators, along with other necessary equipment such as local anesthetic, skin cleanser, drapes, and suture for securing the catheter. Currently available antibiotic-impregnated catheters may decrease the risk of catheter-related bloodstream infection.[98]

Table 15–1 Approximate Mean Femoral and Internal Jugular Vein Diameter Across the Pediatric Age Period

Age	Mean IJV Diameter (mm)	Mean FV Diameter (mm)

Adequate sedation and analgesia not only provide patient comfort during the procedure but also make the procedure easier and safer with less patient movement. Agents with rapid onset and short duration of action, such as midazolam, propofol, and ketamine, are ideal. Even with sedation, local anesthesia should be used to reduce pain and the depth of sedation required for a patient to be comfortable and still.

Full barrier precautions should be used whenever a CVL is placed in the PICU and should include hair cover, mask, careful handwashing, sterile gown and gloves, a large area of skin prepped with antiseptic solution, and a draped sterile field large enough to eliminate the possibility of inadvertent contamination of equipment and sterile surfaces. This technique, when properly applied, has been shown to decrease the risk of catheter-related infection.[99] Skin disinfection with chlorhexidine is superior to povidone-iodine.[100]

The majority of CVLs placed in the PICU are placed using the Seldinger technique[101] This technique is essentially the same regardless of the site used. An introducer needle is placed in the desired vein while aspirating with a syringe. This step can be facilitated by using a bedside ultrasound with appropriate probe designed to visualize the vessel of interest (see later discussion). When the lumen of the needle is fully within the lumen of the vein, blood flows freely into the syringe. The needle should be held in place with one hand while the syringe is disconnected with the other hand. The rate at which blood passively flows from the open needle hub is dependent upon the gauge of the needle and the venous pressure; however, it should not be obviously pulsatile. A J-tipped guidewire is inserted into the open hub of the needle and advanced into the vein (Figure 15-6, *A*). The wire should meet little or no resistance as it is advanced. If resistance is met, attempts to advance the wire should cease. The position of the needle should be adjusted, by either advancing or withdrawing slightly or changing the angle of entry. The wire can be carefully withdrawn and the syringe reattached to the needle in order to reidentify the lumen of the vein. If resistance is met while withdrawing the wire, the needle and wire should be withdrawn as a unit rather than risk breaking or cutting the wire. Once the guidewire is well within the lumen of the vein, a small incision is made adjacent to the needle to enlarge the puncture site to more easily accommodate the dilator and catheter. Next, the introducer needle is carefully withdrawn along the wire holding the wire completely stationary. A dilator of appropriate size is advanced along the wire into the puncture far enough to dilate all tissue planes into the lumen of the vein. The dilator is withdrawn, and the desired catheter is advanced into position along the wire (Figure 15-6, *B*). The guidewire is removed, leaving the catheter in place. Blood should be easily aspirated from all lumens. Each lumen should be filled with sterile saline or heparinized saline to prevent thrombosis.

Several systems for securing catheters are commercially available. The most common technique uses silk suture. A large loop of suture should be placed in the skin, attached through the wings of the catheter hub, and tied tightly

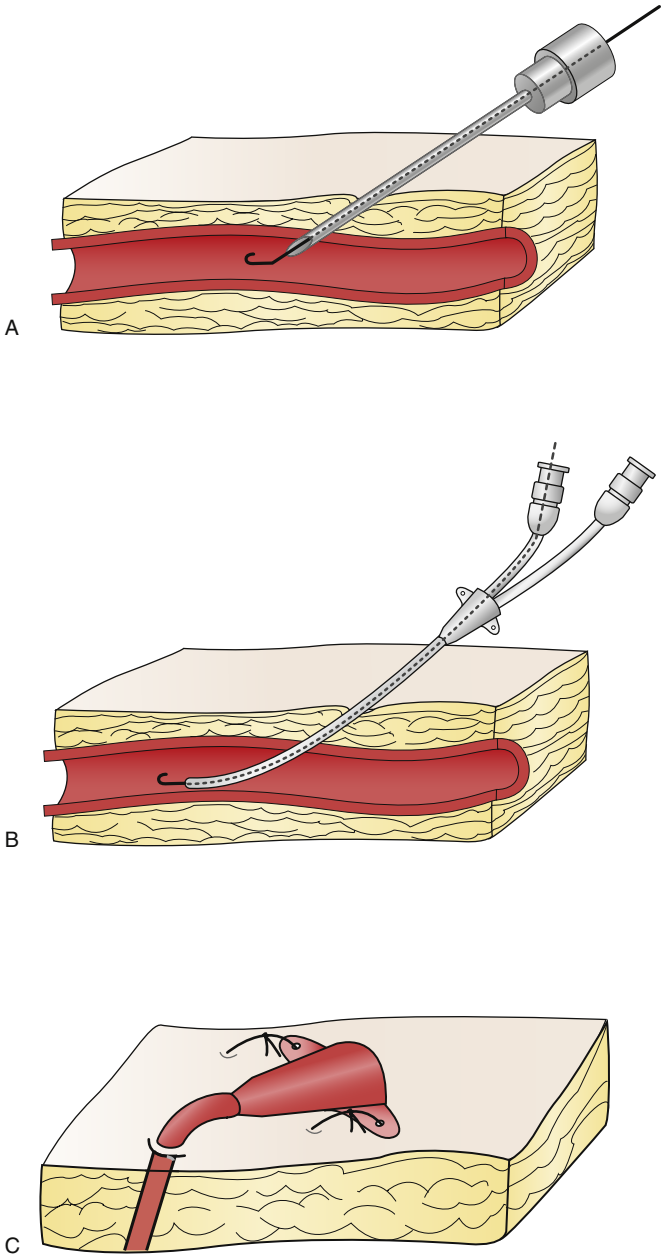

Figure 15–6. **A,** Guidewire is placed through the introducer needle into the lumen of the vein. **B,** Catheter is advanced into the vein lumen along the guidewire. **C,** Hub of the catheter is secured to the skin with suture.

enough to prevent catheter movement but not so tightly as to cause necrosis of the skin within the loop of suture material (Figure 15-6, *C*).

Internal Jugular Vein Cannulation

Multiple approaches can be used to cannulate the internal jugular vein. For each of these approaches, the patient is supine in slight Trendelenburg position, with a roll of bed linen under the shoulders to extend the neck and with the face turned to the contralateral side. The middle or low approach is most commonly used (Figure 15-7, *A*). The introducer needle enters the skin at the apex of the triangle formed by the clavicle and the heads of the sternocleidomastoid muscle at a 30-degree angle to the skin directed toward the ipsilateral nipple. For the anterior approach, the introducer needle enters the skin along the anterior margin of the sternocleidomastoid halfway between the mastoid process and the sternum and is directed at the ipsilateral nipple (Figure 15-7, *B*). Using the posterior approach, the needle enters the skin along the posterior border of the sternocleidomastoid halfway between the mastoid process and the clavicle and is directed toward the suprasternal notch (Figure 15-7, *C*).[102]

Subclavian Vein Cannulation

Place the patient supine in a slight Trendelenburg position. A narrow roll of bed linen is placed beneath the patient, between his or her shoulders. The introducer needle enters the skin inferior to the junction of the middle and lateral third of the clavicle and is directed toward the suprasternal notch. The needle passes slightly inferior to the clavicle and enters the subclavian vein (Figure 15-8).[102]

Femoral Vein Cannulation

The patient is placed in a supine position either flat or in slight reverse Trendelenburg position. A pad of bed linen is placed under the hips to slightly raise them off the bed surface. The leg on the side of catheter placement is slightly abducted and externally rotated. The femoral artery pulse is palpated just distal to the inguinal ligament about halfway between the anterior iliac crest and the pubic symphysis. The femoral vein is approximately 5 mm medial to the femoral artery in infants and toddlers and approximately 10 mm in adolescents and adults. The introducer needle enters the skin 1 to 2 cm distal to the inguinal ligament at an approximately 30-degree angle with the skin surface and in line with the course of the vein, approximately parallel to the axis of the thigh (Figure 15-9).[102]

Use of Ultrasound for Central Venous Line Placement

Since the first description of the Seldinger technique by Sven Seldinger in 1953, percutaneous CVLs have been placed by relying on certain surface anatomic landmarks at the site of insertion. This method is a "blind" method since the operator does not have direct visualization of the central vein that is being accessed. Recently, the use of ultrasound technology to facilitate CVL placement has been described, and since the first report by Legler in 1984, the use of ultrasound to guide CVL placement has become increasingly more popular among many practitioners.

Small, portable bedside ultrasound machines with transducers designed for visualization of vessels are commercially available. Sterile ultrasound gel and transducer covers exist, and they maintain full barrier precautions while placing the CVL.

The ultrasound is used in either of two ways to help with CVL placement:

- Continuous real-time visualization of the central vein and the needle while the needle is being introduced into the lumen of the vein. This can be performed by two operators (one operator holds the ultrasound probe while the other operator introduces the needle) or by a single operator (the ultrasound probe is held with one hand and the needle is introduced with the other hand).

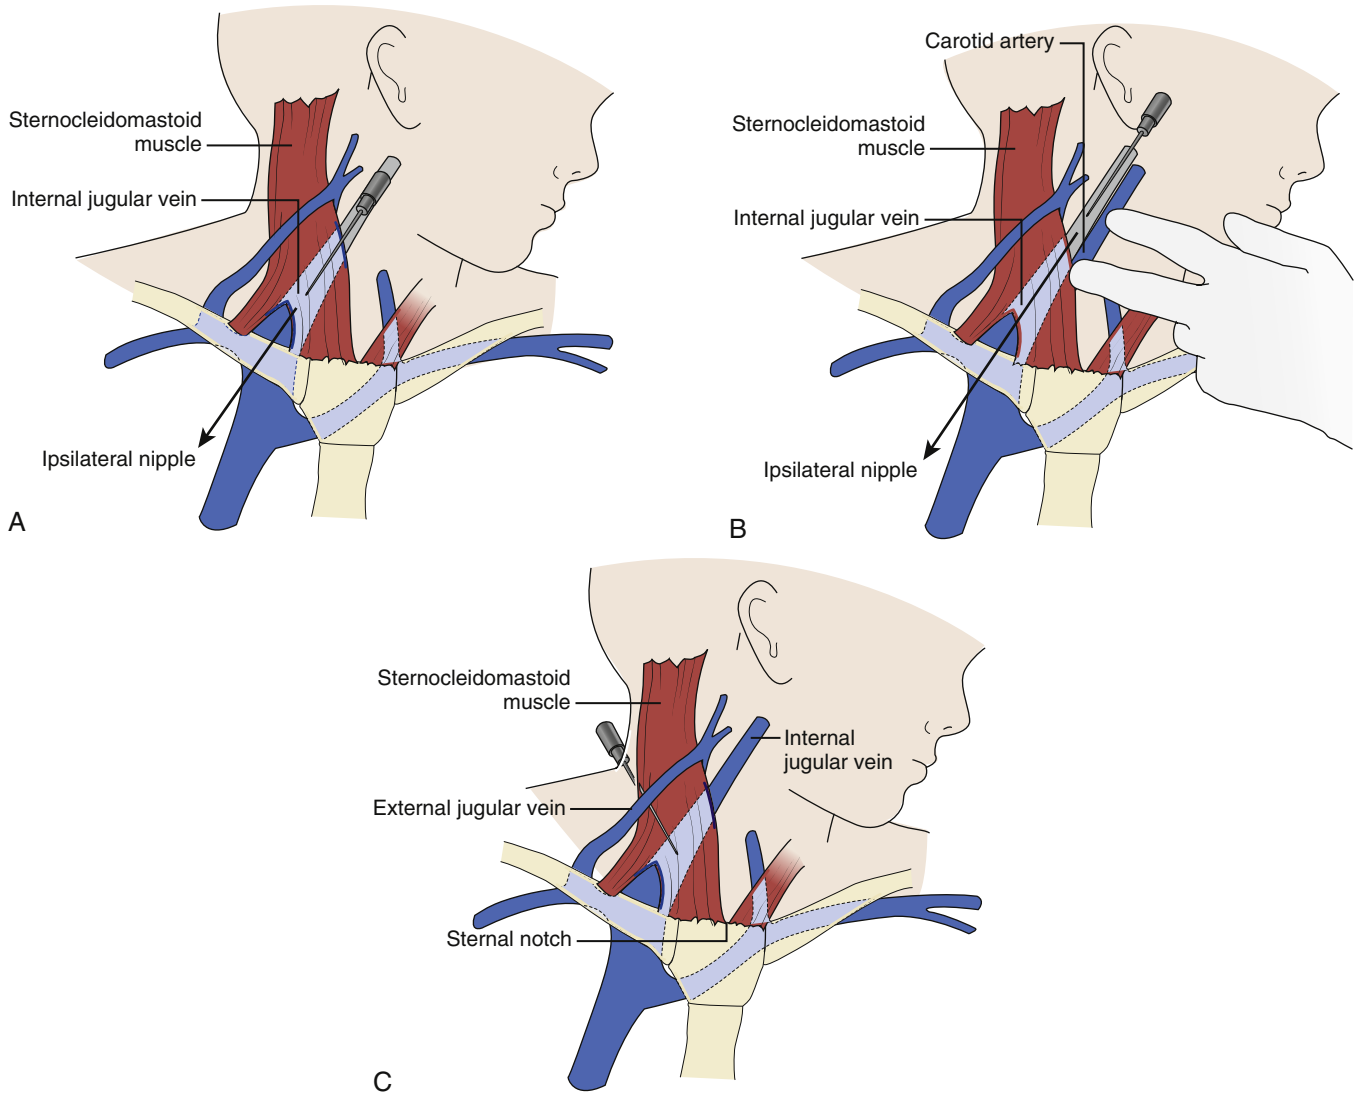

Figure 15–7. Approaches to the internal jugular vein. The patient is supine, in slight Trendelenburg position, with the neck extended over a shoulder roll and the head rotated away from the side of the approach. **A,** Middle approach. The introducer needle enters at the apex of the triangle formed by the heads of the sternocleidomastoid muscle and the clavicle and is directed toward the ipsilateral nipple at an angle of approximately 30 degrees with the skin. **B,** Anterior approach. The carotid pulse is palpated and may be slightly retracted medially. The introducer needle enters along the anterior margin of the sternocleidomastoid about halfway between the sternal notch and the mastoid process and is directed toward the ipsilateral nipple. **C,** Posterior approach. The introducer needle enters at the point where the external jugular vein crosses the posterior margin of the sternocleidomastoid and is directed under its heads toward the sternal notch.

- Direct one-time static visualization of the vein and its respective artery prior to needle insertion, then insertion of the needle without continuous visualization.

In a randomized controlled trial, real-time ultrasound guidance for CVL placement outperformed the static method.[103] The use of ultrasound guidance for CVL placement has been shown in many studies, both in adult and pediatric patients, to result in better success rates and fewer complications as compared to the "blind" surface landmarks method.[104-106] A recent study in pediatric patients showed that ultrasound guidance during CVL placement decreased the complications rates and the placement attempts but did not improve success rates.[107] In experienced hands, ultrasound can be of great help to facilitate CVL placement with fewer complications. Ultrasound offers many benefits that help facilitate CVL placement. It identifies the size of the central vein and the exact relation of the vein and its respective artery, which has been shown in many studies (both in adults and children) to frequently vary from what is depicted in the "classic" anatomy.[108-115] Ultrasound also shows the guidewire inserted inside the vein prior to using the dilator. In addition, ultrasound identifies the patency of the central vein and helps to avoid attempting CVL placement in an already thrombosed central vein. Use of real-time ultrasound for CVL placement is strongly encouraged, and pediatric intensivists should be familiar with this technology.

Complications

The risk of bloodstream infection is significantly increased by the presence of a central venous catheter. The increased risk is true for all catheter locations and increases with the total

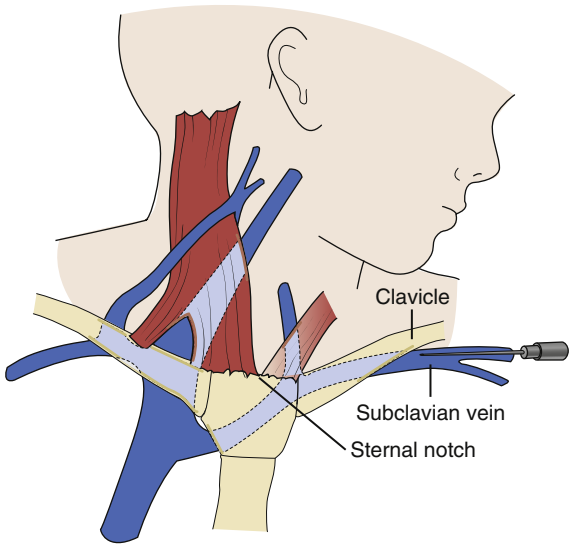

Figure 15–8. Approach to the subclavian vein. The patient is supine, in slight Trendelenburg position, with a small roll along the spine between the shoulders. The needle enters the skin at the junction of the lateral and middle thirds of the clavicle and is directed toward the sternal notch in the horizontal plane.

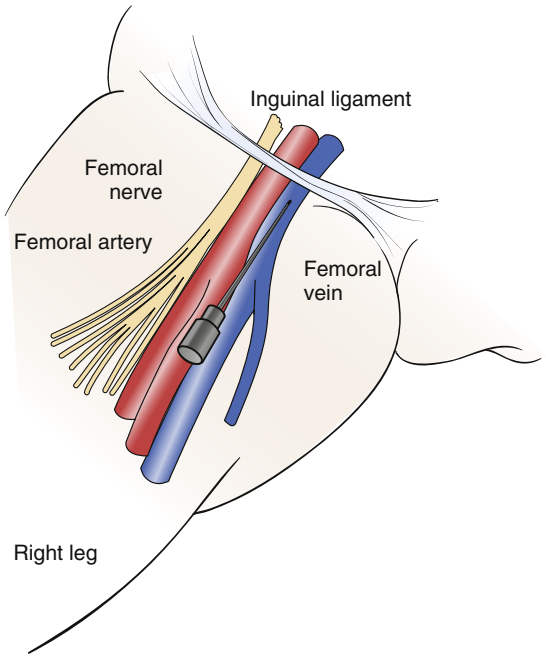

Figure 15–9. Approach to the femoral vein. The patient is flat and supine, with the thigh slightly abducted and externally rotated. The introducer needle enters the skin 2 to 3 cm distal to the inguinal ligament and 0.5 to 1 cm medial to the pulse of the femoral artery.

number of catheter days. Routine changing of uninfected catheters either over a guidewire or to a different anatomic site does not change the risk. Coagulase-negative staphylococci, *Enterococcus* species, *Staphylococcus aureus*, *Enterobacter* species, and *Candida* species account for the majority of infections. The risk of infection is decreased by use of antibiotic-impregnated catheters, full barrier precautions at the time of placement, and careful aseptic technique when the line is accessed.[98,99]

Pneumothorax may result if the lung is punctured during internal jugular or subclavian placement. This complication is less likely with careful patient positioning and attention to anatomic landmarks as the introducer needle is advanced. Chest radiography should be performed after an internal jugular or subclavian catheter is attempted to document that a pneumothorax has not occurred. Thrombosis may occur in the vessel surrounding the catheter. The catheter lumen may become thrombosed.

Bleeding at the time of placement can be serious and potentially life-threatening. Bleeding at the skin puncture site from an inadvertent arterial puncture is easily controlled by direct pressure. However, bleeding caused by injury to a deeper vascular structure may result in difficult-to-control hemorrhage. Veins and arteries may be perforated or lacerated distant from the intended puncture site by the introducer needle, guidewire, vessel dilator, or the catheter itself. Injury to the femoral or iliac vessels may result in pelvic or retroperitoneal bleeding. Lacerations of the internal jugular, subclavian, or innominate veins or the superior vena cava may communicate with the thoracic cavity and result in hemothorax and bleeding that cannot be controlled by direct pressure. Perforation of the heart during catheter placement may cause cardiac tamponade. Bleeding complications are more severe in the presence of a coagulopathy or thrombocytopenia and should be treated, if possible, before central access is attempted, especially if the internal jugular and subclavian sites are to be used.[116,117]

A central venous catheter positioned such that it applies pressure to the wall of the vessel or to the wall of the heart risks causing perforation. This situation may result in acute blood loss or tamponade. Undesirable positioning of a CVL can be detected radiographically and should be corrected as soon as possible.[116,117]

Venous Cutdown

With the widespread use of central venous access and the use of intraosseous access during emergencies, venous cutdown is less commonly performed. Venous cutdown is indicated when percutaneous access is not achievable and the need for IV access warrants the more invasive procedure. Materials needed depend upon the technique of vein cannulation used. The skin should be prepped and draped, and sterile technique should be used. The skin overlying the intended site is opened perpendicularly with respect to the vein. The tissue surrounding the vein is bluntly dissected to completely expose the vein. Ligatures are passed around the vein distal and proximal to the intended site of cannulation. A small venotomy is created and, using the ligatures to control the vein, a catheter is directly passed into the lumen of the vein. The distal ligature can be tightened to control bleeding and the proximal ligature to help secure the catheter (Figure 15-10). Alternatively, an over-the-needle IV catheter can be directly introduced into the exposed vein without creating the venotomy or using ligatures. An introducer needle and then a guidewire can be inserted into the lumen of the vein for Seldinger technique placement. The latter approach is particularly useful for femoral venous cutdown. After the catheter is in place, it is secured with suture material and the wound is closed around the catheter.

The complications of venous cutdown are similar to the complications of other venous access techniques. The risk of bleeding from the open wound should be considered,

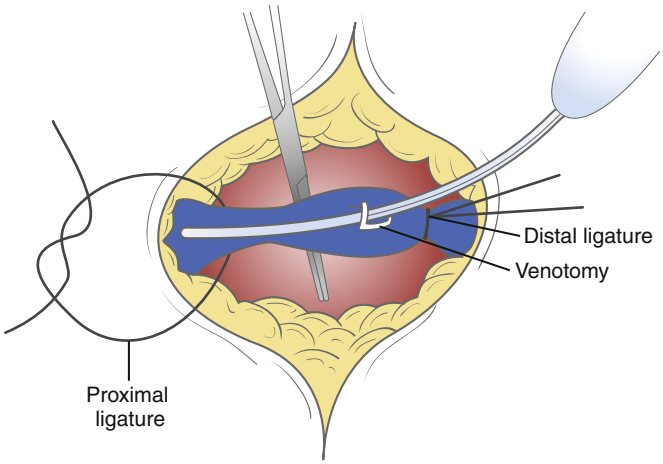

Figure 15–10. Venous cutdown.

especially in patients with increased risk for bleeding (anticoagulation or other coagulopathy). The open wound also increases the risk of infection. Injury to adjacent structures, such as arteries and nerves, during incision and blunt dissection is a risk with cutdown.[102,118,119]

Peripherally Inserted Central Venous Catheters

Peripherally inserted central venous catheters (PICCs) are increasingly used in pediatric intensive care unit (PICU) patients. Historically, these catheters have been used most in neonatal ICUs. For infants and smaller children, often only a single-lumen catheter can be placed. Multilumen catheters may be placed in older children. While PICC lines can often be placed by visible location and/or palpation of veins in the antecubital fossae, ultrasound is frequently used to place these catheters above the antecubital fossa to allow unimpaired elbow flexion. Success is more common when the catheters are inserted in the basilic vein.[120]

PICC lines are most often constructed of soft silicone material. The catheter length is measured prior to catheter insertion, and the catheter trimmed to the appropriate length. Placement of PICC lines is most commonly performed using a modification of the Seldinger technique. A needle or catheter is inserted into the vein, then a guidewire is placed, followed by a dilator. A soft "peel-away" introducer is often inserted next, with the catheter inserted through the introducer sheath, then the sheath is peeled away after the catheter is in place.

When placed by interventional radiologists, the catheter position is frequently verified by real-time fluoroscopy.[121] Outside of interventional radiology suites, chest radiography remains the primary method for documenting the location of the catheter tip.

While PICC lines are associated with a lower risk of placement-related complications, they are subject to the same complications as percutaneous central venous catheters, including catheter-associated infection, thrombosis, perforation, embolization, and fracture.[122-125] When PICC lines become fractured, the catheter may be repaired using manufacturer-provided kits for some catheters. Catheter repair may be associated with increased infection risk.

Pulmonary Artery Catheterization

Pulmonary artery catheter (PAC) monitoring was introduced into practice in 1970 by Swan and Ganz. Recently, because of the invasivness of the procedure and the lack of proven survival benefit for patient management, other less invasive surrogate techniques have significantly decreased the use of the PAC technology.[126-129]

The placement of the catheter can be done at the bedside, but skill is required to avoid complications and for proper interpretation of the hemodynamic data. Most catheters are balloon-tipped and flow-directed, and are able to measure right atrial, pulmonary artery, and pulmonary capillary wedge pressures as well as to determine cardiac output and oxygen saturations in the right heart chambers. Single-lumen catheters may be placed directly into the pulmonary artery at the time of cardiac surgery. Both techniques are used in pediatric patients, but the single-lumen catheter is especially used because of the frequency of pulmonary hypertension complicating the postoperative management of pediatric cardiac patients. The flow-directed, balloon-tipped catheter is usually placed in the ICU to assist in determining the etiology of shock, lactic acidosis, pulmonary edema, pulmonary hypertension, as well as to help guide fluid and vasoactive therapy over time.[130] There are different sizes of pulmonary artery catheters, with different lumens and a thermistor at the tip. Some use a fiberoptic spectrophotometry for continuous measurement of mixed venous oxygen saturation.

Pulmonary artery catheters are indicated for use in pulmonary hypertension, as well as in select patients with severe respiratory failure or severe shock. Pulmonary hypertension may beither be primary or secondary, the latter including pulmonary hypertension in postoperative congenital cardiac patients. These patients are prone to wide swings in PA pressures associated with variations in oxygenation, ventilation, and even sedation. When nitric oxide is used for management of postoperative pulmonary hypertension, direct measurement of PA pressure helps guide therapy. In patients with severe respiratory failure requiring high positive airway pressure with associated hemodynamic compromise, PACs may aid in the diagnosis of the cause of low cardiac output and direct therapy. When oxygen delivery in these patients is significantly limited because of hypoxemia, low cardiac output, or both, measurement of oxygen delivery using variables derived from information provided by the catheter may be useful. In children with severe shock unresponsive to fluid resuscitation and requiring vasoactive infusions, the PAC may better define the hemodynamic profile, thus allowing more specific therapy.

Significant controversy exists regarding the benefits and potential harms caused by this invasive form of hemodynamic monitoring.[131-133] Some randomized clinical trials documented that routine bedside pulmonary artery catheterization not only is not beneficial but may be associated with increased morbidity and mortality,[127] but other centers did not find differences in morbidity or mortality with or without PACs.[131] No studies in pediatric patients have demonstrated better outcomes with the use of the PAC.

Multiple barriers exist to PAC use, including patient risk with placement, the ability to measure similar variables via less invasive measures, increased cost, inaccurate measurement leading to misuse of PAC-derived variables, and incorrect

interpretation and clinical application. Additionally, with the decreased use of this technology, the skill required to maintain competency in placement and interpretation of the data provided presents a significant challenge to many institutions.

Contraindications

There are no specific contraindications to placement of a Swan-Ganz catheter, but there are several relative contraindications, including bleeding diathesis increasing the risk for percutaneous access, as well as severe tricuspid or pulmonary insufficiency, which can make bedside catheter placement prohibitively difficult. Unstable cardiac arrhythmias that are easily triggered by catheter manipulation are also a relative contraindication. Catheter placement for measurement of cardiac output using the thermodilution technique is contraindicated in the presence of intracardiac shunts, tricuspid insufficiency, or pulmonary insufficiency, as the thermodilution measurement will be inaccurate.

Procedure and Equipment

Choosing the most appropriate size and type of catheter is often difficult because a variety of balloon-tipped, flow-directed catheters are available on the market. Catheters are available with two diameters, 5 Fr and 7 Fr. The 5 Fr diameter catheter is most appropriate for patients weighing less than 15 kg, and the 7 Fr diameter catheter is best for patients weighing more than 15 kg. Single-lumen PACs are most commonly placed in the operating room at the time of heart surgery.

The standard PAC is 1 m long. The distance between the proximal variables depends on the catheter. The standards are 10, 15, 20, and 30 cm. Using the correct distance is crucial in order to monitor the appropiate pressure.The PAC is equipped with proximal and distal ports facilitating measurement of intravascular pressures, infusion of vasoactive agents, fluids, and blood sampling. At the tip are a thermistor used to calculate cardiac output and a balloon that may be inflated and deflated as necessary. Some catheters have an additional right ventricular port for temporary pacemaker insertion, and some have a fiberoptic oxygen saturation sensor for continuous measurement of mixed venous oxygen saturation. Other necessary equipment includes a monitor with cardiac output capability or a computer to determine cardiac output using thermodilution, as well as compatible pressure transducers. Carbon dioxide is used in some centers to inflate the balloon so as to minimize the risk of air embolization, although room air is most common. The catheters are placed through a percutanous introducer sheath, which is placed with the same technique as described for central venous catheters.

Before placement, the catheter should be flushed and filled with fluid through which intravascular pressures are transmitted to a transducer. The equipment is then zeroed to atmospheric pressure at the level of the patient's left atrium (midaxillary line, fourth intercostal space) and calibrated. If all air bubbles are not removed from the tubing, they may result in "damping" of the waveform tracing, and consequently, erroneously low systolic pressure. Clots at the tip of the catheter may also alter the wave form.

The site is prepared in sterile fashion with chlorhexidine solution and draped with sterile towels. It is important to drape a wide area with sterile sheets in order to avoid exposure of the

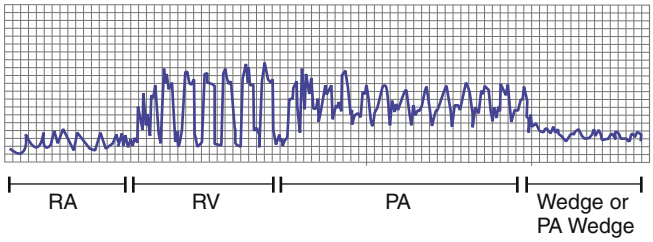

Figure 15–11. Pressure tracing during placement of a pulmonary arterial catheter showing pressures from the right atrium (RA), right ventricle (RV), and pulmonary artery (PA), then pulmonary capillary wedge pressure. *(From Adatia I, Cos P: Invasive and noninvasive monitoring. In Chang AC, editor:* Pediatric cardiac intensive care, *Baltimore, MD, 1998, Lippincott Williams & Wilkins.)*

catheter, because of the length of the PAC. The PAC is inserted through the introducer sheath. A sterile sleeve is placed on the end of the sheath and the catheter is passed through the sleeve, then through the diaphragm and into the sheath.

Anatomically, the preferred sites of insertion are the right internal jugular, left subclavian, right subclavian, and left internal jugular veins. Usually, the placement of the catheter is guided by pressure wave form monitoring (Figure 15-11), but fluoroscopic visualization will occasionally be needed, particularly if the PAC is placed from a femoral site. Once the catheter tip enters the venous circulation, the balloon is inflated with air. From this point, the catheter should be advanced with the balloon inflated so as to prevent damage to the myocardium, cardiac valves, or pulmonary artery branches. If the catheter is withdrawn, the balloon must first be deflated to avoid valvular injury.

The catheter is advanced to the right atrium (RA), then across the tricuspid valve into the right ventricle (RV), and across the pulmonary valve into the pulmonary artery (PA). As the catheter continues to float with the balloon inflated, it will wedge in a branch PA, occluding the blood flow. The pulmonary artery occlusion pressure (PAOP), or wedge pressure (PAWP), will be recorded from the distal lumen. If the balloon is deflated, a PA pressure tracing will be recorded. If the wave forms are not obtained, the balloon should be deflated and the catheter pulled back to the RA before attempting placement again.

After insertion, a chest radiograph is obtained to ensure proper catheter placement and rule out pneumothorax. The caheter tip should be visualized within the proximal third of the hemithorax.

The pressure wave forms are characteristic; when the catheter is advanced to the RA, the atrial trace has a respiratory variation that helps to confirm the catheter is in the thorax. Once in the atrium the balloon is inflated and advanced to the RV, where the trace is characterized by a rapid upstroke in early systole with an equally rapid downstroke at the end of systole. Turning the catheter with a clockwise motion usually helps in passing the PAC. The catheter is advanced to the PA. The PA trace has the same peak systolic pressure of the RV, but as systole ends, the trace shows a slower fall that continues through diastole, because the diastolic pressure in the PA is higher than the RV diastolic pressure. Once in the PA, advance the catheter slightly until a pulmonary wedge trace is seen. This trace is similar to the RA trace, although usually with a higher pressure. PAWP is obtained when the balloon

is inflated and the catheter floats into the wedge position (see Figure 15-11). Because the catheter floats to an area of greatest blood flow in the lung, it most likely will be in an area consistent with West zone III. Zone III is an area where arterial pressure is higher than both venous and alveolar pressure.

Measurement of PAWP is best done at end-expiration to minimize the effect of changes in pleural pressure. Once the wedge is measured and the balloon is deflated, the PA trace should return. If the trace does not change, the catheter should be retracted until the PA trace is seen. The catheter should not be left inflated in the wedge position because of the risk of pulmonary infarction. The catheter is appropriately positioned when the PA pressure trace is present when the balloon is not inflated and the pulmonary capillary wedge trace is present when the balloon is inflated. Once it has been confirmed that the PAC is in good position by pressure trace and radiography, the catheter should be secured in the sleeve and taped to the patient.

Information Acquisition

Much hemodynamic and oxygen delivery information can be obtained from the Swan-Ganz–type pulmonary artery catheter. Multiple hemodynamic pressures can be obtained, including RA pressure, PA pressure, and PAWP. Right atrial pressure is useful for determining preload of the right ventricle. pulmonary artery pressure is useful for determining the presence of pulmonary hypertension both at baseline and with manipulation of oxygenation, ventilation, ventilator pressures, nitric oxide, and other procedures.

PAWP reflects left ventricular preload. In most patients with normal cardiac function and anatomy, right atrial or central venous pressure adequately reflects LV preload as well. However, in the presence of certain congenital heart defects, with significant ventricular dysfunction, or with high mechanical ventilatory pressures, a significant discrepancy may exist between right and left ventricular preload. In such circumstances, measurement of PAWP is useful for guiding fluid and inotropic therapy.

Systemic mixed venous oxygen saturation (Svo_2) can be determined directly and continuously with a catheter containing the fiberoptic oximeter. In the absence of the oximeter, intermittent blood sampling from the distal port when in place in the pulmonary artery allows for Svo_2 measurement.

The thermistor at the tip of the catheter allows for measurement of cardiac output, using the thermodilution method. This method uses the Fick principle, based on the law of conservation of thermal energy. A specific amount of known temperature fluid is injected in the proximal port (upstream), and the temperature change downstream (at the thermistor) is recorded. The change in temperature over time allows for measurement of blood flow, in this case cardiac output. According to Jansen this measure of cardiac output is accurate if the following conditions are met: 1) no loss of cold occurs between the injection site and the thermistor, 2) mixing of the cold injectate (indicator using Fick terms) and the blood is complete, and 3) the temperature change caused by the injection of cold fluid is sufficient to be detected by the thermistor.

To perform thermodilution cardiac output measurements, the catheter must be connected to the thermodilution computer, which is either freestanding or part of the cardiac monitor. A specific volume of injectate, either room temperature or iced, is injected rapidly into the proximal port of the catheter. The temperature difference over time that is detected at the thermistor is recorded as a curve. The computer then integrates the area under the curve, which is inversely proportional to the cardiac output. The cardiac output is calculated and projected. For pediatric patients, this number should be divided by their surface area in meters, giving the cardiac index. The injectate can be either iced or room temperature. The disadvantages to iced injectate include risk of hypothermia in pediatric patients requiring frequent cardiac output measurements, the poor accuracy of the first injection because of warmer fluid in the catheter, and a greater signal-to-noise ratio. Room temperature injectate prevents these problems and yet is accurate when cardiac output is stable. However, in conditions of high or low cardiac output, less variance occurs with iced injectate compared with room temperature injectate. However, for convenience and the safety of pediatric patients, room temperature injectate is recommended.

Usually three to five injections yield adequate results. Some error can be introduced by faulty technique. Injecting variable volumes or injecting with variable rates can result in inaccurate measures. Multiple injections and averaging of the results can overcome these problems. The presence of tricuspid or pulmonary insufficiency can lead to overestimation of cardiac output. Echocardiography may be necessary to rule out the presence of valvular insufficiency. Intracardiac shunts, such as a ventricular septal defect, result in false values for cardiac output. Mechanical ventilation has been shown to alter stroke volume, which can result in variable measures of cardiac output. Therefore, one should perform the injection at the same time in the ventilator cycle to standardize the cardiac output measurements.

Maintenance

Care of the PAC is similar to that for any central venous line. The catheter and sheath should be dressed sterilely at all times and the dressing changed according to protocol. The catheter is housed in a sterile sleeve that allows for aseptic technique if further manipulation is necessary. Pressure transduction of the distal (PA) and proximal (RA) ports and continuous electrocardiographic (ECG) monitoring are mandatory. This setup continually confirms proper placement of the catheter. Whenever the balloon is inflated to determine PAWP, allow the balloon to deflate passively by opening the balloon port and removing the syringe. This step helps prevent balloon rupture. Balloon rupture should be suspected if blood is obtained when aspirating the balloon port. In this situation, remove and then replace the catheter if it is still clinically indicated. As noted earlier, arrhythmias can occur, particularly if the catheter becomes dislodged. A chest radiogram should be assessed daily for catheter position.

Interpretation

The hemodynamic data obtained or calculated with the PAC should be interpreted to make therapeutic decisions.

There are not isolated "good" or "bad" cardiac output (CO) values, but appropriate cardiac output is that which permits an adequate oxygen delivery (Do_2). As a global index of adequacy between consumption (Vo_2) and Do_2, Svo_2 is the target of choice for therapeutic decisions. Svo_2 should be kept above

a threshold value and all other PAC parameters should be used to choose how to maintain Svo_2 above this value. A value between 65% and 70% should be used. This Svo_2 goal can be achieved by fluid administration, blood transfusion, increasing or decreasing inotropic support, and/or vasopressors.[134-136]

Complications

PA catheterization is a significantly invasive procedure. Complications can occur during the Seldinger procedure to access the vein, during the passage of the PAC (across two heart valves), or during catheter use. Bleeding, infection, and pneumothorax may occur during venous access. Arrhythmias can be seen during placement of the PAC or due to dislodgment of the catheter. Their spectrum goes from supraventricular tachycardia while in the RA to premature ventricular beats or even ventricular tachycardia while in the RV. Usually, the arrhythmias cease when the catheter reaches the pulmonary artery. Occasionally lidocaine, amiodarone, and defibrillation may be needed, so they should be readily available. Once the catheter is in place, pulmonary infarction or hemorrhage is a risk. Rupture of the distal pulmonary artery, endothelial damage, and valvular damage have been reported, as well as knotting of the catheter requiring fluoroscopic retrieval. Remove the pulmonary artery catheter as soon as possible to avoid complications.

Summary

Since the introduction of the PAC, controversy has surrounded the technology regarding the benefits and potential harms caused by this invasive form of hemodynamic monitoring. In adult clinical trials, the usefulness of PAC has been challenged because no benefit in patient outcome has been observed, and some retrospective studies have described worse outcomes. Accurate acquisition and interpretation of the data is paramount for making appropriate therapeutic decisions.

Thoracentesis and Tube Thoracostomy

Thoracentesis

Thoracentesis, first described in 1852, is a procedure used to remove fluid or air from the pleural space. In pediatric patients, thoracentesis is most frequently indicated as a diagnostic procedure. Pleural effusions in children are most commonly the result of an infectious process (50% to 70% parapneumonic effusions), with congestive heart failure (5% to 15%) and malignancy being less common causes.[1] Many other conditions may, rarely, cause pleural effusions in children (Box 15-2).

Indications

Thoracentesis may be used to help diagnose the cause of a pleural effusion. It can also be used therapeutically to relieve respiratory distress resulting from large accumulations of fluid or air. If ongoing evacuation is required, tube thoracostomy should be considered (see below). Ultrasound is a useful technique to identify fluid accumulations when there is complete opacification of the hemithorax on chest radiograph, and to help characterize fluid consistency (complicated vs. simple effusions).[2] Ultrasound may also help to identify optimal locations for successful aspiration. [137]

  - Myxedema
  - Sarcoidosis
  - Radiation therapy
  - Immunoblastic lymphadenopathy
  - Familial Mediterranean fever

Contraindications

Thoracentesis has no absolute contraindications. Small fluid accumulations make this procedure difficult and may increase the risk of pneumothorax. Positive pressure ventilation may also increase the risk of pneumothorax. Uncorrected coagulopathy and thrombocytopenia predispose to bleeding complications; however, thoracentesis can generally be accomplished in this setting utilizing a small needle and careful technique. An uncooperative patient can lead to damage to the underlying vascular structures and lung parenchyma. This can be avoided by generous use of sedation and analgesia in pediatric patients.

Preparation

Sedation and analgesia are frequently required to safely perform thoracentesis in pediatric patients. Proper monitoring techniques and medication administration should be utilized in this setting, and are discussed in Chapter 77. Topical local anesthetic agents may reduce the discomfort associated with infiltration of local anesthetics.[138] These agents should be placed at the intended puncture site approximately 15 to 30 minutes prior to the procedure (depending on the agent used) and covered with an occlusive dressing.

Procedure

Box 15-3 lists the supplies and equipment required for thoracentesis.

Technique

If thoracentesis is being performed for evacuation of a pneumothorax, the patient should be placed in the supine position. Aspiration is performed at the second or third intercostal space in the midclavicular line. For the removal of pleural fluid, the patient should, if possible, be place in the upright, seated position. Infants and young children may be held in the burping position by an assistant. The normal site for fluid aspiration is the seventh intercostal space in the posterior axillary line (near the tip of the scapula).

Box 15–3 Supplies and Equipment for Thoracentesis

- Pillows or towels for positioning patient
- Sterile gloves
- Povidone-iodine or chlorhexidine solution
- Commercial thoracentesis tray (for older children and adolescents)
- Or assemble the following items:
  - Sterile gauze sponges
  - Sterile towels or drapes
  - 3- to 5-mL syringe for local anesthetic; 27- to 30-gauge needle for skin infiltration
  - 1% lidocaine; consider sodium bicarbonate to buffer lidocaine
  - Over-the-needle catheter: 14 to 20 gauge depending on the size of the patient
  - 10- or 20-mL syringes for fluid collection
  - Three-way stopcock or tubing extension set with clamp
  - Sterile dressing
  - Tape to secure dressing

The previously placed occlusive dressing should be removed and the site prepped with chlorhexidine and draped with sterile towels. The skin entry site is then generously infiltrated with a local anesthetic using a 27- to 30-gauge needle. The needle is then advanced perpendicular to the skin to infiltrate the underlying subcutaneous tissues, superior portion of the rib, and periosteum. A longer 22- to 25-gauge needle may be needed to accomplish this. The needle is then advanced over the superior border of the rib while applying gentle aspiration until the pleural space is reached. The depth of the needle where fluid aspiration occurs should be noted. An over-the-needle catheter of sufficient length is then used for aspiration of fluid with a syringe. If infection is suspected, a larger catheter (16- to 18-gauge) may be needed.

Aspiration is continued until a sufficient quantity of fluid for diagnostic studies is obtained. A three-way stopcock with attached tubing may be placed on the catheter to facilitate this process. If fluid is being removed for release of respiratory distress, aspiration is continued until fluid flow ceases. The catheter is subsequently removed and a sterile dressing is applied over the entry site.

Complications

The most common complication of thoracentesis is pneumothorax.[137] We recommend that all patients undergoing thoracentesis have a follow-up chest radiograph to evaluate for this possible complication. Hemothorax may occur in patients with abnormal coagulation studies and thrombocytopenia. A platelet count of greater than 50,000 and normal coagulation studies are ideal, but the procedure can be safely performed with careful technique and avoidance of the neurovascular bundle found on the inferior border of the rib. In more urgent settings, platelets and clotting factors may be administered during the procedure. Soft tissue infections can be avoided with use of proper sterile technique. Reexpansion pulmonary edema has been reported in adult patients with removal of large fluid volumes and usually occurs in the first hour following thoracentesis.[139,140] This complication has not been reported in children.

Interpretation

Analysis of pleural fluid is separated into two basic categories: exudates and transudates. The criteria used to distinguish between the two are largely dependent on adult work from 1972 by Light.[141] Box 15-4 lists the Light criteria for differentiating between transudative versus exudative fluid. Elevated triglyceride levels (greater than 110% of serum value) and lymphocyte predominance suggests chylothorax. Elevated amylase suggests pancreatitis or esophageal rupture.[142] Recent advances in polymerase chain reaction (PCR)

Box 15–4 Interpretation of Pleural Fluid

Characteristics of exudative effusions:

- Pleural to serum protein ratio >0.5
- Pleural to serum LDH ratio >0.6
- Pleural fluid LDH more than twice the upper limit of the normal serum value

technology allows for rapid and accurate diagnosis of *Staphylococcus aureus*, *Streptococcus pneumoniae*, and *Mycoplasma* in pleural fluid.[143]

Summary

Thoracentesis is a useful diagnostic procedure for pediatric pleural effusions. It can also be a useful technique for resolution of respiratory distress with significant fluid accumulations and/or pneumothoraces. Thoracentesis is a simple technique that can be performed with high yield and a minimal complication rate.

Tube Thoracostomy

Tube thoracostomy placement is a common procedure in the pediatric critical care setting. Tube drainage of the chest is a therapeutic option employed since the days of Hippocrates. Many options, including less invasive techniques, are now available and are discussed below. Tube thoracostomy is required for a variety of reasons in critically ill pediatric patients. Pneumothoraces can develop spontaneously or as a result of acute lung injury. Large parapneumonic effusions and empyemas resulting from infectious pulmonary processes often require chest tube placement. Hemothoraces or hemopneumothoraces resulting from trauma frequently require drainage. Finally, chylothoraces in postoperative cardiac patients frequently require tube placement and continuous drainage. The technique utilized for placement depends on the nature (thick, thin, transudative, exudative) of the material to be removed.

Contraindications

As with thoracentesis, tube thoracostomy has no absolute contraindications. Attempts should be made to correct coagulopathy to prevent bleeding complications. This can be accomplished via transfusion of serum clotting factors and platelets as needed. However, when emergent or urgent intervention is required, tube thoracostomy should not be delayed to correct coagulopathy.

Supplies and Equipment

Many institutions have specially designed chest tube trays with sterile instruments. Typical requirements include sterile gauze sponges, sterile towels for draping, syringes and needles for local anesthesia, a scalpel and blade, curved Kelly clamps of various sizes, needle driver, suture, and suture scissors. Other materials required are an appropriately sized chest tube, chlorhexidine solution, sterile gloves, a drainage apparatus (such as Pleur-Evac), local anesthetic, and tape.

Technique

Pediatric patients should receive sedation and analgesia for tube thoracostomy placement as for thoracentesis, as described in the previous section. In addition, local anesthesia should be generously used. Up to 0.5 mL/kg of 1% lidocaine (5 mg/kg) or 0.7 mL/kg of 1% lidocaine with epinephrine (7 mg/kg) can be used. The technique for placement depends on the type of material to be removed from the chest. Thin, transudative fluid and pneumothoraces can often be evacuated with placement of a small caliber tube. These tubes, also known as pigtail catheters, range in size from 5 Fr to 9 Fr and are placed via a modified Seldinger technique.[144]

After proper sedation and analgesia, the overlying skin is prepped with chlorhexidine and draped in sterile fashion. A needle attached to a syringe (5 or 10 mL) is inserted in the fourth or fifth intercostal space in the midaxillary line. Continuous suction is applied and the needle is advanced until fluid or air is obtained. A guidewire is then placed through the needle into the pleural space. A small skin incision is made and the overlying skin and subcutaneous tissues are dilated with a skin dilator. A small catheter with multiple side holes is then placed over the wire and advanced into the pleural space. The guidewire is removed and the catheter is attached to a standard chest tube suction device. The tube is anchored to the skin with a suture or a commercially available sutureless skin anchoring device. Placement of pigtail catheters tends to be less painful than traditional tube thoracostomy (described below); however, the viscous fluids encountered with hemothoraces and empyemas generally do not drain well via this technique. Successful treatment of empyema with placement of pigtail catheters and use of fibrinolytic agents (alteplase and streptokinase) has been described.[145]

A variation of this technique allows for placement of larger caliber tubes. After placement of the guidewire as above, progressive skin dilators are used allowing placement of a more standard-sized chest tube. Kits for placement of these over-the-wire devices are commercially available. Caution should be used with placement of these devices in diseases with poor pulmonary compliance and/or pulmonary hyperinflation, as these conditions may predispose to intraparenchymal tube placement and the development of bronchopleural fistulas, which are difficult to treat.[146]

Traditional techniques for tube thoracostomy may be required for drainage of viscous fluids, including cases of empyema and hemothorax. Tube thoracostomy is a painful procedure and requires generous use of sedation and analgesia. Following administration of sedation and analgesia, the patient is placed in the supine position. The skin is prepped with chlorhexidine and draped in sterile fashion. The proper position for placement is the fourth or fifth intercostal space in the midaxillary line. The skin, subcutaneous tissues, intercostal muscles, underlying rib, and periosteum should be generously infiltrated with local anesthetic as described above.

A skin incision in the fourth or fifth intercostal space, large enough to allow placement of the chosen tube, is made parallel to the axis of the rib in the midaxillary line. A curved Kelly clamp is used to bluntly dissect the underlying subcutaneous tissue until the superior border of the upper rib is reached. The clamp is then used to push through and dilate the pleura above the superior border of the rib. In a larger child, the index finger can be used to further dilate the subcutaneous tissues and intercostal muscles. Any intrapleural adhesions can also be manually broken up. The end of the tube is then attached to a clamp and inserted into the pleural space. The clamp is opened and the tube advanced to the proper depth, ensuring all side holes are past the parietal pleura. If possible, the tube should be advanced anteriorly for pneumothoraces and posteriorly for effusions. The tube is then attached to a pleural drainage system.

Many techniques are available for suturing the chest tube in place. The most important aspect of the choice of anchoring method is that the operator removing the tube knows how the tube was secured. Some operators prefer a

horizontal mattress suture on both sides of the tube; others prefer to place a "pursestring suture" that can be pulled together after the tube is removed. If the latter technique is used, no knot is placed at the skin level, but extra suture is wrapped around the body of the tube and then tied to the tube itself. Upon removal, the extra suture serves as skin suture for the wound. Rarely, a suture is inadvertently placed through the tube while the device is anchored. In this event, a technique for cutting the suture using endoscopic scissors has been described.[147] "Needleless" anchoring devices for anchoring tubes without suture (e.g., StatLock Multipurpose, Venetec International, San Diego, Calif.) are commercially available.

Maintenance

Following successful chest tube placement, a chest radiograph should be obtained to verify proper position and to evaluate for resolution of pleural fluid or pneumothorax. Tubes should be evaluated for continued air leak by checking for air bubbles in the leak chamber of the suction apparatus. Ongoing air leak with no evidence of pneumothorax by chest radiograph suggests development of a bronchopleural fistula or airway injury. Some authorities suggest intermittent external negative pressure to "strip" the tube in order to maintain patency, although little evidence supports this practice.[148] Alteplase may also restore patency of tubes clogged by proteinaceous material.[145] Some advocate prophylactic antibiotic use, but little evidence supports this practice.[149]

Timing of tube removal depends on the indication for placement. Tubes placed for pneumothoraces may be removed following resolution of air leak. Our practice is to place these tubes to water seal for at least several hours and obtain a chest radiograph prior to removal. The practice of placing tubes to water seal and evaluating with a chest radiograph is supported in the adult literature.[150] Tubes placed for drainage of pleural fluid may be safely removed once fluid drainage has decrease to 2 to 3 mL/kg over 24 hours. Removal of large tubes may be painful and require analgesia and/or sedation, especially in small children. Tubes may be safely removed during either the inspiratory or expiratory phase.[151]

Complications

Several potential complications exist with placement of chest tubes. Any structure within the thorax may be inadvertently penetrated with use of undue force. For this reason, trocar chest tubes are not recommended for use in children, even in emergent situations. Placement in the lung parenchyma is a relatively common occurrence.[152] This may predispose to development of a bronchopleural fistula. Vascular injury may occur with high placement, and subclavian artery obstruction has been reported as well.[153] Left-sided placement can lead to thoracic duct injury and development of chylothorax. Deep placement may lead to mediastinal perforation.[154] Computed tomography may be used to evaluate the exact placement of chest tubes in cases where inadvertent misplacement or complications are suspected.

Summary

Tube thoracostomy is a common procedure in pediatric critical care. With attention to detail, this procedure may be accomplished safely and with minimal risk. New techniques and smaller caliber tubes may be utilized in select cases. Fibrinolytic agents such as alteplase may be used to restore patency of clogged tubes and may be of therapeutic benefit in cases of empyema.

Paracentesis

Paracentesis is the percutaneous sampling of peritoneal fluid by needle aspiration through the abdominal wall. It is a relatively safe procedure and is useful as a diagnostic tool in the evaluation of patients with ascites. Analysis of ascitic fluid, combined with history and physical examination, frequently confirm the cause of ascites. Paracentesis may also be used for the relief of respiratory distress secondary to massive ascites-induced abdominal distention.

Indications

Paracentesis is indicated in any patient with new-onset ascites, patients with chronic ascites and clinical deterioration, and cases of suspected bacterial peritonitis.[155] Paracentesis with placement of an indwelling catheter and ongoing fluid drainage has been used in the management of abdominal compartment syndrome.[156]

Contraindications

Paracentesis in patients with ascites has no absolute contraindications. Coagulopathy is not a contraindication to paracentesis, although caution should be used in patients with moderate-to-severe coagulopathies.[157-159] Some data suggest that prophylactic transfusion of fresh-frozen plasma, platelets, or other clotting factors prior to paracentesis in patients with coagulopathy is not necessary.[160,161]

To reduce the chance of introducing bacteria into the peritoneal cavity, paracentesis should not be performed through an area of cellulitis.

Procedure

The presence of ascites must be confirmed prior to paracentesis. While the physical examination findings of flank dullness, shifting dullness, and fluid waves support the presence of ascites, in most circumstances ultrasonography should be performed to confirm ascites prior to paracentesis. Ultrasonography is more sensitive than physical examination in diagnosing ascites, can detect small amounts of fluid, and can differentiate free from loculated fluid.[162] Ultrasound guidance may improve the safety and efficacy of paracentesis.[163,164]

Supplies

Box 15-5 lists the supplies required for diagnostic paracentesis.

Technique

For most critically ill patients, the patient is positioned in semisupine (trunk flexed at the hips and upper torso elevated 30 to 45 degrees) or lateral decubitus position.[158,165] The bladder should be emptied by voiding or catheterization. The

site of needle insertion is selected by physical examination or ultrasound location of ascitic fluid, with the preferred site being in the midline, 2 cm below the umbilicus, in the area of the avascular linea alba. In patients with portal hypertension, the linea alba may become vascularized, so a lateral approach may be preferred to reduce the chance of hemorrhagic complications.[166] A lateral approach can be used in the right or left lower quadrant a few centimeters above the inguinal ligament and lateral to the rectus abdominus muscle.[165] Puncture sites in the area of surgical scars should be avoided due to the risk of underlying bowel adhesions.

The entry site is prepared with antiseptic solution such as chlorhexidine or povidone iodine and is draped in sterile fashion. The skin and peritoneum is infiltrated with lidocaine using a small-gauge needle. After attaching a syringe to a needle or catheter appropriate for the patient's age, the needle is inserted through the site of infiltration while traction is applied to the skin in a caudal direction. Use of this Z-track method of insertion is recommended to prevent a direct linear needle track, which could result in a fluid leak after the procedure is completed. The needle is advanced slowly, using negative pressure on the syringe, until a "pop" is felt as the needle passes through the peritoneum and free flow of fluid into the syringe is noted. A spinal needle, if used, can be secured in place with a free hand or hemostat. An over-the-needle catheter, if used, is advanced into the peritoneal cavity, the needle is removed, and the syringe is replaced. Approximately 20 to 40 mL of fluid is collected for diagnostic evaluation. If fluid return stops or is sluggish, changing the patient's position may be helpful. Following removal of the needle or catheter, direct pressure is applied to the insertion site and then a sterile pressure dressing is applied. When ongoing drainage is needed, a pigtail catheter can be placed using Seldinger technique.

Box 15–5 Supplies for Diagnostic Paracentesis

- Antiseptic solution
- Alcohol preps
- Sterile gauze
- Sterile drapes
- Sterile gloves
- 1% lidocaine with or without epinephrine
- 3- to 10-mL syringe with small-gauge needle for local anesthesia
- 22- to 16-gauge spinal needle or intravenous catheter (22- to 20-gauge needle for small children, 16- to 20-gauge needle for larger children)
- 20-mL (or larger) syringe
- Specimen vials

Complications

Potential complications of paracentesis are few but may include persistent leakage of ascitic fluid, bladder or intestinal perforation, introduction of infection with resultant peritonitis, subcutaneous abdominal wall hematoma, and bleeding.[165,171] Persistent leakage of ascitic fluid can be minimized by using the Z-track method for needle insertion. Ongoing fluid leaks can be managed by closing the defect with a suture or applying cyanoacrylate skin adhesive.[167] Bladder emptying decreases the risk of bladder perforation.[166] The risk of intestinal perforation with subsequent complications is minimal, but is increased in patients with previous abdominal surgical procedures and adhesions. This risk can be minimized by avoiding abdominal surgical scars as the needle insertion site.[168,169] The risk of intestinal perforation can be increased if the bowel is markedly distended (as in bowel obstruction), so in these cases, decompression should be considered prior to paracentesis. Appropriate selection of the needle insertion site

Table 15–2 Characteristics of Ascitic Fluid in Various Conditions

Condition	Clinical Characteristics	Laboratory Findings
Portal hypertension	Straw colored, sterile	Total protein <2.5–3 g/dL WBC <250–500, <1/3 neutrophils
Spontaneous bacterial peritonitis	Cloudy or turbid Gram stain positive <10%, cultures may be negative, single organism*	Neutrophils >250 Total protein <1 g/dL LDH and glucose similar to serum
Secondary bacterial peritonitis	Multiple organisms	Total protein >1 g/dL
Chylous ascites	Milky with recent fat ingestion	WBC 1000–5000, predominately lymphocytes Triglycerides >200 mg/dL, cholesterol >48 mg/dL†
Pancreatic ascites	Turbid, brown or bloody	WBC and total protein increased Amylase and lipase levels > serum Amylase levels may be falsely low in young infants‡
Urinary ascites		Protein <1 g/dL; creatinine >serum§
Malignant ascites	Bloody	Protein and LDH elevated
Nephrotic syndrome	Straw colored	Total protein <2.5 g/dL‡
Tuberculous ascites	Yellow or bloody, may have fibrin clots	Total protein >2.5 g/dL WBC >1000, primarily lymphocytes PCR useful¶

minimizes the risk of bleeding. Visible collateral venous channels on the abdominal wall should be avoided. Strict adherence to sterile technique and avoidance of areas of skin or soft tissue infection decrease the risk of infection. Scrotal edema from fluid dissection through fascial planes following paracentesis has been described, typically in patients with massive ascites.

Interpretation

Analysis of ascitic fluid may not yield a definitive diagnosis but is useful in the evaluation of ascites. Clinical assessment identifies the most likely diagnosis, helps determine which tests which should be ordered, and influences the interpretation of results.[155,170]

Studies that should be obtained include total protein, glucose, albumin, LDH, cell count with differential, Gram stain, and aerobic and anaerobic cultures. Other studies to consider are pH, amylase, triglycerides, bilirubin, creatinine, electrolytes, cytology, and cultures and stains for tuberculosis. Corresponding serum chemistries should be obtained for comparison.

Gram stain should be performed on the cell pellet generated from centrifuged fluid.[155] These measures increase the likelihood of recovering or identifying organisms from infected fluid.

Analysis of the serum-ascites albumin gradient (SA gradient) is useful for differentiating between ascites caused by portal hypertension and ascites resulting from other causes. The SA gradient is calculated by subtracting the albumin concentration of the ascitic fluid from the albumin concentration of the serum. An SA gradient of 1.1 g/dL or higher correlates with portal hypertension with 97% accuracy.[155]

The characteristics of ascitic fluid in various conditions are shown in Table 15-2.

Summary

Needle aspiration of ascitic fluid is a relatively safe procedure when performed with appropriate precautionary measures. Analysis of ascitic fluid obtained by paracentesis is useful in the evaluation of patients with new-onset ascites, chronic ascites with clinical deterioration, or suspected bacterial peritonitis. Ongoing drainage through a catheter placed at the time of paracentesis may improve ventilation in patients with massive ascites or reduce complications secondary to intrabdominal compartment syndrome.

Chapter 16

Pediatric Intensive Care in Developing Countries

Frank Shann, Andrew C. Argent, and Suchitra Ranjit

PEARLS

- In the world's 66 high-income countries, the total annual expenditure on health averaged U.S. $4033 per capita in 2006, which was 175 times the $23 per capita available in the 43 low-income countries.
- Overseas development aid from members of the Organisation of Economic Co-operation and Development amounted to only 0.30% of their gross national income in 2007, which was well short of the United Nations' target of 0.70%.
- More than 98% of all child deaths occurred in developing countries in 2007, and 8.4 million of the 9.2 million deaths in children younger than 5 years were preventable.
- Pneumonia is the most common cause of death in children. It causes approximately one third of all deaths in children younger than 5 years.
- Gastroenteritis is the second most common cause of child mortality. It causes approximately 2 million child deaths every year.
- The diagnosis of tuberculosis may be difficult in children because of the paucity of organisms in sputum and other body fluids. Often treatment for tuberculosis must be started without bacteriologic confirmation of the diagnosis.
- Malnutrition contributes to 56% of child deaths, and 83% of this effect is associated with mild to moderate rather than severe malnutrition.
- When treating severe malnutrition, sodium and water intake should be limited, protein intake should be restricted initially, intravenous administration of albumin should be avoided, and calorie intake should be increased gradually.
- Ideally, every child in the world should have access to an intensive care unit with facilities for endotracheal intubation and mechanical ventilation. No ethical justification exists for providing these treatments to children in rich countries while denying them to children in poor countries.
- Providing intensive care is not in the interests of a child if the prognosis is very poor because such care simply prolongs suffering, and it is not in the interests of health services if such care results in poor utilization of limited resources. If the mortality rate in an intensive care unit is greater than 10%, patient selection probably is inappropriate.
- When mortality in children younger than 5 years is greater than 30 per 1000, many deaths are caused by infections. A high proportion of these deaths can be prevented by immunization and primary health care, which are far less expensive than intensive care.

In the year 2007, 136 million children were born in the world. Of these children, 9.2 million died before age 5 years, with 98% of the deaths occurring in developing countries.[1] If the entire world had an mortality rate for children younger than 5 years equal to that of the developed world, only 0.8 million deaths would occur in this age group each year.[1] Therefore, of the 9.2 million deaths in children younger than 5 years that occur each year, 8.4 million are preventable.

Why Lower Child Mortality Rates?

If too many people already exist in the world, is it sensible to try to reduce child mortality rates? First, this question is always asked about other people's children. Second, reducing child mortality rates is important both for humanitarian reasons and to enable lower birth rates.[2] Governments of poor countries are not able to provide old-age or sickness benefits, so having children who survive to adulthood is crucially important to provide security. To increase their chances of having their children survive when mortality rates are high, people need to have many children. A vicious circle is created because high birth rates perpetuate poverty so that governments cannot provide social security, people need children who survive to adulthood, and birth rates remain high. Therefore reducing child mortality rates is a necessary (but not sufficient) condition for reducing birth rates and slowing the growth of the world's population.[2]

Expenditure on Health

In 2006, 1.3 billion people lived in the world's 43 poorest countries (with an annual gross national income of less than U.S. $976 per capita), with an average total annual expenditure on health of only U.S. $23 per capita.[3] In the world's 66 high-income countries, annual expenditure on health averaged U.S.

$4033 per capita, which is 175 times the amount available in low-income countries.

Child Mortality, Infections, and Intensive Care

Most of the unnecessary child deaths in developing countries are caused by infectious diseases, and most of these deaths can be prevented by immunization and basic primary health care. Figure 16-1 shows the relationship between the mortality rate among children younger than 5 years and the percentage of deaths caused by infection.[4] When the mortality rate among children younger than 5 years is less than 20 per 1000 live births, few deaths are caused by infections, and intensive care can make an important contribution to reduce mortality from noninfectious causes such as congenital heart disease and trauma. As the mortality rate among those younger than 5 years increases from 20 to 30 per 1000, the proportion of deaths caused by infections increases rapidly, and the role of intensive care becomes less clear. When the mortality rate among children younger than 5 years is greater than 30 per 1000, many deaths are caused by infections, and a high proportion of these deaths can be prevented by immunization and primary health care, which are far less expensive than intensive care.

Role of Intensive Care

Optimal use must be made of the limited resources available to treat critically ill children in developing countries. Many lives can be saved with effective use of relatively inexpensive therapies, such as intravenous (IV) fluids, oxygen, antibiotics, thermal control, and good nutrition. However, if we define intensive care as endotracheal intubation with the capacity for mechanical ventilation, publicly funded pediatric intensive care probably has little place in communities with a mortality rate among children younger than 5 years that is greater than 30 per 1000 live births. In the rapidly increasing number of communities with intermediate mortality rates among children younger than 5 years of approximately 20 to 30 per 1000, there is a place for the use of either continuous positive airway pressure (CPAP) or intubation and ventilation for carefully selected patients using basic equipment. When resources are limited, admitting only children who have a good chance of long-term survival is important. If the mortality rate among patients in the intensive care unit (ICU) is greater than 10%, patient selection probably is inappropriate.

The main argument in favor of providing endotracheal intubation and ventilation to children in developing countries is that every child in the world should have access to these therapies. No ethical justification exists for providing intensive care to children in developed countries while denying it to children in poor countries. In addition, educated families in developing countries reasonably demand that their children have access to intensive care.

The main argument against providing intensive care in areas with a high mortality rate is that intensive care diverts scarce resources away from far more effective low-cost interventions such as immunization and primary health care. Skilled staff, in particular, are in short supply in many developing countries; if they are used to provide curative services in urban hospitals, the rural poor are at grave risk of being neglected. Strong arguments exist for providing basic public and primary health care to all children rather than intensive care to a small proportion of children.[5] In addition, intubation and ventilation are difficult to do well. Done poorly, they may actually increase the incidence of mortality. For example, a study in six pediatric ICUs in Mexico and Ecuador found that endotracheal intubation and central venous cannulation were associated with an increased incidence of mortality in low-risk admissions.[6]

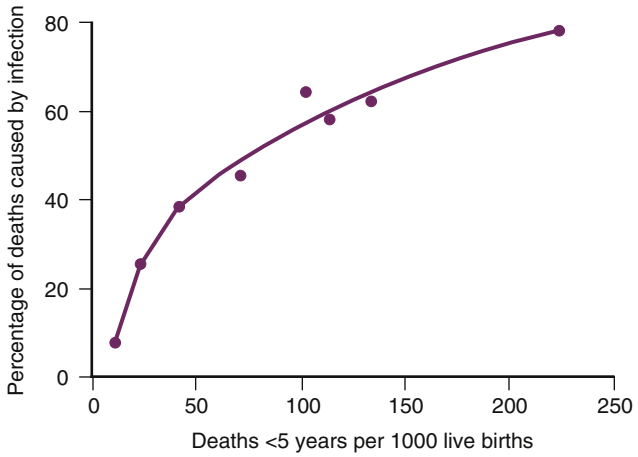

Figure 16–1. Mortality rates in children younger than 5 years and percentage of deaths caused by infection throughout the world. *Data from Murray CJL, Lopez AD:* Global comparative assessments in the health sector: disease burden, expenditures and intervention packages, *Geneva, 1994, World Health Organization.*

Ethical Dilemma

An ethical dilemma exists: children in rich countries have access to intensive care, whereas in poor countries, we can either deny intensive care to children (and perhaps increase the probability that they will be immunized and receive primary health care) or provide intensive care (often at the expense of immunization and primary health care).

This dilemma cannot be resolved while extreme poverty persists in developing countries. Unfortunately, rich countries are doing even less to help now than in the past. Overseas development aid from members of the Organisation of Economic Co-operation and Development amounted to only 0.30% of their gross domestic product in 2007, which was well short of the United Nations' target of 0.70%.[7] Even worse, Organisation of Economic Co-operation and Development member countries now spend more than U.S. $1 billion every day on agricultural subsidies, which is more than six times the amount given in aid and seriously undermines primary producers in developing countries. If developing countries could increase their export share by just 5%, it would generate U.S. $350 billion per year, which is seven times more than the total amount they receive in aid.[8,9]

Causes of Death

More than 98% of all child deaths occur in developing countries, and 8.4 million of the 9.2 million deaths in children younger than 5 years are preventable.[1] Table 16-1 shows that

Table 16–1 Causes of Death in Children Younger than 5 Years in 2005

Cause	No. of Deaths (in Millions)
Pneumonia	2.0
Diarrhea	1.8
Prematurity	1.1
Neonatal sepsis	1.0
Birth asphyxia	0.9
Malaria	0.9
Measles	0.4
Human immunodeficiency virus	0.3
Congenital abnormalities	0.3
Pertussis	0.3
Neonatal tetanus	0.3
Other	1.3
Total	10.6

Data from World Health Organization: *The World Health Report 2005: make every mother and child count,* Geneva, 2005, World Health Organization.

Table 16–2 Approximate Annual Number of Deaths in Children Younger than 5 Years Caused by Individual Pathogens in 1999

Pathogen	No. of Deaths (in Millions)
Pneumococcus	1.2
Measles	1.1
Haemophilus (a, b, c, d, e, f, nonserotypable)	0.9
Rotavirus	0.8
Malaria	0.7
Human immunodeficiency virus	0.5
Respiratory syncytial virus	0.5
Pertussis	0.4
Tetanus	0.4
Tuberculosis	0.1
Hepatitis B	<0.1
Influenza virus	<0.1
Meningococcus	<0.1
Parainfluenza virus	<0.1
Varicella	<0.1
Total	6.7

Data from Shann F, Steinhoff MC: Vaccines for children in rich and poor countries, *Lancet* 354(suppl ii):7, 1999.

most of the deaths are caused by infectious diseases, particularly pneumonia, diarrhea, neonatal sepsis, and malaria, with malnutrition an important contributing factor.[10,11] Table 16-2 shows that the major pathogens are *Streptococcus pneumoniae*, measles, *Haemophilus influenzae*, rotavirus, malaria, human immunodeficiency virus (HIV), and respiratory syncytial virus.[12] The following sections of this chapter discuss individual diseases that are common causes of mortality in children in developing countries, starting with the diseases that cause the most deaths (see Table 16-1). On rare occasions, children with these diseases require intensive care in developed countries. The suggested treatments assume that the child is in a hospital that can deliver a high standard of intensive care. Other hospitals should follow the World Health Organization (WHO) guidelines for the care of children in developing countries.[13-16]

Pneumonia

Pneumonia is the most common cause of death in children. It is the direct cause of 2.0 million deaths each year in children younger than 5 years. It also contributes to mortality from neonatal sepsis, measles, pertussis, and HIV, so pneumonia is an important contributory factor in approximately one third of all deaths in children younger than 5 years.[17,18] A total of 156 million episodes of acute lower respiratory tract infection occur in children each year, 11 to 20 million of which are severe enough to require hospital admission.[17]

Fatal pneumonia in children usually is caused by *S. pneumoniae* or *H. influenzae*. The etiology of pneumonia can be determined accurately only by culture of lung aspirates from children with no antibiotic activity detectable in serum or urine.[19] Most cases of pneumonia in children are caused by aspiration of bacteria from the nasopharynx, and mixed infections with *S. pneumoniae, H. influenzae,* and *Moraxella catarrhalis* are common.[20] *H. influenzae* pneumonia often is caused by nonserotypable strains, as well as by type b and the other serotypes (a, c, d, e, f).[21]

For children who do not respond to penicillin and gentamicin, one should consider differential diagnoses of staphylococcal pneumonia (for which cloxacillin and gentamicin should be administered), HIV infection (often with pneumocystis), chlamydia or mycoplasma (for which azithromycin should be administered), and tuberculosis (see the section in this chapter on tuberculosis).

Antibiotic Treatment

Children with pneumonia who are sick enough to require hospitalization usually should be treated with benzyl penicillin, and they should be treated with benzyl penicillin plus gentamicin if they have very severe pneumonia.[15] The combination of benzyl penicillin and gentamicin has synergistic activity against many strains of *S. pneumoniae* and is always active against *H. influenzae*. Penicillin resistance is *not* an indication for the use of third-generation cephalosporins to treat pneumococcal pneumonia, because they are no more effective than penicillin alone,[22] let alone penicillin plus gentamicin. However, if meningitis caused by a partially resistant strain is present, vancomycin or a third-generation cephalosporin (e.g., cefotaxime or ceftriaxone) should be used if available.

Staphylococcal pneumonia is suggested by a poor response to penicillin and gentamicin, pneumatoceles, pneumothorax, empyema, or associated soft tissue or joint infection. Cloxacillin (or oxacillin, flucloxacillin, or dicloxacillin) and gentamicin given intravenously are appropriate treatments.

Oxygen and Ventilation

Oxygen therapy may be lifesaving in patients with severe pneumonia.[23,24] The most efficient means of administration is 1 to 2 L/min of humidified oxygen via an 8F nasopharyngeal catheter inserted 2 cm less than the distance from the side of the nose to the front of the ear. As well as providing oxygen, this method delivers low levels of CPAP.[25] Care should be taken to (1) remove and clean the catheter every 12 hours, (2) verify that the catheter is not inserted too far (to avoid delivering oxygen into the esophagus), and (3) limit the flow to a maximum of 2 L/min (to avoid distending the stomach). A special low-flow oxygen flow meter with a scale of 0 to 2 or 0 to 3 L/min should be used.

If mechanical ventilation is not available, oxygenation and ventilation can be improved using mask or nasopharyngeal CPAP up to 12 cm H_2O pressure. If endotracheal intubation and mechanical ventilation are available, a sensible plan is to start with low tidal volumes of 6 to 8 mL/kg, positive end-expiratory pressure 8 to 10 cm, inspiratory time 1 second with a rate of 20 to 30 per minute in an infant (assuming no bronchiolitis or asthma is present), and peak pressure less than 30 cm to minimize ventilator-associated lung injury (see Chapters 49 and 50). Failure of the right ventricle may occur as a result of pulmonary hypertension[26]; in this situation, nitric oxide, 5 to 10 ppm (or sildenafil) and high-frequency oscillatory ventilation may be helpful if available.

Fluid Therapy

Patients with pneumonia often exhibit increased secretion of antidiuretic hormone (syndrome of inappropriate antidiuretic hormone secretion),[27,28] and thus children with pneumonia should not be given too much fluid. Hyponatremia usually is caused by excess water rather than sodium deficiency and should be treated by fluid restriction rather than administration of hypertonic saline solution. A small proportion of children with pneumonia have septic shock with capillary leak and hypovolemia, which may be exacerbated by positive pressure ventilation (causing severe hypoperfusion). A helpful procedure in children with this condition may be to insert a central venous catheter and give 10 mL/kg boluses of 4% to 5% albumin or 0.9% saline solution to achieve a central venous pressure of 10 to 12 mm Hg (see Chapters 29 and 103). In the absence of extensive skill and experience, femoral venous catheters are probably the safest to use. Large amounts of fluid initially may be needed to restore the intravascular volume, but thereafter fluid requirements often are only 30% to 40% of normal because the child may have high antidiuretic hormone concentrations.

Feeding

The blood glucose level should be monitored closely and the glucose infusion rate should be adjusted to prevent hypoglycemia. If necessary, 50% dextrose can be infused via the central venous catheter. Continuous small nasogastric feedings should be started from the time of admission as long as no cardiovascular compromise is evident. Full enteral feedings usually can be achieved within 24 to 48 hours. If gastric feedings are not tolerated, nasojejunal feedings may be successful if a nasojejunal tube can be placed (see Chapter 75).

Gastroenteritis

Gastroenteritis is the second most common cause of child mortality. It causes 2 million child deaths every year (see Table 16-1). Particular problems include shock, acid-base abnormalities, electrolyte abnormalities, and secondary bacterial infection.[29] Diarrhea may be a symptom of other disease processes, including sepsis and metabolic abnormalities, so it should not be assumed to be caused by gastroenteritis.

The consequences of fluid loss depend on the rate and the amount of loss. In gastroenteritis, fluid moves from the intravascular space into the gut lumen. Depending on the relative rates of fluid loss and fluid replacement from the extracellular fluid space, patients may be in shock with no clinical signs of dehydration, dehydrated with no features of shock, or dehydrated and in shock. Clinical signs of dehydration occur when approximately 30 to 40 mL/kg of fluid is lost from the body (i.e., 3% to 4% dehydration).[30]

Hypovolemic shock requires immediate and vigorous replacement with isotonic IV fluids. Dehydration can be corrected over 2 or 3 days and usually can be adequately treated with oral ingestion of fluids. The management of dehydration is complicated by the relative inaccuracy of the clinical signs of dehydration (particularly in malnourished or obese children)[30] and by the variable amount of ongoing stool losses (see Chapter 29). During rehydration, the serum sodium concentration should be measured every 4 hours and the rate of fluid and sodium administration adjusted accordingly.

Shock

Shock in patients with gastroenteritis usually is caused by hypovolemia resulting from fluid loss. However, there is a high incidence of bacterial sepsis in patients with severe gastroenteritis. The initial therapy for shock should include provision of oxygen and rapid IV administration of fluid with an electrolyte content similar to plasma (e.g., 0.9% sodium chloride). Shock should be corrected rapidly over 10 to 15 minutes with continuous or frequent assessment of the response. Intraosseous or sagittal sinus vascular access may be required if venous access is difficult.[31] Additional aliquots of fluid should be given under close observation until the patient is normovolemic. Once the patient is normovolemic, inotropic support will be required if the patient still exhibits symptoms of shock. Patients who are hypovolemic from gastroenteritis do not require colloid as volume replacement.

Fluid and Electrolyte Abnormalities

Once intravascular volume has been restored, attention should be paid to the management of the sodium derangements and dehydration (see Chapter 67). Normal hydration should be achieved over 48 to 72 hours. If renal function is normal, the kidneys will resolve most of the electrolyte abnormalities given adequate treatment of shock and gradual replacement of fluid and electrolyte deficits.

Calculation of fluid therapy is more difficult in the presence of ongoing diarrhea, which may amount to 300 mL/kg in 24 hours. Fluid therapy is best monitored using a combination of serial weighing (if accurate scales are available) and electrolyte measurement. If any doubt exists about urine output, a urinary catheter should be inserted to help distinguish between

renal losses and diarrhea. A "metabolic bed" may be used so that stool and urine output can be measured separately. Oliguric renal failure is common, but polyuric renal failure also may occur, particularly in children with severe hypokalemia or hyperglycemia.

Sodium Abnormalities. Hypernatremia may result from excessive water loss, excessive salt intake (usually in poorly constituted rehydration solutions), or a combination of both. It is associated with significant morbidity (especially of the central nervous system) and mortality. Hypernatremia is more common in infancy than in later life and may be associated with the use of formula to feed infants.[3]

Once shock has been treated, the goal of therapy is to reduce the sodium concentration no faster than 0.5 mEq/L/h.[32] Once hypovolemia has been corrected, the remaining fluid deficit should be replaced over 48 to 72 hours using a solution containing approximately 70 mEq/L of sodium.

Hyponatremia may be related to errors of measurement, excessive fluid intake, or excessive sodium loss. Pseudohyponatremia occasionally is seen secondary to hyperlipidemia. Factitious hyponatremia is seen in the context of hyperglycemia or mannitol infusions; measured sodium levels decrease by approximately 1.6 mEq/L for every 100 mg/dL (approximately 5.5 mmol/L) increase in glucose concentration. This factor must be taken into account when calculating fluid management. Severe symptomatic hyponatremia should be treated by giving 4 mL/kg of 3% saline solution intravenously over 2 hours, but the serum sodium concentration should rise by no more than 8 mEq/L on any day of treatment. This rate is ideally monitored with measurement of sodium levels every 2 to 4 hours.

Hypokalemia. Hypokalemia is common in patients with severe gastroenteritis, particularly if rehydration solutions without potassium are used. In the face of bradycardia secondary to severe hypokalemia that is causing poor cardiac output, rapid replacement of potassium may be required to establish a heart rate that is appropriate to the circulatory status of the child. In all other situations, IV potassium supplementation should not exceed 0.5 mEq/kg/h. If polyuria occurs, a safe approach is to provide maintenance fluids and replace urinary losses greater than 2 mL/kg/h with fluid that has an electrolyte content similar to that of the urine.

Hypophosphatemia. Hypophosphatemia is common in patients with severe gastroenteritis and should be treated with IV potassium or sodium phosphate if the child exhibits symptoms. Joules' solution can be provided enterally but may exacerbate diarrhea. Phosphate concentrations less than 0.3 mEq/L usually are associated with severe symptoms and should be treated, but phosphate supplementation is not required with concentrations greater than 0.6 mEq/L unless the child has other associated symptoms.

Metabolic Acidosis. Metabolic acidosis is common in children admitted to the ICU with gastroenteritis. It may be related to hypoperfusion (usually with elevated serum lactate), renal dysfunction with renal tubular acidosis, or ingestion of medication (e.g., salicylates or toxins from traditional remedies). If acidosis persists despite correction of hypovolemia, consider measuring serum lactate and urine ketone levels, excluding the ingestion of toxins such as salicylates and iron, and screening for metabolic disease. Inborn errors of metabolism may be manifested following the stress of an illness such as acute gastroenteritis.

If acidosis is related to excessive loss of bicarbonate via stool or urine, bicarbonate administration may be appropriate. To reduce the risk of sodium overload, a solution of 5% dextrose containing 50 to 70 mEq/L of sodium bicarbonate should be used, with potassium added according to requirements.

Low Birth Weight

Babies born weighing less than 2500 g are said to have a low birth weight. Approximately 1 million low-birth-weight infants die each year (see Table 16-1 and Chapter 46). Small-for-gestational-age births are relatively more common in developing countries than in developed countries. The decision about whether a low-birth-weight baby should be considered premature, small for gestational age, or both is important. Problems associated with prematurity (i.e., babies younger than 37 weeks of gestation) include respiratory distress syndrome, apnea, poor feeding, intraventricular hemorrhage, jaundice, infection, and hypothermia. Problems associated with infants who have a small-for-gestational-age status are intrauterine hypoxia, birth asphyxia, meconium aspiration, hypoglycemia, and infection.

Only the general principles of management of low-birth-weight infants are outlined in this chapter; more detailed information is available elsewhere.[14,33] Vitamin K (1 mg) is administered intramuscularly after birth. The baby should be kept warm (i.e., well wrapped up in a room kept at 27° to 30°C, which is crucially important) and handled as little as possible. Apnea monitors should be used for babies younger than 32 weeks of gestation, and caffeine or aminophylline should be provided if apnea occurs. Cultures are obtained and penicillin and gentamicin administered if there are any signs of infection, including respiratory distress. Use of breast milk and strict handwashing procedures help prevent cross-infection in the nursery. Desaturation can be treated with nasopharyngeal CPAP. Intubation and mechanical ventilation may be helpful if facilities are available, but nasal CPAP is much safer and often is just as effective.[34,35]

Kangaroo care is defined as skin-to-skin contact between the mother and baby with frequent and exclusive or nearly exclusive breastfeeding and early discharge from hospital. Many of the controlled trials of kangaroo care are of poor quality. A Cochrane Review concluded that kangaroo care appears to reduce morbidity, but more well-designed trials are needed.[36]

Breastfeeding on demand is preferred if the baby is active and sucks well. If the baby does not feed well, feeding him or her expressed breast milk with a cup and spoon (not a bottle) is appropriate. If the baby is too weak to feed with a cup and spoon, nasogastric tube feedings are indicated. Close attention to serum glucose is warranted with IV and/or enteral glucose administration as needed to provide 5 to 10 mg/kg/min.

Poliomyelitis, bacille Calmette-Guérin (BCG), and hepatitis B vaccines should be administered before discharge at a time when the baby is fully breast-fed and gaining weight. The mother should be given a solution of ferrous sulfate to give to her child at a dose of 2 mg/kg/day of elemental iron, and follow-up should be scheduled.

Neonatal Asphyxia

Approximately 900,000 infants die every year from asphyxia (Table 16-1).[10,37] This condition may be caused by an hypoxic-ischemic insult during labor or by fetal abnormalities that were present before labor. Asphyxia is more common in small-for-gestational-age babies and carries a grave prognosis in preterm babies. Even if improvement occurs during the first few hours after delivery, the baby should be observed closely for at least 24 hours because rapid deterioration may occur at 6 to 24 hours as cerebral edema develops.

Oxygen should be provided as required to maintain an oxygen saturation greater than 90%. Intubation and mechanical ventilation should be used in the event of airway or breathing compromise and should not be discontinued too early because deterioration may occur 6 to 24 hours after delivery.

Poor cardiac output is common in patients with severe asphyxia because of hypovolemia from capillary leakage and impaired myocardial contractility. Echocardiography may help distinguish among hypovolemia (small left atrium), poor ventricular contractility, and pulmonary hypertension (which should be treated with nitric oxide, if available). After correction of hypovolemia, the total fluid intake initially should be limited to 30 to 40 mL/kg/day.

The baby's temperature should be kept below 37° C. Controlled trials suggest that mild hypothermia with a core temperature of 32° to 33° C is beneficial.[38-40] The blood glucose should be kept in the normal range.

Close surveillance should be undertaken for neonatal sepsis, which can be manifested as asphyxia. Treatment with penicillin and gentamicin is appropriate, and cefotaxime or ceftriaxone should be added if evidence of meningitis is present. Convulsions should be treated with phenobarbital, 20 mg/kg, administered intravenously over 60 minutes. One small study reported that administration of 40 mg/kg of IV phenobarbital to all babies with asphyxia was beneficial,[41] but this treatment may cause dangerous levels of sedation unless ventilation is performed.

Hypocalcemia is treated with IV 10% calcium gluconate, 0.5 mL/kg, over 10 minutes. Corticosteroids are not indicated. Coagulopathy should be treated with fresh-frozen plasma, if available. Vitamin K should be given to all babies. Paralytic ileus and necrotizing enterocolitis are common after severe asphyxia; accordingly, enteral feeds should not be started until bowel sounds are present and the baby passes meconium. Renal failure and hyperkalemia may require treatment with glucose and insulin, an ion-exchange resin enema, or peritoneal dialysis. Babies who do not start to breathe within 48 hours rarely make a good recovery. It is important not to continue treatment if there is no realistic chance of intact survival.

Malaria

Severe malaria is caused by *Plasmodium falciparum*, which is the only species of malaria that causes parasitized erythrocytes to adhere to endothelial cells and produce microvascular disease. At any one time, more than 1 billion people are infected with malaria, and the disease causes 0.9 million deaths each year.[10,42]

Malaria starts with fever, and the patient may exhibit coughing and vomiting. Especially in nonimmune patients, the illness may progress very rapidly over 1 to 2 days, with coma (cerebral malaria), shock, convulsions, anemia, hypovolemia, hypoglycemia, jaundice, respiratory distress, renal failure, and coagulopathy being exhibited.

Diagnosis

The diagnosis is made by examination of thick and thin blood smears (false-negative results may occur with inexperienced staff) or by detection of *P. falciparum* antigen using enzyme-linked immunosorbent assay, polymerase chain reaction (PCR), or immunoassay for parasite lactate dehydrogenase. Commercially available rapid blood tests use a dipstick or test strip with monoclonal antibodies directed against a parasite antigen.[42] They have a sensitivity and specificity greater than 90% for *P. falciparum*.

Severe malaria is present if the patient has severe anemia (hemoglobin <6 g/dL) or hypoglycemia (blood glucose <2.5 mmol/L). In nonimmune patients, severe malaria is present if there is hyperparasitemia (>250,000 parasites/μL or >5% parasitemia), but partially immune patients may have more than 5% parasitized erythrocytes without evidence of clinical illness.

Initial Treatment

Patients exhibiting coma or shock should be intubated and undergo ventilation. Insertion of a femoral venous cannula to allow monitoring of central venous pressure and infusion of drugs should be considered. Hypovolemia should be corrected with 10 mL/kg boluses of 0.9% saline solution; if it is available, 4% to 5% albumin may be preferable to saline solution.[43] If poor perfusion persists despite an adequate central venous pressure, echocardiography may aid in assessing intravascular volume and ventricular contractility (see Chapter 23). Hypoglycemia is common in small children, and their blood glucose concentration should be monitored closely. Convulsions are treated with IV phenobarbital, 20 mg/kg administered over 1 hour, then 5 mg/kg daily.

Routine use of phenobarbital may increase the incidence of mortality in patients who do not undergo ventilation but likely does not do so in patients who do undergo ventilation.[44] Administration of pentoxifylline, N-acetylcysteine, and mannitol probably is not helpful, but use of levamisole may be beneficial.[45]

Antimalarial Drugs

The choice of antimalarial drug depends on which drugs are available and on local drug resistance patterns. The best choice usually is either quinine or artesunate. Evidence suggests that artesunate clears parasites faster than quinine does and increases survival rates,[46] but resistance has been reported recently in Southeast Asia.[47] Patients with severe malaria are infected by a large number of parasites and should always be treated with two antimalarial drugs to reduce the risk of selecting resistant strains with recrudescence of disease.[48]

Artesunate is given in an initial IM or IV dose of 2 mg/kg, then 1 mg/kg/day after 6 hours if the infection is hyperparasitic, then 2 mg/kg daily until the child can swallow.[49,50] When the child can swallow, artesunate should be administered orally. After 7 days of therapy with artesunate, oral mefloquine, 15 mg/kg followed by 10 mg/kg 12 hours later, should be given.

Quinine sulfate (or quinine dihydrochloride) is given in an initial IV dose of 20 mg/kg over 4 hours, then 10 mg/kg is administered intravenously over 2 hours every 12 hours for 7 days.[15] Quinine can be given orally when the child can tolerate it. After 7 days of therapy with quinine, mefloquine, 15 mg/kg orally followed by 10 mg/kg 12 hours later, should be provided.

Quinidine can be used if artesunate and quinine are not available, but quinidine is more likely than quinine to cause cardiac toxicity.[15] Following an IV loading dose of 15 mg/kg quinidine over 4 hours, the drug is administered at a dose of 7.5 mg/kg over 4 hours, every 8 hours, for 7 days. After 7 days of therapy with quinidine, mefloquine, 15 mg/kg orally followed by 10 mg/kg 12 hours later, should be given.

Other Treatment

Bacterial infection is common in children with clinical findings suggestive of cerebral malaria. Following a blood culture, cefotaxime (or penicillin if cefotaxime is not available) and gentamicin are appropriate empirical treatments. Lumbar puncture should be deferred until the child recovers consciousness. Antibiotics are discontinued after 48 to 72 hours if the blood culture is negative and results of a lumbar puncture are normal.

Children with a hemoglobin level of 4 g/dL or less require urgent transfusion with packed erythrocytes. Children with a hemoglobin level of 4 to 6 g/dL should receive a transfusion if they are in a coma or in shock or have more than 10% parasitized erythrocytes.[15,49] Transfusion should occur slowly over 6 hours until a hemoglobin level of 10 g/dL is achieved, taking care to avoid fluid overload in children with severe malnutrition. Use of furosemide is not indicated unless there is evidence of fluid overload (i.e., pulmonary edema with a high central venous pressure). Exchange transfusion, if it can be performed safely, may be beneficial in patients who are in a coma or have renal failure, adult respiratory distress syndrome, or a parasitemia of 10% or more.[51]

No evidence supports the use of corticosteroids,[52] cyclosporin, dextran, heparin, iron chelating agents,[53] or prostacyclin in patients with malaria. The patient should be turned every 2 hours, hypoglycemia should be prevented, and vital signs and fluid balance should be monitored carefully. Acidosis may be associated with severe hyperkalemia initially, but total body potassium often is low and hypokalemia may occur in the recovery phase.

Measles

Despite the effectiveness of measles immunization, more than 400,000 children still die every year as a result of measles (see Table 16-1). It is a devastating viral infection with a case fatality rate up to 30%, particularly in malnourished children. Measles is highly infectious, and its course frequently is complicated by a secondary infection with adenovirus or bacteria.[54,55]

Diagnosis

Measles has a 3- to 5-day prodromal period consisting of coryzal symptoms, fever, cough, and conjunctivitis. Koplik spots develop in the mouth from days 2 to 4. They are seen on the inner surface of the cheeks and have the appearance of salt granules on a red background. A maculopapular rash appears from day 4. The rash starts on the head and neck and spreads to the trunk and the rest of the body over several days. The rash darkens 5 to 6 days after it appears. The skin may peel and have a scaly appearance. Diarrhea is common throughout the early phase of the disease. Upper respiratory tract symptoms may progress to involve the larynx with croup and the remainder of the respiratory system with severe bronchopneumonia.

Persistence of fever for longer than 3 days after the appearance of the rash suggests that there is secondary bacterial infection, often involving the respiratory system. Measles may precipitate features of acute malnutrition. Vitamin A deficiency may be exacerbated by the illness and cause acute xerophthalmia with blindness. An acute allergic encephalitis with demyelination may occur, typically during the second week of the illness as the rash is clearing. Acute measles inclusion body encephalitis may occur and is more common in immunocompromised children. Subacute sclerosing panencephalitis presents some years after the acute infection. Bronchiectasis may be a complication of severe measles pneumonia with secondary infection.

Infection Control

Children are infectious before the rash appears and for up to 7 days after the first symptoms appear. The incubation period is 10 to 12 days. Ensure that all children who came into contact with the infected child have been immunized with measles vaccine. In children older than 4 months, immediate immunization at the time of exposure protects against infection. Younger infants usually are protected by maternal antibodies; however, in communities where maternal antibody levels may be low, every effort should be made to ensure that young infants are not exposed to measles patients, and immunoglobulin should be administered to contacts if possible.

General Measures

The common complications of measles are pneumonia, diarrhea, croup, conjunctivitis, keratitis, xerophthalmia, malnutrition, otitis media, stomatitis, and nosocomial infection.[54,56] Treatment of the acutely ill child includes ensuring adequate oxygenation, obtaining cultures and providing penicillin and gentamicin as needed, and initiating mechanical ventilation. Fluid therapy should be closely tailored to the clinical situation, taking into account factors such as diarrhea and fever. Because hydration status may be difficult to assess clinically, regular weighing facilitates fluid balance assessment. Vitamin A, 200,000 IU/day, should be administered orally for 2 days to reduce mortality and prevent xerophthalmia.[57] Whether immunoglobulin has a role in the treatment of severe measles is not clear.[54] Measles may exacerbate tuberculosis and malnutrition.

Human Immunodeficiency Virus

The vast majority of HIV-infected children are located in the developing world (see Chapter 93). In southern Africa, HIV-related pneumonia is the main cause of admission to hospital[58] and is an important cause of admission to intensive care.[59,60] In the past, children admitted to the ICU with respiratory disease had a very high incidence of mortality, but the rate

has improved gradually with time.[59] Much of the improvement came from the recognition that *Pneumocystis jiroveci* is a major pathogen in these children. Other studies have highlighted the importance of cytomegalovirus, tuberculosis, and bacterial infections, particularly *Staphylococcus aureus*.[58-61]

Little information is available about the long-term outcome of HIV-infected children requiring intensive care in the developing world. However, the impression is that, in the absence of antiretroviral therapy, the majority of these children die within months of being admitted to the ICU. A decision about whether to admit a child to the ICU should be influenced by the medium- to long-term prognosis and not just survival in intensive care.[62] It is not in the interests of a child to provide intensive care if the prognosis is very poor because such care simply prolongs suffering, and it is not in the interests of the health services if such care results in poor utilization of limited resources.

In the absence of antiretroviral therapy, admitting infants with severe infection to the ICU appears to be of limited benefit. However, one consequence of programs directed at reducing maternal-to-child transmission of HIV (using nevirapine or zidovudine) is that the diagnosis of HIV infection in the infant is more complex. Thus there is a place for admitting HIV-exposed (and possibly HIV-infected) infants with severe infection to the ICU while the diagnosis is being established. There is little or no place for prolonged intensive care when the diagnosis of HIV infection is established if antiretroviral therapy is not available. As antiretroviral therapy becomes more generally available in the developing world, the role of intensive care in the management of HIV-infected children will require review.

Pertussis

Pertussis syndrome is caused by *Bordetella pertussis* or *Bordetella parapertussis*. The WHO estimates that 300,000 children die from pertussis each year,[63] but PCR testing has shown that pertussis is much more common than previously thought,[64] so the total number of deaths may be even higher.

The illness starts with rhinorrhea, fever, and a cough that comes in spasms for approximately 10 days until the whoop starts. The cough may last for up to 3 months and recur with subsequent respiratory infections. A large amount of very thick sputum is produced, which may cause a paroxysm of coughing that lasts so long the child becomes cyanotic. After the paroxysm, the child may inspire so strongly that a loud stridor, or whoop, is heard. The cough may be accompanied by expectoration of tenacious mucus or vomiting. Young infants may have no whoop and may present with apnea.[65]

In endemic areas, encephalopathy is common in patients with severe pertussis, and up to one third of infants may present with coma or seizures.[66] The incidence of mortality is high in infants with severe pertussis if the total white blood cell count is greater than 40,000/μL, if they have encephalopathy, or if they need mechanical ventilation for pneumonia. Severe pulmonary hypertension may occur, particularly in children with a white blood cell count greater than 100,000/μL.[67]

Diagnosis

In developing countries, the diagnosis usually must be made on clinical grounds. Pertussis likely is present in children with typical clinical findings who have a lymphocyte count greater than 10,000/μL. Children with a lower respiratory infection and a total white blood cell count of 40,000/μL or more have a high mortality rate, and many of these children probably have pertussis even if they do not have typical symptoms.[68]

Obtaining a culture of *B. pertussis* is difficult, and the sensitivity is low even if the test is performed correctly. Immunofluorescent antibody testing is positive in approximately 80% of cases if the specimen is obtained within 2 weeks of the onset of the cough and erythromycin or chloramphenicol has not been given. PCR for pertussis is sensitive and specific,[64] but the test is difficult to perform and is expensive. In one study, 33% of children with pertussis also had respiratory syncytial virus infection.[64]

Treatment

Antibiotics probably do not alter the course of the illness unless they are given before the paroxysmal cough develops, but they do render the patient noninfectious. In developing countries, chloramphenicol usually is the antibiotic of choice. Chloramphenicol is active against *B. pertussis* and most of the bacteria that cause secondary pneumonia. Erythromycin also is active, but erythromycin stearate is less effective than the estolate and must be given in high doses for 14 days.[69,70] Clarithromycin and azithromycin are highly effective, but they are expensive.[70]

Severe paroxysms should be treated with oxygen and gentle suction. Convulsions can be treated with diazepam, followed by phenobarbital as prophylaxis. The available evidence does not support the use of diphenhydramine, pertussis immunoglobulin, or salbutamol.[71] Four controlled trials of systemic steroid use for pertussis all suggested a benefit, but the studies were not well designed.[72-75] Inhaled steroids appeared to be helpful in one report.[76]

CPAP administered via a nasal mask or prong may be helpful in infants with apnea as an alternative to mechanical ventilation.[77] The prognosis is poor if mechanical ventilation is required for pneumonia in children with pertussis.[78] Exchange transfusion should be considered if the total white blood cell count is more than 100 × 109/L or severe pulmonary hypertension is present.[67]

Tetanus

Tetanus is responsible for 300,000 child deaths each year (see Table 16-1). Most of the deaths result from neonatal tetanus caused by lack of maternal immunization and poor umbilical cord hygiene. Tetanus occurs occasionally in older children with infected wounds but has decreased substantially since the institution of adequate immunization practices. Tetanus toxins affect most body organs and not just the central nervous system. The prognosis depends on age (with higher mortality rates in newborn babies and elderly adults), the source of infection, and delay in treatment.[79] Children with tetanus present with difficulty feeding; trismus; muscle spasms; hypertonicity; convulsions; and autonomic, cardiac, and respiratory instability.

Treatment

If spasms are severe, oxygen should be provided until adequate sedation is achieved with diazepam and chlorpromazine. IV diazepam at a dose of 0.5 mg/kg is administered slowly every

15 to 30 minutes until severe spasms are controlled, and then 0.5 mg/kg is given every 12 hours by nasogastric tube. When given intravenously, diazepam should be diluted 1:20 with 0.9% saline solution and injected slowly over 5 minutes. Diazepam should not be given intramuscularly. After spasms have been controlled with IV diazepam, maintenance doses can be given orally or by nasogastric tube; up to 40 mg/kg/day may be needed as tolerance develops. In addition to diazepam or midazolam, administration of chlorpromazine, 5 mg/kg every 12 hours intramuscularly or by nasogastric tube, is useful. Tracheostomy should be performed in older children with a severe case of tetanus. Paralysis and mechanical ventilation will be needed if severe spasms persist despite heavy sedation.

Autonomic instability may cause large and sudden variations in blood pressure and pulse rate. In patients undergoing ventilation, morphine, 20 to 40 μg/kg/h, may be a helpful addition to diazepam and chlorpromazine. Atropine, clonidine, and magnesium have been used[12] but have not been demonstrated to be superior to careful use of large doses of chlorpromazine, diazepam, and morphine. β-Blockers should not be given.[80]

If human tetanus immunoglobulin is available in IV form, a total dose of 4000 U is recommended, although some centers now use only 500 U. The entire dose can be infused intravenously over 1 hour. Alternatively, 1.5 mL (approximately 100 units) can be administered intrathecally, 1.5 mL can be infiltrated around the umbilicus in patients with neonatal tetanus (after cleaning the stump with hydrogen peroxide), and the remainder can be infused intravenously. If immunoglobulin is given intrathecally, dexamethasone, 4 mg (2 mg in neonates) every 12 hours, should be administered intramuscularly for 5 days. The role of intrathecal administration of tetanus immunoglobulin is unclear,[2] but it may reduce the incidence of mortality if corticosteroids are given as well.[81] If human tetanus immunoglobulin is not available in IV form, 750 units (three ampoules) of intramuscular (IM) human or horse tetanus immunoglobulin on the first day and 500 units on the next 2 days should be given. IM preparations should not be administered by intrathecal injection.

After the site of infection is identified, any necrotic tissue is removed, and benzyl penicillin, 50 mg/kg, is given intravenously every 6 hours. A full course of immunization with tetanus toxoid should be given during convalescence (usually three doses at 2-month intervals).

Tuberculosis

Tuberculosis is common in the developing world. In association with the HIV pandemic, there has been an increase in the incidence of tuberculosis and multidrug-resistant tuberculosis. Most children with tuberculosis do not require intensive care. However, tuberculosis may be an unexpected additional finding during an ICU admission, or it may be the cause of an ICU admission. In one pediatric ICU, tuberculosis was not initially considered as a diagnosis in 30% of eventually confirmed cases.[82] In general, the sputum of children does not contain a large number of *Mycobacterium tuberculosis* organisms, so children are rarely a source of infection. However, in the ICU, children who have *M. tuberculosis* in the sputum may constitute a risk to staff because sputum is aerosolized from an endotracheal tube during suctioning. In the case of young children, the risk of at least one parent being infected is high. In one series of infants younger than 3 months with tuberculosis, 42% of the index cases identified by history were parents, and 30% of the mothers had previously unsuspected pulmonary tuberculosis.[83] Patients' relatives may be a source of infection for staff and other hospital patients.[84] If a child presents with tuberculosis, the public health authorities must be informed, the source of the infection investigated, and appropriate therapy instituted. Children are rarely the source of infection, whereas adults with tuberculosis are highly infectious.

Pathophysiology

In children, tuberculosis usually results from primary infection with *M. tuberculosis* inhaled into the lungs. The organism spreads into the lymphatic system and the mediastinal lymph nodes (setting up the primary focus) and then via the thoracic duct into the bloodstream, with hematologic dissemination throughout the lungs (miliary tuberculosis). Spread to the rest of the body may occur from erosion of the pulmonary vessels and subsequent dissemination via the systemic circulation.

Diagnosis

The diagnosis of tuberculosis may be difficult in children because of the paucity of organisms in sputum and other body fluids. Often treatment for tuberculosis must be started without bacteriologic confirmation of the diagnosis. However, particularly when resistant tuberculosis is possible, every effort should be made to isolate the organism from sputum, body fluids, tissue biopsy, or culture of the suspected sources of infection. Gastric lavage has been shown to be superior to bronchoalveolar lavage,[85] and inducing the expulsion of sputum may be superior to gastric lavage.[86] Table 16-3 summarizes the diagnostic approaches to tuberculosis.

Chest x-ray films showing a miliary pattern, a typical Ghon focus with associated lymphadenopathy, or more diffuse consolidation are strongly suggestive of tuberculosis. Pleural effusions are common, especially in older children. A computerized tomography scan of the chest demonstrates typical lymph nodes with rim enhancement after contrast administration.

Tuberculin tests can be used to aid diagnosis. False-negative results frequently occur in children with malnutrition, immune compromise, overwhelming disease, or recent significant illness. Induration of more than 10 mm at the site of tuberculin administration suggests infection in children who have not received BCG vaccination, whereas induration of more than 15 mm suggests infection in children who have received BCG vaccination.

Presentation to the Intensive Care Unit

Children with tuberculosis who require intensive care usually have an infection of the respiratory tract; however, central nervous system disease or abdominal complications also may cause critical illness. In areas where tuberculosis commonly occurs, the diagnosis should be considered in any child with

Table 16–3 Investigation for Tuberculosis in Children

Investigation	Technique	Problems and Possible Benefits
Gastric lavage	Lavage of the stomach with a variable volume of 0.9% saline solution	Should be performed when the patient has not fed for several hours to avoid contamination of specimen with food; not applicable once patient has been intubated because theoretically the sputum will be removed by suction and will not be swallowed; relatively noninvasive
Induced sputum	Aspirate of the nasopharyngeal secretions following nebulization with 5% saline solution; generally, patients should be given salbutamol prior to nebulization to decrease the risk of bronchospasm related to the hypertonic saline solution	Potential risk to staff because organisms can be nebulized to environment with coughing; better yield than gastric lavage
Bronchoalveolar lavage	Bronchoalveolar lavage of affected areas of the lung	Patient requires general anesthesia; technically difficult and requires expensive equipment if a particular area of the lung is lavaged; can be conducted nonbronchoscopically, but a particular area of the lung cannot then be lavaged; yield not as good as with gastric lavage

acute pneumonia that does not respond to therapy as expected. Radiologic changes in the lung may be surprisingly extensive for the severity of lung disease in patients with tuberculous bronchopneumonia.

Acute respiratory distress syndrome is a well-recognized complication of miliary and bronchogenic tuberculosis in adults but is less common in children.[87-93] Some reports have suggested that steroid therapy may be useful for persons with acute respiratory distress syndrome with miliary tuberculosis, whereas other reports suggest the outcome is worse. No randomized trials on steroid therapy for persons with acute respiratory distress syndrome with miliary tuberculosis have been performed.

Lower Airway Obstruction

Intrathoracic lymph node tuberculosis may cause severe airway obstruction as a consequence of external compression of the airways by circumferential lymph nodes, erosion of the bronchial wall with extrusion of caseous material into the bronchial lumen, or a combination of both. Clinical presentation of airway compression by lymph nodes includes features of lower airway obstruction and a "klaxon cough." Typically a wheeze that is worse on expiration, particularly with forced expiration, is heard. The trapping of air is less than expected based on the severity of the wheeze.

Acute obstruction may be temporarily relieved by use of inhaled epinephrine, and administration of steroids may ameliorate the symptoms.[94] If the airway obstruction does not resolve with steroid therapy or if the obstruction is so severe that supportive ventilation is required, relief may be achieved by surgical intervention.[95-98] Surgery should be preceded by bronchoscopy to define the site of compression and to remove any endobronchial material that is contributing to the obstruction. If the lymph nodes are compressing the trachea or major bronchi, surgical decompression may dramatically relieve symptoms; however, if segmental bronchi are being compressed, surgery is less likely to relieve the symptoms. Surgery usually is effective if the nodes are filled with fluid material. Relieving obstruction caused by hard caseous nodes with extensive surrounding fibrosis often is difficult.

Bronchoesophageal Fistula

An acquired bronchoesophageal fistula can be caused by erosion of peribronchial lymph nodes into both the esophagus and a bronchus.[99,100] The fistula may present either with features of bronchial aspiration of swallowed material and associated coughing or with respiratory failure. Ventilation in this situation is complicated by the constant leak of air from the bronchus into the esophagus and gastrointestinal tract. Fistulas from the esophagus into the pleural space have been described.

Laryngeal Tuberculosis

Tuberculosis may cause laryngeal obstruction, particularly in the setting of HIV infection.[44] In one study, laryngeal tuberculosis accounted for 15.8% of episodes of laryngeal obstruction in HIV-infected children admitted to the ICU.[101] Clinical features include hoarseness and laryngeal obstruction.

Tuberculous Meningitis

Children with tuberculous meningitis usually present to the ICU with a depressed level of consciousness or status epilepticus (see Chapter 65). A lumbar puncture should not be performed on a child who has a depressed level of consciousness, but a computerized tomography scan should be performed to determine if hydrocephalus, cerebral edema, or a mass lesion is present. The typical cerebrospinal fluid features include an increased cell count (usually >500/μL with predominantly lymphocytes, although neutrophils may predominate early in the disease); absence of other bacteria; and high protein levels, relatively low sugar levels, and low chloride levels. Hyponatremia is common because of increased secretion of antidiuretic hormone (which occurred in 71% of cases in one study).[102] Therapy should be started with high-dose antituberculous therapy and

Table 16–4 Drugs Used to Treat Tuberculosis in Children

Drug	Usual Daily Dose	Comment
FIRST-LINE THERAPY		
Isoniazid	10-15 mg/kg orally (max 300 mg), IV or IM	Part of usual three-drug regimen; has marked effect on rapidly dividing organisms dividing cells
Rifampicin	10-15 mg/kg (max 600 mg) orally or IV over 3 hours	Part of usual three-drug regimen; has significant postantibiotic effect
Rifabutin	Dosing for children not established	
Rifapentine	Dosing for children not established	
Pyrazinamide	15-30 mg/kg (max 2 g) orally	
Ethambutol	25 mg/kg orally (max 2.5 g); give 80% of oral dose if given IV	Can be used in young children if resistant organisms suspected; older children should undergo regular visual testing during therapy
SECOND-LINE THERAPY		
Cycloserine	10-15 mg/kg orally (max 1 g)	
Ethionamide	15-20 mg/kg orally (max 1 g)	
Streptomycin	20-40 mg/kg (max 1g) IM	
Amikacin or kanamycin	15-30 mg/kg (max 1 g) IM or IV daily; drug level monitoring essential	
P-aminosalicylic acid (pas)	200-300 mg/kg (max 10 g) in 2-4 divided doses orally	

IM, Intramuscular; *IV,* intravenous.

steroids.[103] Antituberculous drugs such as rifampicin may accelerate the metabolism of steroids, and a high dose may be required.

Tuberculous Pericarditis

Tuberculous pericarditis is an uncommon complication. Occasionally children present with features of shock. The most common presentation consists of long-standing symptoms of illness with some features of pericardial tamponade.[104] Tuberculous pericarditis requires urgent drainage only in cases of significant symptoms or diagnostic concerns. Antituberculous therapy should be started early, and steroids should be given to patients at risk of having constrictive pericarditis develop.[105,106]

Miliary and Abdominal Tuberculosis

Miliary tuberculosis is relatively rare in the ICU but may be associated with tuberculous meningitis and the development of acute respiratory distress syndrome. Abdominal tuberculosis is characterized by marked abdominal lymphadenopathy with associated malabsorption, gut obstruction, or protein-losing enteropathy.

Treatment Regimens

For patients with drug-susceptible tuberculosis, the usual treatment starts with isoniazid, pyrazinamide, and rifampicin,[107] but starting with just isoniazid and rifampicin is acceptable if use of pyrazinamide is contraindicated. If drug resistance is likely, ethambutol or streptomycin should be added. For children diagnosed with tuberculosis during an intensive care admission a daily treatment regimen usually is begun, although treatment subsequently may be given only two or three times per week. One (non-ICU) study showed that therapy with three drugs administered two times per week from the start was as effective as daily therapy.[108]

Many drugs interact with antituberculous therapy, and great care must be taken with all other medications given, particularly anticonvulsant agents, theophylline, paracetamol, antiretroviral drugs, and steroids.[109]

Metronidazole is not a first-line antituberculous agent; however, it has a marked effect against dormant M. tuberculosis under anaerobic conditions. One report from India showed significant improvement in clinical outcome when metronidazole was added to conventional therapy for adults with pulmonary tuberculosis.[110] Steroids may be useful in patients with tuberculous meningitis and when intrathoracic airways are compressed by tuberculous lymph nodes. Table 16-4 summarizes characteristics of tuberculosis antimicrobial drugs.

Poor absorption of drugs from the gastrointestinal tract may occur in critically ill children, especially those with abdominal tuberculosis. If there is doubt about the absorption of medication from the gut, rifampicin and isoniazid should be administered intravenously. Liver toxicity may occur, with adverse effects ranging from mild elevation of transaminases to acute severe hepatic failure and death. All the first-line antituberculous drugs have a marked postantibiotic effect, and daily administration is not essential.

Diphtheria

Diphtheria is an acute infectious disease caused by toxigenic strains of *Corynebacterium diphtheriae*. Since the introduction of immunization, the incidence of diphtheria has decreased

dramatically; however, the WHO estimated that the disease still caused 4000 deaths in children in 2004.[111] Colonization of chronic skin sores by *C. diphtheriae* often induces immunity; as standards of hygiene improve and chronic skin sores become rare, clinical diphtheria becomes more common unless it is prevented by immunization.

The organisms are transmitted by contact or droplet spread. After an incubation period of 2 to 4 days, the organisms invade the pharynx in 90% of pediatric cases, but they may infect the nose, mouth, or skin. Satellite lesions may occur in the stomach, esophagus, or lower airways.[112] Bronchial involvement mimicking bacterial tracheitis has been described.[113]

Course During the First Week

Nasal diphtheria initially may be indistinguishable from the common cold but later may be characterized by a serosanguineous nasal discharge, white patches on the septal mucosa, and erosions on the upper lip. Toxemia usually is mild. Pharyngeal diphtheria is characterized by the development of a pseudomembrane composed of sloughed mucosa plus an inflammatory exudate of neutrophils, fibrin, and bacterial colonies. The membrane typically forms over one or both tonsils and may extend throughout the nasopharynx, oropharynx, and soft palate and down into the larynx. The pseudomembrane initially is white and changes to a dirty gray over time. It is associated with intense underlying inflammation, and attempts to remove the pseudomembrane cause bleeding. The intense inflammation may obstruct the airway, and occasionally the entire pseudomembrane sloughs off and causes airway obstruction.[112] Pharyngeal diphtheria usually is associated with severe toxemia and the development of enlarged cervical lymph nodes with associated edema (bullneck).

Laryngeal and tracheobronchial diphtheria can be primary infections or extensions of pharyngeal lesions. These lesions are relatively rare but can cause severe airway compromise and are associated with severe toxicity.[112] Oral lesions in adults have been described but are rare in children. Skin involvement with formation of slough may occur at any site; toxicity, if present, is mild.

During the initial phase of the illness, systemic features such as pyrexia and toxemia are caused by absorption of toxin from the inflammation site. Disseminated intravascular coagulation, acute renal damage, and acute cardiac failure may occur.[114-116] Fever and toxemia usually resolve after approximately 1 week.

Subsequent Course

During the second or third week of the illness, myocarditis and neurologic problems may occur if the toxin has not been inactivated by administration of antiserum. Myocarditis has been described in 10% to 20% of patients presenting with oropharyngitis. The mortality rate associated with diphtheritic myocarditis ranges from 14% to 60%.[117] Clinical features include rapid onset of cardiac failure with cardiac gallop, muffled heart sounds, and apical murmurs; rhythm disturbances, including sinoatrial node dysfunction, extrasystoles, atrial flutter, atrial fibrillation, nodal rhythm, and ventricular tachycardia; and conduction abnormalities with bundle branch and atrioventricular block. Conduction abnormalities on electrocardiogram were a marker of severe myocardial damage and poor prognosis in one study.[118] A wide range of electrocardiographic changes is seen in persons with myocarditis, ranging from ST-segment changes to extensive infarctlike patterns.[119] On echocardiography, left ventricular dilatation with poor function but retained muscle mass has been described. Biochemical features of myocarditis include increased serum myoglobin, lactic dehydrogenase, and creatine phosphokinase.

Neurologic complications usually occur between 10 days and 3 months after the onset of oropharyngeal disease. Palatal palsies with difficulty swallowing are a common complication during the first 3 weeks of illness. Paralysis of the diaphragm, eye muscles, and skeletal muscles may occur up to 3 months after the onset of disease. Examination of affected nerves has shown degeneration of the myelin sheaths and axon cylinders.[112]

Diagnosis

Early diagnosis and treatment are important for limiting the effects of toxin and minimizing the severity of illness. The initial symptoms are those of any upper respiratory tract infection, but the presence of toxemia with a membrane on the pharyngeal surface in an unimmunized child (or a child immunized in a program in which the refrigeration chain may not have been maintained) should alert the clinician to suspect diphtheria. The organisms can be cultured from a portion of the membrane or from a swab taken from under it. The presence of diphtheroids on Gram's stain is not sufficient evidence of infection; complete cultures should be performed. The presence of an antibody titer to diphtheria toxin may help confirm the diagnosis.

Antibiotics

Penicillin, 50 mg/kg administered intravenously every 4 hours, is a first-line therapy. Once the toxemia settles, a change to intramuscular procaine penicillin, 25,000 to 50,000 units/kg/day or oral phenoxymethylpenicillin, 12.5 mg/kg every 6 hours, is appropriate.[15] Erythromycin is an alternative for patients allergic to penicillin, but some strains of the organism are resistant.[120]

Antitoxin

Antitoxin should be administered as soon as the condition is suspected. Clear evidence exists that mortality rates are higher in children who receive antitoxin late. The antitoxin is made in horses, and a test dose should be given to assess for possible allergy. Diphtheria antitoxin may be difficult to obtain. In the United States, the antitoxin is available only through the Centers for Disease Control and Prevention. In some other countries, less purified antitoxin is available but cannot be given intravenously. The dose of antitoxin is related to the severity of the disease and not to the size of the patient, as shown in Table 16-5.

Supportive Care

Oxygen administered via face mask or nasal prongs should be provided if the child has an oxygen saturation less than 92% in room air. Use of nasal or nasopharyngeal catheters is not advisable because they may precipitate airway obstruction. Performing a tracheostomy may be preferable to endotracheal

Table 16–5 Doses of Antitoxin Used to Treat Diphtheria

Severity of Disease	Dose
Mild disease (nasal and tonsillar)	20,000 U IM
Moderate disease (laryngeal with symptoms)	40,000 U IM or IV
Moderately severe (nasopharyngeal with symptoms)	60,000–100,000 U IV
Malignant disease (combined sites or delayed diagnosis)	60,000–100,000 U IV

IM, Intramuscular; *IV,* intravenous.

intubation if airway obstruction is evident.[121] If endotracheal intubation is attempted, gas induction should be used and great care must be taken not to dislodge pieces of the membrane into the trachea and obstruct the airway. Administration of dexamethasone may help decrease airway edema and relieve obstruction,[114] but it does not reduce the incidence of cardiac and neurologic complications.[122] Palatal palsies that make swallowing difficult may develop, and nasogastric tube feeding may be needed for some time. Patients must be regularly monitored for 3 months after the acute illness because neurologic problems may persist during this time.

Cardiac

Carnitine may have a role in therapy for patients with diphtheria carditis. Animal data and a randomized controlled trial show a decreased incidence of myocarditis and its complications when carnitine is administered.[50,123] Cardiac support may dictate use of inotropes and optimization of preload with diuretics or IV fluid. Ventricular pacing may improve the outcome in children with diphtheritic myocarditis and associated heart block, although one study reported that all patients with third-degree heart block died despite the use of a pacemaker.[118] Prolonged cardiac follow-up may be indicated because there may be a considerable delay between onset of symptoms and development of cardiac dysfunction.[124] Recovery from myocarditis may require more time than previously appreciated.[125]

Prevention of the Spread of Disease

All hospital staff in contact with children with diphtheria should be fully immunized. When possible, patients should be isolated. Alternatively, only fully immunized children should be housed in the same area of the ward. All the patients' contacts must be investigated for the possible presence of diphtheria by obtaining throat swabs and checking immunization status. Patients who have recovered from diphtheria should be immunized with diphtheria toxoid; the dose depends on the patient's age and immunization status.[126]

Dengue

Dengue is an acute febrile illness caused by four different dengue viruses transmitted by Aedes mosquitos (principally *Aedes aegypti*). Dengue symptoms include fever, myalgia, arthralgia, rash, leukopenia, and lymphodenopathy.[127] Dengue usually causes a nonspecific febrile illness. However, it also causes dengue hemorrhagic fever and dengue shock syndrome; the latter is characterized by increased vascular permeability.[127] The risk of severe dengue is greater with the second infection, especially in children. Associated thrombocytopenia, spontaneous bleeding, and disseminated intravascular coagulation are common. Severe dengue is one of the most common causes of pediatric admission to hospitals in Asia, with up to 500,000 cases reported annually to the WHO.[127] Dengue shock syndrome usually occurs between days 3 and 5 of the illness. The risk of death is highest when the pulse pressure is 10 mm Hg or less at the time of presentation.[128]

Fluid Therapy

The main treatment for dengue shock syndrome is prompt, vigorous fluid therapy. Boluses of 20 mL/kg of 0.9% saline solution should be given every 15 minutes until the pulse pressure is at least 30 mm Hg. No evidence exists that colloids are superior to crystalloids for resuscitation, although colloids are often used for severe dengue shock.[129] After resuscitation, normal maintenance doses of fluid are given, with extra boluses of 10 mL/kg if the pulse pressure falls below 30 mm Hg.

Other Treatment

Because of severe capillary leakage, pleural effusion and ascites are common in patients with severe dengue. However, because of the risk of bleeding, centesis should not be undertaken unless fluid accumulation is causing severe respiratory or circulatory embarrassment.[130] A small proportion of children do not respond to aggressive fluid therapy. Patients in respiratory distress may require administration of oxygen and nasal CPAP or mechanical ventilation.

The risks of central venous line insertion usually are greater than the benefits, but if shock persists despite vigorous fluid therapy, a central venous catheter should be inserted if this procedure can be done safely. The risk of bleeding can be reduced by using a femoral venous line. Central venous pressure should be maintained at 10 to 12 cm H_2O. However, if severe lung disease is causing right ventricular failure, central venous pressure may be normal or high even though the child is in a hypovolemic state. In these circumstances, echocardiography should be performed to assess left atrial size (as a measure of intravascular volume) and to locate evidence of impaired ventricular contractility. Hypovolemia should be corrected, and dobutamine, 5 to 15 μg/kg/min, should be administered if ventricular contractility is poor. Bleeding can be severe and often is associated with platelet dysfunction and intravascular coagulation; administration of low-dose heparin, 10 to 15 units/kg/h, and fresh-frozen plasma may be helpful. Platelets should be transfused only if the count is less than 20,000/mm^3 to 40,000/mm^3 with significant bleeding. IV administration of immunoglobulin, 500 mg/kg/day for 5 days, may decrease the rate of bleeding and increase the platelet count. Renal failure may require hemofiltration or peritoneal dialysis. Coma usually results from hypoxic-ischemic injury, cerebral edema, intracranial hemorrhage, or intravascular coagulation, but occasionally it is caused by dengue encephalitis. Corticosteroids and carbazochrome should not be used routinely to treat dengue.[131-133] A report of a single case from

From World Health Organization: *Pocket book of hospital care for children: guidelines for the management of common illness,* Geneva, Switzerland, 2006, World Health Organization, p 176.

Tahiti has suggested that desmopressin may reduce capillary leakage in patients with severe dengue.[73]

Malnutrition

Malnutrition contributes to 56% of child deaths, and 83% of this effect is associated with mild to moderate rather than severe malnutrition.[11] The WHO has published detailed guidelines regarding the management of severe malnutrition for physicians and health workers at the first-referral level (Table 16-6),[15,16] and useful summaries of the management of malnutrition have been published.[134-137]

Severe malnutrition is defined as nutritional edema (kwashiorkor), severe wasting with weight-for-height more than three standard deviations below the median (marasmus), or severe stunting with height-for-age more than three standard deviations below the median.[16] Although improvements in the management of severe malnutrition have lowered the mortality rate from higher than 50%, it remains high, even with intensive management. Kwashiorkor now appears not to be caused by protein deficiency but rather by antioxidant deficiency.[138]

A diagnostic workup for malnutrition should include determination of a blood glucose level, a blood film for malaria, determination of a hemoglobin level, microscopy and culture of urine, microscopy of feces (blood suggests dysentery; Giardia lamblia cysts or trophozoites may be present), a chest x-ray film, and a Mantoux test. Measurement of serum proteins and electrolytes rarely is helpful and may lead to inappropriate therapy. Testing for HIV depends on local circumstances.

Malnutrition mimics many of the clinical signs of dehydration (e.g., sunken eyes, poor skin turgor, and apathy). Malnourished children often have excess body water and sodium, and giving them too much fluid is dangerous. On the other hand, severe sepsis in a malnourished child may be present with remarkably few clinical signs. In particular, no fever may be present, and the mortality rate is high in afebrile patients with malnutrition and sepsis. If the child exhibits shock, hypovolemia should be corrected with 10 mL/kg boluses of 0.9% saline solution (not albumin). Once hypovolemia is corrected, care should be taken not to administer excess sodium and water intravenously. Nasogastric feeding should be used whenever possible; use of IV fluids should be avoided.[15] Benzyl penicillin and gentamicin should be given parenterally after obtaining cultures. The child should be maintained in a normothermic state. The blood glucose level initially should be measured every 4 hours, and hypoglycemia should be treated promptly. Diuretics should not be given for treatment of edema.

The level of total body sodium is high in persons affected with malnutrition, even in the presence of hyponatremia, and thus sodium intake should be restricted. Deficiencies of potassium, magnesium, zinc, copper, selenium, iodine, vitamin A, and folic acid must be corrected immediately. Usually, correction of these deficiencies is best accomplished with the oral or nasogastric administration of an electrolyte solution.[15,135] Iron supplements should be given orally only when the child starts to recover (after the first week of treatment).

After the initial correction of hypovolemia and replacement of any continuing losses, water intake should be limited to 100 to 130 mL/kg/day. Hypoosmolar feedings should be given initially, with a moderate calorie intake of 80 to 100 kcal/kg/day, and protein intake should be restricted to 1.0 to 1.5 g/kg/day.[15,16,135] Albumin should not be given intravenously for treatment of hypoalbuminemia because the liver has a reduced capacity to metabolize protein in malnourished children.[16] Feedings usually are given every 2 hours for the first 2 days, every 3 hours on days 3 to 5, and every 4 hours thereafter. Appetite usually returns after the first 5 to 7 days. The strength of the feedings then can be increased gradually to supply 150 to 220 kcal/kg/day and protein can be increased to 4 to 5 g/kg/day, but fluids still are limited to 130 mL/kg/day.

During treatment of severe malnutrition, sodium and water intake should be limited, protein intake should be restricted initially, administration of IV albumin should be avoided, and calorie intake should be increased gradually. Deficiencies of potassium and magnesium should be corrected early, with empiric antibiotic therapy given and care taken to prevent hypoglycemia and hypothermia.

Conclusion

Ideally, every child in the world should have access to an ICU with facilities for endotracheal intubation and mechanical ventilation. No ethical justification exists for providing these treatments to children in rich countries while denying them to children in poor countries. However, attempting to make intensive care available to all children while many extremely poor countries have so little money to spend on health care is not helpful.

In countries in which the mortality rate in the first 5 years of life is greater than 30 per 1000 live births, most deaths are caused by infections. Using government funding to provide intensive care actually might increase the mortality rate if such care diverts resources away from immunization and primary health care. When the mortality rate for children younger than 5 years is between 20 and 30 per 1000, limited use of intubation and ventilation for carefully selected indications may

have a role. When the mortality rate for children younger than 5 years is less than 20 per 1000, fewer deaths can be prevented by immunization and primary health care, and intensive care can make an important contribution to further reducing child mortality rates.

Self-Assessment Question 1

Which one of the following statements is *not* true?

A. Pneumonia contributes to about one third of all child deaths.
B. Fatal pneumonia in children is usually caused by *S. pneumoniae* or *H. influenzae.*
C. Children with very severe pneumonia should be treated with ceftriaxone (or cefotaxime) if it is available, rather than benzyl penicillin (or ampicillin) and gentamicin.
D. After correction of hypovolemia, most children with pneumonia should be given *less* fluid than a normal child.

Statement C is false.[13,22] *Pneumonia contributes to approximately a third of child deaths, fatal pneumonia is usually caused by* S. pneumoniae *or* H. influenzae, *and maintenance water requirements are often reduced because of increased levels of antidiuretic hormone.*

Self-Assessment Question 2

Which one of the following statements is true?

A. In a child with gastroenteritis, the presence of abnormal tissue turgor, poor peripheral perfusion, or hyperventilation suggests greater than 5% dehydration.
B. Hypovolemia caused by acute diarrhea should be treated with 4% albumin, if available, rather than saline solution to reduce third-space fluid loss.
C. Children with diarrhea and malnutrition may have septicemia and should be treated with penicillin (or ampicillin) and gentamicin even if they are afebrile.
D. Children with diarrhea and malnutrition have large deficits of albumin, sodium, and water and should be given 4% albumin in saline solution at 10 mL/kg/h for the first 6 hours.
E. Hypernatremic dehydration is very dangerous, and the serum sodium should be reduced by at least 2 mmol/L every hour using 0.2% saline solution in 4% dextrose.

Statement C is true.[13] *These clinical signs of dehydration are evident with 3% to 4% dehydration*[30]*; dehydration caused by acute diarrhea should be treated with crystalloid rather than colloid,*[13] *administration of sodium and albumin may cause heart failure in persons affected by malnutrition,*[135] *and the serum sodium should fall no faster than 0.5 mmol/L/h in persons with hypernatremia.*[32]

Chapter 17

Educating the Intensivist

Mary W. Lieh-Lai, Denise M. Goodman, Melinda Fiedor Hamilton, and Kevin M. Valentine

PEARLS

- The principles of adult learning and how they relate to fellowship training are discussed.
- These principles include the influence of the learner's current experience and knowledge and the self-directed and autonomous nature of adult learners.
- The motivation for adults to learn comes from both intrinsic and extrinsic factors.
- Adults learn best by active participation and practice in educational activities.
- To improve practice, adult learners need timely feedback and reinforcement.
- Skill acquisition in medicine is similar to the continuum of human developmental stages with learning that progresses from novice, advanced beginner, competent, proficient, expert, and finally, master.
- The mature clinician is one who reflects upon his or her daily medical experiences to place them in a larger context of previous encounters and critically evaluates his or her own performance, acknowledging both effective and ineffective aspects of patient care.

Pediatric critical care medicine is a discipline dedicated to the care of the critically ill child. It focuses on the sick child as a whole and takes into account the impact of disease on all organ systems, addressing the physical, mental, and emotional needs of the child and those of his or her family as well. The education and training of pediatric intensivists are focused on patient care principles that include resuscitation, advanced life support, management of traumatic injury, postoperative care, application of all modes of mechanical ventilation, renal replacement therapy, cardiovascular support, hemodynamic and neurologic monitoring; management of poisonings, pulmonary, hematologic/oncologic, and metabolic disorders; pharmacologic principles; transplantation; procedural sedation; and infectious diseases. However, the complex needs of the critically ill child also require that intensivists be prepared to assume a leadership role in the coordination of this care among persons from multiple disciplines who are part of the team. In addition, the pediatric intensivist has to develop an understanding of the ethics of critical care medicine and be able to balance complex and high technology care with humanistic principles and respect for the patient as a human being. The intensivist must also develop skills for evaluating medical literature that reports clinical and/or basic science research and develop the ability to teach learners of different levels effectively.

Requirements

The American Board of Pediatrics

The required elements for the education and training of pediatric intensivists in patient care have been defined over time and continue to evolve (see Chapter 1 for the history of the specialty). The American Board of Pediatrics (ABP) has developed a list of content specifications for the subspecialty examination. While this list is not intended to serve as a curriculum, the pediatric intensivist sitting for the examination is expected to be familiar with more than 2000 items listed on 169 pages. The Pediatric Critical Care Medicine Content Outline has 16 sections that include the following: cardiovascular, respiratory, neurology and neuromuscular, infectious disease, immunology and inflammation, renal and electrolytes, metabolism and endocrinology, hematology/oncology, gastroenterology/nutrition, poisonings, toxins and overdoses, trauma and burns, pharmacology, anesthesiology and postoperative care, technical procedures, principles of monitoring, special critical care issues, and core knowledge in scholarly activities. To qualify for the ABP subspecialty examination, applicants are required to have certification in general pediatrics, to have completed training in critical care medicine in a program accredited by the Accreditation Council for Graduate Medical Education (ACGME), and to provide evidence of meaningful research during training.

The Accreditation Council for Graduate Medical Education

Pediatric critical care medicine is one of the accredited subspecialties of the ACGME. As such, oversight for the training programs is provided by the Pediatric Review Committee. In addition to meaningful scholarship by faculty members and trainees, requirements for program accreditation include faculty credentials such as subspecialty board certification, an active role in the training program, and research productivity and funding. Fellowship training requirements include but are not limited to defined patient numbers and adequate opportunity to develop procedural competence, a didactic curriculum that is comprehensive and is regularly implemented, formal education related to developing teaching skills, and evaluation of competency. These requirements are evaluated by the Pediatric Review Committee according

to six competencies, as outlined at the following Web site: www.acgme.org/outcome/comp/GeneralCompetenciesStandards21307.pdf.

ACGME Core Competencies

In 1999, the ACGME initiated an outcome project to design a conceptual framework for education and training according to six common program requirements or general competencies.[1] The objective of the outcome project was to "ensure and improve the quality of graduate medical education."[2] The ACGME recommends that trainees demonstrate the following:

1. *Patient care* that is compassionate, appropriate, and effective for the treatment of health problems and the promotion of health
2. *Medical knowledge* regarding established as well as evolving biomedical, clinical, and cognitive sciences, with the ability to apply these concepts to patient care
3. *Practice-based learning and improvement* involving self-evaluation with regard to patient care, appraisal, and utilization of scientific evidence
4. *Interpersonal and communication skills* that result in effective information exchange and partnership with patients, their families, and other health professionals
5. *Professionalism* manifested through a commitment to professional responsibilities, adherence to ethical principles, and sensitivity to a diverse patient population
6. An awareness of and responsiveness to the health care system and the ability to utilize system resources to provide optimal care in a *systems-based practice*[1]

These core competencies should be used to inform the content of the education program and guide and coordinate evaluation of residents or fellows in their development of medical knowledge.[3]

Duty Hours

While many persons remember fellowship training that involved 16-hour days, being on call every other night, and working on research projects on weekends off, new regulations have led to major changes in fellowship training schedules. In the United States, duty hours are now limited and may be further shortened.[4] The duty-hour restrictions are based on studies suggesting that sleep deprivation causes significant decrements in physician performance in the areas of neurocognition and clinical tasks that result in medical and surgical errors. On July 1, 2003, the ACGME implemented duty-hour regulations for all ACGME-accredited programs. These regulations included limitation of total average work hours to 80 hours per week; limitation of the length of an individual shift to 24 hours plus 6 hours for task completion and handover; the requirement of at least 10 hours off between shifts; and the requirement of at least 4 days off over a 4-week period. More recently, the Institute of Medicine has suggested further shortening of duty hours.[4] Historically the limitation of duty hours is related to the Libby Zion case[5] and the findings of the Bell Commission in New York.[6] Whereas the death of Libby Zion was attributed to the physician trainees' long work hours, the Bell Commission findings indicate that the evidence was not convincing in this regard. Rather, this Commission believed that her death was more likely related to knowledge deficit and lack of supervision of trainees.

While few other issues in medicine have generated emotional discussions of such magnitude within the medical community in the United States, work-hour restrictions have long been in place in Canada, France, and other European nations. Since the implementation of duty-hour restrictions, a number of studies have evaluated the effects of this mandate on patient care. Landrigan et al.[7] studied the effect of work hours on serious medical errors in the intensive care unit (ICU) comparing a traditional work shift of 24 hours or more with every third night on call and an "intervention" schedule that eliminated extended work shifts and reduced work hours each week. The interns made 35.9% more serious medication errors while working under the traditional schedule. In addition, the interns made 5.6 times as many serious diagnostic errors while working a traditional work shift. However, in a more recent study, the same group evaluated the effects of the ACGME duty-hour limits on sleep, work hours, and safety in a group of 220 residents[8] and found no changes in the total numbers of work and sleep hours. More importantly, rates of medication errors, resident depression, and resident injuries did not decrease, and educational ratings did not improve. Volpp et al.[9] studied the effects of duty-hour restriction on the mortality rate of hospitalized Medicare beneficiaries[9] and found no worsening or improvement. On the other hand, Prasad et al.[10] conducted a retrospective cohort study comparing ICU mortality in teaching and nonteaching hospitals before and after implementation of duty-hour regulations and found that there was a decrease in in-hospital mortality rates among ICU patients following the implementation of duty-hour restrictions regardless of teaching or nonteaching hospital status.

Meanwhile, the amount of information and number of skills that have to be acquired and mastered by pediatric intensivists continue to increase. In spite of this situation, Chudgar et al.[11] showed that medical education and teaching methods in the ICU have not changed since the implementation of the ACGME duty hour restrictions. In addition, the program directors who were surveyed were concerned that the new restrictions have negatively affected resident attitudes, continuity of care, and their availability for educational activities. Kairys et al.[12] showed that there has been a decline in the total operative cases reported by graduating surgical residents. In addition to the potential to reduce clinical skills and fracture continuity of care, the plan to further reduce duty hours has generated other concerns. As the work hours of trainees are shortened, patient care tasks have fallen on attending physicians who do not have work-hour limits. This group of physicians tends to be older and they have many other responsibilities that include research, teaching, and administration. Mercurio and Peterec[13] aptly describe this dilemma in their 2009 article in *Pediatrics*, "Attending Physician Work Hours: Ethical Considerations and the Last Doctor Standing." Other concerns include the lack of continuity of physician-patient interactions. Charap[14] writes: "Reducing work hours limits the numbers of patients that residents care for and the extent of residents' involvement with individual patients. By limiting the diversity, intensity, and continuity of physician-patient interactions, our residents will probably have gaps in their clinical skills. These skills are not reflected in in-service or board certification examinations. They deal with recognizing patterns and discerning the very sick patients from the not-so-sick patients."[14]

Regardless of where the road of duty hours takes us, we have to develop novel ways of teaching to ensure that the training of future pediatric intensivists includes all aspects of patient care, education, research, and leadership and that this training takes place within the context of the duty-hour restrictions.

Box 17–1 Principles of Adult Learning

- Relate to learner's current experience and knowledge.
- Adults are self-directed and autonomous.
- Motivation comes from intrinsic and extrinsic factors.
- Adults learn best by active participation and practice.
- Multiple techniques/multiple exposures.
- Timely feedback and reinforcement.

Adult Learning

In developing a curriculum that allows understanding and utilization of the core competencies by trainees as well as continuing medical education for practitioners, the approach to teaching and feedback should be based on principles of adult learning (Box 17-1).[15] Adult learning is fundamentally different from childhood learning, and though a continuum between these two types of learning could be argued, the difference between them is based on several key distinctions. Adult learners have a greater depth and breadth of experiences and knowledge upon which to draw and relate new experience and learning.[15,16] To assimilate new information, adults need to be able to integrate new ideas with what they already know. Furthermore, information that conflicts with what is already believed to be true is integrated more slowly.[17]

Adults are self-directed and autonomous. As a consequence, their education is typically most effective when programs facilitate self-learning with specific goals of acquiring practical information. Motivation for learning is both intrinsic (personal need for new knowledge base or skill set) and extrinsic (professional expectations from colleagues or authority figures). Adults benefit from an appropriately challenging learning environment.[16,17]

Adults learn best when they are active participants in the learning process and are allowed to practice newly acquired skills and concepts.[16,18] Adults have varied experiences and knowledge and do not all learn in the same way. Therefore, a multimodal approach to teaching with multiple exposures to content is more effective than any single approach/exposure method. Finally, adult learners require and often seek out feedback, and therefore they learn more effectively when given timely feedback that reinforces newly acquired information.

The Dreyfus and Dreyfus Model of Skill Acquisition

Stuart Dreyfus, an applied mathematician, and Hubert Dreyfus, a philosopher, developed a model of skill acquisition based on their studies of fighter pilots.[19] This model addresses the stages in the development of professional skills. In addition to being studied in fighter pilots and military personnel, the model has been studied in chess players and car drivers; more recently it has been applied to skill acquisition in clinical medicine. The Dreyfus model proposes that skill acquisition is not different from the continuum of human development, with stages of skill acquisition designated as novice, advanced beginner, competent, proficient, expert, and finally, master. The learner needs to acquire certain skills and learn certain concepts at each level; therefore, teaching methods must match the level of development (Table 17-1).

Methods of Teaching

It is incumbent upon those who oversee the ICU to be responsible for the education of those who occupy it. There are different levels of learners and educators. The faculty physician is the expert or master and serves as the facilitator/educator for medical students, residents, fellows, nurses, and other allied health personnel. This tenet requires the faculty physician to strive constantly to attain and maintain the expert or master status. To have effective teaching in the ICU, the faculty physician must understand that a gap often exists between what faculty physicians and trainees perceive as adequate teaching.[20] Furthermore, one must overcome traditional barriers to education, which include lack of dedicated teaching time, high clinical workload, and poor continuity between faculty physicians and trainees,[20] especially with the requirement of alternative scheduling, such as shift work, to accommodate the 80-hour work week.[11]

Education in the ICU setting consists of teaching basic principles but also includes an ongoing, ever-changing process that depends on new literature and accumulation of medical knowledge. Teaching tools should be designed and selected to optimize improvement of both physician performance and health care outcomes.[18] A learning needs assessment is crucial to effective continuing medical education (CME) and interactive learning associated with opportunities to practice learned materials/skills in an environment that offers sequenced and multifaceted activities.[18] A systematic review that evaluated 37 studies of CME showed that "multiple media, multiple techniques of instruction, and multiple exposures to content are suggested to meet instructional objectives intended to improve clinical outcomes."[21] Many of the features that are instrumental in successful CME initiatives are also principles of successful adult learning. Hence, the tools necessary for educating intensivists should include these principles. Current teaching methods were assessed by a survey of critical care medicine program directors (pediatric, surgery, medicine, and anesthesia), and Table 17-2 summarizes the methods used. The most common method of teaching in the ICU is the bedside, case-based approach, with 80% of programs spending at least 2 hours a day on this activity.[11] Of the methods listed, 45% of the programs wished to have computer or human patient simulation, and 50% would incorporate more Web-based learning modules, which have been shown to be efficacious.[22] Other tools or teaching strategies include debriefing in the ICU,[23] competency-based conference morning report,[24] and changing didactic schedules to accommodate nonstandard work sessions (i.e., shift work).[25]

In 2004, the Society for Critical Care Medicine released "Guidelines for critical care medicine training and continuing medical education,"[26] which addressed the needs of physician education in critical care medicine on a continuum from the resident to the intensivist. Table 17-3 is a representation of the broad scope of educational objectives for critical care medicine fellows and intensivists that includes two broad areas of learning: clinical and administrative.

Teaching at the Patient's Bedside

Case-based teaching at the bedside is thought to be one of the most effective means of educating clinicians in the understanding of disease processes and evaluation and management of critically ill patients. Nothing is more dramatic and unforgettable

Table 17–1 Dreyfus and Dreyfus Model of Skill Development Applied to the Development of Competence in the Subspecialty of Critical Care Medicine

Level of Learning and Characteristics	Examples of Learner Level in Critical Care Medicine	Teaching Implications
NOVICE	**FIRST-YEAR PCCM FELLOW**	
Rule driven Uses analytical reasoning and rules to link cause and effect Synthesis of information is based on knowledge acquired during residency training Big picture may be elusive	Interviews patient and performs a physical examination that is focused on the critical illness May not be able to focus the information on the basis of a differential diagnosis Does not see the big picture	Teach basic critical care concepts Point out subtle but meaningful diagnostic information in the history and physical examination Eliminate irrelevant information Highlight discriminating features and their importance to the diagnosis Encourage reading about two diagnostic hypotheses at the same time
ADVANCED BEGINNER	**SECOND-YEAR PCCM FELLOW**	
Sorts through rules and information to decide what is relevant on the basis of past experience Uses analytical reasoning and pattern recognition to solve problems Able to abstract from concrete and specific information to more general aspects of a problem	Can generate more specific differential diagnosis while obtaining history and physical examination Capable of filtering relevant information to formulate a unified summary of the case Can abstract pertinent positives and negatives from the review of systems and incorporate them into the history of present illness	Expose learner to clinical cases proceeding from common to uncommon Emphasize the use of semantic qualifiers Encourage formulation and verbalization of differential diagnosis and treatment plan Good coaching: help learner become attentive to the meaningful pieces
COMPETENT	**THIRD-YEAR PCCM FELLOW**	
Emotional buy-in allows learner to feel appropriate level of responsibility More expansive experience tips the balance on clinical reasoning from methodical and analytic to identifiable pattern recognition of common clinical problems Sees the big picture Complex/uncommon problems still require reliance on analytical reasoning	Recognizes common patterns of illness based on previous encounters Sees consequences of clinical decisions, which leads to emotional buy-in to learning Will methodically attempt to reason through complex or uncommon problems Responsible for decision-making process	Balance supervision with autonomy in decision making Hold learners accountable for their decisions Don't tell them what to do; ask what they want to do Critical for learner to see a breadth and depth of patient encounters to construct and store in memory a large repertoire of illness scripts Tip the balance from clinical reasoning to pattern recognition
PROFICIENT	**CLINICAL INSTRUCTOR**	
Breadth of past experience allows reliance on pattern recognition of illness: problem solving intuitive Still needs to fall back to methodical and analytic reasoning for managing problems because exhaustive number of permutations and responses to management have provided less experience in this regard than in illness recognition Is comfortable with evolving situations, able to extrapolate from a known situation to an unknown situation Can live with ambiguity	Starts to match findings with those encountered in past experience Data gathering more effective and efficient Sees patient through different lens than the student Engages in process of clinical reasoning to find the best intervention	Needs to work alongside and be mentored by an expert Must develop capacity to know ones' limitations and step back and call on additional resources when stretched beyond one's capabilities
EXPERT	**ASSOCIATE PROFESSOR**	
Thought, feeling, and action align into intuitive problem recognition and intuitive situational responses and management Open to notice the unexpected Clever Discriminates features that do not fit a recognizable pattern	Broad repertoire of illness scripts, based on clinical experience that allows immediate action for majority of clinical encounters Likes to deal with diagnostic dilemmas When presented with diagnostic dilemma, will slow down and look it up	Keep up the challenge Needs ongoing experience and ongoing exposure to interesting and complex cases to avoid complacency and to help transcend beyond this level Should be apprenticed to a master who models the skills of the reflective practitioner and a commitment to lifelong learning

Table 17–2 Methods Used in the Education of Physicians

Teaching Method	%
Bedside, case-based teaching	94.4
Lecture series	79.0
Morbidity and mortality conference	72.6
Syllabus of articles	63.7
Journal club	62.9
Multidisciplinary rounds	60.5
Rounding sheets	58.1
Web-based articles	29.0
Web-based lectures	27.4
Psychomotor skills laboratories	24.0
Full-body simulator	15.3
Cadaver/animal laboratories	8.1
Computer simulation	4.8
Palm pilot algorithms	3.2
Standardized patients	3.2

Modified from Chudgar SM, Cox CE, Que LG, et al: Current teaching and evaluation methods in critical care medicine: has the Accreditation Council for Graduate Medical Education affected how we practice and teach in the intensive care unit? *Crit Care Med* 37:49-60, 2009.

than seeing a patient with fulminant meningococcemia and purpura fulminans. Perhaps less dramatic but just as effective are instances when one palpates a thrill, hears a gallop, feels an enlarged liver or spleen, listens to wheezing or stridor, or performs a detailed neurologic examination in a patient who has experienced a middle cerebral artery stroke or a spinal cord injury. Even medical technology is better taught at the bedside. When the learner is introduced to a child with severe asthma exacerbation who is receiving mechanical ventilation and the learner is shown the flow volume loops exhibited at various ventilator rates and inspiratory:expiratory ratios, she or he is likely to come away with a much better understanding of the principles of mechanical ventilation in someone with a prolonged time constant. The different waveforms on bedside monitors can be used to demonstrate important pathophysiologic principles. Examples include malignant intracranial pressure waveforms with a wide systolic-diastolic variation reflecting the poor compliance of a diffusely swollen brain; the lack of a dicrotic notch in the arterial waveform of someone with hypovolemia; changes in systolic pressure associated with inspiration in a patient with pulsus paradoxus; and the right ventricular tracing of a subclavian venous catheter meant to be in the right atrium that has been inserted too far. Showing trainees extracorporeal membrane oxygenation circuits, continuous veno-venous hemodialysis and ultrafiltration machines, high-frequency oscillators, and ventricular assist devices while they are being used in patient care provides the "aha" moment often not attained while viewing slides in a darkened room during a lecture.

In addition, when trainees present the historical data and physical findings of their patients to the attending physician during bedside rounds, they can be taught to describe the information relating to their patients in a succinct manner and discriminate between important and less important information, develop a list of differential diagnoses, and formulate a treatment plan. They learn to "think on their feet" and can be taught how to put data together to determine a cohesive diagnosis that will lead them to the right conclusions regarding diagnostic and management decisions.

In these days of duty-hour limitations, electronic medical records, and computerized order entry, it is easy to lose sight of the patient and stray from the bedside. However, clinical acumen remains largely dependent on exposure to a large number of clinical cases in building medical knowledge and experience in each learner, no matter what level they are at. Therefore, case-based bedside teaching should always be a major component of clinical teaching. Historically, patients have always been and should continue to be our best teachers.

Procedural Training

In order to provide care to critically ill children, the intensivist needs to learn many procedural skills. These skills include endotracheal intubation, thoracostomy, use of pacemakers,

Table 17–3 Essential Clinical and Administrative Learning Points

Clinical	Administrative
Identify and teach others to identify the need for/provide care for all critically ill patients	Evaluate current ICU hospital policies and suggest improvements
Provide and teach others resuscitation for any patient sustaining a life-threatening event	Triage critically ill patients to optimize care delivery within the institution
Initiate, manage, and wean patients from mechanical ventilation and teach others new methods and devices for management of respiratory failure	Improve resource utilization and maintain patient care quality by facilitating triage of patients to limited institutional critical care beds and caregivers
Initiate critical care to stabilize and manage patients who require transport	Develop programs and change unit practice to improve care of critically ill patients
Instruct other qualified caregivers and the lay public in the theory and techniques of CPR	Develop programs for patient safety monitoring and error reduction
Treat cardiogenic, traumatic, hypovolemic, and distributive shock with conventional and state-of-the-art approaches	Actively participate in quality assurance processes, including morbidity and mortality conferences, process improvement teams, and Joint Commission Accreditation of Healthcare Organizations preparation
Recognize the potential for multiple organ failure and institute measures to avoid or reverse this syndrome	Support the process of assessing patient and family satisfaction and participate in tool development and implementation
Identify life-threatening electrolyte and acid-base disturbances, provide treatment, and monitor outcome	Encourage and enhance good relationships with other health care providers
Identify and initiate discussions involving ethical issues and parent/patients' wishes in making treatment decisions using advance directives and other methods	Understand advanced concepts important for compensation of critical care services and contractual issues related to providing critical care services and performing the business of medicine
Diagnose and treat common and uncommon poisonings	Develop skills for teaching critical care
Teach appropriate use and monitoring of procedural sedation and use advanced pain management strategies	Develop and evaluate curriculum changes for ICU caregivers, fellows, and residents
Diagnose malnutrition and use/monitor advanced nutrition support methodologies	Evaluate, modify, and approve ICU hospital policies
Provide invasive and noninvasive monitoring for titrating therapy; prioritize complex data to support action plan	Improve resource utilization and maintain patient care quality by planning for future needs for institutional and regional critical care resources
Use and teach medication safe practice guidelines and determine cost-effectiveness of therapeutic interventions	Develop programs and change unit, institution, and regional practice to improve care of critically ill patients
Develop skills of ICU nurses and ancillary personnel in caring for critically ill patients and provide in-service education	Use existing tool sets to assess patient and family satisfaction and direct the development of new tools when appropriate
Use, teach, and help enforce methods of infection control	Develop programs and document improvement in patient safety monitoring and error reduction
Communicate effectively with patients, families, and other involved members of the health care team about all treatment decisions and patient prognosis	Develop high-quality relationships with other health care providers
Continue to augment knowledge by assimilating peer-reviewed published medical literature through self-directed learning and CME activities	Teach the business of medicine
Diagnose and treat a sufficient number of patients with critical illness using conventional and state-of-the-art approaches to maintain clinical proficiencies	Develop collaborative and productive relationships with other specialist physicians and model joint clinical planning in managing complex ICU problems

CME, Continuing medical education; *CPR,* cardiopulmonary resuscitation; *ICU,* intensive care unit.

central venous and arterial catheter placement, pericardiocentesis, and others. The ACGME and the ABP require documentation of competency in these skills. Teaching procedural skills should include didactic sessions on related anatomy, indications, and complications. Videos of certain procedures are available on Web sites such as that provided by the *New England Journal of Medicine* (http://content.nejm.org/misc/videos.dtl?ssource=recentVideos). If available, low or high-fidelity manikins should be used to teach proper technique and for practice sessions. Procedural training also should include the components required for the maintenance of aseptic technique, and quality improvement processes must be in place to reduce or eradicate nosocomial infections. Subsequently, trainees should be supervised during their initial attempts at each procedure until they demonstrate adequate skill to proceed independently without excessive risk to the patient.

Simulation Training

Simulation training has been used extensively in the aviation industry since the 1930s. Medical simulation began in the early 1960s with simple resuscitation manikins. This step was followed later by the development of more realistic manikins for training in anesthesiology. For many years, medical simulation did not progress because of the high cost of devices as well as the thought that it was unlikely that complex human physiology could be replicated in a simulator. In the past 20 years, however, much advancement has occurred in high-fidelity medical simulation. Medical simulators are now sophisticated and specialized, ranging from obstetric models to laparoscopic surgical simulators to a simulated premature newborn. In addition to providing a better representation of physiologic and pathophysiologic states, simulators also have become more specific in their design. Low-fidelity medical simulators include partial task trainers, also called procedural trainers, which are designed to train users to perform a defined psychomotor skill. Examples include a partial torso designed to teach central venous cannulation techniques and a manikin head utilized to teach endotracheal intubation. High-fidelity manikins are partial or whole-body manikins that are instructor-driven. Computer software is programmed to produce physiologic signals that are displayed on a computer screen designed to represent a patient on a monitor. Manikins are programmed to display physical findings such as chest rise, breath sounds, pulses, and vocalizations. In a simulated training session, the trainee can gather patient information via the monitor and physical findings demonstrated by the manikin, determine a course of action, and implement a treatment plan. Simulator responses are generated by the instructor via computer control or via preprogrammed algorithms in reaction to diagnostic choices and treatments provided by the trainee. The sessions can be recorded for use in debriefing immediately after the simulation scenario, affording a final opportunity to emphasize the educational objectives of the exercise.

Simulation is a medical educational tool with multiple advantages. Knowledge and skills can be integrated in a real-time fashion, providing opportunities for both teaching and evaluation. Training can be repetitive and standardized and the training environment is safe for the "patient" and "low-stress" for the trainee. Simulation is well suited to education in the ICU. ICUs have complex patients with rapidly changing physiology and acute needs. ICU caregivers work in a multidisciplinary environment that involves complex team dynamics, communication challenges, and high-risk situations. In addition, the ICU is often the site for high-risk procedures. These procedures include pericardiocentesis or emergent central venous catheter insertion and require expertise and the need for the procedure to be performed rapidly yet safely. In the past, these procedures were taught via the "see one, do one, teach one" philosophy. This paradigm was insufficient. The randomness of illness does not always provide trainees with ample opportunity to learn complex skills, and for certain procedures that are performed infrequently, trainees do not have sufficient practice to master the skills. In addition, patient safety frequently dictates that the most experienced caregiver perform the procedure.[27] Simulation allows instruction and psychomotor skills practice in a safe environment along with the ability to educate multiple trainees. Finally, in addition to teaching particular skills, simulators can be programmed to reflect procedure-related complications and medication errors to prepare trainees for such events.

Another advantage of simulation is the ability to provide on-site training. ICUs are filled with complex equipment, may have off-site supply locations, and have personnel with multiple competing demands. Simulators provide the opportunity to replicate this complex environment. They are portable and can be placed within the ICU. This feature provides the advantage of placing the trainee in the setting of patient care, with the opportunity to use actual ICU equipment and supplies within the environment in which they are expected to provide patient care. For example, in a scenario of ventricular fibrillation, the trainee must recognize the dysrhythmia, initiate cardiopulmonary resuscitation (CPR), and call for intravenous epinephrine and the defibrillator. Team members must perform adequate CPR while others obtain the resuscitation cart for access to emergency medications, and still other personnel must retrieve the defibrillator and set it up for use. The simulation exercise helps to emphasize knowledge not only of appropriate treatment of dysrhythmia but also tests the knowledge of resource location and teamwork organization.

It seems fitting to finish this section with a discussion of teamwork in simulation training, because it is one of the most vital components to a well-functioning ICU. Teamwork is necessary to accomplish many tasks in the ICU, from the traditional code team responding to a cardiac arrest to the routine vascular catheter placement in a patient. ICU personnel are expected to function as well-organized teams. However, team members often are unaware of basic teamwork principles and may not have had opportunities to practice teamwork skills. In addition, medical teams are usually ad hoc; that is, it is often unknown which physicians, nurses, or respiratory therapists will have to respond to a patient crisis at any given time. This characteristic adds another layer of difficulty to teamwork training. Again, aviation and anesthesiology have shown us the utility of simulation in teamwork training. In the mid 1980s, the aviation industry developed protocols for Cockpit Resource Management, later changed to Crew Resource Management, or CRM. The field of anesthesia adapted CRM principles to anesthesia training and eventually developed anesthesia crisis resource management protocols.[28,29] Principles of crisis resource management include effective leadership, organization, communication, effective use of resources, and stress management.[29]

Simulation is an effective tool for teamwork training. Hunt et al.[30] used simulated mock codes to evaluate team performance and target educational interventions during emergent resuscitations in North Carolina emergency rooms. Wayne and colleagues[31] also used simulation to assess adherence to Advanced Cardiac Life Support (ACLS) quality indicators during ACLS events. All trainees received traditional training, with some trainees receiving additional ACLS training using a human patient simulator. The simulator-trained group was several times more likely to adhere to American Heart Association standards than were the students who received only traditional training.[31] These are just two of the many studies that show that CRM principles can be effectively evaluated, learned, and applied via simulation with team performance improved when compared with traditional training.

Simulation offers a strong educational opportunity, creating instances to teach, practice, and evaluate. Cognitive and

psychomotor skills can be integrated in a realistic environment while patient and trainee safety is protected. Simulation tools still lack some sophistication that would be useful for ICU training, such as simulated neurologic findings, changes in skin color and temperature, or even capillary refill. Technology, though, continues to advance, and the future of simulation tools is very promising.

Web-Based Education

Numerous resources are available on a wide variety of Web sites. Information is readily available from PubMed and Google. Innumerable "podcasts" are available on various topics. Online textbooks such as *Goodman and Gilman's Pharmacologic Basis of Therapeutics* provide a wealth of information and include video clips of physiologic theories such as activity in the neuromuscular junction. Multiple critical care societies developed and sponsor a Web site on principles of pulmonary artery catheter monitoring called the Pulmonary Artery Catheter Education Program (http://www.pacep.org). Congenital heart lesions and related surgical repairs are shown on a variety of Web sites, including one from the Johns Hopkins Helen B. Taussig Children's Heart Center/Cove Point Foundation Web site (http://www.pted.org/). The Society of Critical Care Medicine hosts an educational Web site that includes the PICU course—a site with more than 30 PowerPoint lectures that can be downloaded for use (http://www.learnicu.org/Clinical_Practice/Fundamentals/RICU/Pages/default.aspx). Some of the presentations now have voice-overs and therefore can be used for independent study. A number of institutions have created Web-based distance education on programs such as Blackboard. The American Academy of Pediatrics has developed a Web-based critical care medicine certifying examination review product (PREP-ICU) containing questions and extensive discussions based on content specifications of the ABP (http://www.aap.org/profed.html). Although Web-based education can never replace patient bedside teaching, it provides ideal supplements for self-study in the context of duty-hour restrictions.

Evaluation and Assessment of Competency

Since the ACGME introduced the use of competency-based outcomes to define the learning experiences of residents and fellows, training programs have struggled with the implementation of these requirements in two domains: how to teach the competencies and how to determine that competency has indeed been achieved. Various methods have been used for evaluation (Table 17-4).

Epstein and Hundert[32] define competence as the "habitual and judicious use of communication, knowledge, technical skills, clinical reasoning, emotions, values, and reflection in daily practice for the benefit of the individual and community being served." They further state that "competence builds on a foundation of basic clinical skills, scientific knowledge, and moral development" and propose that competence is made up of several dimensions, each with a separate set of skills (Box 17-2). In one study, the authors performed a MEDLINE database search from 1966 to 2001 for articles that studied the reliability of measures of clinical or professional competence of physicians. One hundred ninety-five publications were reviewed. The most commonly used methods of assessments were (1) subjective assessment by supervisors; (2) multiple-choice examinations to evaluate factual knowledge and abstract problem solving; and (3) standardized patient assessments of physical examination and technical and communication skills. Rating the performance of trainees on standardized patients, human patient simulation, multiple-choice examinations, and objective structured clinical examinations provides important information regarding basic knowledge and the ability to perform certain skill sets, such as obtaining an accurate history and physical examination or successfully intubating the trachea. However, the evaluation of the ability to apply knowledge to patient care, the capability of working as a team member, and the development of physician-patient relationships can only be assessed by direct observation of real-life patient interactions. Epstein and Hundert[32] found that few of the assessments they reviewed evaluated trainees in terms of clinical reasoning, judgment, time management, learning strategies, and teamwork. They suggest that tools should be developed to assess competency in these domains.

Pangaro[33] writes that we need to invest in a descriptive evaluation by constructing a vocabulary that describes growing expertise that can be used from one year to the next. Such a vocabulary has been developed at the Department of Medicine at the Uniformed Services University, and it describes trainees as they develop competence while advancing from one level to the next. This vocabulary is referred to as Reporter to Interpreter to Manager-Educator (Table 17-5). Pangaro[33] summarizes the issue of assessing competence very well: "The assessment of competence requires a whole series of performances that in each moment of interaction with a patient, the competent physician must bring many qualities to bear, and what they will require varies from patient to patient."

In order to assess competency, we must understand what is being assessed. Once this has been determined, methods of evaluation should be developed. The methods of evaluation must in turn be assessed in terms of their usefulness.

Table 17–4 Methods of Evaluation to Determine Clinical Competency

Method of Evaluation	Settings
Direct observation	Objective structured clinical examination, standardized patients, human patient simulators, procedure fairs
Postrotation tests	Case-based scenarios or vignettes
Subspecialty in-training examinations	Yearly computerized examination administered by the ABP: used to evaluate level of knowledge acquisition, assesses needs of trainees and program components of education
360-degree evaluations	Evaluations from nurses and other allied health personnel and patients and their families provide a picture of the trainees' professionalism and/or communication skills
Clinical vignettes, case-based discussions	Discussion of clinical cases with review of pertinent findings and evidenced-based management points

ABP, American Board of Pediatrics.

Box 17–2 Dimensions of Professional Competence

Cognitive
- Core knowledge
- Basic communication skills
- Information management
- Applying knowledge in real-world situations
- Using tacit knowledge and personal experience
- Abstract problem solving
- Self-directed acquisition of knowledge
- Recognizing gaps in knowledge
- Generating questions
- Using resources (e.g., published evidence, colleagues)
- Learning from experience

Technical
- Physical examination skills
- Surgical/procedural skills

Integrative
- Incorporating scientific, clinical, and humanistic judgment
- Using clinical reasoning strategies appropriately
- Linking basic and clinical knowledge across disciplines
- Managing uncertainty

Context
- Clinical setting
- Use of time

Relationship
- Communication skills
- Handling conflict
- Teamwork
- Teaching others

Affective/Moral
- Tolerance of ambiguity and anxiety
- Emotional intelligence
- Respect for patients
- Responsiveness to patients and society
- Caring

Habits of Mind
- Observations of one's own thinking, emotions and techniques
- Attentiveness
- Critical curiosity
- Recognition of and response to cognitive and emotional biases
- Willingness to acknowledge and correct errors

Adapted from Epstein RM, Hundert EM: Defining and assessing professional competence, *JAMA* 287:226-235, 2002.

Table 17–5 Characteristics of a Trainee Progressing from Reporter to Manager-Educator

Category	Characteristics
Reporter	Accurately gathers and communicates information about his own patients Basic knowledge to know what to look for Being on time Following up results Distinguishes abnormal from normal Confidence to identify and label a new problem Requires sense of responsibility Consistency in achieving bedside skills
Interpreter	Must transition to the ability to prioritize and develop a list of differential diagnoses Requires higher level of knowledge More skill in selecting the clinical findings that support possible diagnoses Applies test results to specific patients Transforms from bystander to active participant in patient care
Manager-Educator	Requires even more knowledge, judgment, and confidence Decides what action needs to be taken Proposes and selects options for patients Self-directed learning: reads deeply Goes beyond the basics Shares new learning with others Has the drive to look for hard evidence on which clinical practice can be based and to determine whether the evidence will stand up to scrutiny

Milestones

The ACGME Outcome Project is composed of several phases. Phase I required that training programs define objectives encompassing the six competencies. In Phase II, the competencies were integrated into the curriculum, and programs expanded the evaluations to assess performance. In Phase III, performance data will be used to make changes to the curriculum, and benchmark programs will be identified in Phase IV.

While there has been success in establishing individual evaluations of competencies such as those listed in Table 17-4, the evaluation of overall competency as trainees advance from one level to the next and their readiness for independent practice is still lacking. More recently, there have been efforts to evaluate training in terms of a developmental continuum. Carraccio et al[34] and Green et al.[26] have addressed this need by designing developmental milestones for training based on the Dreyfus model. For each of the six ACGME competencies, developmental milestones and corresponding evaluation methods are listed, with a time frame at which the trainee is expected to achieve the particular milestone. For example, under the patient care competency, the trainee is expected to achieve competence by the first six months of training. This competency will be evaluated through the use of standardized patients and direct observation. On the other hand, the ability to recognize disease presentations that deviate from common patterns and require complex decision making may take longer to achieve and may be more difficult to assess.

Education in Research, Scholarship, and Leadership

Training in the conduct of research is an integral part of pediatric critical care medicine. Meaningful scholarly activity is required by the ABP for board certification. Research activity

by faculty members and fellows is a key to accreditation of fellowship programs by the ACGME Resident Review Committee. Research in pediatric critical care is discussed in Chapter 4.

The pediatric intensivist has a central role in the education of peers and team members. Therefore, training should include the development of teaching skills that include evidence-based review of the literature, use of audiovisual aids, scientific presentations, and medical writing. In addition, pediatric intensivists are expected to manage ICUs and coordinate team members who provide multidisciplinary care to critically ill patients. As previously noted, simulation can contribute to teaching leadership skills. However, to date, training related to these skills has been lacking. Stockwell et al.[35] found that while training in leadership and management was considered an important aspect of pediatric critical care fellowship, most of the intensivists surveyed in their study felt inadequately prepared for this aspect of their work.

Mentorship

"And so it's been for me these long years. I've carried my mentor everywhere. If I get sloppy, I wonder, "What would he think of me now?" And if I'm in a tight spot clinically, he prods me back to the literature. When I'm impatient with patients, I remember his patience with me. When I'm asked to teach, I do so willingly because that is what he did. When I begin to doubt myself, I remember his belief in me. And if I am ready to quit, I can see him standing there before me in his long white coat, with stern look and stethoscope, and I go on.

What has he been for me, this mentor of mine? He's been like a father to me, but more than a father. He has been my companion in medicine, to help me through the loneliness that medicine can bring and to share with me the joy that medicine can be. My mentor has, through me and those of my students, cared decently and compassionately for countless patients. When I have cured a patient or two, why, so has he."(Michael A. LaCombe, MD, FACP, William Morgan Teaching Symposium, University of Rochester, July 20, 1989.)

Mentorship is defined as a "dynamic, reciprocal relationship in a work environment between an advanced career incumbent (mentor) and a beginner (protégé), aimed at promoting the development of both."[36] Mentorship is at the core of the training of medical students, residents, and fellows in patient care, research, and education. While the benefits to the mentee are often emphasized, it is clear that mentors benefit as well[37,38] because they tend to have greater satisfaction in their careers. Mentorship takes place at many levels. It can begin during medical school, where a mentor may guide and even inspire a student to choose a certain career path. During residency and fellowship, a mentor can be a major component in the development of the trainee's clinical knowledge and patient care skills. In addition, if the resident or fellow decides to pursue a career that includes research, the mentor can help identify a research focus and provide guidance in terms of literature search, writing a proposal, applying for institutional review, and funding sources. For junior faculty members, mentorship provides opportunities to fine-tune clinical skills and diagnostic and therapeutic acumen. Research productivity is further enhanced by guidance in manuscript writing, obtaining extramural grant support, and the conduct of basic science experiments and clinical trials. The mentor can help academic development of the junior faculty member by recommending him or her to local, state, and national committee memberships and enlisting them as co-authors for book chapters and review articles. Mentorship in teaching is important as well. The mentor can help junior faculty members develop teaching skills by example and by providing critique of lectures and audiovisual teaching tools.

While the importance of mentorship in academic development is clear, the process of finding the right mentor and developing the mentor-mentee relationship is altogether much more difficult. How does one find a mentor? First, mentees must decide where they want to be 5 or 10 years down the road. Once this is clear, they can set out to look for their mentors. Some persons recommend that new faculty members and fellows meet with everyone in the department to determine who might be the best fit. Even then, the mentee may find that no one in the department fits that role and may need to look beyond their department or institution. Perseverance is essential. For some mentees, one mentor may not meet all their needs, in which case one may have one mentor for clinical work and another for research activities. Occasionally the relationship may not work out. When that is the case, the mentee should be allowed to seek other mentors without being made to feel that it is wrong to do so. Academic departments should foster mentorship by providing support for mentors that includes faculty development courses and by providing recognition for their efforts. Junior faculty members and fellows should be provided with resources such as lists of senior faculty members who have successfully provided mentorships and what their areas of interest are. A forum should be available to junior faculty members to discuss their academic needs and concerns.

Establishing and Maintaining Competency

In reviewing ratings of performance, Williams and colleagues[39] quote the work of Kane, who defines clinical competence as embodying aspects of knowledge, skills, and judgment referable not only to the situation under observation but generalizable to similar clinical situations.[39] From this perspective, the six core competencies form a useful framework by which the practicing clinician may structure his or her self-directed education and a program to integrate reflective practice into all aspects of professional development.

Medical knowledge and patient care encompass foundational knowledge, technical facility, and professional judgment. The conventional means by which to assess knowledge is through a certification examination. Technical competence may be assessed indirectly, such as through chart reviews, resource utilization, or log books, or directly, such as through videos of patient encounters, standardized patients, or skills labs. The latter, while often used for trainees, are not practical for practicing physicians with multiple competing time demands. One straightforward approach is the establishment of a minimal number of procedures to be completed, after which the clinician is deemed competent. The number is usually set by consensus expert opinion, but it is rarely validated, and arbitrary numerical standards disregard the variability in rates of acquisition and maintenance of skills between individuals. With any method, the data used to assess competence

must meet several standards: the information must be accurate; observers and interpreters must agree on the implications of the findings; the observations must apply to a range of situations; and the tools must be feasible to use.[39] Once a skill is acquired, a number of factors influence maintenance of competency. These factors include repetition, exposure to the procedure under different clinical situations, overall technical facility, and clinical judgment. This last factor embodies both tangible and intangible qualities, including assessing when to perform a procedure and when to defer a procedure and recognizing when conditions deviate from the expected in the middle of the procedure.[39]

Medical judgment is perhaps among the most important attributes of a seasoned clinician and the most difficult to assess. Actual practice requires the application of knowledge to complex clinical situations, which rarely reflect the idealized descriptions of textbook medicine. Contemporary research in medical decision making recognizes that two major modes enter into decision making, System 1 and System 2.[40,41] Croskerry[41] describes System 1 as "intuitive, automatic, fast, frugal, and effortless." We recognize this description as pattern recognition, that is, the immediate grasp that a patient is following an expected trajectory of illness. System 2 is described by the same author as "analytical, deliberate, slower, costly, and effortful."[41] This mode describes the classic diagnostic dilemma, in which critical pieces of clinical data are not concordant with our assumptions regarding the disease process. Unfortunately, it is human nature to undervalue information that differs from our preordained conclusions and to overvalue confirmatory information. The experienced clinician is ever vigilant for misapplying the System 1 style when more cautious analysis is warranted, or vice versa.[40,41]

The core competencies of practice-based learning and systems-based practice may be conceived as a framework by which to reflect upon one's clinical experiences and refine both System 1 and System 2 thought patterns. In this construct, an effort to be "nonjudgmental" is transcended by an emphasis on developing good judgment, which includes understanding one's assumptions and biases when faced with a clinical situation.[42] The most common forum for this sort of approach is the morbidity and mortality conference. In this setting, it would be superficial to merely recount the clinical course; the context in which decisions were made is an essential part of the review. This context includes asking what clinical information was available in real time (not that which is obvious retrospectively), how that data was applied, what the conditions were in the rest of the ICU (because it would be uncommon to practice in an environment with only one critically ill patient), and how input from consultants informed our decision making.[42-45] Moreover, the expectations and understanding of our patients' families are essential elements in our clinical care and should be considered in reviewing the case.

Communication is often cited as the most important factor in both good and bad outcomes. Although communication skills often are believed to be an innate personality characteristic, they can be taught, and one's life experiences can lead to more active, sympathetic listening.[43,46] This trait is essential when dealing with the health care team, families, and patients. By promoting active listening as an essential element of communication, colleagues may find it easier to share subtle changes in patient condition that may be harbingers of a critical change. When we can both listen and provide information in a manner tailored to a family's needs, a nuanced and personalized approach is made possible. Evidence-based practice that is communicated well promotes a culture of high-quality medicine delivered as part of a multidisciplinary team.

The end of formal training as a fellow represents the beginning of a lifelong process of obtaining and refining one's knowledge and judgment, constituting the essence of professional development and maintenance of competency. While the medical profession and society at large has historically assumed proficiency on the part of medical practitioners by virtue of their continued practice, this assumption risks an inappropriate complacency and takes for granted that longevity is tantamount to expertise. Instead, the mature clinician is one who reflects upon his or her daily medical experiences to place them in a larger context of previous encounters and critically evaluates his or her own performance, acknowledging both effective and ineffective aspects of patient care.[43,47]

Critical care is practiced in an atmosphere of innate uncertainty. The available data may be incomplete, the preceding events unclear, and the outcome dependent on multiple interrelated processes. In this environment the practicing intensivist must be able to adapt "on the fly" and also, once a situation is resolved, he or she must be able to step back and pursue generalizable knowledge for the next encounter. The work of Donald Schon discusses "reflection in action," a form of creative problem solving, and "reflection on action," a looking back in an effort to inform future experiences.[48] The aspects of reflective practice that may come to bear include deliberate induction (a search for alternative explanations in addition to the one most readily assumed), deliberate deduction (a logical exploration of the consequences of alternative explanations), a testing and synthesis of these alternative proposals, and openness toward this thoughtful approach in the face of ambiguity, rather than a dogged clinging to one thesis as an anchor in the sometimes chaotic intensive care environment.[45]

Another aspect of lifelong learning is the role that teaching plays in ongoing self-directed learning. By reviewing contemporary literature and synthesizing it, whether for a formal didactic talk or for family and patient information, the seasoned intensivist creates an opportunity to address all aspects of professional development. Previous knowledge and assumptions are challenged in the face of newer scientific evidence. An objective presentation will acknowledge both areas of certainty and uncertainty. Innovations can be applied to clinical situations and compared with past experiences. The role of lifelong teacher is inextricably linked to that of lifelong learner.

The ABP has incorporated this template of professional development into its Maintenance of Certification program. Over time the framework of the six core competencies will become an integral part of ongoing professional development, including a knowledge examination, peer and family evaluations, participation in review and quality improvement activities, and evidence of ongoing clinical activity. Rather than viewing these competencies as administrative hurdles, the wise clinician may view them as reminders of the many facets of professionalism and learning that medical practice provides.

Chapter 18

Critical Care in Public Health Emergencies

Robert K. Kanter

PEARLS

- All-hazard, as well as incident-specific, planning and preparedness for public health emergencies make a difference in patient outcomes.
- The Hospital Emergency Incident Command System provides a leadership framework within and among organizations responding to an emergency, emphasizing flexibility and scalability, with clear lines of authority and consistent communications.
- Triage sorts patients to match their needs with available resources and evolves according to shifting needs and resources. Failures of triage may subsequently incapacitate an entire hospital.
- In order to provide essential interventions, some resource-intensive interventions, ordinarily considered standard in an intensive care unit, may have to be delayed or forgone in a mass critical care situation, because standard care would reduce the population who could receive life-saving care.
- If a public health emergency overwhelms resources despite mass critical care approaches, rationing might be considered. However, at present the public and professional consensus that would serve as the necessary foundation for rationing to be a feasible option is lacking.

Recent public health emergencies (PHEs) in North America have included the attacks of September 11, 2001, Hurricane Katrina and the subsequent flooding of New Orleans, a major nightclub fire in Rhode Island, wildfires in the West, floods in the Midwest, anthrax exposures, severe acute respiratory syndrome, and an influenza pandemic. Important lessons have been learned. All-hazard as well as incident-specific planning and preparedness make a difference. When carried out, public health preparations (including evacuation, shelter, and infection control) limited major health effects. Unavoidable illnesses and injuries were often minor, requiring outpatient treatment or first aid for the vast majority of patients. Even when critical care was necessary, existing resources were adequate to provide standard intensive care when needed. However, small differences in circumstances in any of these recent emergencies might have resulted in much larger numbers of adults and children admitted to adult or pediatric intensive care units (ICUs). It is easy to imagine disasters that would overwhelm existing ICU resources, unless we prepare to provide critical care in larger PHEs. This chapter is written for members of the pediatric critical care team facing a major PHE.

Basic Concepts

National Response Framework and Incident Command System

Responses to major public health emergencies are organized within a National Response Framework, as outlined by the federal Department of Homeland Security.[1] Emergency responses are always coordinated at the most local jurisdictional level possible, usually at the city or county level. Responses to larger disasters need support from adjacent counties, the state, and sometimes from the federal level. The Hospital Emergency Incident Command System (HEICS)[2] provides a leadership framework within and among organizations responding to an emergency. HEICS emphasizes flexibility for any type of event, scalability to the size of the event, clear lines of authority, and consistent communications. Disaster plans at every hospital incorporate HEICS principles.

Ordinary Surge and Mass Critical Care

Critical care responses to PHEs are scaled according to the size and severity of the emergency (Table 18-1).[3-5] Responses are categorized as (1) ordinary surge, (2) temporary reactive mass critical care, and (3) sustained mass critical care. For a sudden-impact event involving modest (10% to 15%) increases above usual peak hospital capacity at one or more local hospitals, ordinary surge methods would suffice to provide normal standards of critical care to all those who need it. Ordinary critical care surge needs are met by canceling elective admissions, quickly discharging all patients who can safely leave the ICU, mobilizing staff, and adding beds, as feasible. Most hospitals have occasional experience with ordinary critical care surge responses.

Mass critical care approaches would be implemented when a very large PHE threatens to overwhelm critical care resources. It is recommended that mass critical care

Table 18–1 Categories of Public Health Emergencies and Critical Care Responses

No. of Patients	Type of Event and Response	Authority to Implement Response
Modest increase (10%-20%) above usual peak capacity	"Ordinary surge" Usual standards of care	Decision making by usual clinical leaders
Up to three times usual peak capacity	Gradual onset, sustained PHE with adequate preparation, resources meet needs, usual standards of care Sudden-impact PHE, needs exceed resources, temporary "reactive" mass critical care, crisis standards of care Sustained PHE, sudden or gradual onset, needs exceed resources, sustained mass critical care, crisis standards of care	Decision making by usual clinical leaders Decision making by hospital incident commander Decision making by state public health official (varies state by state)[4]
Exceeds three times usual peak capacity	Needs overwhelm resources despite mass critical care, mass critical care, and rationing, crisis and palliative standards of care	Legal basis and liability protections are ambiguous[38]

Data from Devereaux A, Christian MD, Dichter JR, et al: Summary of suggestions from the Task Force for Mass Critical Care, *Chest* 133:1S-66S, 2008.
PHE, Public health emergency.

personnel be able to care for up to three times the usual number of critically ill patients for up to 10 days without outside help. In these circumstances, population-based goals would attempt to maximize numbers of survivors by providing immediate lifesaving interventions to all persons who need them and delaying or forgoing other interventions. Thus standards of mass critical care are not equivalent to normal circumstances and should be considered to be crisis standards of care. Sudden impact events that stress the resources of a community may require the implementation of temporary reactive mass critical care. Experience with a massive surge of critically injured patients after a major fire demonstrated the satisfactory outcomes that are possible as a result of well-organized responses that included elements of the temporary reactive mass critical care approach.[6] A sustained PHE that exceeds resources over a wide area may require the sustained implementation of mass critical care. No historical precedents exist for sustained mass critical care.

In many states existing laws would permit mass critical care to be implemented on a temporary reactive basis under the authority of an individual hospital's incident commander for a sudden impact event that threatens to overwhelm the resources of a hospital. PHE powers are defined on a state-by-state basis.[7] Where laws exist to authorize sustained mass critical care, this authority is generally at the level of a state public health official.

Mass critical care, whether temporary or sustained, should guarantee the following lifesaving interventions that can be performed immediately: (1) mechanical ventilation, (2) fluid resuscitation, (3) vasopressors, (4) antidotes and antibiotics, and (5) analgesia and sedation.

Lifesaving mass critical care interventions would be extended to much larger than usual numbers of patients by the following approaches: (1) Substitution of equivalent available interventions for scarce or unavailable treatments; (2) adapting nearly equivalent available interventions instead of other scarce or unavailable treatments; (3) conservation of resources; and (4) reuse of some single-use items. Such modifications from usual practices would be proportional to the gap between needs and resources and would be implemented in an organized way by each hospital's HEICS.

Pediatric Critical Care Needs and Resources in a Public Health Emergency

If a PHE affected persons of all ages equally, then children aged 0 to 14 years would account for 20% of the patients and children aged 0 to 19 years would account for 28% of the patients.[8] Younger patients may be more vulnerable to infections, dehydration, toxins, and trauma and are less able to protect themselves in a dangerous environment. Thus children may be overrepresented in a patient population during a PHE. Accidents involving a child-specific activity or terrorism intentionally targeting children may result in a patient population predominantly made up of children. Some planning scenarios considered by the Department of Homeland Security exceed the entire national critical care capacity.[3]

Survival rates from high-risk pediatric conditions tend to be better when children receive care at pediatric hospitals.[9-12] The younger the patient, the more age-specific are the treatment requirements. A national survey estimated a pediatric ICU (PICU) peak capacity of 54 beds per million pediatric population.[13] Because normal PICU occupancy exceeds 50%, fewer than 30 vacant PICU beds per million age-specific population are generally available in a region. Because each region may only be served by a single or a few pediatric hospitals, events that disable a pediatric hospital may disproportionately degrade regional pediatric care.

Quantitative models indicate that survival in a PHE would be better if pediatric patient surge is distributed to pediatric beds throughout a region, rather than overloading facilities near the scene of an emergency.[14] Appropriate utilization of pediatric hospitals would be promoted by clear identification of pediatric hospitals.[15,16] Unfortunately, control of patient distribution may be impossible in a PHE.[17] As a result, all hospitals must be prepared to care for some children.[18] Even if pediatric regional resources are used optimally, hospital vacancies to accommodate pediatric surges are empirically much more limited than for adult patients.[19] Whether or not patients are distributed optimally to hospitals, outcomes from a hypothetical large PHE are likely to be better with mass critical care approaches.[14,20]

When the PICU Is Notified of a Sudden-Impact Public Health Emergency

When a sudden-impact PHE is announced, PICU clinical leaders must immediately focus attention on safety of patients and staff. The hospital's HEICS is activated. Normal operations continue until other instructions are received. Staff who are already in the hospital report to their normal assigned work area, notifying their supervisor of their arrival. PICU clinical leaders review the hospital disaster plan, including job action sheets, and discuss pertinent aspects with the staff. When possible, the PICU clinical leaders will be informed about type, number, and arrival time of anticipated patients. However, such information is often unavailable and inaccurate. Scheduled admissions are reviewed for potential cancellation. Patients in the PICU are evaluated for transfer to a lower level of care or discharge.

Based on the initial assessment, ICU leaders need to determine the number of additional patients who could be accommodated with available staff, equipment, supplies, and space to provide normal standards of care. Additional needs for staff, equipment, and supplies should be communicated through appropriate channels in the HEICS. Additional staff is called in when HEICS instructs the staff present to do so. Staff already in the hospital may be reassigned by HEICS. Staff responding from outside should report to a labor pool area for assignment. Areas designated for expansion of services and overflow are prepared when instructed by HEICS.

As information about the event becomes available, PICU physician and nurse leaders provide incident-specific just-in-time teaching to staff when warranted. Just-in-time teaching is especially important when less experienced supplemental providers are assigned to the PICU.

Rapidly accommodating patients from the emergency department (ED) or operating room will be essential in allowing those areas to continue receiving new patients. At all times, clinical leaders must maintain awareness of the environment, operational problems, disaster-related communications, and reactions of staff, patients, and families.

Emergency Department Phase

To provide continuity in patient care, the PICU team must interact closely with the ED. In some cases, PICU staff may be temporarily reassigned to work in the ED. Therefore, the critical care team should be familiar with the ED perspective on disaster responses.

Triage

Triage sorts patients to match their needs with available resources. Triage is an evolving process relative to shifting needs and resources. Prehospital field triage and care is beyond the scope of this chapter, but when it is effective, patients are selected who will benefit from ED care. Some mild patients not requiring ED care may have been overtriaged, and others may arrive at the ED without prehospital assessment. The worried may well constitute a large proportion of patients arriving at an ED. Severely ill or injured patients may arrive later than those with less serious conditions in a sudden impact emergency. Triage categories are assigned in the ED by an experienced clinician whose sole role is to act as triage officer. Elements of the triage process may have to be repeated later according to evolving imbalances of patient needs and resources.

Triage at the ED is performed according to the nature of the PHE. When potential contamination of victims by toxins is involved, initial triage outside the hospital first identifies those needing immediate decontamination to protect the patient, staff, and entire hospital facility. Likewise, when a highly transmissible virulent infection is involved, triage prior to entering the ED identifies and isolates potentially infectious patients at the earliest time to avoid exposing staff and other patients. Failures of triage at the early stages of decontamination and infection control may subsequently incapacitate an entire hospital. When pertinent, the patient's medical record should clearly indicate decontamination procedures done and the patient's infection control status.

Physiologic triage identifies patients needing immediate lifesaving interventions. Physiological triage tools identify patients in five categories: (1) those needing immediate lifesaving interventions; (2) those who need significant intervention that can be delayed; (3) those needing little or no treatment: (4) those who are so severely ill or injured that survival is unlikely despite major interventions; and (5) those who have already died. Care of patients triaged to group 4, those who are so severely ill or injured that survival is unlikely, must deviate most significantly from usual approaches to intensive care. Because of overall demands on the system, scarce resources must be allocated to other patients who are more likely to survive. Group 4 patients are sometimes referred to as "expectant." Expectant patients are defined by current resource constraints as well as physiological observations. Palliative care is always provided to expectant patients. Also see the discussion of rationing at the end of this chapter.

It is beyond the scope of this chapter to advocate one triage tool in preference to others. No single tool is always rapid, completely accurate, appropriate to all ages and disorders, and already familiar to all providers.[21] Staff should be familiar with the physiological triage tool in use locally.

Decontamination

When indicated, decontamination reduces toxic effects for the victim and avoids contamination of staff and the hospital facility. The airway is monitored and maintained during decontamination. Antidotes are given after cleaning the site of administration. Age-specific issues include hypothermia in infants and behavioral limitations. Warm water may prevent hypothermia. Young children need assistance undressing, while some older children resist undressing and require encouragement and some privacy.[22,23]

Infection Control

For a public health emergency involving a highly virulent transmissible infection, infection control must begin outside the ED entrance and continue without interruption in the hospital while the patient is infectious. Infection control practices can be summarized as follows[24]:

1. Standard precautions apply to all patients, regardless of infection status (hand hygiene; use of gloves, gown, mask,

eye protection, depending on the anticipated exposure; and safe injection practices).
2. Contact precautions are used when infection may be spread by direct contact. When a single-patient room is not available, more than 3 feet separation between beds reduces sharing of items between patients. Staff should wear a gown and gloves for contact with the patient or contaminated objects.
3. Droplet precautions prevent transmission of pathogens spread through close respiratory contact. Because these pathogens do not remain infectious over long distances, special air handling is not required. When a single-patient room is not available, more than 3 feet separation with a curtain between beds reduces droplet transmission. Staff should wear a mask for close contact with the patient.
4. Airborne precautions prevent transmission of infections transmissible over long distances when suspended in the air. A negative pressure isolation room reduces airborne transmission. Staff should wear a mask or fit-tested N-95 respirator, depending on disease-specific recommendations. Infection control practices for specific clinical syndromes are detailed in standard references[24] and later in this chapter.

Keeping Families Together, Identifying and Tracking Children, Child Safety

Hospital care of children is more efficient, more effective, and less stressful when the child is accompanied by a family member or familiar caregiver. This need must be balanced against other triage considerations. Unaccompanied children must be properly identified, tracked, and reunited with their families, requiring proper identification of adult caregivers before releasing children to them. Pediatric safe areas in hospitals with appropriate staff supervision are necessary. Sample child identification and tracking documents have been designed.[18]

Intensive Care Unit Phase

For a sudden impact event in which the ED phase lasts a few hours, the ICU phase may last weeks. On admission to the PICU, a "tertiary survey" is performed to detect injuries and disorders that were overlooked in the rapid primary and secondary survey done previously. For standard interventions, template orders and an abbreviated hospital record may extend the capacity of an overloaded workforce. Every effort must be made to guarantee the essential critical care interventions: mechanical ventilation, fluid resuscitation, vasopressors, antibiotics and antidotes, and sedation and analgesia.

In order to provide essential interventions, some resource-intensive interventions that are ordinarily considered standard in an ICU may have to be delayed or forgone in a mass critical care situation, because standard care would reduce the population who could receive lifesaving care. Interventions that may have to be delayed include invasive hemodynamic monitoring, intracranial pressure monitoring, early renal replacement therapy, extracorporeal membrane oxygenation, parenteral nutrition, and frequent recording of fluid balances and vital signs.[3,25] Clinical decision making may have to be based more often on clinical judgment and less often on laboratory and imaging studies.

PICU Operations in a Gradual Onset and Sustained Public Health Emergency

Many of the same considerations pertain in sudden-impact and gradual-onset PHEs. However, a gradual onset allows event-specific preparation. Resources can be augmented and procedures can be developed and practiced. Staff can be trained. Experience in the early phase of the emergency would provide evidence to refine event-specific recommendations. Very rapid publication of such experience has provided rapid evolution of management recommendations in recent PHEs such as the spread of severe acute respiratory syndrome, the H1N1 influenza epidemic, and anthrax exposures.

Space

Patient care space may be adapted by converting single patient spaces to be used by two or three patients. After exhausting PICU space, additional space for mass critical care also may be adapted by using intermediate care units, postanesthesia care units, EDs, procedure suites, or non-ICU hospital rooms. Overflow of critically ill adolescents or young adults may be shared between PICUs and adult ICUs. Overflow of young infants or term newborns may be shared by PICUs and neonatal ICUs. Nonhospital facilities should only be used for mass critical care if hospitals become unusable.

Personnel

Supplemental providers may include physicians, nurse practitioners, physician assistants, nurses, respiratory therapists, pharmacists, and emergency medical technicians who have skills in non-ICU pediatrics or nonpediatric critical care. Rapid credentialing procedures, just-in-time education, and close supervision by experienced PICU clinicians would promote the role of supplemental providers.

Mechanical Ventilation

Mechanical ventilation is detailed in other chapters of this textbook. Most hospitals have only a small supply of standard ventilators and circuits in excess of usual ICU capacity. It may be necessary to consider temporary use of transport and anesthesia ventilators and bilevel positive pressure breathing devices.

Some pediatric hospitals use a single type of ventilator for patients of all sizes, with appropriate circuits and software algorithms. In other hospitals, ventilators usually used for adults that have high compliance circuits and adult algorithms may have to be adapted for use in infants or small children. Some difficulties may be encountered. The inspiratory flow or pressure sensor may not be sensitive to an infant's small inspiratory effort. Thus triggering of inspiration may fail for synchronized intermittent mandatory ventilation, assist control, or pressure support. Likewise, ventilator algorithms to terminate pressure support inspiration may fail in the presence of air leaks around endotracheal tubes. A substantial air leak around an uncuffed endotracheal tube may result in frequent ventilator alarms indicating low pressure or low exhaled tidal volume.

In a volume-controlled mode, adult ventilators may be unable to provide small tidal volumes and inspiratory flow appropriate for a small infant. Pressure-dependent losses of tidal volume in compressible spaces of adult ventilator circuits exaggerate breath-to-breath variation in delivered tidal volume if peak inspiratory pressure varies with patient effort or changing respiratory mechanics. Difficulties in providing small tidal volumes, as well as variation in ventilation due to leaks around uncuffed endotracheal tubes, may be alleviated by using a time-cycled, pressure-limited mode of ventilation.

Supplemental providers need considerable assistance in caring for an infant on a ventilator. Maintaining endotracheal tube patency, stabilization, and proper cuff inflation and evaluating episodes of hypoxia are challenges even for experienced PICU clinicians.

Manual Ventilation

Few hospitals stockpile enough mechanical ventilators to support three times the usual number of ICU patients. The temporary use of manual ventilation with a self inflatable bag may be essential to meet mass critical care goals. Manual ventilation is labor intensive, tiring to operators, and may expose staff to infection risks as a result of close prolonged bedside contact. However, manual ventilation has been used successfully via tracheostomy tubes for days in a polio epidemic,[26] temporarily for hours via endotracheal tubes in a power failure,[27] and during weather emergencies.[28-30] In the patient transport setting, manual ventilation provides similar gas exchange compared with mechanical ventilation.[31-33] Work to manually deliver small tidal volumes to an infant is less than that needed for an adult. Infection risks are negligible except for specific transmissible infections. Self-inflating bags can be used with ambient air or low-flow oxygen. When temporary manual ventilation is provided until mechanical ventilators are available, outcomes are likely to be superior to the outcomes in cases of untreated respiratory failure. Just-in-time training and supervision of supplemental providers may improve their performance in providing appropriate gas exchange and avoiding barotrauma.

Equipment and Supplies

Mass critical care can only be provided if essential equipment and supplies are available on site. Resupply and rental deliveries may be impossible during a PHE. Thus hospitals must balance the benefits of an adequate stockpile against costs of keeping items on site that may never be used.

The Task Force on Mass Critical Care[3] has recommended that a hospital first should target a mass critical care capacity of three times the usual maximum ICU capacity for 10 days. On-site stockpiles per mass critical care treatment space are planned accordingly (summarized in Table 18-2). Warming devices for infants are necessary to avoid cold stress.

While many interventions may be carried out by adapting nearly equivalent equipment and supplies, some adult equipment cannot be adapted to infants and small children. It is essential to stock adequate numbers of resuscitation masks, endotracheal tubes, suction catheters, chest tubes, intravenous catheters, and gastric tubes in pediatric sizes. In a crisis, resuscitation bags intended for adults can be used to manually ventilate infants. However, small resuscitation bags intended for infants cannot provide an adequate tidal volume for an adult or child.

If cuffed endotracheal tubes are used, it may be possible to cover all pediatric needs with 3.0-, 4.0-, 5.0-, and 6.0-mm cuffed tubes, reducing the need to stock uncuffed tubes in all other sizes. Guidelines for mass critical care ventilators have been provided.[3,34] Because few institutions will have enough ventilators to serve three times the usual number of ICU patients, the option to temporarily provide manual ventilation depends on having adequate numbers of self-inflatable resuscitation bags and endotracheal tubes immediately available.

Table 18–2 Equipment and Supply Stockpiles for Mass Critical Care*

Device	Minimum No. per Patient
Manual resuscitator	1.3
Closed circuit suction catheter	1.3†
Endotracheal tubes	1.6†
Yankauer suction device	1.3
Central venous catheters	1.3†
Peripheral venous catheters	6.5†
Intravenous crystalloid solution	20 L
Gastric tubes	1.3†

*Information is provided for selected items. See reference 3 for the full list.
†Numbers refer to a standard adult size. For infants and children, this number must be supplied in a range of pediatric sizes. A larger number of peripheral venous catheters would account for the greater difficulty in achieving venous access in infants.

Medications

In order to extend medication stockpiles in mass critical care, rules should be formulated ahead of time regarding appropriate substitutions, dose and frequency reductions, converting parenteral to enteral administration, restrictive indications, and shelf-life extension.[3] Experience in recent PHEs indicates that very large quantities of analgesics and sedatives are essential.[6,35] Weight-based dosing may be simplified to improve efficiency by specifying a limited number of weight range categories. When time constraints make it difficult to weigh patients, length-based estimates of weight may suffice.[36]

Critical Care in Specific Types of Public Health Emergencies

While all-hazard planning prepares for PICU operations across all types of PHEs, some responses must be event-specific. These responses are detailed extensively in standard references.[24,37] In addition to general critical care support, event-specific hospital responses and treatments are briefly outlined in Table 18-3. For any type of emergency, clinical interventions also will be necessary for illnesses and injuries that are indirectly related or unrelated to the primary event. These illnesses and injuries include patients hospitalized prior to the onset of the PHE.

Table 18–3 Specific Types of Public Health Emergencies and Event-Specific Management

Type of Event	Infrastructure	Decontamination	Infection Control	Disorders/Event-Specific Interventions
Pandemic (influenza, SARS)	Need for negative pressure isolation		Depending on organism, usually a combination of standard, droplet, airborne precautions	Pneumonia, sepsis Antibiotics/antiviral according to organism Antibiotics for bacterial coinfection
Major earthquake	Extensive damage Mass evacuation likely		Standard precautions	Multiple trauma including crush injuries requiring renal replacement therapy
Hurricane	Extensive damage Mass evacuation likely		Standard precautions	Multiple trauma
Nuclear detonation (terrorism)[40]	Extensive damage Mass evacuation likely	Radiation Contamination of body orifices, wounds, skin Treatment of life-threatening injuries is the priority	Standard precautions	Multiple trauma, burns, radiation (bone marrow, immunosuppression, gastrointestinal)
Radioactive dispersal bomb (terrorism)[41]	Local damage and contamination	Radiation Contamination of body orifices, wounds, skin Treatment of life-threatening injuries is the priority	Standard precautions	Multiple trauma, burns, radiation (bone marrow, immunosuppression, gastrointestinal)
Chemical attack Nerve agent (terrorism)		Essential, must be rapid	Standard precautions	Antidotes (atropine, pralidoxime) Anticonvulsants Bronchodilators
Chemical attack Vesicants/blister agent (terrorism)		Essential, must be rapid	Standard precautions	Chemical burns, potential airway injury
Chemical attack Pulmonary agent such as chlorine, phosgene (terrorism)		Move to fresh air Irrigate eyes, mucous membranes, skin	Standard precautions	Airway and pulmonary edema
Biologic attack Anthrax (terrorism)		If known, direct exposure to spores	Standard precautions	Ciprofloxacin Doxycycline
Biologic attack Pneumonic plague (terrorism)			Droplet precautions	Streptomycin Gentamycin
Biologic attack Smallpox (terrorism)			Standard, contact, and airborne precautions	Vaccination

Rationing

If a PHE overwhelms resources despite mass critical care approaches, rationing might be considered. Rationing might occur on a first-come first-served basis or by selecting patients most likely to survive as a result of brief lifesaving interventions. Such criteria have been suggested for selecting adults for mass critical care when needs exceed resources.[3,38] Proposed eligibility criteria include absence of severe chronic conditions, predicted mortality not exceeding an arbitrary upper limit, and improving clinical status on periodic reevaluations.

At the present time, neither evidence nor consensus of opinion nor law supports the concept of rationing, much less a particular rationing procedure. For PHE rationing to be a feasible option, public and professional consensus is a necessary foundation. Only then could states create a legal basis and liability protections.[39] Better evidence is needed to formulate eligibility criteria and operational plans for PHE rationing.

Structure and Function of the Heart

V. Ben Sivarajan, Steven M. Schwartz, and Julien I.E. Hoffman

PEARLS

- The basic form of the human heart and great vessels is complete 8 weeks after conception, after which the structures grow and mature. Recent data does show some limited capacity for hyperplasia that persists even into adulthood.
- The parietal pericardium is a stiff membrane that surrounds the heart loosely, separated from the heart by a small amount of lubricating pericardial fluid.
- Immediately after birth, there is a large increase in total body oxygen consumption and cardiac output to approximately twice its later values.
- Although large arteries are regarded as conduits and capillaries as vessels allowing transport of substances to and from the tissues, many substances can move across arterial walls.
- Standard echocardiographic assessments (ejection and shortening fraction) reflect myocardial performance (load-dependent measure) as opposed to true contractility. Assessments of adequacy of ventricular-vascular coupling (adequacy of contractile status with a given preload given the afterload conditions) can be assessed by noninvasive (relationship between Vcf and shortening fraction) or invasive (conductance catheter assessments of Es and Ea) methods.

Anatomic Development and Structure

Gross Anatomy

The basic form of the human heart and great vessels is complete 8 weeks after conception, after which the structures grow and mature. The ventricular mass enlarges by cellular hyperplasia and hypertrophy; hyperplasia previously assumed to cease after birth has recently been shown by carbon-14 dating to occur at an annual turnover rate of 1% at age 25 years, decreasing to half that value by age 75 years.[1] Increase of ventricular volumes is believed to depend on the increasing flow through each ventricle; diverting flow from a ventricle is believed to cause hypoplasia of that ventricle and its associated great artery. Before birth, left and right ventricles have equal wall thickness. After birth and clamping of the umbilical cord, there is a rise in systemic vascular resistance and a decrease in pulmonary vascular resistance; as a result, the left ventricle becomes thicker than the right ventricle. Left ventricular wall thickness is proportional to the logarithm of age from conception.[2] The ventricular septum is flat in the fetus. After birth, it bulges into the right ventricle and functions like part of the left ventricle. In the embryo, coronary arteries form in the embryonic epicardial tissue[3] and join the aorta to supply flow to the thickening heart muscle, which can no longer get enough blood from sinusoids from the ventricular cavity.

Muscle fibers in the ventricles form a complex helical array. Fibers in the left ventricular midwall are circumferential, parallel to the atrioventricular groove. From this position the fibers twist gradually as they move toward each surface so that at the epicardial surface they are 75 degrees and at the endocardial surface 60 degrees from the circumferential fibers.[4] Some investigators believe that the muscle fiber layers form one continuous sheet that is wrapped around itself like a turban.[5] When the ventricle is dilated, the fiber angles change and become less effective in ejecting blood.[6]

Microscopic Anatomy

The myocardium is a syncytium made of branching fibers, each consisting of bundles of myocytes in series. The myocytes are joined to adjacent myocytes by the intercalated disc, a set of mechanical junctions: adherens junctions with N-cadherin, catenins, and vinculin; desmosomes with desmin, desmoplakin, desmocollin, and desmoglein; and gap junctions with connexins and N-cadherin.[7-9] The gap junctions transmit the electrical impulse from one cell to the next.

Myocyte

The major components of the myocyte are the sarcomeres, which contain the myofibrillar contractile apparatus; the mitochondria, which contain enzymes for energy production; the sarcolemma, which contains the cell envelope and its extensions into the cytoplasm; the sarcoplasmic reticulum; and the cytosol. The numerous proteins in these structures not only play a role in normal function but, if abnormal for genetic or extraneous reasons, contribute to myocardial dysfunction.[10]

Contractile Apparatus

The functional unit is the sarcomere, defined as the structure between two transverse Z lines,[11-13] representing discs that contain proteins such as α-actinin and filamin that connect the

actin and titin filaments of adjacent myocytes. On each side of the Z line is a light zone, the I (isotropic) band, and in the center of the sarcomere are two dark zones, the A (anisotropic) bands, separated by a light H band in the middle of which is a dark thin M band (Figure 19-1). The I bands contain paired thin filaments of actin coiled in a helix and attached to the Z lines. In humans, cardiac α-actin makes up 80% of the actin in fetuses and neonates, while skeletal α-actin makes up 60% of the total in adults.[14] Two long tropomyosin filaments lie in the grooves between each pair of actin filaments (Figure 19-2).[15] Every 400 Å, near the crossover points of two actin filaments, is a troponin complex with the following three distinct troponins: (1) troponin T, which binds troponin to tropomyosin; (2) troponin I, which inhibits actin-myosin interaction; and (3) troponin C, which is a high-affinity calcium receptor. The thin actin filaments overlap with thick myosin filaments at the A bands. These myosin filaments are composed of light and heavy chains. The light chains coil around each other to

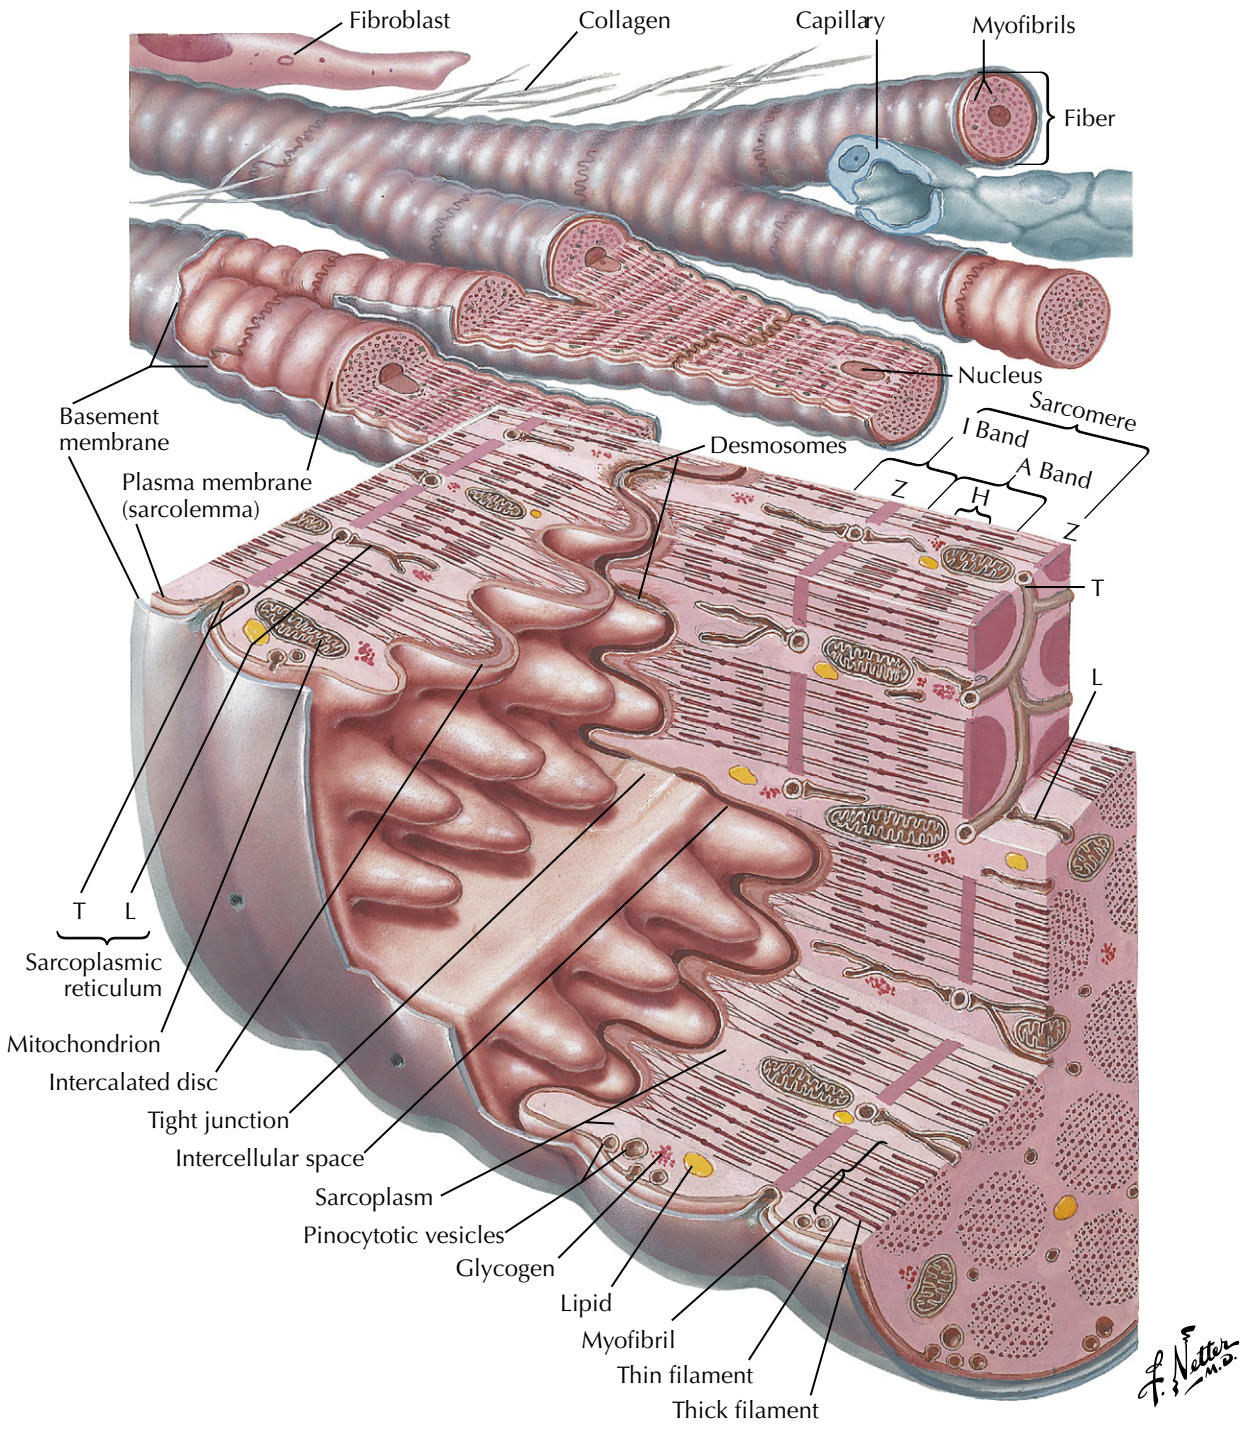

Figure 19–1. Diagram of cardiac muscle unit showing organization of structural and contractile elements. *(Netter illustration from www.netterimages.com. Elsevier Inc. All rights reserved.)*

form the long core of the myosin molecule. The heavy chains form globular myosin heads that project from the sides of the thick filament toward the actin molecules (see Figure 19-2). A collar of cardiac myosin-binding protein C encircles the thick filaments. Mutations of this protein are a common cause of hypertrophic cardiomyopathy.[16] Between two A bands there is usually a thin lighter band, the H band, which has myosin but no actin filaments.[13,15]

Titin, the largest known molecule (molecular weight 3-3.6 MDa, 1 mm long), is the third most abundant fibrillar protein. It extends from the Z band to the M band, has two isoforms, and is the main protein responsible for the elastic behavior of the myocyte.[17] It is essential for sarcomere assembly and for sensing sarcomere length[18] and, with myomesin (not shown in figure), supports the actomyosin filaments (see Figure 19-2).

Myocytes have fewer myofibrils and more water and cytoplasm before birth than after birth, and the myofibrils do not have the uniformly parallel arrays that they will have after birth.[19]

Sarcolemma and Sarcoplasmic Reticulum

The cell membrane contains receptors, ion channels, pumps, and exchangers. It has indentations overlying the Z bands, and from these indentations small tubules termed T (for transverse) tubules penetrate the cell. Abutting against the T-tubules are dilated expansions of the sarcoplasmic reticulum (junctional reticulum or cisternae), which join the free sarcoplasmic reticulum, a network of longitudinal tubules inside the cell that surround the thick (myosin) filaments. These tubular systems modulate the entry of calcium to, or its exclusion from, the cytoplasm.[11,19]

The cisternae contain the calcium-binding protein calsequestrin, whereas the longitudinal tubules contain phospholamban and the adenosine triphosphate (ATP)-dependent calcium pump.[19,20] Phospholamban inhibits the affinity of the sarcoplasmic reticulum Ca^{2+}-ATPase (SERCA) pump for calcium, and phospholamban phosphorylation relieves the inhibition and increases calcium entry with a resulting increase in inotropy.[21-24] In heart failure, phospholamban phosphorylation is decreased by an increase in unphosphorylated calcineurin,[25] leading to decreased SERCA activity.[26,27] A similar decrease in SERCA has been found in sepsis[28] and in some forms of dilated cardiomyopathy.[29] Cisternae store and release activator calcium, whereas longitudinal tubules remove calcium from the cytosol. Calcium release is primarily via the calcium-activated calcium release channel termed the ryanodine receptor. Both T-tubules and sarcoplasmic reticulum are sparse, undifferentiated, and disorganized early in gestation but increase and differentiate markedly late in gestation and after birth in mammals. Therefore the immature heart depends mainly on extracellular sources for activator calcium,[15,19] partly explaining its marked calcium sensitivity.

Cytoplasm

During development, the proportion of mitochondria in the myocyte increases, particularly at the time of birth, and mitochondria become larger and develop more complex cristae.[19]

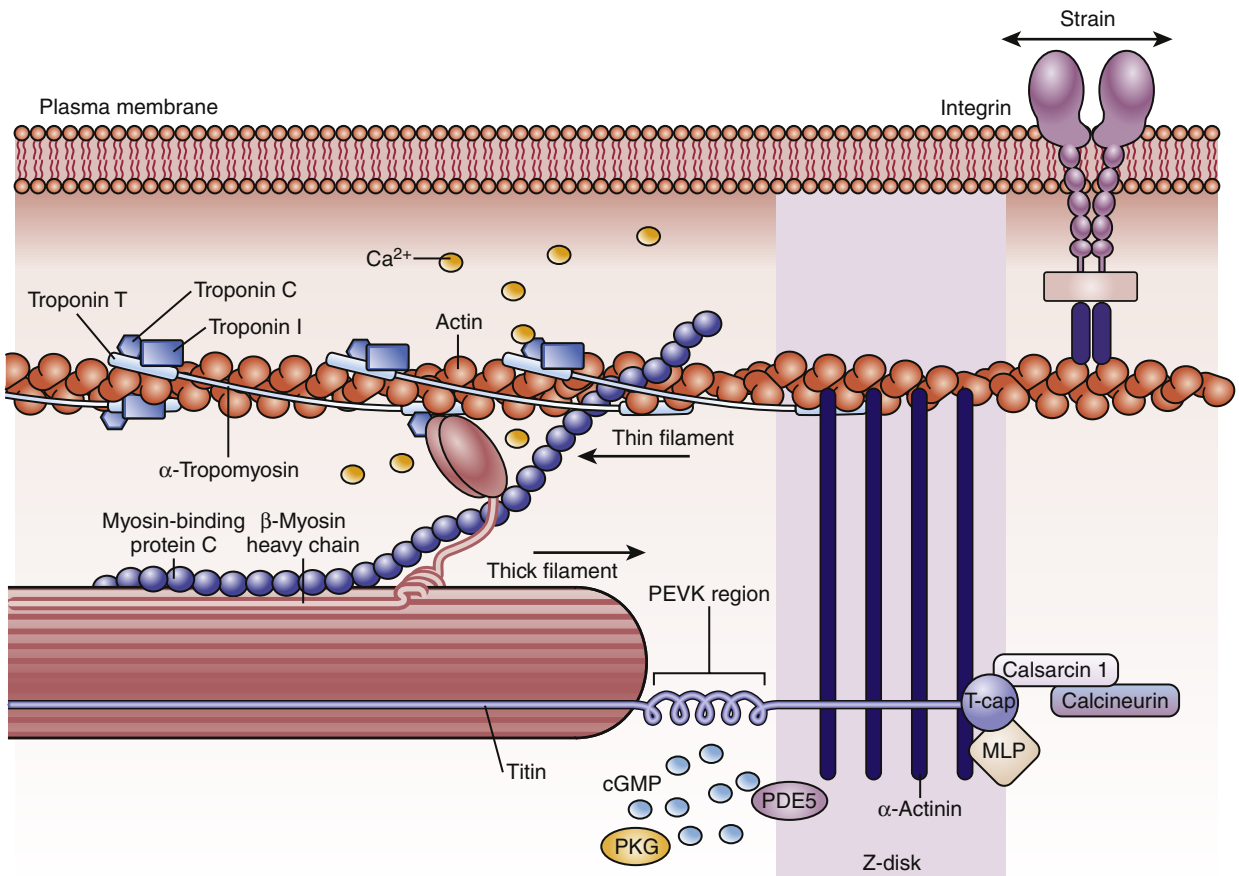

Figure 19–2. Diagram showing the integration of myofibril contraction (actin-myosin complex formation) to attachments to the Z-lines and cytoskeleton via various ultrastructural proteins. *(Modified from Mudd JO, Kass DA: Tackling heart failure in the twenty-first century,* Nature *451:919-928, 2008.)*

In the adult, approximately 30% to 40% of the muscle mass is made up of mitochondria. The cytosol contains other calcium-binding proteins[19,30] and other major proteins such as tubulin and desmin.

Cytoskeleton and Extracellular Matrix

For contractile proteins to shorten the whole myocyte, they must be linked to both the cell membrane and the extracellular matrix. Longitudinal connections are made via the Z lines, representing discs that contain proteins such as α-actinin and filamin which connect the actin and titin filaments of adjacent myocytes.[31,32] More lateral connections are made by the extrasarcomeric skeleton. There is an intermyofibrillar cytoskeleton with intermediate filaments, microfilaments, and microtubules.[31,33-35] Desmin intermediate filaments provide a three-dimensional scaffold throughout the extrasarcomeric cytoskeleton and connect longitudinally to adjacent Z discs and laterally to subsarcolemmal costameres.[33,35] Costameres are subsarcolemmal domains located in a periodic pattern, flanking the Z lines and overlying the I bands on the cytoplasmic side of the sarcolemma.[36-40] They contain the focal adhesion-type complex, the spectrin-based complex, and the dystrophin/dystrophin-associated protein complex. The focal adhesion-type complex, made up of cytoplasmic proteins such as vinculin, ankyrin, and talin, connects with cytoskeletal actin filaments with transmembrane proteins such as the dystroglycans and the sarcoglycans.[41-43] Dystrophin is linked to dystroglycan, laminin, and actin. These proteins help to fix sarcomeres to the lateral sarcolemma, stabilize the T-tubular system, and connect the sarcolemma to the extracellular matrix. Voltage-gated sodium channels colocalize with dystrophin, spectrin, ankyrin, and syntrophins. Potassium channels interact with the Z line and intercalated discs. In many of the genetic dilated cardiomyopathies, these proteins are abnormal,[44-46] thereby explaining the abnormal muscle function.

Extracellular collagen plays a major role in cell-cell and cell-vessel interactions and in ventricular stiffness.[47-50] With maturation, more collagen is type III and less is type I.[51] The relationship between sarcomeres and cytoskeleton changes with maturation, perhaps accounting for maturational differences in the resting sarcomere's mean length in myocytes.[52] In addition, cell adhesion proteins stimulated by growth factors from the myocyte are in greatest amount in the neonate, decrease with postnatal age, but increase again during hypertrophy.[53,54] Other elements in the extracellular matrix (e.g., laminin, fibronectin, and tenascin) play a major role during morphogenesis and during contraction[55] and are important mediators in hypertrophy.

Nerves and Receptors

Adrenergic, muscarinic, and other receptors appear early and are functional even before innervation. Parasympathetic innervation precedes sympathetic innervation in all species.[19,56,57] Innervation is present in the earliest viable human premature infants but may not be fully mature. Innervation is most advanced in species that are most independent immediately after birth.

Cardiac sympathetic nerve fibers come from cervical sympathetic and stellate ganglia. Right sympathetic nerves innervate the right and anterior surfaces of the heart. Left sympathetic nerves innervate the left and posterior surfaces. Vagal nerve fibers descending from medullary centers supply both atria and ventricles and the proximal portion of the bundle of His; the distal part of the bundle of His has only sympathetic nerve supply. Sympathetic and vagal afferents leave the heart and carry information from baroreceptors that respond to high pressures in the ventricles and to lower pressures in the atria, cavae, and pulmonary veins and from chemoreceptors that respond to locally produced substances such as bradykinin and prostaglandin.[58]

Ductus Arteriosus

The ductus arteriosus forms from the embryonic left sixth aortic arch and joins the main pulmonary artery that separates from the truncus arteriosus. The ductus is kept open by a balance between prostaglandin E2 (PGE2) and endothelin-1 (ET-1), both of which are formed in its wall and circulate from other sites. Initially, the ductus is very sensitive to the dilating action of PGE2, but later in gestation it becomes less sensitive to dilator and more sensitive to constrictor prostaglandins.[59-61] After birth, oxygen reacts with a cytochrome P-450 and causes release of ET-1 (the most powerful ductus constrictor).[62] A switch from dilator to constrictor prostaglandins occurs. In addition, oxygen modulates the function of mitochondrial electron chain transport by increasing the generation of H_2O_2, inhibiting voltage-gated potassium channels in ductus smooth muscle, thereby opening voltage-gated L-type Ca^{2+} channels to cause influx of calcium and ductus constriction.[63-65] These constrictor effects overpower the dilating effect of nitric oxide, which is released from the ductus when oxygen tension rises.[66] The ductus constricts, usually within the first 24 hours and almost invariably within 3 weeks. The lumen then becomes permanently occluded by fibrosis.[61,67]

Physiologic Development and Function

Myocardial Mechanics—Cardiac Sarcomere Function

Excitation-Contraction Coupling

When an electrical impulse reaches cardiac muscle, myocyte membranes depolarize. Extracellular calcium in high concentration at the sarcolemmal membrane and the T-tubules enters the cell rapidly. Spread of electrical excitation into the myocyte via the T-tubules also causes release of intracellular calcium from the sarcoplasmic reticulum.[11,68,69]

Cytosolic calcium increases from a concentration of 10^{-7} M in diastole to 10^{-5} M in systole. When the calcium that entered the cytosol binds to troponin C, the inhibitory effect of troponin I is antagonized, and a conformational change of troponin and tropomyosin exposes the actin-myosin binding sites.[11,15,68,69] These sites interact with the myosin heads to form the cross-bridges (Figure 19-3). The myosin heads rotate, generate force, and move the actin filaments, just as oars move a boat through the water. Interaction between actin and myosin pulls the two Z lines toward each other, shortening the muscle and generating force. Increasing intracellular calcium results in greater cross-bridge formation and a greater generated force. Isoforms of the troponins and tropomyosin change during development, but the functional effects of these changes are unknown.[19,70] However, troponin I is less sensitive to a fall in pH in the fetus than in the adult, which could be protective in perinatal acidosis.

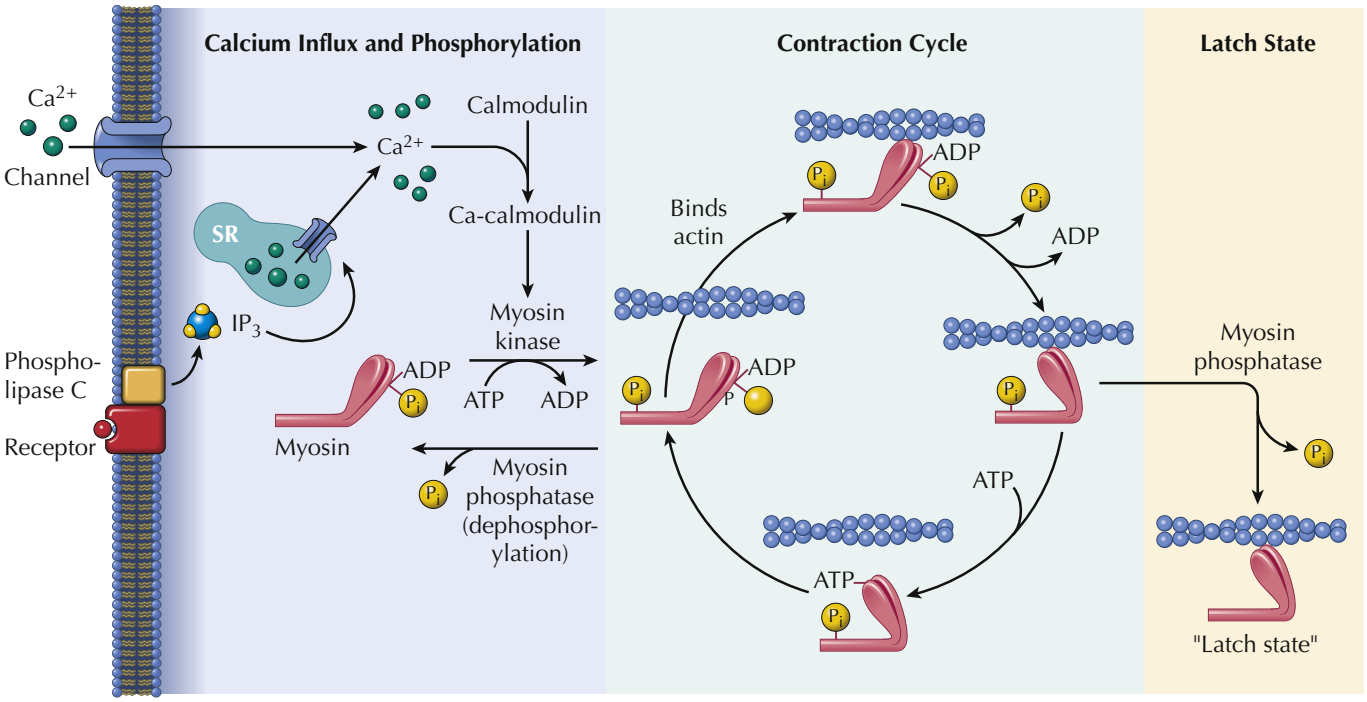

Figure 19–3. Diagram of cardiomyocyte calcium cycling and adenosine-triphosphate (ATP) utilization during actin-myosin complex formation. *(Netter illustration from www.netterimages.com. Elsevier Inc. All rights reserved.)*

The myosin head contains an ATPase that liberates energy from ATP. The activity of the ATPase determines the velocity of shortening of unloaded muscle by affecting the rate of attachment and detachment of the cross-bridges.[19,71] In most mammalian species, fetal myocardium contains V_3 myosin isoform (having two β heavy chains) with a high ATPase activity rate. In humans and most of the larger mammals, however, almost all ventricular myocardial myosin is V_3 isoform at any age, although human atria contain V_1 myosin isoform.[19]

Sarcomere Length-Tension Relationships

Sarcomere length-tension relationships have been investigated in isolated cardiac muscle strips, usually papillary muscle with its nearly parallel fibers. The muscle strip is placed in a water bath. One end is tied to a lever and the other to a force transducer (Figure 19-4, *A*). Weights attached to the other end of the lever extend the muscle to any desired length before contraction (preload); excessive stretching is prevented by a stop. Other weights added to the lever after initial length is set affect the muscle only after contraction has started and so are termed the afterload. The muscle can be stimulated to contract by an electrical impulse. Instruments for measuring muscle length, sarcomere length by laser diffraction, calcium entry by various fluorescence methods, and a host of other specialized functions can be added.[69,72,73]

Stretching relaxed muscle produces an exponential-like increase in passive tension (Figure 19-4, B). This elasticity results mainly from titin.[17,73-75] At very low sarcomere lengths, the actin filaments from each Z line overlap each other. As the sarcomere lengthens, the Z lines move farther apart and a gap appears between the two sets of actin filaments. When the sarcomere reaches a length of approximately 2.2 μm, there is a maximal overlap between actin and myosin filaments.[13,69,71] (Figure 19-4, *C*). At longer muscle and sarcomere lengths, actin and myosin filaments overlap less. The maximal sarcomere length is 3.0 μm. Further elongation of the muscle occurs by slippage of fibers and not by further sarcomere lengthening.[13,69,71]

Active contraction is studied in two ways[72] (Figure 19-4, *D*). First, muscle is stimulated to contract at different initial muscle lengths but is not allowed to shorten (isometric contraction). At the shortest lengths no force is generated; the muscle remains slack. As sarcomere lengths increase, force is generated and increases to reach a maximum at sarcomere lengths of approximately 2.2 μm. At longer sarcomere lengths, there may even be a decrease in force.[71]

If, at any length, passive tension is subtracted from the tension generated during isometric contraction, the resulting curve demonstrates active tension as a function of length (Figure 19-4, *B*).

Second, if afterload is small, the contracting muscle generates an appropriate force and then shortens while force remains constant (isotonic contraction). The rate of shortening is fastest at the onset of shortening, and from it, the velocity of shortening is measured (Figure 19-4, *D*). The shortening velocity ranges from zero when the load is so heavy that it prevents shortening to a maximum when the external load is zero[69]; however, true zero loading is impossible because of internal viscosity and elastic forces.[19,71] Increases in cytosolic calcium increase the force generated during contraction but have little influence on the maximal velocity of shortening.

In fetal lambs, the passive tension of muscle strips is abnormally high. Active tension per mm^2 cross-sectional myocyte area at any given afterload is below adult values but is

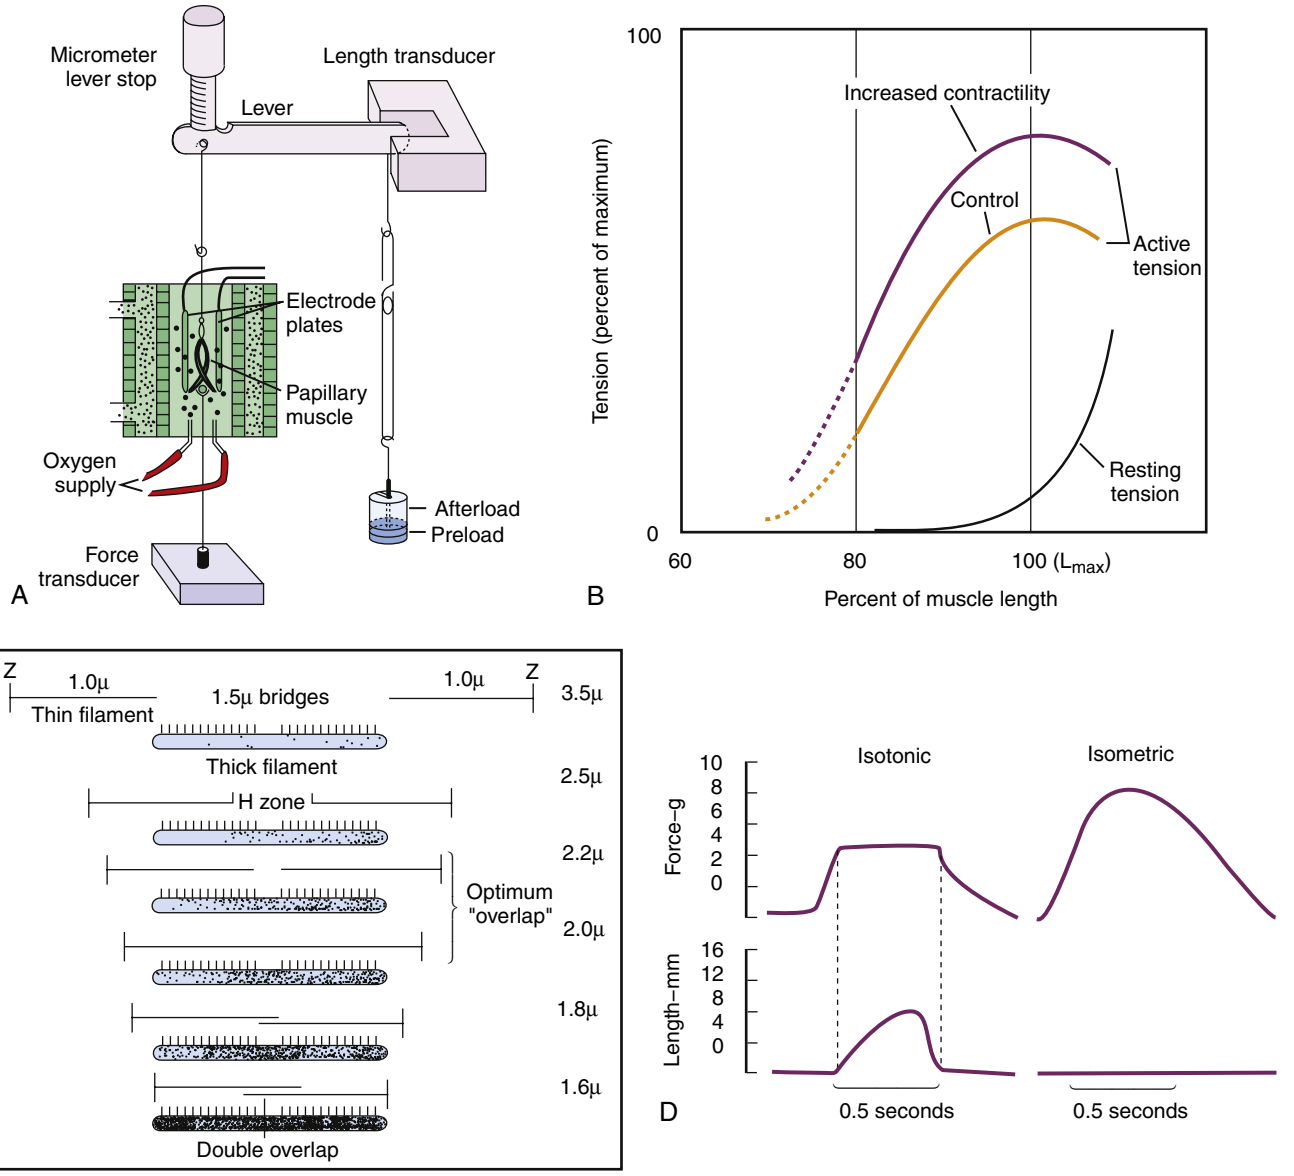

Figure 19–4. **A,** Diagram of isolated muscle strip in a water bath and attached to transducers for measuring force and length. Preload is set by the lever stop. proportional to the reduced number of myofibrils.[19,30,57] Contractile material accounts for approximately 60% of cardiac muscle in adults, but only 30% in fetuses. The extent and velocity of shortening are reduced in fetal heart muscle, but correcting for the amount of contractile machinery suggests the intrinsic performance of fetal and adult actin-myosin filaments is similar.[19] The change from fetal to adult performance seems to occur fairly soon after birth, when the myofibrillar array becomes regular and when the T-tubules and the sarcoplasmic reticulum develop into their adult form.[19] For this reason, prematurely born infants (and, to a lesser extent, full-term infants) have a much-reduced ability to tolerate an increase in afterload and are exquisitely sensitive to reductions in serum calcium concentrations.

Myocardial Mechanics—Myocardial Receptors and Responses to Drugs

α_1-adrenoceptors appear early in gestation and in many species reach their highest density in the neonate.[19,56,76] These developmental changes may be associated with the normal cell hypertrophy that occurs during development. By contrast, β-adrenoreceptors increase progressively with age. Both β_1 and β_2 are present on myocytes.[77,78] In addition, histamine H_2,

vasoactive intestinal polypeptide (VIP), adenosine A_1, acetylcholine M_2, and somatostatin receptors have been identified. They act on the myocyte's contractile apparatus through one of two main pathways.

The major pathway involves the membrane-bound receptor–G protein–adenylate cyclase complexes. G proteins include the Gs (stimulatory) and Gi (inhibitory) proteins.[79] In their inactive state, these G proteins include α, β, and γ subunits and guanine diphosphate (GDP). When agonists stimulate β-adrenergic, histamine, or VIP receptors, the G proteins undergo a conformational change. The changes induce the Gs protein to exchange its GDP for guanine triphosphate (GTP) and release the β and γ subunits. The Gs-α-GTP complex interacts with adenylate cyclase to convert ATP to cyclic adenine monophosphate (cAMP), which activates a variety of protein kinases to phosphorylate proteins including voltage-dependent calcium channels, phospholambin, and troponin I. Consequently, calcium entry during depolarization and during uptake of calcium into the sarcoplasmic reticulum storage pool is increased, thus increasing contractility. The Gs-α-GTP complex has intrinsic GTPase activity that converts GTP to GDP. The β and γ subunits rejoin the complex, which now is available for further activation by the receptor. In this way, as long as receptors are occupied by the agonist, the Gs cycle produces increasingly more cAMP, thereby amplifying the stimulatory signal. The Gi protein complex undergoes a similar cycle when adenosine, acetylcholine, or somatostatin receptors are stimulated; however, activating Gi protein reduces cAMP formation and decreases contractility. β_2 adrenergic receptors also couple to Gi in addition to Gs.[80] Gi in this context is thought to oppose the effects of Gs to some degree, including limitation of the acute positive inotropic response to adrenergic stimulation and offering some protection from apoptosis.[81-83]

Another signal-transducing system in the human heart is the phospholipase C-diacylglycerol-inositol triphosphate pathway, activated by α_1-adrenergic and M_2-muscarinic receptors.[84-86] Occupation of the receptors activates phospholipase C, which cleaves phosphatidylinositol triphosphate in the cell membrane to produce diacylglycerol and inositol triphosphate. The former activates protein C kinase in the membrane, which may hinder the effects of cAMP. The latter facilitates calcium release from the sarcoplasmic reticulum. This pathway is important in smooth muscle contraction but is of less importance in heart muscle.

In heart failure, the number of β_1-adrenergic and VIP receptors are down-regulated, and β_2-adrenergic receptors are uncoupled from G proteins.[21,77,78,87,88] These changes make the myocardium less responsive to circulating or locally released catecholamines or VIP and play a role in the reduced contractility observed in heart failure. Treating heart failure with β-adrenergic blocking agents not only has reversed the receptor changes, but has also been associated with improved function of muscle strips in adult patients.[89-92]

Coupling of β-adrenoreceptors is incomplete at birth. Milrinone is an agent that stimulates contractility by inhibiting phosphodiesterases; it bypasses the adenylate cyclase system. Although previously thought to be ineffective in the newborn,[93] a multicenter randomized trial[94] and subsequent widespread use has confirmed its efficacy in the neonatal population.[95,96] Since contractile mechanisms are almost fully developed at birth, the majority of mechanisms controlling contractility (except for changes in the source of calcium) are in place at birth.

Myocardial Mechanics—Integrated Muscle Function

Relationship Between Muscle Strips and Intact Ventricles

Preload stretching a muscle strip is equivalent to end-diastolic fiber length of the intact ventricle. This length can be measured by various devices in animals, but in the intact human ventricle it is best related to end-diastolic diameter or volume. Frequently, end-diastolic pressure has been used interchangeably with end-diastolic volume as an index of preload, but this usage can be misleading if the distensibility of the ventricle changes or if pressure outside the heart (pericardial or intrathoracic) rises.[97-100]

Afterload is more complicated in the intact ventricle. Commonly, aortic systolic pressure is equated with afterload. However, in the muscle strip, afterload represents the force exerted by the muscle during contraction, and pressure and force are not the same.[75,101,102] It is preferable to calculate circumferential wall stress, which at the midwall is a function of ventricular pressure, diameter, and wall thickness. Both peak systolic and end-systolic wall stress can be used to assess ventricular function.

Calculations of wall stress are based on the Laplace relationship:

$$\text{Wall Stress} = \frac{Pr}{2h}$$

where P is pressure, r is radius of curvature, and h is wall thickness. Because the left ventricle is not a regular sphere, particularly in systole, the Laplace formula is an oversimplification.[103] A fairly simple and accurate formula was developed by Grossman and colleagues[104]:

$$\text{Wall stress} = \frac{1.35PD}{4h(^{1h}/_{D})}$$

where P is pressure, D is left ventricular minor axis dimension, and h is wall thickness at the level of the minor axis. This equation can be written as:

$$\text{Wall stress} = \frac{Pr}{2h}\left(\frac{1.35}{1+\frac{h}{r}}\right)$$

that is, as the Laplace equation modified by the expression in parentheses. Note that if the left ventricle dilates acutely, wall stress rises markedly because r gets bigger and h gets smaller.

The major findings from studies of muscle strips have been confirmed in intact ventricles. Increasing preload increases the pressure generated by an isolated ventricle that is not allowed to eject, as observed in the last century by Otto Frank. If the ventricle is allowed to eject, then increased preload allows the heart to eject the same stroke volume against an increased afterload or else to eject a greater stroke volume against a constant afterload. This is the Starling component of the Frank-Starling law.[105,106] The mechanism of this response is twofold: (1) lengthening the sarcomere narrows it and places the myosin and actin fibrils closer together for stronger interaction, and (2) increased calcium sensitivity is mediated in some way

by titin stretching.[18] If an inotropic drug is given, then contractility increases and from a given fiber length greater force of contraction is achieved. This is a phenomenon seen every day in the intensive care unit.

The force-frequency relationship can be determined in intact hearts[107,108] by examining the response of the maximal rate of change of pressure (dP/dt max) in the ventricles after premature beats. The results in intact ventricles and muscle strips are similar. Subsequently, Seed and colleagues[109] applied this technique to humans with normal or abnormal left ventricular function and found an optimal R-R interval of 800 ms. They also examined dP/dt max for two beats given at optimum intervals after the premature stimulus. As expected, the first normal beat after the premature beat was potentiated because the extra calcium introduced into the cytosol by the premature beat was available to potentiate the first beat after the premature stimulus. The second postpremature beat also was potentiated, but less so. They used the ratio of the potentiation of these two beats to calculate the fraction of calcium recirculating from one beat to the next. This amount was constant in any one patient but was much less in those with left ventricular dysfunction.

Pressure-Volume Loops

If left ventricular pressure and volume are measured simultaneously, the resulting pressure-volume loop gives information about ventricular function and can be used to assess myocardial contractility in the intact heart.

The modern approach to analyzing these loops is based on the elastance concept of Suga and Sagawa.[110-112] Elastance is the ratio of pressure change to volume change. Consider an isolated ventricle containing a balloon that can be inflated to different volumes. At each volume the ventricle is stimulated to contract and generates a peak systolic pressure (Figure 19-5, *A*). As volumes increase, so do the peak systolic pressures generated, and the relationship is linear (Frank's law). The line joining the peak pressures intercepts the volume axis at a positive value, termed V_0, that indicates the unstressed volume of the ventricle. The equation for this line is as follows:

$$P_{es} = E_{es}(V_{es} - V_0)$$

where P_{es} is end-systolic pressure, E_{es} is slope of the line, V_{es} is end-systolic volume, and V_0 is unstressed volume. If contractility increases (more calcium enters the cells), the ventricle can generate greater pressures at any given volume, thereby generating a steeper pressure-volume line (higher value of E_{es}; dashed line I in Figure 19-5, *A*). If contractility decreases, the ventricle generates lower pressures at any given volume, and the pressure-volume line is less steep (lower value of E_{es}; dotted line D in Figure 19-5, *A*). E_{es} is also termed E_{max}.

If the ventricle is allowed to eject, the typical pressure-volume loop shown in Figure 19-5, *B,* is seen. During diastolic filling, volume increases and diastolic pressure rises slightly because of the increase in passive tension. At the end of diastole, isovolumic systole occurs, and ventricular pressure rises with no change in volume. When ventricular pressure exceeds aortic pressure, the aortic valve opens, blood is ejected, and ventricular volume decreases. Ejection ends, and pressure falls to diastolic levels as isovolumic relaxation occurs. The pressure and volume reached at the end of systole are those that would have been attained by the isolated ventricle at that same end-systolic volume. In other words, at a given volume,

Diagrams illustrating the concept of ventricular elastance. **A,** Isolated ventricle contracting at volumes 1, 2, and 3, generating corresponding pressures. *Purple line I* indicates results at increased contractility. *Blue line D* indicates results at decreased contractility. *V_0,* resting (unstressed) volume. **B,** Ventricular pressure-volume loops achieving end-systolic pressures of 1, 2, and 3 at corresponding volumes. *Purple line I* indicates results at increased contractility, with greater end-systolic pressures at each volume. *Blue line D* indicates results at decreased contractility. From a given end-diastolic volume, either the same ejection fraction is delivered at a lower end-systolic pressure *(dotted line 1)* or the same end-systolic pressure is achieved but at a much smaller stroke volume and ejection fraction *(line 4).* **C,** When the ventricular end-diastolic volumes *(EDV)* increase as afterload increases, as is normal, then stroke volume can be maintained, even though ejection fraction decreases. If contractility is decreased *(blue line),* then stroke volume can be maintained only with increasing end-diastolic pressures. *1, 2, 3,* End-systolic volumes and pressures at normal contractility. *I, II, III,* End-systolic volumes at decreased contractility.

no higher pressure can be generated (loop 1; Figure 19-5, *B*). The decrease in volume during ejection is the stroke volume which, divided by the end-diastolic volume, gives the ejection fraction; normally, ejection fraction is greater than 65%.

If afterload is suddenly increased by raising aortic pressure, the normal heart responds as shown in Figure 19-5, *B*. In the first beat after the increase, the ventricle has to generate a higher pressure before the aortic valve opens (loop 2). It then ejects but cannot eject a normal stroke volume because that would require higher pressure from the same end-diastolic length (preload). In fact, the end-systolic volume is that which is appropriate for the higher pressure (compare Figure 19-5, *A* and *B*). If different afterloads are used, the end-systolic pressure-volume points define a sloping line that is the same as the line obtained in the isolated heart at those same volumes; this is the maximal ventricular elastance (E_{es}) or end-systolic elastance (E_{es}) line. If ventricular contractility increases, then the ventricle can attain higher ejection pressures at any given

volume, and the end-systolic pressure-volume points lie on a steeper line that lies above and to the left of the normal line (purple line I in Figure 19-5, *B*). If ventricular contractility decreases, then the ventricle cannot generate normal pressures at any given end-diastolic volume, and the end-systolic pressure-volume line lies below and to the right of the normal line (blue line in Figure 19-5, *B*). Note from Figure 19-5, *B*, that, from a given end-diastolic volume, the ventricle with impaired contractility can either eject a normal stroke volume at much reduced pressures or eject at a normal pressure only by reducing its stroke volume drastically (loop 4).

In beats that follow a sudden increase in afterload, the ventricles adjust. Because of the reduced stroke volume in the first beat, the end-systolic volume is larger than normal. During diastole, however, a normal stroke volume enters the ventricle so that end-diastolic volume increases (loop 2 in Figure 19-5, *C*). In normal ventricles, the increased end-diastolic fiber length causes little increase in diastolic pressure. The pressures during ejection and the end-systolic pressure-volume point are unchanged, but stroke volume and ejection fraction increase. After a few more cycles, a new equilibrium is established (loop 3) in which the ventricle ejects a normal stroke volume at the higher afterload. The ejection fraction, however, is subnormal because although the stroke volume is normal, the end-diastolic volume is increased. The ventricle has adapted to the higher afterload by increasing end-diastolic fiber length, a phenomenon described by Starling and discussed by Ross[101,102] under the term preload reserve. If the ventricle has decreased contractility (dashed loops), the same pattern of response occurs, but with some important differences. With decreased contractility, the ventricle cannot eject a normal stroke volume from a normal end-diastolic volume. Compensation results in a larger than normal increase in end-diastolic volume, even at normal afterloads. Any increase in afterload causes a further increase in end-diastolic volume, and this increase causes diastolic pressures to rise to high values that cause pulmonary congestion. The normal preload reserve has been used up in the attempt to eject a reasonable stroke volume against a modestly increased afterload. In more depressed hearts, even normal afterloads cannot be handled by the ventricle without a pathologically raised diastolic pressure in the ventricles or a drastic decrease in stroke volume. Note that in these hearts, because of the relatively flat slope of the maximal ventricular elastance line, a slight reduction of afterload produces a relatively large increase in stroke volume and a relatively large decrease in ventricular end-diastolic volume and pressure. This is one of the mechanisms for cardiac improvement with afterload reduction.

The normal right ventricular (RV) pressure-volume curve is triangular in shape, unlike the more rectangular left ventricular (LV) pressure-volume curve.[113] This difference is accounted for by a relative lack of isovolumic contraction and relaxation times in the RV. The normally low afterload of the RV and the high compliance of the outflow portion of the ventricle allow ejection to begin almost instantaneously after the onset of contraction and proceed through pressure decline so that there is near complete emptying of the ventricle by the end of systole and the ejection time of the RV thus spans the entire period of systole. An important consequence of this relationship is that even small increases in RV afterload begin to make the RV pressure-volume curve begin to resemble the normal LV pressure-volume curve, with isovolumic contraction and relaxation times becoming more prominent.[114] Ejection fraction is reduced, although stroke volume may be maintained due to RV dilation,[115] and the thin-walled RV may handle this new physiology quite poorly.

Assessing Myocardial Contractility

An index of contractility must reflect the ability of the ventricle to perform work independent of changes in preload and afterload. Contractility can perhaps best be defined as the alterations in cardiac function that occur secondary to changes in cytosolic calcium availability or sarcomere sensitivity to calcium. Thus, β-adrenergic agonists or phosphodiesterase inhibitors, which increase cytosolic calcium, and thyroxine, which alters myosin ATPase sensitivity to calcium in some species by altering the dominant isoform, are positive inotropic agents. However, quantifying contractility in the intact heart or assessing contractile effects of an intervention is difficult[72] because all indices of contractility are indices of overall performance and are not independent of the other determinants of performance. For example, cardiac output is an excellent index of the systolic performance of the intact ventricle, but it is not a useful index of contractility because of its high sensitivity to preload, afterload, and heart rate. It is convenient to divide methods of assessing contractility into those based on early events in the cardiac cycle (isovolumic phase indices) and those that occur later (ejection phase indices).

Isovolumic Phase Indices. The concept of maximal velocity of contraction against zero load (V_{max}) once was popular, but the complexity of the mechanics of cardiac muscle made it difficult to assess what would have been the true index, namely, V_{max} of the contractile element alone.[116] In practice, too, it is not possible to abolish internal loading of the muscle fiber. Applying this concept to the intact heart was even more difficult.[117]

As a substitute for V_{max}, investigators used dP/dt max (maximal rate of change of ventricular pressure) or dP/dt at a developed ventricular pressure of 40 mm Hg. These values usually are achieved before the aortic valve opens and are relatively unaffected by changes in preload. The index is, however, affected markedly by changes in afterload and so must be used with care when afterloads are very different. This method is more useful for measuring acute changes in contractility than for assessing absolute contractility.

Ejection Phase Indices. The index of contractility most commonly used today is the maximal (end-systolic) ventricular elastance of Suga and Sagawa, which is independent of changes in preload (see previous text). Several different afterloads must be obtained, and either ventricular volumes must be measured or echocardiographic dimensions must be used as substitutes for volumes. The most clear-cut results have been obtained when reflex changes in contractility are prevented, which may explain why the relationship is less well established in conscious than in anesthetized animals.[75,118] Several studies have shown that the maximal elastance line often is alinear and gives a negative intercept on the pressure axis, that is, a negative resting volume.[119,120] To deal with this simply, some investigators use the values of E_{max} in the mid-range of pressures.[120]

Ejection fraction and velocity of shortening also provide information about ventricular function. Because these two variables depend on afterload (see Figure 19-5), it is necessary to adjust for changes in afterload. This adjustment has been

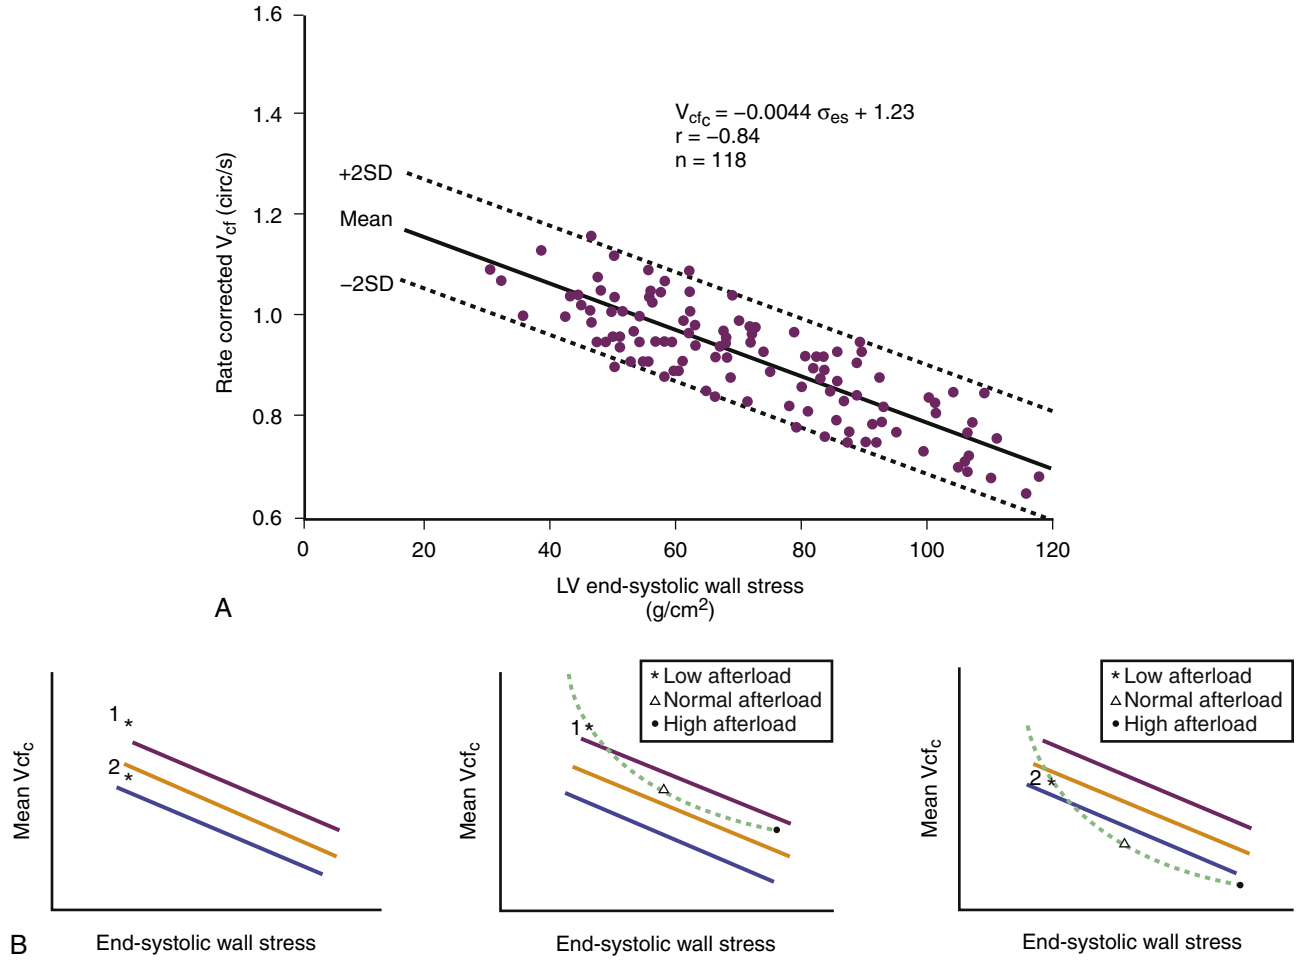

Figure 19–6. **A,** Relationship between rate-corrected mean velocity of fiber shortening *(Vcf)* and left ventricular *(LV)* end-systolic wall stress. *(From Colan SD, Borow KM, Neumann A:* J Am Coll Cardiol *4:715, 1984.)* **B,** Possibility of misinterpreting the relationship between mean velocity of fiber shortening and end-systolic wall stress. *Left,* Data point 1 is more than two standard deviations *(SD)* above normal relation (taken from left panel), suggesting increased contractility. Data point 2 is within the normal range, suggesting normal contractility. *Middle,* Alternative explanation for point 1 is that contractile state is normal, but points obtained at very low afterloads follow a hyperbolic, not a linear, relationship. *Right,* Alternative explanation for point 2 is that contractility is decreased, but because of the hyperbolic relationship and the low afterload it appears within the "normal" linear range. *(Adapted from Banerjee A, et al:* J Am Coll Cardiol *23:514, 1994.)*

made in adults and children[121-126] by providing normal data for the relationship between end-systolic wall stress and either velocity of shortening or ejection fraction (Figure 19-6). However, the relationship is not linear,[127] so single-point determinations are of little use.

Ventricular Function Curves

Sarnoff and Mitchell[128] introduced the ventricular function curve. They measured LV diastolic pressure and stroke work, then infused fluids and examined the relationship between the two variables (Figure 19-7, *A*). If contractility increased, the curve shifted up and to the left; at any end-diastolic pressure, a greater stroke work was achieved. If contractility decreased, the curve shifted down and to the right. One problem with this technique, recognized by Sarnoff, was that curvilinearity of the diastolic length-pressure relationship produced an S-shaped curve when relating stroke work to end-diastolic pressure and that techniques for measuring fiber length or ventricular volume were inadequate. In addition, using pressure instead of fiber length or volume may lead to misinterpretations if pericardial or pleural pressures change substantially. Several groups of investigators adapted this function curve to examine the stroke volume to end-diastolic pressure relationship, but this is even less satisfactory because stroke volume is affected by the resulting increases of afterload.

More recently, the relationship of stroke work to end-diastolic fiber length or ventricular volume has been examined in conscious dogs with autonomic blockade.[105] This relationship, termed preload recruitable stroke work, was linear and independent of changes in afterload (Figure 19-7, *B*). The line intercepted the length or volume axis at values close to the unstressed length or volume, that is, at the length or volume that the ventricle has at zero transmural pressure. Calcium infusion increased the slope of the line without changing the intercept on the length axis. Subsequently, the same group extended this analysis to ischemic ventricles.[129] Depression of ventricular function shifted the stroke work to end-diastolic segment length relationship to the right (increased intercept) and decreased the slope. This concept and the ventricular elastance concept have much in common. Both require measurements of wall force, stroke work, ventricular volume, or minor

axis diameter and changing them over a range so that the lines or areas defining these indexes can be obtained.

Pericardial Function

The parietal pericardium is a stiff membrane that surrounds the heart loosely, separated from it by a small amount of lubricating pericardial fluid. Intrapericardial pressure is negative, reflecting the negative intrapleural pressure. On the other hand, the pericardium exerts a surface pressure on the heart that would exist even if all fluid were removed. If the pericardium had holes in it, fluid would leak out and there would be no fluid pressure, but the heart still could be compressed. This surface pressure varies in different regions but, in general, is similar to right atrial pressure.[99,130] As a result, in the usual situation transmural diastolic pressure across the wall of the left ventricle is not the same as left ventricular diastolic ventricular pressure. It can be estimated by subtracting right atrial pressure from LV pressure. The pericardium can restrict dilatation of the LV if there is a tense pericardial effusion (tamponade)[131] and if the ventricles dilate acutely. Thus if the ventricles enlarge because of sudden volume load or sudden myocardial depression, the pericardium becomes tense and restrains further enlargement of the ventricles.[99,100]

In some patients with acute myocardial ischemia, left ventricular diastolic pressure can be greatly increased without much change in ventricular volume because of tension in the pericardium. This mechanism makes it difficult to interpret changes in diastolic pressure-volume relations only in terms of myocardial stiffness.[97,98,130,132,133]

Ventricular Interaction

A closely related mechanism is ventricular interaction.[132] For example, if right ventricular output decreases, a series interaction reduces left ventricular filling and, therefore, LV output. Second, a direct interaction occurs because the left and right ventricles share the ventricular septum and are contained within the same relatively rigid pericardium. Consequently, RV distension, as in acute pulmonary embolism or congestive heart failure, pushes the septum to the left, thereby decreasing LV volume and preload. The resulting decrease in cardiac output should not be taken to indicate LV dysfunction.[99,134,135] Additionally, the LV generates a substantial portion of RV contractility[136] and the decrease in cardiac output that occurs with acute RV failure with an intact pericardium is at least partially attributable to a decrease in LV performance.[137] Cardiac output can be improved in this situation by opening the pericardium.

The effects of pericardial restraint and ventricular interaction come into play during positive-pressure ventilation.[138] With a normal circulation, an increase in intrathoracic pressure will decrease transmural pressures, end-diastolic volumes, and stroke work of both ventricles. However, in the context of the normal circulation, these changes have no observable clinical effects. In congestive heart failure, however, where pericardial restraint regulates total cardiac volume, increased intrathoracic pressure decreases RV transmural pressure, filling, and volume, resulting in increased LV transmural pressure, end-diastolic volume, and stroke work via the Frank-Starling relationship. The ultimate effect of increased intrathoracic pressure in congestive heart failure (from a common intervention such as positive-pressure ventilation) is highly dependent on intravascular volume status. In volume-depleted patients, the effects on the right heart will predominate, resulting in further reductions in cardiac output. Adequate volume status, however, will allow the beneficial effects of increased intrathoracic pressure on the LV to dominate, resulting in an increase in cardiac output.

Diastolic Ventricular Function

Diastolic function concerns the rate and extent of ventricular relaxation.[98,139] Many forms of heart disease manifest abnormalities of both systolic and diastolic function, but one or the other form of dysfunction may predominate and determine the type of therapy needed.

Diastolic dysfunction is manifested mainly by increased ventricular diastolic pressure at normal or even low ventricular volume.[139] This can result from increased passive stiffness of the ventricles because of chronic infiltrates (e.g., amyloid), myocardial scars, constrictive pericarditis, or diffuse myocardial fibrosis. It also can result from impaired relaxation. Normally, relaxation of ventricular muscle in diastole is rapid and associated with rapid release of calcium bound to troponin and its subsequent uptake by the sarcoplasmic reticulum. Removal of calcium allows actin-myosin cross-bridges to dissociate and the sarcomeres to lengthen, thereby permitting the ventricle to dilate. Any decrease in calcium removal because of abnormalities in major contractile proteins or transport processes decreases the rate and extent of relaxation.[73,140,141] Ischemia is one major factor that impairs calcium metabolism and diastolic ventricular function, but many other forms of heart disease have similar effects.[26,29,108,142] Clinically, diastolic function is assessed by relating end-diastolic pressure and volume, by observing the rate of ventricular filling by angiography or by Doppler studies of the mitral valve inflow, by measuring the peak rate of fall of ventricular pressure (−dP/dt max), or by calculating the time constant of the fall in ventricular pressure.

Neural Control of the Heart

The heart can function without any cardiac nerves, for example, after cardiac transplantation. However, the response to exercise in these denervated hearts is slow and due to increases in circulating catecholamines and the rise in body temperature. In intact animals and humans, β-adrenoreceptor blockade blunts the heart rate increase with exercise and abolishes inotropic response, as judged by the increase in dP/dt max.[143]

Studies of the neural control of the heart must consider the basal level of sympathetic and parasympathetic tone.[143] In conscious animals, resting sympathetic tone is low, and resting parasympathetic tone is high. Therefore sympathetic blockade has little effect on heart rate and myocardial contractility, but parasympathetic blockade causes marked tachycardia. On the other hand, many anesthetics depress the sympathetic nervous system, leading to impaired contractility and bradycardia. Postoperatively, patients often have high circulating catecholamine concentrations, and the effects on myocardial function depend on the balance of catecholamine concentrations, stimulation of the sympathetic nervous system by pain, and the extent of myocardial depression caused by the drugs used for sedation.

The carotid and aortic baroreceptors respond to changes in arterial blood pressure. If basal sympathetic tone is low, as is normal, then inhibiting sympathetic tone by raising aortic pressure has little effect on myocardial contractility. On the other hand, lowering arterial pressure causes a reflex increase in sympathetic tone, with increases in heart rate and contractility. Baroreceptor sensitivity increases throughout gestation in fetal lambs[144] but may decrease after birth.[145] Also in fetal lambs, denervating the baroreceptors did not alter mean arterial blood pressure or heart rate, but did increase the variability of pressure and heart rate. Similar increased variability of pressures but not of heart rate occurred in adult sheep.[146] Denervation in the fetuses in the same study also decreased peripheral resistance.

Carotid and aortic chemoreceptors are stimulated by low P_{O_2}, high P_{CO_2}, and low pH, but the changes have to be marked, and even then the increase in myocardial contractility is modest. The fetus seems to be less sensitive than the adult to chemoreceptor stimulation.[147] The bradycardia that accompanies severe hypoxemia results from vagal stimulation. During exercise or hemorrhage, plasma catecholamines increase markedly, but the inotropic responses are different. With exercise, dP/dt max increases by as much as fourfold, the peripheral vascular bed is dilated, and cardiac output increases, whereas with hemorrhage, dP/dt max increases by only 30% to 50%, cardiac output falls, and most vascular beds vasoconstrict. Thus, the pattern of sympathetic neural stimulation rather than the circulating catecholamine concentrations determines how the heart responds to these stimuli.

Vagal effects on the heart are shown most prominently by changes in heart rate, but their effects on myocardial contractility depend on the existing level of sympathetic tone. Vagal stimulation has little effect on myocardial contractility given little sympathetic tone, but markedly reduces the inotropic effects of increases in circulating catecholamines or sympathetic nerve stimulation. Conversely, blockade of muscarinic receptors can intensify the myocardial contractile response to sympathetic stimulation.

Cardiac Output

Cardiac output in the fetus is determined mainly by heart rate because of a limited capacity to increase stroke volume. This limitation results partly from decreased diastolic distensibility and partly from positive extracardiac pressures.[148] Consequently, fetal bradycardia is detrimental to blood flow and oxygen delivery. The fetal heart, however, can respond to increased preload (Starling's law) with increased stroke volume, provided there is no concomitant increase in afterload.[149] Usually, infusion of fluid into an animal causes arterial pressure to rise, and the increased afterload tends to inhibit the increase in stroke volume that would otherwise occur.[149-151] Immediately after birth, there is a large increase in total body oxygen consumption and cardiac output to about twice its later values (per unit body size).[152]

This increase has been related to an increase in adrenergic receptors stimulated by fetal thyroid hormones.[153] In addition, because at birth approximately 80% of the infant's hemoglobin is in the form of fetal hemoglobin, the reduced ability of this hemoglobin to unload oxygen at the tissue level compels the infant to have a higher cardiac output than the infant will have 4 to 6 weeks later.[152] Therefore the neonate has limited cardiac output reserve and the heart has near-maximal contractility.[154,155] These features make the neonate unusually susceptible to diseases that impair cardiac function. The Frank-Starling mechanism, however, is intact at this time.[156] Evidence indicates β-adrenoreceptor stimulation helps the neonatal ventricle adapt to volume loads.[157] Thus β-adrenoreceptor blockade might be expected to be much more harmful in the neonate than in the older person with minimal sympathetic tone.

Myocardial Metabolism: Normal Myocardial Energy Metabolism

Basic Metabolic Processes

Basal metabolic processes can be studied by measuring oxygen uptake, production of heat, or utilization of high-energy phosphates. In isolated papillary muscle, most of the oxygen consumed is used in generating force (internal work), approximately 15% is used in shortening (external work), approximately 20% is used for basal metabolic processes (protein synthesis, sarcolemmal Na-K transport) and approximately 10% is used for the activity of Na/K-ATPase and Ca-ATPase.[158-160] Similar conclusions can be drawn from studies of whole hearts.[161]

The myocardium has a brisk rate of metabolism, consuming approximately 8 to 10 mL oxygen/100 g muscle/min under basal conditions. Potassium-induced cardioplegia can reduce myocardial oxygen consumption, but "resting" cardiac muscle still consumes more than five times as much oxygen as does resting skeletal muscle. During maximal exercise, the myocardium may consume as much as 60 to 80 mL oxygen/100 g muscle/min.[162]

Cardiac energy is generated by oxidizing substrates to carbon dioxide and water. During this process, energy is both used and stored, and most of the stored energy is in the form of ATP. When needed, ATP breaks down to adenosine diphosphate (ADP) or adenosine monophosphate (AMP) and releases energy for contractile or transport processes.[163] The substrates for energy production can be glucose, lactate, or fatty acids.[164] In a mixture, the fatty acids are preferred over the others, and an increase in plasma fatty acid concentrations, as in fasting or sympathetic stimulation, suppresses oxidation of carbohydrates by the heart.[55,164] Therefore lactate consumption or extraction cannot be used as an accurate guide to cardiac metabolism unless the concentration of the fatty acids is evaluated at the same time.[165] ATP is usually generated by oxidative phosphorylation. Various transport systems move the substrates into the mitochondria for oxidation by the tricarboxylic cycle. Other transport systems move the ATP out of mitochondria into the cytosol, where they can break down and supply energy. The ATP is replenished by transfer of a high-energy phosphate moiety from creatine phosphate to ADP, mediated by the enzyme creatine kinase.[163,166] When oxygen supply is restricted, ATP can be generated by anaerobic glycolysis, an inefficient but useful temporary pathway. Furthermore, products of glycolysis, if they accumulate, inhibit key enzymes and interfere with further ATP production. Therefore the myocardium is unable to build an oxygen debt without further depressing energy production and, hence, contractility. Oxidative metabolism is so important to the heart that more than 30% of the mass of the myocardium is mitochondria.[158]

Fetal lamb ventricles have the same oxygen consumption per unit mass as the adult left ventricle. Because fetal oxygen content is lower than that in the adult, however, myocardial blood flow per unit mass is about twice as high in the fetus as in the adult.[167,168] Oxidative capacity is relatively lower, and glycogen stores and glycolytic flux are relatively higher in the fetal heart. This condition may explain why the immature heart is more resistant to hypoxemia than is the adult heart, provided an adequate supply of glucose is available for glycolysis. The main substrates used by the fetal heart are glucose, lactate, and pyruvate, although ketones, amino acids, and short- and medium-chain fatty acids also can provide energy.[169] After birth, long-chain fatty acids become the predominant substrates. For these reasons, prolonged severe hypoglycemia can seriously depress cardiac function in the neonate but is unlikely to do so in the older person.

L-Carnitine is essential for fatty acid transport across the mitochondrial membrane. Most of the body's carnitine is produced endogenously when protein degradation releases trimethyl-lysine, which is transformed into carnitine. Carnitine is present in red meats and dairy products (including breast milk), but only small amounts are present in vegetable products. It can be absorbed by the intestine, is not broken down in the body, and is excreted by the kidney.

In all except young infants, the preferential source of energy for myocardial function comes from the β-oxidation of long-chain fatty acids. After fatty acids enter the cell, they are activated to fatty acid (or acyl) coenzyme A (CoA) compounds by palmitoyl-CoA synthetase, then linked by carnitine palmitoyl transferase I to carnitine to form acylcarnitines, thus releasing CoA. The acylcarnitines cross the mitochondrial membrane, and at the inner surface of the membrane another enzyme, carnitine palmitoyl transferase II, transfers the fatty acids back to CoA. The fatty acids can now undergo β-oxidation with the production of ATP. These enzymes also help transport acylcarnitine esters of CoA out of the mitochondria. These esters are toxic in high concentrations. Fetuses and neonates have decreased activity of carnitine palmitoyl transferase and palmitoyl-CoA synthetase, so glucose, lactate, and short-chain fatty acids are the preferred myocardial energy substrates at this age.[19,170]

Endogenous carnitine production usually is sufficient for growth, but plasma (and tissue) carnitine concentrations may decrease after 1 month of parenteral nutrition without carnitine supplements. Energy demands increase when renal excretion of carnitine increases in conditions of burns, sepsis, starvation, or after surgery; with excess excretion in Fanconi syndrome; with drugs such as valproic acid, pivampicillin, and pivmecillinam, which bind to carnitine and are excreted; with decreased production during chronic hemodialysis; and with cirrhosis of the liver.[171,172] Carnitine concentrations may be low in very premature infants.[173] Ischemia of heart or skeletal muscle depletes carnitine in the affected tissues, as does chronic congestive heart failure.[174,175] Most cases of severe carnitine deficiency in children, however, result from inherited defects in intermediary metabolism.[176]

Carnitine deficiency may produce acute or chronic syndromes, including a Reye-syndrome–like encephalopathy, hypoglycemia, myopathy, cardiomyopathy, and failure to thrive. Once the diagnosis is established, treatment is with a diet high in carbohydrates and short-chain fatty acids, plus carnitine supplements by mouth (25-300 mg/kg/day) or even intravenously if needed. Patients with congestive heart failure who do not show overt evidence of carnitine deficiency may improve after taking carnitine supplements.[175]

Determinants of Myocardial Oxygen Consumption

In 1958, Sarnoff and Mitchell[128] reported that pressure work by the heart consumed more oxygen than did volume work and found a good correlation between the area under the LV

pressure curve in systole (termed the tension-time index) and left ventricular oxygen consumption. Subsequently, others found that peak wall tension (or stress) was a better predictor of left ventricular oxygen consumption.[177-180] It is important to take account of wall thickness and ventricular dimensions in estimating myocardial oxygen consumption, which is why the tension-time index, which ignores wall stress, is not a good predictor. Increases of contractility or heart rate also increase myocardial oxygen consumption, but because they decrease ventricular size and thus wall stress, increased oxygen consumption is not as great as would be expected from studies in muscle strips.[181]

Stroke volume is an added predictor of myocardial oxygen consumption.[12,182-185] The approaches used include examining the area within the pressure-flow loop. This approach has been extended by Suga and colleagues,[112,186-191] who concluded that the best predictor of LV oxygen consumption was the area in the pressure-volume loop plus the area representing end-systolic pressure energy (Figure 19-8). By subtracting the contributions of basal myocardial metabolism, they were able to show that the oxygen consumption–pressure-volume area (PVA) relationship was independent of contractile state. Further studies by these investigators showed that PVA-independent oxygen consumption was a function of contractility, defined by E_{max}. Certain interventions, for example, acidosis, made the slope of this relation between PVA-independent V_{O_2} to E_{max} steeper, that is, they decreased the efficiency of the system.

Because oxidizing fats uses up more oxygen than does oxidizing carbohydrates, theoretically more oxygen should be used per unit of work when burning fatty acids. Though not consistently demonstrated, there are a few good studies of this phenomenon.[166]

Myocardial Oxygen Demand-Supply Relationship

One way of assessing myocardial oxygen demand is to note that it is roughly proportional to the ventricular systolic pressure generated and the duration of systole, that is, to the area under the real-time pressure curve of the ventricle in systole: the systolic pressure-time index (SPTI).[192,193] SPTI is dramatically influenced by cardiac afterload; for instance, aortic stenosis raises SPTI (at constant stroke volume). The correlation between SPTI and myocardial oxygen demand is imperfect because it does not take into account wall stress, which involves radius and wall thickness, or contractility.[194]

Because left ventricular myocardial perfusion is restricted to diastole (see Chapter 20), myocardial oxygen supply is proportional to both duration of diastole and myocardial perfusion pressure in diastole. In general, diastolic myocardial perfusion pressure can be represented graphically as the difference between superimposed aortic and left ventricular pressure curves. The area between these curves, from the instant of aortic valve closure in diastole to reopening of the aortic valve in systole, has been termed the diastolic pressure-time index (DPTI) and is proportional to

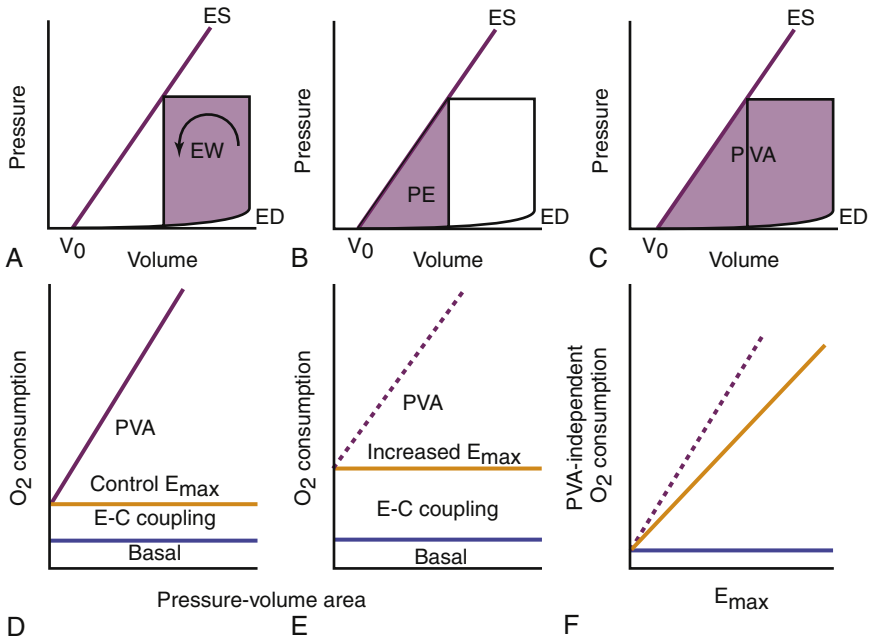

Figure 19–8. Relationship of myocardial oxygen consumption to the pressure volume area (PVA). **A,** Ventricular pressure-volume loop with pressure plotted on the ordinate and volume on the abscissa. *Arrow* shows the direction of inscription of the loop. *ED,* End-diastolic pressure-volume line; *ES,* line of end-systolic pressure-volume points (end-systolic elastance); *EW,* area representing external mechanical work; V_0, unstressed ventricular volume. **B,** *Shaded area* to the left of the pressure-volume loop in the pressure-volume diagram represents potential energy (PE). **C,** Total area (PVA) is the sum of the external mechanical work area (EW) and the potential energy area (PE). **D,** PVA is linearly proportional to oxygen consumption, but some oxygen consumption is independent of PVA. The PVA-independent oxygen consumption shown below the *upper horizontal line* results from excitation-contraction (E-C) coupling and basal oxygen consumption. **E,** When contractility is increased, as indicated by the increased value for E_{max}, the relationship between PVA and oxygen consumption is unchanged, but PVA-independent oxygen consumption increases. **F,** Relationship between E_{max} and PVA-independent oxygen consumption is linear. With myocardial depression, the slope of this relationship is steeper *(dashed line).* Thus for any value of E_{max}, PVA-independent oxygen consumption is increased so that myocardial efficiency is reduced. *(Data from references 61, 62, 125-127.)*

subendocardial blood flow. When multiplied by arterial oxygen content, this index correlates with subendocardial oxygen supply.[195]

The ratio DPTI × Arterial oxygen content/SPTI (Figure 19-9) is a fair indicator of myocardial oxygen balance. At critical levels, subendocardial ischemia occurs.[192,193] This ratio is worsened by tachycardia, which shortens diastole and the duration of myocardial perfusion; by elevation of end-diastolic pressures in the ventricles; or by elevation of coronary sinus pressure. It is adversely affected by low aortic diastolic pressure (as in shock, aortic valve insufficiency, or other large diastolic runoff lesions) and by elevated ventricular systolic pressure (as in aortic stenosis, systemic hypertension, or pulmonary hypertension). The ratio is favorably affected by balloon aortic counterpulsation, which elevates aortic diastolic pressure and reduces systolic afterload. Given the imperfect nature of this ratio, too much emphasis should not be placed on any given value, but two points are clear: (1) a fall in the ratio in any patient moves that patient toward a supply:demand imbalance and (2) any ratio less than the 8.9 that typifies normal subjects likely indicates myocardial ischemia.[196]

Effects of Myocardial Ischemia on Cardiac Function and Metabolism

Ischemia indicates a flow that is inadequate to supply the demand for oxygen by an organ or tissue; it also implies reduced clearance of metabolites.[197,198] The second part of the definition is what distinguishes ischemia from hypoxemia, in which there is a normal flow with a decreased oxygen delivery. Because the heart cannot sustain an oxygen debt, inadequate oxygen supply rapidly decreases the energy supply to the muscle cells, which cease to contract normally. If a branch of the left coronary artery is severely narrowed or occluded acutely, within 5 to 15 seconds the myocardium supplied by that branch stops contracting, turns blue, and bulges and thins during each systole. If the acute ischemia is global, that is, all coronary arteries have similar reductions in oxygen supply, then the subendocardial muscle becomes ischemic first because this muscle has the lowest coronary flow reserve.

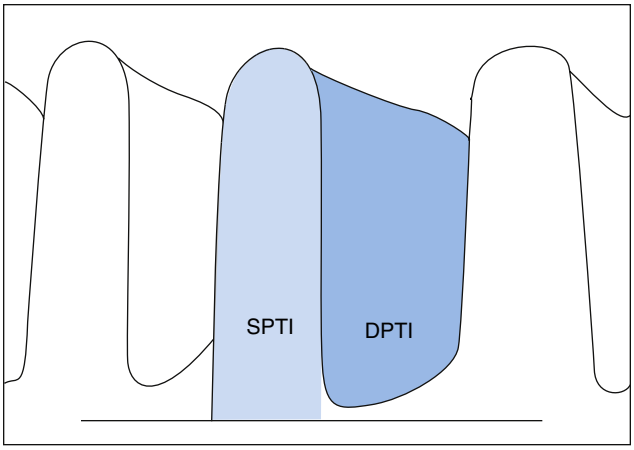

Figure 19–9. Systolic pressure time index (SPTI) reflects myocardial work and oxygen demand. Diastolic pressure time index (DPTI) reflects myocardial blood flow. *(Adapted from Fuhrman BP: Regional circulation. In Fuhrman BP, Shoemaker WC (eds):* Critical care: state of the art, vol 10, *Fullerton, CA, Society of Critical Care Medicine, 1989.)*

Subendocardial function is selectively decreased.[199-201] Global cardiac contractility decreases. Cardiac pump function is impaired, but survival is possible. More extensive global ischemia leads to death. Chronic imbalance of oxygen supply and demand leads to death of the affected muscle cells, producing either a localized infarct or diffuse, perhaps patchy, subendocardial fibrosis as occurs commonly with severe aortic stenosis, cyanotic heart disease, or dilated cardiomyopathy (see Chapter 20).

Temporary imbalance of supply and demand leads to two patterns of response, depending on the duration of the ischemia. If a branch coronary artery is occluded for 15 to 30 minutes and then the occlusion is removed, flow returns to normal rapidly, but the muscle may not contract normally for many hours. Some biochemical changes that occurred take many hours to reverse. This phenomenon is known as reperfusion injury or stunning.[202-205] It should be distinguished from the "no reflow" phenomenon in which, after a longer occlusion, release of the occlusion is followed by incomplete restoration of flow because of myocardial edema, cell swelling, plugging by neutrophils, and endothelial damage. Stunning may occur after prolonged cardiopulmonary bypass surgery and may account for some of the cardiac depression that often is observed in the early recovery period.[206,207]

Chronic ischemia of moderate severity causes myocardial hibernation, an adaptive response that leads to metabolic down-regulation and reduction of flow without extensive cell death.[208-211] Regional function is reduced, but restoration of flow leads to functional recovery. This phenomenon is best known from studies of coronary artery disease but can be present in some children with normal coronary arteries and subendocardial ischemia.

Many biochemical changes occur when the heart becomes ischemic, and which are the primary causes of the dysfunction is not always clear. As soon as oxygen supply is cut off, all components of the mitochondrial electron chain become reduced because of the absence of the final electron acceptor. Nicotinamide adenine dinucleotide (NAD) is reduced to NADH within 2 seconds after the onset of sudden ischemia.[212] Glycogenolysis increases rapidly, thereby helping to supply ATP, but then is progressively inhibited by increasing concentrations of hydrogen ion, NADH, and lactate. (This inhibition is less marked with pure hypoxemia because the associated high flows help to wash out these inhibitory metabolites.) The stores of high-energy phosphates become depleted. First creatine phosphate decreases, then ATP concentrations fall. For example, after sudden arterial occlusion, creatine phosphate is almost completely depleted within 3 minutes, and ATP is reduced to 35% of control concentration within 15 minutes. ATP is degraded to ADP and AMP, which then is deaminated to adenosine. Adenosine in turn is rapidly broken down to inosine and hypoxanthine. Because of these changes, the nucleotide pool of cardiac muscle is depleted so that even after flow is restored, a long time is required before normal high-energy stores are replenished. Furthermore, during ischemia, xanthine dehydrogenase in the tissues is converted to xanthine oxidase, which catalyzes the conversion of hypoxanthine to xanthine and superoxide radicals. These in turn can be converted by superoxide dismutase into hydrogen peroxide, which can be converted by catalase to produce highly reactive hydroxyl radicals. These free radicals can react with lipids in the cell membranes and cause lipid peroxidation,

which produces several toxic and arrhythmogenic substances and impairs the functions of the cell membrane.[213] Oxygen-derived free radicals can be introduced by activation of neutrophils by the damaged endothelium and by the formation of peroxynitriles from nitric oxide.

Accompanying these changes are accumulations of hydrogen ions, lactate, and many other catabolites. These entities create an osmotic load within the cells, with resultant swelling of the cells and the mitochondria. The cell and mitochondrial membranes become impaired, and myoglobin and enzymes such as creatine kinase leak out of the cell, as do essential ions such as magnesium and potassium. Free calcium may accumulate in the cytosol (because of loss of chelating agents) and the mitochondria, particularly during reperfusion, and this calcium load may be highly detrimental to cell function. Finally, ischemia is associated with decreased myocardial carnitine concentrations, defective transport of long-chain fatty acids into the mitochondria, and accumulation of toxic acylcarnitine esters of CoA. These changes further delay the recovery of energy production and muscle contraction.

Systemic Vasculature

General Anatomy

The large arteries are elastic. Their media contain concentric lamellae of perforated elastic tubes cross-linked by transverse collagen (type III) and smooth muscle.[47,214] When smooth muscle contracts, the wall becomes stiffer. Smaller arteries have fewer lamellae. The media is bounded by the external and internal elastic laminae, beyond which are the adventitia with nerves and vasa vasorum and the intima with sparse fibrous tissue and a metabolically active endothelium, respectively. Arterioles have no lamellae and only a thin media with circular or spiral smooth muscle; the only elastic tissue is in the inner and outer elastic laminae. Capillaries are thin-walled and nonmuscular, ideal for transport of materials into and from the tissues; however, they contain pericytes that have myosin, actin, and tropomyosin and so might have some contractile function. Veins have medial muscle but thinner walls relative to lumen diameter than do arteries. Their endothelium may have different properties. The numerous extracellular matrix components are reviewed by Buga and Ignarro.[215] The developmental aspects of blood vessels are reviewed by Stenmark and Weisen.[216]

Physiologic Mechanisms

General features. Although large arteries are regarded as conduits and capillaries as vessels allowing transport of substances to and from the tissues, many substances can move across arterial walls. Oxygen and carbon dioxide can diffuse across arteriolar walls, and lipoproteins can penetrate the walls of large arteries. Whether atheromatous deposits form in arteries depends on the balance of the amount of lipoprotein that enters and leaves the arterial wall. This balance depends on the concentration and chemical nature of lipoproteins and the action of components of the wall, such as glycosaminoglycans, in binding altered lipoprotein molecules and preventing their transit through the wall.

Arteriolar tone controls peripheral resistance and, with cardiac output, determines blood pressure and regional flow. Regions of the circulation may differ markedly in their patterns of vascular regulation. A potent stimulus for increased vascular resistance in one region of the circulation may have a different effect in another. For example, during hemorrhagic shock, flow is maintained to heart and brain but is reduced to muscle, kidneys, and gut. Venous and venular tone, together with diuretic and antidiuretic factors, determine blood volume and venous pressure.

The two active components of the systemic circulation are the medial smooth muscle and the endothelium. They both have receptors for innumerable agonists and antagonists that diffuse from autonomic nerve endings, circulate from remote regions, or are produced locally. The smooth muscle is responsible for vasoconstriction or vasodilatation. The vascular endothelium is one of the metabolic powerhouses of the body, and has several major functions:

1. Endothelial cells play important roles in the response to injury by causing leukocyte adhesion and extravasation, mediated by cell adhesion molecules such as selectins, cadherins, and integrins.[215,217]
2. They are intimately bound up with coagulation[215,218] by virtue of the production of procoagulant (e.g., platelet-activating factor [PAF], von Willebrand factor, fibronectin, and factors V and X) and anticoagulant factors (e.g., heparan, dermatan sulfate, thrombomodulin, and ectonucleotidase) and by the production of nitric oxide and PGI_2, which inhibit platelet aggregation and degranulation.
3. They regulate capillary permeability by producing ET-1 (increase) or PGE1 (decrease) and respond with increased plasma leakage to substances such as bradykinin, histamine, thrombin, oxygen radicals, and PAF.
4. They regulate smooth muscle contraction in response to shear stress, in keeping with an overriding principle that shear rate must be kept constant within narrow limits to prevent endothelial damage.[219,220] In general, most of the vascular resistance resides in microvessels smaller than 150 μm in diameter,[221] which are subject to the controls discussed here.

Any increase in local organ flow resulting from a decrease in resistance in these microvessels increases shear stress in the larger upstream arteries. This increase is sensed by endothelial integrins,[222] which set off a cascade of responses that relax smooth muscle by activating Ca^{2+}-sensitive K^+ channels and hyperpolarizing the endothelial cell membrane and by releasing acetylcholine, nitric oxide, PGI_2, ATP, and substance P.[215,222] A chronic increase in shear stress activates the nuclear factor-Kβ transcription complex and induces a number of early response genes.[215,222]

Control of vascular tone**.** In general, regional circulations regulate their flow so that they obtain required amounts of oxygen and nutrients. Any or all of the mechanisms discussed may be invoked. Vasomotor tone is strongly influenced by several mechanisms: (1) innervation and neural processes, (2) circulating endocrine and neuroendocrine mediators, (3) blood gas composition, (4) local metabolic products, (5) endothelial-derived factors, and (6) myogenic processes.

Receptors responsive to neural products (norepinephrine, acetylcholine, neuropeptides) are found throughout the circulation. Nevertheless, innervation and receptor distributions are organ specific, which allows rapid, patterned, coordinated redistribution of blood flow and an orchestrated response to hypoxia, changes in posture, and hemorrhage. Although these receptors respond to circulating agonists

(including angiotensin II and adrenal epinephrine) and to those liberated locally, they are generally associated with innervation by autonomic nerves. In general, presynaptic α-adrenergic stimulation causes norepinephrine release and vasoconstriction. β-adrenergic stimulation generally causes vasodilatation. Cholinergic stimulation (whether sympathetic or parasympathetic) generally causes vasodilatation (see Chapter 31).

In all organs, sensory and efferent nerve endings contain nonadrenergic, noncholinergic (NANC) peptides, for example, neuropeptide Y, VIP, calcitonin gene-related peptide (CGRP), and substance P.[116,223-234] Neuropeptide Y is colocalized and released with norepinephrine[235] and VIP is colocalized with acetylcholine and released upon stimulation of vagal nerve endings. Most of these peptides except neuropeptide Y are vasodilatory, and they help modulate blood pressure and regional flows. Substance P and CGRP are released when sensory nerves are stimulated by capsaicin, thus accounting for the flushing that accompanies the eating of hot peppers. (Many neuropeptides also occur throughout the central nervous system, where they may play roles in cardiovascular regulation.)

Humoral regulators of vascular tone and blood volume include angiotensin, adrenomedullin, aldosterone, arginine vasopressin (AVP), bradykinin, histamine, serotonin, thyroxine, natriuretic peptides, and various reproductive hormones. Most of these regulators have both direct effects and secondary effects, which tend to be organ-specific or regional. They tend to have altered concentrations in hypertension, congestive heart failure, or shock, and their antagonists are used in therapy. Some agents, such as histamine, serotonin, and thyroxine, probably affect peripheral resistance only in abnormal states and are not physiologic regulators.

Angiotensin plays a special role in the homeostasis of blood pressure. Its concentration increases in hemorrhagic or hypovolemic shock, following increased renal production of renin that produces angiotensin I from angiotensinogen. Angiotensin I is converted to active angiotensin II by angiotensin-converting enzyme (ACE) in the endothelium, especially in the pulmonary vessels. However, angiotensin II also is produced locally in the heart and vessel walls by renin that enters from the blood and perhaps by other local proteases.[236,237] It causes generalized vasoconstriction in both systemic and pulmonary circulations, but locally it stimulates the release of vasodilating prostaglandins in lung and kidney. Angiotensin II, via angiotensin I receptors, plays a role in cardiac and smooth muscle cell hypertrophy. In excess, it results in cardiac inflammation, fibrosis, and apoptosis.[238-241]

Adrenomedullin, originally found in pheochromocytomas, is produced in many normal cell types, including endothelium. Among its many actions are long-lasting vasodilatation and diuresis.[242,243] It shares homologous sequences with CGRP, calcitonin, and amylin.[244] Its release may be stimulated by ET-1. It may play a role in treating heart failure.[245]

Aldosterone, known primarily for its effect on sodium excretion and potassium retention, has indirect central effects on blood pressure.[246-248] Its concentration increases when renin release is stimulated. In patients with congestive heart failure, its decreased breakdown in the liver accounts for very high blood concentrations, which are harmful to the heart and blood vessels. Inhibition of aldosterone by spironolactone may have great clinical value.[247,249,250]

AVP, which is released from the axonal terminals of magnocellular neurons in the hypothalamus, causes vasoconstriction by stimulating VP_1 receptors. However, at low concentrations, AVP dilates coronary, cerebral, and pulmonary vessels. It is an antidiuretic hormone that acts on VP_2 receptors in the renal collecting ducts.[251] Its concentration is low in septic shock,[119] with ventricular arrhythmias, and after cardiac surgery,[252] but is increased in myocardial and hemorrhagic shock, congestive heart failure, and cirrhosis of the liver.[106,251,253] Selective AVP antagonists promote free water excretion without concomitant electrolyte excretion[253-256] and are useful in treating fluid overload in patients with congestive heart failure, cirrhosis of the liver, and the syndrome of inappropriate antidiuretic hormone secretion without causing electrolyte imbalance.

Bradykinin is a potent pulmonary and systemic vasodilator released locally by the action of proteolytic enzymes on kallikrein after tissue injury.[257-260] Bradykinin is metabolized by kininase II, which is the same as ACE, so ACE inhibitors not only reduce angiotensin II production but increase bradykinin concentrations. Bradykinin also causes endothelial cell release of tissue-type plasminogen activator.[261]

Histamine, released by mast cells in response to injury, is a potent vasodilator in most regions of the circulation but causes vasoconstriction in the lung. It also increases endothelial permeability.[262] No evidence indicates histamine plays a part in normal vasoregulation.

The natriuretic peptides are released from the heart when it is distended in congestive heart failure. They cause vasodilatation and increased diuresis. A-natriopeptide (mainly from atria) and B-natriopeptide (from ventricles) are released from myocardial cells, and C-natriopeptide is released from cardiac endothelium.[262-266] A recombinant B-natriopeptide (nesiritide) was initially shown to be safe and potentially more effective than dobutamine in treating acute severe congestive heart failure.[263-266] This is currently being tested in a large multinational randomized controlled trial (ASCEND-HF).[267] These natriopeptides and the kinins are broken down by neutral endopeptidase. Inhibition of this breakdown combined with inhibition of ACE by vasopeptidase inhibitors (e.g., omapatrilat) greatly augments vasodilatation.[268-273]

Serotonin probably acts mainly in the central nervous system, but peripherally it can act on S_1 receptors to produce vasodilatation and on S_2 receptors to cause vasoconstriction. It also augments the action of other vasoconstrictors.[271,272]

Tissue levels of oxygen and carbon dioxide reflect adequacy of perfusion and oxygen delivery. These blood gases are potent determinants of regional blood flow and have effects that differ among regions of the circulation. They also have a more general effect mediated by carotid chemoreceptors.

Local metabolic regulation of vasomotor tone provides an ideal homeostatic mechanism whereby metabolic demand can directly influence perfusion. For instance, adenosine, which accumulates locally when tissue metabolism is high and tissue oxygenation is marginal, causes pronounced vasodilatation in the coronary, striated muscle, splanchnic, and cerebral circulations. Cerebral autoregulation has been suggested to take advantage of local metabolite production as an indicator of adequacy of blood flow. According to the argument, when perfusion pressure falls, cerebral blood flow might decline but for local accumulation of vasodilating metabolites. The perivascular concentration of these metabolites is restored to normal as flow rises, washing out the metabolites. Potassium is

released from muscle in response to increased work, ischemia, and hypoxia.[273] Hypokalemia causes vasoconstriction.[274,275] Hyperkalemia, within the physiological range, causes vasodilatation by stimulating K_{ir} channels.[276-278] Many of the agents previously discussed are produced locally and are effective as circulating hormones. At least four different types of potassium channels are present on arterial smooth muscle cells[278]: voltage-activated channels (K_v), calcium-activated channels (BK_{Ca}), inward rectifiers (K_{ir}), and ATP-dependent channels (K_{ATP}). These channels are activated by vasodilators. As a result, the cells hyperpolarize, voltage-dependent calcium channels close, intracellular calcium concentrations decrease, and vasodilatation results.[279] Pharmacological vasodilators, such as cromakalim, pinacidil, and diazoxide, directly activate K_{ATP} channels, as do endogenous vasodilators such as CGRP, VIP, prostacyclin, and adenosine.[279] Inhibitors of K_{ATP} channels, such as glibenclamide, cause vasoconstriction.

The endothelial lining of blood vessels plays a prominent role in the regulation of vascular tone.[280] In addition to its roles in the elaboration of vasoactive eicosanoids[281] and in the metabolism of angiotensin, the endothelium secretes several other categories of vasoactive substances, including adrenomedullin (discussed previously), nitric oxide, endothelial cell hyperpolarizing factor, and endothelins.

Endothelium-derived relaxing factor (EDRF) has been identified as nitric oxide.[282] Nitric oxide is a potent vasodilator released from endothelium after stimulation and accounts for some or all of the activity generally ascribed to other agonists. For instance, acetylcholine causes constriction of vessels stripped of their intima and causes dilatation only in the presence of the vascular endothelium.[280] Adenosine, prostacyclin, and epinephrine dilate vessels stripped of their endothelium. Bradykinin, substance P, thrombin, and potassium cause only endothelium-dependent relaxation. Nitric oxide also is released from endothelium when flow increases, an example of positive feedback. Nitric oxide increases smooth muscle soluble guanylate cyclase activity, raises muscle cyclic GMP, and thereby relaxes vascular smooth muscle (see Chapter 48). In addition to EDRF, endothelial-derived hyperpolarizing factors, which are probably epoxyeicosatrienoic acids and hydrogen peroxide, are now thought to play major roles. The hydrogen peroxide is produced by the action of superoxide dismutase on superoxide anions that are generated by the metabolism of ATP.[283]

The vascular endothelium elaborates the endothelins (ET-1, ET-2, ET-3), a family of compounds that are vasoactive, structurally related peptides. ET-1 is the most potent vasoconstrictor known. It also promotes mitogenesis and stimulates the renin-angiotensin-aldosterone system and the release of vasopressin and atrial natriuretic peptide.[247,284-287] These peptides act on one of two receptor subtypes: ET_A and ET_B. ET_A is located mainly on vascular smooth muscle cells and is responsible for mediating vasoconstriction and cell proliferation. ET_B is present predominantly on endothelial cells and mediates vasorelaxation, as well as ET-1 clearance. Endothelins cause local vasoconstriction or vasodilatation, depending on dose and location in the circulation.[288] Individual endothelins occur in low levels in the plasma, generally below their vasoactive thresholds. This finding suggests they are primarily effective at the local site of release. Even at these levels, however, they may potentiate the effects of other vasoconstrictors such as norepinephrine and serotonin.[289] Endothelin antagonists, such as bosentan, now are being used, specifically in the setting of pulmonary arterial hypertension.[290,291]

Myogenic responses of vessels are changes in smooth muscle tone in response to stretch or increased transmural pressure. An increase in inflow pressure causes a rise in vessel wall tension and transmural pressure[292] that causes localized vasoconstriction. The reverse occurs when inflow pressure falls. The mechanisms of this response are complex. There probably is initial sensing by surface integrins,[293] followed by activation of cation channels with calcium entry.[294] In some way, protein kinase C, MAP kinases, and Rho kinase are also involved.[295-297]

As expected, a complex interplay exists among myogenic, flow-mediated, and metabolic regulation of vessel tone.[298] The relative importance of these mechanisms likely varies in different vascular beds.

Autoregulation

In all organs, when inflow pressure is suddenly raised or lowered while oxygen consumption remains constant, flow rises or falls transiently but then returns to the earlier value. The phenomenon is termed *autoregulation*. Myogenic tonic response is partly responsible for this phenomenon, but it is not the only mechanism. Some investigators believe tissues have oxygen sensors that respond to transient increases or decreases in oxygen supply.[299-301] Others believe the process is mediated by greater or lesser release of nitric oxide carried to the tissues by hemoglobin in the form of S-nitrosohemoglobin or by ATP release by the red blood cell.[301-306] Carbon monoxide produced by the action of hemoxygenase in endothelium and smooth muscle may play a regulatory role.[307-310]

Regional Circulation

Peter Oishi, Julien I.E. Hoffman, Bradley P. Fuhrman, and Jeffrey R. Fineman

PEARLS

- When delivering critical care, one must understand the specific properties that characterize the various regional circulations because therapies that benefit one region may be detrimental to another.
- Vascular tone is influenced by (1) innervation and neural processes, (2) circulating endocrine and neuroendocrine mediators, (3) local metabolic products, (4) blood gas composition, (5) endothelial-derived factors, and (6) myogenic processes.
- The transition from the fetal pulmonary circulation to the postnatal pulmonary circulation is marked by a dramatic fall in pulmonary vascular resistance and rise in pulmonary blood flow. The failure to successfully make this transition is integral to a number of neonatal and infant diseases.
- An important feature unique to the cerebral circulation is the presence of a blood-brain barrier. As a result, the cerebral vasculature responds differently than other vascular beds to humoral stimuli.
- Regulation of myocardial perfusion is tailored to match regional myocardial oxygen supply to demand over the widest possible range of cardiac workload. Increases in myocardial oxygen demand must be met by increases in myocardial blood flow.
- Critically ill patients are at risk for impaired splanchnic blood flow that can impair the two chief functions of the gastrointestinal system: (1) digestion and absorption of nutrients, and (2) maintenance of a barrier to the translocation of enteric antigens. Splanchnic ischemia is associated with an increased incidence of morbidity and mortality in critically ill patients.
- Although renal blood flow remains constant over a wide range of renal artery perfusion pressures, urinary flow rate varies as a function of renal perfusion pressure.

General Features

General Anatomy

Vascular anatomy is generally described in terms of distinct layers. Moving from the innermost layer outward are the metabolically active endothelium, the intima (with nerves and vasa vasorum), the media, and the adventitia. The composition of these layers differs among vessel types (some vessels have fewer layers), depending on the position and function of the vessel within the circulation.

The large arteries are elastic. Their media contain concentric lamellae of perforated elastic tubes cross-linked by transverse collagen and smooth muscle. The wall becomes stiffer when its smooth muscle contracts. Smaller arteries have fewer lamellae. The media are bounded by the internal and external elastic laminae. Arterioles are less elastic, have no lamellae, and have thin media with circular or spiral smooth muscle and inner and outer elastic laminae. Capillaries have thin walls and are nonmuscular, which is ideal for transport of materials into and from the tissues. Veins have medial muscle but have thinner walls relative to lumen diameter than do arteries. The vascular endothelium has important metabolic characteristics that may differ between vessel types (i.e., arteries vs. veins) and in different regions.[1,2]

Basic Physiology

Blood flow to a regional vascular bed is primarily determined by inflow pressure, vascular resistance, and outflow pressure. Inflow pressure is usually systemic arterial pressure. Outflow pressure approximates venous pressure but at times may exceed venous pressure if vascular tone is great enough to close the circulation above venous pressure or if external pressure impinges on the vasculature.

In a model to explain the relation of arterial pressure to flow, the circulation is represented by two capacitance vessels separated by a resistance. A standpipe full of blood is allowed to discharge its contents into the arterial vasculature (the proximal capacitance). Blood flows across the resistance site (the arterioles), traverses the venous vasculature (the distal capacitance), and drains to a reservoir at some outflow pressure (P_o), taken for this example to be atmospheric (Figure 20-1).

The pressure head of the system (P_i) is generated by the weight of the column of blood in the standpipe and is proportional to its height (P_i = blood column height in cm H_2O). As the standpipe discharges, the height decreases and P_i decreases. This, in turn, decreases the rate of flow (Q) through the vasculature. Q decreases almost linearly with P_i until the column is quite low. Ultimately, flow will cease while there is still pressure in the standpipe. The pressure at which flow ceases is the critical closing pressure of the circulation (P_{cc}).[3] Lower P_i is insufficient to maintain vessel patency and to permit continued flow (Figure 20-2).

Incremental resistance to flow is generally defined as the change in pressure per unit change in flow (dP_i/dQ). At pressures well above critical closing pressure, this is nearly identical to the vascular resistance (R), defined clinically as:

$$R = (P_i - P_0) / Q$$

When P_i does not greatly exceed P_{cc} but P_{cc} does greatly exceed P_o, however, incremental resistance can differ substantially from this clinical estimate. Thus an increase in P_{cc} can be confused with a true increase in incremental resistance. For example, a diagnosis of intrinsic pulmonary vascular disease (e.g., pulmonary arterial hypertension) based on measured pulmonary artery pressures in a patient receiving mechanical ventilation with high airway pressures (that raise P_{cc}) may be spurious.

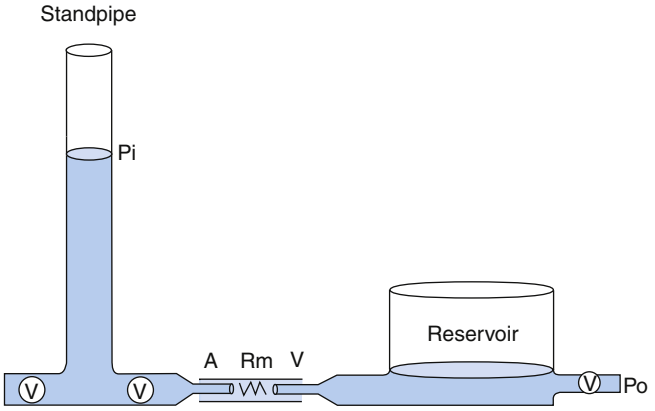

Figure 20–1. Model for facilitating interpretation of vascular pressure-flow relations. When valves (V) are properly positioned, fluid filling the standpipe to height Pi discharges across the circulation to the reservoir at outflow pressure Po. *A,* Artery; *Rm,* microvascular resistance; *V,* vein.

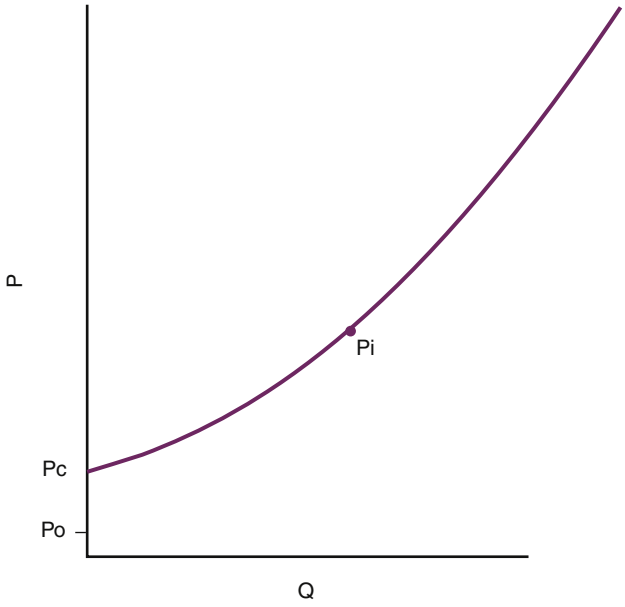

Figure 20–2. As the standpipe in Figure 20-1 discharges, Pi falls. Flow consequently slows and ultimately stops when Pi = Pc, the critical closing pressure of the circulation. Pi only reaches outflow pressure Po if Po ≥ Pc. *P,* Pressure; *Q,* rate of flow.

Venous Return and Cardiac Output

A second model illustrates the relationship of cardiac output to intrinsic mechanical properties of the systemic vasculature. In this model, the heart acts as a roller pump, creating a circulation much like that achieved during extracorporeal membrane oxygenation (Figure 20-3).

The roller pump displaces blood from the veins to the arteries, where some builds up before the resistive barrier of the arterioles. The higher the Q, the more blood resides in the arteries and the less in the veins. This complex partitioning of the blood volume depends on arterial capacitance (C_a), venous capacitance (C_v), and arteriolar incremental resistance to flow. At maximal Q, P_i is high and arterial blood volume ($P_i \times C_a$) is high, so much of the vascular blood volume is displaced to the arteries, and venous pressure (P_v) approaches P_{cc}. No further increase in roller pump speed can be sustained because any further increase in P_i would drive venous pressure substantially below venous critical closing pressure, causing vessel collapse and preventing venous return.

As Q is reduced, by turning down the roller pump, P_i falls and the volume of blood that resides in the arterial circuit also declines. This phenomenon allows more blood to reside in the veins, and venous pressure rises. As Q approaches zero, venous pressure approaches the mean circulatory pressure (P_m) (Figure 20-4). The importance of this model is that it can be used to illustrate the role of venous return as an independent determinant of cardiac output.

In its simplest form, cardiac output and central venous pressure of the intact circulation can be assumed to behave as illustrated in Figure 20-5. An increase in venous pressure distends the heart and elevates cardiac output. This behavior of the heart (see Chapter 19) can be superimposed on pressure flow characteristics of the vasculature. Venous return and cardiac output achieve equilibrium at one theoretical point for any given state of cardiac function (Starling curve) and simultaneous set of vascular characteristics (venous return curve).

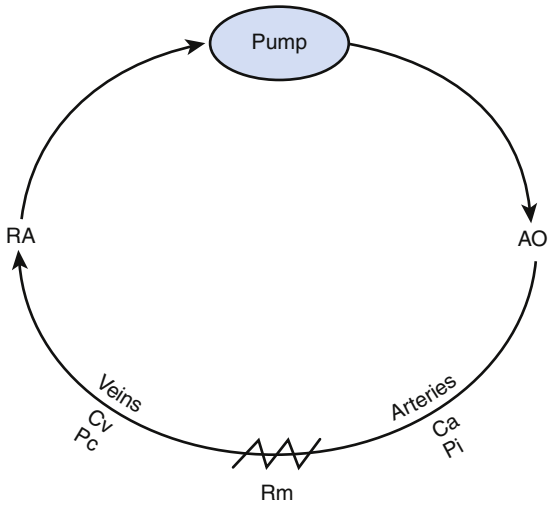

Figure 20–3. Model for facilitating interpretation of the relation of venous return to right atrial pressure. The heart is replaced by a mechanical roller pump. The right atrium (*RA*) is drained by the pump, and blood is infused into the aorta (*AO*). Blood then traverses the arteries, which have a capacitance (*Ca*) at an inflow pressure (*Pi*) determined by flow rate and microvascular resistance (*Rm*). Blood then returns through veins having capacitance (*Cv*) and critical closing pressure (*Pc*) to the right atrium.

This imaginary point defines a unique equilibrium relation of cardiac output to venous pressure. This venous return curve is dramatically influenced by changes in blood volume, vascular capacitance, and vascular resistance.

Transfusion elevates the maximal venous return that can be achieved without venous closure. Phlebotomy has the opposite effect. Because neither transfusion nor phlebotomy directly alters resistance or capacitance, the slope of the curve is not altered (Figure 20-6). Both interventions alter mean circulatory pressure because both interventions change blood volume.

Acute alterations in vascular capacitance can be expected to have effects similar to transfusion or phlebotomy, but any disparity between the change in C_a and the change in C_v will change the slope of the venous return curve.

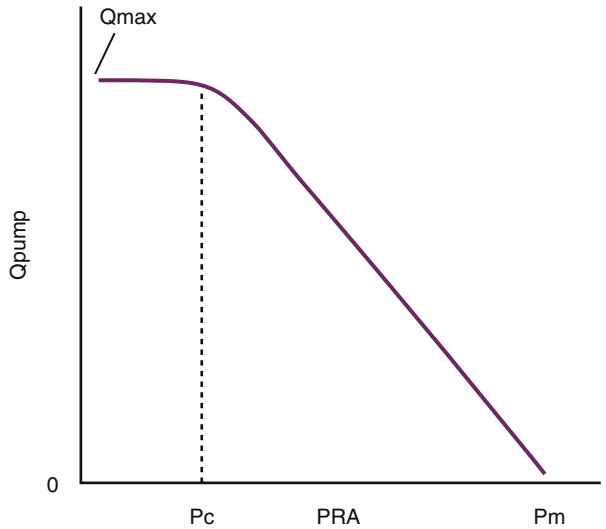

Figure 20–4. Venous return curve. As pump flow (*Qpump*) varies, right atrial pressure (*PRA*) is altered by redistribution of blood between arteries and veins. Qpump cannot be increased above Qmax because PRA would fall below critical closing pressure (*Pc*) of the venous circulation. *Pm*, Mean circulatory pressure of the vasculature at no flow; *Qmax,* Maximal flow.

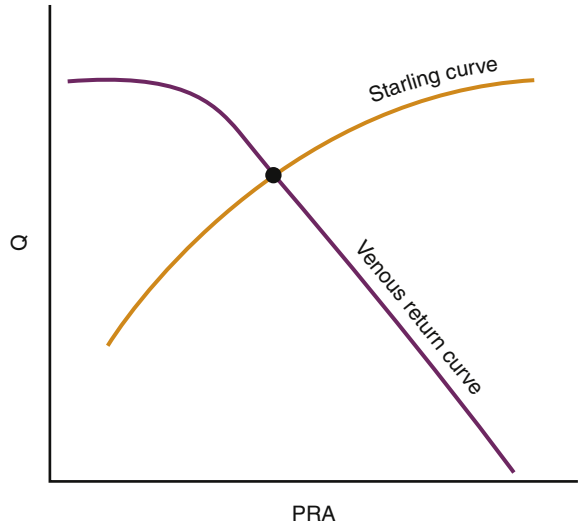

Figure 20–5. Theoretical superimposition of venous return and Starling curves. For any state of the heart and vasculature, these curves intersect at a point that characterizes right atrial pressure (*PRA*) and cardiac output (*Q*).

Isolated manipulation of incremental resistance would alter the maximum venous return attainable without venous collapse, yet it would not alter mean circulatory pressure. Changes in incremental resistance thus change the slope of the venous return curve (see Figure 20-6).

In clinical practice, it is unusual for any of these changes in vascular mechanics to occur in isolation. For instance, arteriolar dilation and dilation of other capacitance vessels often occur together. Arteriolar dilation and dilation of capacitance vessels have opposite effects on the venous return curve and, consequently, different effects on cardiac output. For this reason vascular volume expansion often is required in combination with nitroprusside or milrinone infusions to ensure adequacy of cardiac output despite successful reduction in cardiac afterload.

In patients with sepsis, toxic vasodilation may cause either high or low cardiac output, depending on associated changes in venous capacitance. Adequacy of vascular volume expansion, venous capacitance, vascular resistance, and the inotropic state of the heart can all profoundly influence cardiac output in patients with sepsis. Patients in septic shock are warm only if the circulation is adequately filled, cardiac function is sufficient, and incremental resistance is low.

Critical Closing Pressure

In many organs, as inflow pressure is lowered Q decreases, and it ceases at a pressure—the critical closing pressure (P_{cc})—that is higher than venous pressure. The probable mechanism

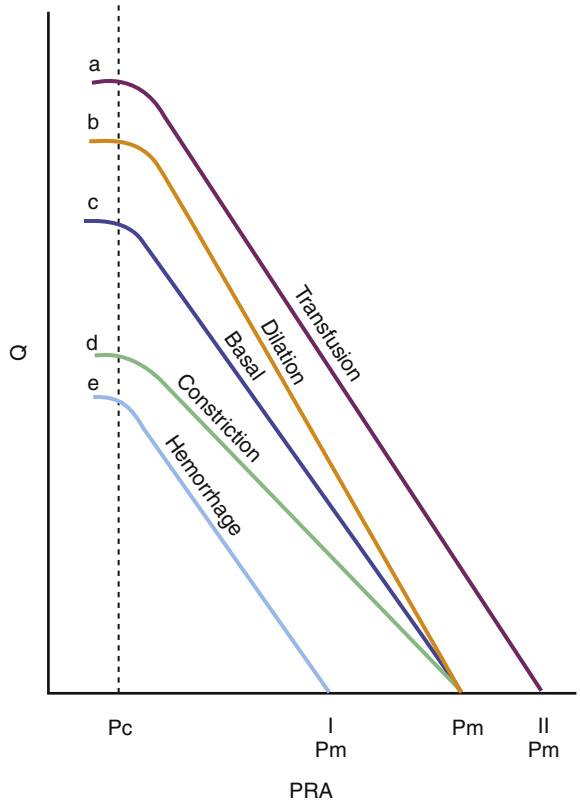

Figure 20–6. Effects of changing blood volume and microvascular resistance on the venous return curve. Curves *a*, *c*, and *e* are parallel but have different mean circulatory pressure (*Pm*) at zero flow. Curves *b*, *c*, and *d* are nonparallel but have the same Pm. *Pc*, Critical closing pressure; *PRA*, right atrial pressure; *Q,* flow.

is the vascular waterfall or Starling resistor. In 1910 Jerusalem and Starling described a device that was designed to control afterload to the left ventricle and that made possible the study of cardiac contractility.[4] The device consisted of a collapsible rubber tube traversing a pressurized glass chamber (Figure 20-7). When pressure surrounding the rubber tube exceeded the outflow pressure set by the reservoir, surrounding pressure opposed the flow of blood and became the true outflow pressure of the device. The physiologic counterpart of this phenomenon occurs in small vessels surrounded by tissue pressure. In the heart, for example, a Starling resistor effect occurs in extramyocardial coronary veins, although evidence also exists for critical closure of small arterioles. No one has yet demonstrated vessel closure directly, but this might not be necessary because as small vessels narrow when they are compressed, the wall becomes convoluted, and blood cells might become obstructed by the folds even when externally the vessel does not appear to be closed.

Autoregulation

In all organs, when inflow pressure is suddenly raised or lowered while oxygen consumption remains constant, flow rises or falls transiently but then returns to its former value; this phenomenon is termed *autoregulation*. Myogenic tonic response is in part responsible for this phenomenon, but it is not the only mechanism. Some investigators have shown that tissues have oxygen sensors that respond to transient increases or decreases in oxygen supply, and other studies indicate that the process is mediated by greater or lesser release of nitric oxide carried to the tissues by hemoglobin in the form of S-nitrosohemoglobin.[5-7] Other locally produced gases such as hydrogen sulfide[8] and carbon monoxide also may play a role.[9,10] Evidence indicates that some autoregulatory mechanisms are specific to individual microcirculations (e.g., macula densa signaling in the renal circulation).

Distensibility and Compliance

The distensibility of a vessel is defined as the change in volume as a proportion of the initial volume for a given change in pressure:

$$\text{Distensibility} = (\Delta V / \Delta P) / V$$

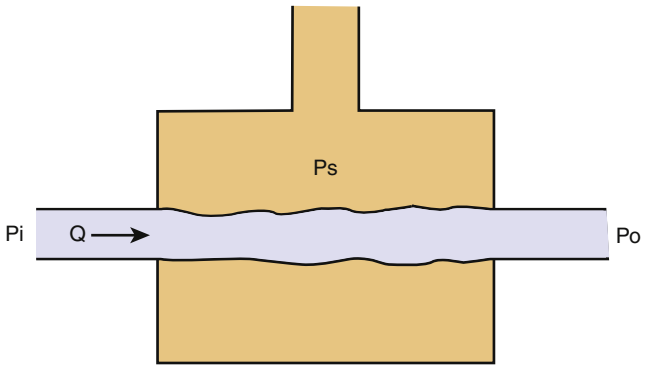

Figure 20–7. Starling resistor is a compressible conduit exposed to surrounding pressure (*Ps*). When Ps is less than outflow pressure (*Po*), Ps does not oppose blood flow. When Ps is between inflow (*Pi*) and outflow pressures, it opposes blood flow. No flow is possible when Ps exceeds Pi. *Q*, flow.

where V is volume and P is pressure. Veins are much thinner than arteries and are about eight times more distensible. Multiplying distensibility by volume yields $\Delta V/\Delta P$, which is the definition of compliance. Because venous volume is usually more than three times arterial volume, venous compliance is about 20-fold to 30-fold greater than arterial compliance. As a result, whenever fluids are infused, the bulk of the fluid volume is accommodated in the veins.

Vascular Resistance

Under normal circumstances, vascular resistance is the major control of organ flow and can be understood by considering the resistance of a Newtonian liquid passing through a rigid tube as defined by the Hagen-Poiseuille equation:

$$R = (8/\pi)(1/r^4)\eta$$

where R is resistance, l is tube length, r is the internal radius of the tube, and η is the fluid viscosity. Blood is not a Newtonian fluid, but this fact does not affect the accuracy of calculated vascular resistance much. However, vascular beds do contain many "tubes" in parallel. Thus for vascular systems a factor k is added that represents the number of vessels. The equation thus becomes:

$$R = (8/\pi)(1/kr^4)\eta$$

Because the length and number of vessels and blood viscosity are relatively constant at any one time, change in vessel radius is the major factor responsible for a dynamic change in vascular resistance. Because of the fourth power factor, small changes in radius cause large changes in resistance. Vessel radius is influenced by vascular elasticity and transmural pressure but is mainly regulated by changes in vessel wall smooth muscle tone.

Vascular Impedance

Resistance is strictly a steady-state concept. In a pulsatile system the factors affecting the relationship of pressure dissipation to flow are resistance resulting from friction and viscosity, fluid inertia, and vessel wall compliance that combine to produce an *impedance* to flow that varies with frequency. At zero frequency, steady-state resistance is approximated by the change in mean pressure over flow, but substantial contributions are made by the first three harmonics that are ignored by this calculation.

Local Regulatory Mechanisms

Regions of the circulation may differ markedly in their patterns of vascular regulation. A regulatory stimulus can have multiple effects that differ from one location to another. An agent that potently regulates vascular resistance in one region of the circulation may have no effect in another. For example, during hemorrhagic shock, flow is maintained to the heart and brain but is reduced to muscles, the kidneys, and the gut.

Vascular tone is strongly influenced by several mechanisms: (1) innervation and neural processes, (2) circulating endocrine and neuroendocrine mediators, (3) local metabolic products, (4) blood gas composition, (5) endothelial derived factors, and (6) myogenic processes.

Innervation and Neural Processes

Receptors responsive to neural products (e.g., norepinephrine and acetylcholine) are found throughout the circulation. Nevertheless, innervation and receptor distribution are organ specific, allowing rapid, patterned, coordinated redistribution of blood flow and an orchestrated response to events such as hypoxia, changes in posture, and hemorrhage. Although these receptors respond to circulating agonists (including adrenal epinephrine) as well as to those liberated locally, they generally are associated with innervation by autonomic nerves. In general, presynaptic α-adrenergic stimulation causes norepinephrine reuptake, whereas postsynaptic α-adrenergic stimulation causes norepinephrine release and vasoconstriction. β-Adrenergic stimulation generally causes vasodilation. Cholinergic stimulation (whether sympathetic or parasympathetic) generally causes vasodilation (see Chapters 25 and 117).

Circulating Endocrine and Neuroendocrine Mediators

Humoral regulators of vascular tone include angiotensin, arginine vasopressin, bradykinin, histamine, and serotonin. Of less certain significance are aldosterone, thyroxine, antinatriuretic peptide, and various reproductive hormones. Most of these regulators have both direct effects and secondary effects, which tend to be organ specific or regional in nature. Angiotensin plays a special role in the homeostasis of blood pressure and is produced in persons with hemorrhagic or hypovolemic shock. It causes generalized vasoconstriction in both systemic and pulmonary circulations, but locally it stimulates the release of vasodilating prostaglandins in the lung and kidney. Bradykinin is a potent pulmonary and systemic vasodilator released locally by the action of proteolytic enzymes on kallikrein after tissue injury. Histamine is released by mast cells in response to injury and is a potent vasodilator in most regions of the circulation but causes vasoconstriction in the lung.

Local Metabolic Products

Local metabolic regulation of vasomotor tone provides an ideal homeostatic mechanism whereby metabolic demand can directly influence perfusion. The precise mechanisms underlying the coupling of blood flow with metabolic activity remain unclear. One theory holds that as the metabolic rate increases, so too does the formation of some vasodilating substance. Thus the regional vasculature relaxes, allowing more oxygen to be delivered in support of this work. As flow rises, the metabolites are washed out, restoring their concentration to normal. Adenosine, for instance, which accumulates locally when tissue metabolism is high and tissue oxygenation is marginal, causes pronounced vasodilation in the coronary, striated muscle, splanchnic, and cerebral circulations. Another example is potassium, which is released from muscle in response to increased work, ischemia, and hypoxia.[11] Hypokalemia causes vasoconstriction, and hyperkalemia, within the physiological range, causes vasodilation.[12,13]

An increasing amount of data demonstrate the importance of the local redox state on the regulation of blood flow through the microcirculation. Reactive oxygen species such as superoxide, hydrogen peroxide, and peroxynitrite have been shown to influence normal regulatory processes and to participate in the pathophysiology of a wide array of cardiovascular disorders. For example, the rapid reaction of nitric oxide (NO) with the superoxide anion results in the formation of peroxynitrite, a potent oxidant. While peroxynitrite is known to have cytotoxic properties, under normal conditions peroxynitrite inhibits leukocyte adherence and platelet aggregation without evidence of cellular injury.[14,15] In disease states, however, peroxynitrite can lead to protein nitration and deoxyribonucleic (DNA) damage. In addition, elevated levels of superoxide may decrease the bioavailability of NO, leading to abnormal vasomotion.[16]

Blood Gas Composition

Tissue levels of oxygen and carbon dioxide have been shown to reflect adequacy of perfusion and oxygen delivery.[17] These blood gases are potent determinants of regional blood flow and have effects that differ from one region of the circulation to another. They also have a more general effect mediated by carotid chemoreceptors.

Endothelial-Derived Factors

The vascular endothelial cells are capable of producing a variety of vasoactive substances that participate in the regulation of normal vascular tone. These substances, such as NO, carbon monoxide (CO), hydrogen sulfide, and endothelin-1 (ET-1) are capable of producing vascular relaxation and/or constriction, modulating the propensity of the blood to clot, and inducing and/or inhibiting smooth muscle migration and replication (Figure 20-8).[18,19] The understanding of the role of the vascular endothelium and the factors it produces in regulating blood flow in health and disease has resulted in several treatment strategies that target, mimic, or augment endothelial processes. Examples include inhaled NO for pulmonary hypertension, L-arginine supplementation for coronary artery disease and the pulmonary vasculopathy of sickle cell disease, phosphodiesterase inhibitors (i.e., sildenafil, which prevents the breakdown of cyclic guanosine 3′5′-monophosphate [cGMP]) for pulmonary hypertensive disorders, endothelin receptor antagonists for pulmonary hypertensive disorders and vasospasm following subarachnoid hemorrhage, and NO inhibitors for refractory hypotension resulting from sepsis.[20-25] Indeed, many older therapies used to promote vascular relaxation, such as nitrovasodilators, affect endothelial function, a fact that until relatively recently was not appreciated.

NO is a labile humoral factor produced by NO synthase from L-arginine in the vascular endothelial cell. NO diffuses into the smooth muscle cell and produces vascular relaxation by increasing concentrations of cGMP via the activation of soluble guanylate cyclase. NO is released in response to a variety of factors, including shear stress (flow) and the binding of certain endothelium-dependent vasodilators (such as acetylcholine, adenosine triphosphate [ATP], and bradykinin) to receptors on the endothelial cell. Basal NO release is an important mediator of both resting pulmonary and systemic vascular tone in the fetus, newborn, and adult, as well as a mediator of the fall in pulmonary vascular resistance normally occurring at the time of birth.[26-29] Dynamic changes in NO release are fundamental to the regulation of all vascular beds.

CO is a labile humoral factor produced by the action of hemoxygenase on heme in many tissues, including endothelial cells. Hemoxygenase-1 is constitutive and hemoxygenase-2 is inducible. CO interacts with NO, is an independent stimulator of cGMP, relaxes smooth muscle, inhibits its replication, and

has powerful antithrombotic and antiinflammatory effects. It is beginning to enter the field of clinical medicine.[10,30]

Hydrogen sulfide is produced in most tissues by a variety of mechanisms and may be the ultimate sensor that is stimulated by oxygen deficit or excess.[8] Hydrogen peroxide may be even more important.

ET-1 is a 21-amino-acid polypeptide also produced by vascular endothelial cells.[31] The vasoactive properties of ET-1 are complex, and studies have shown varying hemodynamic effects on different vascular beds. However, its most striking property is its sustained hypertensive action. In fact, ET-1 is the most potent vasoconstricting agent discovered, with a potency 10 times that of angiotensin II. The hemodynamic effects of ET-1 are mediated by at least two distinctive receptor populations, ET_A and ET_B. The ET_A receptors are located on vascular smooth muscle cells and mediate vasoconstriction, whereas the ET_B receptors may be located on endothelial cells and mediate both vasodilation and vasoconstriction. Individual endothelins occur in low levels in the plasma, generally below their vasoactive thresholds, which suggests that they are primarily effective at the local site of release. Even at these levels, they may potentiate the effects of other vasoconstrictors such as norepinephrine and serotonin.[32] The role of endogenous ET-1 in the regulation of normal vascular tone is presently unclear.[33] Nevertheless, alterations in ET-1 have been implicated in the pathophysiology of a number of disease states.[34]

Endothelial-derived hyperpolarizing factor (EDHF), a diffusible substance that causes vascular relaxation by hyperpolarizing the smooth muscle cell, is another important endothelial factor. EDHF has not yet been identified, although it is likely an epoxyeicosatrienoic acid, but current evidence suggests that the action of EDHF is dependent on K^+ channels (Figure 20-8).[35] Activation of potassium channels in the vascular smooth muscle results in cell membrane hyperpolarization, closure of voltage-dependent calcium channels, and ultimately vasodilation. Potassium channels are also present in endothelial cells. Activation within the endothelium results in changes in calcium flux and may be important in the release of NO, prostacyclin, and EDHF. Potassium channel subtypes include ATP-sensitive K^+ channels, Ca^{2+}-dependent K^+ channels, voltage-dependent K^+ channels, and inward-rectifier K^+ channels.[35]

The breakdown of phospholipids within vascular endothelial cells results in the production of important byproducts of arachidonic acid, including prostacyclin (PGI_2) and thromboxane. PGI_2 activates adenylate cyclase, resulting in increased cyclic adenylate monophosphate production and subsequent vasodilation, whereas thromboxane results in vasoconstriction via phospholipase C signaling (Figure 20-8). Other prostaglandins and leukotrienes also have potent vasoactive properties.

Myogenic Processes

In 1902, Bayliss[36] described an intrinsic increase in vascular tone in response to elevated intravascular pressure. This myogenic response results in alterations in vascular tone following changes in transmural pressure or stretch.[37] This response is especially important at the arteriolar level and is thought to participate in regional autoregulation. Increases

in intravascular pressure and/or stretch result in an increase in arteriolar smooth muscle tone, while decreasing pressures have the reverse effect. The precise mechanisms mediating this response are unclear, but a role for dynamic changes in intracellular Ca^{2+} and myosin light chain phosphorylation has been documented.[38] More recent work has focused on the role of tyrosine phosphorylation pathways, ENaC, transient receptor potential channels, potassium channels, and alterations in Ca^{2+} sensitivity in this response.[39-43] Moreover, the myogenic response varies between the regional circulations and between vessels within a given circulation.

Regional Circulations

Pulmonary Circulation

Maldevelopment and/or maladaptation of the pulmonary vascular bed are important components of several neonatal and infant disease states (e.g., chronic lung disease, persistent pulmonary hypertension of the newborn, and congenital heart disease). Because strategies aimed at altering postnatal pulmonary vascular resistance are commonly used in the management of these cases, an understanding of the regulation of postnatal pulmonary vascular tone is important.

The morphologic development of the pulmonary circulation affects the physiologic changes that occur in the perinatal period. In the fetus and neonate, small pulmonary arteries have thicker muscular coats than similarly located arteries in the adult. This muscularity is, in large part, responsible for the pulmonary vascular reactivity and high resistance found in the fetus. In fetal lamb lungs fixed at normal in utero perfusion pressures, the medial smooth muscle coat is most prominent in the smallest arteries (fifth- and sixth-generation arteries; external diameter 20-50 μm). During the latter half of gestation, the medial smooth muscle thickness remains constant in relationship to the external diameter of the artery.[44] Similar observations utilizing slightly different techniques have been made in human lungs.[45,46] Within the first several weeks after birth, the medial smooth muscle involutes and the thickness of the media of the small pulmonary arteries decreases rapidly and progressively.[47]

Following this perinatal transition, the medial layers of the proximal pulmonary vascular bed are completely encircled by smooth muscle. Moving distally, muscularization becomes incomplete (arranged in a spiral or helix) and disappears completely from the most peripheral arterioles.[46] In these arterioles, an incomplete pericyte layer is found within the endothelial basement membrane. Smooth muscle precursor cells reside in the nonmuscular portions of the partially muscular pulmonary arteries.[48] Under certain conditions, such as hypoxia, these cells may rapidly differentiate into mature smooth muscle cells.[48]

Subsequently, from infancy to adolescence, the arteries undergo progressive peripheral muscularization. In the adult, complete circumferential muscularization extends peripherally such that the majority of small pulmonary arteries are completely muscularized.

Normal Fetal Circulation

In the fetus, normal gas exchange occurs in the placenta and pulmonary blood flow is low, supplying only nutritional requirements for lung growth and performing some metabolic functions. Pulmonary blood flow in near-term lambs is about 100 mL/100 g wet lung weight, representing between 8% and 10% of the total output of the heart.[49] Pulmonary blood flow is low despite the dominance of the right ventricle, which in the fetus ejects about two thirds of the total cardiac output. Most of the right ventricular output is diverted away from the lungs through the widely patent ductus arteriosus to the descending thoracic aorta, from which a large proportion reaches the placenta through the umbilical circulation for oxygenation. In young fetuses (at about halfway through gestation), pulmonary blood flow is approximately 3% to 4% of the total combined left and right ventricular outputs of the heart (fetal cardiac output). This value increases to about 6% at about four fifths through gestation, corresponding temporally with the onset of the release of surface active material into lung fluid. This step is followed by another progressive slow rise in pulmonary blood flow, reaching about 8% to 10% near term.[49] Fetal pulmonary arterial pressure increases with advancing gestation. At term, mean pulmonary arterial pressure is about 50 mm Hg, generally exceeding mean descending aortic pressure by 1 to 2 mm Hg.[50] Pulmonary vascular resistance early in gestation is extremely high relative to that in the infant and adult, probably because of the low number of small arteries. Pulmonary vascular resistance falls progressively during the last half of gestation, new arteries develop, and cross-sectional area increases; however, baseline pulmonary vascular resistance is still much higher than after birth.[50,51]

Changes in the Pulmonary Circulation at Birth

After birth, with initiation of ventilation by the lungs and the subsequent increase in pulmonary and systemic arterial blood O_2 tensions, pulmonary vascular resistance decreases and pulmonary blood flow increases by eightfold to tenfold to match systemic blood flow (300 to 400 mL/min/kg body weight). This large increase in pulmonary blood flow increases pulmonary venous return to the left atrium, increasing left atrial pressure. Then the valve of the foramen ovale closes, preventing any significant atrial right-to-left shunting of blood. In addition, the ductus arteriosus constricts and closes functionally within several hours after birth, effectively separating the pulmonary and systemic circulations. Mean pulmonary arterial pressure decreases, and by 24 hours of age, it is approximately 50% of mean systemic arterial pressure. Adult values are reached 2 to 6 weeks after birth (Figure 20-9).[52,53]

The decrease in pulmonary vascular resistance with ventilation and oxygenation at birth is regulated by a complex and incompletely understood interplay between metabolic and mechanical factors, which in turn are triggered by the ventilatory and circulatory changes that occur at birth. Physical expansion of the fetal lamb lung without changing O_2 tension increases fetal pulmonary blood flow and decreases pulmonary vascular resistance, but not to newborn values.[54] A very small proportion of this decrease relates to replacement of fluid in the alveoli with gas, which allows unkinking of the small pulmonary arteries, and to the changes in alveolar surface tension, which exert a negative dilating pressure on the small pulmonary arteries, maintaining their patency.[55] Physical expansion of the lung also releases vasoactive substances such as PGI_2, which increases pulmonary blood flow and decreases pulmonary vascular resistance in the fetal goat and lamb.[56] There also is net production of PGI_2 by the lung with the initiation of ventilation at birth.[56] In addition, inhibitors

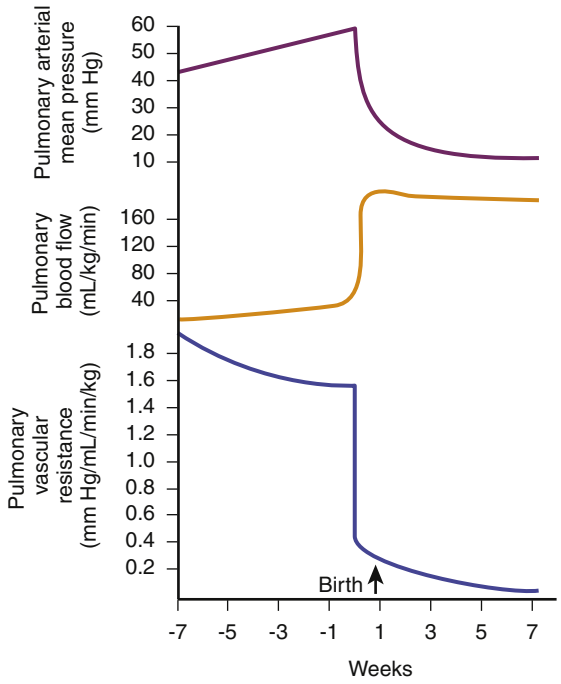

Figure 20–9. Changes in mean pulmonary arterial pressure, pulmonary blood flow, and pulmonary vascular resistance at birth. *(Data from Morin FC III, Egan E: Pulmonary hemodynamics in fetal lambs during development at normal and increased oxygen tension,* J Appl Physiol *73:213-218, 1993;* and *Soifer SJ, Morin FC III, Kaslow DC et al: The developmental effects of prostaglandin D2 on the pulmonary and systemic circulations in the newborn lamb,* J Dev Physiol *5:237-250, 1983.)*

of prostaglandin synthesis (such as indomethacin or meclofenamic acid) not only block PGI_2 production but also attenuate the increase in pulmonary blood flow and decrease in pulmonary vascular resistance that occur with physical expansion of the fetal lung, although not the changes that occur with oxygenation.[57] Therefore PGI_2 (or perhaps, but less likely, another metabolite of arachidonic acid) plays an important role in the increase in pulmonary blood flow and decrease in pulmonary vascular resistance that occur in association with the mechanical component (stretch) of ventilation at birth.

Ventilation of the fetus without oxygenation produces partial pulmonary vasodilatation, whereas ventilation with air or oxygen produces complete pulmonary vasodilatation. The exact mechanisms of oxygen-induced pulmonary vasodilation during the transitional circulation remain unclear. The increase in alveolar or arterial O_2 tension may decrease pulmonary vascular resistance either directly by dilating the small pulmonary arteries or indirectly by stimulating the production of vasodilator substances such as PGI_2 or NO. In particular, NO has been implicated as an important mediator of the decrease in pulmonary vascular resistance at birth associated with increased oxygenation.[58-63] However, the immediate decrease in pulmonary vascular resistance minutes after birth is not attenuated by NO inhibition. Therefore the decrease in pulmonary vascular resistance with initiation of ventilation and oxygenation consists of at least two components. First is partial pulmonary vasodilatation caused by physical expansion of the lung and the production of prostaglandins (PGI_2 and PGD_2). This process probably is independent of fetal oxygenation and results in a modest increase in pulmonary blood flow and a decrease in pulmonary vascular resistance. Second is a further maximal pulmonary vasodilatation associated with fetal oxygenation, which is not necessarily dependent on prostaglandin production. This process results in an increase in pulmonary blood flow and a decrease in pulmonary vascular resistance to newborn values. This latter pulmonary vasodilatation is likely caused by the synthesis of NO. Both components are necessary for the successful transition to extrauterine life. An additional mechanism by which vasodilatation occurs is related to the stimulation by increased shear forces of endothelial cells to produce both NO and PGI_2. It is possible that after the initial fall in pulmonary vascular resistance because of another mechanism, this particular mechanism acts to maintain pulmonary vasodilatation.

Control of the perinatal pulmonary circulation therefore probably reflects a balance between factors producing pulmonary vasoconstriction (low O_2, leukotrienes, other vasoconstricting substances) and those producing pulmonary vasodilatation (high O_2, PGI_2, NO, other vasodilating substances). The dramatic increase in pulmonary blood flow with the initiation of ventilation and oxygenation at birth reflects a shift from active pulmonary vasoconstriction in the fetus to active pulmonary vasodilatation in the newborn.

Failure of the pulmonary circulation to undergo this normal fall in pulmonary vascular resistance at birth (persistent pulmonary hypertension of the newborn) is associated with a variety of conditions, including aspiration syndromes, sepsis, in-utero stress events, and certain congenital heart defects (e.g., obstruction of pulmonary venous drainage and a single ventricle with restrictive atrial septum).

Regulation of Postnatal Pulmonary Vascular Resistance

After the immediate postnatal state, the pulmonary circulation is maintained in a dilated, low-resistance state. Because the inflow pressure of the pulmonary circulation is quite low, a vertical gradation to the distribution of blood flow in the lung occurs. Hydrostatic pressure must be adjusted for vertical height above the left atrium, both at the inflow and at the outflow of every alveolar capillary unit. For example, given a pulmonary artery mean pressure of 20 cm H_2O (zeroed at the level of the left atrium), an alveolar-capillary unit 12 cm above the left atrium will face an inflow pressure of only 8 cm H_2O. A left atrial pressure of 5 cm H_2O would generate no opposing outflow pressure to alveolar capillary units more than 5 cm above the left atrium. Critical closing pressure of postcapillary vessels therefore would set outflow pressure for a unit 10 cm above the left atrium. Were intrinsic vascular resistance identical throughout the lung, flow at any vertical height would be determined by hydrostatic driving pressure (inflow-outflow) and would be greatest at the base and least at the apex of the lung. West, Dollery, and Naimark[64] reported that this phenomenon partitions the lung into three vertical regions (Figure 20-10). Zone I vessels are higher above the left atrium than pulmonary artery pressure (expressed in cm H_2O) and are not perfused by the pulmonary artery. Zone II vessels lie above the height defined by the hydrostatic left atrial pressure but below the height of pulmonary artery pressure. These units are perfused in proportion to the driving pressure across them, which is approximately pulmonary artery pressure less vertical height (or critical closing pressure, whichever is higher). Zone III vessels lie at a vertical height less than outflow pressure expressed in cm H_2O. Driving pressure across these units

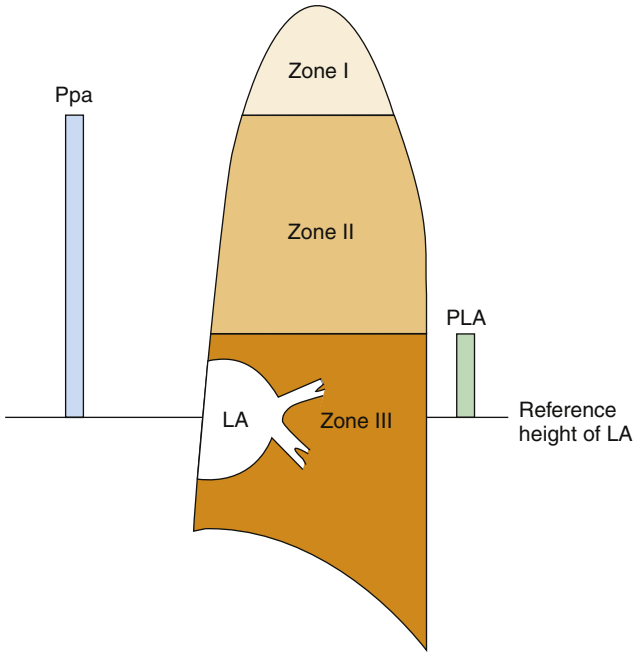

Figure 20–10. The lung is divided vertically into three regions. Zone I alveolar capillary units are unperfused because they see no functional inflow pressure. Zone II units are perfused in proportion to their height above the left atrium (*LA*). Zone III vasculature is more uniformly perfused because gravity has comparable effects on inflow and outflow pressures. *Ppa,* pulmonary artery pressure; *PLA,* left atrial pressure. *(Modified from Fuhrman BP: Regional circulation. In Fuhrman BP, Shoemaker WC, editors:* Critical care: state of the art, vol 10, *Fullerton,* CA, *1989, Society of Critical Care Medicine.)*

is independent of height because inflow and outflow pressures are comparably influenced by gravity. Zone I likely does not exist in a supine neonate.

Because small pulmonary arteries course along with the branching airways and small pulmonary vessels are intimately related with alveoli, airway pressure can directly modulate pulmonary blood flow.[65] Alveolar pressure can be loosely translated into surrounding pressure for alveolar vessels. Positive airway pressure applied to the lung can impinge on alveolar vessels whenever alveolar pressure exceeds the other determinants of outflow pressure. During positive pressure ventilation, outflow pressure of the pulmonary circulation may be determined predominantly by the mechanics of ventilation. The lung is partitioned into zones, but the distribution of flow becomes a complex function of alveolar pressure as well as left atrial and critical closing pressures.

To further complicate this view of the pulmonary circulation, lung volume and alveolar pressure both change during positive pressure ventilation. During inspiration, extraalveolar and corner vessels are dilated by radial traction, reducing their resistance to flow, whereas alveolar vessels narrow and elongate.[66] During lung inflation, alveolar surface tension rises, diminishing the transmission of alveolar pressure to alveolar vessels.[67] Evidence also indicates that, in the infant lamb, lung stretch may directly augment pulmonary vascular tone in a manner that is dependent on calcium flux and subject to calcium channel blockade using verapamil.[68] In fact, it is clear that mechanical ventilation can have profound direct effects on the intact pulmonary circulation that depend on the waveform of airway pressure applied and not on mean airway pressure alone.[69,70]

In heterogeneous lung disease, the application of positive airway pressure can modulate and redistribute blood flow away from ventilated regions and toward unventilated regions of the lung by directly increasing the pulmonary vascular resistance of lung segments exposed to elevated airway pressure, that is, segments not protected by consolidation or airway obstruction.[44]

Evidence suggests that basal release of NO and the subsequent increase in smooth muscle cell concentrations of cGMP partly mediate the low resting pulmonary vascular resistance of the newborn.[28,71] Other vasoactive substances—including histamine, 5-hydroxytryptamine, bradykinin, and metabolites of arachidonic acid by the cyclooxygenase and lipoxygenase pathways—have been implicated in mediating postnatal pulmonary vascular tone. However, their precise roles are not well elucidated.

Two of the most important factors affecting pulmonary vascular resistance in the postnatal period are oxygen concentration and pH. Decreasing oxygen tension or pH elicit pulmonary vasoconstriction of the resting pulmonary circulation.[72] Alveolar hypoxia constricts pulmonary arterioles, diverting blood flow away from hypoxic lung segments and toward well-oxygenated segments.[73] This process enhances ventilation-perfusion matching and is a unique pulmonary vascular response to hypoxia, which is probably greater in the younger animal than in the adult.[74] The mechanism of alveolar hypoxic pulmonary vasoconstriction, which remains to be defined, is the subject of several extensive reviews.[75] Acidosis potentiates hypoxic pulmonary vasoconstriction, and alkalosis reduces it.[72] The exact mechanism of pH-mediated pulmonary vasoactive responses is incompletely understood but appears to be independent of $Paco_2$.[76] Alveolar hyperoxia and alkalosis often are used to relax pulmonary vascular tone because they generally relieve pulmonary vasoconstriction while having little apparent effect on the systemic circulation as a whole. However, detrimental effects of hypocarbia or respiratory alkalosis on cerebral and myocardial blood flow may occur.[77]

The lung is innervated, but neural effects on pulmonary vascular resistance appear to be of little consequence to basal tone. However, pulmonary neurohumoral receptors are sensitive to α-adrenergic, β-adrenergic, and dopaminergic agonists. Therefore vasoactive agents that stimulate these receptors will affect the vascular tone of both the pulmonary and systemic circulations. The degree of pulmonary versus systemic alterations induced by these agents is variable and often dictated by the relative tone of each vascular bed at a given time. Therefore the response of these agents is difficult to predict in an individual critically ill patient.

A selective pulmonary vasodilator was long sought for treatment of pulmonary hypertension because (with the exception of oxygen) the response of the pulmonary circulation to humoral vasoactive agents is generally similar to that of the systemic circulation. To date, inhaled NO is the most commonly used agent for selective pulmonary vascular dilation. It is worth noting that its selectivity is not based on a differential effect in the pulmonary and systemic circulations. Rather, when delivered as an inhaled gas, NO is rapidly bound to hemoglobin and inactivated, thus limiting its effects to the pulmonary circulation. Other agents with rapid metabolism (i.e., inhaled prostacyclin) also are being studied via inhalational delivery routes to take advantage of this pharmacologic selectivity.[78]

Cerebral Circulation

Although the general principles governing the circulation certainly hold true for the cerebral circulation, blood flow to the brain is specially regulated to facilitate the myriad of complex functions that the brain oversees.

In adults, the brain (which makes up 2% of body mass) receives approximately 14% of the cardiac output and accounts for close to 20% of the body's O_2 consumption. In neonates, the brain receives up to 30% of cardiac output and accounts for 50% or more of total oxygen consumption and up to 98% of produced hepatic glucose consumption. Other organ systems receive a larger percentage of the total cardiac output (e.g., the lung) and utilize greater amounts of oxygen (e.g., skeletal muscle), but the brain is unique in its intolerance for diminished blood flow. In fact, although some favorable outcomes have been reported, severe if not irreversible damage often occurs after just minutes of circulatory arrest under normal conditions.[79-82]

Blood is supplied to the brain by the carotid and vertebral arteries. The common carotid artery bifurcates, forming the internal carotid artery (ICA) and external carotid artery. The ICA gives rise to its major branches—the posterior communicating, anterior cerebral, middle cerebral, and anterior choroidal arteries—which comprise the anterior circulation. The vertebral arteries give rise to the anterior spinal and posterior inferior cerebellar arteries before merging to form the basilar artery, which in turn gives rise to the anterior inferior cerebellar, superior cerebellar, and posterior cerebral arteries. These vessels comprise the posterior circulation. Venous drainage from the superficial and deep cerebral veins enters the dural sinuses and exits the cranium mostly via the internal jugular vein, although the vertebral veins are important secondary pathways available for venous outflow.[83]

The cranium has three compartments: tissue, cerebrospinal fluid (CSF), and blood. The Monro-Kellie doctrine states that these compartments occupy a relatively fixed space and that an increase in one compartment can only occur at the expense of another. For example, when brain swelling occurs, CSF and cerebral venous blood must be displaced if intracranial pressure (ICP) is to remain unchanged. As the limits of CSF and blood evacuation are approached, ICP rises. Raised ICP and/or venous obstruction can impede cerebral blood flow (CBF). Cerebral perfusion pressure (CPP), generally defined as the difference between the mean arterial pressure and the ICP, is thus a more accurate descriptor of cerebral inflow pressure. CBF will decline when the CPP falls below the lower limit of the autoregulatory curve. In the setting of raised ICP or venous hypertension, this process occurs even in the face of elevated systemic arterial pressures.

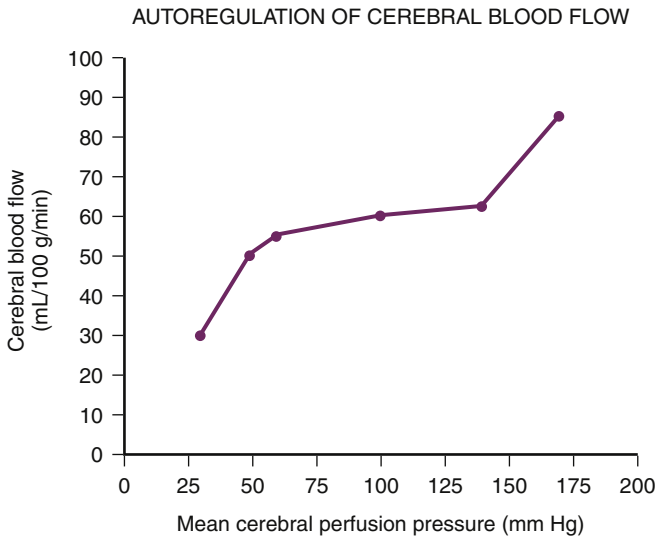

Figure 20–11. Cerebral blood flow (*CBF*) autoregulates at perfusion pressures between 50 and 160 mm Hg. Below 50 mm Hg, CBF falls. Above 160 mm Hg, CBF rises. *(Modified from Fuhrman BP: Regional circulation. In Fuhrman BP, Shoemaker WC, editors:* Critical care: state of the art, vol 10, *Fullerton, CA, 1989, Society of Critical Care Medicine.)*

At rest, CBF is approximately 50 mL/100 g tissue/min.[84] Cerebral oxygen consumption is surprisingly high, averaging 3.2 mL/100 g tissue/min. Glucose is the primary energy substrate, although ketones can be utilized during periods of starvation. The brain has no functional capacity to store energy and thus is completely dependent on a steady supply of O_2 because up to 92% of its ATP production results from the oxidative metabolism of glucose.[79-82]

An important feature unique to the cerebral circulation is the presence of a blood-brain barrier (BBB). The vascular endothelium of brain capillaries forms a continuous sheet, with adjacent cells joined by tight junctions. Unlike the endothelium of nonneural capillaries, vascular endothelium does not contain intercellular clefts through which water-soluble particles can traverse, and pinocytosis is markedly diminished. However, the lipid-soluble substances CO_2 and O_2 can freely diffuse across the endothelium. Metabolically important components such as glucose, lactate, and amino acids depend upon specific carrier proteins to facilitate their diffusion into the brain. Furthermore, the BBB has a biochemical component, with high levels of degradative enzymes that protect the vascular smooth muscle and extracellular fluid from the effects of circulating vasoactive substances, such as catecholamines.[85] Thus, as a result of the BBB, the cerebral vasculature responds differently than other vascular beds to humoral stimuli. However, humoral stimuli can significantly alter the vascular tone of large cerebral arteries and can affect blood flow to parts of the brain that lack a complete BBB such as the choroid plexus, the median eminence, and the area postrema.[86,87]

For more than 60 years it has been recognized that CBF remains constant over a wide range of mean systemic arterial pressures[88] (Figure 20-11). Constant CBF is maintained in the face of increasing inflow pressures by compensatory vasoconstriction. Conversely, in the setting of low systemic arterial pressures (i.e., low inflow pressures), the cerebral vasculature dilates to maintain steady CBF. At systemic arterial pressures outside the autoregulatory range, further dilation or constriction can no longer maintain blood flow. At high pressures, disruption of the BBB ensues, with subsequent edema and even hemorrhage from ruptured cerebral vessels. At low pressures CBF begins to fall, with continued decreases leading to ischemia and ultimately brain death.[80,89-91] Importantly, normal cerebral autoregulation can be impaired in the setting of disease. Traumatic brain injury, subarachnoid hemorrhage, and stroke, for example, all can abolish or impair the normal autoregulatory response.[92-95]

Although the brain's ability to autoregulate flow is well established, the mechanisms underlying it are not completely understood.[91] A myogenic response appears to be especially

important in the setting of raised CPP. Large- and medium-sized cerebral arteries, including the ICA, have been shown to constrict both in vitro and in vivo in response to elevated transmural pressures. While small arteries and arterioles primarily modulate cerebral resistance during normotension, at higher pressures (greater than 110 mm Hg), the large cranial vessels dominate. Thus at high perfusion pressures, smaller more delicate vessels are protected by changes in upstream resistance.[91,96]

In marked contrast to other vascular beds, neural stimuli have relatively little effect on basal CBF. Cerebral vessels display extensive perivascular innervation, especially by the sympathetic nerves arising from the superior cervical sympathetic ganglia, but the brain is well protected from circulating catecholamines by the BBB. Thus many of the vasoactive agents used in the critical care setting (α- and β-adrenergic agonists) have minimal effects on resting cerebral vascular tone. Mild to moderate electrical stimulation, as well as surgical resection of both the sympathetic and parasympathetic nervous system, does not alter cerebral vascular tone under resting conditions. However, vigorous sympathetic stimulation, as would occur with strenuous exercise or hypertension, does result in vasoconstriction of large- and medium-sized cerebral vessels.[82] Thus while a neurogenic mechanism may not mediate cerebral vascular resistance under normal conditions, it does provide protection during times of stress.[96-98] Indeed, patients with chronic hypertension have been shown to have a rightward shift of the autoregulatory curve.[82,91]

With the advent of sophisticated methods of detecting and measuring CBF, such as radioactive xenon, positron emission tomography scanning, and functional magnetic resonance imaging (MRI), intracerebral regional circulatory variations could be mapped and were found to correlate with local central nervous system activation.[84,99,100] Blood flow to the occipital cortex increases with visual stimulation.[101] Motor activity augments flow to the motor strip and speech enhances flow to Broca's area.[102,103] CBF decreases during deep sleep but returns to normal awake levels during rapid eye movement sleep.[104]

As in other vascular beds, it appears that CBF is linked or "coupled" to changes in metabolism.[105-107] For example, hypothermia decreases the cerebral metabolic rate of oxygen , and therefore CBF, in both animal and human studies.[108-111] Seizure activity and fever both increase the cerebral metabolic rate of oxygen and CBF, which explains the deleterious consequences of both conditions for patients with raised ICP.[112] The mechanisms underlying this coupling of blood flow and metabolism are still unclear. A number of substances have been shown to affect cerebrovascular tone, including carbon dioxide, oxygen, hydrogen ions, lactic acid, histamine, potassium ions, prostaglandin, ET-1, NO, and adenosine.[80,82]

Carbon dioxide plays a critical role in the regulation of CBF. In fact, a linear increase in CBF is seen with increasing $Paco_2$, making CO_2 one of the most potent known cerebral vasodilators.[113,114] Carbon dioxide exerts its effect via a reduction of the perivascular pH. Whereas arterial H^+ cannot cross the BBB, CO_2 can easily diffuse into the brain. Carbonic anhydrase facilitates the reaction between CO_2 and H_2O, forming carbonic acid with subsequent dissociation producing H^+ ions. Perivascular acidosis dilates the cerebral vasculature, while alkalosis leads to vasoconstriction.[115,116] In this way the cerebral vasculature is distinct in that respiratory acidosis and alkalosis alter tone and CBF, while metabolic acidosis and alkalosis do not.[114,117] Interestingly, abnormal CO_2 reactivity has been associated with several disease processes, including traumatic brain injury, subarachnoid hemorrhage, stroke, carotid stenosis, and congestive heart failure.[92-94] Indeed, abnormal CO_2 vasoreactivity has been used as a means to prognosticate in some disease states.[94,95]

Several studies have demonstrated that the cerebral vasculature adapts in the setting of chronically elevated $Paco_2$, with changes in the pH of the brain extracellular fluid.[118] This finding has obvious implications for the clinician attempting to treat raised ICP with chronic hyperventilation.

Arterial oxygen tension (Pao_2) also participates in the regulation of CBF. Arterial hypoxia dilates cerebral vessels at Pao_2 below 40 to 50 mm Hg (Figure 20-12).[113] The relation between CBF and arterial oxygen content is almost linear, and cerebral oxygen delivery can be maintained unless arterial oxygen content falls below 4 vol%. Hyperoxia does not appear to be a very potent stimulus for vasoconstriction, however.[113,119] Hypoxic vasodilation is not limited to the cerebral circulation. Efforts to fully elucidate this phenomenon continue, but it is known that adenosine and both $Ca2^+$-activated and ATP-activated potassium channels are particularly important. Adenosine, which leads to vasodilation through an increase in cyclic adenylate monophosphate, has been found to increase more than fivefold with hypoxia.[120-123] Adenosine also is critical in autoregulation, with experimental data revealing a sixfold rise in brain adenosine levels as mean arterial pressure falls from 135 mm Hg to 45 mm Hg.[124]

A large body of evidence, both in animals and humans, implicates NO in a number of important processes within the cerebral circulation.[119,125-130] Nitric oxide antagonists have been shown to mitigate the normal increase in CBF brought on by neuronal activation.[127,131,132] Multiple lines of evidence suggest that NO has a role in the maintenance of basal cerebrovascular tone.[133] Exogenously administered inhibitors of

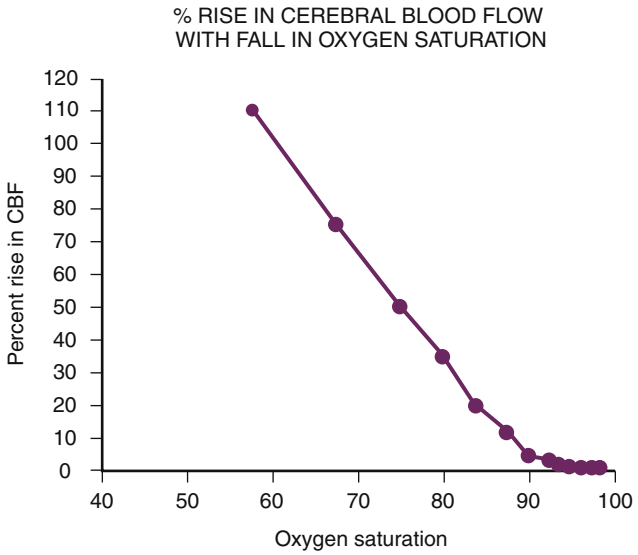

Figure 20–12. Arterial hypoxia dilates cerebral vessels and maintains cerebral oxygen delivery. *CBF,* Cerebral blood flow. *(Modified from Fuhrman BP: Regional circulation. In Fuhrman BP, Shoemaker WC, editors:* Critical care: state of the art, vol 10, *Fullerton, CA, 1989, Society of Critical Care Medicine.)*

nitric oxide synthetase (NOS) constrict cerebral vessels and decrease CBF in the basal state of several species, including humans.[132,134-137] Interestingly, asymmetric dimethylarginine, an endogenous and potent inhibitor of NOS that has been implicated in a number of vascular disorders, is produced in the brain, but its precise role in regulating CBF has not yet been clarified.[138,139] Vascular reactivity to CO_2 also is strongly influenced by NO.[140] One human study found decreased major coronary artery flow in response to hypercapnia following NOS inhibition.[119] Similar results have since been confirmed by others and have been documented in animal work as well.[126,136,140] CO_2 reactivity is not completely ablated, however, suggesting that other factors also contribute. Further, in a neuronal-NOS-knockout mouse model, CO_2 reactivity remained intact, again suggesting redundant systems underlying the response.[140-142] Clinically, it is noteworthy that nitroprusside and other NO donor compounds can dilate cerebral vessels.[143] This process greatly complicates the management of hypertension in patients with increased ICP. In that setting, nitroprusside, for example, may reduce arterial pressure but raise CBF and blood volume, thereby causing herniation to occur.

Vasodilation in response to acetylcholine, oxytocin, substance P, histamine, ET-1, adenosine diphosphate, ATP, and prostaglandin have all been shown to be NO dependent.[35] In some studies NOS inhibition was found to blunt the increase in blood flow in response to hypoxia.[125] A role for NO in other disease states also has been demonstrated recently. Treatment with L-arginine, the substrate for NOS, and tetrahydrobiopterin, an important cofactor for NOS, reverse impaired endothelial function caused by acute hypertension, hypercholesterolemia, and atherosclerosis.[144-146] In addition, impaired NO signaling is important in the pathophysiology of subarachnoid hemorrhage in which endothelial dysfunction has been well documented. Dysfunctional NO signaling may be an important cause of vasospasm in that setting. A number of mechanisms have been proposed, including decreased endothelial NOS activity, alterations in soluble guanylate cyclase activation and cGMP production, inactivation of NO by hemoglobin, and increased superoxide anion production.[147-151] Furthermore, alterations in vascular tone in response to shear force are mediated, at least in part, by NO.[35]

Prostacyclin, a metabolite of arachidonic acid, is another important dilator of the cerebral vasculature. The cyclooxygenase enzymes COX-1 and COX-2 both appear to be involved in basal cerebral vascular tone and in the vasodilation associated with various stimuli, such as inflammation and hypoxia, depending on the species investigated.[35,81,82]

ET-1 is another important mediator of cerebrovascular tone.[152] Both ET_A and ET_B receptors have been identified in the cerebral vasculature.[153] When given in high concentrations, ET-1 constricts cerebral vessels, probably via ET_A receptor activation.[154] In low concentrations, however, ET-1 relaxes cerebral vessels via endothelial cell ET_B receptor activation, a response that is NO dependent. Sarafotoxin 6c (a selective ET_B agonist) causes cerebral vasodilation.[153] However, ET_A and combined receptor antagonists do not alter basal cerebrovascular tone.[35] Recently, ET-1 has been identified as an important mediator of vasospasm following subarachnoid hemorrhage.[154,155] ET-1 levels are increased following subarachnoid hemorrhage. Associated with this increase, ET_A receptor levels, smooth muscle cell ET_B receptor levels (which mediate vasoconstriction), and endothelin-converting enzyme activity are increased.[156] The potential clinical use of endothelial receptor antagonists following subarachnoid hemorrhage is under investigation, with promising preliminary results.[21]

Reactive oxygen species, especially superoxide, have been shown to participate in the regulation of cerebral vascular tone. Production of superoxide anion has been associated with acute hypertension, seizures, head injury, meningitis, and cerebral ischemia.[157-161]

Coronary Circulation

Right and left coronary arteries arise from sinuses of Valsalva and course over the surface of the heart. Nutrient branches penetrate the myocardium to supply both superficial (epicardial) and deep (subendocardial) layers of the muscle. Venous blood drains primarily to the coronary sinus, although some returns by way of anterior coronary veins to the right atrium or via sinusoids directly to the ventricles.

Myocardial workload (which sets myocardial oxygen demand) is determined not only by the needs of the heart but by the demands of the body as well. Furthermore, the heart is required to generate its own perfusion pressure. Accordingly, regulation of myocardial perfusion is tailored to match regional myocardial oxygen supply to demand over the widest possible range of cardiac workload and under conditions fashioned not so much for maximal cardiac efficiency but rather for benefit of the body.

Normally over a cardiac cycle myocardial perfusion is approximately the same per gram of tissue in the outer (subepicardial), mid, and inner (subendocardial) layers of the left ventricle, but the dynamics during the cardiac cycle are complicated.[11] At the end of diastole, when the ventricle is relaxed and tissue pressures are probably under 10 mm Hg in any layer of the left ventricle, pressures in the intramural arteries are probably similar to each other and to aortic pressure. At the beginning of systole, tissue pressure rises to equal intracavitary pressure in the subendocardium but then falls off linearly across the wall to about 10 mm Hg in the subepicardium.[162] These pressures are for an instant added to those inside the vessels because the vessels walls are not rigid, and as a result, intravascular pressures in subendocardial arteries exceed aortic pressures, but aortic pressures are higher than pressures in subepicardial arteries.[163] These pressure gradients and the greater shortening of subendocardial versus subepicardial muscle fibers during systole compress the subendocardial vessels and squeeze blood out of them both forward into the coronary sinus and backward toward the epicardium.[164-166] In fact, narrowing of the subendocardial vessels facilitates thickening and shortening of the myocytes.[167] This backflow enters the subepicardial arteries to supply their systolic flow.[163] In systole, some forward flow does indeed occur into the orifices of the coronary arteries but does not perfuse the myocardium; it merely fills the extramyocardial arteries.[11,163,168] In fact, often reverse flow occurs in the epicardial coronary arteries.[169] In early diastole, blood flows first into the subepicardial vessels that have not been compressed but takes longer to refill the narrowed subendocardial vessels. Given enough time and perfusing pressure, all the myocardium will be perfused, but if diastole is too short or perfusion pressure is too low, subendocardial ischemia occurs. Right ventricular myocardium, on the other hand,

normally is perfused both in systole and in diastole (Figure 20-13) because of lower tissue pressures.[170,171] We would expect perfusion of the hypertrophied right ventricle of a persons with severe pulmonic stenosis or tetralogy of Fallot to resemble that of the left ventricle.[172]

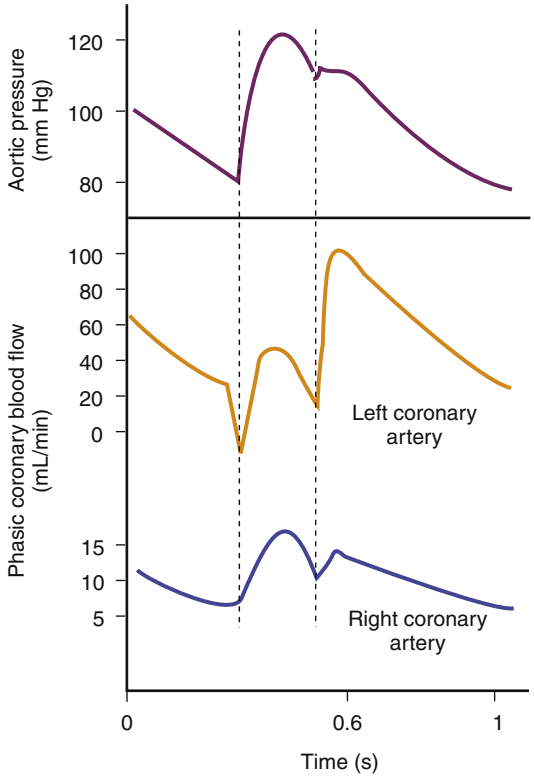

Figure 20–13. Myocardial blood flow is modulated by ventricular wall tension. Most of the perfusion of the left ventricular myocardium occurs in diastole. *(Modified from Berne RM, Levy MN:* Cardiovascular physiology, *ed 7, St Louis, 1997, Mosby.)*

Myocardial Oxygen Demand-Supply Relationship

The left ventricle extracts most of the oxygen from the blood passing through the myocardium; coronary sinus oxygen saturation is normally about 30%. Therefore increases in myocardial oxygen demand have to be met by increases in myocardial blood flow. At rest, left ventricular myocardial blood flow is about 80 to 100 mL/100 g/min, and with maximal exertion, left ventricular oxygen consumption increases about fourfold, as does left ventricular blood flow in normal people and animals.[173] If coronary perfusion pressure does not change during exertion, the increased flow has to be achieved by a decrease in coronary vascular resistance; the response is termed *metabolic regulation*.

Coronary vascular resistance has three components: a basal low resistance in the arrested heart with maximally dilated vessels, an added resistance when vessels have tone, and a phasic resistance added whenever the ventricle contracts.[174,175] In the beating heart with vessels maximally dilated by a pharmacologic dilator, the second of these resistances is absent. Perfusion of the left ventricular myocardium then produces a steep pressure-flow relation that is linear at higher flows but usually curvilinear at low pressures and flows (Figure 20-14, *A*). Because the vessels are maximally dilated, flow is uncoupled from metabolism and depends only on driving pressure and resistance. If heart rate is increased, maximal flow at any perfusion pressure decreases because the heart is in a relaxed state for a smaller proportion of each minute.

If tone is allowed to return to the coronary vessels, then the pressure-flow relationship can be assessed at different perfusion pressures after cannulating the left coronary artery. It is necessary to do this because when cardiac metabolism and blood flow are coupled, increasing aortic blood pressure will increase coronary flow not only by increasing perfusion pressure but also by increasing myocardial oxygen demand. Under normal conditions coronary blood flow is autoregulated, such

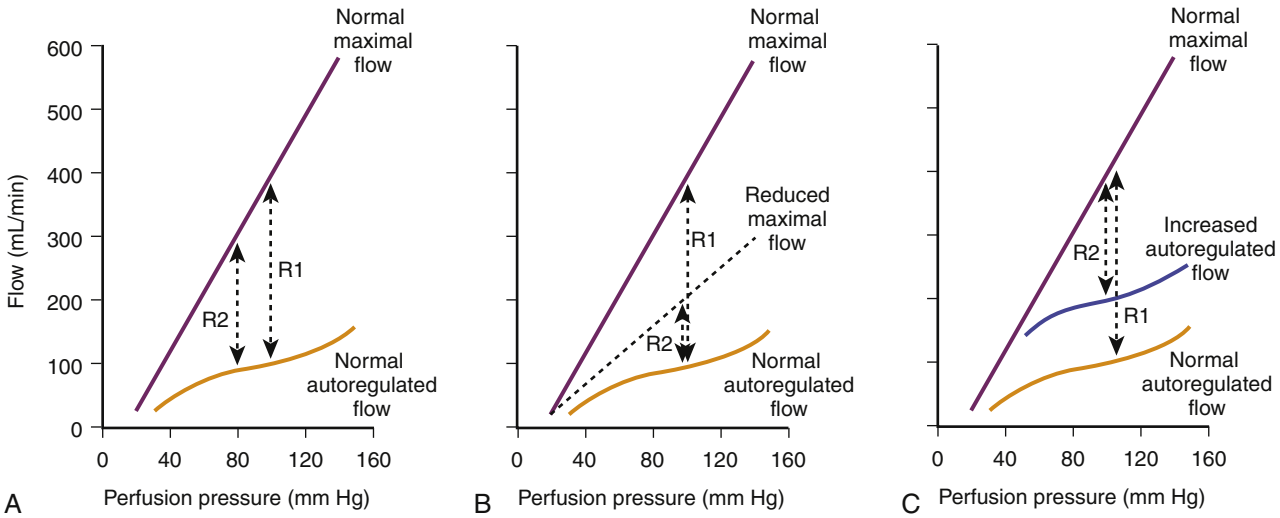

Figure 20–14. **A,** Normal pressure-flow relations in the left coronary artery during normal autoregulated flow and during maximal vasodilation. Values are appropriate for a left ventricle weighing approximately 100 g. *R1, R2,* Coronary flow reserve measurements at two different coronary perfusing pressures. **B,** Effect on coronary flow reserve of a reduced maximal flow. At the same coronary perfusing pressure, flow reserve is reduced from the normal R1 to R2. **C,** Effect on coronary flow reserve of an increased autoregulated flow. Reserve is reduced from R1 to R2.

that if perfusion pressure is raised or lowered from its normal value, there is a range over which almost no change in flow occurs; a rise in pressure has caused vasoconstriction, and a fall in pressure has caused vasodilatation.[176] At perfusion pressures above some upper limit, flow increases, probably because the pressure overcomes the constriction. More importantly, at pressures below about 40 mm Hg (but varying, as discussed later), flow decreases predominantly in the deep subendocardial muscle (see Fig. 20-14, *A*), indicating that some vessels have reached maximal vasodilatation and can no longer decrease resistance to compensate for the decreased perfusion pressure. In these vessels, flow and pressure are directly related. If this pressure dependency occurs, then further decrease in perfusion pressure decreases local blood flow below the required amount, or if myocardial oxygen demands increase at the same low perfusion pressure (as will occur if the ventricle becomes dilated), the requisite increase in flow will not occur. These two conditions cause subendocardial ischemia.

At any given pressure, the difference between autoregulated and maximal flows is termed *coronary flow reserve*.[177-179] (Coronary flow reserve can be measured in units of mL/min, but also can be assessed by a dimensionless flow reserve ratio derived by dividing maximal flow by resting flow.) Flow reserve depends on perfusion pressure because of the steepness of the pressure-flow relation in maximally dilated vessels. Coronary flow reserve indicates how much extra flow the myocardium can get at a given pressure to meet increased demands for oxygen; if reserve is much reduced, then flow cannot increase sufficiently to meet demands and myocardial ischemia will occur. What the figure does not show is that coronary flow reserve is normally lower in the subendocardium than in the subepicardium and that decreases in coronary flow reserve are always more profound in the subendocardium than in the subepicardium.

If autoregulated flow is normal but maximal flow is decreased, as indicated by the decreased slope of the pressure-flow relation during maximal dilatation (Figure 20-14, *B*), then coronary flow reserve will be reduced. Such a change can occur with marked tachycardia; a decrease in the number of coronary vessels because of small vessel disease, as in some collagen vascular diseases, especially systemic lupus erythematosus; increased resistance to flow in one or more large coronary vessels because of embolism, thrombosis, atheroma, or spasm; impaired myocardial relaxation because of ischemia; myocardial edema; a marked increase in left ventricular diastolic pressure; marked increase in left ventricular systolic pressure if coronary perfusion pressure is not also increased, as in aortic stenosis or incompetence; and an increase in blood viscosity, most commonly seen with hematocrits greater than 65%.

Coronary flow reserve also can be reduced if maximal flows are normal but autoregulated flows increase (Figure 20-14, *C*). Increased myocardial flows above normal values can occur with exercise, tachycardia, anemia, carbon monoxide poisoning, leftward shift of the hemoglobin oxygen dissociation curve (as in infants with a high proportion of fetal hemoglobin), hypoxemia, thyrotoxicosis, acute ventricular dilatation (because of increased wall stress), inotropic stimulation by catecholamines, and acquired ventricular hypertrophy. Ventricular muscle mass increases without a concomitant increase in conducting coronary blood vessels if hypertrophy develops a few months after birth. Ventricular hypertrophy returns wall stress to normal, and myocardial flow per minute per gram of muscle is approximately normal. Therefore total left ventricular flow is increased in proportion to ventricular mass, but because maximal flow per ventricle is usually unchanged, the coronary flow reserve is diminished. Often autoregulated flow is increased and maximal flows are reduced at the same time, for example, with severe tachycardia or cyanotic heart disease with hypoxemia, ventricular hypertrophy, and polycythemia. Under these circumstances, coronary flow reserve can be drastically reduced. A third mechanism that reduces coronary flow reserve is a shift to the right of the pressure-flow line. If with maximally dilated vessels diastolic coronary flow is measured at different mean diastolic perfusion pressures, a pressure-flow line is obtained that is linear at higher pressures but curved in the low pressure-flow region.[180,181] Zero flow occurs at a pressure of about 8 to 12 mm Hg; this is the critical closing pressure that is above right atrial pressure.[182,183] The whole pressure-flow line can be shifted to the right by several factors, the most important of which are pericardial tamponade, a rise in right or left ventricular diastolic pressures, and α-adrenergic stimulation. Such a rightward shift decreases flow reserve. It is important to note that because the line of maximal pressure-flow relations slopes up and to the right, any decrease in that slope (Figure 20-14, *B*), any increase in autoregulated flow (Figure 20-14, *C*), or any rightward shift of the slope raises the pressure at which autoregulation fails to compensate for decreased perfusing pressure. It also is important to reemphasize that any decrease in coronary flow reserve affects the subendocardium predominantly, so that autoregulation will fail first and ischemia will occur in the subendocardium before these changes occur in the subepicardium.[184] The predominant reduction in subendocardial flow and reserve is particularly marked when left ventricular diastolic pressure is very high.

The interactions between myocardial blood flow and ventricular function are of particular importance when ventricular hypertrophy is present. Myocardial wall stress is regulated within a fairly narrow range, with or without myocardial hypertrophy. Consequently, myocardial blood flow per unit mass is fairly constant at about 1 mL/min/g of the left ventricle at rest.[185-190] Strauer and colleagues[186,188,191,192] have shown a close relationship between peak wall stress in systole and the ratio of left ventricular mass to volume. If no hypertrophy is present, coronary flow reserve is normal, but it is reduced if the left ventricular mass is increased. Should the heart dilate acutely, then the mass-to-volume ratio decreases, wall stress and myocardial oxygen consumption increase, and coronary flow reserve falls. If ventricular dilatation is marked, subendocardial ischemia can be present. Decreasing ventricular dilatation by afterload and preload reduction reverses these unfavorable events and is another reason for the resulting improvement in ventricular function.

Right ventricular myocardial blood flow follows the general principles regarding coronary blood flow, but differences exist that are related to the low right ventricular systolic pressure and the fact that alterations in aortic pressure change coronary perfusing pressure without altering right ventricular pressure work. If the normal right ventricle is acutely distended, for example, by pulmonary embolism, right ventricular failure eventually occurs; the increased wall stress increases its oxygen consumption, but the raised systolic pressure reduces the

coronary flow, so that when supply cannot match demand, right ventricular myocardial ischemia occurs.[193] Raising aortic perfusing pressure mechanically or with α-adrenergic agonists increases right ventricular myocardial blood flow, relieves ischemia, and restores right ventricular function to normal. Improved coronary flow is not the only mechanism of this improvement; the increased left ventricular afterload moves the ventricular septum toward the right ventricle and improves left ventricular performance.[194] If right ventricular pressure is chronically elevated so that right ventricular hypertrophy occurs, as in persons with pulmonic stenosis, many forms of cyanotic congenital heart disease, and some chronic lung diseases, then right ventricular myocardial blood flow behaves in the same way as left ventricular blood flow, with one exception.[195-197] If aortic pressure is lowered, left ventricular pressure also decreases, as does left ventricular work and oxygen consumption. In the right ventricle, however, the workload may not be reduced (if there is no ventricular septal defect), and thus an imbalance between myocardial oxygen supply and demand may occur. The worst imbalance occurs when aortic systolic pressure is maintained but coronary perfusing pressure decreases, which can occur in a child with tetralogy of Fallot who has too large an aortopulmonary anastomosis. The high aortic and left ventricular systolic pressures mandate an equally high right ventricular systolic pressure, but the low diastolic aortic pressure reduces coronary perfusion pressure in diastole and can cause both left and right ventricular ischemia and failure.[198]

Gastrointestinal Circulation

The maintenance of adequate splanchnic blood flow in critically ill patients is important. In a globally compromised circulation, the gastrointestinal system is particularly prone to injury, impairing its two chief functions: the digestion and absorption of nutrients and the maintenance of a barrier to the translocation of enteric antigens.[199-204] Moreover, splanchnic ischemia has been associated with multiple organ failure and an increased incidence of morbidity and mortality in these patients.[205-208]

The three major arteries supplying blood to the gastrointestinal circulation arise directly from the aorta. The celiac artery supplies blood to the stomach, liver, and spleen. The superior mesenteric artery supplies the small intestine, the pancreas, and the proximal colon, while the inferior mesenteric artery supplies the remaining middle and distal colon. There is extensive collateral blood flow.[83] Total flow accounts for 20% to 25% of the cardiac output in the resting unfed state.[209]

The gastrointestinal circulation has multiple levels of regulation that can be broadly divided into intrinsic and extrinsic mechanisms. Intrinsic mechanisms include local metabolic processes, locally produced vasoactive substances, and myogenic reflexes. Extrinsic factors include circulating vasoactive substances, neural innervation, and general hemodynamic forces.[209-211] Neural input arising from the medulla oblongata through preganglionic fibers of the intermediolateral area of the spinal cord participates in the regulation of large blood vessels (>50 μm), largely through sympathetic α-adrenergic control.[212,213] Blood flow to the intestinal circulation, like other vascular beds, is autoregulated such that oxygen delivery remains fairly constant, with inflow pressures varying from 30 to 120 mm Hg.[211,214-216] Oxygen, carbon dioxide, H^+ ions, and adenosine are important local metabolic mediators of this process.[217-223] Other important vasoactive mediators of intestinal blood flow include serotonin, histamine, bradykinin, and prostaglandin, although their role in autoregulation is unclear.[224-228] Finally, various gastrointestinal hormones and peptides released from the intestinal mucosa and intestinal glands including gastrin, vasoactive intestinal polypeptide, cholecystokinin, secretin, glucagon, enkephalins, somatostatin, and kallidin are known to have vasoactive properties.[209,229]

A phenomenon unique to the gastrointestinal circulation is the increase in flow following the consumption of nutrients.[230] This postprandial intestinal hyperemia appears to involve multiple factors. However, the composition of the chyme is particularly important.[231] In fact, luminal distention, mechanical stimulation, and extrinsic neural stimulation are not necessary for the response to occur.[209,232-234] Lipids in combination with bile salts are the most potent triggers for postprandial hyperemia.[235-237] Glucose is the most potent single stimulus for this response.[238] Blood flow to skin and skeletal muscle decreases and cardiac output increases during postprandial hyperemia.[230] Furthermore, nutrients that induce the largest increase in blood flow elicit the largest oxygen debt within the intestinal villi.[239-244]

Interestingly, this postprandial hyperemia may be protective in some instances of low blood flow to the intestinal mucosa. Glucose has been shown to ameliorate mucosal ischemia in models of septic and hemorrhagic shock, and early enteral feeding has been advocated in human studies as well.[245-247] Conversely, enteral feeding also has been associated with bowel ischemia and injury in some patients, such as premature infants, thus complicating decisions around enteral feeding during or following low-flow states.[248-250]

Increasing data demonstrate a large role for NO in the regulation of gastrointestinal blood flow. Endothelial NOS is expressed throughout the gastrointestinal vasculature, including the liver and pancreas.[251] A number of stimuli such as shear stress, adenosine, bradykinin, and serotonin activate endothelial NOS production of NO.[252] NO, at least in part, mediates basal mesenteric and hepatic blood flow. Inhibitors of NOS decrease splanchnic blood flow and increase hepatic pressure.[253,254] Indeed, a number of studies implicate endothelial dysfunction—and aberrations in nitric oxide signaling in particular—in portal hypertension and cirrhosis.[255-257] NO also participates in the maintenance of the mucosal barrier function and is further protective by virtue of its inhibitory effect on platelet and leukocyte adhesion.[258] Furthermore, postprandial hyperemia has been shown to involve adenosine-mediated NO release.[259,260] Finally, neuronal nitric oxide synthase and inducible nitric oxide synthase are important in both normal and abnormal gastrointestinal motility and gastrointestinal inflammatory disorders, respectively.[261-266]

While NO is integral to gastrointestinal health and disease, therapies for gastrointestinal disorders that utilize the NO signaling cascade are sparse. Inhibition and potentiation of NOS activity have been studied for the treatment of portal hypertension with mixed results.[258,267,268] NO donor agents have been investigated as therapy for diseases with impaired mucosal barrier function, such as gastric ulcerative disease. These therapies also have had limited success.[269,270]

ET-1 is another important mediator of intestinal blood flow. The intestinal vasculature displays increased vasoconstriction in response to ET-1 compared with other vascular beds.[271-273]

This finding has particular importance for gastrointestinal blood flow in critically ill patients because ET-1 levels have been found to be elevated following surgery and in association with a number of disease states, including hypoxia, pancreatitis, and sepsis.[274-280] Endothelial-receptor antagonism ameliorates ischemic injury to the bowel in several models of low-flow states.[281,282] Interestingly, as in the pulmonary circulation, developmental changes appear to occur in the activity of ET-1.[283] Infusion of ET-1, however, results in sustained vasoconstriction of intestinal vessels across age groups.[216]

Finally, it should be remembered that drugs used to augment systolic blood pressure and/or to enhance cardiac output could have various effects on the gastrointestinal circulation. Fenoldopam, a dopamine-1 receptor agonist, has been shown to improve intestinal perfusion during hemorrhage.[284] However, findings on more common agents such as norepinephrine, dopamine, and vasopressin have had mixed results depending on the doses used and the models or clinical situations studied.[285-289] Thus investigations continue to be aimed at determining the optimum strategy to improve overall cardiac output and oxygen delivery without compromising flow to specific organs, such as the bowel.

Renal Circulation

Blood flow to the kidneys greatly exceeds the metabolic needs of the organs themselves. In an adult weighing 70 kg, combined renal blood flow is approximately 1200 mL/min, accounting for more than 20% of the total cardiac output supplying organs that represent under 0.5% of total body weight.[290] This high renal blood flow is necessary to support glomerular filtration so that solute and fluid homeostasis can be maintained.

Blood is supplied to the kidneys by the renal arteries, which branch to form the interlobar, arcuate, and interlobular arteries. Interlobular arteries progress to form the afferent arterioles, which lead to the glomerular capillaries within the glomerulus, the site of fluid and solute filtration. The distal glomerular capillaries reform into the efferent arterioles, which then lead to a second capillary system, the peritubular capillaries. An elevated hydrostatic pressure within the glomerular capillaries supports filtration, whereas a much lower pressure within the peritubular capillary system supports absorption.[290] Alterations in the resistances of the afferent and efferent arterioles regulate these pressures and allow for dynamic changes in renal function in response to overall fluid and solute needs.[291] The venous system branches in a fashion similar to the arterial supply, and blood eventually enters the inferior vena cava from the renal veins.

Renal blood flow is proportional to the difference between renal artery pressure (which is generally equivalent to systemic arterial pressure) and renal vein pressure, and it is inversely proportional to the renal vascular resistance. In general, three vascular segments make up the renal vascular resistance: the interlobular arteries, afferent arterioles, and efferent arterioles.[292-294] Regulation of renal vascular resistance can be broadly divided into extrinsic mechanisms and intrinsic mechanisms. Extrinsic mechanisms, which include the sympathoadrenal system, atrial natriuretic system, and renin-angiotensin-aldosterone axis, modulate renal blood flow by alterations in intrarenal vascular tone, mesangial tone, intravascular volume, and systemic vascular resistance.[290] Intrinsic mechanisms, which primarily alter afferent arteriolar resistance, are responsible for the autoregulation of renal blood flow in response to changes in renal perfusion pressure.[295]

The juxtaglomerular apparatus, which is comprised of the afferent and efferent arterioles, the macula densa, and the glomerular mesangium, is an important site in the regulation of renal perfusion and glomerular filtration. Glomerular filtration is largely a function of glomerular filtration pressure, which in turn is dependent upon renal perfusion pressure and, importantly, the balance between afferent arteriolar and efferent arteriolar tone. Increased efferent arteriolar tone increases glomerular filtration by increasing glomerular pressure, whereas increased afferent arteriolar tone has the opposite effect.

Endogenous epinephrine and norepinephrine derived from sympathetic neural input has various effects on renal perfusion and glomerular filtration. Mild sympathetic output preferentially constricts the efferent arterioles, thereby increasing glomerular pressure and filtration.[296] However, intense sympathetic discharge results in afferent arteriolar constriction, which decreases glomerular filtration.[297] Furthermore, sympathetic stimulation of afferent arterioles results in renin release, which leads to increased sodium reabsorption and fluid retention. Sympathetic stimulation can affect renal blood flow more generally by alterations in systemic arterial pressure. Clinically, norepinephrine has been shown to increase renal perfusion and renal function (measured by changes in creatinine clearance) in patients with septic shock.[298]

Angiotensin II, produced by cleavage of angiotensin I by the enzyme angiotensin-converting enzyme, also has important effects on renal perfusion. Like catecholamine stimulation, the effects of angiotensin II are dose related. At low levels, angiotensin II results in efferent arteriolar constriction, whereas at high levels both the afferent and efferent arterioles are constricted.[296,299] Angiotensin II alters renal blood flow further by alterations in intravascular volume through aldosterone and arginine vasopressin and by increasing systemic vascular resistance.

Arginine vasopressin (AVP) is synthesized in the anterior hypothalamus and released from the posterior pituitary gland. It plays a critical role in maintaining serum osmolality within a narrow range. Both V_1 and V_2 receptors have been identified.[300,301] V_2 receptors are located on the renal collecting ducts, and stimulation results in increased reabsorption of water.[302,303] Activation of V_1 receptors on systemic vessels results in vasoconstriction. Interestingly, V_1 receptor activation in the pulmonary vasculature results in vasodilation, at least in part via NO production.[304] Triggers for AVP release include changes in serum osmolality, hypovolemia, and hypotension. Patients with septic shock have been shown to have decreased levels of AVP, which has led to the use of AVP supplementation clinically.[305] Unlike catecholamines and angiotensin II, high levels of AVP appear to preferentially constrict efferent arterioles, which preserves glomerular filtration.[306]

ET-1 has diverse effects on the kidney.[307] In general, endothelin results in vasoconstriction, decreased renal perfusion, and decreased glomerular filtration. ET-1 constricts both the afferent and efferent arterioles.[308] ET-1 also has been shown to stimulate cell proliferation within the kidney. Conversely, ET-1 also may promote natriuresis through ET_B-receptor activation.[309] Furthermore, alterations in ET-1 signaling have been implicated in a host of renal diseases, including acute and chronic renal failure, essential hypertension, glomerulonephritis, renal fibrosis, and renal transplant rejection.[307,310-315]

Important vasodilators within the renal circulation include prostaglandins and atrial natriuretic peptide (ANP). The vasodilating prostaglandins (D_2, E_2, and I_2) are synthesized from arachidonic acid by the enzyme phospholipase A_2.[316-318] Most of the important vasoconstricting factors, such as catecholamines, angiotensin II, and AVP, stimulate the release of prostaglandins, promoting increased renal perfusion and glomerular filtration.[319] ANP is produced within the atrial myocytes and is released in response to increased atrial stretch. Through cGMP signaling, ANP results in afferent arteriolar dilation and increased renal perfusion and glomerular filtration. ANP also antagonizes the actions of endogenous catecholamines, angiotensin II, and AVP.

Like other organ systems, renal blood flow is autoregulated via mechanisms intrinsic to the renal vasculature.[290] Early studies demonstrate that renal blood flow and glomerular filtration remain constant at renal artery perfusion pressures of between 80 and 180 mm Hg.[295,320] Importantly, urinary flow rate is not constant within the autoregulatory range, but rather changes as a function of renal perfusion pressure. The precise mechanisms underpinning this autoregulation are unclear. However, recent evidence indicates that the mechanisms are likely complex, involving interactions between tubuloglomerular feedback and myogenic processes that protect the kidney from damage in the setting of hypertension and also regulate renal function.[321-323]

An increasing amount of data suggest that NO plays an important role in normal renal function and that alterations in NO signaling may mediate renal pathophysiology.[324-328] Techniques that utilize intrarenal NO antagonism decrease renal blood flow and increase systemic arterial pressure. Intramedullary administration of NO inhibitors increases afferent arteriolar tone with lesser effects on the efferent arterioles.[324] Various experiments demonstrate that NO signaling modulates angiotensin II–mediated vasoconstriction. Furthermore, NO appears to modulate salt and water reabsorption within the nephron independent of changes in glomerular filtration or renal blood flow.[326] Chronic NO antagonism was found to increase systemic arterial pressure, decrease medullary blood flow, and result in a positive sodium balance. The administration of L-arginine, the substrate for NO production, has been shown to abrogate the development of hypertension to salt in salt-sensitive rats and to decrease blood pressure in spontaneously hypertensive rats.[325,328]

Reactive oxygen species also participate in the regulation of renal blood flow, largely by altering the bioavailability of NO.[329,330] Superoxide dismutase attenuates the development of hypertension in spontaneously hypertensive rats.[330-332] Furthermore, superoxide dismutase diminishes angiotensin II–induced vasoconstriction and increases renal medullary blood flow.[330,333]

A number of disease states that affect critically ill patients result in the loss of renal autoregulation. Acute tubular necrosis, septic shock, hepatic failure, and cardiopulmonary bypass all have been associated with renal dysfunction and a loss of renal autoregulation.[334-337]

Conflicting Needs of Regional Circulations

Individual regional circulations respond to threats to homeostasis both independently and in concert. This response is natural because individual organs have their own separate needs. Yet each region also has a responsibility to the body as a whole. At times individual need and responsibility conflict. Life-threatening illness accentuates these "conflicts of interest." An example follows.

Pulmonary vascular resistance is pathologically elevated in persistent pulmonary hypertension of the newborn and idiopathic pulmonary hypertension and in certain patients with congenital cardiac disease, chronic pulmonary disease, or acquired cardiac disease. This problem is often managed acutely by hyperventilation, which is easily induced and requires no sodium or osmotic load. However, hypocarbic alkalosis is a vasoconstrictor in brain and myocardium, while metabolic alkalosis has little acute effect on cerebral circulation. A good understanding of the regulation of regional circulations is necessary to adequately arbitrate this conflict. The treatment of elevated pulmonary vascular resistance following caval-pulmonary anastomosis for single ventricle physiology is an excellent example of this conflict. In this postoperative setting, mild elevations of pulmonary vascular resistance may decrease pulmonary blood flow and venous return. With this anatomy, pulmonary blood flow is dependent upon superior vena cava venous return. If hyperventilation is utilized to decrease pulmonary vascular resistance, hypocarbic alkalosis decreases CBF and subsequent superior vena cava return. This process may result in a net decrease in pulmonary blood flow and desaturation.

Another example occurs in the daily treatment of persons with an acute lung injury. The lung is responsible for gas exchange for the entire body. When it fails or becomes frankly inefficient as a result of disease, other organs may be subjected to hypoxia, hypercarbia, and acidosis. Positive pressure ventilation may be essential to life. Yet mechanical ventilation can impede cardiac output (see Chapter 26), and increasing ventilator pressures with high inspired oxygen concentrations may induce further lung injury. The need for positive pressure ventilation may impose a trade: good peripheral perfusion with desaturated blood for less perfusion, better arterial oxygen content, and lower risk of iatrogenic lung injury. Decisions based on optimal oxygen delivery are generally global. Bowel and brain vascular beds autoregulate to blood pressure, but cerebral vessels dilate to hypoxia, whereas mesenteric vessels constrict. The bowel might benefit from a different combination of P_{O_2}, cardiac output, and blood pressure than the brain, although any of several combinations of these parameters might be associated with the same net oxygen delivery.

It is possible that unsuccessful arbitration among regional circulations contributes to the genesis of the syndrome of multiple organ systems failure (see Chapter 104). An increasing understanding of the mechanisms that regulate regional microcirculatory blood flow will lead to new and improved treatments that optimize blood flow and allow the intensivist to successfully arbitrate the regional blood flow "conflict of interests" that will best serve the short- and long-term interests of the critically ill patient.

Chapter 21

Principles of Invasive Monitoring

Jeremy S. Hertzig, Jacqueline M. Evans, and Kenneth A. Schenkman

PEARLS

- Hemodynamic monitoring refers to measurement of the functional characteristics of the heart and the circulatory system that affect the perfusion of tissues with oxygenated blood.
- Hemodynamic monitoring can be performed invasively or noninvasively and can be used for diagnosis, surveillance, or titration of therapy.
- The central venous waveform is composed of three waves (a, c, and v) and two wave descents (x and y).
- The arterial waveform has three components: rapid upstroke, dicrotic notch, and runoff.
- Cardiac output can be calculated using the Fick method or measured directly via thermodilution.
- Continuous Svo_2 monitors can guide goal-directed therapy in patients who are in septic shock.
- A pulmonary artery catheter can be used to measure cardiac output and indices of oxygen delivery and extraction.

Role of Invasive Hemodynamic Monitoring

Since William Harvey's observation in the early 1600s that the heart pumps blood in a continuous circuit, the function of the circulatory system has been the subject of intense scrutiny. Hemodynamic monitoring refers to measurement of the functional characteristics of the heart and the circulatory system that affect the perfusion of tissues with oxygenated blood in order to maintain homeostasis and to remove byproducts of metabolism. Several different types of invasive hemodynamic monitoring can be used concurrently to guide management. The goal of hemodynamic monitoring is to provide more accurate diagnoses and to guide additional interventions to deliver improved care to the critically ill patient.

In his 1733 report "Statical essays: containing haemastaticks; or, an account of some hydraulick and hydrostatical experiments made on the blood and blood-vessels of animals," Hales[1] described early experiments in horses in which he was the first to measure central venous pressure (CVP). Figure 21-1 depicts Hales and an assistant in the process of these early experiments.

Clinical hemodynamic assessment at the bedside begins with noninvasive measurements such as heart rate (HR), blood pressure, urine output, and peripheral perfusion. Other noninvasive studies that may contribute to assessment of hemodynamic status include electrocardiograms, chest radiographs, and echocardiography. Frequently, in the pediatric intensive care unit (ICU) these measurements are supplemented by invasive hemodynamic measures that require entrance into the intravascular space. Such invasive hemodynamic measurements include placement of central venous catheters to assess right atrial filling pressures and to measure mixed venous oxygen saturation, arterial catheters to assess arterial blood pressure, and pulmonary artery catheters to assess left-sided pressures, cardiac output (CO), and vascular resistance. Although invasive hemodynamic monitoring can provide the skilled intensivist with a plethora of valuable information, it is not meant to take the place of or minimize the extensive amount of information that can be gained by less invasive techniques. Successful use of invasive hemodynamic measurements necessitates the requisite skills to obtain these measures safely and with utmost attention to the multiple potential risks imposed upon the patient. Furthermore, for invasive hemodynamic measurements to be useful, the clinician must be able to successfully interpret the information provided by the measurements. Finally, as with any technology, the use of invasive hemodynamic monitoring is in evolution, and it is incumbent upon the clinician to be familiar with developments as they arise and with current controversies regarding these procedures.

This chapter aims to be a practical guide to the use of hemodynamic monitoring in the pediatric ICU. The chapter reviews general principles of measurement and then discusses the three main types of invasive hemodynamic monitoring: central venous catheter, arterial catheter, and pulmonary artery catheter. It addresses the indications and controversies, sites of insertion, interpretation of waveforms, and potential complications. It also reviews CO monitoring and calculation of oxygen consumption and delivery. Chapter 15 discusses the specific techniques for gaining access in order to make these measurements.

Indications for Invasive Hemodynamic Measurements

The three main indications for invasive hemodynamic monitoring are diagnosis, surveillance, and titration of therapy. Diagnosis may include the differentiation of septic shock (through assessment of factors such as diminished right heart filling pressures or preload and decreased systemic vascular resistance) from cardiogenic shock (which is characterized

by elevated left heart pressures and afterload). Surveillance implies observation over time. The purpose of surveillance may be to assess the stability of a patient at risk for adverse changes or to determine the response to therapy. Invasive measurements performed for diagnostic purposes often are continued for surveillance purposes. Titration of therapy often is based on information gleaned from invasive measurements.

Principles of Measurement

Intensive care clinicians rely on a wide variety of measurement systems to assess patient clinical status and response to therapy. However, not all clinicians have a good understanding of how physiologic variables are measured, and some may not be able to troubleshoot monitoring systems or recognize when information obtained is inaccurate. A detailed discussion of monitoring is beyond the scope of this chapter, but a basic understanding of the principles of measurement is helpful in deciding which measurements to trust and how to assess a monitoring system for accuracy. Detailed descriptions of monitoring systems are provided elsewhere.[2-4]

Signal Analysis

Measurements generally are made directly by comparison with known standards or indirectly by use of a calibration system. Determination of length or weight usually is made by direct comparison with a standard ruler or standard mass. Most invasive measurements in the ICU are made indirectly, therefore requiring use of a calibration system. Thus understanding the basis for calibration of a system is important to determine the validity of the measurement.

Measurement systems detect and transform signals so that they can be presented in an interpretable way to the user. Signals can be characterized as static or dynamic. Slowly changing signals, such as body temperature, can be thought of as static. Hemodynamic measurements change from moment to moment and thus are dynamic. Physiologic signals may be periodic; for example, arterial pressure is periodic because it varies with the cardiac cycle.

Complex periodic signals, such as an arterial pressure waveform, can be described mathematically as the sum of a series of simpler waveforms called a Fourier series. Alternatively, the arterial tracing can be thought of as a sum of simpler waveforms, sine waves, and cosine waves. Figure 21-2 depicts an arterial pressure waveform as the sum of the first six terms in the Fourier series. The sum of the first six terms in the series forms a waveform similar to the original tracing. Adding additional terms from the Fourier series, or higher harmonics, results in an increasingly better representation of the actual

waveform. In general, to reproduce a pressure tracing without loss of significant characteristics for clinical use, the measurement system must have an accurate frequency response to approximately 10 times the fundamental frequency (first 10 harmonics).

The sampling rate of a measurement system determines how often a physiologic value is measured. For body temperature, sampling every few minutes might be sufficient, but for arterial pressure measurement, a higher rate is needed. This principle may seem obvious, but as an example of the importance of sampling rate, consider the number of points needed to define a circle. If we place three equidistant points on a circle, we describe a triangle, not a circle. Similarly, four points describe a square. If we increase the number of points (sampling rate), we can describe the circle more completely. For a sine wave, the minimum frequency of sampling needed to preserve the waveform is twice the frequency. This mathematical minimum is known as the Nyquist frequency.[2] For complex waveforms such as arterial pressure tracings, the sampling rate must be at least twice the highest frequency component in the waveform.

Measurement Systems

Hemodynamic monitoring in the clinical setting usually uses a fluid-coupled system where changes in pressure are transmitted via a column of (uncompressible) fluid in a (ideally incompressible) tube to a mechanical transducer. The mechanical transducer, usually a displaceable screen diaphragm, converts a change in pressure to an electrical signal, which can be processed and displayed. In laboratory settings, vascular pressures can be measured by a transducer at the point of interest rather than remotely as in the clinical setting. Measuring pressure at the point of interest—directly in the aorta, for example—decreases loss of signal integrity because of the measurement system. Most clinical pressure measuring systems have sufficient fidelity for clinical purposes. However, compliance, resistance, or impedance in the pressure tubing can result in damping or alteration of the recorded signal. The presence of bubbles in the fluid can further damp the recorded signal.

Errors in Measurement

The ideal measurement system determines the actual or "true" value for the measured variable. However, determination of a true value may be difficult. Every measurement system is subject to various errors. Errors in measurement can be classified as either systematic or random. Systematic errors occur in a predictable manner and are reproduced with repeated measures. Bias in a measurement system—for example, a baseline offset—results in a systematic error. Random errors are unpredictable and do not recur predictably with repeated measures.

Accuracy of a measurement is defined by the difference between the measured and true values, divided by the true value. Precision is defined by the reproducibility of the measurement; thus a more precise system yields more similar values for repeated measures under the same conditions than does a less precise system. Imprecision can be thought of as a representation of random errors, whereas bias can be thought of as a representation of systematic errors.

Calibration

Many measurement systems are linear, that is, based upon an assumption that the relationship between the inputs and outputs from a measurement device can be fitted to a straight line. This assumption allows a system to be calibrated under two conditions, with the rest of the values falling on the line defined by those two points. Actual nonlinearity of the system adversely affects the measurements.

Calibration is a process in which the reading, or output of a device, is adjusted to match a known input value. For example, an electronic pressure transducer may be calibrated against a mercury manometer. If the input to the device is zero, the output should be adjusted so that the reading also is set to zero. This "zeroing" reduces any baseline offset, thus reducing systematic errors in subsequent readings. The system then is calibrated to a nonzero value, for example, 100 mm Hg pressure, and the system gain is adjusted to read this value as well.

Frequency Response

The ability of a measurement system to accurately measure an oscillating signal, such as arterial blood pressure, is dependent upon the system's frequency response. The system can either overestimate or underestimate the true amplitude of a signal. If the system is overdamped, the value reported underestimates the amplitude, and waveform characteristics may be lost. Resonance in the system may result in overestimation of the amplitude. Measurement of arterial systolic pressure—the amplitude of the arterial waveform—may be inaccurate because of overdamping, and important waveform characteristics may be lost if the frequency response of the measurement system is poor. Figure 21-3 illustrates the effects of dampening on measurement of blood pressure.

Impedance

Impedance is the ratio of the change in blood flow along a vessel to the change in the pressure in the vessel. Impedance has both resistive and reactive components. In a pulsatile system such as the cardiovascular system, resistance alone does not fully describe the impediment or impedance to forward flow of blood. The caliber, length, and arrangement of the blood vessels and the mechanical properties of the blood determine resistance in the blood vessels. Reactance includes compliance of the vessels and inertia of the blood and thus is a dynamic component of impedance. This is important because the pulsatile nature of the cardiovascular system is dynamic.

When blood is propelled through a vessel at a branch point, a reflected pressure wave back toward the heart increases the impedance of the system. The major sites of wave reflection from vessel branching are from vessels approximately 1 mm in diameter.[3] Thus these small vessels contribute significantly to overall impedance. Figure 21-4 shows the relationships between pressure and flow velocity with distance along the length of the aorta. Because blood pressure increases with distance from the heart and flow velocity decreases with distance, the impedance increases toward the peripheral vasculature. Hemodynamic measuring systems are essentially physical extensions of the vascular system; thus the configuration and characteristics of the tubing and transducer system can alter the overall effect of impedance.

Invasive Techniques

Central Venous Pressure Catheters

Indications

Indications for CVP catheter placement in pediatric patients include assessment of right heart filling pressure (CVP), monitoring of large fluid shifts between the intravascular and the extravascular space, infusion of vasoactive substances, monitoring mixed venous oxygen saturation for goal directed therapy of sepsis, and infusion of hyperosmolar fluids and/or irritants.[5-7]

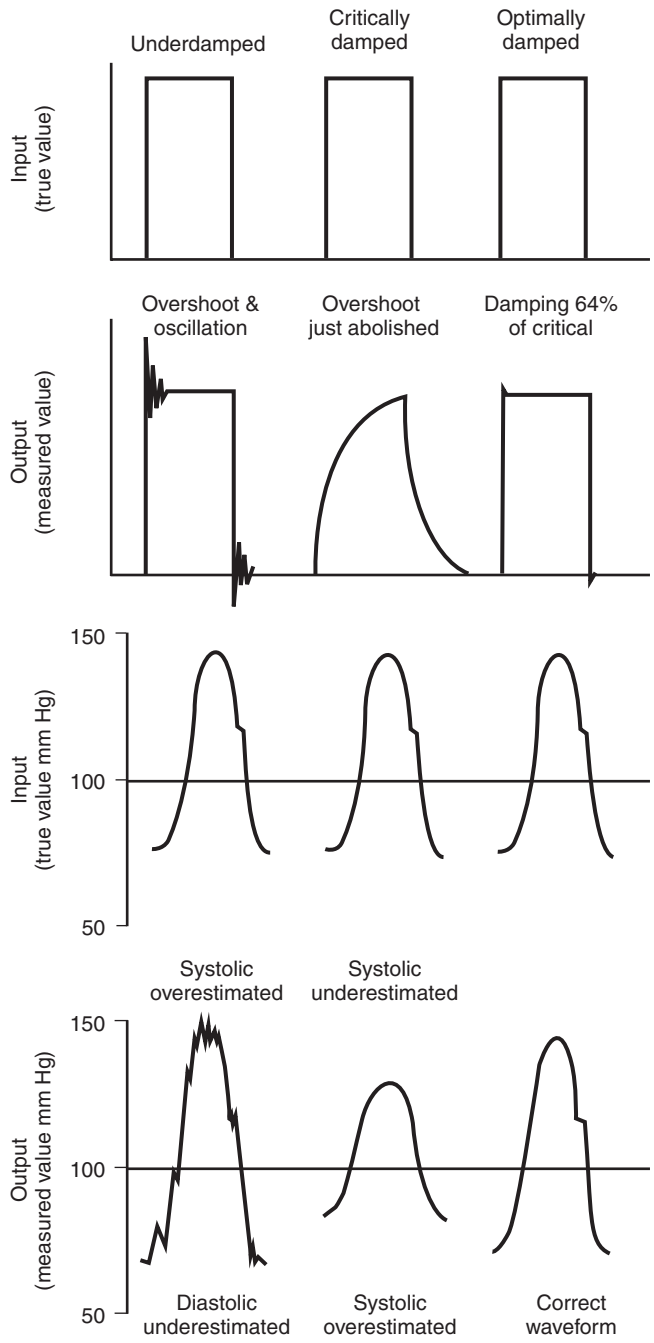

Figure 21–3. Effects of dampening on blood pressure measurement. **Upper two graphs** depict the response to a square-wave input from three different blood pressure transducers with different dampening. **Lower two graphs** show the effect of dampening on blood pressure measurement. *(From Chatburn RL: Principles of measurement. In Tobin MJ, editor:* Principles and practice of intensive care monitoring, *New York, 1998, McGraw-Hill.)*

Interpretation of Waveforms

CVP is a measure of right atrial pressure, although it may be measured in the inferior or superior vena cava (SVC). It is a measure of preload—the force or load on the right ventricle during relaxation or filling. CVP is measured at the end of diastole, just prior to ejection. Final filling of the right ventricle occurs at the end of atrial contraction. When the tricuspid valve is open during diastole, the right atrium and right ventricle form a continuous column; therefore right atrial pressure reflects right ventricular end-diastolic pressure. CVP is used to measure filling pressure or preload and as such is an indicator of volume status. It is commonly used in patients with hypovolemic or septic shock in whom volume resuscitation is desirable prior to institution of vasopressor therapy. In patients with decreased right ventricular function or pulmonary hypertension, an increased CVP well beyond normal limits may be observed, and further fluid resuscitation may promote the development of congestive heart failure. Increases in the positive end-expiratory pressure can decrease preload despite a paradoxically increased CVP. Finally, increases in extrathoracic pressure, such as that caused by increased abdominal distension, can increase CVP.

The CVP waveform is divided into three components: *a*, *c*, and *v* waves (Figure 21-5). Each component can be correlated with a specific portion of the electrocardiogram (ECG) tracing. The a wave occurs with atrial contraction and is seen after the P wave of the electrocardiogram during the PR interval. Thus the mean value of the a wave approximates right ventricular end-diastolic pressure. Canon a waves (Figure 21-6), which are enlarged a waves seen when the right atrium is ejecting against a closed tricuspid valve, may be seen when atrioventricular discordance occurs (i.e., during junctional ectopic tachycardia, ventricular tachycardia, or heart block).

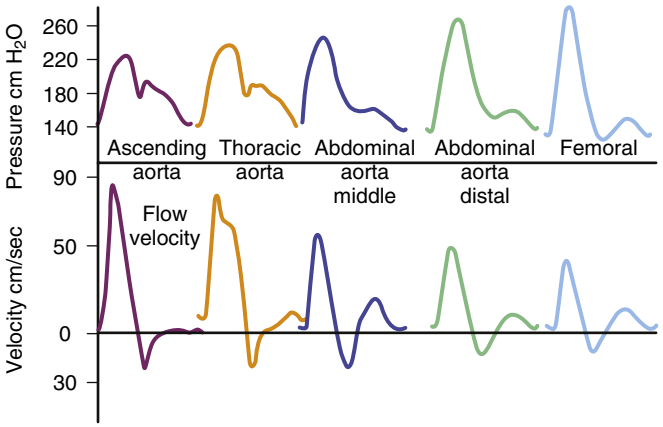

Figure 21–4. Pressure pulses and flow velocity at various points in the systemic arterial circulation. Data were obtained from dogs and are similar to measurements made in humans. The data indicate that both peak and pulse pressure increase with distance from the heart, whereas oscillation in flow velocity shows a progressive decrease. Consequently *impedance* (discussed in the text) must increase toward the periphery. *(From Perloff WH: Invasive measurements in the PICU. In Fuhrman BP, Zimmerman JJ, editors:* Pediatric critical care, *ed 2, St Louis, 1998, Mosby.)*

The c wave occurs in early systole with closure of the tricuspid valve and is seen at the end of the QRS complex in the RST junction. The v wave occurs during filling of the right atrium in late systole prior to opening of the tricuspid valve and is seen between the T and P waves of the ECG. The v wave is increased in the setting of tricuspid regurgitation. The x descent is the decrease in pressure after the a wave, reflecting atrial relaxation. The y descent is the decrease in pressure that occurs after the v wave as the tricuspid valve opens and passive filling of the right ventricle occurs.

Continuous Mixed Venous Oxygen Saturation

Mixed venous oxygen saturation (Svo_2) can be measured continuously by using a specially designed central venous catheter. These catheters have two to three lumens and have the same capabilities of the catheters previously described. The Svo_2 catheters use reflection spectrophotometry and are able to read hemoglobin oxygen saturation continuously. The reflected light is dependent on the oxygenated and deoxygenated hemoglobin concentration in the circulating blood.[8]

Svo_2 is another parameter used to monitor the relationship between oxygen delivery and demand and is often used as a surrogate for cardiac index. Rivers et al.[9] showed that when continuous Svo_2 monitoring was used to guide resuscitation and hemodynamic support in patients with severe sepsis and septic shock, survival rates improved. Recent guidelines set forth by the American College of Critical Care Medicine/Pediatric Advanced Life Support have recommended goal-directed therapy with a target Svo_2 of ≥70% in children and adolescents who are in septic shock.[7] A randomized controlled trial conducted by Oliveira and colleagues[10] supported the use of these guidelines in children and adolescents with severe sepsis or fluid-refractory septic shock.

Ideally, the catheter should be placed in the right internal jugular, with the tip taking measurements in the SVC. Svo_2 measurements obtained from the inferior vena cava exhibit greater variability because of fluctuations in splanchnic oxygen utilization and thus are less reliable. Svo_2 measurements from the right atrium contain coronary sinus blood and are more desaturated because of the high oxygen extraction rate of the myocardium. Studies in critically ill children have evaluated Svo_2 measurements obtained in the pulmonary artery and the SVC. Concordance analysis showed appropriate agreement in the measurements between these two sampling sites.[11] This finding has clinical importance because the use of pulmonary artery catheters (PACs) has declined, while central venous line use has increased.[12] Continuous Svo_2 monitoring can alert the intensivist to early changes in hemodynamic status and allows for less frequent opening of the central line for blood sampling and thus less risk of infection. Percutaneously placed Svo_2 central lines have even been used to monitor patients undergoing complex cardiac surgery, thus avoiding the risks associated with transthoracic lines following surgery.[13]

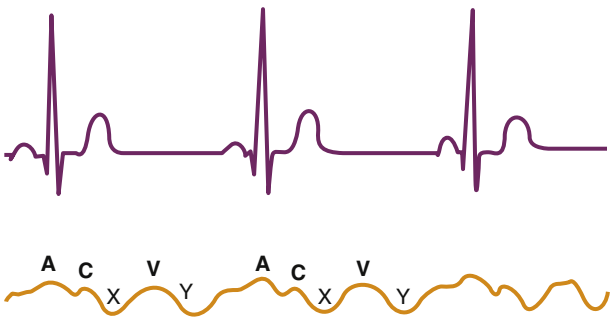

Figure 21–5. Central venous pressure (*A*) tracing with corresponding electrocardiogram (ECG). The a wave is produced by atrial contraction and occurs after the P wave of the ECG during the PR interval. The c wave (*C*) is produced by closure of the tricuspid valve and takes place early in systole at the end of the QRS complex in the RST junction. The v wave (*V*) is caused by rapid filling of the right atrium late in systole prior to opening of the tricuspid valve and is seen between the T and P waves of the ECG. The x descent (*X*) reflects the decrease in pressure in the right atrium after the *a wave* as the tricuspid valve is pulled away from the right atrium by the right ventricle as it contracts during systole. The y descent (*Y*) is the decrease in right atrial pressure that occurs after the *v wave* as the tricuspid valve opens and blood moves from the right atrium into the right ventricle. *(From O'Rourke RA: The measurement of systemic blood pressure: normal and abnormal pulsations of the arteries and veins. In Hurst JW, editor:* The heart, *New York, 1990, McGraw-Hill.)*

Arterial Pressure Catheters

Indications

The transition to direct monitoring of arterial blood pressure dates back to the mid 1950s when two separate studies compared invasive arterial measurements and noninvasive or cuff measurements in healthy adults.[14,15] Van Bergen and colleagues[15] noted a frequent difference between direct and indirect measurements, with indirect measurements increasingly lower than direct measurements as the systemic blood pressure increased. The greatest disparity was found in young hypertensive patients. Similarly, Cohn and Luria[16] observed that invasive arterial pressures were significantly greater than cuff pressures and emphasized the importance of direct measurements of systemic arterial pressure when caring for patients

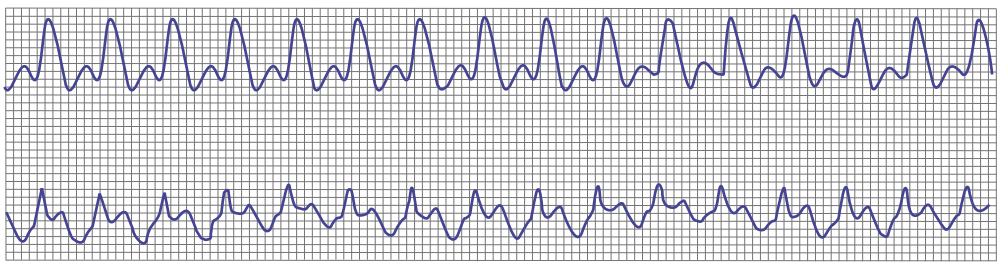

Figure 21–6. Canon a waves are enlarged a waves seen when the right atrium is ejecting against a closed tricuspid valve. These waves are typically seen when atrioventricular discordance occurs, such as during junctional ectopic or ventricular tachycardia or heart block.

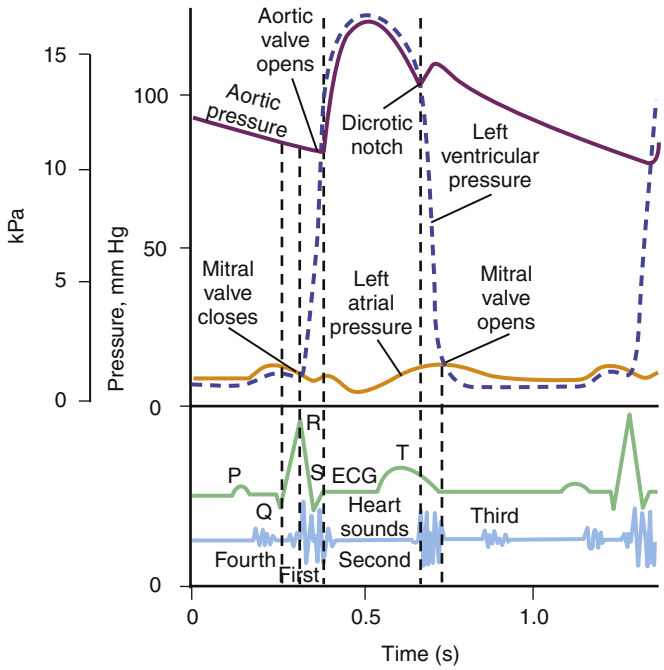

Figure 21–7. Aortic, left ventricular, and left atrial pressure waveforms as they correspond to the electrocardiogram (ECG), opening and closing of the aortic and mitral valves, and heart sounds. Note the presence of the dicrotic notch on the descending limb of the aortic waveform. *(From Peura RA: Blood pressure and sound. In Webster JG, editor:* Medical instrumentation: application and design, *Boston, 1978, Houghton Mifflin.)*

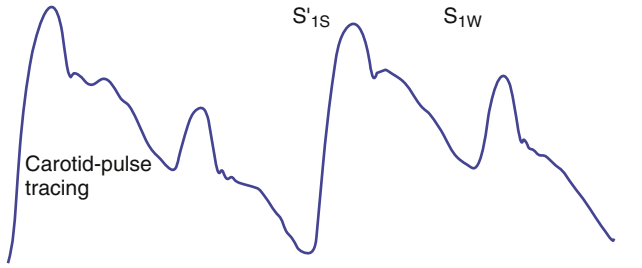

Figure 21-8. Pulsus alternans occurs with left ventricular failure and is characterized by regular variations in the peak amplitude of systolic pressure during sinus rhythm. *(Adapted from Cha K, Falk RH: Images in medicine: pulsus alternans,* N Engl J Med *334:834, 1996.)*

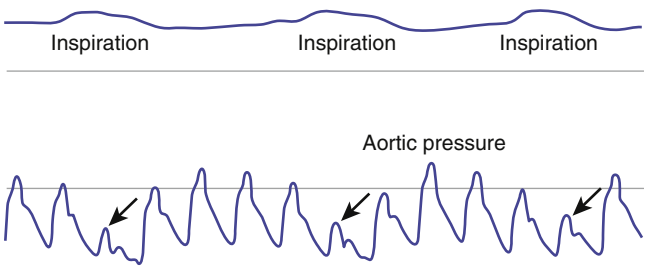

Figure 21–9. Pulsus paradoxus is characterized by an exaggerated decrease in the systolic blood pressure during inhalation. It is commonly seen in conditions marked by great swings in intrathoracic pressure, such as in status asthmaticus, or when there are changes in cardiac function as in pericarditis. In severe hypovolemia pulsus paradoxus also can be observed as a result of a decrease in preload. *(Adapted from Wu LA, Nishimura RA: Images in clinical medicine: pulsus paradoxus,* N Engl J Med *349:7, 2003.)*

with hypotension and shock. Continuous direct monitoring of arterial blood pressure should be considered when treating patients who require more than minimal vasopressor therapy.

Indications for arterial catheterization include continuous monitoring of systemic arterial blood pressure, frequent blood sampling, and withdrawal of blood during exchange transfusions.[17] In addition to the value of the measurements themselves, these measurements provide components of derived measures of CO and oxygen delivery.

Interpretation of Waveforms

Systolic blood pressure (SBP) in children varies greatly with age and gender. As with the CVP waveform, the arterial waveform can be correlated with specific parts of the cardiac cycle. The arterial waveform has three main components (Figure 21-7): (1) a rapid upstroke and downslope that correlates with systolic ejection, (2) a dicrotic notch that correlates with closure of the aortic valve, and (3) a smooth runoff that correlates with diastole. The dicrotic notch or incisura is decreased in situations of hyperdynamic CO in which left ventricular output and stroke volume (SV) are increased, pulse pressure is widened, and diastolic blood pressure (DBP) is increased (e.g., surgical systemic-to-pulmonary shunts, patent ductus arteriosus, aortic regurgitation, anemia, fever, sepsis, hypovolemia, and exercise).[18] Conversely, cardiac tamponade and severe aortic stenosis can narrow the pulse pressure and are associated with a deflection (anacrotic notch) on the ascending limb of the waveform.[18]

Systolic pressures measured in the periphery typically are greater than those measured more centrally because of pulse amplification of pressure waves reflected back from arterial branch points[18,19] (see Figure 21-4). More peripheral sites, such as the radial artery, have greater SBP and lower DBP than more central sites and thus taller and narrower waveforms with greater pulse pressures (difference between SBP and DBP). Important to note is that the mean arterial pressure (MAP in Equation 1) represents the area under the waveform curve, and the overall magnitude of the reading remains the same regardless of the location of the tracing.

$$MAP = DBP + (SBP - DBP)/3 \quad (1)$$

The appearance of the arterial waveform also provides clinical information to the observer. Pulsus alternans (Figure 21-8) is observed when regular variations occur in the amplitude of the peak systolic pressure during sinus rhythm. This phenomenon can be seen in patients with severe left ventricular failure. Pulsus paradoxus (Figure 21-9) demonstrates an exaggerated decrease in the systolic pressure (>10 mm Hg) during the inspiratory phase of the respiratory cycle. This phenomenon can be observed in patients with pericarditis, pulmonary hyperinflation, and decreased intravascular volume.

Pulmonary Artery Catheters

History and Controversy

In 1847, Claude Bernard, a French researcher with widespread interests in experimentation, described a method for recording intracardiac pressures in animals by inserting a glass tube in the heart.[20] However, the true pioneers of cardiac catheterization were two other Frenchmen: Jean Baptiste Auguste

Chaveau, at that time a veterinarian interested in the relationship between the dynamic motion of the heart and heart sounds, and Etienne-Jules Marey, a physician interested in the physiology of the circulation. In the early 1860s, using techniques adapted from Bernard's work, Chaveau and Marey inserted a double-lumen catheter into the right atrium of a horse to record phasic changes in intracardiac pressures as they simultaneously recorded the apical impulse.[20-23]

Right heart catheterization was not considered a safe practice in humans until the early twentieth century. In 1929, Werner Forssman, a German surgeon, secretly performed a right heart catheterization on himself. Forssman had been interested in the work of Bernard, Chaveau, and Marey and wanted to advance their techniques in order to apply them to humans. In direct contradiction to his supervisor's instructions, Forssman inserted a urinary catheter into his own left antecubital vein and then advanced it approximately 1 foot to the head of his humerus. He then went to the radiology department and asked a nurse to hold up a mirror while he advanced the catheter the remainder of the way to his right atrium under fluoroscopic guidance. Forssman performed right heart catheterizations on himself a total of nine additional times without adverse consequences and expanded his findings by demonstrating the feasibility of injecting contrast dye during the procedure.[24,25]

In the early 1940s, Andres Cournand and Dickinson Richards, working at Bellevue Hospital in New York City, continued Forssman's work. They performed right heart catheterization in healthy humans and in those with cardiac failure.[25-28] In 1956, Forssman, Cournand, and Richards won the Nobel Prize in Physiology or Medicine for their discoveries relating to heart catheterization and pathologic changes in the circulatory system. They were the first investigators to measure pulmonary capillary wedge pressures using cardiac catheterization.[29,30]

In 1953, Michael Lategola and Hermann Rahn,[31] two pulmonary physiologists from Rochester, New York, performed experiments in dogs in which they were the first to use a self-guiding balloon-tipped catheter to measure pressures in the pulmonary circulation. Seventeen years later, Swan et al[32] at the University of California, Los Angeles, used this technique to assess right heart pressures in humans and in doing so brought this methodology to the bedside, where it is still used today.

During the past 3 decades, much debate has occurred regarding the safety and efficacy of PACs in critically ill adults,[33-42] with multiple calls for a moratorium on PAC usage.[43,44] One randomized, controlled clinical trial underscored the lack of evidence supporting a benefit to therapy directed by PACs compared with standard care,[38] while another showed no significant effect on morbidity and mortality when PACs were used early in patients with sepsis, acute respiratory distress syndrome, or both.[39] An evidence-based review of PAC use reported no added benefit to its routine use, unless it is associated with a defined clinical protocol.[40] Shah and collegues[41] performed a meta-analysis of 13 randomized clinical trials of the impact of PAC use in critically ill patients and found that it conferred no added benefit, nor did it cause an increase in mortality or hospital days. They concluded that use of evidence-based protocols in combination with PACs may prove to be beneficial. Studies have revealed a significant lack of knowledge and expertise on the part of physicians using PACs, suggesting the tool itself may not be the cause of the problems often associated with the PAC.[45,46] An international consensus recently reviewed the available literature on the use of hemodynamic monitoring in patients with shock. They concluded that the routine use of PACs was not indicated.[47] Notably, Friese and colleagues[42] reviewed more than 53,000 patients from the National Trauma Data Bank and found that PACs were used in the management of more severely injured trauma patients. They found that patients who arrived in severe shock and those aged 60 years or older had an associated survival benefit when a PAC was used.[42]

With regard to pediatric patients, the Pulmonary Artery Catheter Consensus Conference, based on a consensus of expert opinions, concluded that the PAC was useful for clarifying cardiopulmonary physiology in critically ill infants and children with pulmonary hypertension, shock refractory to fluid resuscitation and/or low-to-moderate doses of vasoactive medications, severe respiratory failure requiring high mean airway pressures, and on rare occasions multiple organ failure.[48] They found no data indicating that PAC use increases mortality in children; however, they also failed to find any controlled trials that proved a benefit of PAC use. The panel recommended PAC use for selected patients and called for randomized, controlled trials, a registry of PAC use, and studies to assess the impact of PAC use on cost and duration of ICU/hospital stay.[48]

Indications

Although still controversial, current indications for PAC use in children include septic shock unresponsive to fluid resuscitation and vasopressor support,[49-51] refractory shock following severe burn injuries,[52] congenital heart disease (CHD),[51] multiple organ failure,[53] and respiratory failure requiring high mean airway pressures.[51,54]

Capabilities of PACs include determination of CVP, pulmonary artery pressure (PAP), and pulmonary artery occlusion pressure (PAOP), also referred to as pulmonary capillary wedge pressure (Pw). PAOP is a measurement of left atrial pressure and left ventricular end-diastolic pressure (when the mitral valve is open). PACs also are used to assess CO, Svo_2, oxygen delivery (Do_2) and consumption (Vo_2), and pulmonary vascular resistance (PVR) and systemic vascular resistance (SVR). A fundamental application of the PAC is to examine the function of the right and left ventricles separately. PACs are used to establish diagnoses, guide response to therapy, and assess the determinants of oxygen delivery. PACs are especially helpful in cases of discordant ventricular function.

One of the most common uses of the PAC in infants and children is monitoring pulmonary pressures during and after repair of CHD. In addition to flow-directed balloon-tipped PACs, transthoracic left atrial catheters often are used in these patients.[55] Use of PACs has altered the management of children with CHD by identifying residual anatomic defects and diagnosing pulmonary hypertensive crisis.[56,57] The ability to monitor PAP provides the means to titrate response to inhaled nitric oxide and other pulmonary vasodilators.[58,59] The lack of response to inhaled nitric oxide may suggest a residual structural anomaly in postoperative patients and indicate the need for repeat cardiac catheterization and/or repair.[59] In addition to monitoring for pulmonary hypertensive crisis, PACs can be used to assess the effects of changes in concentration of inspired CO_2 on mean pulmonary artery pressure (MPAP), pulmonary vascular resistance index (PVRI), and cardiac index (CI).[60]

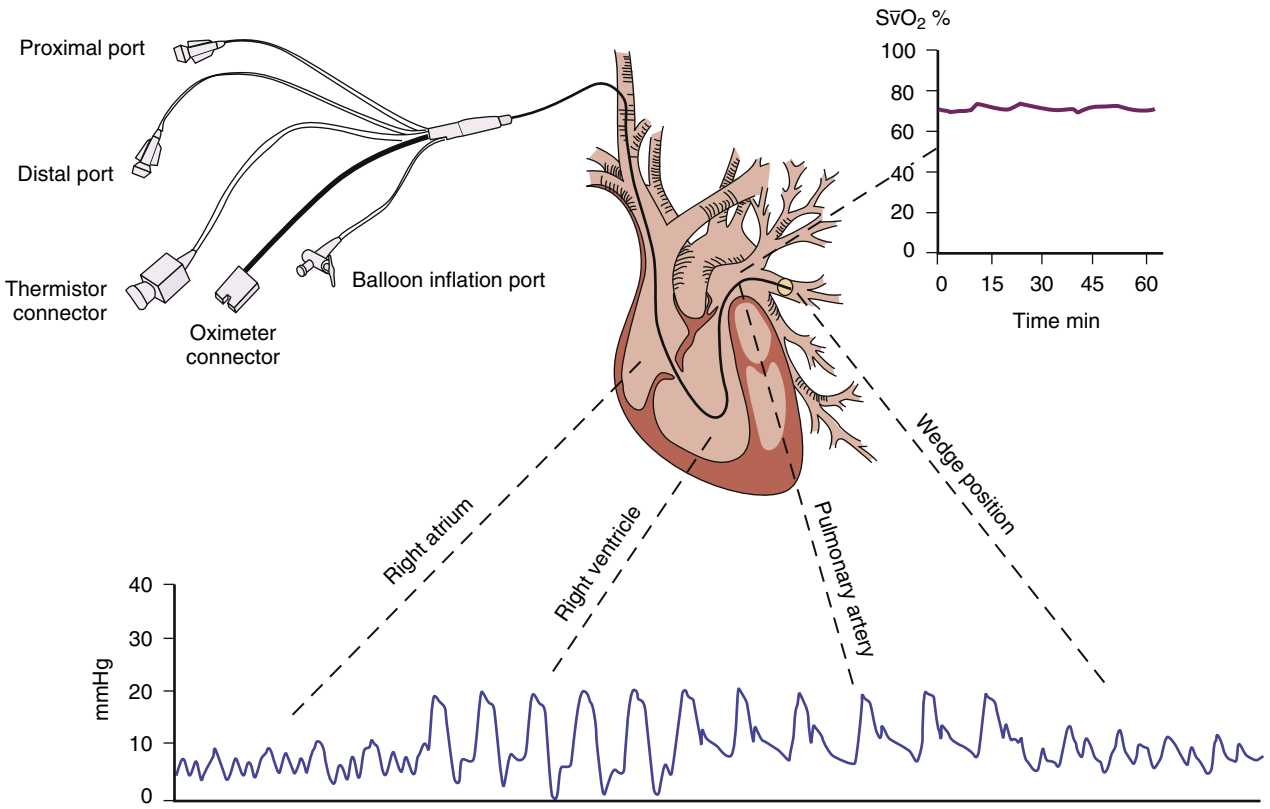

Figure 21–10. Components and functional features of a thermodilution flow-directed pulmonary artery catheter. The flexible multilumen catheter with the balloon at the distal tip inflated is in the wedge position. The proximal ends of the five lumens are labeled. The distal port is connected to a pressure measurement system for catheter insertion and subsequent monitoring. When the distal tip is within the central venous circulation, the balloon is inflated to enhance flow direction of the tip through the right atrium into the right ventricle and then to the pulmonary artery. Recorded pressures (*lower panel*) correspond to these locations, confirming the course of the catheter. The *last tracing on the right* corresponds to the "wedge" position, commonly reflecting pressure transmitted from the left atrium via the pulmonary veins and capillaries. *Upper right panel* shows an example of a continuous Svo_2 (venous oxygen saturation) tracing from the fiberoptic monitor available on adult-size catheters. *(Modified from Daily EK, Tilkian AG: Hemodynamic monitoring. In Tilkian AG, Daily EK, editors:* Cardiovascular procedures, diagnostic techniques and therapeutic procedures, *St. Louis, 1986, Mosby.)*

Catheter Ports

PACs contain the following ports (Figure 21-10). The proximal port is located 15 cm from the tip in 5F catheters and 30 cm from the tip in larger catheters. It opens into or near the right atrium. The proximal port provides access for infusion of fluid or drugs, injection of cold saline solution as indicator (thermodilution method), CVP monitoring, and blood sampling. In infants or small children, PAC placement via the internal jugular or subclavian vein may result in the improper location of the proximal port before the right atrium such that the port lies inside the sheath or outside the body. Therefore it is essential to verify not only the placement of the distal tip in the pulmonary artery but also the location of the proximal port in the right atrium.

The distal port opens at the tip of the catheter. It is used for monitoring PAP and PAOP, for blood sampling of mixed venous blood gases, and for infusion of fluids. By monitoring pressure continuously through this port during catheter placement, the location of the tip can be determined from the characteristic pressure tracings shown in Figure 21-10. After placement, PAP should be monitored continuously in order to identify inadvertent migration into the pulmonary capillary bed or "wedged" position. It is important to allow the catheter tip to "float" into the wedged position only when actively measuring PAOP in order to minimize risk of pulmonary artery infarct or rupture.

The balloon inflation port inflates the balloon, which is located 1 cm proximal to the catheter tip. The balloon is inflated for flow-directed catheter placement and for PAOP monitoring.

The thermistor is located just proximal to the balloon and connects to a bedside computer to measure changes in the temperature of pulmonary artery blood.

The oximeter uses a fiberoptic-based sensor to continuously measure the Svo_2.

Larger catheters also may have cardiac pacing ports. An adult-sized catheter is available for "continuous" CO determination when coupled with an appropriate bedside computer (see Figure 21-10).

Measurement of Cardiac Output

CO is the volume of blood pumped by the heart each minute, or SV multiplied by the number of ejections per minute or HR (CO = HR × SV) and often is expressed as CI, which is CO divided by the body surface area (BSA) in m^2. The normal range for infants and children is approximately 3.3 to 6 L/min/m^2.[61,62] Two methods for calculating CO are discussed here: the Fick method and thermodilution.

Fick Method

In 1870, Adolph Fick, a brilliant mathematician, was the first to study the relationship between blood flow and gas exchange in the lungs using a mathematical model.[63] Fick hypothesized that the amount of oxygen extracted by the body from the blood must equal the amount of oxygen taken up by the lungs during breathing. Fick also reasoned that the flow of blood through the lungs must equal the CO to the remainder of the body in the absence of a shunt. If the amount of oxygen consumed by the body and the amount of oxygen extracted by the body from the blood can be determined, then the CO can be determined. In Fick's time, oxygen consumption was measured using a basal metabolism spirometer, and the oxygen content in arterial and venous blood was measured using a rudimentary method. In his *Compendium der Physiologie des Menschen,* Fick reported that the CO of the resting adult was 4.6 L/min.[63] This value is consistent with values obtained from healthy patients using modern methods. Although Fick's method remains the gold standard, it is rarely used in the ICU because it is less practical than the more commonly used thermodilution method described in the next section. However, Fick's method is commonly used in the cardiac catheterization laboratory because the required data are readily available in this setting, although oxygen consumption typically is estimated.

As noted previously, Fick's equation is based on the assumption that the amount of oxygen extracted by the body from the blood equals the amount of oxygen taken up from the lungs during breathing.

The amount of oxygen extracted by the body from the blood equals the difference in oxygen content of arterial (Ca_{O_2}) and venous blood (Cv_{O_2}) in mL/L, also referred to as arterial-mixed venous oxygen content difference (avD_{O_2}), multiplied by the total amount of blood pumped through the lungs or body (CO).

The oxygen content of the blood is a function of the hemoglobin (Hb) concentration of blood in g/dl, the arterial or venous oxygen saturation (Sa_{O_2} or Sv_{O_2}) expressed in decimal form, and the arterial or venous partial pressure of arterial oxygen (Pa_{O_2} or Pv_{O_2}) in mm Hg. The oxygen-carrying capacity of adult Hb is 1.34 ml O_2 per gram Hb, and the Bunsen solubility coefficient of O_2 in plasma at 37° C equals 0.003. A true Sv_{O_2} is measured in the pulmonary artery; however, in the presence of an intracardiac shunt, Sv_{O_2} should be measured in the SVC.

$$Ca_{O_2} = 10 \times [(1.34 \times Hb \times Sa_{O_2}) + (Pa_{O_2} \times 0.003)] \quad (2)$$

$$Cv_{O_2} = 10 \times [(1.34 \times Hb \times Sv_{O_2}) + (Pv_{O_2} \times 0.003)] \quad (3)$$

Note that the units for oxygen content in this chapter are milliliters of oxygen per liter of blood rather than milliliters of oxygen per deciliter of blood, as is in many other sources. (Thus the values for Ca_{O_2} and Cv_{O_2} must be converted to mL/L by multiplying in a correction factor of 10 dL/L.) Expressing oxygen content in these units allows for easy computation of CO, which is expressed as liters per minute.

The avD_{O_2} is the difference between Ca_{O_2} and Cv_{O_2} and normally ranges from 20 to 78 mL/L.[62]

$$avD_{O_2} = Ca_{O_2} - CV_{O_2} \quad (4)$$

As noted earlier, the amount of oxygen extracted (consumed) by the body from the blood equals avD_{O_2} multiplied by the amount of blood that flows through the lungs (Q_P). Assuming Q_P equals the flow of blood through the systemic circulation (Q_S), then Q_P is a measure of CO. (Note that pulmonary and systemic blood flows cannot be assumed to be identical in children with CHD with single-ventricle physiology or with shunts).

$$O_2 \text{ extraction} = (Ca_{O_2} - Cv_{O_2}) \times CO \quad (5)$$

The amount of oxygen taken up by the lungs equals the amount of oxygen consumed by the body. According to Fick, the amount of oxygen extracted by the body from the blood (Equation 5) equals oxygen consumption (V_{O_2}).

$$(Ca_{O_2} - Cv_{O_2}) \times CO = V_{O_2} \quad (6)$$

CO can be calculated by rearranging Equation 6:

$$CO = V_{O_2} / (Ca_{O_2} - Cv_{O_2}) \quad (7)$$

As noted in Equations 2 and 3, the amount of dissolved oxygen in blood (Pa_{O_2} or Pv_{O_2}) contributes an almost negligible amount to the oxygen content and can be left out for ease of computation. By rearranging Equation 7, a rough estimate of CO can be calculated rather easily at the bedside without use of a PAC:

$$CO = V_{O_2} / (1.34 \times Hb \times (Sa_{O_2} - Sv_{O_2}) \times 10) \quad (8)$$

Oxygen consumption can be measured using the metabolic cart or taken from standardized tables.[11] Hb concentration can be measured directly. Sa_{O_2} can be taken from the pulse oximeter. Sv_{O_2} can be measured by the oximeter at the distal end of the PAC or determined from a venous blood gas sample from a catheter in the internal jugular or subclavian vein.

These data also can be used to calculate the intrapulmonary shunt fraction, which is the fraction of blood that passes through unventilated areas of lung:

$$Qs / Qt = (Cpv_{O_2} - Ca_{O_2}) / (Cpv_{O_2} - Cv_{O_2}) \quad (9)$$

where Ca_{O_2} is systemic arterial oxygen content and Cv_{O_2} is mixed venous oxygen content.

Cpv_{O_2} is the theoretical oxygen content in a normal pulmonary vein and can be calculated using the alveolar gas equation:

$$Cpv_{O_2} = 10 \times [1.34 \times Hb \times Spv_{O_2} + Ppv_{O_2} \times 0.003] \quad (10)$$

where Spv_{O_2} is pulmonary vein O_2 saturation and Ppv_{O_2} is pulmonary vein p_{O_2}.

For the normal lung, Ppv_{O_2} can be estimated from the alveolar air equation, and Spv_{O_2} is presumed to be 1.0:

$$Ppv_{O_2} = P_{AO_2} = (Pi_{O_2} - P_{wp}) - Pa_{CO_2} / R \quad (11)$$

where P_{AO_2} is alveolar partial pressure of oxygen, Pi_{O_2} is inspiratory p_{O_2}, P_{wp} is vapor pressure of water (47 mm Hg at 37° C), Pa_{CO_2} is arterial CO_2, and R is respiratory quotient, which is normally assumed to be 0.8.

The normal shunt fraction is 3% to 7%.

Thermodilution Method

In 1921, Stewart[64] first described an indicator-dilution method for measuring CO. Flow was calculated by measuring the change in concentration of an indicator over time. The "ideal" indicator is "stable, nontoxic, uniformly distributed,

and [does] not leave the system between sites of injection and detection. However, it should be rapidly cleared in a single circulation time to prevent recirculation interfering with measurement."[65] Initially indocyanine green was used as an indicator, but recirculation was problematic because the dye is unstable and accumulates.

In 1953, Fegler[66,67] demonstrated that a change in the heat content of blood could be used as an indicator for CO measurement. A bolus of cold liquid of a known temperature is injected into or proximal to the right atrium. A thermistor near the PAC tip in the pulmonary artery or a pulmonary artery branch measures a change in the temperature of the blood as the bolus passes by the end of the catheter. A computer calculates the flow by integrating the change in temperature at the thermistor.

The first law of thermodynamics, the conservation of heat, is the fundamental principle underlying thermodilution. Thermodilution makes several assumptions: physiologic conditions must remain constant during the period of observation, all heat exchange occurs between the indicator and the blood without heat loss to the surrounding tissues, mixing of the injectate and blood is complete upstream of the temperature measurement, and the temperature sensor is sufficiently sensitive, accurate, and rapidly responsive to depict accurately the change in temperature over time.

Measurement of CO using the thermodilution method can be understood by examining a modified version of the Stewart-Hamilton equation.[65] V_1 is injectate volume (in mL), Tb is temperature of the pulmonary artery at baseline (in degrees Celsius), Ti is temperature of the injectate (in degrees Celsius), K^1 is density factor that equals the specific heat of the injectate multiplied by the specific gravity of the injectate, divided by the product of the specific heat and specific gravity of blood, and K^2 is constant that figures in the dead space of the catheter and the loss of heat from the injectate as it moves through the catheter. The denominator of the equation is the integral of the change in the temperature of the blood (Tb) over time (t) (adapted from reference 65):

$$CO = V_1(Tb - Ti)\, K^1K^2 / \int \Delta Tb(t)dt \qquad (12)$$

The computer generates a CO curve with the area under the curve inversely related to the magnitude of the CO. In settings of low CO, less warm blood flows with the injectate, and the injectate stays cooler. The difference between the injectate temperature and that of the blood remains large, and the CO curve has a high domed shape, with a slow return to baseline temperature (Figure 21-11, *A*). In situations of high CO, more pulmonary artery blood flows with the injectate and the temperature of the injectate approaches or equals that of the blood more rapidly. In these situations, because the difference between the final temperature of the injectate and that of the blood is small, the CO curve rapidly returns to baseline following a sharp spike from the cold injectate (Figure 21-11, *B*). In extreme low-flow states, the change in temperature of the injectate resulting from handling alone, before the injectate even enters the catheter from the proximal port, may be greater than the change caused by warming of the injectate by the flow of blood.

A correction factor is added to the equation to account for warming of the injectate because of handling alone; however, the correction factor may be inaccurate if the injection is too slow or the syringe is held in the injector's hands for too long. Therefore CO readings should be made as quickly as possible and should be repeated until three successive readings are within 15% of each other. Other sources of error include a falsely elevated CO because of inadvertent warming of the thermistor when it is up against the wall of the pulmonary artery. The thermodilution method generally should not be used in patients with an intracardiac shunt; however, if the shunt fraction is less than 10%, the error likely is negligible.[18]

Calculation of Oxygen Delivery and Consumption

Metabolic derangements, such as fever, sepsis, and shock, interfere with oxygen delivery (Do_2) to and consumption by (Vo_2) the tissues. The Svo_2 is a measure of the oxygenation of blood returning to the heart. Svo_2 is measured continuously by the fiberoptic oximeter (see description of PAC ports in the catheter ports section) and normally ranges from 65% to 75%. The oxygen extraction ratio (ERo_2) is $avDo_2$ (see Equation 4) divided by Cao_2 (Equation 2) and usually is approximately 25%[61,62]:

$$ERo_2 = avDo_2 / Cao_2 \qquad (13)$$

Do_2 also can be expressed as the product of CI and Cao_2 and Vo_2 as the product of CI and $avDo_2$. The normal value for Do_2 is 620 ± 50 mL/min/m^2, whereas Vo_2 typically ranges from 120 to 200 mL/min/m^2.[61,62]

$$Do_2 = CI \times Cao_2 \qquad (14)$$

$$Vo_2 = CI \times avDo_2 \qquad (15)$$

Refer to Table 21-1 for a summary of the hemodynamic parameters that can be derived from a PAC.

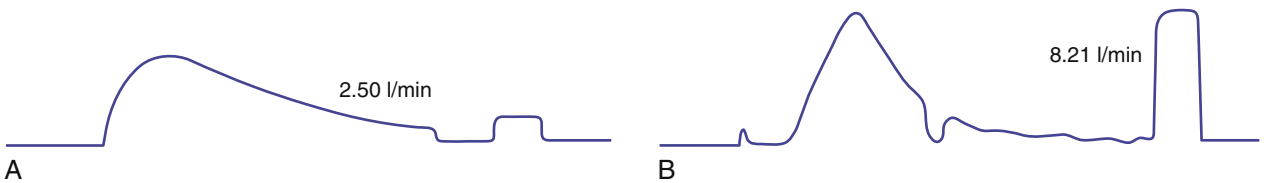

Figure 21–11. A, In the thermodilution method for calculation of cardiac output, a known amount of solution with a known temperature is injected rapidly in a proximal port. This solution mixes with the surrounding blood and cools. The temperature is then measured downstream by thermistor bead in the pulmonary catheter tip. When cardiac output is low, more time is needed for the temperature to return to the known baseline, and the area under the curve is inversely proportional to the cardiac output. **B,** When cardiac output is increased, the cool solution is carried faster through the heart, and a smaller area under the curve is produced. *(Adapted from Headley JM:* Invasive hemodynamic monitoring: physiological principles and clinical applications, *Irvine, CA, 2002, Edward Lifesciences.)*

Table 21–1 Hemodynamic Parameters

Parameter	Formula	Normal Range	Units
Cardiac index	CI = CO/BSA	3.5 – 5.5	L/min/m^2
Stroke index	SI = CI/heart rate × 1000	30 – 60	mL/m^2
Arterial-mixed venous O_2 content difference	$avDo_2 = CaO_2 - Cvo_2$	30 – 55	mL/L
O_2 delivery	$Do_2 = CI \times O_2$	620 ± 50	mL/min/m^2
O_2 consumption	$Vo_2 = CI \times avDo_2$	120 – 200	mL/min/m^2
O_2 extraction ratio	$ERo_2 = avDo_2/Cao_2$	0.26 ± 0.02	
Arterial oxygen content	$(1.34 \times Hb \times Sao_2) + (Pao_2 \times 0.003)$		mL/L
Venous oxygen content	$(1.34 \times Hb \times Svo_2) + (Pvo_2 \times 0.003)$		mL/L
Fick principle	$Vo_2 = CO \times (Cao_2 - Cvo_2)$		
Systemic vascular resistance index	SVRI = 80 × (MAP – CVP)/CI	800 – 1600	dyne–sec/cm^5/m^2
Pulmonary vascular resistance index	PVRI = 80 × (MPAP – PAOP)/CI	80 – 200	dyne–sec/cm^5/m^2
LV stroke work index	LVSWI = SI × MAP × 0.0136	56 ± 6	gm-m/m^2
RV stroke work index	RVSWI = SI × MPAP × 0.0136	0.5 ± 0.06	gm-m/m^2

$avDO_2$, Arterial-mixed venous content difference; *BSA,* body surface area in m^2; *CaO_2*, O_2 content of systemic arterial blood in ml/L;*CI,* cardiac index; *CO,* cardiac output; *CvO_2*, O_2 content of mixed venous blood in ml/L; *CVP*, central venous pressure in mm Hg; *DO_2,* oxygen delivery; *ERo_2,* O_2 extraction ratio*; Hb,* hemoglobin; *LVSWI*, left ventricular stroke index; *MAP*, mean systemic arterial pressure in mm Hg; 80 is the conversion factor used for the units in the table; *MPAP*, mean pulmonary arterial pressure in mm Hg; *PAWP*, pulmonary artery wedge pressure in mm Hg, which is approximately equal to the left atrial pressure under many circumstances; *Pvo_2,* partial oxygen pressure in mixed venous blood; *PVRI*, pulmonary vascular resistance index; *RVSWI*, right ventricular stroke work index; *SI,* stroke index; *Svo_2,* venous oxygen saturation; *SVRI*, systemic vascular resistance index;*Vo_2*, oxygen consumption. Interpretation of Waveforms

The waveforms corresponding to the right atrium and the systemic arterial blood pressure were discussed in previous sections. The pressure in the right atrium ranges from approximately 3 to 12 mm Hg. As the PAC passes into the right ventricle, the diastolic pressure drops to 0 to 10 mm Hg and the systolic pressure increases to 13 to 42 mm Hg.[18] As the catheter enters the pulmonary artery, the diastolic pressure increases to 3 to 21 mm Hg while the systolic pressure remains relatively similar to that of the right ventricle, 11 to 36 mm Hg.[18] Once the catheter tip advances into the pulmonary capillary bed and the pulmonary artery is occluded by the inflated balloon, the measured pressure decreases to 2 to 14 mm Hg.[18] By recognizing the changes in the various tracings, the movement of the catheter tip can be followed through the chambers of the right heart and into the pulmonary circulation, without simultaneous imaging.

The waveforms are affected by the components of the respiratory cycle. As expected, the effects of respiration differ during spontaneous breathing (negative pressure) versus mechanical ventilation (positive pressure). During spontaneous ventilation, PAPs decrease during inhalation and increase during exhalation. In contrast, during mechanical ventilation, PAP increases during inhalation and decreases during exhalation. The cyclical changes induced by the respiratory cycle cause the tracings to take on a sinusoidal pattern once the tip of the catheter enters the thorax. The effects of respiration on PAC determinations can be minimized by measuring pressures at the end of expiration, when pleural pressures are closest to zero.

Because CVP is a measure of preload or filling of the right ventricle, it reflects changes in volume status, right ventricular function, and pulmonary vascular tone. Similarly, PAOP measures filling pressures of the left atrium and ventricle. When the pulmonary artery is occluded, the pressure from the left atrium is transmitted back to the catheter tip. During diastole, when the mitral valve is open and the aortic valve is closed, a continuous fluid-filled column is formed from the catheter tip to the left ventricle, and PAOP is equivalent to the left ventricular end-diastolic pressure. In patients with cardiogenic shock, an elevated PAOP may reflect decreased function of the left ventricle. Rather than provide further fluid resuscitation or preload, increasing contractility or decreasing afterload may be preferable. Afterload is the load that the heart must eject blood against and is inversely related to SV (volume of blood ejected by the heart with each beat) and CO. It is determined by the impedance of the vasculature, ejection pressure, preload, and ventricular wall stress.

According to Laplace's law, ventricular wall stress (T) is proportional to ventricular transluminal pressure (P) (Intraluminal pressure – Extraluminal pressure) and radius (r) and is inversely related to twice the wall thickness (t):

$$T = P \times r/2t \quad (16)$$

For a given pressure, wall stress is increased by an increase in radius (ventricular dilation); therefore volume administration may increase ventricular diameter and consequently wall stress. Thus afterload is preload dependent. Similarly, during spontaneous breathing the transluminal pressure and consequently the wall stress increase, whereas during mechanical ventilation (positive pressure) the transluminal pressure and wall stress both decrease. Ventricular hypertrophy increases wall thickness and therefore decreases wall stress.

Resistance

To understand resistance, returning to Ohm's law is helpful: voltage (V) varies directly with resistance (R) and current (I):

$$V = IR \quad (17)$$

Rearranging Equation 17 by substituting pressure for voltage and flow for current gives Equation 18:

$$R = (Pin - Pout)/Q \quad (18)$$

where *R* is resistance, *Pin* is pressure going into a vessel, *Pout* is pressure exiting the vessel, and *Q* is flow. According to Poiseuille's law, the resistance of flow through a tube varies directly with the viscosity of the fluid and the length of the tube and is inversely proportional to the radius to the fourth power multiplied by pi (π):

$$R = 8\eta l/\pi r^4 \quad (19)$$

where η is viscosity, *l* is length, and *r* is radius. Unfortunately, Poiseuille's law assumes uniform viscosity, length, and radius, none of which holds true in the case of the pulmonary or systemic circulation; however, the principles behind the law are valuable in understanding the major determinants of resistance.

By substituting the appropriate values into Equation 16, the formulas for SVR and PVR can be derived. CO is substituted for Qs and Qp in the absence of a right-to-left or left-to-right shunt or single-ventricle physiology. In the case of the equation for PVR (Equation 21), PAOP is substituted for pulmonary vein pressure in determining Pout:

$$SVR = (MAP - CVP)/CO \quad (20)$$

$$PVR = (MPAP - PAOP)/CO \quad (21)$$

SVR and PVR are measured in mm Hg × minute × L^{-1} (or mm Hg/L per min). These units also are referred to as hybrid resistance units or Wood units after the cardiologist Paul Wood.[18] By multiplying by 80, hybrid resistance units or Wood units can be converted to the centimeter-gram-seconds (cgs) system, where resistance is measured as dynes sec/m^2/cm^5 also known as absolute resistance units.

PVR and SVR often are indexed for BSA (in square meters). The systemic vascular resistance index (SVRI) and pulmonary vascular resistance index (PVRI) are measured as dynes sec/m^2/cm^5:

$$SVRI = 80 \times (MAP - CVP)/CI \quad (22)$$

$$PVRI = 80 \times (MPAP - PAOP)/CI \quad (23)$$

SVRI usually is 800 to 1600 dynes sec/m^2/cm^5 in children[62,63] and 2180 ± 210 in adults.[68]

Calculation of Intracardiac Shunt

If the oxygen saturations throughout the cardiopulmonary circulation are known, derivation of the values for the ratio of pulmonary to systemic blood flow or intracardiac shunt (Qp/Qs) is possible:

$$Qp = Vo_2/(1.34 \times 10 \times Hb\,(Spvo_2 - Spao_2)) \quad (24)$$

$$Qs = Vo_2/(1.34 \times 10 \times Hb\,(Sao_2 - Svo_2)) \quad (25)$$

$$Qp/Qs = (Sao_2 - Svo_2)/(Spvo_2 - Spao_2) \quad (26)$$

where $Spvo_2$ is oxygen saturation in the pulmonary vein and $Spao_2$ is oxygen saturation in the pulmonary artery. In the absence of severe intrapulmonary shunt, $Spvo_2$ approaches 98% to 100%. In a complete mixing lesion, $Spao_2$ and Sao_2 should be equal by definition, enabling Sao_2 to be substituted for $Spao_2$.

Directly and Indirectly Measured Variables

Measurements from PACs include directly and indirectly measured or derived variables. Directly measured variables include CVP, MAP, MPAP, PAOP, CO, Sao_2, and Svo_2. Derived parameters include CI, PVR, SVR, PVRI, and SVRI (as noted earlier), as well as SV (in mL/beat) and stroke volume index (SVI; in mL/beat/m^2). Stroke index (SI) normally is 30 to 60 mL/m^2.[61,62]

$$SV = CO/HR \quad (27)$$

$$SVI = SV/BSA \quad (28)$$

Left ventricular stroke work index (LVSWI) and right ventricular stroke work index (RVSWI) normally are 56 ± 6 and 0.5 ± 0.06 gm-m/m^2, respectively.[61,62] Note all values are for pediatric patients unless otherwise indicated.

$$LVSWI = SI \times MAP \times 0.0136 \quad (29)$$

$$RVSWI = SI \times MPAP \times 0.0136 \quad (30)$$

Conclusions

Invasive hemodynamic monitoring provides the intensivist with valuable information regarding the condition of critically ill children. Correct interpretation of this information is necessary to optimally aid in the management of these patients whose condition is often complex. New noninvasive monitoring modalities are emerging that may eventually replace the need for these invasive measurements, but thus far invasive monitoring remains a cornerstone of pediatric critical care medicine.

Chapter 22

Assessment of Cardiovascular Function

Melvin C. Almodovar, Thomas J. Kulik, and John R. Charpie

PEARLS

- Cardiovascular assessment and monitoring in the pediatric intensive care unit requires careful integration of physical findings, laboratory studies, and electronic data to make appropriate therapeutic decisions.
- Noninvasive monitoring includes physical examination, chest radiography, echocardiography, blood pressure monitoring, and pulse oximetry. Invasive monitoring includes intravascular and intracardiac monitoring, cardiac output measurements (thermodilution or Fick method), and laboratory studies.
- Appreciating the quantity of therapy required to achieve and sustain adequate systemic oxygen delivery and perfusion pressure is useful for the clinician to understand the patient's overall condition, discern the patient's trajectory, and anticipate associated consequences of current management choices.
- Management of patients with single-ventricle physiology (such as the neonate with hypoplastic left heart syndrome) poses several unique challenges to the cardiac intensivist, including optimization of pulmonary-to-systemic blood flow ratios for best systemic oxygen delivery.

Pediatric patients undergoing surgical treatment for congenital heart disease (CHD) or those with severe systemic illnesses such as sepsis and other causes of multiple organ system failure commonly have impaired cardiovascular function.[1,2] In addition to treating the primary disease process, the pediatric intensivist should use strategies to reliably assess and monitor cardiovascular function, which specifically involves assessing adequacy of oxygen delivery (DO_2) and systemic perfusion pressure, the primary determinants of tissue oxygenation.

Cardiovascular Function

The function of the heart and vasculature is to deliver oxygen (O_2) and other nutrients to various tissues in order to meet the metabolic demands of the organism. Mild to moderate depression of DO_2 normally is compensated by augmented O_2 extraction at the tissue level, thereby maintaining a stable level of oxygen consumption (VO_2). When DO_2 falls below some critical level, this compensatory mechanism fails and a state of O_2 supply dependency exists[3] such that any further drop in DO_2 leads to a parallel fall in VO_2.[4-6] Under a state of supply-dependent O_2 consumption, affected tissues and organs attempt to maintain homeostasis partly through anaerobic metabolism. Several studies suggest the initial metabolic response to hypoxemia or decreased DO_2 differs between the newborn and older ages and varies among different vascular beds. In adults at rest, DO_2 is in great excess of VO_2. This "O_2 surplus" means moderate reductions of O_2 transport are generally well tolerated without compromise of VO_2. In contrast to the adult, the metabolism of the newborn may be particularly susceptible to modest alterations in O_2 transport because of the high resting demands for O_2, the ease with which these demands can be increased by small environmental changes, and the apparently limited reserve for augmenting cardiac output (CO) or O_2 extraction acutely.[7,8] Thus it is crucial that cardiovascular assessment and monitoring in the pediatric intensive care unit (ICU) involve continuous and reliable evaluation of the adequacy of systemic perfusion and DO_2 in order to select appropriate hemodynamic support strategies.

Quantity of Therapy

If one considers hemodynamic monitoring not only in terms of DO_2 and perfusion pressure but also in terms of what therapy is required to produce a given level of tissue oxygenation, one gains a much better understanding of the overall "condition" of the patient. It is therefore important to monitor not only DO_2 and perfusion pressure but also the "quantity of therapy" (QOT) needed to procure and maintain adequate tissue oxygenation. Consider two hypothetical 6-month-old infants, Destiny and Dakota, 2 hours after repair of tetralogy of Fallot. They have identical (and adequate) DO_2 and perfusion pressure, but Destiny has a left atrial (LA) pressure of 6 mm Hg and a right atrial (RA) pressure of 8 mm Hg, whereas Dakota has received volume infusion to achieve an LA pressure of 6 mm Hg and an RA pressure of 15 mm Hg. Assuming that the levels of intravascular volume provided are exactly those needed to achieve the (identical) DO_2 values and perfusion pressures, it is clear that the physiologies of these two patients are different. The clinician who has learned what to expect relative to the QOT in any given set of circumstances will find Dakota's sufficient tissue oxygenation only mildly

reassuring and asks: Is there substantial residual right ventricular (RV) outflow tract obstruction or other problem(s) that I need to know about? Will Dakota have sufficient DO_2 in 10 hours when post-bypass myocardial depression is at its worst? Might additional therapy secure adequate DO_2 at a lower filling pressure, thereby minimizing adverse effects of systemic venous hypertension? As this example illustrates, the QOT concept is useful for three reasons:

1. The QOT is, in part, a function of the patient's overall "condition" and can reflect anatomic or physiologic problems that require further exploration.
2. Physiologic trajectory is key, especially early in the course of certain illnesses or after cardiopulmonary bypass, when DO_2 predictably declines over the first 12 hours.[2] Taking into account the QOT relative to tissue oxygenation at any point in time helps one better estimate the likelihood of the need for augmented support (e.g., mechanical support of the circulation) as time passes.
3. Some therapies (e.g., fluid infusion to obtain high filling pressure, or high airway pressure) while helpful at a point in time, can be pernicious over the longer run: High venous pressure, especially in infants, causes third spacing of fluid, and the effect of ventilator-associated lung injury on lung function can be devastating. By using high central venous or airway pressures, the intensivist is, in effect, incurring a debt to secure short-term perfusion that will have to be repaid later. Experienced clinicians always take the QOT into account in their work, thus influencing their level of concern about a patient and guiding subsequent timing and choice in adjusting therapy.

Almost any form of therapy might be included in the QOT concept, but we will focus on medical therapies that have the most important effect on hemodynamics, including DO_2 and perfusion pressure. These therapies include inotropic/vasoactive agents, volume infusion, and airway pressures used during mechanical ventilation. The amount of inotropic and vasoactive drugs administered, assuming that they are used appropriately, seems to be a crude indicator of patient illness.[2] Volume infusion to achieve adequate filling pressure is required even for the normal heart, but the QOT concept applies when higher than normal filling pressure is needed to maintain adequate CO. The consequences of high filling pressures are body edema (especially in infants), pleural and other cavity space effusions, and pulmonary edema. If high venous pressure is coupled with systemic hypotension (e.g., with a "failing" Fontan circulation), there may be critically reduced trans-tissue perfusion pressure with a potentially negative impact on cerebral and splanchnic perfusion.

With respect to mechanical ventilation, the need for high mean airway pressure (P_{aw}) is most commonly a reflection of lung disease, but pulmonary edema on a hydrodynamic basis may occasion the use of high P_{aw} for optimal lung recruitment. High P_{aw} can reduce venous return to the heart, increase pulmonary vascular resistance (PVR), and contribute to ventilator-associated lung injury.

Variables that Determine Tissue Oxygenation

Tissue oxygenation is directly related to both DO_2 and systemic arterial blood pressure (SAP). DO_2, the quantity of O_2 delivered to the tissues per minute, is the product of systemic blood flow (SBF), which equals CO except in patients with certain cardiac malformations, and arterial O_2 content:

$$DO_2\ (\text{mL/min}) = 10 \times CO\ (\text{L/min}) \times CaO_2\ (\text{mL/100 mL blood}),$$

where *CO* is cardiac output or SBF in L/min or L/min/m^2 and Cao_2 is quantity of O_2 bound to hemoglobin plus the quantity of O_2 dissolved in the plasma in arterial blood. The O_2 content of arterial blood (mL O_2/dl blood) equals:

$$CaO_2 = (SaO_2 \times Hgb \times 1.36) + (PaO_2 \times 0.003)$$

where Sao_2 is arterial O_2 saturation, *Hgb* is hemoglobin concentration (g/dL), *1.36* (constant) is the amount of O_2 bound per gram of hemoglobin (mL) at 1 atm of pressure, Pao_2 is arterial partial pressure of O_2, and *0.003* (constant) multiplied by the PaO_2 equals amount of O_2 dissolved in plasma at 1 atm. The quantity of dissolved O_2 is generally considered to be negligible in the normal range of Pao_2. Hypoxia, because of poor gas exchange within the lungs (i.e., intrapulmonary shunt), or in the setting of CHD with right-to-left shunting, is an important determinant of blood O_2 content.

CO is the product of stroke volume (quantity of blood ejected per beat) and heart rate, and SAP is determined by CO and systemic vascular resistance (SVR). The four primary determinants of cardiac function are preload (which determines the precontractile lengths of the myofibrils), end-systolic wall stress (function of systemic blood pressure and physical characteristics of the arterial system, ventricular wall thickness, and chamber dimension), myocardial contractility, and heart rate. These determinants of ventricular function can be altered by many factors in the intensive care setting. Preload, or end-diastolic volume, is affected by ventricular compliance (rate and extent of cardiomyocyte relaxation and cardiac connective tissue), intravascular volume, and intrathoracic pressure. Expansion of the heart resulting from transmural filling pressure, rather than the LA pressure per se, determines the force of contraction. Therefore, intrathoracic (or intrapericardial) pressure is a key determinant of preload. Ventricular hypertrophy, vasodilator and diuretic therapies, and positive pressure mechanical ventilation all adversely affect preload. Similarly, cardiac function is inversely related to afterload, or end-systolic wall stress. Anatomic obstructions and systemic or pulmonary hypertension may negatively affect ventricular systolic and diastolic function. Excessively fast or slow heart rates and inappropriately timed atrial contraction (relative to ventricular systole) may negatively affect ventricular function. Finally, myocardial contractility often is negatively affected by the following factors: hypoxemia, acidosis, hypomagnesemia, hypocalcemia, hypoglycemia, hyperkalemia, cardiac surgery, sepsis, and cardiomyopathies.

Monitoring Tissue Oxygenation

CO can be assessed qualitatively by physical examination and other modalities and quantitatively by a variety of techniques using invasive and noninvasive devices, laboratory data, and other clinical indicators. DO_2 is easily derived if systemic blood flow can be measured, but it is only indirectly inferred if this information is lacking.

Qualitative Assessment of Cardiac Output

Physical Examination

The physical examination often is the initial and the most common technique used to assess and monitor cardiovascular function. Significantly diminished CO may manifest as diminished peripheral pulses, cool or mottled extremities, and delayed capillary refill. However, certain clinical signs of low CO may be unreliable depending on the particular diagnosis. For example, in the context of cardiac lesions associated with a large arterial pulse pressure (e.g., severe aortic insufficiency and aortopulmonary shunts), peripheral pulses may be increased despite low CO and reduced systemic DO_2. Patients in septic shock often are peripherally vasodilated and warm despite hypotension and reduced tissue DO_2. Impaired oxygenation may present as cyanosis of the skin, lips, and/or nail beds. Central cyanosis from either cardiac or respiratory causes results from arterial O_2 desaturation. In contrast, peripheral cyanosis results from vasoconstriction and low blood flow at the microcirculatory level. In some patients, cyanosis is a relatively subtle physical finding, particularly if the patient is anemic or has a dark complexion. Hydration status can be assessed by skin turgor, dryness of mucous membranes, and fullness of the anterior fontanel (in infants), but these manifestations of hydration status relate mostly to interstitial fluid and may poorly reflect intravascular volume, which must be directly measured.

Cardiac auscultation for abnormal heart sounds, including valve clicks, rubs, gallops, and murmurs, may provide the first indication of a significant functional or structural cardiac abnormality, although these sounds do not directly reflect DO_2. Unfortunately, the lack of a heart murmur, especially in low CO states, does not necessarily rule out a significant residual cardiac lesion. The presence of crackles on pulmonary auscultation, particularly in the older pediatric patient, may signify pulmonary edema. However, crackles are nonspecific and may be caused by lung disease or fluid overload, in addition to disorders of cardiac structure or function. Finally, jugular venous distension and hepatomegaly often are indicative of high right-sided filling pressures often associated with RV dysfunction.

Chest Radiography

Although the chest radiograph is of little value in assessing a patient's hemodynamic profile per se, it may be helpful for assessing certain aspects related to cardiovascular status. Provided the chest radiograph is technically adequate, the clinician can assess heart size, contour and configuration, pulmonary vascularity, pleural effusions, lung parenchyma, and abdominal situs. Some of these findings, when abnormal, may help determine the etiology of cardiovascular dysfunction. Increased pulmonary arterial vasculature may be indicated by enlarged pulmonary arteries in the hila that radiate toward the periphery of the lung. Conditions that increase pulmonary blood flow (PBF, or Q_p) at least twice normal also increase the size of the pulmonary arteries. Increased pulmonary capillary pressure may be inferred by the presence of pulmonary edema. The edema may present as a "fluffy" hilum but may have a more diffuse granular appearance in neonates. Pleural effusions may accompany pulmonary edema, particularly in conditions associated with poorly compensated congestive heart failure. Increased pulmonary venous markings are indicative of elevated pulmonary venous pressures of any cause, although usually from decreased left ventricular compliance or obstruction in the pulmonary veins or left atrium.

In the early postoperative period, the most important information obtained from the chest radiograph is (1) the positions of the endotracheal tube, chest tubes, and intracardiac lines; (2) the presence of extrapulmonary fluid or air; and (3) the presence of pulmonary edema. The cardiothoracic ratio gives a quantitative estimate of cardiac size, which is obtained by dividing the transverse measurement of the cardiac shadow in the posteroanterior view by the width of the thoracic cavity. Cardiomegaly is present if this value is greater than 0.5 in adults and 0.6 in infants. Although useful for assessing left ventricular (LV) enlargement, the cardiothoracic ratio is not as sensitive to RV enlargement. RV enlargement results in lateral and upward displacement of the cardiac apex on the posteroanterior view and filling of the retrosternal space on the lateral view. It is perhaps more important to know what the chest x-ray may not reveal; significant cardiac problems, such as constrictive pericarditis, acute fulminant myocarditis, and even acute pericardial tamponade often are associated with a normal-sized heart on a chest radiograph.

Quantitative Assessment of Cardiac Output

Quantitative measures of CO in the ICU can be obtained by a variety of techniques, including the Fick method, thermodilution, the dye dilution techniques, and Doppler echocardiography. Each of the first three methods applies a similar principle of dilution of an indicator: O_2, cold, or indocyanine green dye, respectively. The change in concentration of a substance is proportional to the volume of blood in which it is being diluted. In general, thermodilution is the method most widely used in the intensive care setting. However, for conditions of low CO, the Fick method is more reliable than the thermodilution or dye dilution techniques. Conversely, the Fick method is less accurate in conditions of high systemic blood flow because of difficulty in measuring narrow arteriovenous O_2 differences in the blood.

Thermodilution Technique

The thermodilution technique requires use of a specialized pulmonary artery (PA) catheter. CO is calculated by injecting a known volume of iced water or saline solution into the right atrium (proximal catheter port) and measuring the temperature change at the catheter tip in the PA. CO is calculated by the following equation:

$$CO = 1.08 \times V_i\,(T_b - T_i) / e_0 T_b(t)dt$$

where V_i is injectate volume (mL), T_b is temperature of blood, T_i is injectate temperature, and $T_b(t)dt$ is area under the curve. In general, thermodilution CO measures are performed using a completely automated system, and the calculations are performed by a computer. This method (as with any indicator dilution method) requires complete mixing and thus is most accurate in situations where a mixing chamber is located proximal to the thermistor. It is generally used only in patients who do not have intracardiac or great vessel–level shunts or an insufficient valve between the injection site and the sampling site. The injection must be made rapidly because a slow injection will give a falsely elevated CO. Possible sources of

error with this method include inaccurate measurement of the volume of injectate or of the temperature of the blood or injectate, close approximation of the thermistor to a vessel wall, and inadequate mixing, as is sometimes seen in venous systems with low flow.

Fick Method

According to the Fick principle, CO equals O_2 consumption divided by the arteriovenous O_2 content difference:

$$CO = VO_2 / (CaO_2 - CvO_2)$$

where VO_2 is O_2 consumption (mL/min) and CaO_2 and CvO_2 are arterial and venous O_2 content (mL O_2/100 mL blood), respectively. Care must be taken to select the appropriate sampling site for a true mixed venous blood sample. With a normal heart, the best site to obtain a mixed venous sample is within the PA. If a left-to-right shunt is present, however, the mixed venous site should be the cardiac chamber proximal to the site of the shunt. When a site other than the PA is used for the mixed venous site, the resultant value for arteriovenous O_2 difference is a less reliable reflection of the absolute CO, but it can be used for serial observations and for monitoring response to therapy over time.

Because measuring VO_2 in the intensive care setting requires special equipment and is somewhat cumbersome, the arteriovenous O_2 difference is often used as an indirect measure of CO. A wide arteriovenous O_2 difference generally reflects a low CO and indicates a large O_2 extraction by the tissues, whereas a narrow arteriovenous O_2 difference usually reflects a high CO. Unfortunately, studies suggest VO_2 is quite variable for any individual patient in an intensive care setting.[9] Furthermore, mixed venous O_2 saturation (and, hence, arteriovenous O_2 difference) may be misleading in patients with decreased tissue O_2 extraction.[10,11]

Doppler Echocardiography

Doppler techniques can be used to measure CO using the mean velocity of systolic flow, the heart rate at the time of measurement, and the cross-sectional area of the artery in which measurements are being made (usually the ascending aorta):

$$CO = A \times V \times HR$$

where *A* is the area of the orifice, *V* is integrated flow velocity, and *HR* is heart rate. To determine the integrated flow velocity, the area under the Doppler curve must be measured. The area of the aortic orifice is commonly obtained by measuring the aortic diameter from the two-dimensional image, where A = 0.785 ∞ d2. This technique requires special care for accurate Doppler interrogation of blood flow and is seldom used in the critical care unit.

Pulse Oximetry

Pulse oximetry measures the quantity of hemoglobin saturated with O_2 in peripheral arterial blood. It depends on two principles: (1) oxygenated and reduced hemoglobin have different absorption spectra; and (2) at constant light intensity and hemoglobin concentration, O_2 saturation of hemoglobin is a logarithmic function of the intensity of transmitted light (Beer Lambert law). Two wavelengths of light that have different absorption spectra for reduced hemoglobin and oxyhemoglobin are transmitted from the light-emitting diodes through the arterial bed. Light absorption at the two wavelengths is compared, yielding the ratio of oxyhemoglobin to reduced hemoglobin, or the O_2 saturation. Pulse oximeters have a high potential for error at saturations below 80%.[12] Furthermore, the O_2 dissociation curve flattens out at the high range so that at saturations greater than 95%, large changes in PaO_2 accompany small changes in saturation. This phenomenon should be kept in mind when monitoring premature infants, for whom it is important to avoid hyperoxia.

Other Measures of DO_2

Acid-Base Status

When tissue hypoxia occurs and affected tissues and organs resort, in part, to anaerobic metabolism, increased production of lactate, CO_2, and hydrogen ions occurs. The anion gap, the difference in unmeasured serum anions and unmeasured serum cations, can yield information regarding the cause of metabolic acidosis. If the anion gap is normal (8 to 16 mEq/L), loss of bicarbonate has occurred, usually via the kidneys or gastrointestinal tract, or rapid dilution of the extracellular fluid has occurred.

Blood Lactate

Blood lactate concentration is a laboratory measure that indirectly reflects perfusion.[13,14] Blood lactate measurements are extensively utilized for monitoring and evaluating response to therapy. We observed that initial absolute blood lactate levels were less important than the temporal trend in lactate concentrations for predicting mortality in postoperative cardiac patients.[15] Unfortunately, the specificity of blood lactate is imperfect and may lack sensitivity for detecting supply-dependent O_2 consumption, particularly if it is only regional. In addition, blood lactate depends on hepatic metabolism and the rate of production and clearance.

Gastric Tonometry

Gastric tonometry, a technique available for clinical use in adult and some pediatric ICUs, allows indirect assessment of perfusion by measuring gut intramucosal pH or partial pressure of carbon dioxide.[16,17] It may have an advantage over blood lactate concentration in that it can uncover regional hypoxia and hypoperfusion involving the gut and can be adapted for continuous online measurement.[17] Nonetheless, this technique assumes that a critical reduction in O_2 transport manifests in the splanchnic circulation before it can be detected systemically (probably a reasonable assumption), and tonometric methods are not entirely noninvasive.

Urine Output

Urine output generally reflects CO, but oliguria may occur in the first 24 hours after open heart surgery, especially in neonates, even in the context of good CO and blood pressure. It is therefore important to consider urine output in the context of other indicators of organ perfusion, and not as an isolated variable. It should also be noted that the kidneys are quite sensitive to perfusion pressure and that good systemic blood flow coupled with low systemic arterial pressure (due to low SVR) may adversely affect urine output more than other measures of tissue perfusion.

Near-Infrared Spectroscopy

Near-infrared spectroscopy (NIRS), a noninvasive technique that has been applied to assess systemic and regional oxygen transport in several clinical and laboratory studies,[18-26] is gaining acceptance, particularly in patients with CHD, as a means of trending regional DO_2 or as a surrogate for mixed venous O_2 saturation or systemic DO_2.[27] Abdominal site NIRS has been shown to correlate with simultaneous intramucosal pH measurements by gastric tonometry in neonates and infants with CHD undergoing catheter-based or surgical intervention.[28] In an experimental setting in which DO_2 is controlled, NIRS has been used to correlate cytochrome *aa3* (the terminal link in the electron transport chain responsible for mitochondrial respiration), VO_2, and lactate flux.[23] Thus NIRS has the potential to identify a critical regional reduction in O_2 transport at the cellular level.

Systemic Arterial Blood Pressure

Invasive Blood Pressure Monitoring

Intravascular pressure monitoring often is essential in the management of critically ill neonates and infants in the intensive care unit. Typically, an end-hole catheter is inserted into a vessel (or cardiac chamber) and connected to a pressure transducer by a coupling system composed of fluid-filled extension tubing, a stopcock for withdrawing blood and balancing the transducer to atmospheric pressure, and a continuous infusion device to flush out blood and air. The transducer translates pressure into an electrical signal that can be processed through a preamplifier into a waveform or numerical display on a monitor. The pressure transducer must be properly calibrated, dampened, and positioned (at mid chest level). Inaccurate measurements can occur for a variety of reasons.

In the pediatric population, blood pressure is age-dependent and is a relatively insensitive marker of CO and DO_2. Because blood pressure is the product of CO and SVR, hypotension may result from diminished CO and/or decreased SVR.[29] Because the treatment options are different, distinguishing low CO from low SVR is important.

Noninvasive Blood Pressure Monitoring

The auscultatory method of blood pressure measurement with a cuff and pressure gauge is difficult if access to the patient is limited, if the patient is small or uncooperative, and when frequent recordings are required. Therefore two techniques, Doppler and oscillometric measurements, have been developed. The Doppler technique uses a Doppler ultrasound probe that is applied to the radial or brachial artery. A cuff wrapped around the upper arm is inflated until the audible Doppler signal is obliterated and then deflated until the signal first becomes audible again (systolic blood pressure). This method has been validated in low-flow states and in small children.[30] The oscillometric method has the advantage of being readily automated. The device for indirect noninvasive mean arterial pressure (Dinamap) is based on the principle that blood flow through a vessel produces oscillation of the arterial wall that may be transmitted to an inflatable cuff encircling the extremity. As cuff pressure decreases, a characteristic change occurs in the magnitude of oscillation at the levels at which systolic, diastolic, and mean pressures are registered. Accuracy of Dinamap blood pressures has been validated in children, and it correlates well with direct intravascular radial artery pressures.[31] The accuracy of these two techniques relates to the cuff size. If the cuff is too narrow, the pressure recorded may be erroneously high; if the cuff is too wide, the pressure recorded may be too low. Both techniques are unreliable and inadequate in patients with low CO, hypotension, dysrhythmias, significant edema, or systemic vasoconstriction.

Central Venous or Intracardiac Pressure Monitoring

Pressures also can be measured in the cardiac chambers or in the pulmonary vasculature. However, the necessity for intravascular or intracardiac lines should always be carefully considered, and they should be removed as soon as the clinical condition permits. The placement of relatively large catheters in small vessels for prolonged periods carries a risk of thrombosis and systemic thromboembolism.

Central venous access affords the opportunity to measure central venous pressure (CVP), deliver drugs or high osmolarity nutritional solutions, and repeatedly sample blood to monitor venous O_2 saturations and for other laboratory studies. Intraarterial lines offer the opportunity to continuously monitor arterial pressure and for intermittent blood gas analysis.

Intravascular pressures provide information about ventricular preload and afterload. RV preload is assessed by the CVP. The CVP is determined by a variety of factors, including patient age, preoperative status (i.e., a patient with RV hypertrophy and increased RA pressure), cardiac performance, intrathoracic pressure, blood volume, vasopressor therapy, and status of the pericardium. The CVP *a wave* reflects atrial contraction and the *v wave* reflects atrial filling. Serial measurements of CVP are frequently used to evaluate the response to fluid administration. RV afterload can be assessed using a PA catheter. This catheter is particularly important for monitoring pulmonary artery pressure and therapeutic response to vasodilators in patients with elevated PVR. The PA wedge pressure reflects LA pressure (in the absence of pulmonary vein stenosis). In the postoperative cardiac patient, a direct LA line can be placed to directly assess LV preload. LV afterload is assessed by measurement of SAP, provided no LV outflow tract obstruction is present.

Assessing Variables that Affect the Quantity of Therapy

If it is important to take into account the QOT needed to secure adequate tissue perfusion, it follows that one would like to assess the variables that affect the QOT. Table 22-1 summarizes the effect of abnormalities of cardiovascular and pulmonary function on QOT. What follows is a brief description of how these cardiovascular variables may be assessed in the critical care unit.

Ventricular Systolic Function

Precise measurement of ventricular systolic function is difficult,[32] especially in the critical care setting. A commonly used surrogate is the echocardiographic demonstration of ventricular wall excursion/shortening. LV shortening and ejection fractions can be measured using echocardiography with

Table 22–1 Cardiovascular Function and Quantity of Therapy

Cardiac System Variable	Impact on QOT
CARDIAC FUNCTION	
↓ Ventricular systolic function	↑ Filling pressure, ↑ inotropic/pressor support
↓ Ventricular diastolic function	↑ Filling pressure, ↑ pressor support
Abnormal rhythm	↑ Filling pressure, ↑ inotropic/pressor support
Intracardiac structural lesions (↓ efficiency)	↑ Filling pressure, ↑ inotropic/pressor support
Single ventricle with A-P shunt (↓ efficiency)	↑ Filling pressure, ↑ inotropic/pressor support
PERIPHERAL VASCULATURE	
↑ SVR	↑ Ventricular work → ↑ filling pressure, ↑ inotropic/pressor support
↓ SVR	↑ Filling pressure, ↑ inotropic/pressor support
↑ PVR Two ventricles	↑ Ventricular work → ↑ filling pressure, ↑ inotropic/pressor support
Aortopulmonary shunt	↓ PBF → ↓ O_2 → ↑ filling pressure, ↑ inotropic/pressor support
Bidirectional Glenn	↑ SVC pressure
Fontan	↑ filling pressure, ↑ inotropic/pressor support
VASCULAR FUNCTION	
"Leaky" vascular bed → edema → volume infusion → edema	↑ Filling pressure, ↑ inotropic/pressor support
PULMONARY FUNCTION	
↓ Lung compliance, ↓ gas exchange	↑ Airway pressure → ↓ venous return → ↑ systemic venous pressure, barotrauma

reasonable accuracy, but these variables are influenced by preload and afterload and by inotropic conditions. RV morphology makes echocardiographic measurement of systolic function even more problematic, despite a variety of described techniques to assess this variable.[33] For either ventricle, most often one resorts to a qualitative assessment of ventricular wall excursion as a crude estimate of systolic function. Although cardiac magnetic resonance angiography/magnetic resonance imaging can accurately measure LV and RV ejection fraction, it often is of limited practical utility in the critically ill pediatric patient.

Ventricular Diastolic Function

Ventricular diastolic function also is very difficult to measure precisely. In the critical care unit, diastolic dysfunction is usually manifested as a need for increased filling pressures for a given magnitude of ventricular output. Echocardiography sometimes will demonstrate an apparently underfilled ventricle despite adequate or high filling pressures, but most often a lack of compliance is inferred from high filling pressures alone. Echocardiographic measures of ventricular compliance exist, but many clinicians have found them to be of limited practical value. It is important to emphasize that *transmural filling pressure*, not atrial pressure per se, is what determines diastolic filling; elevated pericardial or intrathoracic pressure will reduce ventricular filling for any given atrial pressure.[34]

Rhythm Disturbance

A variety of abnormal rhythms can decrease systemic perfusion and therefore lead to increased QOT. A surface electrocardiogram may be sufficient to delineate the type and mechanism of an arrhythmia; however, especially with tachycardia, all too often one cannot clearly discriminate P waves from the T and QRS deflections. The use of atrial leads in conjunction with limb leads can be exceedingly helpful for both diagnosing and treating arrhythmias in postoperative patients. Alternatively esophageal electrodes sometimes can be helpful, although they are somewhat cumbersome to use (and cannot always effect atrial capture). It is important to frequently and carefully re-assess the rhythm, because significant changes (e.g., from sinus rhythm to junctional ectopic tachycardia) may escape casual detection.

Abnormal Systemic Vascular Resistance

Abnormal systemic vascular resistance is determined by the following equation:

$$SVR = (SAP - CVP) / CO$$

where *SAP* is mean systemic arterial pressure (mm Hg), *CVP* is mean central venous pressure (mm Hg), and *CO* is cardiac output, usually indexed to surface area (L/min/m^2).

Increased SVR can be useful when CO is insufficient for adequate systemic perfusion pressure with normal SVR. On the other hand, SVR increased beyond that needed for adequate SAP increases systemic ventricular afterload and may therefore negatively affect CO.[35] For reasons discussed in the following section on single ventricle physiology, increased SVR also may result in excess PBF in patients with an aortopulmonary shunt. Finally, increased SAP in a newly postoperative patient may contribute to excessive bleeding. In contrast, low SVR can cause systemic hypotension despite adequate or supra-normal CO. Anecdotal observations and some published information indicate that low SVR may occur after cardiac surgery, as well as with other systemic illnesses (e.g., sepsis).

As previously noted, because CO is infrequently measured in pediatric intensive care units, SVR is most commonly inferred from observation of cutaneous perfusion and SAP. Indeed, it is important to evaluate systemic hypotension in the context of cutaneous perfusion (brisk capillary refill suggests low SVR), because rational therapy for decreased SVR with adequate CO (vasopressor support) is quite different from that useful for hypotension due to inadequate CO.

Increased Pulmonary Vascular Resistance

The clinical consequences of increased PVR are directly related to the specific cardiac anatomy and physiology. With two separate ventricles, high PVR can reduce systolic and diastolic

function of the pulmonary ventricle and limit its output. In patients with a physiologically large aortopulmonary shunt, increased PVR, up to a point, can be useful because it reduces what would otherwise be excessive PBF. On the other hand, if PVR is too high, or in the setting of an excessively restrictive aortopulmonary shunt, inadequate PBF results. With a bidirectional Glenn circulation, elevated PVR may result in upper body congestion and hypoxemia. With a Fontan circulation, high systemic venous pressure, low CO, and hypoxemia (if a fenestration is present) may occur.

In patients with a structurally normal cardiovascular system, measuring PVR is analogous to measurement of SVR and is subject to the same practical difficulties. Echocardiographic estimation of RV pressure is a useful surrogate, using a tricuspid regurgitant jet, pulmonary regurgitant jet, or interventricular septal position. Unfortunately, in the absence of significant tricuspid regurgitation (or another defect that allows a pressure gradient to be measured between the right ventricle and a chamber of known pressure), echocardiographic estimation of RV pressure is crude.

For patients with an aortopulmonary shunt, PVR is rarely measured in the intensive care unit; determining PBF requires measuring VO_2 (an assumed VO_2 is questionable because it is so variable[9]), pulmonary arterial O_2 saturation, and pulmonary venous O_2 saturation. Because pulmonary venous catheters are rarely used, pulmonary venous O_2 saturations are usually assumed; however, this is a potential source of significant error, because these saturations are variable and unpredictable.[36] Most important, pulmonary artery pressure is essentially never measured in the critical care unit in patients with shunts. For these patients, even estimating PVR is problematic because many variables (e.g., PVR, systemic blood pressure, PBF and CO, hematocrit, and VO_2) influence the most obvious manifestation of increased PVR, low systemic arterial O_2 saturation. Circumstantial data may be used to infer that PVR is not elevated in hypoxemic patients with an aortopulmonary shunt; for example, echocardiographic demonstration of narrowing of the shunt suggests that increased PVR is likely not the cause of the hypoxemia. Alternatively, an increase in systemic arterial O_2 saturation with inhaled nitric oxide also would suggest that baseline PVR is increased.

Measuring PBF in patients with a cavopulmonary palliation (e.g., bidirectional Glenn, hemi-Fontan, and Fontan) also can be done using the Fick method (thermodilution cannot be used to measure PBF because of inadequate mixing of the cold indicator in the systemic venous pathway). From a practical standpoint, increased PVR in this setting often is inferred from high systemic venous pathway pressures (superior vena caval pressures in a bidirectional Glenn patient), taking into consideration possible anatomic obstruction in the superior vena cava, pulmonary arteries, or pulmonary veins or increased systemic ventricular end-diastolic pressures.

Inefficient Circulation

The most important fundamental ways that structural defects can result in an inefficient circulation in patients with cardiac structural lesions are: (1) increased ventricular afterload (e.g., RV or LV outflow tract obstruction), (2) increased ventricular volume load (e.g., ventricular septal defect and atrioventricular valve regurgitation), (3) impaired ventricular filling (e.g., atrioventricular valve stenosis), (4) reduced PBF with shunting into the systemic circulation, (5) mixing of pulmonary and systemic venous blood, and (6) D-transposition of the great arteries physiology (i.e., PVR predominantly directed to the PA and SVR predominantly directed to the aorta). Impaired coronary perfusion resulting in ventricular ischemia is perhaps not, conceptually, a problem of efficiency but a structural lesion that needs to be considered. Many patients have some combination of these lesions. It is beyond the scope of this chapter to discuss the evaluation of cardiac patients relative to structural lesions and their impact on DO_2, systemic perfusion pressure, and QOT. Suffice it to say that it is exceedingly important that the anatomy and associated physiology of patients with cardiac malformations be very well defined. Echocardiography is the single most useful modality for delineating cardiac structure (and often even physiology) in the critical care unit. Cardiac catheterization and angiography remain important diagnostic and therapeutic tools, and magnetic resonance imaging and computed tomography are sometimes helpful.

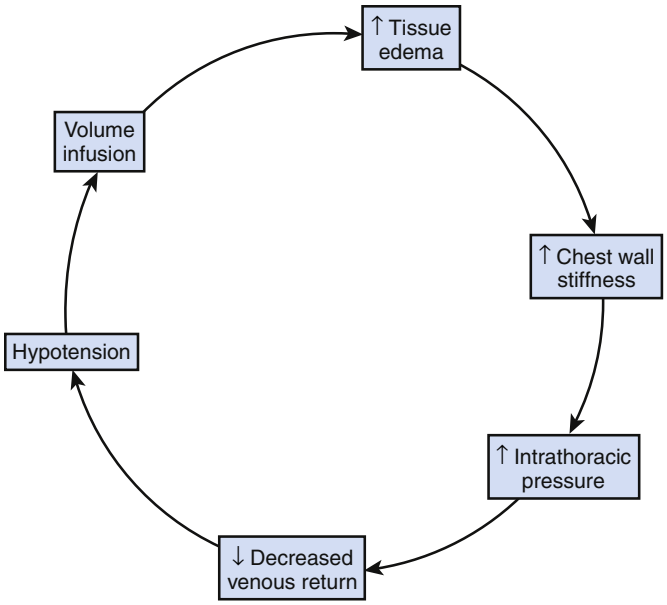

Figure 22–1. Flow diagram.

Vascular Integrity

By vascular integrity we refer to the ability of the vascular (mostly microvascular) bed to keep fluid where it mostly belongs—in the intravascular space. Leaky blood vessels result in organ, chest wall, and peripheral edema and fluid in the thoracic and abdominal cavities. This situation is exacerbated by high CVP and tends to be self-perpetuating, especially in infants (see Figure 22-1).

It is important to assess third spacing, particularly in infants, where opening the chest may help minimize the hemodynamic effects of chest wall edema in post-cardiac surgical patients. Similarly, assessment for abdominal compartment syndrome due to ascites may allow surgical or catheter-based evacuation with improved pulmonary mechanics and urine output. Also, because progressive edema, even if relatively benign early on, is likely to eventually become a significant problem, this finding should figure prominently in the clinician's overall assessment of the patient's condition.

Pulmonary Function

Pulmonary dysfunction due to edema or acute or chronic lung injury can be a major physiological liability for the obvious reasons related to impaired gas exchange. In addition, insofar as increased P_{aw} is required for adequate gas exchange, venous return to the heart may be impaired. This can be especially important in special circumstances, such as the patient after cavopulmonary palliation. Williams and colleagues[37] nicely showed the unfavorable impact of small increments of positive end-expiratory pressure in patients after Fontan palliation, which, as careful inspection of their data reveals, was mostly due to decreased venous return. Increased P_{aw}, especially if it causes overinflation of the lungs, also can increase PVR. Finally, increased P_{aw}, if applied for sufficient duration, can take a long-term toll by chronic reduction in lung function.

It is beyond the scope of this chapter to describe all available techniques for evaluating lung function. However, high P_{aw} is an important component of QOT and should lead the intensivist to consider alternatives (e.g., permissive hypercapnia or extracorporeal life support).

Physiology of the Patient with a Single Ventricle

Patients with single-ventricle physiology differ from children with two functioning ventricles in many ways. They pose several unique challenges to the pediatric intensivist. For many patients with a single ventricle, initial palliation in infancy may involve placement of an aortopulmonary (e.g., modified Blalock-Taussig) or right ventricle to PA ("Sano") connection as a source of PBF. The total output of the single-ventricle circulation is thus the sum of the pulmonary (Q_p) and systemic (Q_s) blood flows. The relative percentage of blood flow to the pulmonary and systemic circulations depends, in part, on the resistance in each vascular bed. Because PVR usually is substantially lower than SVR soon after birth, the size (diameter, length, and vessel of origin) of the aortopulmonary shunt is also a major contributor to total resistance to flow in the pulmonary circuit and hence an important determinant of Q_p/Q_s. SVR is often the single most important variable influencing Q_p[38] and the one most amenable to manipulation in the intensive care unit. In patients with a single ventricle who have complete admixture of systemic and pulmonary venous blood, arterial O_2 saturation is influenced not only by lung function (e.g., pulmonary venous O_2 saturation) but also by Q_p and myocardial function (which influences Q_s and, hence, mixed venous O_2 saturation) (Figures 22-2 and 22-3).

Computer modeling of shunt-dependent single-ventricle physiology[31] suggests that a $Q_p/Q_s \sim 1.0$ is ideal for optimizing systemic O_2 availability for a given pulmonary venous O_2 saturation, CO, and VO_2. The arterial O_2 saturation, considered in isolation, is a very poor indicator of Q_p/Q_s, because a low mixed venous O_2 saturation will depress arterial O_2 saturation, even in patients with a high Q_p/Q_s. Accurately measuring Q_p/Q_s, which equals systemic arterial O_2 saturation minus systemic venous O_2 saturation divided by pulmonary venous O_2 saturation minus pulmonary arterial O_2 saturation, requires determining O_2 saturation in blood in the proximal superior vena cava (SVC), as distinct from RA or inferior vena cava, and is subject to the previously noted variability and unpredictability of pulmonary venous O_2 saturations. That said, estimating Q_p/Q_s using the SVC O_2 saturation (as mixed venous) and the arterial O_2 saturation

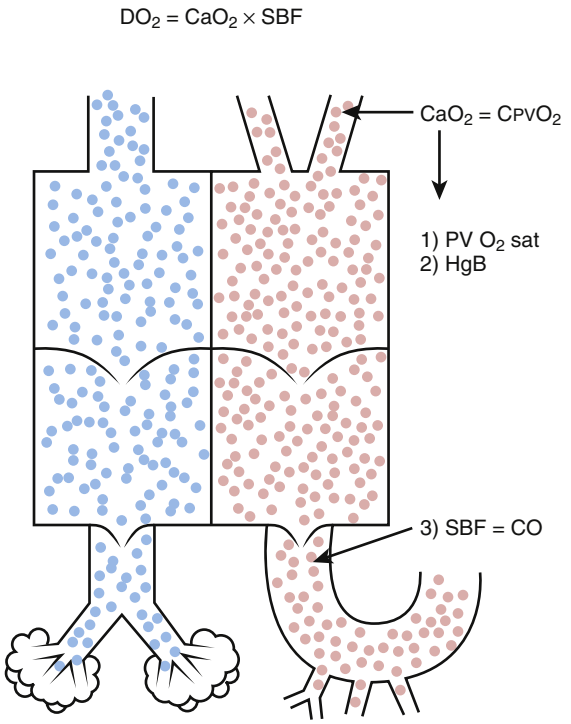

Figure 22–2. Cartoon depicting the variables that determine systemic oxygen delivery (DO_2) with a normal heart. Blue dots depict desaturated (systemic venous) blood and red dots depict fully saturated (pulmonary venous) blood. *CaO_2,* Systemic arterial blood O_2 content; *CO,* cardiac output; *$CpVO_2$,* pulmonary venous blood O_2 content; *HgB,* blood hemoglobin concentration; *PvO_2 sat,* pulmonary venous O_2 saturation; *SBF,* systemic blood flow. Dissolved O_2 in the blood is ignored.

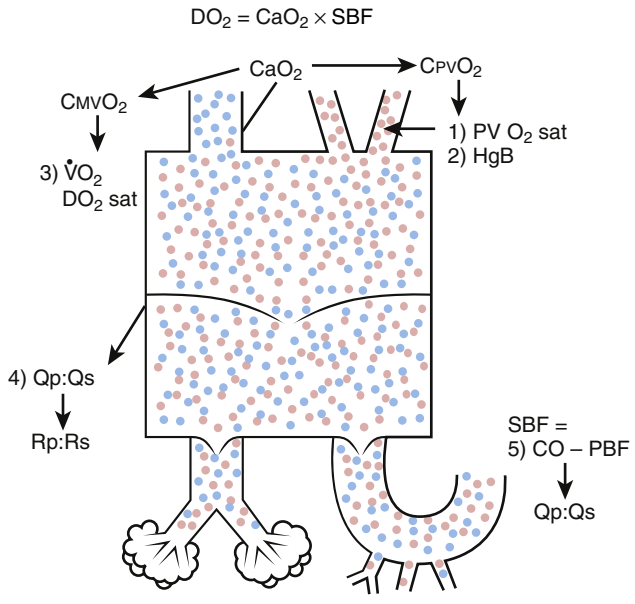

Figure 22–3. Cartoon depicting the variables that determine systemic oxygen delivery (DO_2) with a cardiac malformation resulting in complete mixing of systemic and pulmonary venous blood. Blue dots depict desaturated (systemic venous) blood and red dots depict fully saturated (pulmonary venous) blood. *CaO_2,* Systemic arterial blood O_2 content; *$CMvO_2$,* systemic venous O_2 content; *CO,* cardiac output; *$CpVO_2$,* pulmonary venous blood O_2 content; *HgB,* blood hemoglobin concentration; *PvO_2 sat,* pulmonary venous O_2 saturation; *PBF,* pulmonary blood flow; *Qp:Qs,* ratio of pulmonary to systemic blood flow; *Rp:Rs,* ratio of pulmonary to systemic vascular resistance; *SBF,* systemic blood flow; *VO_2,* total body O_2 consumption. Dissolved O_2 in the blood is ignored.

(which is also the PA O_2 saturation) and assuming the pulmonary venous O_2 saturation is very helpful in estimating whether a patient with single ventricle and an aortopulmonary shunt has appropriate (i.e., associated with optimal systemic DO_2), increased, or decreased Q_p/Q_s. However, it is important to note that Q_p/Q_s is merely a number when considered in isolation. It must be placed into the context of the patient's overall status, considering the parameters previously outlined for assessing systemic DO_2. In particular, in patients following single-ventricle palliation, a progressive decline in the serum lactate concentration (regardless of the initial postoperative concentration) is a fairly sensitive and specific marker for early survival. In contrast, rising lactate levels is generally a robust predictor of early postoperative cardiovascular collapse or need for mechanical support unless therapy can improve the hemodynamic picture.[15]

It should be noted that the physiology is somewhat different in patients with two ventricles and an aortopulmonary shunt (e.g., tetralogy of Fallot with severe RV outflow tract obstruction and a modified Blalock-Taussig shunt). Because PBF usually is made up of both systemic arterial blood and systemic venous blood, arterial O_2 saturation is higher for a given amount of PBF and cannot be calculated using systemic arterial O_2 saturation as the PAO_2 saturation.

Although the cardiopulmonary physiology of patients with bidirectional Glenn palliation differs somewhat from that of others (e.g., the apparent paradoxical relationship between alveolar ventilation and arterial O_2 saturation[39,40]), cardiovascular assessment is much the same as for other patients. Two things are worth noting, however. First, because arterial O_2 saturations often increase significantly during the first several postoperative hours after Glenn palliation, lower than desired but acceptable O_2 saturations early on do not necessarily imply inadequate palliation. Second, although some degree of upper body edema and duskiness is not unusual soon after an operation, marked upper body congestion suggests the possibility of obstruction of the SVC to PA pathway, which requires prompt evaluation. Echocardiography may be sufficient to interrogate this pathway, although angiography may be required.

Evaluation of postoperative Fontan patients is also much the same as for other postoperative cardiac patients, but because Fontan patients are particularly sensitive to factors that impede transit of blood across the lungs and into the ventricle, it is important to identify any such factors, especially remediable ones, very early on in the struggling patient. Anatomic abnormalities that might have little clinical importance in other circumstances (e.g., partial obstruction of one or more pulmonary veins) can have a marked impact on the early postoperative Fontan patient. The same goes for modestly increased PVR and mildly decreased ventricular compliance. Catheters in the central systemic veins and left atrium are useful for estimating PVR and ventricular compliance, and the previously noted measures of systemic perfusion are helpful. The sick postoperative Fontan patient may pose the perfect storm of marginal SAP, acutely elevated CVP (relative to preoperative CVP), and hypoxemia (from right-to-left shunting of highly desaturated systemic venous blood through a fenestration), all complicated by the use of inotropic agents (which increase myocardial and total body VO_2). The experienced intensivist will consider these multiple variables, including the QOT, in aggregate when evaluating the patient.

Echocardiography and Noninvasive Diagnosis

James C. Huhta

PEARLS

- When congenital heart disease or myocardial dysfunction is suspected during the management of a neonate or child in the intensive care unit, echocardiography is the noninvasive diagnostic tool of choice.
- Difficulty in oxygenation may be an indication for a noninvasive study. The goals are to (1) confirm normal intracardiac anatomy, (2) assess intracardiac shunting as a cause of cyanosis, (3) assess left and right ventricular function, (4) assess right-sided heart pressures, (5) assess valve competence, and (6) look for pleural or pericardial effusion.
- In neonatal patients, it is important to assess the status of the ductus arteriosus and to measure the aorta-to-pulmonary artery pressure difference.
- In the postoperative period, information about the right ventricular pressure and pulmonary-to-systemic flow ratio facilitates manipulation of pulmonary vascular resistance.

Since the early 1980s, echocardiography (also known as ultrasonic imaging of the heart and cardiovascular system) has been at the forefront of advances in pediatric cardiology. This technology allows imaging of anatomy, assessment of ventricular function, and determination of peripheral blood flow velocities in both arteries and veins. This noninvasive technique has enhanced the assessment of fetal and neonatal congenital heart disease and facilitated the management of postoperative and other patients in the pediatric intensive care unit. Early in the history of pediatric cardiology, the electrocardiogram was the dominant tool for exploration of intracardiac anatomy, whereas chest radiography was the screening tool for signs of congestive heart failure and abnormalities of extracardiac anatomy, such as pulmonary artery size and vascularity. Now, complete anatomic and physiologic assessment can be obtained in the neonate and in the fetus at 20 weeks of gestation. Intracardiac and extracardiac anatomy can be defined in most patients, and details of the physiologic state, such as fluid balance, cardiac output, and myocardial contractility, can be determined noninvasively.

The technique of echocardiography and the practice of "echocardiology" have changed the practice of pediatric cardiology by largely replacing cardiac catheterization/angiography for the diagnosis of congenital malformations. Combined with use of prostaglandin for maintaining the patency of the ductus arteriosus, echocardiography has dramatically reduced the need for emergency cardiac catheterization in neonates. Most patients with congenital heart disease detected in the neonatal period can undergo palliative surgery without cardiac catheterization. Most definitive surgical repairs can be performed successfully without the risk of invasive studies. Pulsed, continuous-wave, color, and tissue Doppler have added important capabilities for anatomic and functional assessment. Intraoperative and postoperative management of congenital heart defects has been aided by the addition of transesophageal echocardiography (TEE). This mode can improve resolution in neonates and older patients in whom transthoracic imaging is difficult, and greatly aids the surgeon by providing immediate feedback about the quality of the repair prior to separation from the heart-lung machine. Higher-resolution imaging systems continue to evolve. Multielement transducer technology and advances in high-speed computing, three-dimensional real-time imaging, color Doppler, and tissue Doppler have facilitated the assessment of systolic and diastolic function of the myocardium.[1] This chapter focuses on the detection of congenital heart disease in pediatric patients presenting with cardiopulmonary compromise at any age and illustrates the use of TEE for physiologic assessment and management.

Diagnosis of Congenital Heart Disease

Comprehensive analysis of cardiovascular anatomy requires a step-by-step segmental approach. In certain complex congenital malformations, portions of the heart may be absent or malpositioned. Delineation of cardiac anatomy may require that data obtained from several echocardiographic windows be combined. A complete, step-by-step approach to cardiac diagnosis includes the diagnosis of atrial situs diagnosis; identification of the chambers and their interconnections; and systematic assessment of valves, septa, coronaries, systemic and pulmonary veins, and aortic anatomy. Imaging of the thymus and diaphragm is part of the detailed echocardiographic examination.

The segmental approach is based on the principle that all aspects of abnormal cardiovascular morphology can be

broken down into discrete, mutually exclusive descriptors, allowing unambiguous delineation of any complex congenital malformation. The schema must include information on the presence, position, and connection of each cardiac segment. Classically, three segments have been recognized: atria, ventricles, and great arteries. By describing the anatomic segments and indicating the normality or abnormality of each, a complete description of the cardiac anatomy is possible. It now is possible to code cardiac anatomic abnormalities by segmental analysis.[2]

Cardiac Function Assessment

Echocardiography is a tomographic anatomic tool, but it also provides dynamic information about cardiac function and structure. Observations about the cardiac walls, their movement, thickness, and degrees of shortening and thickening can be extremely useful in determining segmental and global cardiac function. In general, the shortening fraction of the left ventricle should be at least 28% (end-diastolic minus end-systolic divided by end-diastolic dimension), and the walls of the left ventricle should move inward symmetrically.

Doppler echocardiography can provide functional information that is not available by any other method. Pulsed Doppler can interrogate a site in the circulation and measure the direction and speed of blood flow in systole and diastole. For example, sampling in the aorta allows comparison of upper and lower body resistances to blood flow by revealing the direction of flow in systole and diastole. The structure and function of the cardiac valves can be determined, perhaps the most powerful application of echocardiography. For example, atrioventricular (AV) valve regurgitation can be diagnosed and its severity, which depends on many technical and physiologic factors, can be estimated. In addition to visualizing a ventricular septal defect (VSD), the jet of a left-to-right shunt can be detected by pulsed Doppler, with the pressure gradient quantified by continuous-wave Doppler (using the simplified Bernoulli equation: Pressure gradient = 4V2, where *V* is peak velocity), and the defect spatially localized by color Doppler. Using the continuity equation and the proximal isovelocity surface area (PISA) concept, flow area and volume can be calculated in left-to-right shunts, and the regurgitant volume and area can be calculated in AV valve regurgitation. Pulmonary artery pressure often can be estimated using the peak velocity of the tricuspid regurgitation jet, and the severity of semilunar stenosis or coarctation can be estimated using the peak and mean gradients. This hemodynamic information can be integrated into the segmental description using the anatomic segment as the finding and the functional aspect as the modifier. For example, the morphologic mitral valve is an anatomic site and location, for which regurgitation might be a modifier. This step-by-step approach to diagnosis answers specific questions about cardiac function and screens for congenital and acquired abnormalities.[3,4]

Structure-Oriented Approach

Adult-oriented, two-dimensional echocardiographic reports usually are based on standard views of the cardiac anatomy that are highly reproducible. The investigators describe the appearance of a given cardiac lesion as seen on a standard parasternal, apical, or subcostal scan. However, this approach can lead to diagnostic errors when applied to congenital heart disease.[5] For example, a scan of an aortopulmonary window from the right ventricular outflow tract can simulate the origin of the aorta from the right ventricle (i.e., transposition of the great arteries). In congenital heart disease, the various views must be integrated, scanning from one echocardiographic window to another to obtain a complete anatomic examination. Although the echocardiographic examiner with experience learns to identify the normal appearances of the heart without congenital defects from various echocardiographic windows, a structure-oriented or anatomic approach always is superior to an approach based on standardized views.

Achieving high sensitivity in the detection of congenital heart disease requires a compulsive approach in order to locate rare anatomic variations that may be important. For example, coronary artery anomalies, such as a coronary originating from the pulmonary artery, can be reliably detected using a standardized approach to defining the origins and courses of the coronary branches.[6]

Segmental Analysis: Situs Diagnosis

Determination of cardiac position and atrial-visceral situs is a standard portion of the echocardiographic assessment of congenital heart disease and is the foundation of the segmental approach. Atrial situs and atrial morphology are diagnosed together, and four possibilities exist: solitus (normal), inversus, and heterotaxy that may be right atrial isomerism or left atrial isomerism. For example, for situs solitus, the morphologic right atrium is on the right and the morphologic left atrium is on the left. Abnormal atrial situs and cardiac malposition, such as dextrocardia, frequently are associated. Both can be diagnosed by obtaining a short-axis scan of the abdomen, identifying the spine and the inferior vena cava and the descending aorta. The location of the cardiac apex is important for later scanning from the apex. Subcostal scanning above the diaphragm immediately shows the position of the cardiac apex. From this scan below the diaphragm, the position of the inferior vena cava and aorta can usually be identified, and their location with respect to the spine identifies the situs (Figure 23-1).

The descending aorta and inferior vena cava are oriented symmetrically with respect to one another, with the inferior vena cava to the right in situs solitus and to the left in situs inversus. In right atrial isomerism, the aorta and inferior cava run together on either side of the spine, with the cava anterior. A venous structure that courses behind the aorta and does not enter the heart suggests azygos continuation of the inferior vena cava, which is associated with left atrial isomerism. These patients usually have separate, anomalous hepatic venous connections to the heart. Occasionally, atrial appendage morphology can be identified and the diagnosis of atrial situs confirmed directly. A broad-based atrial appendage usually is a morphologic right one, and a narrow-based appendage is a morphologic left one. Symmetrical appendages suggest atrial isomerism. Situs diagnosis is important clinically for the care of the intensive care patient. Complex congenital malformations occur predictably with right and left isomerism, and asplenia (associated with right atrial isomerism) may place the child at risk for recurrent or persistent infection. Left isomerism is associated with a high rate of gastrointestinal obstruction after birth.

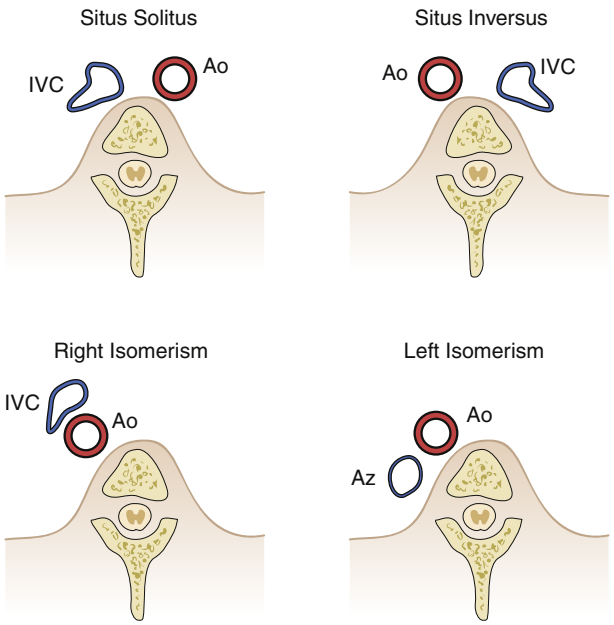

Figure 23–1. Situs by echocardiography. Situs solitus is normal, and the aorta (*Ao*) and inferior vena cava (*IVC*) are symmetrically positioned adjacent to the spine. In situs inversus, there is a mirror image relationship. In right atrial isomerism, the IVC and Ao run together on either side of the spine. In left isomerism, there is azygos continuation of the IVC (*Az*) located retroperitoneally with the Ao.

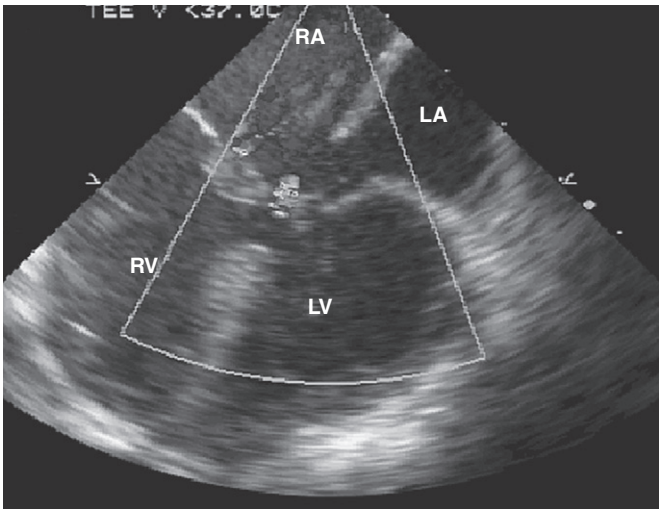

Figure 23–2. Atrioventricular canal defect with dextrocardia. A large primum atrial septal defect and ventricular septal defect are present. Note the mitral and tricuspid valves are at the same level. *LA,* Left atrium; *LV*, left ventricle; *RA*, right atrium; *RV*, right ventricle.

Segmental Analysis: Atrioventricular Connection

Description of the connection of the atria and ventricles (i.e., AV connection) requires knowledge of both atrial and ventricular morphology. The echocardiographic criteria for a morphologic left ventricle include insertion of the mitral valve at the crux of the heart farther from the cardiac apex than that of the tricuspid valve, two normally placed left ventricular papillary muscles, mitral semilunar continuity, a typical elliptical, smooth septal wall, and a fishmouth appearance of a mitral valve having two commissures. In the absence of typical offsetting of the AV valves and with cardiac malposition, the trabecular pattern of the ventricles sometimes can be recognized: the smooth wall pattern of the left ventricle and the coarser, more heavily trabeculated pattern of the right ventricle. The appearance of the ventricular outflow tracts may aid in ventricular morphologic diagnosis and should be observed as part of the segmental approach. Normally, there is continuity between the mitral valve of the left ventricle and the aortic valve, but muscle of the right ventricular outflow tract separates the tricuspid and pulmonary valves. The most reliable criterion for identifying the morphologic right ventricle is tricuspid valve chordal attachments to the septum. With an atrial septal defect of the primum type, the AV valves are at the same level (Figure 23-2).

Four patterns of AV connection exist: concordant (normal); discordant; univentricular through a single inlet (tricuspid or mitral atresia), double inlet, or common inlet; and ambiguous (two ventricles with atrial isomerism). When the morphologic right atrium connects normally to the morphologic right ventricle and the left atrium connects to the left ventricle, AV concordance is present. When this connection is reversed and the morphologic right atrium connects to the morphologic left ventricle, AV connection is discordant and sometimes is referred to as ventricular inversion. Patients with these abnormalities have "corrected transposition"; they may present with complete heart block and have a high incidence of associated congenital cardiac malformations, such as VSD and pulmonary stenosis. They usually also have ventriculoarterial discordance. AV discordance occurs rarely, and in these cases the ventriculoarterial connection is normal.

If most of the AV connection is to one ventricle, the connection is univentricular through one valve (single inlet with atresia of the other valve), double inlet (two AV valves), or common inlet (common AV valve). A common inlet ventricle is part of the spectrum of AV septal defect (AV canal) in which hypoplasia of one of the ventricular chambers occurs and the AV connection is predominant to the other.

The accuracy of echocardiographic imaging in the diagnosis of AV connection is unsurpassed by other modalities. Occasionally, an inexperienced observer confuses a common inlet with a common (four-leaflet) valve with a single inlet, but this should not be a problem after experience is gained with imaging the variations of AV septal defect. Identification of the lower atrial septum unequivocally identifies the crux of the heart and points to a single inlet with atresia of the other valve. The general consensus is that echocardiography in experienced hands is the best method for assessing AV connection and abnormalities of the cardiac valves.

Segmental Analysis: Ventriculoarterial Connection

Ventriculoarterial connection is the manner in which the great arteries and semilunar valves connect to the ventricular outflow tracts. Normally, the morphologic right ventricle connects to the pulmonary valve and the morphologic left ventricle connects to the aortic valve. Four possibilities exist: concordant (normal); discordant (right ventricle to the aorta and left ventricle to the pulmonary trunk); double outlet (usually the right ventricle); and single outlet (aortic or pulmonary atresia or truncus arteriosus).

The most common type of abnormality of ventriculoarterial connection is transposition of the great arteries, in which the morphologic right ventricle gives rise to the aorta and the morphologic left ventricle gives rise to the pulmonary trunk (ventriculoarterial discordance) (Figure 23-3). To diagnose this abnormality, the great vessels must be identified. The pulmonary artery is identified by its branching pattern into left and right pulmonary arteries and ductus arteriosus, and the aorta is identified by the coronary, carotid, and subclavian arteries. Both great vessels may originate from one ventricle (usually the morphologic right ventricle), creating a double-outlet right ventricle. If the aortic or pulmonary valve is atretic, a single-outlet ventricle is the result. Another example of a single outlet is truncus arteriosus, in which a single truncal valve originates from the ventricular mass but overrides the ventricular septum. The ventriculoarterial connection is designated as a single outlet with an overriding truncal valve. In complex malformations, including right atrial isomerism with the asplenia syndrome, the AV septal defect often is associated with a double-outlet right ventricle. In cases of tetralogy of Fallot, overriding of the aortic valve is often present so that almost half of the valve annulus appears to arise from the right ventricle. Mitral aortic continuity is present and, except for the rare circumstance in which more than 50% overriding of the aortic valve occurs, the ventriculoarterial connection in tetralogy of Fallot is concordant.

Reports of neonates with abnormalities of ventriculoarterial connection and children with transposition of the great arteries show that echocardiography can accurately detect these abnormalities. A newborn with cyanosis caused by transposition can be diagnosed without catheterization, and most neonates now undergo surgery without catheterization.

Ventricular and Atrial Septa

Atrial Septum

Before birth, the atrial septum usually bows toward the morphologic left atrium because of the significant blood flow to the left side of the heart through the fossa ovalis. After birth, aneurysmal bowing of the atrial septum may be a clue to right-to-left or left-to-right intertrial shunting. Color Doppler studies have confirmed that left-to-right shunting through a patent foramen ovale is a normal finding soon after birth, particularly if the ductus arteriosus has not closed. After the infant reaches age 6 weeks, persistent shunting at the atrial level is considered abnormal if the color diameter of the shunt is greater than 4 mm.

Results of echocardiographic imaging of atrial septal defects are good. Detailed analysis of the venous connections is needed to exclude partial anomalous pulmonary venous return, for example. The triage of patients with an atrial defect requires detailed measurements of the rims of the defect to determine whether the patient is a candidate for device closure of the defect in the catheterization laboratory. The popular Amplatzer device straddles the hole, effectively closing it permanently. Another practical application of echocardiography is evaluation of the atrial defect created by balloon atrial septostomy or blade and balloon techniques.

A thin strand of tissue in what appears to be a common atrium suggests right atrial isomerism. The upper atrial

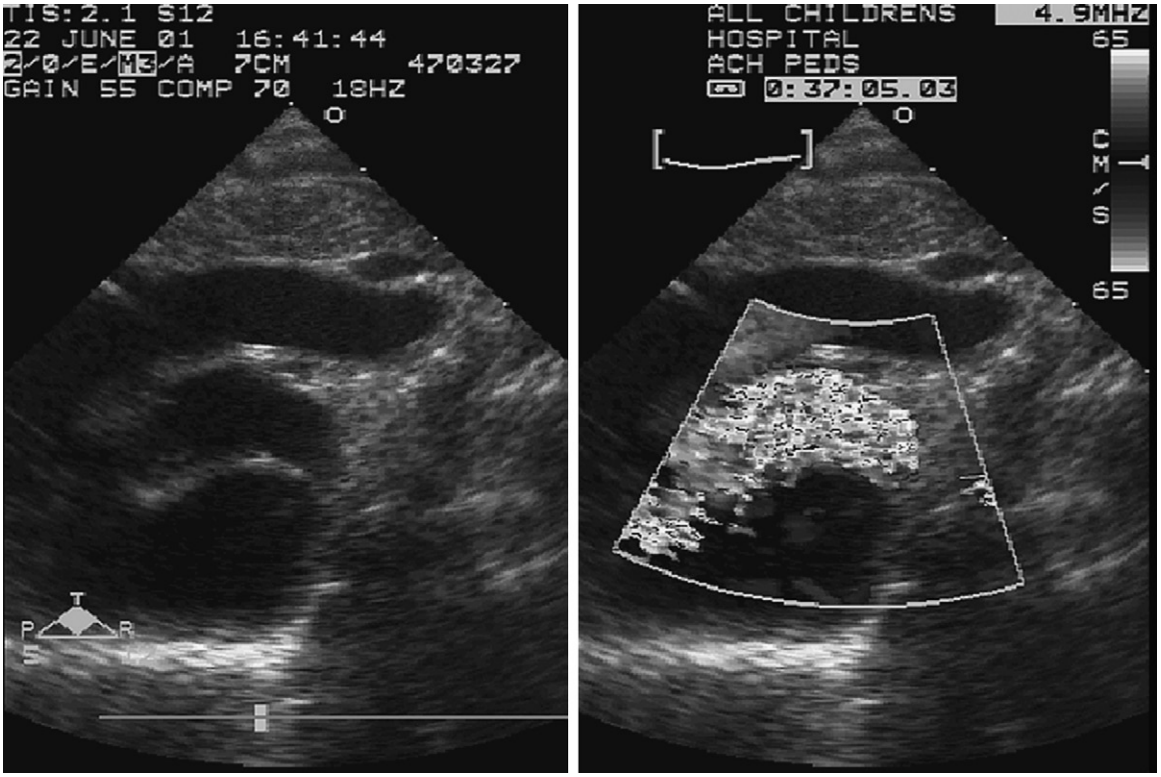

Figure 23–3. Transposition of the great arteries (discordant ventriculoarterial connection). Note the parallel exit of the anterior aorta and posterior pulmonary artery.

septum where a sinus venosus defect may occur can be difficult to evaluate in an older child, but color flow mapping has improved the accuracy of diagnosis in all forms of atrial septal defect (Figure 23-4; also see Figure 23-9).

Ventricular Septum

Defects of the ventricular septum can be analyzed using multiple tomographic imaging approaches, and defects can be separated into perimembranous, muscular, and subarterial. An inlet perimembranous defect (AV canal-type defect) can be differentiated from complete AV canal by the presence of the central fibrous body at the internal crux of the heart (Figure 23-5). Small, muscular VSDs and even a significant defect in the perimembranous region may be missed by imaging alone, but color Doppler has substantially improved the sensitivity of echocardiography in detecting muscular defects. Color may be crucial for detection of multiple VSDs. The details of complicated interventricular communications in the trabecular septum may be aided by angiography or a detailed evaluation using TEE. TEE with color Doppler appears adequate for evaluation of these patients, especially when they are older. Three-dimensional echocardiography offers the promise of improved spatial orientation and delineation of the defect(s).

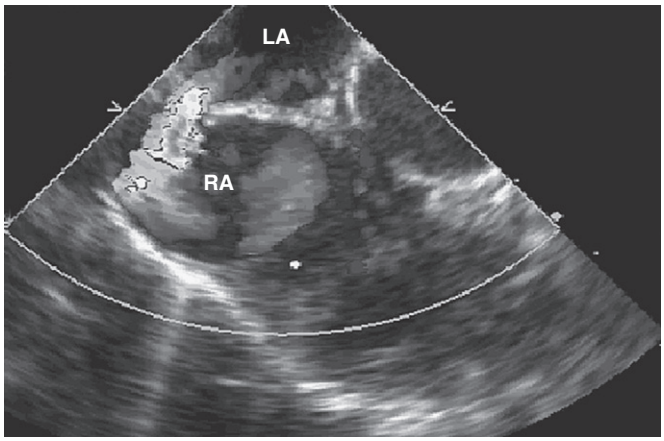

Figure 23–4. High sinus venosus atrial septal defect between the left atrium *(LA)* and right atrium *(RA)*. Left-to-right shunting is seen by color Doppler (*blue* flow away from the transducer with aliasing).

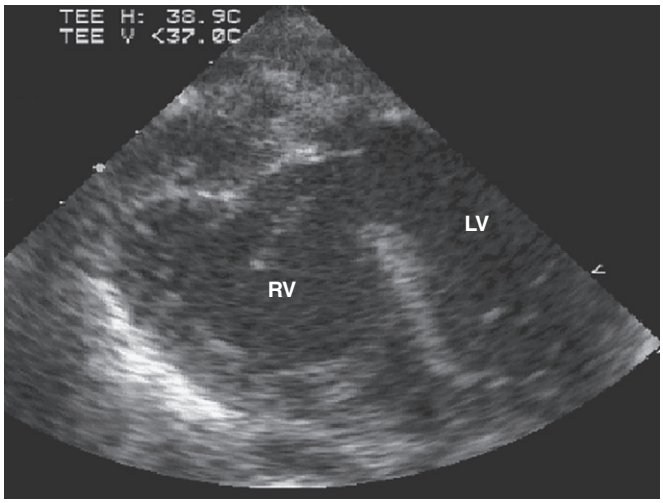

Figure 23–5. Ventricular septal defect between the left ventricle *(LV)* and right ventricle *(RV)*. The defect is in continuity with the tricuspid valve and therefore is a perimembranous defect.

Segmental Analysis: Valves

Atrioventricular Valves

A wide variety of malformations may involve the left or right AV valves. The mitral or tricuspid valve may be abnormally positioned, stenotic, regurgitant, or hypoplastic, or the valve may have a cleft or exhibit prolapse, straddling, or Ebstein malformation. The pattern of opening on real-time imaging is augmented by Doppler or M-mode functional assessment. Almost all forms of congenital abnormalities of the mitral valve can be recognized immediately by imaging alone, with the possible exception of supravalvar mitral ring, in which the ring may adhere to the valve tissue. The normal papillary muscles in this disorder differentiate it from most other congenital forms of mitral stenosis. Color flow mapping and continuous-wave Doppler more effectively evaluate the hemodynamics of AV valve stenosis than do invasive techniques. Regurgitation of AV valves can be detected with excellent sensitivity, and color Doppler can be used to grade the severity of regurgitation of the AV and semilunar valves (Figure 23-6).

Semilunar Valves

Semilunar valves (either pulmonary or aortic) are described by their age-adjusted size, cusp morphology, and pattern of opening. Because the size of a valve annulus reflects the flow through it, hypoplasia of the valve annulus is usually associated with severe stenosis. Echocardiographic imaging may detect this condition, doming of a stenotic valve, or muscular hypertrophy of infundibular stenosis. Abnormal coaptation of the semilunar valve cusps also correlates with regurgitation of the valve. Because of flow variability through a stenotic valve, a flow-independent method, known as the continuity equation, may be useful. The ratio of mean velocity at the valve to velocity below the valve is used to estimate the ratio of effective subvalvar to valvar area. As a rule of thumb, a peak velocity of stenosis that is four times the velocity below the valve is predictive of critical narrowing of functional valve area. Prosthetic valves may be present in the pediatric population and require a combination of transthoracic and transesophageal echocardiographic assessment.

Segmental Analysis: Veins

Systemic Venous Connections

Segmental diagnosis of systemic venous connection is possible by echocardiography before and after birth. Systemic venous return may be typical of the atrial situs (e.g., azygos continuation with left atrial isomerism). Systemic venous return that is abnormal in situs solitus may be normal if the situs is not solitus. Normal inferior and superior venae cavae connecting to the right atrium indicate a normal systemic venous connection to the morphologic right atrium. It is important to image the inferior vena cava connecting to the heart and its extensions into the abdomen, so that hepatic veins connecting separately to the atrium are not mistaken for it. Each of the systemic venous segments, including the right superior

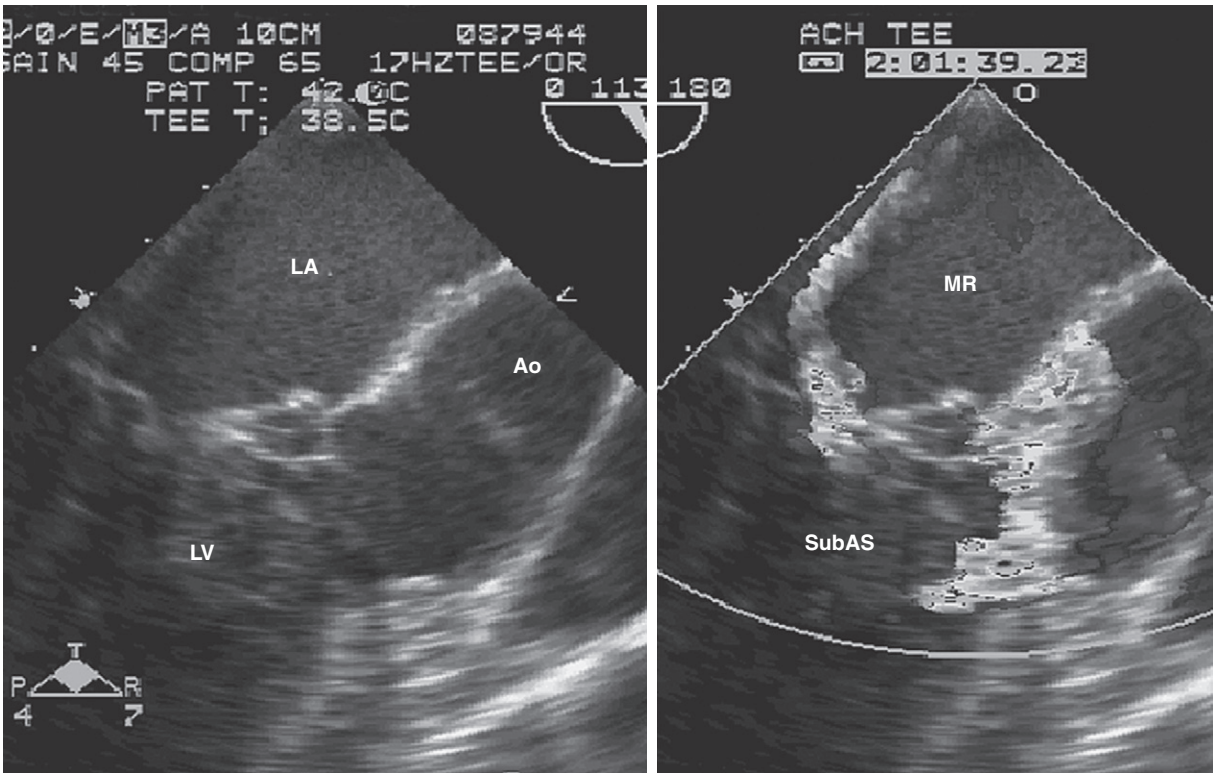

Figure 23–6. Mitral regurgitation *(MR)* between the left ventricle *(LV)* and the left atrium *(LA)* created by a subaortic membrane causing subaortic stenosis *(SubAS). Ao,* Aorta.

vena cava, left superior vena cava, inferior vena cava, coronary sinus, and hepatic veins, should be examined individually.

Systemic Venous Anomalies

A persistent left superior vena cava is present in up to 10% of patients with congenital heart disease and can be detected by echocardiography and confirmed by contrast studies. Persistent left superior vena cava is the most common venous defect, and is present in 0.5% of patients without congenital cardiac defects. Rarely does this minor defect require attention, except to document its presence in case surgical management is needed for other forms of congenital heart disease. If the persistent left superior vena cava appears to be connected to the left atrium or drains to this site because of unroofing of the coronary sinus, cyanosis results. In this case, echocardiographic contrast injection in the left arm shows immediate opacification of the left atrium. A sinus venosus atrial septal defect can direct superior vena caval drainage to the left atrium, causing mild cyanosis in an otherwise normal child.

Pulmonary Veins

Each pulmonary vein connecting to the morphologic left atrium must be imaged in a sequential fashion. A four-chamber view often reveals at least two pulmonary veins connecting to the left-sided morphologic left atrium. The suprasternal scan may demonstrate all four pulmonary veins connecting to the left atrium (the so-called "crab" view). Total anomalous pulmonary venous connection can be detected with high sensitivity, depending on the experience of the examiner. Although accurate diagnosis of isolated total anomalous pulmonary venous connection can be made in neonates and infants, the ability of any noninvasive tool to exclude an isolated partial anomalous connection of one vein has not been tested. Color Doppler can confirm pulmonary venous flow in the location where the vein is thought to be connecting. Detection of variations of pulmonary venous obstruction depends on Doppler imaging. Direct visualization of all four pulmonary veins is mandatory before corrective surgery for any defect, especially for atrial septal defect or anomalous pulmonary venous connection. Any deviation from the usual anatomy should prompt a complete angiographic study or a detailed study by magnetic resonance imaging, which in experienced hands can clarify the defect. Severely cyanotic neonates with atrial isomerism usually have abnormalities of pulmonary venous connection and may require angiography prior to palliative surgery.

Segmental Analysis: Coronary Arteries

The coronary arteries are examined in a sequential fashion to detect abnormalities. One approach is summarized in Box 23-1. The two proximal coronary arteries are identified, the proximal branching of the left is visualized, the distal course of the right and left coronaries is imaged in the AV valve grooves, and the distal anterior and posterior descending branches are imaged. If intracardiac repair is contemplated, the origin of the coronary vessels and their courses must be visualized using a segmental approach. Any coronary passing between the two semilunar valve annuli is abnormal. With the exception of aneurysm detection in Kawasaki disease or the abnormal origin of the common left or right coronary artery, the ability of ultrasonography to define abnormalities of the coronary circulation is limited. Use of TEE can significantly improve diagnosis of the intramural course of coronary arteries. In the case of fistulae, enlargement of one of the coronaries can usually

Box 23–1 Coronary Artery Segmental Analysis

- Define both proximal arteries from the aorta.
- Image the bifurcation of the left coronary.
- Exclude coronary passing between the aortic and pulmonary arteries.
- Confirm normal direction of flow in the left coronary.
- Examine the distal courses of the coronaries.

be detected, and pulmonary atresia with a significant fistula can be diagnosed. In our experience, an isolated coronary fistula can be repaired without bypass, and the entry site can be defined by color Doppler.

Anomalous origin of one or both coronaries from the pulmonary trunk can be detected with high specificity using high-frequency two-dimensional color Doppler and a low peak repetition frequency. Any electrocardiographic evidence of coronary insufficiency should prompt immediate coronary angiography if surgical intervention is contemplated. With experience, imaging studies of the coronary artery anatomy in tetralogy of Fallot and transposition should be successful. All patients with tetralogy should undergo assessment of the coronaries to define the origin of the left anterior descending branch before a right ventriculotomy is performed.

Segmental Analysis: Aorta

Segmental analysis of the aorta and congenital abnormalities that affect it includes assessment of the (1) ascending aorta, (2) aortic arch branching, (3) aortic isthmus, and (4) descending aorta. Echocardiography is highly accurate for diagnosing abnormalities of the aorta in neonates, infants, and children. Each segment of the aorta is located in a slightly different tomographic plane, requiring a sequential, segmental approach. Normal branching of the right innominate artery indicates a left aortic arch with normal branching. Branching to the left indicates a right aortic arch with mirror-image branching. A left-sided patent ductus arteriosus is the most common abnormality of the aorta. Color and continuous-wave Doppler echocardiography are indicated in every study to detect ductal shunting (Figure 23-7).

Coarctation of the aorta, which in the neonatal period has a typical appearance that includes hypoplasia of the transverse aortic arch and right ventricular enlargement, can be diagnosed by echocardiography. The typical Doppler pattern confirms the diagnosis if the ductus has closed. The presence of a posterior ledge and a transverse arch that is similar in size to the left subclavian artery makes the diagnosis. With an open ductus, the flow pattern may be mildly turbulent without gradient. In patients with a large VSD, the status of the aorta always should be investigated to exclude coarctation. In hypoplastic left heart syndrome with aortic atresia, the patent ductus arteriosus has bidirectional shunting similar to that seen in interrupted aortic arch. In hypoplastic left heart syndrome, the ascending aorta is small, with reversed flow in the arch (Figure 23-8).

In adults, the segmental analysis of the aorta is less reliable, but Doppler techniques have significantly improved the detection of aortic obstruction in cases where imaging had been poor. TEE allows identification and measurement of internal mammary branches.

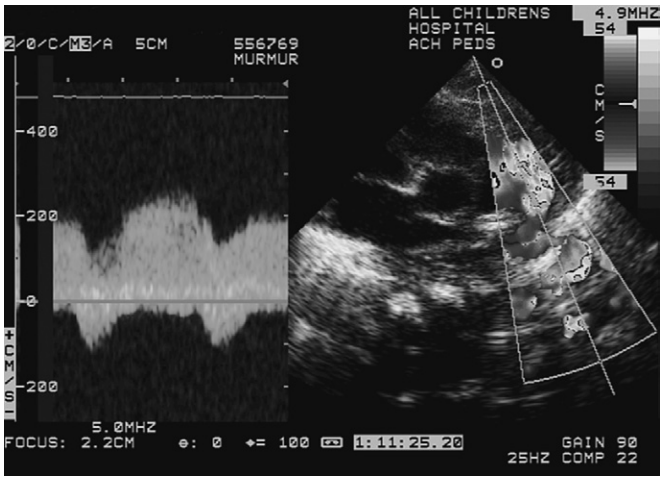

Figure 23–7. Patent ductus arteriosus in a neonate with a heart murmur. *Left,* Left-to-right shunt velocity is measured by continuous-wave Doppler as a peak of 2.3 m/s. *Right,* Left-to-right shunt into the pulmonary artery is seen by color Doppler.

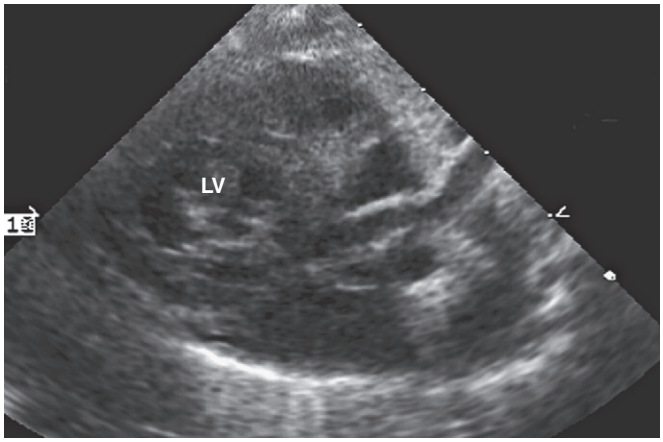

Figure 23–8. Small ascending aorta in a neonate with aortic atresia (hypoplastic left heart syndrome). Note the large remnant of left ventricle *(LV).*

Systemic Arteriovenous Fistulas

Systemic arteriovenous fistulas cause enlargement of the artery feeding the fistula and generalized enlargement of the aorta. Sequestration and hepatic and cerebral fistulas are most common. Sequestration of the lung and other fistulas causing an obligatory shunt can be detected, but require careful technique. The defect known as a *vein of Galen* malformation may simulate coarctation of aorta because of the aortic isthmus morphology created by branching of the ductal flow to the upper and lower body. Cerebral angiography is required for preoperative definition of small-vessel anatomy.

Pulmonary Arteries

The most common abnormality of the pulmonary arteries that indicates congenital heart disease is hypoplasia. The pulmonary arteries normally are confluent in the midline, and this detail of anatomy is important when planning a palliative approach to cyanotic congenital heart disease. Abnormalities of the origin or size of the pulmonary arteries may occur. In

severe right ventricular outflow tract obstruction in neonates, pulmonary artery hypoplasia is associated with a reciprocal increase in the size of the aorta, and the ratio of size of the pulmonary arteries to the aorta may be useful in diagnosing the abnormality and making surgical decisions where the ability of the pulmonary vascular bed to carry the total combined cardiac output is questionable. Assessment of the details of the distal arteries requires angiography or magnetic resonance imaging. A pulmonary arteriovenous fistula presents with cyanosis and enlargement of the pulmonary arteries and veins on echocardiography, and should be confirmed by angiography and pulmonary venous oxygen saturation measurements.

Tetralogy of Fallot with pulmonary atresia and major aortopulmonary artery collaterals may be difficult to evaluate. The neonate with this condition can be differentiated from a neonate with ductal-dependent pulmonary supply by the oxygen saturation when off prostaglandin and by imaging the ductus and poorly developed confluent pulmonary arteries. All patients with collateral arteries and multifocal pulmonary supply must undergo complete angiographic evaluation prior to surgery. Comparison of the sum of the diameters of the right and left pulmonary arteries with the diameter of the descending aorta can be useful in planning surgery.

Ventricular Function Assessment and Hemodynamics

Temporal resolution of two-dimensional echocardiography is limited by the scanning rate limits of the equipment. M-mode techniques, on the other hand, interrogate the heart at a much higher rate (800 to 1500 times per second) and allow tracking of the ventricular wall and valves at rapid rates of movement. The most useful application of M-mode echocardiography is the measurement of absolute cardiac chamber dimensions and wall thicknesses and their dynamic changes. Normal values for the systolic and diastolic dimensions of the left atrium and ventricle increase with age and body size, and comparison of right and left heart measurements to normal ranges should be part of every echocardiogram. M-mode parameters from the left ventricle can be used to estimate the wall stress of the left ventricle and its dynamic changes and the rate of relaxation. Systolic function can be estimated by measuring shortening fraction (SF): SF = (End-diastolic dimension − Systolic dimension)/End-diastolic dimension. In normovolemic patients, dimensional shortening of the left ventricular endocardial cavity can be used to estimate stroke volume.

Diastolic function can be assessed using tissue Doppler techniques and may be useful in the diagnosis of cardiac transplant rejection. Tissue Doppler is a technique by which low-velocity, high-intensity signals from the valve annuli and cardiac walls are examined to assess contraction and relaxation of the myocardium. New advances in the calculation of segmental wall strain are being studied. An easily obtained nongeometric parameter that is useful for assessment of right and left ventricular performance is the myocardial performance index. The so-called *Tei index* is the ratio of the isovolemic contraction time to the ejection time of the ventricle. This nongeometric index is useful for detecting systolic or diastolic function abnormalities when ventricular shape is not ideal, as in the morphologic right ventricle.

Valvular regurgitation allows estimation of the first derivative over time of the pressure change in the ventricle using the continuous-wave Doppler waveform. Practically, this can be calculated by measuring the time (in seconds) from the waveform at the 1 and 3 m/s points and dividing it into 32, which yields dP/dt (in millimeters of mercury per second).

Contrast Echocardiography

An ultrasonic contrast agent is a substance that stabilizes microbubbles in solution, which are large enough to reflect ultrasound but small enough that they disappear rapidly and are physiologically safe. The agent may be as simple as an injection of saline into the circulation during two-dimensional echocardiographic imaging or as complex as precision-engineered microbubbles of polysaccharide that dissolve in the circulation after injection. Advances in bubble technology allow imaging of myocardial capillary perfusion. Contrast also can be useful in defining the identity of an imaged structure. For example, a structure under the aortic arch may be confusing but can be confirmed to be the innominate vein by echocardiographic contrast injection in a left arm vein. In congenital heart disease, the major application of contrast echocardiography is in the postoperative patient with residual shunts or as a means to exclude congenital heart disease. Systemic venous injection of contrast fills the right side of the heart sequentially, and the site of residual right-to-left shunting can be defined. In the neonatal or pediatric intensive care unit, contrast injections using agitated saline can detect right-to-left interatrial shunting in cases of persistent pulmonary hypertension with difficulty oxygenating the patient.

Transesophageal Echocardiography

The indications for TEE in patients with congenital heart disease are expanding because TEE greatly aids intracardiac imaging. TEE is a technique that pediatric cardiologists cannot be without in surgical practice or in the care of the critically ill neonate or child. As with any new technique, there has been a learning curve, but the methods are now well developed and useful.[7] Use of training guidelines and frequent continuing education is desirable.[8] Biplane probes now come in many sizes so that even in neonates weighing 2.5 to 5 kg, a biplane probe can be passed safely in the operating room under general anesthesia, with minimal hemodynamic compromise. Multiplane probes for pediatric patients are improving slowly. Current technology allows use of a multiplane probe in patients weighing as little as 5 kg.

The reproducibility of quantitative measurements with TEE is good, that is, they are reproducible to within 5% for multiple examiners. TEE has special value in pediatric practice, particularly in left ventricular outflow obstruction and assessment of AV and semilunar valves. Assessment of mitral regurgitation is important after repair and re-repair of AV canal defects. TEE can identify the type and severity of mitral regurgitation and is superior to transthoracic echocardiography or cineangiography.[9,10]

Complications of TEE are more common in smaller patients. Failure to pass the probe occurs in approximately 0.8% of children with congenital heart disease, and airway obstruction occurs in approximately 1%.[11]

Echocardiography can be used during transcatheter closure for precise positioning of a device or coil. TEE also is useful

during ductal closure. Intraoperatively, ductal patency can be monitored during minimally invasive procedures.[12] For example, in neonates with critical aortic stenosis, balloon positioning can be monitored using TEE. Guidance of radiofrequency ablation catheters can be facilitated with TEE, particularly where single-ventricle anatomy is present.

Cardiac output can be estimated by TEE from the minute distance (time-velocity integral) measured in the descending aorta. Assessment of ventricular function using Doppler to estimate the first derivative of pressure in the left ventricle (dP/dt) is useful for identifying patients in need of inotropic support.[13]

The use of preoperative and postoperative TEE is increasing in the intensive care unit. Critically ill infants and children and those on assisted circulatory devices can be optimally evaluated this way. The average duration for performance of TEE includes approximately 42 minutes of technician time and 32 minutes of physician time.

Adults with congenital heart disease are best studied by TEE. Reviews of TEE use in pediatric patients suggest the technique will be increasingly utilized in the future[14,15] (Box 23-2). Combined use of TEE echocardiography and CT and MRI imaging shows comparable results in current studies.[16]

Specific Lesions

Shunts

Shunting lesions are well seen from the multiple-view possibilities offered by TEE. Shunts at the atrial level, for example, are most accurately defined by TEE. Defects at the fossa ovalis can be quantitated with regard to size and shunt. Sinus venosus defect can be readily seen, and the associated anomalies of pulmonary venous drainage detailed (Figure 23-9).

VSDs can be studied in detail, and multiple coexisting VSDs can be distinguished. The most common VSD is perimembranous VSD, which often is partially occluded by tricuspid valve tissue. The larger defects in this position may extend into either the inlet or the outlet septum. With experience, both size and position can be determined (Figure 23-10). Shunt is defined by color Doppler. Shunting through the patent ductus arteriosus can be observed from high probe positions.

Complex Heart Defects

Evaluation of complex congenital heart defects requires a segmental approach, exactly as with transthoracic imaging. For example, with a single AV valve, the situs, AV connection, and ventriculoarterial connection must be defined. With hypoplastic left heart syndrome, the function of the tricuspid valve is important, and the atrial septum should be assessed at each preoperative examination because of the possibility of late constriction. The details of AV canal defect can be defined, and the commitment of the valves and valvular function can be analyzed. With pulmonary artery atresia, a high-velocity jet from the right ventricle to right atrium is seen (Figure 23-11).

Left Heart Lesions

TEE can define left ventricular outflow obstruction with great accuracy. Details of the aortic valve, subvalvar region, and mitral valve can be easily seen. Three-dimensional imaging is now possible in real time, but with low resolution in the infant and child. This situation is expected to improve significantly in the future. TEE can precisely define the structure and function of the aortic valve and subaortic area. No other imaging tool performs as well in examining the fine structure of the cusps and the presence of regurgitation. After the Ross procedure, in which the pulmonary valve is transplanted into the left ventricular outflow tract, neoaortic valve function can be evaluated without difficulty.

Regurgitation of the mitral valve can be diagnosed, but assessment of the valve requires information about the mechanism of the regurgitation. A posteriorly directed jet is consistent with mitral valve prolapse. Doppler can be used to assess the hemodynamics, including dP/dt (Figure 23-12).[13]

Right Heart Lesions

In general, the right ventricular outflow tract is more difficult to evaluate by TEE because it is farther away from the transducer. Nonetheless, the details of tetralogy of Fallot can be seen and communicated to the surgeon in the operating room. The presence of complicating lesions can be defined. Accurate assessment of tetralogy of Fallot can be accomplished before and after surgery. The right ventricle to pulmonary artery gradient can be assessed using continuous-wave Doppler. The tricuspid valve can be seen well, and the details of its leaflets, chordal attachments, and function can be assessed. This observation is particularly important in infants with pulmonary atresia, intact septum, and hypoplasia of the valve. More than absolute measurements, diastolic and systolic function and structure of the valve best predict its potential for growth.

Special Considerations after Chest Trauma

Trauma to the chest can result in dissection or transection of the aorta. TEE imaging is the best technique for examining the ascending and descending portions of the aorta.

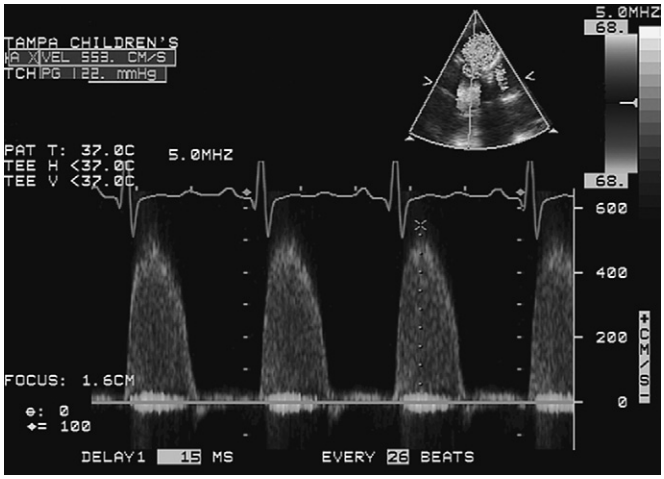

Figure 23–12. *Left,* The rate of upstroke of mitral regurgitation is quantified by measuring the time from the 1 to the 3 m/s points on the waveform, in this example 15 ms. dP/dt = 32 ∏ 15 ms ∞ 1000 = 2133 mm Hg/s, which is normal. *Right,* Mitral regurgitation from an apical view with alignment of the continuous-wave Doppler cursor.

Myocardial contusion can be recognized after edema develops in the myocardial wall, but may be suspected when cardiac enzyme elevations are disproportionate to the degree of myocardial dysfunction. Air in the chest may make transthoracic echocardiography difficult but often does not hamper a transesophageal approach.

Safety of Ultrasound

Significant adverse effects of ultrasound imaging, M-mode, or Doppler evaluation have not been reported. The potentially negative bioeffects of ultrasound can be classified as those caused by either cavitation or heating. Cavitation refers to the development of tiny, gas-filled bubbles that resonate at the ultrasonic frequency and induce neighboring particles of liquid to vibrate, potentially damaging the ultrasound-transmitting medium. Practically, the sound intensities used for echocardiography (typically 10 W/cm^2) are almost an order of magnitude less than those known to produce cavitation. Thermal effects may result from heat generated in the tissue. To

reach the thermal threshold for damage using modern ultrasonic intensities, an average intensity of 1000 W/cm^2 must be applied for hours.

Higher intensities with pulsed Doppler have the potential to cause cavitation, and concerns regarding Doppler use for first-trimester fetal assessment are being investigated.

Costs and Benefits

One major reason for the rapid proliferation of ultrasound use in pediatric practice is that the technique is noninvasive and generally painless. Ultrasound equipment is less expensive than radiographic equipment. Indications for cardiac catheterization are being reassessed. The development of echocardiography as an extension of the clinician's other assessment skills has decreased the need for catheterization, especially in neonatal patients. Echocardiography has the potential to decrease the cost of medical care for these patients.

For the most effective cardiovascular use of ultrasound, the physician should be involved in both the performance of the study and its interpretation. A more physician-intensive diagnostic process may benefit the patient but may be more expensive than comparable tests performed by technicians.

Trends

Technology is changing so rapidly that it is difficult to predict which technique will be optimal for a given lesion 5 years from now. The rapid development of nuclear magnetic resonance for imaging and spectroscopy is beginning to show potential. Rapid CT has potential to create high-quality, three-dimensional images in pediatric patients with a very short duration of exposure. These two modalities will become indispensable for assessment of extracardiac anatomy and the coronary arteries. Positron emission tomography can be used to assess myocardial perfusion, although it is rarely used in pediatric patients at this time. Emerging areas in echocardiography include the development of contrast agents, some of which allow myocardial blood flow assessment by ultrasonography; tissue characterization techniques; automated cardiac function assessment; three-dimensional real-time imaging and color Doppler display as well as stress and strain-rate assessment in three dimensions; invasive imaging probes for intracardiac imaging; transesophageal imaging in neonates for intraoperative functional assessment; and offline three-dimensional reconstruction of cardiac images from ultrasound datasets. One thing is certain, the roles of the various noninvasive diagnostic modalities used in assessing congenital heart disease will require continued reevaluation.

Chapter 24

Diagnostic and Therapeutic Cardiac Catheterization

Peter C. Laussen and Joshua Salvin

PEARLS

- The cardiac catheterization laboratory plays important diagnostic and therapeutic roles in the management of children in the pediatric intensive care unit.
- For patients with cardiac disease whose critical care course is not progressing as expected, early-exploration diagnosis of unsuspected or residual defects by cardiac catheterization often improves outcomes.
- To derive the maximum benefit from hemodynamic, angiographic, and interventional procedures, effective communication between the intensive care physician and the interventional cardiologist before, during, and after the procedure is essential.

The cardiac catheterization laboratory plays an important diagnostic and therapeutic role in the management of children in the critical care environment. Obtaining comprehensive hemodynamic data in the catheterization laboratory helps formulate and tailor management strategies. In the postoperative patient, the diagnosis of unsuspected or residual cardiac anatomic defects, using hemodynamic data and angiography obtained during cardiac catheterization, may enable therapeutic surgical or catheter-directed interventions to improve a patient's outcome. Numerous interventions can be performed during cardiac catheterization, such as balloon dilation of stenotic blood vessels, atrioventricular, and semilunar valves; device closure of intracardiac and extracardiac shunts; and radiofrequency ablation of an arrhythmic focus. The pediatric critical team must be aware of the possible benefits and limitations of catheterization procedures, and effective communication between the intensive care physician and the physician performing the procedure is crucial.

Catheterization Laboratory Environment

Cardiac catheterization laboratories usually are remote from the intensive care unit and rarely are configured to accommodate critical care personnel and equipment. Relative to patient size, the lateral and anteroposterior cameras used for imaging are in close proximity to the patient's head and neck, limiting access to the airway. A mechanical ventilator and monitors around the patient further confine the space in which the critical care team works and limit access to the patient during a procedure. In addition, the environment is darkened to facilitate viewing of images, and full monitoring, either invasive or noninvasive, must be established before the procedure begins. Because of limited access to the patient and airway, end-tidal capnography and pulse oximetry are mandatory to ensure adequate ventilation and oxygenation during the procedure and to provide immediate detection of disconnection or dislodgment of the endotracheal tube that could inadvertently occur during movement of the catheterization table and cameras. The environment is cooler because of computer and x-ray equipment, and children may become hypothermic from conductive and convective heat loss; this is a particular problem in neonates and infants. In addition, frequent flushing of the catheters and sheaths to prevent clotting or air embolism may contribute to hypothermia. Unnecessary exposure of the child must be prevented, and convective warming blankets used where possible. Care must be taken when positioning a patient on the catheterization table because of the risk to pressure areas and of nerve traction injury. In particular, brachial plexus injury may occur when the patient's arms are positioned above the head for prolonged periods to enable better exposure for the lateral camera. To facilitate femoral vein and arterial access, the pelvis is commonly elevated from the catheterization table. This position may displace abdominal contents cephalad, restricting diaphragm excursion and increasing the risk for respiratory depression in a sedated patient.

Safe transportation of a critically ill child from the intensive care unit to the catheterization laboratory can be a significant challenge but should not be a deciding factor as to whether or not the procedure should be performed. Safe transport requires planning and multidisciplinary coordination. This process includes physician and nursing staff accompanying the patient with complete monitoring and resuscitation equipment, respiratory therapy staff to assist with ventilation and establishing mechanical ventilation in the catheterization laboratory if indicated, coordinating timing with the catheter laboratory staff to prevent needless delays, assistance with establishing adequate space for equipment and patient access in the laboratory, and correct positioning on the catheterization table to enable access for both the catheterizer and intensive care staff as necessary.

Adequate sedation and anesthesia during cardiac catheterization are essential to facilitate acquisition of meaningful hemodynamic data and to assist during interventional procedures. For the most part, hemodynamic or diagnostic catheterization procedures can be performed with the patient under sedation.[1] For many interventional procedures, sedation may be appropriate; however, for procedures that are associated with significant hemodynamic compromise or are prolonged, general anesthesia is preferable. Whatever technique is used, hemodynamic data must be attained in conditions as close to normal as possible. For accurate calculation of the intracardiac shunt, reducing the inspired oxygen concentration to room air may be necessary, although this step requires close collaboration with the catheterizer because lowering Fio_2 may be inadvisable in patients with significant desaturation and lung injury.

Hemodynamic and Oxygen Saturation Data

Hemodynamic cardiac catheterization may not be necessary when echocardiographic analysis with Doppler measurements and color flow mapping is complete and unambiguous. However, in patients with complex cardiac anatomy, severe low cardiac output state, pulmonary hypertension, severe lung injury of uncertain etiology, or with concerns for important residual anatomic lesions after cardiac surgery, physiologic data from catheterization may provide important information.[2] Catheterization allows description of the direction, magnitude, and approximate location of intracardiac and intrapulmonary shunts. Intracardiac and intravascular pressures are measured to determine the presence of obstructions and whether shunt orifices are restrictive or nonrestrictive. Pressure gradients across sites of obstruction must be considered in light of estimated cardiac output, as a small pressure gradient measured at a time of low cardiac output is misleading.

Normally, no significant change in oxygen saturation from venae cavae to pulmonary artery is observed. In the child with congenital heart disease, the superior vena cava provides the simplest mixed venous oxygen saturation. A greater than 5% to 10% increase in oxygen saturation from the superior vena cava through to the pulmonary artery suggests the presence of a left-to-right shunt at the level of the right atrium with an atrial septal defect (ASD), in the right ventricle (RV) with a ventricular septal defect (VSD), and in the pulmonary artery with a patent ductus arteriosus (PDA) or aorto-pulmonary artery collateral vessels.[3] The magnitude of the left-to-right shunt can be calculated by applying the Fick equation to the pulmonary and systemic vascular beds separately (assuming O_2 uptake and consumption are equal):

$$Qp = VO_2 / (SpvO_2 - SpaO_2)\ (Hb)\ (1.36)\ (10) \quad (1)$$

$$Qs = VO_2 / (SaO_2 - SsvcO_2)\ (Hb)\ (1.36)\ (10) \quad (2)$$

where *Qp* is pulmonary blood flow, *Qs* is systemic blood flow, Vo_2 is oxygen consumption, $Spvo_2$ is pulmonary vein saturation (which can be assumed to be 0.96 in the absence of significant pulmonary disease), $Spao_2$ is pulmonary artery saturation, Sao_2 is arterial oxygen saturation, $Ssvco_2$ is superior vena cava oxygen saturation, and *Hb* is hemoglobin. (Note that saturation data in the equations is expressed as a decimal number and not as a percentage, e.g., 98% saturation = 0.98.)

In pediatric patients, the pulmonary and systemic flows usually are indexed to body surface area:

$$CI = Qs / BSA \quad (3)$$

where *CI* is cardiac index and *BSA* is body surface area.

Thermodilution can be used to calculate the cardiac output in pediatric patients, although it is confounded by the presence of intracardiac or extracardiac shunts.[4] Although measurement of oxygen consumption is preferable[5] because assumed values are unreliable in patients with critical illness and in those requiring substantial hemodynamic support, the practical reality is that the majority of catheterization laboratories tend to assume oxygen consumption.[6] The inherent error of all calculations should always be considered, particularly with respect to flow and resistance calculations.

The pulmonary to systemic blood flow ratio (Qp/Qs) can be derived simply from the measured oxygen saturation values because all other variables cancel out (from Equations 1 and 2):

$$Qp / Qs = (SaO_2 - SsvcO_2) / (SpvO_2 - SpaO_2) \quad (4)$$

The patient whose aortic blood is fully saturated can be assumed to have no significant right-to-left intracardiac shunt. However, when a right-to-left shunt is present, oxygen saturations also should be obtained from the pulmonary veins, left atrium, and left ventricle to determine the source of desaturated blood. Pulmonary venous desaturation implies a primary pulmonary source of venous admixture (e.g., pneumonia, atelectasis, or other pulmonary disease).

Vascular resistance is calculated by the change in pressure divided by the flow (Dp/Q):

Pulmonary vascular resistance (PVR) =

$$(Mean\ PAP - Mean\ LAP) / Qp \quad (5)$$

Systemic vascular resistance (SVR) =

$$(Mean\ AoP - Mean\ SVCP) / Qs \quad (6)$$

where *PAP* is pulmonary artery pressure, *LAP* is left atrial pressure, *AoP* is aortic pressure, *SVCP* is superior vena cava pressure, *Qp* is pulmonary blood flow, and *Qs* is systemic blood flow.

Once again for pediatric patients, the vascular resistance usually is indexed to body surface area and expressed as Wood units:

$$PVR = (Mean\ PAP - Mean\ LAP)(BSA) / Qp \quad (7)$$

$$SVR = (Mean\ AoP - Mean\ SVCP)(BSA) / Qs \quad (8)$$

Assessment of Critical Illness

The cardiac catheterization laboratory can be useful in a number of situations during the management of critically ill infants and children who have structurally normal hearts (Table 24-1) or congenital heart disease. Fluoroscopy can be used to assist with placing difficult central venous or pulmonary artery lines, performing pericardiocentesis and pleurocentesis, and assessing diaphragm function.

Patients with pulmonary hypertension can benefit from investigation in the catheterization laboratory. Catheterization may help diagnose or rule out structural disease involving the pulmonary arteries or pulmonary veins, as in cases of

multiple thromboembolic disease or undiagnosed pulmonary vein stenosis. Data obtained during catheterization are important for evaluation of the response of pulmonary vasculature to vasodilator treatment, for example, with increased Fio_2 or inhaled nitric oxide.[7] Such evaluation and measurement of a specific response is important for longer-term management strategies of patients with pulmonary hypertension. In the presence of a left-to-right shunt and elevated PVR, pressure and saturation measurements often are repeated with the patient breathing 100% oxygen to assess both the reactivity of the pulmonary vascular bed and any contribution of ventilation/perfusion abnormalities to hypoxemia. If breathing 100% oxygen and inhaled nitric oxide increases pulmonary blood flow and dramatically increases Qp/Qs (with a fall in PVR), potentially reversible processes such as hypoxic pulmonary vasoconstriction may be contributing to the elevated PVR. The patient with a high, unresponsive PVR and a small left-to-right shunt may have extensive pulmonary vascular damage from the underlying lung injury or irreversible obstructive pulmonary vascular disease.

The reactivity of the pulmonary vascular bed and change in PVR are important components to the assessment of patients potentially listed for cardiac transplantation. An elevated PVR or pulmonary artery pressure is a risk factor for cardiac transplantation. PVR likely is elevated in patients with heart failure associated with left atrial hypertension. However, if PVR decreases with 100% FiO_2 or inhaled nitric oxide when these patients are tested during pretransplant catheterization, they still may be suitable candidates for cardiac transplantation.

Patients who present with severe cardiac failure because of myocarditis or idiopathic dilated cardiomyopathy or intractable dysrhythmias often require cardiac catheterization, not only for hemodynamic assessment but also for endomyocardial biopsy. Biopsies in these circumstances can be associated with significant morbidity, and treatment of the baseline condition should not be delayed until catheterization is performed.[8,9] The risk of myocardial perforation is particularly increased in infants with thin-walled ventricles, and biopsy should be reconsidered in infants with a very dilated and poorly functioning left ventricle. Patients who have a low cardiac output state associated with fulminant myocarditis are at risk for dysrhythmias during catheterization, and resuscitation resources must be immediately available, including mechanical support. The catheterization study and desire for a biopsy in an effort to establish a diagnosis must not take priority over efforts to support the circulation and maintain cardiac output.

Table 24–1 Indications for Cardiac Catheterization or Management in the Catheterization Laboratory of Pediatric Intensive Care Patients with Noncongenital Heart Disease

Diagnostic	• Hemodynamic evaluation of intracardiac and intravascular pressures and oxygen saturations • Evaluation of persistent hypoxemia: Pulmonary vein desaturation Decreased pulmonary blood flow Intracardiac right to left shunt • Cardiac output measurement • Pulmonary hypertension assessment and reactivity • Fluoroscopy: Central venous catheter position Diaphragm movement • Myocardial biopsy
Therapeutic	Pericardiocentesis Pleurocentesis Radiofrequency catheter ablation of an arrhythmogenic focus

Transcatheter Radiofrequency Ablation

Pediatric patients undergoing radiofrequency catheter ablation (RFCA) vary in age and diagnosis.[10] Ablation may be necessary in newborns or infants with persistent reentrant tachycardia or ectopic atrial tachycardia[11,12] and in older children with ectopic foci but otherwise structurally normal hearts that are refractory to or poorly controlled by conventional antiarrhythmic drugs. If an incessant dysrhythmia, particularly a supraventricular tachycardia such as ectopic atrial tachycardia or permanent junctional reciprocating tachycardia, is the primary cause of a dilated poorly contracting heart at the time of presentation, electrophysiologic study and mapping of the dysrhythmia focus may be important diagnostic steps performed in the catheterization laboratory. Elective mechanical support of the circulation with extracorporeal membrane oxygenation (ECMO) may be indicated in order to preserve hemodynamic stability during ablation.[13] Successful RFCA in this circumstance may enable recovery of ventricular function.[14]

An increasing population of patients undergoing ablation consists of those with previous surgical repair of congenital heart defects. Patients with persistent volume or pressure load on the right atrium and those who required an extensive incision and suture lines within the right atrium, such as following a Mustard, Senning, or Fontan procedure, may be at increased risk for supraventricular tachyarrhythmias (SVT) such as atrial flutter and fibrillation.[15,16] Ventricular tachyarrhythmias may develop late after repair of certain congenital heart defects, such as right ventricular outflow tract reconstruction for tetralogy of Fallot.[17]

RFCA procedures can be lengthy. Because children find it difficult to lie still for prolonged procedures, endotracheal general anesthesia is usually preferred. In addition, patients must remain immobile to prevent catheter movement at the time of ablation, because sudden patient movement may result in creation of a radiofrequency lesion at an incorrect site. For instance, if the focus is close to the atrioventricular (AV) node, inadvertent movement might displace the catheter and cause permanent AV conduction blockade.

On occasion, holding ventilation in either inspiration or expiration may be necessary to ensure adequate contact of the ablation catheter with the arrhythmic focus. For the most part, RFCA procedures are well tolerated hemodynamically and blood loss is minimal. During mapping, the focus is stimulated and the tachyarrhythmia induced. This situation may result in hypotension but usually is short-lived and can be readily converted via intracardiac pacing. If hypotension is prolonged and intracardiac conversion is unsuccessful, transthoracic cardioversion may be necessary; therefore a defibrillator should be immediately available.

Congenital Heart Disease

Although most congenital heart defects can be evaluated noninvasively by echocardiography or, more recently, by magnetic resonance imaging, further preoperative evaluation by angiography is essential in some instances to assist with surgical planning.

Patients with pulmonary atresia and intact ventricular septum (PA/IVS) require careful examination of the coronary anatomy prior to decompressing the RV either surgically or with catheterization techniques, because of the possible presence of fistulas from the RV to the coronary artery circulation.[18,19] RV to coronary artery fistulas can be seen on echocardiography, but selective right ventricular angiography and aortography, or even selective coronary angiography if necessary, are important to determine any associated coronary stenoses or atresia (RV-dependent coronary circulation).[20] Myocardial ischemia can occur if the right ventricle pressure decreases after the outflow tract is opened, leading to arrhythmia and myocardial failure. At another end of this spectrum, patients with tetralogy of Fallot and pulmonary atresia often have diminutive native pulmonary arteries. Aortopulmonary collaterals may contribute greatly to pulmonary blood flow. Angiography can delineate the exact location and anatomy of these collaterals and, if indicated, may be followed by coil occlusion of aortopulmonary collaterals that provide dual supply to the native pulmonary arteries. It is important to know the extent of collateral vessels prior to surgery and cardiopulmonary bypass because of the risk for impaired systemic perfusion from excessive runoff to the pulmonary circulation.

Patients with hypoplastic left heart syndrome with mitral stenosis and aortic atresia (MS/AA) may also be at higher risk for early mortality after stage one palliation with the Norwood procedure.[21] Analogous to the PA/IVS patient population, patients with MS/AA may have left ventricle-subepicardial coronary artery fistulae, and be at risk for inadequate myocardial protection during cardiopulmonary bypass and ischemia following stage one palliation. Preoperative coronary angiography may be warranted in this subgroup prior to surgical palliation.[22] Finally, preoperative angiography may be useful in patients with obstructed total anomalous pulmonary venous connection (TAPVC). While pulmonary venous anatomy can often be determined by noninvasive methods, palliative transcatheter approaches to relief of pulmonary venous obsruction may be lifesaving in the critically ill neonate.[23,24]

Therapeutic Interventions in the Newborn

Interventional cardiac catheterization has matured. Many specific anatomic defects can be treated in the catheterization laboratory to alleviate the need for surgical intervention.

Atrial Communication Procedures

The first therapeutic procedure performed in the catheterization laboratory for congenital heart disease was balloon atrial septostomy (BAS) in newborns diagnosed with transposition of the great arteries (TGA) with intact ventricular septum.[25] A BAS usually is needed in newborns with TGA to facilitate mixing of systemic and pulmonary venous return at the atrial level prior to the arterial switch operation. This procedure can be performed by echocardiographic guidance[26] (Figure 24-1) or in the cardiac catheterization laboratory if additional diagnostic information is required or there are potential vascular

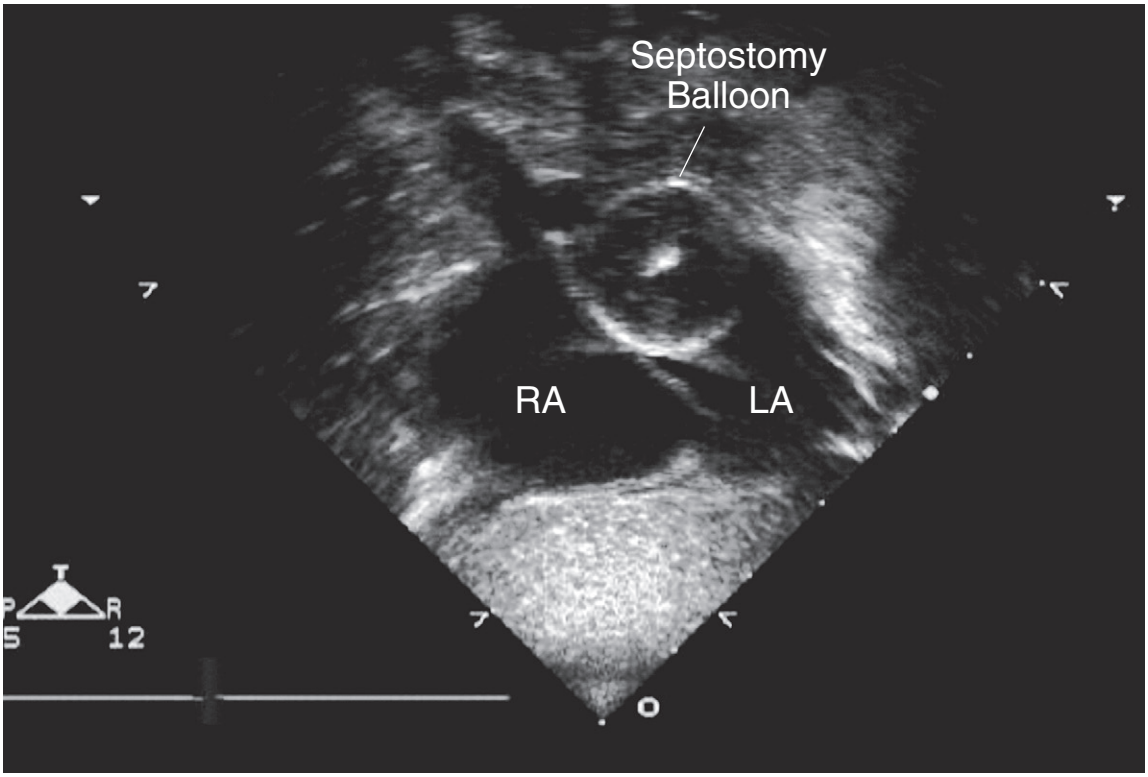

Figure 24–1. Echocardiography-guided balloon atrial septostomy. From the subcostal view, the septostomy balloon is easily seen as it inflates in the left atrium *(LA)*. ***RA,*** Right atrium.

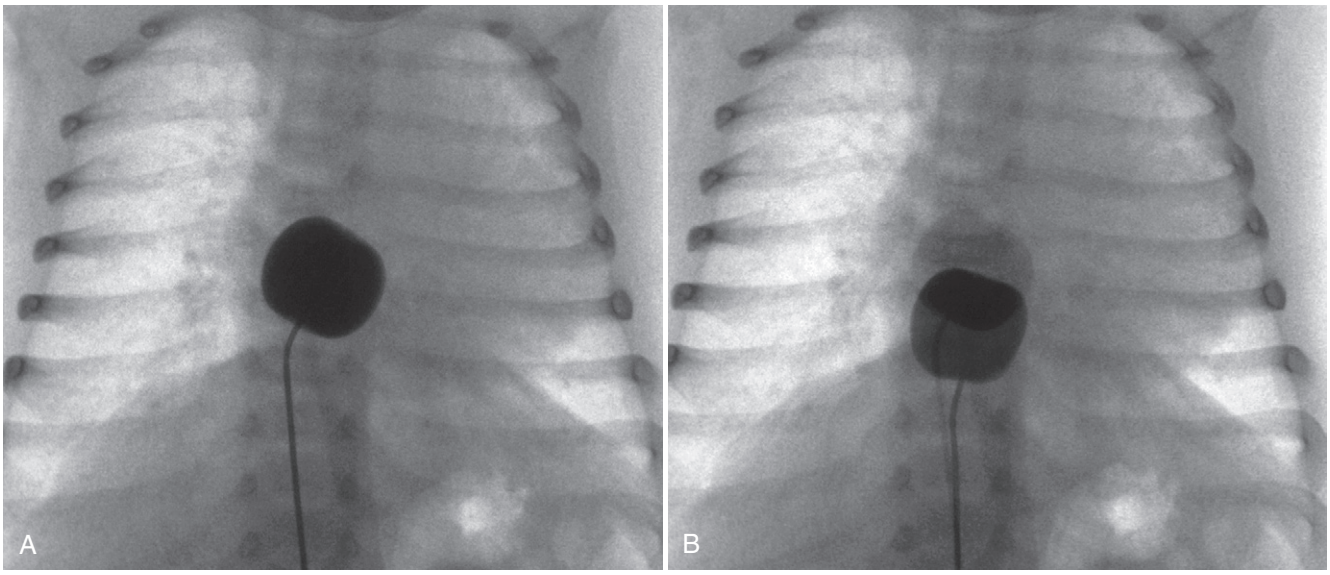

Figure 24–2. Fluoroscopy-guided balloon atrial septostomy. **A,** The balloon is inflated with diluted contrast and positioned in the left atrium. **B,** The balloon is rapidly "jerked" across the atrial septum, resulting in a tear in the septum primum and enabling complete mixing of blood in the atria.

access problems. Via either the femoral or umbilical vein, a balloon catheter is advanced across the atrial defect from right atrium to left atrium (Figure 24-2, *A*) and its position is confirmed by echocardiographic or fluoroscopic guidance. The balloon is inflated to the desired volume and jerked back to the right atrium to tear the septum primum (Figure 24-2, *B*). While it has been reported that BAS may be associated with an increased risk for embolic neurological injury, this has not been the experience at our institution and others. It is always preferable to facilitate mixing at the atrial level and reduce left atrial pressure and risk for pulmonary hypertension prior to cardiac surgery and the arterial switch procedure. The BAS can be performed under fluoroscopic or echocardiographic guidance, and whatever the mode of imaging, it is important that anticoagulation with 50 U/kg of heparin be administered prior to balloon inflation and tearing of the atrial septum.[27-29]

In some patients with a single-ventricle lesion (such as mitral atresia or hypoplastic left heart syndrome) and who also have a restrictive or near intact atrial septum, the left atrial pressure may be very high at birth, causing pulmonary edema and pulmonary artery hypertension. The physiology in this circumstance is identical to that of patients with obstructed TAPVC. Patients usually are cyanotic with a low cardiac output state, and urgent dilation of the atrial septum to lower the atrial pressure and improve mixing can be lifesaving.[30,31] It also allows the pulmonary artery pressure to decrease and pulmonary edema to resolve prior to stage 1 palliation. It is important to appreciate that the atrial septum often is thickened in these patients, which is quite different than the thin-walled restrictive foramen ovale of patients with TGA. Because of its thickness, disruption of the septum using a balloon atrial septostomy technique is usually not possible. In addition to the thickened atrial septum, the atrial cavity size usually is small, so inflating a balloon in the left atrium without causing myocardial injury or tearing a pulmonary vein may be difficult. Instead, decompression of the pulmonary atrium can be achieved with a Brockenbrough transseptal puncture (Figure 24-3, *A*), followed by an atrial septoplasty involving balloon dilation of the thickened or restrictive atrial septum and possible stent placement across the defect to maintain a gradient across the septum of 4 to 6 mm Hg (Figure 24-3, *B*). Because of the degree of cyanosis and the low cardiac output state, concurrent resuscitation with volume replacement, inotrope support, and mechanical ventilation are usually necessary during this procedure until adequate mixing is established and pulmonary veins are decompressed.

Pulmonary Balloon Valvotomy

Congenital pulmonary valve stenosis may present as a murmur heard in the newborn period. If the obstruction is mild, intervention with balloon dilation can be deferred. Newborns with critical pulmonary valve stenosis or pulmonary valve atresia have severe restriction or absence of antegrade flow across the right ventricular outflow and, as a result, have ductus arteriosus-dependent pulmonary blood flow. Balloon dilation in the catheterization laboratory is the therapeutic procedure of choice (Figure 24-4).[32,33] A balloon catheter is passed over a guidewire antegrade across the pulmonary valve, and balloon dilation, usually up to 120% size of the pulmonary valve annulus, is performed. Heart block and ventricular ectopy may occur with wire manipulation in the RV but usually are transient. Antegrade flow across the pulmonary valve may not increase significantly after balloon dilation until right ventricular compliance improves, and continuation of prostaglandin E1 (PGE1) infusion to maintain patency of the ductus arteriosus for several days following balloon dilation may be necessary. Perforation of the relatively thin right ventricular outflow tract with the guidewire is a potential complication, particularly in low-birth-weight and premature newborns.

Aortic Balloon Valvotomy

The newborn with critical valvar aortic stenosis who develops hypotension and acidosis as the ductus arteriosus closes requires resuscitation with PGE1 to restore aortic flow, plus mechanical ventilation and inotropic support to achieve stabilization before an intervention is performed. Balloon dilation

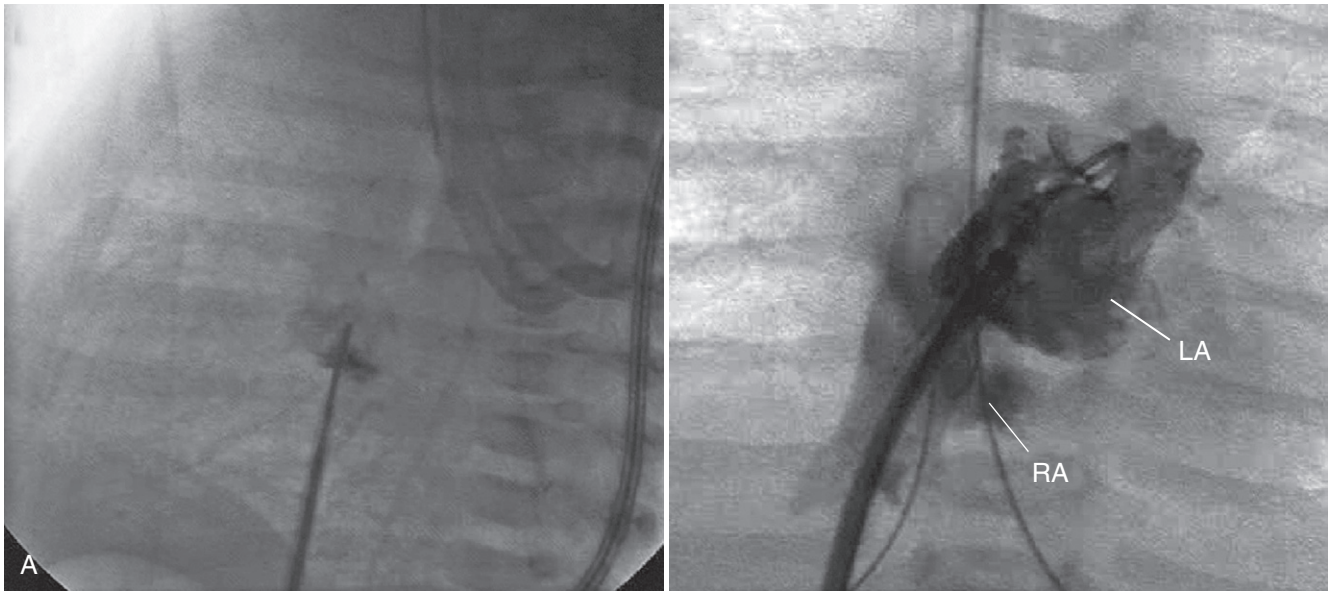

Figure 24–3. Atrial septoplasty in a newborn with restrictive atrial septum and hypoplastic left heart syndrome. **A,** Lateral view of a Brockenbrough transseptal needle introduced across the thickened atrial septum and contrast injected into the small left atrium. **B,** Anteroposterior view following stent placement across the thickened atrial septum. Contrast is seen equally in both the left atrium (*LA*) and the right atrium (*RA*).

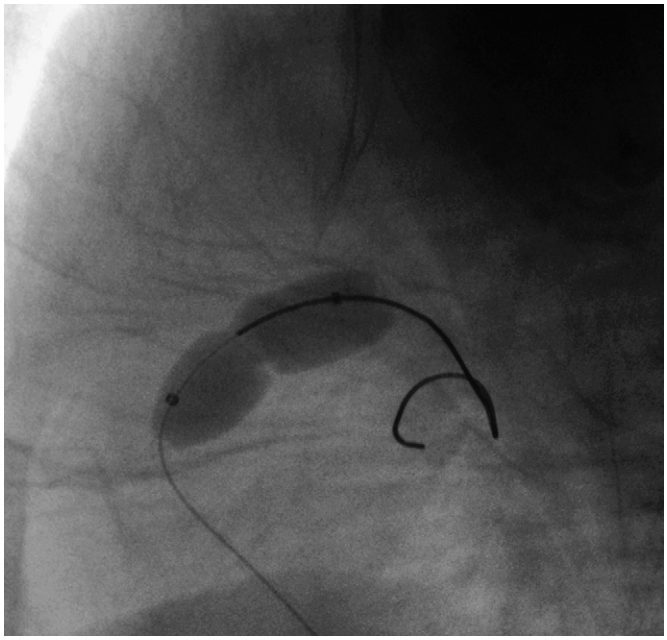

Figure 24–4. Pulmonary valvuloplasty in a newborn with severe pulmonary valve stenosis. Lateral view with balloon catheter centered across a stenotic pulmonary valve. As the balloon is inflated, a "waist" representing the stenotic valve is seen.

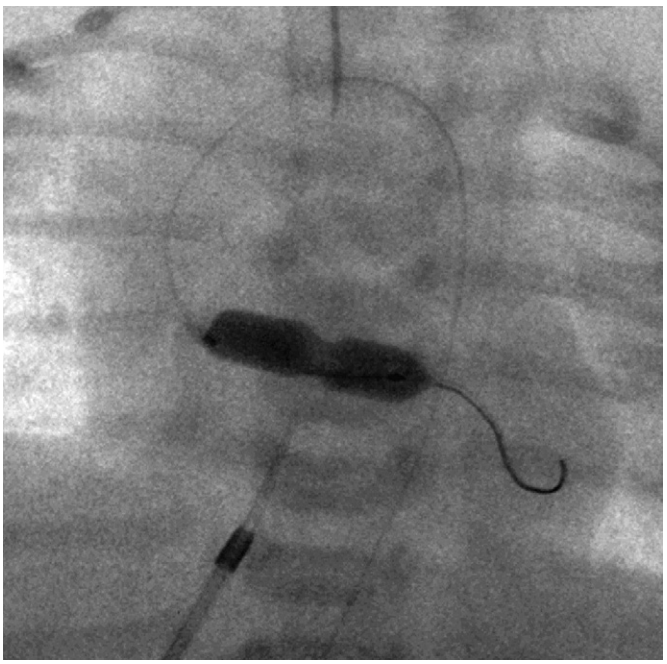

Figure 24–5. Aortic valvuloplasty in a newborn with critical aortic stenosis. Anteroposterior view with retrograde catheter course from the femoral artery. The balloon, also with the "waist" apparent, is seen being inflated across the aortic valve.

of the stenotic aortic valve during cardiac catheterization is the preferred intervention (Figure 24-5),[34] although surgical valvotomy under direct vision using cardiopulmonary bypass (CPB) is the surgical alternative. At catheterization, a guidewire is passed either retrograde (via femoral artery) or antegrade (via femoral vein) across the aortic valve. A balloon catheter is passed over the wire and serial dilations performed up to 90% to 100% size of the aortic valve annulus. The pressure gradient across the aortic valve is remeasured after each dilation, and an ascending aortogram is obtained to evaluate aortic valve regurgitation. Because of the initial minimal flow across the valve, balloon dilation of critical neonatal aortic stenosis usually is well tolerated. Despite the successful relief of obstruction, antegrade flow across the valve may not increase significantly until left ventricular compliance and function improve; therefore continuation of PGE1 infusion, mechanical ventilation, and vasoactive drugs following dilation for some days may be necessary. Until flow across the

valve increases, the residual gradient across the aortic valve will be underestimated by echocardiography, and serial studies usually are necessary to track the evolving gradient and left ventricular function. Other complications include possible mitral valve damage from a relatively stiff guidewire if an antegrade approach is used for dilation, and possibly ventricular fibrillation and an acute low cardiac output state secondary to coronary ischemia in patients with a hypertrophied ventricle.

Perioperative Interventional Procedures

A thorough understanding of the anatomy and morphology of complex congenital heart defects is essential for successful management of patients with complex congenital heart disease. This is particularly critical when establishing a diagnosis and planning surgical intervention. Important for the successful perioperative management in the intensive care unit is a thorough understanding of the pathophysiology of various defects. This understanding includes not only the preoperative pathophysiology associated with defects but also the potential alteration in pathophysiology related to surgical repair and/or development of complications in the postoperative period. As a general guide, if patients are not progressing as expected and low cardiac output persists, early cardiac catheterization should be performed to investigate and exclude the possibility of undiagnosed or residual structural defects. Despite biases to the contrary, early postoperative catheterization can be performed by an experienced catheterizer and anesthetic team with no significant increased risk of adverse events.[35,36] Transcatheter treatment of congenital cardiac defects continues to evolve and expand, and in some circumstances is effectively replacing the need for conventional intraoperative surgical procedures.[37] This experience has a significant impact on the severity and complexity of illness seen in the operating room and interventional laboratory. For example, several centers are routinely palliating hypoplastic left heart syndrome with a hybrid approach including transcatheter-based ductal and atrial septal stents along with pulmonary artery bands, with favorable intermediate stage results.[38] Transcatheter pulmonary valves have been successfully inserted in patients with right ventricular outflow tract conduit dysfunction.[39] Additional interventions now routinely performed in the catheterization laboratory include angioplasty, often combined with transcatheter placement of endovascular stents, for treatment of systemic and pulmonary arterial and venous stenoses, and device occlusion or embolization of systemic-to-pulmonary arterial communications, venous channels, fistulas, muscular VSDs, ASDs, and PDAs.

Risks and Complications

Placement of catheters in and through the heart increases the risk for dysrhythmias, perforation of the myocardium, damage to valve leaflets and chordae, cerebral vascular accidents, and air embolism. Use of radiopaque contrast material may cause an acute allergic reaction (rare in children with the use of nonionic contrast media), pulmonary hypertension, renal impairment, and myocardial depression. Blood loss may be sudden and unexpected when large-bore catheters are used or vessels are ruptured. More insidious blood loss may occur over several hours in heparinized small children or neonates because of bleeding around the catheter site or multiple aspirations and flushes of catheters. Transfusion requirements and appropriate vascular access should be continually assessed.

Arrhythmias, albeit transient, may be recurrent and even fatal if not promptly treated. Arrhythmias include catheter-induced SVTs, ventricular tachycardia, ventricular fibrillation, and occasionally complete heart block requiring temporary transvenous pacing support. On most occasions, removing the wire or catheter resolves the arrhythmia, but full resuscitation and cardioversion equipment must be available in case the arrhythmia does not resolve.

The complications of various interventional procedures are related in part to the type of procedure, but all share the risks associated with percutaneous vascular access with large catheters that course through the heart and vessels.[40-43] Table 24-2 lists the specific problems that can occur during various transcatheter procedures. Overall adverse event (AE) rates are in the range of 5% to 18%, with higher AE rates reported in interventional (20%) versus noninterventional (10%) catheterization procedures.[44] Many complications are potentially life-threatening, and successful treatment of complications depends on prompt action by critical care physicians and/or anesthesiologists cooperating closely with the interventional cardiologists who are manipulating the catheters.

Balloon Dilation of Pulmonary Arteries

Pulmonary artery balloon dilation and stent placement to relieve stenosis is a common procedure performed in the catheterization laboratory.[45] Pulmonary artery stenoses may be congenital or acquired lesions. They may be discrete, involving the main or branch pulmonary arteries, or multiple, involving distal segmental vessels. The increase in pulmonary artery pressure and fixed resistance to antegrade pulmonary blood flow may have related and deleterious consequences, which include the following:

1. An increase in the afterload on the RV, which in turn causes right ventricular hypertension. The RV can cope with a significant pressure load for some time. However, as right ventricular end-diastolic pressure increases and tricuspid regurgitation possibly develops, right atrial pressure increases and manifests as hepatomegaly, ascites, and persistent or recurrent pleural effusions.
2. Reduced antegrade flow across the pulmonary outflow, which in turn reduces preload to the left ventricle and contributes to a low cardiac output state. Further, the hypertrophy of the ventricular septum reduces the compliance of the left ventricle and increases left ventricular end-diastolic pressure.
3. An increase in right ventricular pressure and ventricular hypertrophy may compromise coronary blood flow. Hypotension or tachycardia with altered coronary filling time may cause myocardial ischemia, with the subendocardium at particular risk.
4. If the pulmonary valve is incompetent, for example, following right ventricular outflow reconstruction for repair of tetralogy of Fallot with or without pulmonary atresia, a considerable amount of pulmonary regurgitation may occur that causes an additional volume load on the RV, leading to right ventricular dilation and systolic failure. In addition, the increased pulsatility to the branch pulmonary arteries may cause extrinsic compression of the main stem bronchi.

Table 24–2 Potential Complications in the Catheterization Laboratory

Procedure	Representative Lesion	Complications
Hemodynamic evaluation	Congenital heart disease Pulmonary hypertension Postoperative course; progress not as expected, persistent low cardiac output state, inability to wean from mechanical ventilation, persistent chylous effusions; evaluate residual intracardiac shunt or outflow tract obstruction	Blood loss requiring transfusion Air embolism Vascular access; trauma, dissection, occlusion, perforation Myocardial perforation and tamponade Arrhythmias; ventricular and supraventricular tachycardia, ventricular fibrillation, complete heart block
Coil embolization	Aortopulmonary collaterals Systemic-pulmonary shunts	Fevers Excessive hypoxemia Systemic embolization
Transcatheter device closure	Patent ductus arteriosus Atrial septal defect Ventricular septal defect Baffle leak	Air or device embolization Blood loss Interference with AV value function Arrhythmias; ventricular arrhythmias, complete heart block
Balloon and stent dilations	Pulmonary artery stenosis	Pulmonary artery tear and hemorrhage Pulmonary edema: high flow False aneurysm Right ventricle ischemia
	Pulmonary valve stenosis	As above Pulmonary valve regurgitation
	Mitral valve stenosis	Mitral insufficiency Pulmonary hypertension
	Coarctation of the aorta	Aortic dissection Hypertension
	Right ventricular conduit	False aneurysms Stent embolization
Atrial septotomy	Transposition of the great arteries, mitral stenosis (atresia), and restrictive atrial septum	Perforation of the heart and tamponade

Patients with persistent signs of right ventricular failure, such as low cardiac output state, hepatomegaly, ascites, recurrent pleural effusions (particularly if chylous in nature), and inability to wean from mechanical ventilation, should be considered for catheterization. Although echocardiography may help determine a specific problem, catheterization provides quantitative data that can direct vasoactive support and enable interventions such as pulmonary artery dilation, coiling of collateral vessels, and creation of an atrial communication that allows an atrial level right-to-left shunt.

The function of the right ventricle is critical, and often the cause of complication is related to pulmonary artery dilation. At the time of balloon dilation, cardiac output may decrease significantly, causing hypotension, bradycardia, arterial oxygen desaturation, and a fall in end-tidal CO_2. Because the balloon is inflated for only a few seconds and provided preload is maintained, the procedure usually is well tolerated and the circulation usually recovers spontaneously. Patients who have a hypertrophied, poorly compliant RV with intraventricular pressures at systemic or suprasystemic levels may not tolerate the sudden increase in afterload associated with balloon dilation, even for a short period. In particular, myocardial ischemia and arrhythmias may occur, causing severe acute right ventricular failure and loss of cardiac output. General anesthesia and controlled ventilation are recommended prior to intervention in this at-risk group of patients.

Pulmonary artery disruption is signaled by local extravasation of contrast in the lung parenchyma, sudden hemodynamic deterioration from cardiac tamponade or acute hemothorax, or sudden onset of hemoptysis.[46] The tear in the pulmonary artery may be confined (Figure 24-6, *A*) and therefore controlled, or unconfined, resulting in hemodynamic collapse and the possible need for immediate surgical intervention. The potential for pulmonary artery disruption is increased because of the high pressure used to inflate the balloon and maintain tension on the vessel wall to tear the intima and media. The risk for pulmonary artery disruption may be increased in early postcardiac surgery patients if the dilation is performed across a recent pulmonary artery anastomosis. The safe time frame to wait for the anastomosis to heal before attempting balloon dilation has not been determined. If the patient is stable without signs of right ventricular failure or low cardiac output state, we prefer to wait 6 weeks after surgery before proceeding with balloon dilation. However, early balloon dilation may be necessary in the immediate postoperative period, particularly if the patient has severe right ventricular failure, low cardiac output state, or inability to wean from mechanical ventilation. Provided the dilation is performed cautiously with all resuscitation facilities immediately available, successful balloon dilation can be achieved in the immediate postcardiac surgery period.[47] Cutting balloons have been added to the options available for achieving successful balloon dilation.[48] The relative safety between a cutting balloon and high pressure dilations is unknown, but a high index of suspicion should be maintained in patients with peripheral pulmonary artery stenosis treated with a cutting balloon. In the presence of substantial hemoptysis, immediate

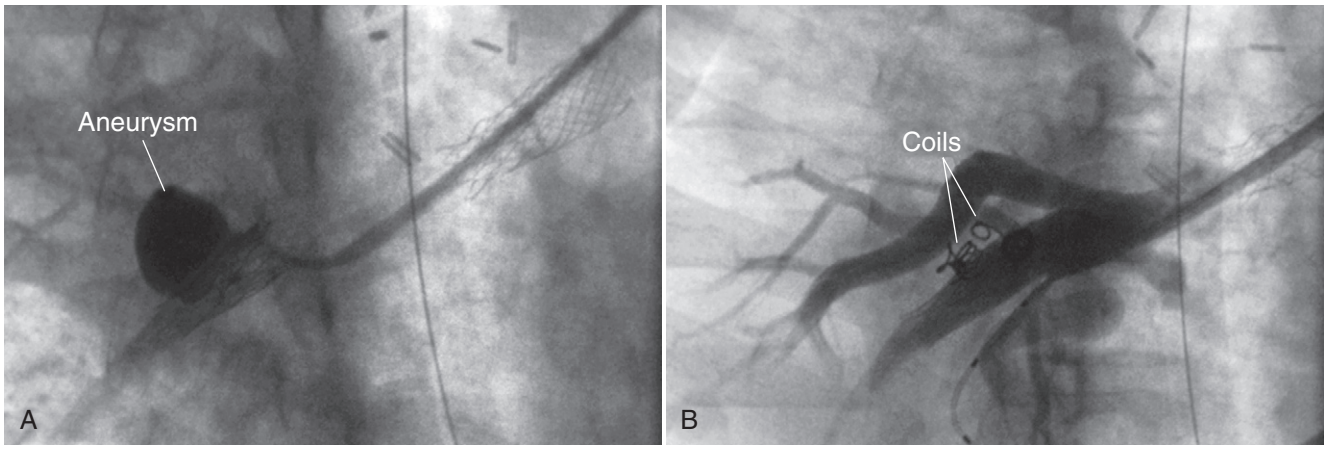

Figure 24–6. Pulmonary artery trauma in a patient with multiple peripheral pulmonary artery stenoses. **A,** Pulmonary artery aneurysm following balloon dilation. Note that a stent has been placed but the aneurysm is still present. **B,** Resolution after coils are placed in the neck of the aneurysm.

endotracheal intubation is indicated for airway control and ventilation. Hypertension and further airway stimulation should be avoided, the addition of positive end-expiratory pressure may be useful, and instillation of 1 mL of 1:100,000 epinephrine via the endotracheal tube may help reduce immediate bleeding by causing vasoconstriction of mucosal vessels. An immediate intervention by the catheterizer to tamponade the disrupted branch pulmonary artery with a balloon catheter may be lifesaving. Permanent occlusion of the vessel with a coil (Figure 24-6, *B*) or covered stent may be necessary to prevent further hemorrhage.

Transient unilateral or unilobar pulmonary edema is also seen in the setting of pulmonary artery dilation. This finding is related to sudden large increases in pulmonary blood flow and distal pulmonary artery pressure after dilation in a previously underperfused pulmonary vascular bed. Pulmonary edema after dilation usually occurs immediately following balloon dilation but can be delayed for up to 24 hours. Pulmonary edema and disruption of a pulmonary artery can occur abruptly, in isolation, or together, during pulmonary artery dilation procedures. Both can cause the appearance in the airway of frank blood or blood-tinged edema fluid in substantial quantities.

Patients who have a dilated RV secondary to a long-standing volume load, such as chronic pulmonary regurgitation, are at risk for arrhythmias and low output during catheter manipulations and interventions. As noted earlier, on most occasions the changes in rhythm are short-lived and settle once the catheters are withdrawn. Nevertheless, anesthesia and airway control are recommended if the circulation is compromised, and a defibrillator and transvenous pacing must be immediately available.

Potential movement at the time of critical balloon dilation or stent placement must be prevented. Dilation of pulmonary arteries is painful and often causes patients to waken from sedation and move. In addition, dilation of the pulmonary arteries may induce coughing. The coughing usually is not a problem for isolated pulmonary artery dilation, but if the patient moves during stent placement, lobar or segmental branch pulmonary arteries may be obstructed inadvertently by the stent. Therefore the patient must be immobile, and additional sedation should be considered immediately prior to stent placement.

Occlusion Device Insertion

Although device closures of PDA and ASD are commonly performed interventions in the catheterization laboratory, they are relatively uncommon procedures in pediatric intensive care patients. A persistent left-to-right shunt at the atrial level contributing to right ventricular volume overload, increased pulmonary blood flow, and inability to wean from mechanical ventilation may be one indication for occlusion, although often the ASD must be of considerable size to cause these symptoms and may be too large for safe deployment of the device. Conversely, a large right-to-left shunt across an ASD may result in significant cyanosis and increase the risk for paradoxical embolism and cerebral vascular accident. A similar circumstance exists in patients who have undergone a fenestrated Fontan operation. Placement of a PDA or ASD device usually is associated with minimal hemodynamic disturbance. Although placement can be performed in most patients using sedation techniques,[49] endotracheal tube placement for airway protection may be necessary if transesophageal echocardiography is used to guide device placement.

Indications for VSD device placement include closure of a residual or recurrent septal defect, preoperative closure of defects that may be difficult to reach surgically while on CPB (Figure 24-7, *A*), and closure of acquired defects such as those due to myocardial infarction or trauma.[50] A residual VSD may cause considerable volume load to the ventricles and result in a low cardiac output state and congestive heart failure requiring prolonged mechanical ventilation and inotropic or vasoactive support. In contrast to our experience with closure of PDAs or ASDs, transcatheter VSD device closures are prolonged procedures that are often associated with profound hemodynamic instability and blood loss.[51] Although the clinical condition of patients undergoing VSD device placement may vary considerably, the preoperative clinical condition or ASA (American Society of Anesthesiologists physical classification) status is not a sole predictor of hemodynamic disturbance during device placement. Rather, it is the technique necessary for deploying the occlusion device that results in significant hemodynamic compromise; therefore all patients are susceptible. Factors contributing to hemodynamic instability include blood loss, arrhythmias from catheter manipulation

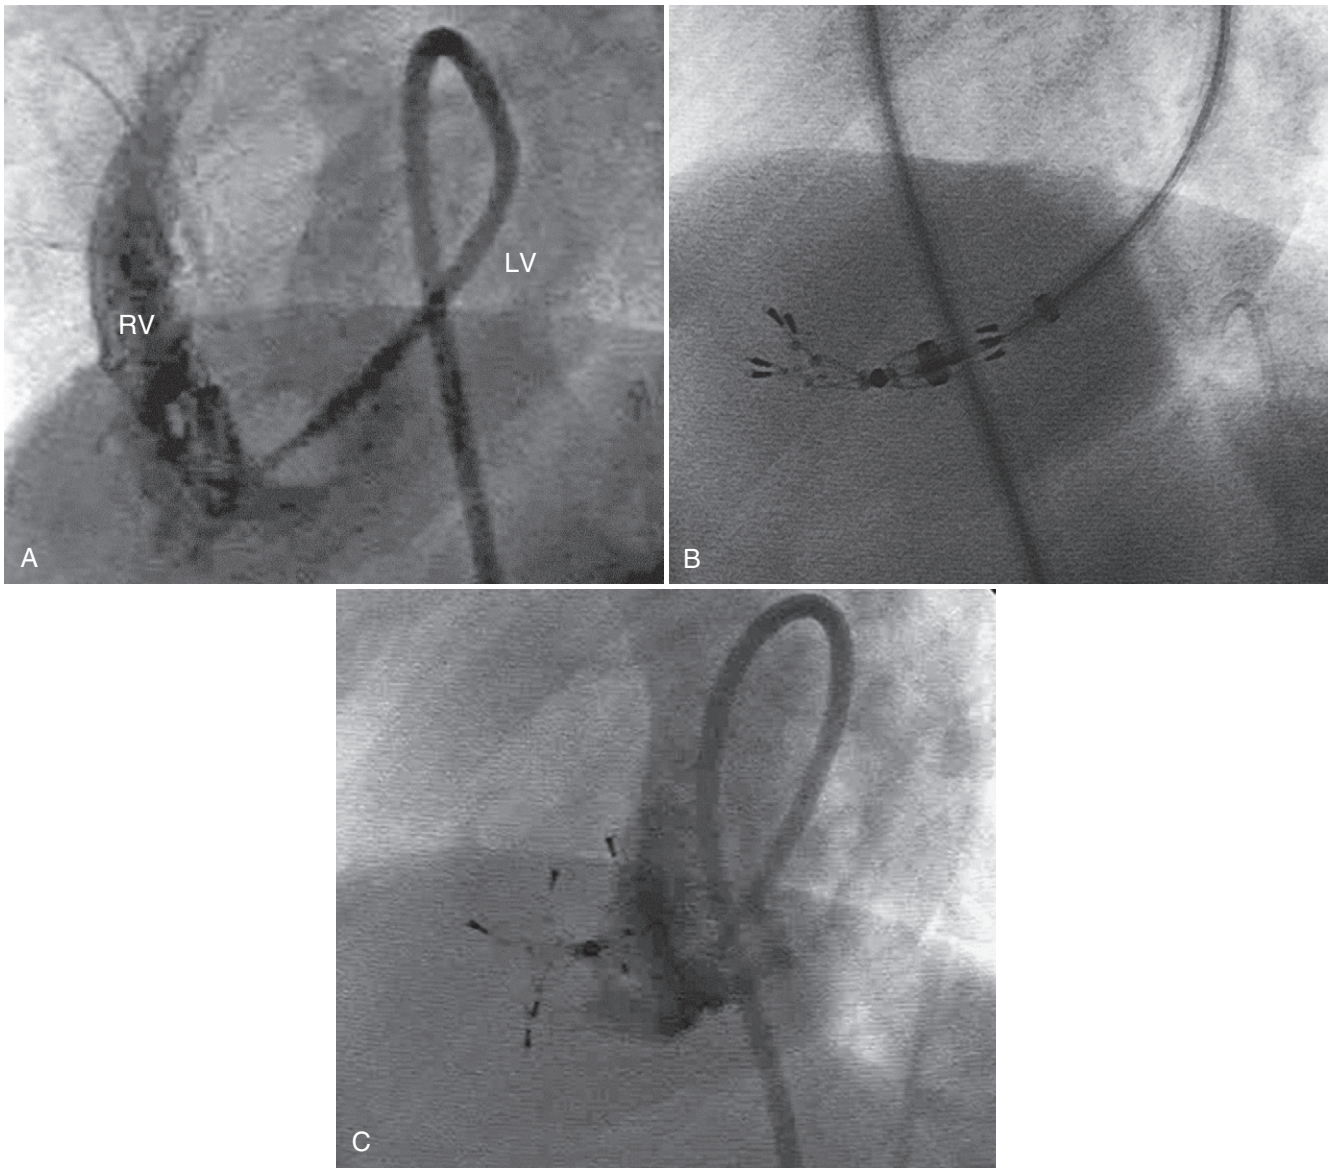

Figure 24–7. Ventricular septal defect closure using the CardioSEAL. **A,** Long axial oblique view of the interventricular septum reveals an apical muscular defect. The catheter course is from the inferior vena cava, the right atrium, across the atrial septum to the left atrium, and across the mitral valve to the left ventricle (***LV***). **B,** Same projection demonstrates dense delivery. The long sheath has been retracted over the arms positioned in the right ventricle (***RV***) and is still covering the left-sided arms. During this stage of the procedure, hemodynamic instability occurs with the large sheath and delivery system interfering with ventricular contraction and valve function. **C,** Left ventricular angiogram after device release.

in the ventricles and across the septum, atrioventricular or aortic valve regurgitation from stenting open of valve leaflets by stiff wire/catheters, and device-related factors such as malposition of the umbrella with arms impinging on valve leaflets or dislodgment from the ventricular septum.

Because of the large sheath required for positioning of the delivery pod and device (Figure 24-7, *B* and *C*) and the need for frequent catheter changes through the sheath, considerable blood loss may occur (often concealed by drapes) and the risk for air embolism is increased. In patients with intracardiac shunts, air embolization may be life-threatening and can be diagnosed by fluoroscopy. When unoccupied by the device carrier system and collapsed device, the large delivery sheath represents a potential space for air accumulation and subsequent delivery into the heart. In addition, when the entry port of the large delivery sheath is open during removal and reinsertion of various catheters and devices, extreme inspiratory efforts may introduce air into the heart. Air in the right atrium may be shunted across an ASD even in the presence of nominal left-to-right shunting. Left heart air embolization produces ST-segment elevation and, often, hemodynamic changes as it passes into the aorta. The resultant ST-segment changes, hypotension, arterial desaturation, and bradycardia generally respond to aspiration and then sealing of the entry port, along with administration of atropine and inotropic and pressor support to maintain coronary perfusion. Meticulous purging of air from the catheter system and sealing of open ports should help minimize the incidence of air embolism. Use of controlled positive-pressure ventilation through an endotracheal tube in an anesthetized, paralyzed patient also may decrease the potential for transcatheter air embolus.

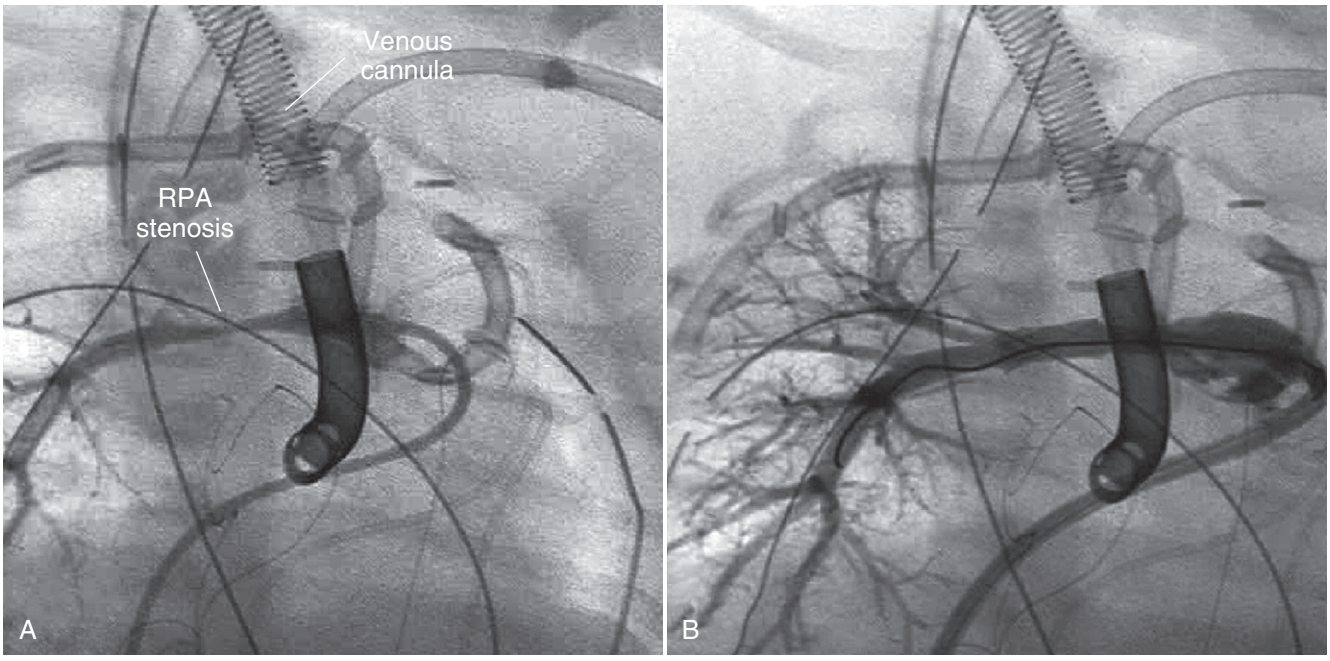

Figure 24–8. Catheterization procedure in a patient undergoing extracorporeal membrane oxygenation (ECMO). **A,** Note ECMO cannula and monitoring lines. A right pulmonary artery angiogram reveals significant proximal right pulmonary artery (*RPA*) stenosis. **B,** Much improved distal right pulmonary artery flow following stent placement across the stenotic area.

Cardiac Catheterization and Extracorporeal Membrane Oxygenation

Cardiac catheterization may be necessary in patients supported with ECMO for either diagnostic or therapeutic procedures, often to facilitate subsequent weaning and decannulation.[52] Reversible respiratory failure and pulmonary hypertension remain common indications for ECMO, but mechanical support of the failing circulation using ECMO has been increasingly used, given indications including refractory low cardiac output state, unexpected cardiac arrest, failure to wean from CPB, severe cyanosis, and refractory arrhythmias.[13,53] ECMO has also been used as a highly successful tool in the resuscitation of patients following hemodynamic deterioration due to catheter-induced complications, low output, or hypoxemia.[54]

A small number of published series have described the feasibility and utility of cardiac catheterization of patients supported by ECMO.[47,52,55,56] As the use of ECMO for supporting the circulation after cardiac surgery has increased,[57] so has the potential utility of cardiac catheterization during ECMO. Indications for catheterization have included assessment of surgical repair and interventions to treat residual defects, left heart decompression via a percutaneous transatrial vent in order to prevent overdistension of the left ventricle, hemodynamic assessment and myocardial biopsy in patients with fulminant myocarditis/cardiomyopathy, and catheter-based interventions such as arrhythmia ablation.[58] Despite the high risk, few complications during catheterization were reported in the series, and the complications did not contribute to morbidity or mortality.

It is important to have a high index of suspicion for residual lesions in postoperative cardiac surgery patients who cannot be weaned from ECMO within 72 hours of expected myocardial recovery.[53] Transthoracic echocardiography is often limited in this setting because of less satisfactory windows for standard views and altered hemodynamics during ECMO. Catheterization during the course of ECMO can make possible the diagnosis of residual lesions that could limit successful weaning from ECMO (Figure 24-8, *A* and *B*). Early catheterization and subsequent interventions may facilitate recovery of myocardial function, reduce ECMO duration, and lessen the potential for ECMO-related complications.

Pharmacology of the Cardiovascular System

Marc G. Sturgill, Michael Kelly, and Daniel A. Notterman

PEARLS

- Clinical acumen is needed to distinguish between the need for an inotropic agent, which is used to increase cardiac contractility, and the need for a vasopressor agent, which is used to increase vascular tone.
- The failing myocardium may need to be supported with an agent that increases contractility and reduces afterload, such as milrinone or dobutamine.
- Multiple polymorphisms have been discovered in receptors relevant to the intensivist. Although the clinical importance of these polymorphisms has yet to be determined, physicians need to stay abreast of changes in this rapidly expanding area.

In many pediatric critical care units, disorders of the cardiovascular and respiratory systems are the most frequent reasons for admission. Children with these disorders constitute a large group who may require pharmacologic support to maintain adequate end-organ perfusion and oxygenation. The catecholamines are the class of drug most often utilized for this support and remain a mainstay of therapy for the pediatric critical care physician, although the role of other agents has expanded. The bipyridines inamrinone and milrinone have been used in the support of patients with hemodynamic compromise of varying etiologies. In addition, the role of vasopressin and terlipressin in the management of patients with vasodilatory shock or after cardiopulmonary bypass, and of nesiritide in patients with decompensated congestive heart failure, continues to be investigated. This chapter examines the clinical pharmacology of the five clinically useful catecholamines as well as these newer agents and the venerable cardiac glycosides.

Mechanisms of Response

Pharmacologic manipulation of the cardiovascular system often entails increasing the inotropic state of the myocardium or altering the tone of the systemic vascular tree so as to improve perfusion. The final common mediator for both processes is the concentration of calcium in the cytosol. The pathway by which pharmacologic agents affect this parameter is a function of their specific cell surface receptors.

Adrenergic Receptors

Catecholamines modify cellular physiology by interacting with a specific adrenergic receptor. The classic paradigm of α and β classes of adrenergic receptors remains unchanged, although new subtypes and sub-subtypes continue to be investigated. Currently three subtypes of α_1 receptors and three subtypes of α_2 receptors have been described and three subtypes of β receptors are recognized.[1] Advances in the biology of the adrenergic receptor have led to a greater understanding of role of the α receptor in the heart, adrenergic receptor regulation of cardiac myocyte apoptosis, and the coupling of the β_2 receptor to more than one G protein. The discovery of various polymorphisms for the adrenergic receptors has served to add even more complexity, but the clinical relevance of many of these polymorphisms has yet to be elucidated. Despite this increase in our understanding of the adrenergic receptor, the clinical classification of the catecholamines into α and β agents remains functionally unchanged (Table 25-1).

Signal Transduction

Adrenergic receptors mediate their effects through G proteins and as such are classified as G protein coupled receptors. The adrenergic receptor itself contains seven membrane-spanning α-helical domains, an extracellular N-terminal segment, and a cytosolic C-terminal segment (Figure 25-1). G proteins are heterotrimeric proteins consisting of α, β, and γ subunits, each of which has multiple subfamilies.[2] There are at least 20 α subunits, five β subunits, and six γ subunits. The action resulting from a ligand binding to a particular adrenergic receptor is a function of the specific type of subunits compromising the G protein receptor complex. An evolving concept is spontaneous receptor activation, as described for the β_2 adrenergic receptor.[3,4] In this model, the receptor "toggles" between different conformational states, of which some are active and each of which may be bound to different G proteins. Binding of a ligand may stabilize or invoke a shift to a particular conformation and in doing so promote changes in the expression of second messengers, most commonly protein kinases. Hence the response of ligand binding may not only depend on the ligand involved but the state of the receptor at the time of binding.

Adrenergic receptors typically are coupled to one of three types of G proteins: G_s, G_i, or G_q. G_s proteins produce an increase in adenylate cyclase activity, while G_i proteins

Table 25–1 Adrenergic Receptors: Physiologic Responses, Agonist Potency, and Representative Antagonists

Receptor	G Protein	Physiologic Response	Agonist	Antagonist
α_1	G_q	Increase $InsP_3$, 1,2-DG, and intracellular Ca^{+2}; muscle contraction; vasoconstriction; inhibit insulin secretion	E > NE > D	Prazosin
α_2	G_i	Decrease cAMP; inhibit NE release; vasodilation; negative chronotropy	E > NE	Yohimbine
β_1	G_s	Increase cAMP; inotropy, chronotropy; enhance renin secretion	I > E ≥ D ≥ NE	Propranolol, metoprolol
β_2	G_s	Increase cAMP; smooth muscle relaxation; vasodilation; bronchodilation; enhance glucagon secretion; hypokalemia	I ≥ E > D > NE	Propranolol
D_1	G_s	Increase cAMP; smooth muscle relaxation	D	Haloperidol, metoclopramide
D_2	G_i	Decrease cAMP; inhibit prolactin and β-endorphin	D	Domperidone

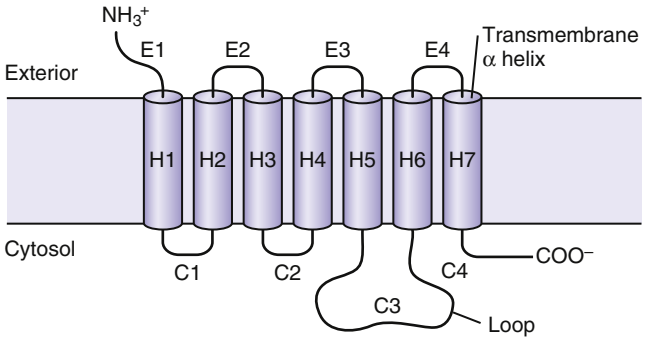

Figure 25–1. Schematic representation of typical G protein–coupled receptor with seven membrane spanning regions (H1–H7), cytoplasmic (C1–C4), and extracellular (E1–E4) loops. *(From Lodish H et al:* Molecular cell biology, *ed 4, New York, 1999, WH Freeman.)*

promote a decrease in adenylate cyclase activity. G_q protein receptors stimulate phospholipase C to generate diacylglycerol and inositol 1,4,5-triphosphate. The nature of the G protein is usually a function of the type of α subunit (α_s, α_I, α_q, and $\alpha_{12/13}$).[5] Events involving interaction of G proteins, the receptor protein, and adenylate cyclase are summarized in Figure 25-2. In the example of the G_s protein, ligand binding to the coupled receptor causes a conformational change in the G protein, resulting in guanosine diphosphate (GDP) disassociating from the Gsα subunit and guanosine triphosphate (GTP) binding to the α subunit. This GTP-G_α complex then disassociates from the $G_\beta\gamma$ subunit and binds to adenylate cyclase, leading to an increase in activity of this enzyme. Adenylate cyclase catalyses the conversion of adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP), thus increasing cellular levels of cAMP. G_i proteins have a different α subunit; when the $G_{i\alpha}$ GTP complex binds to adenylate cyclase, the enzyme is inactivated. By inhibiting this enzyme, G_i-coupled receptor agonists produce a decrease in the cellular concentration of cAMP. The specific cellular response that follows an alteration in the concentration of cAMP depends on the specialized function of the target cell.[6] Typically, an increase in concentration of cAMP leads to activation of a cAMP-dependent protein kinase. These kinases then phosphorylate and activate other structures and enzymes. Many compounds other than adrenergic agents also increase intracellular levels of cAMP. The question of how different agents produce specific responses through the expression of common second messengers continues to be investigated. One proposed mechanism involves anchoring proteins, such as A kinase anchoring proteins. These proteins localize protein kinase A (PKA) to particular cellular locales and also may offer binding sites for other regulatory proteins.[7] Similarly, anchoring proteins for both the active and inactive forms of protein kinase C have been described.[8] Different subtypes of anchoring proteins may serve to create another level of specificity in the effector response for a particular ligand by confining the response to a particular area.

β-Adrenergic Receptors

Myocardial β_1-adrenergic receptors are associated with G_s. When this receptor type is engaged by an agonist agent, the result is enhanced activity of adenylate cyclase and a rise in the concentration of cAMP. This process activates PKA. PKA in turn phosphorylates voltage-dependent calcium channels, increasing the fraction of channels that can be open and the probability that these channels are open, producing an increase in intracellular calcium concentration (Figure 25-3).[9] Calcium then binds to troponin C, allowing for actin-myosin cross bridge formation and sarcomere contraction. In addition, PKA phosphorylates phospholamban, relieving the disinhibitory effect of the unphosphorylated form on calcium channels in the sarcoplasmic reticulum. The accumulation of calcium by the sarcoplasmic reticulum is thus enhanced, increasing the rate of sarcomere relaxation (lusitropy) and subsequently increasing the amount of calcium available for the next contraction. This process leads to both enhanced contractility and active diastolic relaxation.

The question of a PKA-independent mechanism by which β-adrenergic receptors can activate calcium channels remains controversial.[10] Experimental evidence indicates that β_1 receptors are preferentially coupled to cardiac calcium channels in a cAMP-independent mechanism; however, a binding site on the calcium channel has not been delineated.[11,12] β_2-adrenergic receptors have been shown to physically complex, with the calcium channel v1.2 in neuronal tissue.[13] Of note,

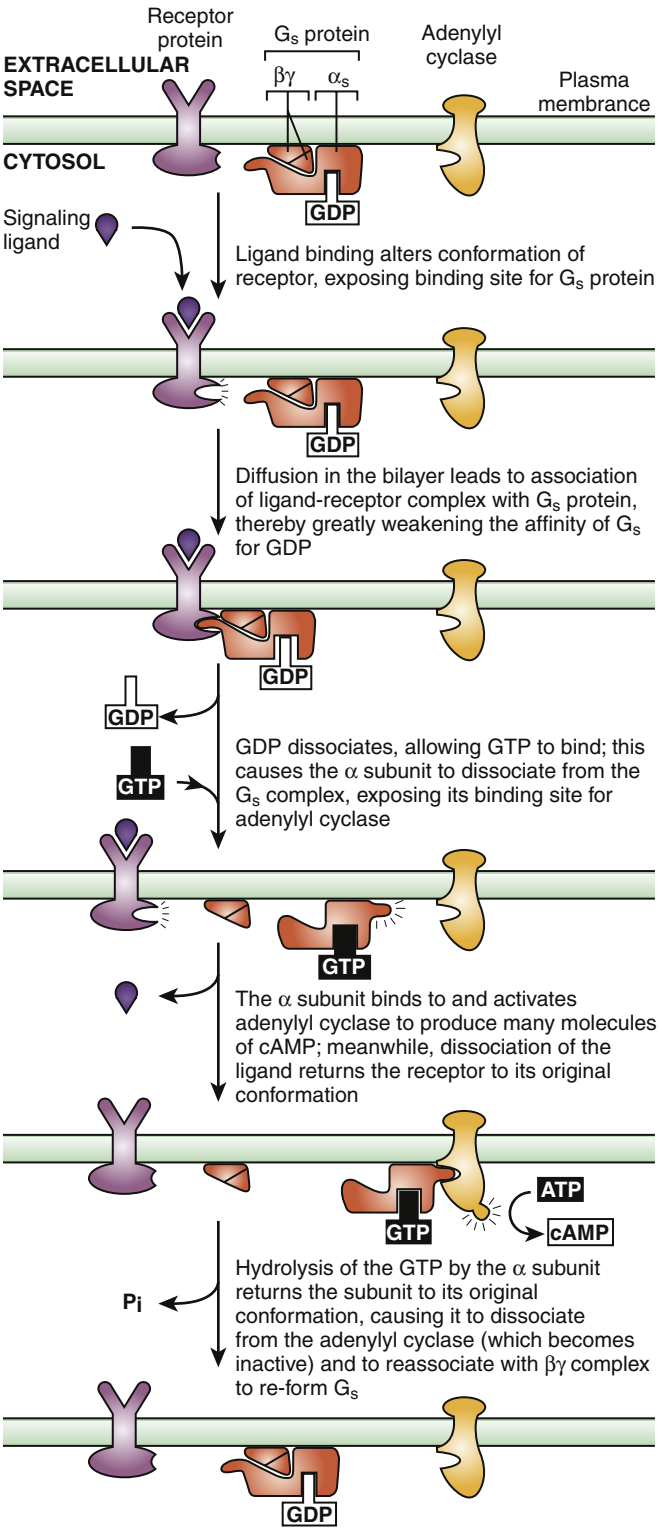

Figure 25–2. Adrenergic receptor complex. When the receptor is engaged by an appropriate ligand (e.g., isoproterenol for a β_1 receptor), the receptor associates with the α_s polypeptide of the G_s protein. This causes the α_s to extrude GDP and incorporate GTP; α_s then associates with and activates the adenylate cyclase. The process is terminated when GTP is hydrolyzed to GDP and α_s dissociates. *(©1994 From Molecular Biology of the Cell 3E by Alberts et al. Reproduced by permission of Garland Science/Taylor Francis LLC.)*

whereas it was once believed that the β_2 receptor had little presence and no role in the heart, recent evidence suggests just the opposite. β_2 receptors are present in the heart and in fact couple with both G_s and G_i.[14] The response to β_2 activation in the heart remains controversial. β_2 activation is actually more effective at increasing cAMP levels than β_1 activation, but the effect on PKA is localized rather than diffuse, as is the case following β_1 activation. This effect could be due to the localization of receptor signaling by the G_i component. Evidence for this hypothesis is that treatment with pertussis toxin (an inhibitor of G_i) transforms the β_2 signal from a local one to a diffuse one.[15] In summary, the role of β_2 receptors in the heart and the signaling processes involved are not fully resolved.[5,16] Their role in the failing heart and implications for disease also remain to be elucidated.[17,18] To add further complexity, functional β_3 receptors have been demonstrated in the heart and appear to have a negative inotropic effect.[19]

In vascular smooth muscle, both β_1 and β_2 receptors are present, although β_2 receptors predominate.[1] The β_2 receptor is coupled to G_s; therefore, activation of β_2 receptors promotes formation of cAMP. The resulting activation of cAMP-dependent protein kinase in vascular smooth muscle, however, stimulates pumps that remove calcium from the cytosol and also promotes calcium uptake by the sarcoplasmic reticulum. As cytosolic calcium concentration decreases, smooth muscle relaxes and the blood vessel dilates. Adrenergic receptors also have been demonstrated on the endothelium and are capable of producing relaxation of the vessel.[20] The exact mechanism involved, including the role of nitric oxide and the subtype of β receptors involved, remains under investigation.[1,21]

α Receptors

Vascular smooth muscle contraction is mediated via α_1 adrenergic receptors, of which there are three subtypes: 1A, 1B, and 1D. The individual contributions of each of these subtypes to the control of vascular tone remains an active area of investigation. Each subtype may be expressed in all of the vascular beds, but it is thought that one type will predominate for a particular bed.[22] A mouse knockout model of the α_{1D} receptor showed that α_1 binding in the aorta was lost but preserved in the heart. The knockout model also had lower blood pressures and a decreased response to norepinephrine.[23] α_{1A} and α_{1B} are thought to be involved in both the heart and vasculature.[24,25] A knockout model of α_{1A} demonstrated decreased blood pressure and response to phenylephrine.[22] An animal model of overexpression of the α_{1A} receptor was associated with marked increase in cardiac contractility without a change in blood pressure or heart rate.[26] In a knockout model of α_{1B} receptors in mice, chronic exposure to norepinephrine did not lead to cardiac hypertrophy or vascular remodeling.[27] Overexpression of a mutant α_{1B} receptor led to increased expression of mitogen-activated protein kinases and decreased responsiveness to isoproterenol in isolated cardiac preparations.[28] Thus while α receptors may have an inotropic effect less than that of β-adrenergic receptors, they do have significant effects in the myocardium. Interestingly, in patients with heart failure, downregulation of β receptors has been noted while α receptors are preserved.[29] The α_1 receptor is coupled to the family of $G_{q/11}$ proteins, which act independently of cAMP. Signal transduction across this receptor is initiated by the activation of phospholipase C, which hydrolyzes phosphatidylinositol 4,5-biphosphate to inositol 1,4,5-triphosphate ($InsP_3$) and 1,2

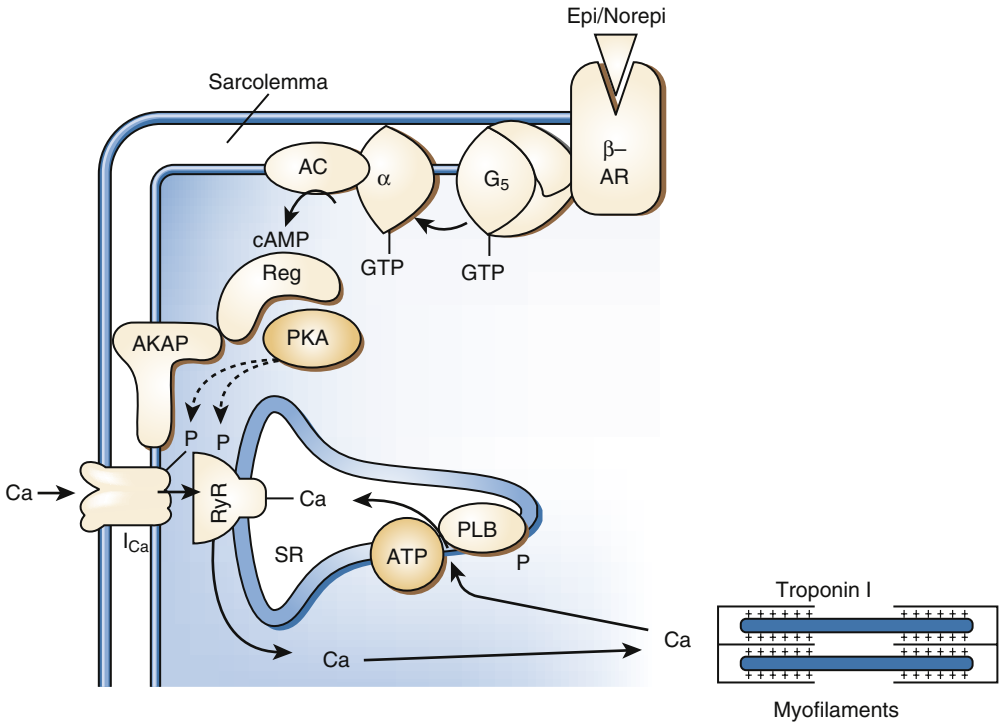

Figure 25–3. β_1-Adrenergic receptor signaling cascade. Agonist (epinephrine/norepinephrine [Epi/Norepi]) to β-adrenergic receptor (*β-AR*) results in the α subunit binding to GTP, which activates adenylate cyclase (*AC*). AC then converts adenosine triphosphate (*ATP*) to cyclic adenosine monophosphate (c*AMP*), which binds to regulatory unit (Reg) on protein kinase A (*PKA*). PKA then promotes an increase in the intracellular concentration of calcium (*Ca*) by acting on voltage-gated channels (I_{Ca}) and on the sarcoplasmic reticulum (*SR*). Calcium then promotes sarcomere contraction. *AKAP,* A kinase anchoring protein; *PLB,* phospholamban; *RyR,* ryanodine receptor. *(From Bers DM: Nature 415:198, 2003.)*

diacylglycerol (1,2DG). $InsP_3$ binds to specific receptors on the sarcoplasmic reticulum, causing a release of calcium into the cytosol, and promotes movement of extracellular calcium into the cell. 1,2DG with calcium activates protein kinase C (PKC), which regulates movement of calcium into the cytosol (Figure 25-4). In vascular smooth muscle, medium light chain kinase is activated as a result and phosphorylates myosin light chain 2, leading to smooth muscle contraction.[30] It also has been shown that a similar mechanism underlies the inotropic effect of the α_1 receptor in the myocardium.[31] The α_{1A} receptor appears to be the most efficiently coupled of the different subtypes.[32] The α_1 receptors also activate calcium influx through voltage-dependent and voltage-independent calcium channels.[33] The α receptors also promote the activation of the mitogen-activated kinase family, which are key regulators of cell growth.

Receptor Downregulation

The mechanisms described provide numerous sites at which the activity of the system can be modified, thereby affecting the sensitivity of target cells to both exogenous and endogenous catecholamines. Some of these receptor modifications are clinically important to the critical care physician. The best-documented type of modification involves agonist-mediated receptor desensitization. Exposure of receptors to agonists markedly reduces the sensitivity of the target cell to the agonist. Within seconds to minutes after agonist binding, the receptor may be uncoupled as a result of receptor phosphorylation. The receptor may be phosphorylated by PKA or PKC or by a member of the family of G receptor kinases (GRKS). These kinases, which include β-adrenergic receptor kinases 1 and 2, phosphorylate only receptors that have agonist bound. Compared with PKA and PKC, phosphorylation by GRKS enhances the ability of β arrestin, a cytosolic protein, or clathrin to bind to the receptor and disrupt further signaling. The role of GRKS has been established for β_1, β_2, and α_2 receptors.[17,34] Sequestration of receptors within the target cell and degradation of sequestered receptors is another mechanism by which receptors are downregulated. The desensitization of α_1 receptors has been extensively reviewed.[35] Homologous desensitization is mediated by GRKS, which are activated by soluble $G_{\beta\gamma}$ subunits and phosphatidylinositol biphosphate. As with the other adrenergic receptors, once phosphorylated, the receptors are internalized into vesicles. The α_1 receptors also demonstrate heterologous desensitization, in which a second messenger kinase, generated as a result of ligand binding, inactivates the receptor and prevents any further signaling from the receptor. In addition to agonist-mediated desensitization, other stimuli also have been implicated in downregulation, including endotoxin, tumor necrosis factor, and congestive heart failure (CHF).[36] Lymphocyte β-adrenergic receptor density in children with CHF was reduced in proportion to the degree of elevation in plasma norepinephrine concentration.[37] Several pharmacologic agents, such as corticosteroids and ketotifen, are thought to upregulate β-adrenergic receptors, and evidence exists that both immaturity and senescence are associated with β-adrenergic receptor desensitization.[38]

Polymorphisms

With the rapid advances in molecular biology, knowledge of polymorphisms within the genetic code has increased dramatically. Polymorphisms within the adrenergic receptors (see Table 25-2) is reviewed briefly here. The reader also is directed toward a recent comprehensive review.[39] Two polymorphisms have been described in the β_1 receptor. At position 49, glycine may

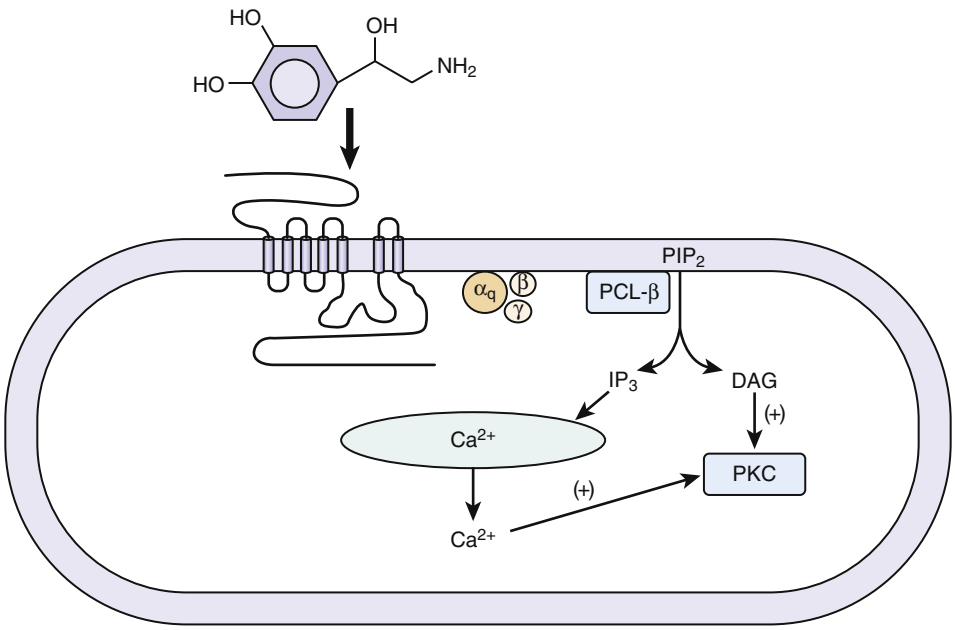

Figure 25–4. α_1-Adrenergic receptor signaling cascade. Binding of an agonist such as norepinephrine to a G protein–coupled receptor activates the $G_{q/11}$ protein, leading to disassociation of the α and βγ subunits. Phospholipase C (*PLC-β*) is activated in turn and cleaves phosphatidylinositol 4,5-biphospate (*PIP_2*) to inositol 1,4,5-triphosphate (*IP_3*) and diacylglycerol (*DAG*). IP_3 and DAG promote an increase in intracellular calcium through the sarcoplasmic reticulum and protein kinase C (PKC). *(From Zhong H, Minneman KP: Alpha-1 adrenoreceptor subtypes,* Eur J Pharm *375:26, 1999.)*

Table 25–2 Common Polymorphisms of Adrenergic Receptors

	Position		Alleles		
Receptor	**Nucleotide**	**Amino Acid**	**Major**	**Minor**	**Clinical Effect**
$A_{1A}AR$	1441	492	Cysteine*	Arginine	
$A_{2A}AR$	753	251	Asparagine	Lysine	
$A_{2B}AR$	901-909	301-303		Deletion Glutamic acid glutamic acid glutamic acid	
$A_{2C}AR$	964-975	322-325		Deletion	Minor allele associated with abnormal vasomotor regulation

be substituted for serine. The frequency of the minor allele (gly) is about 15%. In cell culture studies, the minor allele is associated with enhanced agonist-promoted downregulation and increased affinity for agonists.[40] Another polymorphism occurs at position 389, where glycine may be substituted for arginine. This position is in the carboxy terminus, a site involved with binding with the G protein. In a fibroblast cell line, the arginine alleles (wild type) were observed to have higher levels of adenyl cyclase expression with agonist binding, representing more efficient coupling.[41] In a model utilizing isolated human myocardial tissue, the wild type allele (Arg 389) was associated with enhanced inotropic potency in response to norepinephrine,

although maximal force generated did not differ between the two alleles.[42] Another study demonstrated higher resting heart rates and diastolic blood pressure in patients with the Arg 389 allele.[43] Three polymorphisms have been demonstrated in the β_2 receptor. Of note, at position 164, isoleucine may be substituted for threonine. This polymorphism is associated with a threefold decrease in affinity for agonist binding.[44] In a transfected cell line, the Ile-164 type is associated with decreased basal adenyl cyclase activity and decreased activity after agonist stimulation.[45] Similar results were found in a study of patients heterozygous for the Ile-164 allele. These patients had blunting of the increase in both heart rate and duration of systole during terbutaline infusion, with a trend toward lower systolic blood pressure.[46] A single polymorphism has been delineated in the α_1 receptor; it does not appear to have any clinical significance. A restriction fragment length polymorphism was identified in the gene for the α_{2C} receptor.[47] This polymorphism was associated with abnormal vasomotor regulation, sodium excretion, and platelet function. The presence of both the Arg 389 β_1 receptor polymorphism and a deletion polymorphism in the α_{2C} receptor in black patients has been shown to increase the risk of heart failure.[48] This study is an example of the difficulty in linking genetic variations to the clinical scenario in that a single polymorphism may not have an effect except in the presence of another polymorphism. None of these particular polymorphisms has yet been shown to have a significant role in the pediatric intensive care unit (PICU), but they no doubt will continue to add to our understanding of the adrenergic pathways.

Vasopressin Receptors

Arginine vasopressin (AVP) is a nonpeptide hormone synthesized in the supraoptic and paraventricular nuclei of the hypothalamus. Three subtypes of vasopressin receptors exist, known as V_1, V_2, and V_3 (or V_{1b}). V_2 receptors are present in the renal collecting duct, while V_1 receptors are located in the vascular bed, kidney, bladder, spleen, and hepatocytes, among other tissues.[49] AVP is released in response to small increases in plasma osmolality or large decreases in blood pressure or blood volume.[50] The plasma osmolality threshold for release of AVP is 280 mOsm/kg; above this threshold there is a steep linear relation between serum osmolality and AVP levels.[50] Changes of at least 20% in blood volume are needed to effect a change in AVP levels, although levels may then increase by twentyfold to thirtyfold.[50] Hypovolemia also shifts the response curve for AVP to osmolalar changes to the left and increases the slope of the curve (Figure 25-5). Vasopressin can produce vasoconstriction through V_1 receptors in the vascular bed (discussed later), but it also activates V_1 receptors in the central nervous system (CNS), including receptors in the area postrema.[51] This region is responsible for the reflex bradycardia seen with AVP infusion. This reflex attenuates the increase in blood pressure that would result from the vasoconstrictor effects of AVP.[52,53] In fact, vasopressin causes a greater reduction in heart rate than other vasoconstrictors.[49] Thus if this feedback loop is abolished, AVP induces a greater vasopressor response than other agents.[51]

V_1 Receptors

Vasopressin receptors belong to the family of G protein–coupled receptors. V_1 receptors are coupled to G_q and V_2 receptors are coupled to G_s.[50] When vasopressin binds to the

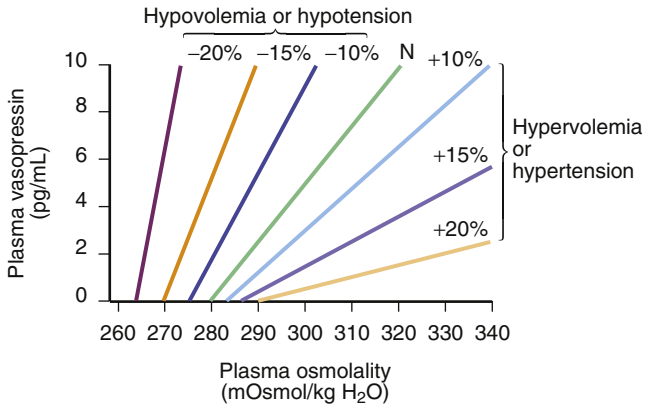

Figure 25–5. Relationship between plasma vasopressin levels and plasma osmolality. As hypovolemia worsens, vasopressin levels increase for any given plasma osmolality. *(Modified from Robertson GL, Athar S, Shelton RL: Osmotic control of vasopressin function. In Androli TE, Grantham JJ, Rector FC Jr, editors:* Disturbances in body fluid osmolality, *Bethesda, MD, 1977, American Physiological Society.)*

V_1 receptor, phospholipase C is activated with the eventual production of $InsP_3$ and 1,2 DG. These molecules serve to increase the release of calcium from the endoplasmic reticulum as well as increase the entry of calcium through gated channels (Figure 25-6).[54] The increase in intracellular calcium leads to an increase in the activity of myosin light chain kinase. This kinase acts upon myosin to increase the number of actin-myosin cross bridges, enhancing contraction of the myocyte. Of note, vasopressin has been shown to produce vasoconstriction in the skin, skeletal muscle, and fat while producing vasodilatation in the renal, pulmonary, and cerebral vasculature.[55] This effect may be mediated though nitric oxide or may be a function of the isoform of adenyl cyclase with which the receptor is coupled.[56] AVP also has been shown to increase the pressor effects of catecholamines, although in two different vascular smooth muscle cell lines, AVP had opposing effects on isoproterenol-induced activation of adenyl cyclase.[57-59] Other effects of vasopressin binding to V_1 receptors are also shown in Figure 25-6.

AVP also may increase vascular tone by interacting with so-called ATP-sensitive potassium channels termed K_{ATP}.[60] Activation of K_{ATP} channels hyperpolarizes the cell, closes calcium channels, and prevents contraction.[61,62] The result may be to protect the cell.[63] AVP can induce PKC, which in turn inhibits the K_{ATP} channel when the cellular concentration of ATP is low.[64] Inhibition of the K_{ATP} channels allows for cell depolarization and calcium entry, resulting in vasoconstriction (Figure 25-7).[65] V_1 receptors also have been demonstrated to have a weak positive inotropic effect in the heart, although the clinical significance of this effect has not been established.[66]

Receptor Downregulation

As with adrenergic receptors, vasopressin receptors undergo downregulation. AVP promotes the phosphorylation of it own receptor immediately after binding. The receptor is removed from the cell surface within 3 minutes after binding.[67] As with adrenergic receptors, G protein–coupled receptor kinases catalyze the phosphorylation of the receptor. PKC also mediates this reaction and may serve as the means by which other agents downregulate the vasopressin receptor in a heterologous manner.[67]

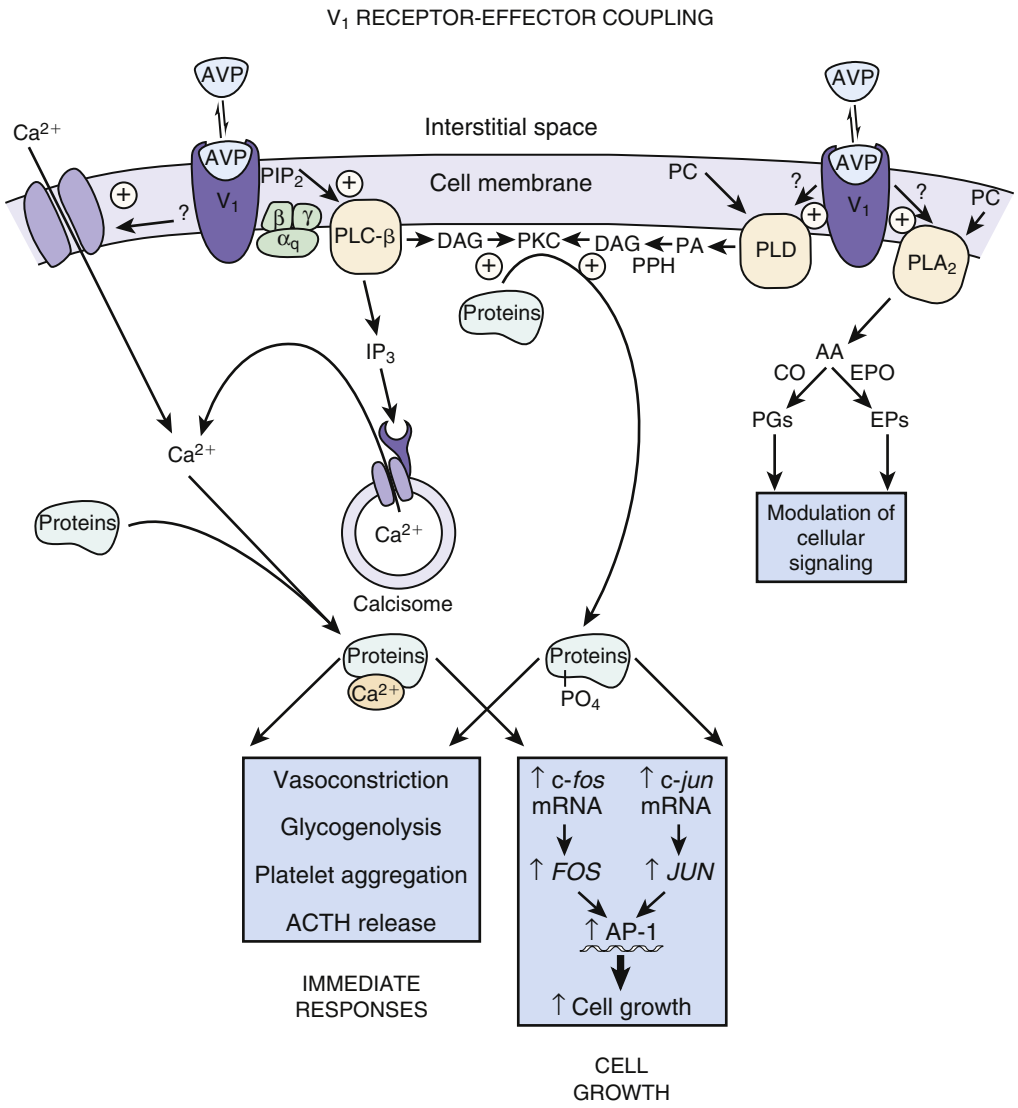

Figure 25–6. V_1 receptor signaling cascade. Binding of arginine vasopressin (AVP) to the V_1 vasopressin receptor (V_1) leads to activation of phospholipase C (*PLC-β*) via the Gq protein with the production of inositol 1,4,5-triphosphate (IP_3). IP_3 promotes an increase in intracellular calcium, resulting in figure. *AA,* Arachidonic acid; *ACTH,* adrenocorticotropic hormone; *AP-1,* transcription factor consisting of heterodimer of FOS and JUN; *CO,* cyclooxygenase; *DAG,* diacylglycerol; *EPO,* epoxygense; *EPs,* epoxyeicosatrienoic acids; *PA,* phosphatidic acid; *PC,* phosphatidylcholine; *PGs,* prostaglandins; PIP_2, phosphatidylinositol 4,5-biphosphate; *PKC,* protein kinase C; PLA_2, phospholipase A_2; *PLD,* phospholipase D; *PPH,* phosphatidate phosphohydrolase. In Hardman JG, Limbird LE, editors:* Goodman and Gilman's the pharmacologic basis of therapeutics, *ed 10, New York, 2001, McGraw Hill.)*

Polymorphisms

Although numerous mutations in the V_2 receptor exist and result in nephrogenic diabetes insipidus, much less is known about the V_1 receptor. One study established two polymorphisms in the V_1 receptor gene but failed to establish a linkage with hypertension.[68]

Phosphodiesterase Regulation of cAMP

Phosphodiesterases are a class of enzyme that catalyze the hydrolysis of cAMP and cGMP into AMP and GMP, respectively. Therefore, these enzymes can downregulate the signals transducted by cAMP, such as PKA activity (discussed previously). Several families of this enzyme exist, each with subtypes. Phosphodiesterase III (PDE3) is present in many cell types, including cardiac myocytes, vascular smooth muscle cells, adipocytes, platelets, and pancreatic islet cells. PDE3 has a much higher Vmax for cAMP than it does for cGMP and therefore is functionally a cAMP esterase.[69] Different isoforms of PDE3 are present in cardiac (PDE3A1) and vascular smooth muscle cells (PDE3A2) and are localized to different cellular compartments and as such are able to regulate the function of their target enzymes in response to particular cellular signals.[70] The C-terminus of the enzyme codes for the central catalytic core that is the active binding site and the N-terminus coding region may determine cellular targeting.[70] The bipyridines, such as milrinone, are competitive inhibitors of PDE3; that is, they bind to PDE3, preventing the enzyme from binding to cAMP.[71,72] They appear to bind near the binding site for cAMP, although different PDE3 inhibitors may have different binding sites.[73] Inhibition of PDE3 produces an increase in cAMP. This increase in

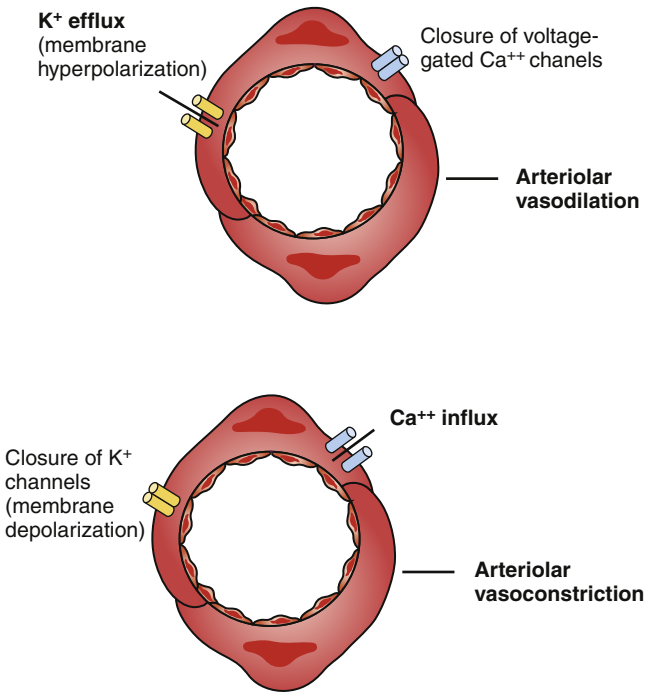

Figure 25–7. K^+ channels vascular tone. Diffusion of K^+ through open K_{ATP} channels in vascular smooth muscle cell results in membrane hyperpolarization, closure of voltage-gated Ca^{2+} channels, and decreased intracellular calcium, resulting in vasodilation. Closing of K_{ATP} channels has the opposite effects. *(From Jackson W: Ion channels and vascular tone,* Hypertension *35:173-178, 2000.)*

cAMP results in a positive inotropic effect in the myocardium and vasodilatation in the systemic and pulmonary vasculature.[74] In contrast, methylxanthines such as theophylline, which inhibit all phosphodiesterases, cause levels of both cGMP (thought to decrease contractility) and cAMP to increase. This dual increase attenuates their inotropic effects. Bipyridines also may enhance contractility by increasing the sensitivity of myofilaments to cytosolic calcium.[75] Milrinone has also been shown to enhance the sarcomere uptake of calcium and thereby augment left ventricular (LV) relaxation (lusitropy).[76] In the peripheral vasculature, PD3 inhibitors may produce vasodilatation via a cGMP mechanism.[77] The bipyridines offer the combination of positive inotropy, lusitropy, and afterload reduction. It has been speculated that long-term exposure to PDE inhibitors may result in adrenergic receptor desensitization via heterologous desensitization, although this has not been demonstrated clinically.[78]

ATPase Inhibition

Membrane-bound sodium-potassium adenosine triphosphatase (Na-K ATPase) is responsible for maintaining electrochemical gradients across the cellular membrane. It does so by extruding three molecules of sodium from the cell and incorporating two molecules of potassium into the cell, both against their respective concentration gradients. This process occurs at the cost of one molecule of ATP. The enzyme consists of an α and β subunit; there are four subtypes of α and three of β.[79] The β subunit may be involved in the trafficking of the enzyme.[80] The α subunit contains both the binding site and catalytic site.[79] The isoforms expressed are dependent on the type of tissue.[81] The putative mechanism of action of the cardiac glycosides is inhibition of the Na-K ATPase pump, which results in an increase in intracellular sodium. The elevated level of intracellular sodium then effects a decrease in the activity of the sodium/calcium exchange (NCX) pump. This pump exchanges three molecules of extracellular sodium for one molecule of intracellular calcium.[82,83] The net result is a rise in intracellular calcium and, in the cardiac myocyte, enhanced contractility. The particular α isoform expressed may affect the function of the enzyme. In a mouse knockout model, animals heterozygous for α_1 ($\alpha_1^{-/+}$) and α_2 ($\alpha_2^{-/+}$) were generated.[84] The cardiac myocytes from α_2 heterozygous animals demonstrated a hypercontractile state when compared with control subjects (similar to that seen with the administration of cardiac glycosides). In contrast, the α_1 heterozygous animals had a hypocontractile state. The authors note that this phenotype is similar to that seen with cardiac glycoside toxicity. Although the classical explanation has been described, the precise mechanism for the increase in intracellular calcium with Na-K ATPase inhibition remains controversial. Some studies have demonstrated a rise in intracellular calcium without the expected concomitant rise in intracellular sodium, suggesting that perhaps the NCX pump was not involved.[85,86] In contrast, a study in mice lacking the NCX pump demonstrated that ouabain (a Na-K ATPase inhibitor) did not increase intracellular calcium.[87,88] No evidence exists to suggest the development of tolerance to digoxin with long-term use.[89]

Developmental Issues

It is often stated that the immature myocardium is less sensitive to inotropic agents than the adult heart. The exact nature of the mechanism responsible for these differences represent an area of active investigation. The majority of studies involve animal models or isolated human tissue. Because there are inherent differences between intact healthy animal models and the ill child, as well as pharmacokinetic differences between the infant and adult patient, caution must be exercised when extrapolating laboratory data to the bedside.[90] Nonetheless, a brief review of developmental differences is appropriate.

Age-related differences exist in the response of the developing myocardium to inotropic agents, receptor regulation, and calcium handling.[82,91] In puppy heart models, the inotropic response to dopamine and isoproterenol increases with increasing age.[92,93] Maximal developed pressure and relaxation velocity in response to isoproterenol were higher in adult rabbit hearts compared with neonatal hearts.[94] However, in a model of rat ventricular myocytes, zinterol (a selective β_2 agonist) increased intracellular calcium gradients and cAMP accumulation and augmented cell shortening in neonatal myocytes at much lower concentrations than in adult myocytes.[95] Sun,[96] in a rabbit model, showed that isolated adult hearts had a greater increase in systolic function in response to isoproterenol than did neonatal hearts but that the response to continuous infusions was less attenuated in the neonatal hearts, suggesting less desensitization. In another study,[97] neonatal rat hearts did not show any evidence of homologous uncoupling in response to isoproterenol. In fact, the receptors demonstrated an enhanced response after prolonged exposure to agonist. This response occurred despite increased activity of β-adrenergic receptor kinase 1, which mediates receptor uncoupling and sequestration. The ability of the neonate to resist desensitization may be helpful given the higher levels of catecholamines present in the newborn period. The mechanism by which neonatal receptors accomplish this was examined in a rat model of the response

of cardiac and hepatic cells to isoproterenol and terbutaline.[98] Neonatal hearts did not show any evidence of desensitization with either single injections of or prolonged exposure to isoproterenol or terbutaline. Adult hearts had evidence of both homologous and heterologous desensitization to isoproterenol but not terbutaline. In marked contrast, neonatal hepatic cells demonstrated homologous desensitization to either single doses of or prolonged exposure to isoproterenol and terbutaline. In fact, there was increased sensitivity to agents that increase adenyl cyclase through nonadrenergic mechanisms. These results suggest that the resistance of neonatal myocytes to desensitization is the result of processes downstream from the adrenergic receptor and may involve developmental changes in the expression of adenyl cyclase isoforms or the compartmentalization of PKA activity.

Another area of difference is the handling of intracellular calcium. In the adult heart, the majority of released calcium is derived from the sarcoplasmic reticulum, but this is less so in the neonatal heart.[82] Calcium flux across the sarcolemma is the predominant source of calcium utilized in excitation-contraction coupling. Neonatal rabbit hearts express more NCX protein than do adult hearts. With maturation, expression of NCX decreases, accompanied by enhanced contractility. In addition, differences between neonatal and adult hearts could be demonstrated on the concentration-response curves for ouabain (dP/dt min) and calcium (dP/dt min), but not for isoproterenol.[94] An experimental agent that blocks the NCX did not increase contractility in the neonatal heart, although it did have an inotropic effect on adult myocardium.[94] The role of voltage-gated calcium channels as the source of intracellular calcium in the neonatal myocardium is unclear. Studies suggest that these channels are the major source of intracellular calcium, although their exact role is unclear.[82,99,100]

Developmental differences also may exist in the expression of phosphodiesterase (PDE) isoforms. In a model of rabbit ventricular myocytes, administration of IBMX (a nonselective PDE inhibitor) and rolipram (a PDE type IV inhibitor) increased intracellular calcium currents in neonatal cells both at baseline and in response to isoproterenol but not in adult cells. In contrast, milrinone (a PDE type III inhibitor) increased intracellular calcium currents at baseline and in response to isoproterenol only in the adult cells.[101] Thus it would appear that in the neonatal myocardium, PDE type IV may be the dominant isoenzyme that regulates intracellular calcium currents.

Developmental changes also may involve the peripheral vascular system. In developing swine, Gootman[102] found that the peripheral vascular response to several adrenergic agonists developed at different rates and that complete reflex integration was not present at birth. He predicted that overall responses to stress or to treatment with these agents would be age dependent. Gootman's physiological studies are complemented by receptor-binding studies that indicate that developmental changes exist in the adrenergic receptor content of a variety of organs, although more recent work indicates that lymphocyte β-adrenergic receptors are fully mature and functional at birth.[103,104] Structural and ultrastructural differences also exist between immature and mature hearts. These differences include reduced ventricular compliance, greater ventricular interdependence, and a reduction in the ratio of myocardial contractile to noncontractile protein in the immature heart. The net effect is that the immature myocardium neither responds to nor tolerates volume loading as well as the adult heart. In addition to this diminished "preload reserve," the baseline heart rate of infants and children is quite high, which limits the extent to which tachycardia can augment cardiac output before diastolic filling is compromised.

The combination of impaired preload reserve, limited chronotropic reserve, and reduced sensitivity of the heart and peripheral vasculature to adrenergic agents implies that the response of the immature organism to the infusion of inotropic and vasopressor agents may differ from the pattern noted in adults.[105,106]

Sympathomimetic Amines

Virtually all sympathomimetics currently used to treat hemodynamic problems are catecholamines. This class includes the endogenous compounds epinephrine, norepinephrine, and dopamine and the synthetic products isoproterenol and dobutamine. Catecholamines have a β-phenylethylamine core with hydroxyl (OH) substituents at the 3 and 4 aromatic ring positions (Figure 25-8). Minor differences in molecular substitution about the N-terminus or the α or β carbons produce marked differences in activity. Structure-activity relationships are complex for the catecholamines and have been reviewed; it is possible to generalize by noting that increasing size of the substituent on the amino group enhances β-adrenergic activity, whereas decreasing size is associated with α-adrenergic selectivity.[107] Tyrosine serves as the base compound for the synthesis of catecholamines. Tyrosine hydroxylase catalyzes the conversion of tyrosine to dopa, which undergoes decarboxylation, producing dopamine. Dopamine β-hydroxylase converts dopamine to norepinephrine. In the adrenal medulla, norepinephrine is converted to epinephrine by n-methyl transferase (Figure 25-9).

Catecholamines are subject to several different elimination processes.[107a] Infused dopamine provides an example in which elimination occurs through a variety of processes. A small proportion is excreted unchanged in the urine. It is likely that a proportion undergoes neuronal reuptake. The principal means of elimination appears to be O-methylation by catechol O-methyltransferase (COMT) to form metanephrines, followed by either sulfoconjugation (by phenolsulfotransferase) or by deamination (by monoamine oxidase [MAO]) to homovanillic acid.[108] Substitution at the α carbon determines the rate of deamination by MAO.[109] The contribution of these pathways to total body clearance of catecholamines varies with age and the particular circulatory bed. In newborn lambs, the lungs accounted for 35% of the total body clearance of norepinephrine and 15% of the clearance of epinephrine. Inhibition of MAO by desipramine decreased pulmonary clearance to near zero and decreased total body clearance of norepinephrine and epinephrine clearance by 51% and 30%, respectively.[110] In adult rabbits, inhibition of COMT and MAO simultaneously decreased pulmonary clearance of norepinephrine, epinephrine, and dopamine but had only minor effects on total body clearance.[111] Inhibition of COMT did not change extracellular levels of catecholamines in the CNS.[112] Furthermore, individual differences in COMT activity are not well correlated with dopamine clearance.[113] The liver and gut have been shown to clear between 30% to 52% of the circulating norepinephrine and epinephrine.[114,115] It is likely that processes or drugs that disturb these routes of elimination will decrease the overall metabolic clearance of catecholamines. Organ dysfunction associated with critical illness is known to increase the blood concentration of dopamine during a given

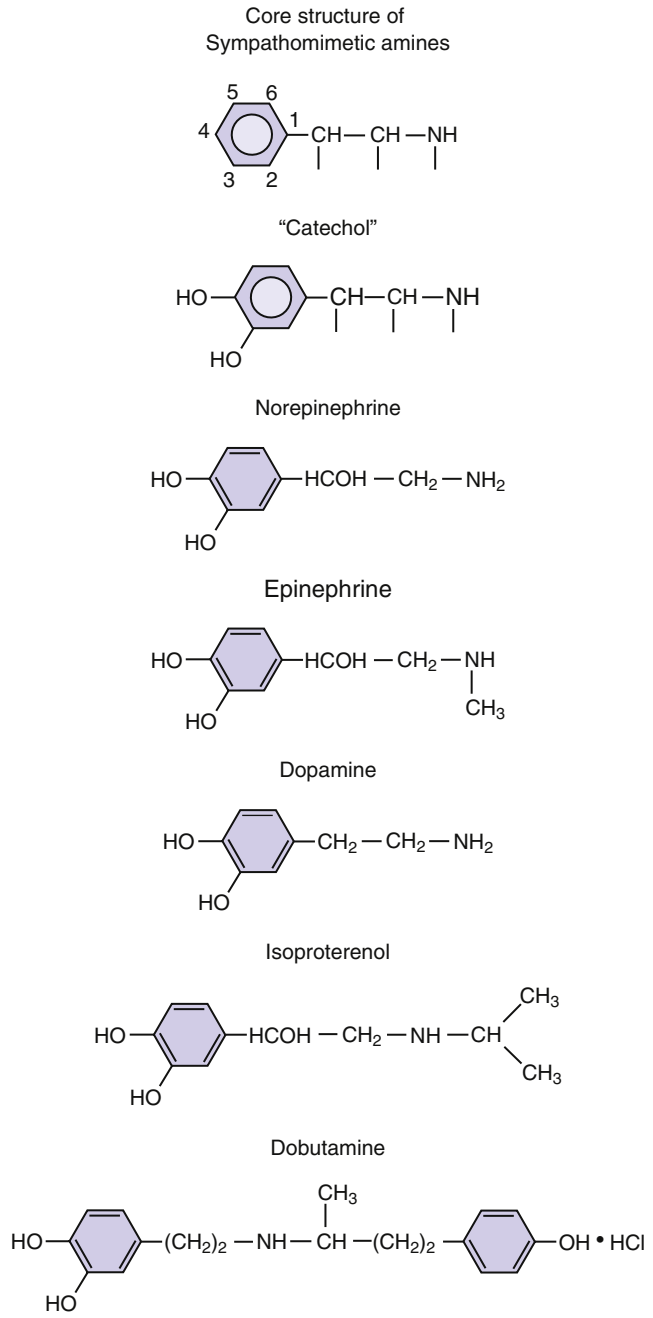

Figure 25–8. Chemical structure of the catecholamines. *(Modified from Chernow B, Rainey T, Lake R: Endogenous and exgoenous catecholamines in critical care medicine,* Crit Care Med *10:409, 1982.)*

infusion rate of the compound. For example, with liver dysfunction the clearance of dopamine is reduced.[116]

It is practical to divide the properties of catecholamines into their inotropic and vasopressor effects. An inotropic agent increases stroke work at a given preload and afterload. Typically, these agents engage receptors of the β_1-adrenergic class. Agents that stimulate β_1-adrenergic receptors also tend to increase heart rate modestly, unless other properties of the drug prevent this increase. Some inotropic agents also activate β_2 receptors, promoting peripheral vasodilatation and reflex tachycardia. In addition, the improvement in cardiac output these agents provide may permit a reflex relaxation of vascular tone and systemic vascular resistance.

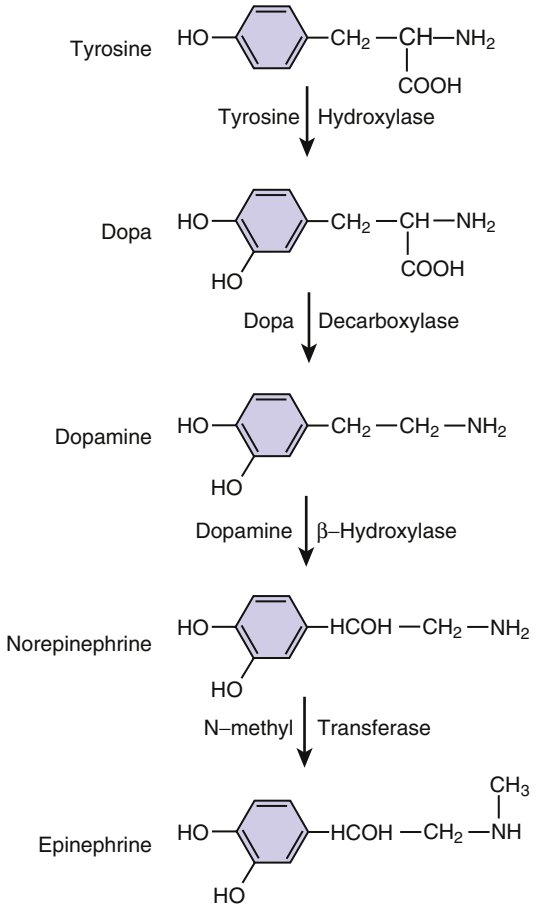

Figure 25–9. Biosynthetic pathways of the endogenous catecholamines. *(Modified from Chernow B, Rainey T, Lake R: Endogenous and exgoenous catecholamines in critical care medicine,* Crit Care Med *10:409, 1982.)*

A vasopressor agent increases peripheral vascular tone, elevating systemic vascular resistance and blood pressure. Typically, vasopressors engage α_1-adrenergic receptors, causing contraction of vascular smooth muscle. In principle, the physician will use a vasopressor agent to treat peripheral vascular failure and an inotropic agent when the major problem is impaired cardiac contractility. In practice, most available agents display a blend of inotropic, chronotropic, and vasopressor activity. Norepinephrine has both inotropic and vasopressor effects, although it is most commonly used as a vasopressor agent. Phenylephrine (a noncatecholamine) has considerable specificity for the α-adrenergic receptor; so it is almost a pure pressor. Isoproterenol and dobutamine have little α-adrenergic agonist activity but considerable activity at the β receptor; they are mostly used as inotropes. Epinephrine and dopamine have both inotropic and vasopressor activity. At relatively low infusion rates, they enhance myocardial function and increase heart rate (β_1 and β_2). At higher rates, pressor activity (α_1) becomes manifest.

Dopamine

Basic Pharmacology

In the enzymatic pathway leading from tyrosine to epinephrine (Figure 25-9), decarboxylation transforms L-dopa to dopamine. Dopamine is a central neurotransmitter and is also found in sympathetic nerve terminals and in the adrenal

medulla, where it is the immediate precursor of norepinephrine. In healthy persons, plasma levels of dopamine are in the range of 50 to 100 pg/mL.

Clinical Pharmacology

Dopamine simulates dopamine (D_1 and D_2) receptors located in the brain and in vascular beds in the kidney, mesentery, and coronary arteries (Table 25-3).[117] It also stimulates α and β receptors, although the compound's affinity for these receptors is lower. D_1 receptors are coupled to G_s and thus enhance adenylate cyclase and produce a rise in cAMP, which evokes vasodilatation. This increases blood flow to these organs and may enhance renal solute and water excretion by the kidney. Dopamine also modulates release of aldosterone and prolactin (D_2 receptors), which also may affect renal solute clearance.[118] The physiological role of dopamine has been extensively reviewed.[119,120]

In healthy adult volunteers, infusion rates between 1 and 10 μg/kg/min increase stroke volume and cardiac output without major effect on heart rate or blood pressure.[121-123] These infusion rates are associated with plasma concentrations of 50 to 100 ng/mL. Low infusion rates augment renal sodium excretion; intermediate rates (10 μg/kg/min) produce chronotropic and inotropic effects, and still higher infusion rates increase vascular resistance.[124] Renal blood flow, glomerular filtration rate, and sodium excretion are maintained or even increase during dopamine infusion in patients with poor cardiac output. Work by Gundert-Remy and colleagues[125] in healthy adults indicated that even at a relatively low infusion rate of 400 μg/min (5 to 6 μg/kg/min) there is significant augmentation of heart rate and blood pressure that likely plays a role in improved renal function.

Evidence for the view that infants display reduced sensitivity to dopamine is not conclusive. In support of reduced sensitivity, Perez and associates[126] found that in critically ill neonates, infusion rates of 50 μg/kg/min did not cause clinically evident impairment of cutaneous or renal perfusion. Some experimental evidence for diminished sensitivity to dopamine in infants also exists; however, this evidence is limited to studies in immature animals. A contrary observation was made by Padbury and co-workers,[127] who measured cardiac output in a group of infants and found that mean blood pressure increased at doses of 0.5 to 1 μg/kg/min, whereas heart rate increased beyond 2 to 3 μg/kg/min. Cardiac output and stroke volume increased before heart rate, and systemic vascular resistance (SVR) did not change within the range of dopamine infusion rates (0.5 to 8 μg/kg/min). The threshold values obtained were 14 ± 3.5 ng/mL for increase in mean blood pressure, 18 ± 4.5 ng/mL for increase in systolic blood pressure, and 35 ± 5 ng/mL for increase in heart rate. The steady-state concentration at infusion rates between 1 and 2 μg/kg/min was 16.5 ± 3.4 ng/mL. Thus newborns may exhibit clinical response at doses as low as 0.5 to 1 μg/kg/min. Seri and colleagues[128] demonstrated an increase in blood pressure without a change in heart rate in premature infants. Doses ranged from 2.5 to 7.5 μg/kg/min.[128] Interestingly, in this study, a greater increase in blood pressure was associated with a lower gestational age. The authors attributed this finding to the enhanced α adrenergic sensitivity of the immature myocardium.

Infused dopamine crosses the blood-brain barrier in preterm neonates but was shown not to increase blood flow velocity in the middle cerebral artery; dopamine inhibits the release of prolactin, thyrotropin, growth hormone, and the gonadotropins, but the clinical significance of these effects is unclear.[128-130] A study in 35 very low birth weight neonates with hypotension randomly assigned to receive dopamine or dobutamine confirmed an inhibitory dopamine effect on prolactin, thyroid-stimulating hormone, and thyroxine secretion. However, hormone levels rapidly normalized following the discontinuation of the dopamine infusion, and the authors speculated that there would be no long-term consequences.[131] This study also confirmed that dopamine is significantly more effective for blood pressure support in this population than dobutamine. The effectiveness of dopamine for blood pressure support also was shown in a separate study in 17 premature neonates with hemodynamically significant patent ductus arteriosus. A mean dopamine infusion rate of 8 μg/kg/min significantly increased systemic arterial pressure (30 ± 3 to 41 ± 5 mm Hg; $P < .05$), pulmonary artery pressure (25 ± 5 to 32 ± 8 mm Hg; $P < .05$), and superior vena caval blood

flow (130 ± 40 to 170 ± 44 mL/kg/min; $P < .05$), leading to a decrease in left-to-right ductal shunting of blood flow.[132]

Low infusion rates of dopamine are frequently employed to augment renal function during critical illness.[133] Although evidence exists that this treatment may increase the fractional excretion of sodium and the creatinine clearance, a large randomized, double-blind placebo control study of low-dose dopamine (2 μg/kg/min) administered to critically ill patients at risk of renal failure did not show any benefits.[134,135] The study group and the control group did not differ in peak creatinine concentration, need for renal replacement therapy, length of ICU or hospital stay, or mortality. Seri and colleagues[128] demonstrated an increase in urine output among premature infants associated with an increase in blood pressure and decrease in renal vascular resistance with dopamine, although they did not take into account the role of postnatal physiologic changes in urine volume. Use of low-dose dopamine in pediatric and neonatal ICUs to augment renal function is not uncommon despite the lack of evidence to suggest a beneficial effect.[136]

Pharmacokinetics

Plasma dopamine clearance ranges from 60 to 80 mL/kg/min in normal adults and is lower in patients with renal or hepatic disease.[116,137] In subjects with normal renal function, the elimination half-life of infused dopamine is approximately 2 minutes.[138] Among critically ill children, the elimination half-life is 26 ± 14 minutes, and in neonates the elimination half-life is 5 to 11 minutes.[139,140] Age has a striking effect on clearance of dopamine, and clearance in children younger than 2 years of age is approximately twice as rapid as it is in older children (82 vs. 46 mL/kg/min).[116] Wide interindividual variations in the rate of dopamine clearance have been reported in critically ill children as well as in healthy adults.[141,142] Dopamine clearance may also decrease after 24 hours of continuous infusion.[7] Allen and colleagues[113] confirmed that during the first 20 months of life, clearance of infused dopamine decreased by almost 50%, with an additional 50% decrease from ages 1 to 12 years. Another study did not show a correlation between age and dopamine clearance, although the patients in this study had a mean age of 37 months.[141] Age-related differences in COMT activity cannot account for the higher dopamine clearance values exhibited in neonates.[113] Banner and colleagues[143] studied the pharmacokinetics of infused dopamine in 15 patients ranging in age from 3 days to 8 years and noted nonlinear behavior, possibly resulting from saturable plasma protein binding in neonates. Although dopamine clearance correlated significantly with body weight, the authors questioned the utility of evaluating total body clearance in this age group. Differences in the rate of sulfoconjugation as a route of elimination also may contribute to the wide variations in the clearance of dopamine in critically ill children.[113,116,141] The possible role of concomitantly administered dobutamine on the clearance of dopamine has been suggested by some authors, but an in vitro study showed that although dopamine and dobutamine are competitors for both COMT and MAO, the concentrations achieved under clinical situations are unlikely to produce clinically significant levels of inhibition.[140,144] A pharmacokinetic difference between children and infants, rather than a difference in receptors or myocardial sensitivity, may account for the observation that infants require and tolerate higher infusion rates. Dopamine crosses the human placenta, but the effect on the fetus is not known. The pharmacokinetics of dopamine and other cardiovascular drugs has been reviewed.[145]

Clinical Role

Clinicians use dopamine to enhance renal function and to exploit its inotropic and vasopressor properties. Dopamine has been shown to be an effective inotropic and vasopressor agent in neonates and infants with a variety of conditions associated with circulatory failure, including hyaline membrane disease, asphyxia, sepsis syndrome, and cyanotic congenital heart disease.[146,147] Very few trials of pharmacological therapy for hypotension in the neonate have been conducted. Osborn and colleagues[148] found that although dopamine increases blood pressure, dobutamine produced a greater increase in blood flow, as judged by superior vena cava flow. Four other trials showed that dopamine was more effective than dobutamine in treating hypotension, but there was no difference in mortality.[149] Fewer data evaluating the efficacy of dopamine in older children are available. However, it remains a mainstay of pharmacologic support for the child with inadequate perfusion. Dopamine is recommended as the first-line agent for children with fluid refractory septic shock and has been recommended for adults as well, but this topic is debated.[150-152] Dopamine also may be appropriate for children with mild impairment of myocardial function and hypotension after resuscitation from cardiac arrest.[153,154] Severe impairment of vascular tone or of cardiac contractility suggest the need for other agents. Children with primary myocardial disease not complicated by frank hypotension will benefit from a more selective inotropic agent such as dobutamine or milrinone. Infusion rates of dopamine needed to improve signs of severe myocardial dysfunction may be associated with troublesome tachycardia or dysrhythmia and may increase myocardial oxygen consumption disproportionately to myocardial perfusion.

Although dopamine is used extensively following cardiac surgery, reports indicate that dopamine is less effective following cardiac surgery in infants than it is in older children or adults.[155] Lang and colleagues[156] treated five children with dopamine following cardiac surgery. For the group as a whole, hemodynamic improvement did not occur at infusion rates less than 15 μg/kg/min. When cardiac output did increase, it was attributed to an increase in heart rate rather than to improved stroke volume. Another study indicated that following cardiac surgery, dopamine and dobutamine have similar inotropic efficacy, but that dopamine was associated with pulmonary vasoconstriction at dosages greater than 7 μg/kg/min in the absence of α-adrenergic blockade.[157] Dopamine at 10 μg/kg/min improved right ventricle (RV) function after RV injury in a young swine model.[158] Increased RV ejection fraction with a decrease in end-systolic RV volume was noted in premature hypotensive infants treated with dopamine.[159] To treat shock associated with hypotension, therapy is initiated with an infusion rate of 5 to 10 μg/kg/min. The rate of infusion is increased in steps of 2 to 5 μg/kg/min, guided by evidence of improved blood flow (skin temperature, capillary refill, sensorium, and urine output) and by restoration of a blood pressure that is appropriate for age. Infusion rates greater than 25 to 30 μg/kg/min of dopamine are not customary, even if they maintain a "normal" blood pressure. At infusion rates of this magnitude, the effect on blood pressure is likely to represent

an increase in SVR (α-adrenergic activation) rather than cardiac output. A requirement for a dopamine infusion of this magnitude suggests that the physician reexamine the physiological diagnosis or select a different agent, such as epinephrine or norepinephrine.

Adverse Effects

Dopamine toxicity is mainly cardiovascular, resulting in tachycardia, hypertension, and dysrhythmia. Dopamine is less likely to produce severe tachycardia or dysrhythmias than either epinephrine or isoproterenol.[160] With the possible exception of the bipyridines, all inotropes increase myocardial oxygen consumption because they increase myocardial work. If the resulting increase in oxygen consumption is balanced by improved coronary blood flow, the net effect on oxygen balance is beneficial. When shock is caused or complicated by myocardial disease, improved myocardial contractility may reduce preload and afterload, improve coronary perfusion pressure (increase oxygen supply), and prolong diastolic coronary perfusion by reducing heart rate. If the same drug is administered to a patient with normal myocardial contractility, the result may be an increase in cardiac oxygen consumption without an increase in oxygen delivery to the myocardium. Tachycardia, by both increasing oxygen consumption and shortening diastole, is a particular burden. Thus the effect of dopamine on myocardial oxygen balance is better than that of isoproterenol, but not as good as dobutamine, amrinone, and milrinone.[161] Dopamine depresses the ventilatory response to hypoxemia and hypercarbia by as much as 60%.[162] Dopamine (and other β-agonists) decrease PaO_2 by interfering with hypoxic vasoconstriction.[163] In one study dopamine increased intrapulmonary shunting in patients with acute respiratory distress syndrome (ARDS) from 27% to 40%.[164] The effect of dopamine on perfusion to the splanchnic bed is widely debated. Evidence suggests that dopamine may increase splanchnic blood flow during sepsis and after cardiac surgery, increase gastric pH, and lead to less lactate production than epinephrine.[165-168] However, dopamine may increase blood flow or oxygen delivery but reduce oxygen consumption in patients with sepsis.[169,170] In infants and children who have undergone cardiac surgery, dopamine may have several endocrinologic effects. Prolactin levels are decreased, the pulsatility of growth hormone is decreased in infants, and thyrotropin levels are decreased.[118] Dopamine can cause or worsen limb ischemia, gangrene of distal parts and entire extremities, and extensive loss of skin.[171] Infusion rates as low as 1.5 μg/kg/min have been associated with limb loss. Because dopamine promotes release of norepinephrine from synaptic terminals (and is also converted to norepinephrine in vivo), it is more often associated with limb ischemia than other adrenergic compounds. Extravasations of dopamine should be treated immediately by local infiltration with a solution of phentolamine (Regitine, 5 to 10 mg in 10 mL of normal saline solution) administered with a fine hypodermic needle.[172]

Preparation and Administration

Dopamine hydrochloride is available in 5-mL vials at concentrations of 40 mg/mL, 80 mg/mL, and 160 mg/mL, and as 250 mL or 500 mL premixed solutions for infusion at concentrations of 0.8 mg/mL, 1.6 mg/mL, and 3.2 mg/mL in 5% dextrose.[139] Dopamine is administered by central vein to avoid the risk of skin injury resulting from extravasation. In an emergency, dopamine may be administered through an intraosseous needle.[173] Table 25-4 and Table 25-5 provide information regarding preparation of infusions and compatibility.[174,175] Table 25-4 presents a dilution method sometimes referred to as the "rule of 6." Evidence suggests that preparation of medicated infusions on patient care units, rather than in a hospital pharmacy, is associated with an increased incidence of medication errors. Therefore several groups and agencies now discourage use of the rule of 6 or any other system that involves nonstandard medication concentrations. Practitioners should consult the policies of their institution before prescribing any of the drugs listed in Table 25-4. Dopamine is not compatible with some of the 3-in-1 solutions utilized for parenteral nutrition or with sodium bicarbonate.[176] Dopamine is stable in solutions of 5% dextrose or normal saline solution for 24 hours to 84 hours.[176a,177]

Interactions

Dopamine is metabolized by MAO, and concurrent use of a MAO inhibitor (e.g., pargyline) potentiates its effect.[107] In this rare circumstance the initial dosage of dopamine should be reduced to one tenth the usual dosage.[178] Both α-adrenergic blockers and β-adrenergic blockers antagonize the effects of dopamine; dopamine antagonists such as metoclopramide or haloperidol also may attenuate response to dopamine. An increase in dopamine infusion rate will overcome the receptor blockade if necessary.

Summary

Dopamine is used to treat mild to moderate cardiogenic or distributive (septic; hypoxic-ischemic) shock associated with moderate degrees of hypotension. In the absence of hypotension, acute severe cardiac failure is treated with dobutamine or amrinone. When septic or cardiogenic shock is complicated by severe hypotension, epinephrine, or norepinephrine is preferred, depending on hemodynamic measurements (Table 25-6).

Norepinephrine

Basic Pharmacology

Dopamine is hydroxylated at the β-carbon to produce norepinephrine, the principal neurotransmitter of the sympathetic nervous system (Figure 25-8 and Figure 25-9). Because there is no substituent on the N (amino)-terminus, norepinephrine has little β_2 activity and is considerably less potent at that receptor than epinephrine.[107] It is a moderately potent α and β_1 agonist.

Clinical Pharmacology

Infusion in normal subjects elevates SVR because α-adrenergic stimulation is not opposed by β_2 stimulation.[107] Reflex vagal activity reduces the rate of sinus node discharge, thereby blunting the expected β_1 chronotropic effect. In normal subjects renal, splanchnic, and hepatic blood flows decrease. The increase in afterload may augment coronary blood flow. This effect may be enhanced by α-adrenergic receptors located in the coronary arteries, although in coronary arteries from explanted human hearts, the vasodilatation in response to norepinephrine was mediated via β_2 receptors.[179] Norepinephrine does have inotropic effects on the heart, mediated via α_1 and β_1 receptors. The proportion of inotropic response related to α_1 stimulation may be affected by the pressure load on the right ventricle.[180] In the failing heart, the relative contribution from each type of adrenergic receptor appears to be equal.[181] In the isolated rat heart, the inotropic effects of norepinephrine are diminished in the presence of a nitric oxide synthetase inhibitor but restored when a nitric oxide donor is present.[182] Interestingly, the contractile effects of norepinephrine in the rat are lost when it is pretreated with peroxynitrite.[183] In healthy volunteers norepinephrine produces a decrease in creatinine clearance because of the effect on renal blood flow; however, in patients with hypotension, the improvement in global perfusion may actually produce an increase in urine output.[184]

The acute hemodynamic effects of norepinephrine are compared with those of epinephrine and isoproterenol in Figure 25-10. Experience in critically ill children indicates that the hemodynamic responses are not different from those observed in adults. Use of norepinephrine in 18 neonates with persistent pulmonary hypertension–associated heart dysfunction revealed significant increases in systemic blood pressure (33 ± 4 to 49 ± 4 mm Hg; $P < .05$) and left ventricular output (172 ± 79 to 209 ± 90 mL/kg/min; $P < .05$), along with improvement in postductal transcutaneous oxygen saturation (89% ± 1% to 95% ± 4%; $P < .05$), pulmonary-to-systemic blood pressure ratio (0.98 ± 0.1 to 0.87 ± 0.1; $P < .05$), and a 20% increase in the velocity of pulmonary artery blood flow ($P < .05$).[185] In a separate study in 22 neonates with septic shock refractory to fluid support, dopamine, and/or dobutamine, norepinephrine (mean infusion rate 0.5 ± 0.4 μg/kg/min) significantly increased mean arterial blood pressure (36 ± 5 to 51 ± 7 mm Hg; $P < .001$) and urine output (1 ± 0.5 to 1.7 ± 0.4 mL/kg/hr; $P < .05$), while decreasing blood lactic acid concentrations (4.8 ± 2.3 to 3.3 ± 1.8 mmol/L; $P < .01$).[186]

Pharmacokinetics

Basal plasma levels of norepinephrine are much higher than basal plasma levels of epinephrine (250 to 500 vs. 20 to 60 pg/mL). The minimum concentration at which norepinephrine produces detectable hemodynamic activity is at least 1500 to 2000 pg/mL, suggesting that endogenous plasma norepinephrine simply represents "spillover" from sympathetic activity and that norepinephrine is not a true hormone.[187] The

Table 25–6 Selecting Inotropic and Vasopressor Agents for Specific Hemodynamic Disturbances in Children

	Blood Pressure or SVR		
Hemodynamic Pattern	**Normal**	**Decreased**	**Elevated**
SEPTIC SHOCK			
Stroke index ↑ or ↔		Norepinephrine	
Stroke index ↓	Dobutamine or dopamine	Dopamine or epinephrine (or dobutamine and norepinephrine)	Dobutamine plus vasodilator and/or PDIII inhibitor
Cardiogenic shock	Dobutamine or dopamine or PDIII inhibitor, **nesiritide**	Dopamine or epinephrine	Dobutamine plus vasodilator and/or PDIII inhibitor, **nesiritide**
Myocardial dysfunction* (complicating critical illness)	Dobutamine or dopamine or PDIII inhibitor, **nesiritide**	Dopamine or epinephrine	Dobutamine plus vasodilator and/or PDIII inhibitor, **nesiritide**
Congestive heart failure	Dobutamine or dopamine or PDIII inhibitor, **nesiritide**		Dobutamine plus vasodilator and/or PDIII inhibitor, **nesiritide**
Bradycardia		Isoproterenol	

*For example, acute respiratory distress syndrome or anthracycline therapy.
PDIII inhibitor, Amrinone or milrinone; SVR, systemic vascular resistance.

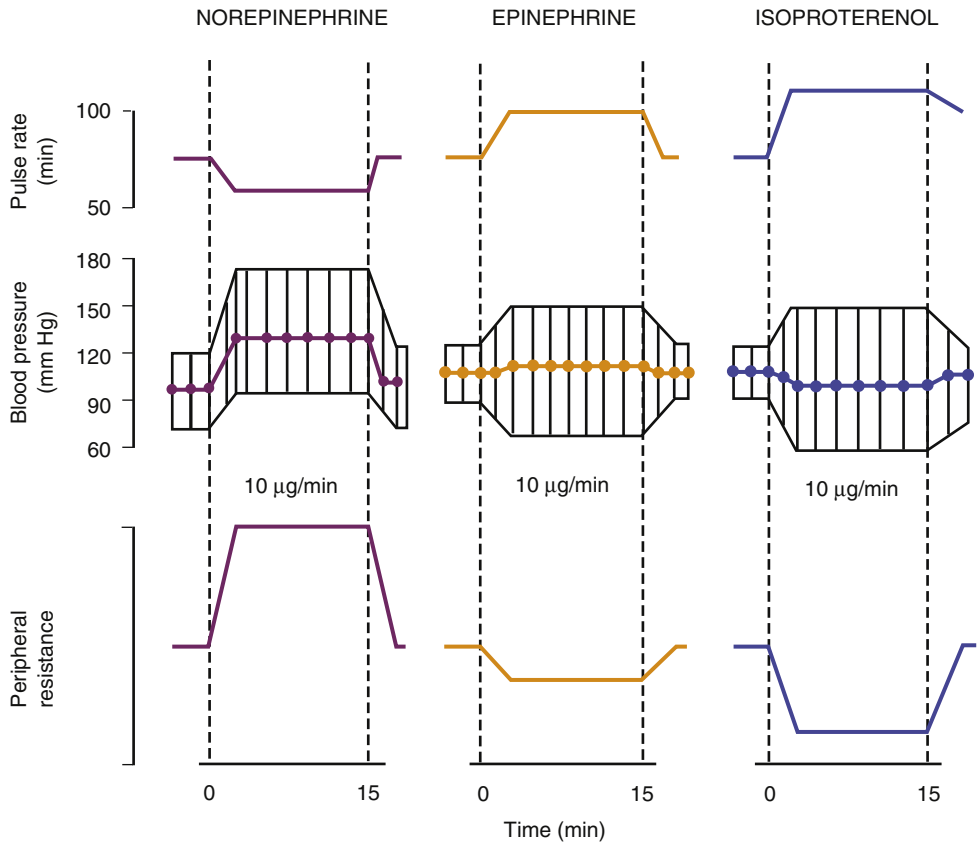

Figure 25–10. Effects of intravenous infusion of norepinephrine, epinephrine, and isoproterenol in adult humans. *(Modified from Allwood MJ, Cobbold AF, Ginsberg J: Peripheral vascular effects of noradrenaline, isopropylnoradrenaline and dopamine,* Br Med Bull *19:132, 1963.)*

clearance of norepinephrine in healthy adults is 24 to 40 mL/kg/min, with the half-life averaging 2 to 2.5 minutes.[188] The clinical effect of norepinephrine ceases within 2 minutes of the infusion being stopped.[188] Little pharmacokinetic information in children is available. Norepinephrine is inactivated by reuptake into nerve terminals, with some elimination occurring by enzymatic degradation in the liver, adrenal glands, and kidney, either by methylation to normetanephrine (by COMT) or by oxidative deamination.[189] Most of the metabolites formed by either MAO or COMT are then reduced or oxidized further. 3-Methoxy-4-hydroxymandelic acid is the major metabolite in the urine.[107]

Clinical Role

Norepinephrine improves perfusion in children with low blood pressure and a normal or elevated cardiac index. Septic shock is the usual context in which norepinephrine is beneficial. Norepinephrine is administered only after intravascular volume repletion and is best guided by estimates of cardiac output and SVR. Very little experience on the use of norepinephrine to treat distributive shock in children has been published; however, publications concerning adult patients provide a rationale for using this agent in patients with hypotension that is unresponsive to volume repletion and infusion of dopamine.[190-193a] In children, norepinephrine is the recommended agent for warm shock refractory to fluid loading and dopamine.[150] A prospective, unblinded randomized study (in adults) indicates that norepinephrine is superior to dopamine for treating hypotension and other hemodynamic abnormalities associated with hyperdynamic septic shock. In this study, the average infusion rate for norepinephrine was 2.7 μg/kg/min compared with the average dopamine dose of 22 μg/kg/min.[194] Others have reported that somewhat lower average dosages (0.4 μg/kg/min) were effective in adults with sepsis.[195] Coronary and renal blood flow increased in lambs at a dose of 0.4 μg/kg/min while mesenteric blood flow decreased.[196] Thus titration is important and may entail fairly rapid escalation of dosage. Norepinephrine produces increases in SVR, arterial blood pressure, and urine flow. It is most valuable in the context of tachycardia because infusion of the drug does not produce significant elevation of heart rate and may even lower heart rate through reflex mechanisms. In a study of adults with abdominal sepsis, norepinephrine infusion was associated with increases in systemic blood pressure and SVR. Stroke volume increased as heart rate declined. Cardiac index did not change, although creatinine clearance increased substantially.[195] Norepinephrine has been shown to improve right ventricular performance in adults with hyperdynamic septic shock.[194]

The usual starting dosage is an infusion of 0.1 μg/kg/min (Table 25-7), with a goal of elevating perfusion pressure so that the flow to vital organs is above the threshold needed to meet metabolic requirements.[197] Arbitrary values of SVR or blood pressure are not appropriate end points for therapy, and the lowest infusion rate that improves perfusion as judged by skin color and temperature, mental status, urine flow, and reduction in plasma lactate level should be used.[198]

Other causes of distributive shock (e.g., vasodilator ingestion and intoxication with CNS depressants) also should respond to norepinephrine infusion when the predominant hemodynamic problem is low SVR and blood pressure.

Table 25–7 Suggested Infusion Rates for Inotropic and Vasopressor Agents (μg/kg/min)

Agent	Clinical Indication	
	Inotropic	Pressor
Dopamine	2-15	>12
Epinephrine	0.05-0.5	0.10-1
Norepinephrine		0.05-1
Vasopressin		0.0002-0.002*
Dobutamine	2.5-20

Milrinone†	0.25-0.75	
Nesiritide†	**0.01**	
Isoproterenol	0.05-1	

*mU/kg/min; the optimal dosage and infusion rate have not been established in children.
†Loading dose required.

Adverse Effects

The increase in afterload that norepinephrine produces should increase myocardial oxygen consumption, but norepinephrine may reflexively decrease heart rate, which should reduce oxygen consumption and improve diastolic coronary perfusion.[107] Injudicious use of norepinephrine will lead to compromised organ blood flow. Norepinephrine infusion may elevate blood pressure yet not improve clinical indices of perfusion. This type of poor clinical response is usually associated with a low cardiac index, stroke volume, LV stroke work index, and an elevated pulmonary capillary wedge pressure.[190,191] Employing excessive dosages or using norepinephrine to elevate blood pressure without improving perfusion may produce multiple organ system failure.

Preparation and Administration

See Tables 25-4 and 25-5 for information regarding preparation and compatibility. Norepinephrine bitartrate is available in 4 mL ampules at a concentration of 1 mg/mL.[188] Norepinephrine should be diluted in 5% dextrose or 5% dextrose in 0.9% sodium chloride for preparation of infusions. Norepinephrine is administered only by central venous catheter, except in extreme emergency. Extravasation of norepinephrine should be treated immediately by local infiltration with a solution of phentolamine (Regitine, 5 to 10 mg in 10 mL of normal saline solution) administered with a fine hypodermic needle.[188,172] As with dopamine, norepinephrine should be administered by a syringe type of infusion device.

Interactions

Tricyclic antidepressants potentiate the action of norepinephrine by reducing neuronal uptake of the compound.[188] MAO inhibitors do not appear to enhance the activity of infused norepinephrine. α-Adrenergic blocking agents reduce efficacy of norepinephrine.

Summary

Norepinephrine is the agent of choice when the principal hemodynamic disturbance involves hypotension with an abnormally low SVR and a normal or high cardiac output after fluid resuscitation (Table 25-6). Septic shock is the usual indication, but it is frequently useful in other diseases associated with distributive shock.

Epinephrine

Basic Pharmacology

Epinephrine is synthesized in the adrenal medulla where it is formed from norepinephrine by addition of a methyl group to the N-terminus.[160] The reaction is catalyzed by N-methyltransferase (Figure 23-9). Epinephrine is a hormone, and endogenous levels of epinephrine change with the physiological state of the organism via afferent input to the adrenal medulla. Resting levels are less than 50 pg/mL; heavy exercise produces concentrations of 400 pg/mL or greater.[187] In a group of critically ill children not receiving catecholamines, epinephrine levels between 0 and 1378 pg/mL at admission (mean, 508 pg/mL) have been reported.[198a] Epinephrine activates α, β_1, and β_2 receptors. It is a principal hormone of stress and produces widespread metabolic and hemodynamic effects, which have been extensively reviewed.[160]

Clinical Pharmacology

β_1 receptors are affected by very low concentrations of epinephrine; consequently, one of the early effects of epinephrine infusion is activation of β_1 receptors in the myocardium and conducting systems, which accelerates phase 4 of the action potential. The rate of sinoatrial node discharge and heart rate increase, and systolic time intervals are shortened. The inotropic state of the myocardium is also enhanced, producing an increase in force of contraction and rate of rise of pressure. Evidence indicates that myocardial oxygen consumption is out of proportion to the increase in force of contraction, decreasing myocardial efficiency.[160] High concentrations of epinephrine or exposure to the compound when the myocardium is sensitive because of infarction, operation, or myocarditis may produce serious atrial and ventricular dysrhythmias.[160]

Stimulation of peripheral β_2 receptors promotes relaxation of resistance arterioles; SVR decreases and diastolic blood pressure falls (Figure 25-10). The decrease in SVR enhances the direct chronotropic effect of epinephrine. Higher plasma concentrations are associated with activation of vascular α receptors, and SVR increases. Higher doses also are associated with an increase in pulmonary vascular resistance, from direct effect and as a result of increased venous return to the right side of the heart.[160] The effect of epinephrine on the pulmonary vasculature may vary as a result of the dose used.[158] During infusion of epinephrine, hepatic and splanchnic blood flow increase, while renal blood flow may be reduced.[160]

The thresholds for producing these effects in healthy adults have been examined.[187] Normal basal levels are around 40 pg/mL. Heart rate accelerates between 50 and 100 pg/mL; changes in blood pressure (systolic blood pressure increases, diastolic blood pressure decreases) occur between 75 and 100 pg/mL. Various metabolic effects (hyperglycemia, hyperglycemia, cytogenesis, and glycolysis) occur between 150 and 200 pg/mL. Concentrations of this magnitude are achieved during therapeutic infusion of the drug. Other metabolic effects include hypophosphatemia and hypokalemia. Desensitization to elevated levels of epinephrine occurs rapidly and may be present prior to administration of exogenous catecholamines in the ICU.

Pharmacokinetics

In healthy male volunteers the plasma clearance of epinephrine is 35 to 89 mL/kg/min.[199,200] The elimination half-life is approximately 1 minute.[138] Epinephrine is methylated by COMT to metanephrine in the liver and kidneys or deaminated via the action of MAO.[140] It also may be metabolized by extraneuronal uptake.[189] The resulting catabolites then may be conjugated to sulfate or glucuronide and excreted in the urine. A wide interindividual variation in clearance is observed in healthy adults. In critically ill children receiving epinephrine at doses from 0.03 to 0.2 μg/kg/min, plasma concentrations at steady state ranged from 0.67 to 9.4 ng/mL and were linearly related to dose.[201] In this study, clearance ranged from 15 mL/kg/min to 79 mL/kg/min, demonstrating wide interindividual variation as with dopamine. It also should be noted that variability between the ordered dose of catecholamines and the measured dose have been noted.[202] Combined with the interindividual variation in clearance, there may be significant differences in serum levels between patients receiving the "same" dose of epinephrine or dopamine.

Clinical Role

Epinephrine is employed to treat shock associated with myocardial dysfunction. Thus it may be appropriate for treatment of cardiogenic shock that is unresponsive to dopamine or following cardiac surgery.[180] In a model of RV injury, epinephrine increased pulmonary artery blood flow and RV power with greater efficiency than did dopamine or dobutamine.[158] It also may be used to increase pulmonary flow across left to right shunts.[118] The patient with sepsis who does not improve adequately after intravascular volume repletion and treatment with dopamine or dobutamine may benefit from an infusion of epinephrine. Epinephrine is most likely to be useful when hypotension exists in the context of a low cardiac index and stroke index ("cold shock").[150] At modest infusion rates (0.05 to 0.1 μg/kg/min), SVR decreases slightly; heart rate, cardiac output, and systolic blood pressure increase. At intermediate infusion rates, α_1-adrenergic activation becomes important but is balanced by the improved cardiac output and activation of vascular β_2 receptors. Even though epinephrine constricts renal and cutaneous arterioles, renal function and skin perfusion may improve. Very high infusion rates (more than 1 to 2 μg/kg/min) are associated with significant α_1-adrenergic-mediated vasoconstriction; blood flow to individual organs will be compromised, and the associated increase in afterload may further impair myocardial function. The effects of epinephrine on splanchnic blood flow continue to be investigated. Studies have shown decreased splanchnic blood flow, decreased oxygen uptake, and increased lactate with epinephrine compared with norepinephrine despite similar increases in global oxygen delivery.[203] Dopamine led to a decrease in lactate and an increase in arterial pH, whereas epinephrine was associated with increases in lactate and metabolic acidosis despite similar increases in cardiac index and oxygen delivery.[165] At a dose of 3.2 μg/kg/min in newborn piglets, epinephrine increased SVR and PVR, with a decrease in hepatic blood flow and oxygen delivery and an increase in lactate.[204] However, these effects may be a result of the dosages used as well as concomitant catecholamines that are employed. Seguin and colleagues[205] demonstrated increased gastric blood flow with epinephrine compared with norepinephrine with dobutamine. They note that the doses of norepinephrine they used were higher than in previous studies. Other studies have shown that the degree of shock also may influence splanchnic blood flow.[206] In a study involving adult patients with septic shock, stepwise infusion of epinephrine was associated with linear increases in cardiac rate, mean arterial pressure (MAP), cardiac index, LV stroke work index, oxygen consumption, and oxygen delivery. In that study, neither pulmonary nor systemic vascular resistance was affected by epinephrine infusion.[108]

Epinephrine also has been evaluated in the treatment of hypotension in very low birth weight infants.[207] Epinephrine increased blood pressure and the heart rate without decreasing urine output in infants with hypotension who were not responding to a dopamine infusion up to 15 μg/kg per minute. Urine output tended to increase among infants who had been oliguric.

Bolus injections of epinephrine are used to treat asystole and other nonperfusing rhythms. The recommended initial dosage is 0.01 mg/kg (10 μg/kg or 0.1 ml/kg of the 1:10,000 solution).[208] The recommendation that subsequent doses be tenfold greater (so-called "high-dose epinephrine") has been deemphasized. Although initial studies utilizing high-dose epinephrine were encouraging, recent publications indicate no improvement in return of spontaneous circulation or survival after high-dose epinephrine following out-of-hospital cardiac arrest in children or adults.[209,210] Epinephrine may be given by endotracheal tube; the dosage is 100 μg/kg. Intraosseous administration is appropriate for both bolus and continuous administration of epinephrine. The dosage is the same as for intravenous injection. Epinephrine by infusion is also the agent of choice for hypotension or shock following successful treatment of cardiac arrest. Shock following an episode of hypoxemia or ischemia is usually cardiogenic and may respond to epinephrine infusion.

Preparation and Administration

Epinephrine for injection is available in 1-mL ampules at a concentration of 1 mg/mL, vials at concentrations of 0.1 mg/mL (1:10,000) and 1 mg/mL (1:1,000), and auto-injector syringes at concentrations of 0.15 mg/0.3 mL and 0.3 mg/0.3 mL.[208] The 1:10,000 injection may be administered undiluted. The 1:1000 injection must be diluted with 0.9% sodium chloride for injection prior to administration; that is, 1 mg (1 mL) epinephrine 1:1000 diluted with 9 mL 0.9% sodium chloride to a final concentration of 0.1 mg/mL (1:10,000). To prepare a continuous infusion of epinephrine, 1 mg (1 mL) of 1:1000 should be diluted with 250 mL of 0.9% sodium chloride or 5% dextrose in water (D5W) to a final concentration of 4 μg/mL. Epinephrine should be infused by a syringe type of pump into a central vein. Consult Tables 25-4 and 25-5 for further dilution and compatibility information.

Adverse Effects

Epinephrine produces CNS excitation manifested as anxiety, dread, nausea, and dyspnea.[161] Enhanced automaticity and increased oxygen consumption are the main serious cardiac toxicities.[160] Extreme tachycardia carries a substantial oxygen penalty, as does hypertension. A severe imbalance of myocardial oxygen delivery and oxygen consumption produces characteristic electrocardiogram changes of ischemia. A subischemic but persistently unfavorable ratio of oxygen delivery to consumption also may be harmful to the myocardium.

This subject has not been adequately examined in the setting of critical illness in children. Epinephrine produces tachycardia. Increases in infusion rate lead to successively more serious events, including atrial and ventricular extrasystoles, atrial and ventricular tachycardia, and, ultimately, ventricular fibrillation. Ventricular dysrhythmias in the pediatric age group are not common but may occur in the presence of myocarditis, hypokalemia, or hypoxemia. Hypokalemia is produced by epinephrine infusion because of stimulation of β_2-adrenergic receptors, which are linked to sodium-potassium-ATPase located in skeletal muscle.[211] Infusion of 0.1 μg/kg/min lowered serum potassium by 0.8 mEq/L. Hyperglycemia results from β-adrenergic-mediated suppression of insulin release. Epinephrine is an α_1-adrenergic agonist, and infiltration into local tissues or intraarterial injection can produce severe vasospasm and tissue injury.[160] Concurrent activation of β_2 receptors by epinephrine limits vasospasm, and local injury to tissue is less frequent than with either norepinephrine or dopamine.

Epinephrine overdosage is serious. Several neonates died when inadvertently subjected to oral administration of huge amounts of epinephrine.[212] The syndrome mimicked an epidemic of neonatal sepsis with shock and metabolic acidosis. Intraaortic injection in infants (per umbilical artery) produces tachycardia, hypertension, and renal failure. Intravenous overdosage of epinephrine is immediately life-threatening. Manifestations include myocardial infarction, ventricular tachycardia, extreme hypertension (up to 400/300 mm Hg), cerebral hemorrhage, seizures, renal failure, and pulmonary edema. Bradycardia also has been observed. Manifestations of acute overdosage are treated symptomatically. β-receptor antagonists such as propranolol are contraindicated. Hypertension is treated with short-acting antihypertensives (e.g., nitroprusside).

Interactions

Tricyclic antidepressants and antihistamines such as diphenhydramine may potentiate the effects of epinephrine; use of fluorinated anesthetic agents such as halothane may increase the frequency of ventricular dysrhythmia.[160,213-215] Administration of epinephrine with a β-adrenergic antagonist such as propranolol may be dangerous because of residual unopposed α_1 activity; the result can be severe hypertension and bradycardia terminating in asystole. The concomitant use of α- or β-adrenergic antagonists also may antagonize the therapeutic effects of epinephrine.

Summary

Epinephrine is useful in treating shock associated with myocardial dysfunction and hypotension. In pediatric critical care, the most frequent indications for epinephrine infusion are cardiogenic shock, septic shock associated with reduced stroke volume, and shock following severe hypoxemia-ischemia (see Table 25-6).

Isoproterenol

Basic Pharmacology

Isoproterenol is the synthetic N-isopropyl derivative of norepinephrine (see Figure 25-8). The bulky N-terminal substituent confers β (β_1 and β_2) receptor specificity; the compound does not affect the α-adrenergic receptor. Thus the principal cardiovascular activities of isoproterenol relate to its inotropic, chronotropic, and peripheral vasodilator effects.[160]

Clinical Pharmacology

Isoproterenol enhances cardiac contractility and cardiac rate.[160] Peripheral vasodilatation produces a fall in SVR, augmenting the direct chronotropic action of the drug. Significant tachycardia ensues. Systolic blood pressure increases while mean and diastolic pressures fall (see Figure 25-10). If they were normal prior to infusion of isoproterenol, mesenteric and renal perfusions fall; however, if the subject was in shock, then the increase in cardiac output associated with isoproterenol administration may result in an increase in blood flow to these tissues.[160] Isoproterenol increases myocardial demand for oxygen and decreases supply by reducing diastolic coronary filling. If intravascularly the patient is fluid depleted, hypotension may complicate initiation of isoproterenol infusion.

Pulmonary bronchial and vascular bed β_2-adrenergic receptors produce bronchodilation and pulmonary vasodilatation, respectively.[216] For this reason isoproterenol by continuous intravenous infusion was employed as adjunctive therapy in children with refractory or rapidly worsening status asthmaticus.[69] At present, continuously nebulized albuterol and intravenous infusion of albuterol or terbutaline have largely supplanted isoproterenol for this indication.

Isoproterenol has few important metabolic effects. Hyperglycemia is not usually observed, although the drug does promote release of free fatty acids. Isoproterenol infusion causes sympathetic neurons to release norepinephrine, producing an increase in plasma levels of norepinephrine; however, this effect relative to the hemodynamic response to isoproterenol has not been studied.[189]

Pharmacokinetics

Isoproterenol is metabolized by COMT.[160] The plasma elimination half-life of isoproterenol is 1.5 to 4.2 minutes.[217,218] Information about therapeutic isoproterenol concentrations is not available in critically ill patients. In healthy volunteers, tachycardia and increases in stroke volume were observed at 50 pg/mL.[189]

Clinical Role

In the past isoproterenol was used for a variety of indications, including septic shock and cardiogenic shock associated with myocardial infarction; however, newer agents such as dopamine and dobutamine, together with a more subtle understanding of the pathophysiology of shock, have limited the use of this compound to very few specific indications.

Isoproterenol may be used to treat hemodynamically significant bradycardia.[219] However, epinephrine infusion is probably preferable.[197] When bradycardia results from heart block, placement of a pacemaker is definitive treatment. Bradycardia due to anoxia is treated by administering oxygen and improving gas exchange.

Preparation and Administration

Isoproterenol is available in 1 mL and 5 mL ampules at a concentration of 0.2 mg/mL (1:5000).[220] Prior to administration, dilute 1 mL (0.2 mg) to a final volume of 10 mL with 0.9% sodium chloride for injection or D5W to a final concentration of 20 μg/mL (1:50,000). To prepare an intravenous infusion of

isoproterenol, 1 to 10 mL of 1:5000 injection should be diluted with 500 mL of D5W to a final concentration of 0.4 to 4 μg/mL. The reader is directed to Table 25-4 for further dilution information.

Adverse Effects

Adverse effects associated with isoproterenol include fear, anxiety, restlessness, insomnia, and blurred vision.[220] Other effects may include headache, dizziness, tinnitus, sweating, flushing, pallor, tremor, nausea, vomiting, and asthenia. Cardiovascular effects may include ventricular tachycardia and other ventricular dysrhythmias that may be life-threatening. Isoproterenol may cause hypertension and also can cause severe hypotension.

Interactions

The concomitant administration of a halogenated general anesthetic such as halothane or an intravenous methylxanthine such as aminophylline may potentiate the adverse cardiovascular effects of isoproterenol.[220] Propranolol given before an operation to repair tetralogy of Fallot attenuates the response to isoproterenol postoperatively.[221] Isoproterenol decreases serum theophylline concentrations during concomitant therapy of status asthmaticus, and it may be necessary to increase theophylline dosage when isoproterenol therapy is initiated and reduce theophylline dosage when isoproterenol is discontinued.[222]

Summary

Isoproterenol is rarely used to treat children or adults. In the acute setting, it may play a role in the treatment of symptomatic bradycardia. Although it is effective adjunctive therapy for respiratory failure associated with status asthmaticus, more selective β_2 agonists are safer to use and are preferred.

Dobutamine

Basic Pharmacology

The structure of dobutamine, a synthetic catecholamine, resembles dopamine in that the β carbon is not hydroxylated. Unlike other catecholamines, there is a large aromatic substituent on the N-terminus. Like isoproterenol, dobutamine is administered as a racemate; (+) dobutamine is a strong β agonist and an α antagonist, and (–) dobutamine is an α agonist and a weak βagonist.[223] That dobutamine delivers significant inotropic and usually trivial chronotropic and vasopressor activity has been ascribed to this blend of receptor activities.

Clinical Pharmacology

In adults with CHF, dobutamine increased cardiac index from 2.4 to 2.9 L/min/m, decreased LV end-diastolic volume and increased the LV dP/dt.[224] Although renal function and urine output may improve as the increase in cardiac output fosters relaxation of sympathetic tone and improved perfusion, dobutamine did not improve indices of renal function compared with dopamine in critically ill patients.[135] Dobutamine improved RV systolic function and decreased pulmonary vascular resistance in piglets with RV injury.[158] In healthy children, dobutamine increased LV systolic function and relaxation.[225] In the newborn piglet, dobutamine increased superior mesenteric and renal artery blood flow after 60 minutes, increased cardiac index, and decreased SVR.[226] A threshold model with a log-linear dose-response relationship above the threshold has been demonstrated in critically ill term and preterm neonates and in children between 2 months and 14 years of age.[141,227] In one small study, dobutamine infusion (10 μg/kg/min) was associated with increases in cardiac output (30%), blood pressure (17%), and heart rate (7%). The thresholds for these increases were 13, 23, and 65 ng/mL, respectively, demonstrating that dobutamine is a relatively selective inotrope with little effect on heart rate at customary infusion rates.[228] Somewhat greater thresholds for improved cardiac output were observed in a second group of children and in infants, but in all studies, dobutamine improved cardiac contractility without substantially altering heart rate unless high infusion rates were employed.[227,229] Dobutamine has been shown to increase cerebral blood flow velocity but not cerebral oxygen consumption in patients with septic shock.[230]

Pharmacokinetics

The plasma elimination half-life of dobutamine in adults is approximately 2 minutes.[138] CHF increases the volume of distribution. In adults with CHF the terminal elimination half-life ($t_{½\beta}$) of dobutamine has been reported to be 2.37 minutes, with an apparent volume of distribution of 0.2 L/kg and total body clearance of 2.33 L/min/m^2.[231] Reported clearance values in children have ranged from 32 to 625 mL/kg/min in one study and from 40 to 130 mL/min/kg in another.[143,228] Infusions in the range used clinically yield plasma dobutamine concentrations from approximately 50 to 190 ng/mL in children and adults.[228] The principal route of elimination is methylation by COMT, followed by hepatic glucuronidation and excretion into urine and bile.[160] 3-O-methyldobutamine also represents a major route of elimination for dobutamine, with up to 33% of the infused drug being eliminated as the sulfoconjugated compound.[232] Dobutamine also is cleared from the plasma by nonneuronal uptake. Some investigators have reported nonlinear elimination kinetics, but other data suggest that dobutamine's kinetics can be adequately described by a simple first-order (linear) model.[141,143,145,228]

Clinical Role

In adults dobutamine produces improvement in a variety of conditions associated with poor myocardial performance, such as cardiomyopathy, atherosclerotic heart disease, and acute myocardial infarction. Dobutamine has been used following surgery for myocardial revascularization, cardiac transplantation, and other procedures associated with postoperative myocardial dysfunction, although undesirable chronotropic effects have been recorded when it has been used after cardiac surgery.[233] It is not clear that septic shock is an appropriate context in which to prescribe dobutamine, unless the primary disturbance is complicated by myocardial dysfunction. Although impaired myocardial performance can be demonstrated early in patients with septic shock, the main problem relates to regulation of vascular tone, and preferred agents are those that increase systemic vascular resistance. When ventricular dysfunction becomes an important complicating factor, however, dobutamine may be a useful adjunct. In this context, dobutamine alone or in combination with dopamine has produced an increase in cardiac output, LV stroke work, and blood pressure.[89] As indicated in Table 25-6, dobutamine also can be combined with norepinephrine

in treating the patient with myocardial dysfunction that is associated with hyperdynamic shock (e.g., a child who has received a cardiotoxic agent to treat cancer and in whom septic shock subsequently has developed).

Several studies in infants and children demonstrate that dobutamine improves myocardial function in a variety of settings.[141,227,228] Stroke volume and cardiac index improve without a substantial increase in cardiac rate. SVR and pulmonary vascular resistance (PVR) may decrease toward normal.[234] Dobutamine has been evaluated in children following cardiac surgery with cardiopulmonary bypass. In a study by Bohn and colleagues,[90] dobutamine enhanced cardiac output by increasing heart rate; indeed, tachycardia prompted discontinuation of the infusion in several patients. The expected fall in SVR was not observed in children who received the drug after cardiopulmonary bypass. The authors found no benefit compared with isoproterenol or dopamine. These differences between adults and children may be due to the fact that myocardial dysfunction and CHF are not characteristic of the circulatory status of many children undergoing repair of congenital heart disease. Unlike in adults, the indication for the operation involves abnormalities in ventricular architecture or abnormal circulatory anatomy. Berner and associates[235] found that children undergoing operations for mitral valve disease responded to dobutamine with an increase in stroke volume, whereas children with tetralogy of Fallot repair did not, and their cardiac output increased only through a higher heart rate. A more recent report by the same group indicated that following repair of tetralogy of Fallot, dobutamine did enhance cardiac output when it was combined with atrial pacing to increase heart rate. Isoproterenol without pacing provided a higher cardiac output than either dobutamine alone or dobutamine in combination with pacing.[236] Booker and colleagues[157] found that dobutamine and dopamine had equivalent inotropic effects in children following cardiac surgery. Specific indications for prescribing dobutamine in the pediatric age group are those associated with low output CHF and a normal to moderately decreased blood pressure (see Table 25-6). Typical examples include viral myocarditis; cardiomyopathy associated with use of anthracyclines, cyclophosphamide, or hemochromatosis (related to hypertransfusion therapy); or myocardial infarction (Kawasaki disease).

Dobutamine is *not* a first-line agent to treat low output states that are caused by intracardiac shunt or abnormal cardiac chamber structure. Dobutamine is used following corrective or palliative cardiovascular surgery in the child; however, in this context, its use also should be limited to occasions in which demonstrated or suspected myocardial dysfunction exists. Dobutamine may be of adjunctive value in treating myocardial dysfunction that complicates a primary condition such as ARDS or septic shock. Rarely, however, will it be appropriate to use dobutamine as the sole agent to treat hemodynamic compromise associated with sepsis, ARDS, or shock following an episode of severe hypoxia-ischemia.

Adverse Effects

Dobutamine usually increases myocardial oxygen demand. In subjects with myocardial dysfunction, coronary blood flow and oxygen supply improve with the increase in demand. However, if dobutamine is used when myocardial contractility is normal, oxygen balance will be adversely affected.[237] Tachycardia greatly increases oxygen use by the heart and should prompt a reduction in the dosage of dobutamine (or use of an alternate agent).

Although dobutamine is less likely than other catecholamines to induce serious atrial and ventricular dysrhythmias, these may occur in patients receiving dobutamine, particularly in the context of myocarditis, electrolyte imbalance, or high infusion rates.[234] Dobutamine and other inotropes should be administered cautiously to patients with dynamic LV outflow obstruction (hypertrophic aortic stenosis). Prolonged infusion of dobutamine inhibits the second wave of adenosine diphosphate induced platelet aggregation; in a few adult patients petechial bleeding attributed to dobutamine has developed.[238]

Preparation and Administration

Dobutamine is available at a concentration of 12.5 mg/mL in 20-mL, 40-mL, and 100-mL vials.[239] Prior to administration, dobutamine must be diluted to a final concentration of no greater than 5 mg/mL. Dobutamine also is available in premixed infusion bags at concentrations of 0.5 mg/mL, 1 mg/mL, 2 mg/mL, and 4 mg/mL in D5W. For further information regarding dilution and compatibility, refer to Table 25-4 and Table 25-5. Therapy is initiated at a rate of 2.5 to 5 μg/kg/min (see Table 25-7). One should consider a change to epinephrine if no substantial improvement occurs with infusion rates of 20 μg/kg/min.

Adverse Effects

Adverse cardiovascular effects may include hypertension, tachycardia, and ectopic heart beats.[239] Dobutamine also may cause headache, nausea, vomiting, paresthesia, and dyspnea. Dobutamine also may decrease serum potassium concentrations.

Interactions

The concomitant use of a β-adrenergic antagonist such as propranolol may antagonize the cardiovascular actions of dobutamine.[239] Halogenated anesthetic agents such as halothane may potentiate the adverse cardiovascular effects of dobutamine. Dobutamine may increase the insulin requirement of diabetic patients, and dobutamine may interfere with measurement of chloramphenicol by high-performance liquid chromatography.[240,241]

Summary

Dobutamine is a positive inotropic agent that should be reserved to treat poor myocardial contractility. Following cardiac surgery, dobutamine may be used when contractility is abnormal. For septic shock and other acute hemodynamic disturbances, dobutamine is an adjunct when the primary problem is complicated by poor myocardial function (see Table 25-6). In this context, concomitant use of a vasopressor such as norepinephrine may be appropriate.

Vasopressin

Basic Pharmacology

Vasopressin is a highly conserved hormone, and vasopressin-like peptides are present in numerous species. Its main function is to preserve fluid balance in the organism. In humans, it is released in response to two main stimuli: increases in plasma osmolality and decreases in effective circulating volume or

blood pressure. Although vasopressin has long been used for the treatment of diabetes insipidus, its name derives from its vasopressor effect. Vasopressin has a number of effects beyond volume regulation. It acts as a neurotransmitter in the CNS, has a role regulating adrenocorticotropin hormone release, and is involved in thermoregulation, platelet aggregation, and smooth muscle contraction in the uterus and gastrointestinal tract.[49,50]

Clinical Pharmacology

As noted previously, the response patterns are different for the two stimuli for vasopressin release. An increase in plasma osmolality above 280 mOsm/kg leads to a dramatic increase in the release of vasopressin from the posterior pituitary, and the hormone exerts its effect by increasing water reabsorption in the renal collecting duct. The dose/response curve is so steep that when osmolality is 290 mOsm/kg, vasopressin levels exceed those that produce maximal urinary concentration. In contrast, the threshold for release in response to hypovolemia or hypotension is much higher, with decreases of greater than 20% required. However, once the threshold is reached, plasma levels rise twentyfold to thirtyfold (far exceeding levels seen with hyperosmolality).[50] Vasopressin exerts its hemodynamic effects via the V_{1a} receptor, which is coupled to G_q. In the peripheral vasculature, intracellular calcium is increased, enhancing contraction and restoring systemic vascular tone. Vasopressin also inhibits potassium channels, further increasing intracellular calcium.[62,242] Baroreceptors in the left atrium, LV, and pulmonary veins sense changes in volume while baroreceptors in the carotid sinus and aorta sense changes in arterial pressure.[50] Decreased pressure leads to a reduced rate of firing and release of the tonic inhibition of vasopressin release.[49]

Vasopressin is a potent vasopressor when present in the plasma at high concentrations. At the lower concentrations associated with the vasopressin response to hyperosmolarity rather than hypotension, it does not elevate blood pressure because the resulting decrease in heart rate offsets the increase in SVR. For this reason, vasopressin was not considered to be a clinically useful agent to treat hypotension.[243] Landry and colleagues[244] measured plasma vasopressin levels in 19 patients with septic shock and 12 patients with cardiogenic shock (all receiving catecholamine support). Surprisingly, plasma levels of vasopressin were not elevated in patients with septic shock (mean 3.1 pg/mL; normal <5 pg/mL). Patients with cardiogenic shock had an expected mean level of 22.7 pg/mL. Vasopressin infusion (0.04 units/min intravenously) in 10 patients with septic shock who were receiving catecholamines produced an increase in SVR and MAP, which was associated with a decrease in cardiac index (CI). The resulting plasma level of vasopressin was 30 pg/mL, an appropriate concentration considering the level of hypotension. Therefore vasopressin plasma levels are inappropriately low in patients with vasodilatory septic shock, possibly because of impaired baroreflex-mediated secretion. The authors hypothesized that this phenomenon contributes to the hypotension of vasodilatory septic shock.

It appears that in the early stages of septic shock, vasopressin levels are higher than normal but decrease to either low levels or levels that represent a relative deficiency (normal level in the setting of hypotension) as shock continues.[245] This pattern has also been shown in a model of hemorrhagic shock.[246] In this study, neurohypophysis stores of vasopressin were depleted. In three patients with septic shock and low levels of vasopressin, the high intensity signal from the posterior pituitary on T1 weighted magnetic resonance imaging was lost, suggesting depletion of vasopressin.[245] Hence vasopressin deficiency may occur early in vasodilatory shock and contribute to its pathogenesis.

Pharmacokinetics

Vasopressin circulates as a free peptide and does not exhibit any protein binding.[55] It is degraded rapidly in the kidneys and liver, with 5% to 15% of an intravenous dose eliminated unchanged in the urine.[178] Renal failure or hepatic insufficiency can prolong the elimination half-life.[247,248] The normal elimination half-life is 10 to 20 minutes.[178]

Clinical Role

The original report by Landry and colleagues[244] has generated intense investigation into the clinical applications of vasopressin in the setting of vasodilatory shock. The same group prospectively evaluated vasopressin in patients with vasodilatory shock after placement of an LV assist device.[249] At a dose of 0.1 units/min, vasopressin increased MAP and SVR but not CI. Among patients with a high level of endogenous vasopressin, the increase in blood pressure tended to be less. A rapid response to vasopressin was noted in all patients, allowing for the dose to be decreased to as low as 0.01 units/min. This group also published experience with vasopressin in patients with septic shock and children after cardiac surgery.[250,251] In five patients with septic shock, vasopressin was given at doses ranging from 0.03 to 0.05 units/min. Again, blood pressure and SVR increased, allowing for discontinuation of catecholamine support in four patients. In 11 children, vasopressin was used to treat hypotension following cardiac surgery. At doses ranging from 0.0003 to 0.002 units/kg/min, vasopressin increased blood pressure within 1 hour, and the epinephrine infusion could be decreased in five of eight patients. Two patients who had echocardiographic evidence of poor function died. The remaining nine patients with vasodilatory shock survived and were discharged from the ICU. The authors cautioned against the use of vasopressin in patients with cardiogenic shock, in view of the potential effect on CI. Vasopressin levels were measured in three patients; two had an absolute deficiency and one had a relative deficiency of vasopressin. In adults, vasopressin deficiency (relative or absolute) was associated with shock following cardiopulmonary bypass. Hemodynamic function improved with vasopressin, and the need for other vasopressors decreased.[252] In a small double-blind randomized study, prophylactic vasopressin (0.03 units/minute) decreased the need for norepinephrine and ICU length of stay in patients receiving angiotensin-converting enzyme inhibitors who underwent cardiopulmonary bypass.[253] In another small study (N = 10), patients admitted to a trauma unit with the diagnosis of septic shock were randomly assigned to placebo or vasopressin at 0.04 units/min if they remained in shock with catecholamine support.[254] In the treatment group (n = 5), systolic blood pressure and SVR increased. Other vasopressors were discontinued within 24 hours in patients receiving vasopressin; in only one patient in the placebo group was other vasopressor support discontinued. In a larger, prospective, randomized study, the combination of vasopressin and norepinephrine was evaluated versus

norepinephrine alone in patients with catecholamine resistant vasodilatory shock.[255] Vasopressin was given at a dose of 0.06 units/min. The patients in the vasopressin-norepinephrine arm had a lower heart rate and higher blood pressure, SVR, and CI. They also had reduced requirements for norepinephrine; additionally, the norepinephrine group had a higher rate of new-onset dysrhythmias. Gastric perfusion also was better preserved in the vasopressin group.

In summary, in several studies of patients with vasodilatory shock, vasopressin has been shown to improve blood pressure, increase SVR, lessen the need for catecholamines, improve markers of myocardial ischemia and improve urine output.[139,256-258] Published experience in pediatric patients with septic shock is limited. Bojko and colleagues[259] published an abstract based on one case. At a dose of 0.02 units/min, blood pressure and SVR index increased and urine output improved with subsequent discontinuation of catecholamine therapy. Liedel and colleagues[260] published their experience with five patients, ranging in age from 2 weeks (23 week premature infant) to 14 years. Doses utilized were between 0.0006 units/kg/min and 0.008 units/kg/min (one patient was given 0.06 units/min). In all five patients, blood pressure increased (in one patient, blood pressure increased briefly prior to rapid deterioration and death) and catecholamine support could be decreased. In three patients, urine output improved. No formal randomized trial of vasopressin in pediatric patients with septic shock or following cardiac surgery has been published to date. Vasopressin also has been used as a vasopressor in children undergoing evaluation for brain death.[261] At a dose of 0.04 units/kg/h, blood pressure increased and α agonist support was decreased. No deleterious effect on organ function was noted.

Vasopressin also has become part of the Advanced Cardiac Life Support protocol for ventricular fibrillation in adults.[153] For children, however, the guidelines state that insufficient evidence exists, based on inconsistent results in adult patients, to make a recommendation either for or against the use of vasopressin in children who experience cardiac arrest.[262] Mann and colleagues[263] published their experience with vasopressin during cardiopulmonary resuscitation in pediatric patients. In six events involving four patients, vasopressin was given at a dose of 0.4 units/kg after conventional therapy had failed to achieve restoration of spontaneous circulation (ROSC). In all six events, pulseless electrical activity was the initial rhythm; at the time vasopressin was given, four patients were in asystole, one had pulseless ventricular tachycardia, and one had ventricular fibrillation. In four events (three patients), ROSC was achieved for more than 60 minutes. Of the two patients who survived for longer than 24 hours, one was discharged home in a condition close to her neurologic baseline; in the other patient, care was electively withdrawn. A recent review of the American Heart Association National Registry of Cardiopulmonary Resuscitation in children suggested a lower rate of return of spontaneous circulation (ROSC) in patients to whom vasopressin was administered during in-hospital resuscitation.[264] The authors emphasize that this result should be interpreted with caution, however, because vasopressin was only administered in 5% of the 1293 cases reviewed, in cases involving resuscitation efforts and vasopressin use after epinephrine had failed.

Preparation and Administration

Vasopressin is available at a concentration of 20 pressor units per mL in 0.5-mL, 1-mL, and 10-mL vials.[178]

Adverse Effects

Few adverse events have been reported with the use of vasopressin in the setting of vasodilatory shock. Elevation of liver enzymes and total bilirubin with a decrease in platelet count has been noted, and one series noted six cardiac arrests among 50 patients receiving vasopressin for hemodynamic support.[257,265] All six patients had "severe refractory shock," and five were receiving a vasopressin dose greater than 0.05 units/min. In 30% of patients receiving vasopressin, ischemic skin lesions of the distal limbs, trunk, or tongue were noted to develop. Preexisting peripheral arterial occlusive disease and the presence of septic shock were identified as risk factors.[265] Extravasation of vasopressin from a peripheral intravenous catheter was associated with skin necrosis.[266]

Interactions

The antidiuretic effect of vasopressin may be antagonized with the concomitant administration of epinephrine, heparin, lithium, or demeclocycline.[178] Tricyclic agents, chlorpropamide, carbamazepine, clofibrate, phenformin, and fludrocortisone may exert additive antidiuretic effects when used in combination with vasopressin. The concomitant use of vasopressin with a ganglionic blocking agent can enhance the pressor effect of vasopressin.

Summary

Vasopressin is a recent addition to the PICU practitioner's armamentarium for the treatment of decreased systemic vascular resistance. Its use may elevate blood pressure and urine output in patients with catecholamine refractory vasodilatory shock. The optimal dose has yet to be determined and the pharmacokinetics of the drug in conditions such as septic shock or after cardiopulmonary bypass need to be investigated. It may have a role in the future in pediatric advanced life support. Vasopressin should not be used in settings where impaired myocardial function is the principal problem. Controlled trials in the pediatric age group are urgently needed and should be accompanied by appropriate pharmacokinetic measurements.

Terlipressin

Basic Pharmacology

Telipressin (N_{α}-triglycyl-8-lysine vasopressin) is a synthetic analogue of lysine vasopressin, the endogenous vasopressin peptide found in mammals such as marsupials and pigs (arginine vasopressin is endogenous to humans).[267] Following intravenous administration, the three glycyl groups on terlipressin are enzymatically cleaved by endopeptidases, resulting in prolonged release of the active lysine vasopressin moiety. As a result, terlipressin has a longer duration of vasoconstrictive action (4 to 6 hours) than does arginine vasopressin (6 to 20 minutes).[267,268] Interestingly, the vasoactive effects of terlipressin are due in part to direct terlipressin effects and not solely to the liberated lysine vasopressin moiety.[269,270]

Clinical Pharmacology and Adverse Effects

Clinical trials in adults with refractory septic shock have demonstrated the ability of terlipressin administered as 1- to 2-mg intravenous boluses to significantly increase systemic vascular

resistance and MAP, PVS, and urine output, along with a reduction in blood lactate levels and the use of vasoactive catecholamines.[268,271-273] However, terlipressin also exhibits a number of troublesome adverse effects on the myocardium, including significant reductions in cardiac index, heart rate, oxygen delivery index, and oxygen consumption index. Trials are currently in progress to identify the optimal dosing strategy, including low-dose bolus or continuous intravenous infusion regimens.

A limited number of trials in children with refractory septic shock suggest a similar pharmacodynamic profile as that observed in adult patients.[274-277] A study in 14 children (mean age 5.6 years) with septic shock refractory to fluid resuscitation and vasopressors evaluated the addition of terlipressin intravenous boluses at an initial dose of 7 μg/kg twice daily, titrated based on blood pressure response to 20 μg/kg every 6 hours.[275] Terlipressin was associated with significant increases in mean arterial pressure (54 ± 3 to 72 ± 5 mm Hg; $P = .001$) at 10 minutes, and urine output (1.6 ± 0.5 to 4.3 ± 1.2 mL/kg/h; $P = .011$) at 1 hour after administration. The investigators also noted a significant reduction in heart rate (153 ± 6.5 to 138 ± 7.5 beats per minute; $P = .003$) at 12 hours, and a trend toward an increase in Pa_{O2} (95.1 ± 12.3 to 110.1 ± 20.5 mm Hg) and decrease in oxygenation index (10.2 ± 2.2 to 9.2 ± 1.7). Terlipressin has also been administered in the setting of prolonged pediatric cardiopulmonary resuscitation.[278] Terlipressin was administered as a 15 to 20 μg/kg intravenous bolus to 7 infants and children (age range, 2 months to 6 years) with asystole, representing eight episodes of cardiac arrest, who were undergoing cardiopulmonary resuscitation and had failed to respond to conventional therapy. Return of spontaneous circulation was achieved in six of the eight cardiac arrest episodes, with four patients surviving to discharge from the hospital. These results should be interpreted with caution until information from additional studies is available.

Bipyridines

Inamrinone, milrinone, enoximone, and piroximone are nonsympathomimetic inotropic agents. The structure (not a catecholamine) of inamrinone and milrinone are is shown in Figure 25-11. Inamrinone and milrinone are currently available for intravenous use only. As described previously, the pharmacologic effects of the bipyridines result from selective inhibition of phosphodiesterase III and not from interaction with adrenergic receptors or inhibition of sodium-potassium ATPase.[72] These agents produce positive inotropic and lusitropic effects on isolated ventricular tissue as well as relaxation of vascular smooth muscle. They often are used to improve myocardial contractility and to decrease ventricular afterload.

Inamrinone

Clinical Pharmacology

Administration of phosphodiesterase inhibitors to subjects with CHF results in an increase in cardiac output and a reduction of SVR, central venous pressure, and pulmonary capillary wedge pressure.[279] Heart rate is not affected. In a newborn lamb model it was demonstrated that amrinone is a direct pulmonary vasodilator, and this effect occurred at lower dosages than those effecting increase in cardiac output.[280] When amrinone is administered to patients whose volume is depleted

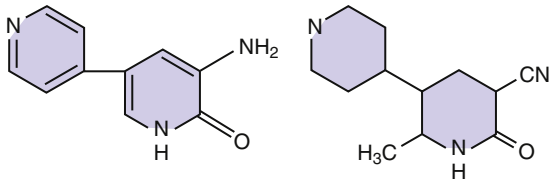

Figure 25–11. Structure of amrinone plus milrinone.

intravascularly or in whom the expected improvement in cardiac output does not occur, hypotension may result.[281] It is likely that improvement in cardiac function is due to a combination of a positive inotropic effect and a direct reduction of preload and afterload.[72,282] In patients with CHF, the amelioration in global hemodynamic function is associated with an improvement in the ratio of myocardial oxygen delivery to consumption.[283] Inamrinone may improve contractility in patients who have failed to respond to catecholamines and may further increase the CI even in patients who have responded to dobutamine. Therapeutically effective concentrations are in the range of 2.0 to 7.0 μg/mL, and there is a strong correlation between concentration and improvement in hemodynamic function.[284] Inamrinone reduces PVR in children with intracardiac left-to-right shunts. In one study, children with elevated PVR exhibited a 47% reduction in PVR upon infusion of amrinone.[130] The PVR/SVR ratio decreased by 45%. In these children, both pulmonary blood flow and left-to-right shunt increased. In children with normal pulmonary pressure, amrinone infusion was associated with a decrease in SVR but not PVR. Inamrinone may be undesirable in children with an elevated pulmonary artery pressure associated with a high-flow left-to-right shunt but normal PVR. Conversely, the phosphodiesterase type III inhibitors may be an effective adjunctive therapy in the child with elevated PVR and reduced pulmonary blood flow. Inamrinone increases CI and decreases SVR after the Fontan procedure.[285] It has been questioned whether the inotropic effects of amrinone derive more from its ability to decrease systemic vascular resistance than from a positive inotropic effect.[286] Bailey and colleagues[287] compared the effects of nitroprusside and inamrinone. Although both agents decreased SVR to a similar extent, inamrinone increased the cardiac index and produced a greater increase in the ratio of change in cardiac index to change in mean arterial blood pressure. In infants following cardiac surgery, inamrinone increased LV fractional shortening and the mean velocity of circumferential fiber shortening and decreased LV end diastolic wall stress.[288]

In a cell culture line, inamrinone was shown to decrease the expression of nF-kappa β and inducible nitric oxide synthetase in cardiac myocytes exposed to lipopolysaccharide and tumor necrosis factor-α. IL-1_{β} production in response to tumor necrosis factor-α was also decreased, as was intercellular adhesion molecule expression.[289] The authors of the study note that the results imply that inamrinone is acting downstream at a central point for proinflammatory signaling. The clinical implications of these findings have yet to be explored.

Pharmacokinetics

Inamrinone is metabolized by N-acetyltransferase; in addition, up to 40% is eliminated unchanged in the urine.[290] In healthy adults, the half-life of inamrinone in "slow acetylators" is 4.4

hours and in "fast acetylators" is 2.0 hours.[291] It is unclear if this difference is clinically important.[292] Protein binding is not extensive. One study of children younger than 1 year following cardiopulmonary bypass found that the half-life was prolonged in those younger than 4 weeks and that volume of distribution (1.7 to 1.8 L/kg) was threefold greater than others have reported in adults.[284] A second study among children older than 1 month found wide interpatient variability in pharmacokinetic measurements. No relation was found between age and any measured pharmacokinetic parameter. Average clearance was approximately 1.2 mL/kg/min, with a range of 0.4 to 2.2 mL/kg/min. The mean half-life was 5.5 hours.[202] No correlation was noted between inamrinone pharmacokinetics and hepatic or renal function. In infants younger than 1 month, half-life is increased and clearance is decreased.[292] Neonates were noted to have a smaller volume of distribution at steady state.[292]

Clinical Role

In adults with CHF, phosphodiesterase type III inhibitors are safe and effective when given intravenously, and their clinical place in short-term management of patients with refractory heart failure is clearly established. Bipyridines are most useful in management of children and adolescents with isolated cardiac dysfunction, particularly when it is due to myocardial failure, or in the setting of decreased cardiac output following cardiopulmonary bypass. They provide both inotropic and afterload reduction and may be an alternative to coadministration of dobutamine and an afterload-reducing agent (see Table 25-7). Although inamrinone has been shown to be useful in increasing cardiac index and decreasing SVR in children following cardiac surgery, its role has been largely supplanted by milrinone because of concern over thrombocytopenia induced by inamrinone (seethe section that follows on adverse effects).

Preparation and Administration

Inamrinone lactate is available in 5 mg/mL vials for injection.[293] Loading doses may be administered undiluted over 2 to 3 minutes. In adults the manufacturer recommends an inamrinone loading dose of 0.75 mg/kg, which may be repeated once. This dose is followed by a continuous infusion of 5 to 10 μg/kg/min. Maintenance infusions should be prepared in 0.45% or 0.9% Sodium Chloride Injection United States Pharmacopeia (USP) at a final concentration of 1 to 3 mg/mL. Inamrinone is not compatible with 5% Dextrose USP or furosemide. The dosage in children has not been conclusively established, although the publication previously cited contains a suggestion for a much higher loading dose (children younger than 1 year of age: initial intravenous inamrinone bolus of 3.0 to 4.5 mg/kg in four divided doses followed by a continuous infusion of 10 μg/kg/min; neonates: a similar bolus followed by a continuous infusion of 3 to 5 μg/kg/min).[284] These recommendations are supported by a second study, in which this regimen was associated with a generally satisfactory plasma concentration of ianmrinone.[290] As with the catecholamines, significant differences between the ordered concentration and the measured concentration of inamrinone have been shown.[290]

Adverse Effects

Inamrinone produces reversible dose-dependent thrombocytopenia (incidence 2.4%), which is more common during prolonged therapy. This finding was not seen in the largest published pediatric study, but case reports suggest that it occurs in children as well.[284] In one series, thrombocytopenia developed in eight of 18 patients.[294] The plasma concentration of inamrinone did not correlate with thrombocytopenia, although the levels of *n*-acetylamrinone were increased in the patients with thrombocytopenia. Supraventricular and ventricular dysrhythmias have occurred during infusion of inamrinone but may have been related to the underlying condition of the patient. Fatal progressive hypotension not responsive to peritoneal dialysis has been reported for inamrinone overdose.[295] When inamrinone or milrinone is infused too rapidly during the loading dose, hypotension is produced. This problem is exacerbated in patients whose volume is depleted.

Interactions

The concomitant use of inamrinone and digoxin results in additive inotropic effects.[293] The combined use of inamrinone and disopyramide was associated with profound hypotension in a single patient during clinical testing; as a result concomitant use is not recommended.

Milrinone

Clinical Pharmacology

A derivative of inamrinone, milrinone shares the same mechanism of action and pharmacodynamic profile. The major advantage is that, unlike inamrinone, milrinone does not appear to evoke thrombocytopenia. In adults, milrinone acts both as an inotrope and vasodilator. In adults with CHF, milrinone causes a much greater decrease in left and right filling pressures and SVR than does dobutamine, even at equivalent contractility dosing.[296] Compared with dobutamine, milrinone produces a greater reduction in SVR for a given degree of improvement in inotropic state.[297] Blood pressure is well maintained, even in the face of reduced SVR, because of the associated improvement in contractility and stroke volume. Increasing doses of milrinone have been shown to correlate with increasing mixed venous oxygen saturation (Svo_2).[298] It has been extensively used following cardiac surgery and in adults with CHF, where it increases cardiac index and reduces SVR, filling pressures, and, often, systemic blood pressure.[74,299,300] When given perioperatively, milrinone attenuated decreases in gastric mucosal pH in patients undergoing coronary artery bypass grafting.[301] Splanchnic oxygenation improved and systemic levels of endotoxin and IL-6 were decreased. Although a cell culture study failed to show a decrease (with a possible increase) in proinflammatory markers in response to milrinone, milrinone decreased serum levels of IL-1β and IL-6 following cardiopulmonary bypass.[216,289] The decrease in IL-6 correlated inversely with levels of cAMP.

Several studies have evaluated milrinone in children following surgery for congenital heart disease. In one study, a loading dose of 50 μg/kg followed by a continuous infusion of 0.5 μg/kg/min was associated with mild tachycardia and a slight decrease in systemic blood pressure.[302] Cardiac index increased from 2.1 to approximately 3.1 L/min/m^2, while SVR index and PVR index decreased from approximately 2100 to 1300 and 488 to 360 dyne-sec/cm^5/m^2, respectively. In a recently completed double-blind, placebo-controlled trial, high-dose milrinone (75 μg/kg bolus followed by continuous infusion at 0.75 μg/

kg/min) was associated with a decreased incidence of low cardiac output syndrome.[119] Length of hospital stay was similar among the treatment groups, but prolonged stay (greater than 15 days) was more common in the placebo arm. Milrinone also has been evaluated in children with nonhyperdynamic septic shock (i.e., normal to low CI and normal to elevated SVR). In a double-blind crossover study, milrinone increased CI, stroke volume index, and oxygen delivery while decreasing SVR.[302a] No differences in blood pressure or PVR were seen. Milrinone was given at a dose of 0.5 μg/kg/min as a continuous infusion after a bolus dose of 50 μg/kg.

Pharmacokinetics

In contrast to inamrinone, milrinone is approximately 70% bound to plasma proteins, with approximately 85% renal elimination.[303] Hepatic glucuronidation accounts for a minor elimination pathway. In healthy adults, milrinone has an apparent volume of distribution of 0.32 ± 0.08 L/kg, clearance of 6.1 ± 1.3 mL/kg/min, and an elimination half-life of 0.8 ± 0.22 hours.[303] Both renal dysfunction and congestive heart failure affect the elimination profile of milrinone, extending the elimination half-life to approximately 2 hours.[304] In infants and young children undergoing cardiac surgery, the weight-adjusted clearance of milrinone was shown to increase with age, ranging from 2.6 mL/kg/min at age 3 months to 5.6 mL/kg/min at age 22 months.[305] In a separate study of milrinone in infants and children (ages 1 to 13 years) following open heart surgery, milrinone clearance was significantly lower in infants than in children (3.8 ± 1 versus 5.9 ± 2 mL/kg/min, respectively).[306] Importantly, the milrinone clearance values for both infants and children were significantly higher than the clearance of milrinone reported in adults following cardiac surgery (2 ± 0.7 mL/kg/min).[307] In the pediatric study just described, the plasma concentration versus time data fit a two-compartment model.[306] The apparent volume of distribution by area (Vβ), which reflects the volume of distribution during the terminal elimination phase, was not significantly different between infants and children (0.9 ± 0.4 versus 0.7 ± 0.2 L/kg). However, the value reported for infants differed significantly from the value reported in adults following cardiac surgery (0.3 ± 0.1 L/kg). [307] In children with septic shock, the median half-life of milrinone was 1.5 hours.[308] Plasma levels did not correlate with changes in CI or SVR. One patient with acute renal failure had an eightfold increase in the serum level of milrinone even though the same dosing regimen was used as in the patients without renal failure.

Clinical Role

Based on its shorter elimination half-life and possibly a lower incidence of thrombocytopenia, milrinone is generally preferred to amrinone for pediatric patients.[305] Milrinone may be used to increase cardiac contractility following cardiac surgery and may have a role in improving perfusion in patients with "cold shock." Its properties as a vasodilator also would suggest that milrinone may be useful in the setting of pulmonary hypertension.[309]

Preparation and Administration

Milrinone lactate is available in 10-mL, 20-mL, and 50-mL single-dose vials, each at a concentration of 1 mg/mL, and in 100-mL and 200-mL flexible containers at a concentration of 200 μg/mL in 5% dextrose.[310,311] Loading doses may be drawn from a single-dose vial and administered undiluted over 15 minutes. A loading dose of 50 μg/kg is generally used in children.[302,305] For preparation of maintenance infusions, milrinone should be diluted with 0.45% or 0.9% Sodium Chloride Injection USP or 5% Dextrose Injection USP to a final concentration of ≤200 μg/mL. Maintenance infusion rates are generally initiated at 0.5 μg/kg/min, titrated to clinical response. Based on the higher clearance and volume of distribution values previously discussed, Ramamoorthy and colleagues[306] suggested a loading dose and initial maintenance infusion rate of 104 μg/kg and 0.49 μg/kg/min, respectively, in infants, and 67 μg/kg and 0.61 μg/kg/min, respectively, in children. In patients not given a loading dose of milrinone, changes in CI and plasma levels of milrinone after 3 hours were similar to those seen in patients given a loading dose.[312] Milrinone is not compatible with furosemide but is compatible with a large number of drugs used in the PICU, including dopamine, epinephrine, fentanyl, and vecuronium.[313,314]

Adverse Effects

In the largest pediatric study, serial measurements showed no difference in platelet count over time (baseline, 36 hours, 72 hours, and discharge) by treatment arm, and there was no difference in the incidence of thrombocytopenia (platelet count less than 50,000) during the study infusion (7.4% placebo, 8.8% low dose, and 2.6% high dose).[119]

Summary

The bipyridines offer an attractive combination of positive inotropy with decreased SVR. The bipyridines are likely to be effective in short-term management of the infant and child with myocardial disease. Milrinone has an established role in the management of impaired cardiac contractility following cardiopulmonary bypass; its role in other settings has not been conclusively established by randomized trials.

Nesiritide

Basic Pharmacology

Nesiritide is a recombinant human B (brain)-type natriuretic peptide (rhBNP) that exerts a direct vasodilatory effect on arterial and venous blood vessels, along with potent natriuretic and diuretic effects on the kidney.[193,315] These effects result from the binding of rhBNP to natriuretic peptide receptors A and B on vascular smooth muscle cells, endothelial cells, kidney, and adrenal gland; inhibition of peripheral vascular sympathetic neurotransmission; and inhibition of the renin-angiotensin-aldosterone pathway (Figure 25-12).[164,193,315,316] Binding to natriuretic peptide receptors A and B activates guanylyl cyclase, resulting in an intracellular rise in cGMP.[164,317] cGMP regulates vascular smooth muscle relaxation via a decrease in intracellular calcium.[317]

Endogenous BNP is secreted primarily by the left ventricle, with increased wall tension thought to be the main stimulus for secretion.[318] BNP seems to exert a protective effect on the heart, maintaining homeostasis (preventing excess accumulation of salt and water) in the setting of early heart failure.[164] Indeed, plasma BNP concentrations are higher in patients with CHF, with the increase strongly correlated with the degree of LV dysfunction.[164] BNP levels also have been used to differentiate cardiac from noncardiac causes of respiratory

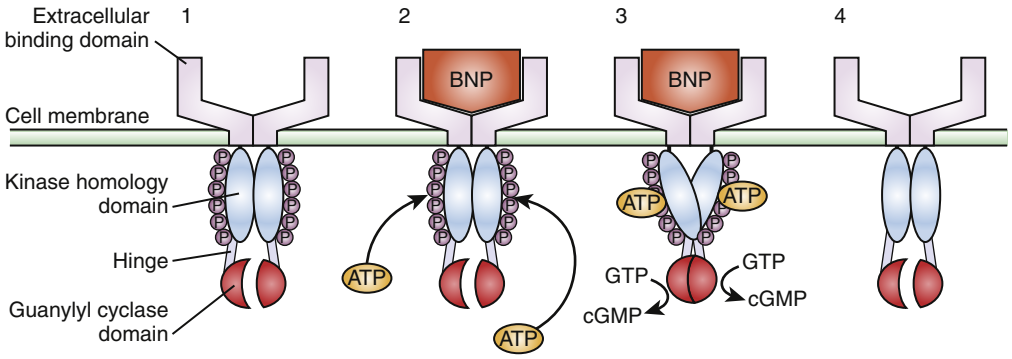

Figure 25–12. Interaction of brain natriuretic peptide (*BNP*) with type A natriuretic peptide receptor (*NPR-A*). NPR-A is a member of the family of transmembrane guanylyl cyclase (*GC*) receptors and is comprised of an extracellular natriuretic peptide binding site, a juxtamembraneous kinase homology domain (*KHD*), and two active guanylyl cyclase catalytic sites. (1) In the basal state, phosphorylation of the KHD enhances binding affinity for BNP and inhibits guanylyl cyclase activity. (2) Binding of BNP to the peptide binding site triggers the binding of adenosine triphosphate (ATP) to the KHD. (3) ATP binding induces a conformational change in the KHD and hinge region, resulting in activation of guanylyl cyclase and the conversion of GTP to the intracellular second messenger cyclic guanosine monophosphate (*cGMP*). cGMP subsequently produces the physiologic effects of BNP by regulating the activity of various third messengers, including phosphodiesterase (*PDE2* and *PDE3*) and protein kinase enzymes (*PKG I* and *PKG II*), and by reducing the intracellular concentration of calcium. cGMP reduces intracellular calcium by inhibiting calcium influx via L-type calcium channels and by enhancing calcium efflux via calcium-magnesium ATPase and the sodium-calcium exchanger. (4) The conformational change in the KHD also triggers the activity of phosphatase enzymes, resulting in transient dephosphorylation of the KHD and nonresponsiveness to subsequent BNP binding. *(Modified from Potter LR, Hunter T: Guanylyl cyclase-linked natriuretic peptide receptors: structure and regulation,* J Biol Chem *276:6057-6060, 2001; Kuhn M: Molecular physiology of natriuretic peptide signaling,* Basic Res Cardiol *99:76-82, 2004 and Lucas KA, Pitari GM, Kazerounian S et al: Guanylyl cyclases and signaling by cyclic GMP,* Pharmacol Rev *52:375-413, 2000.)*

distress in infants and children and have been shown to correlate with the presence of hemodynamically significant patent ductus arteriosus in neonates.[319-321a]

Clinical Pharmacology

The hemodynamic effects of nesiritide in adult patients with decompensated CHF include a reduction in both preload (decreased pulmonary capillary wedge pressure) and afterload (decreased systemic vascular resistance), resulting in an increase in CI even though BNP appears to exert no direct inotropic effects.[297,322-326] The diuretic and natriuretic effects of nesiritide resulted in fewer patients requiring concomitant diuretic therapy in comparison with nitroglycerin or dobutamine.[297,327] In contrast to dobutamine, nesiritide appears not to be arrythmogenic.[328] The most common adverse effect of nesiritide is hypotension; however, this effect is not associated with reflex tachycardia.[323,328]

The beneficial effects of nesiritide have been confirmed in a limited number of studies involving infants and children with heart failure.[276,315,329-331] These studies consistently revealed significant improvement in urine output with nesiritide administration. Significant hemodynamic changes were not consistently observed, although pulmonary artery catheters were placed in only one reported trial. A placebo-controlled trial in children with dilated cardiomyopathy undergoing right heart catheterization revealed significant reductions in pulmonary capillary wedge pressure, mean pulmonary arterial pressure, and systolic blood pressure with nesiritide administration.[329] Nesiritide was generally well tolerated, although a retrospective review of nesiritide administration to neonates (mean postnatal age 16 ± 8 days) at one institution reported an 18% incidence of hypotension requiring intervention.[331]

Pharmacokinetics

Nesiritide is administered by intravenous infusion and in adults follows a two-compartment pharmacokinetic model, with a brief distribution half-life of approximately 2 minutes, followed by a terminal elimination half-life of only 18 minutes.[193,323] The apparent volume of distribution is 0.19 L/kg, essentially reflecting distribution into extracellular fluid. Nesiritide is eliminated via binding to natriuretic peptide receptor C on target cell surfaces (internalization and enzymatic degradation), hydrolysis by neutral endopeptidase-24.11 on the surface of vascular endothelial cells, and by the kidney via glomerular filtration. Dosage adjustment is not indicated in patients with renal dysfunction. Pharmacokinetic information is not available in infants or children.

Preparation and Administration

Nesiritide can be reconstituted using any of the following preservative-free diluents (250 mL bag): 5% Dextrose in Water Injection, USP; 0.9% Sodium Chloride Injection, USP; or 5% Dextrose and 0.2% Sodium Chloride Injection, USP.[193,332] Each 1.5-mg vial of nesiritide is reconstituted with 5 mL of diluent and the resulting solution withdrawn and added to the 250-mL bag, yielding a final nesiritide concentration of 6 μg/mL. The reconstituted solution must be administered within 24 hours of preparation.

Nesiritide is administered as a 2 μg/kg intravenous bolus (drawn from the 250-mL infusion bag) pushed over 60 seconds, followed by an initial continuous infusion rate of 0.01 μg/kg/min.[193] To avoid or minimize hypotension, titration should be limited to increments of 0.005 μg/kg/min no more often than every 3 hours, to a maximum of 0.03 μg/kg/min.

Adverse Effects

Symptomatic hypotension has been reported in approximately 4% of adult patients receiving nesiritide.[193] Careful blood pressure monitoring is therefore advised, and nesiritide is not recommended in adults with baseline systolic blood pressure less than 100 mm Hg. Nesiritide may decrease renal function in patients with severe CHF whose kidney function is dependent on renin-angiotensin-aldosterone function.

Drug Interactions

Symptomatic hypotension with nesiritide may be more common in patients concurrently receiving angiotensin-converting enzyme inhibitors.[193]

Clinical Role

Nesiritide appears to offer a number of potential advantages in patients with decompensated heart failure, including rapid improvement in hemodynamic measurements and symptoms.[323] Nesiritide is also devoid of the arrhythmogenic properties associated with dobutamine and milrinone. Nesiritide is not approved by the Food and Drug Administration for pediatric use, and pediatric information is limited.

Digitalis Glycosides

The role of digoxin in the acute care of critically ill children has always been limited by a narrow therapeutic range, slow onset of action, and the potential for life-threatening adverse effects. With the advent of new therapies for both the acute and chronic management of CHF and myocardial dysfunction, its role has been further decreased. A review is offered here as the practitioner in the PICU may still encounter patients taking the drug, particularly for control of dysrhythmias. Digoxin, as do the catecholamines and other drugs discussed in this chapter, exerts its inotropic effects by increasing intracellular calcium.

Basic Pharmacology

The cardiac glycosides consist of a steroid moiety with one to four sugar molecules attached.[333] The number and composition of the associated sugar molecules affect the pharmacokinetics of the specific glycoside; all digitalis glycosides have similar pharmacodynamic properties. Glycosides bind to and inhibit sodium-potassium ATPase. Binding of digoxin to ATPase is affected by serum potassium. Hyperkalemia depresses digoxin binding, whereas hypokalemia has the opposite effect, accounting in part for potentiation of digoxin-induced dysrhythmias during hypokalemia.[334] As described earlier in this chapter, inhibition of ATPase produces an increase in intracellular calcium and enhances the inotropic state of the myocardium.

Clinical Pharmacology

In patients with CHF, the positive inotropic action of digoxin leads to increased cardiac output and reductions in filling pressures, edema, and sinus node rate. In a study of 10 adult patients with acute myocardial failure, a single dose of 10 μg/kg of digoxin produced a 69% increase in LV stroke work index, a 25% reduction in wedge pressure, a 16% to 28% increase in cardiac index, and a 25% increase in stroke index within 2 hours of infusion.[131] Many of these changes were present within 60 minutes. In infants, digoxin is known to produce changes in echocardiographic measurements that are associated with an improved inotropic state, although detailed invasive hemodynamic measurements have not been made in infants or children.[25,229,335,336] When CHF is due to obstructive lesions or left-to-right shunts, it is more difficult to demonstrate benefit than when CHF is due to myocardial failure.

In patients with CHF who have a sinus rhythm, administration of digoxin produces a decrease in heart rate, likely because of improvement of the inotropic state and withdrawal of compensatory sympathetic activity. In addition, digoxin enhances vagal tone by increasing baroceptor sensitivity and by directly stimulating central vagal centers,[334] which causes direct slowing of heart rate in addition to that permitted by improved function. Another effect of digoxin-mediated enhanced vagal tone is slowed conduction of atrial impulses through the atrioventricular node to the ventricle. This property is exploited in use of digoxin to control or treat supraventricular rhythm disturbances such as supraventricular tachycardia and atrial flutter or fibrillation. This aspect of digitalis pharmacology is reviewed in Chapter 28.

Use of digoxin in the PICU is further complicated by the large number of pharmacokinetic and pharmacodynamic interactions between digoxin and other pharmacologic agents used in critical care.[337] For example, carvedilol (a β-blocker) has been shown to decrease the elimination of digoxin in children, necessitating a reduction in digoxin dosage.[338] Toxicity is a major limiting factor in administering digitalis glycosides to critically ill patients. The most frequent side effects are gastrointestinal; the most serious are disturbances in cardiac rhythm.[25,316,333] Digitalis toxicity is reviewed in several of the references.[339,340] In adults and older children the dominant manifestations of digoxin toxicity are tachydysrhythmias such as ventricular premature contractions, ventricular tachycardia, and ventricular fibrillation. Atrial tachycardia and junctional tachycardia also may be noted. Bradycardia and A-V conduction block are noted with acute, profound intoxication. In infants enhanced vagal tone and diminished sympathetic activity alter this pattern; the dominant findings are A-V conduction block and sinus bradycardia.

Digitalis toxicity is made more likely by factors that increase myocardial irritability, such as myocarditis, ischemia, hypoxemia, or catecholamine support. Hypokalemia and alkalosis also potentiate digoxin-induced dysrhythmias. Treatment of digoxin toxicity involves supportive treatment and correction of electrolyte disturbances.[341] Specific pharmacologic support (e.g., with atropine, lidocaine, phenytoin, or magnesium sulfate) may be necessary (although frequently unsuccessful), and in life-threatening circumstances, treatment with digoxin-specific Fab antibody fragments is indicated.[342]

Pharmacokinetics

The dosage of digoxin prescribed for young children and infants is much higher than that applied to older children and adults. In the past, this disparity was ascribed to the incorrect belief that developmental immaturity was associated with decreased myocardial sensitivity to digitalis. It is now understood that neonates are not less sensitive to digoxin but eliminate digoxin more rapidly.[25] Clearance is dependent on age, although there is wide interindividual variation during the first year of life.[278] Thus infants may require higher loading ("digitalizing") and maintenance dosages to achieve a therapeutically effective plasma concentration of 1 to 2 ng/mL. Distribution of digoxin is relatively

slow; therefore plasma levels will be misleadingly elevated if determined sooner than 6 hours following administration of a dose. At distribution equilibrium, the concentration of digoxin in the heart is 15 to 30 times greater than that in the plasma. In the nonacutely ill child, the half-life of digoxin is 36 hours with a clearance of 8.6 L/h.[58] Digoxin is eliminated by the kidney through glomerular filtration and renal tubular secretion, through renal tubular mechanism, including the efflux pump, P-glycoprotein (P-gp). A polymorphism that decreases the activity of this enzyme was associated with increased serum digoxin levels.[343] Elimination is also strongly affected by renal dysfunction, complicating use of the agent in the critically ill child.

Clinical Role

The role of digoxin in the care of the pediatric patient continues to be refined and narrowed. Its role as an inotropic agent has been supplanted by other drugs (milrinone, for example) with a more favorable pharmacodynamic profile in the acute setting. The use of digoxin to improve cardiac function in children with systemic to pulmonary shunts also has decreased greatly, and its use primarily now is in control of certain dysrhythmias and the improvement of systolic function in children without structural lesions.[340] Because digoxin does not produce β-adrenergic receptor desensitization and has beneficial effects by virtue of decreased sympathetic activity, it continues to have a clinical role.

Preparation and Administration

Digoxin for injection is available in concentrations of 250 μg/mL and a pediatric formulation of 100 μg/mL.[337] Digoxin may be administered undiluted, or it may be diluted with sterile water for injection, D5W, or 0.9% sodium chloride for injection. A dilution of at least fourfold (1 mL digoxin/4 mL diluents) must be used to avoid precipitation.

Adverse Effects

Cardiovascular adverse effects may include sinus bradycardia, atrioventricular block, ventricular tachycardia, and other dysrrhythmias.[337] Gastrointestinal adverse effects of digoxin include nausea, vomiting, anorexia, diarrhea, constipation, abdominal pain, and abdominal distension. Other effects may include visual disturbances, photophobia, headache, muscle weakness, fatigue, drowsiness, dizziness, vertigo, seizures, and neuropsychiatric abnormalities.

Interactions

The adverse cardiovascular effects of digoxin may be potentiated by agents that lower serum potassium or magnesium concentrations, such as thiazide diuretics, loop diuretics, ethacrynic acid, amphotericin B, corticosteroids, polystyrene sodium sulfonate, and glucagon.[337] The concomitant administration of digoxin with intravenous calcium results in additive or synergistic inotropic and adverse cardiovascular effects. β-adrenergic antagonists can cause complete heart block when administered with digoxin. The concomitant use of digoxin with succinylcholine or sympathomimetics increases the risk of dysrhythmias. Digoxin has a narrow therapeutic index; serum digoxin concentrations are increased with concomitant administration of amiodarone, flecainide, quinidine, propafenone, verapamil, captopril, itraconazole, and indomethacin.

Summary

Digitalis glycosides are effective inotropic agents that have the desirable property of slowing rather than accelerating heart rate. As a result of its narrow therapeutic window, long half-life, and the emergence of newer medications, the role of digoxin in the acute setting has diminished.

Conclusion

There continues to be a growing understanding of the mechanisms underlying adrenergic receptor signaling, the control of vascular tone, and the influence of genetic polymorphisms on the pathways involved in these processes. Despite this growing understanding, the therapeutic options for supporting the patient with evidence of impaired end-organ perfusion has not significantly changed. The catecholamines remain the mainstay of therapy, with dopamine often the initial drug of choice for either inotropic or vasopressor support. Epinephrine or norepinephrine is used when poor cardiac performance or decreased systemic vascular tone, respectively, is the hemodynamic derangement and perfusion is not improving with dopamine. Milrinone (or amrinone) or dobutamine can be used to increase myocardial contractility if there is no frank hypotension. Milrinone is particularly useful for hemodynamic support after surgery for congenital heart disease. Vasopressin has emerged as an option for vasodilatory shock that is resistant to catecholamine therapy. Often the clinical picture is mixed and the patient may require both inotropic and vasopressor support. Careful attention to the clinical signs of end-organ perfusion and an understanding of cardiovascular pharmacology are necessary for the care of these patients.

Chapter 26

Cardiopulmonary Interactions

Bradley P. Fuhrman

PEARLS

- Mechanical ventilation can alter right ventricular preload and ejection, pulmonary vascular resistance, left ventricular preload, and left ventricular afterload.
- In patients who are hypovolemic, effects of positive airway pressure on right ventricular preload generally predominate, whereas in patients who have myocardial dysfunction, effects on left ventricular afterload may predominate.
- Changes in arterial pulse pressure over the respiratory cycle help to predict which patients will increase cardiac output with fluid resuscitation.
- Changes in arterial pulse pressure over the respiratory cycle on pulmonary end-expiratory pressure (PEEP) compared to changes in pulse pressure over the respiratory cycle at zero PEEP may identify those patients whose cardiac output has been adversely effected by PEEP.
- Respiratory effort imposes critical loads on the heart, and respiratory muscle failure from inadequate circulation is a final common pathway to death in shock and circulatory impairment.

Both spontaneous and mechanical ventilation affect the circulation in predictable ways. The cardiovascular system also has important effects on respiration, ventilation, and gas exchange.

Effects of Ventilation on Circulation

For clarity of discussion, wherever the term *positive pressure ventilation* is used in this chapter, the patient is presumed to respond passively, as though subjected to neuromuscular blockade.

As shown by Cournand[1] in his sentinel paper, mechanical ventilation can have important effects on circulation. The magnitude of these effects may be accentuated by factors that compromise cardiovascular adaptability, such as hypovolemia, cardiac dysfunction, or disordered vascular tone.

Mechanical ventilation can alter right ventricular preload and ejection, pulmonary circulation, left ventricular preload, and left ventricular afterload. These interactions may occur simultaneously and yet not act in the same direction on cardiac output. The net effect on cardiac output depends on which interaction predominates over the course of the respiratory cycle. For this reason, it is often easier to rationalize an interaction than to predict it.

Right Ventricular Filling and Stroke Volume

The effects of mechanical ventilation on filling of the right heart are the best understood of the various heart-lung interactions and are generally the preponderant effects on cardiac output. They are mediated by changes in intrathoracic pressure and venous return over the respiratory cycle. Spontaneous breathing and positive pressure mechanical ventilation have opposite effects on intrathoracic pressure, which largely explains their different effects on cardiac output.

Venous Return

The mean systemic pressure of the circulation (P_{ms}) is thought to be the inflow pressure driving blood toward the right ventricle.[2] This driving pressure is not measurable in the intact patient, but it can be thought of as the static mean pressure that might exist throughout the circulation if there were no blood flow.[3] P_{ms} approximates the weighted average of pressures in venous reservoirs throughout the body during the circulation of blood.[4] The backpressure that opposes flow toward the right heart is the right atrial pressure (P_{ra}). The impact of these pressures on return of venous blood to the heart is described by the venous return curve (Figure 26-1, *A*). Picture the systemic circulation as compliant arteries and veins separated by high-resistance arterioles and a pump that receives venous return and propels it into the arteries (Figure 26-1, *B*). The faster the pump circulates the blood, the more blood piles up before the arterioles and the higher the arterial pressure will be. In contrast, the faster the pump moves blood from vein to artery, the less blood resides on the venous side of the circuit and the lower the venous pressure will be. As the pump is slowed down, venous pressure rises until flow reaches zero and pressure equilibrates throughout the circulation at P_{ms}. Resistance to venous return (R_{vr}) is the reciprocal of the slope of the linear part of the venous return curve. Simply stated:

$$\text{Venous return} = (P_{ms} - P_{ra}) / R_{vr} \quad (1)$$

P_{ms} is sensitive to the volume of blood in the circulation and to the capacitance of the venous reservoir. It can be altered by transfusion, volume infusion, hemorrhage, and diuresis. It also is sensitive to changes in venous tone. P_{ms} is an extrathoracic

measurement and is less sensitive than P_{ra} to changes in intrathoracic pressure.[5] P_{ra}, in contrast, is quite sensitive to changes in intrathoracic pressure.

At functional residual capacity (FRC), the thorax exerts recoil force, tending to spring outward, whereas the lung exerts recoil force (mostly as a result of alveolar surface tension), tending to collapse inward. These forces result in subambient pleural pressure. The cardiac fossa, or juxtacardiac space, which surrounds the pericardium and heart, shares in this balance of forces and has slightly negative pressure at apneic FRC. At any right atrial volume, P_{ra} is influenced by juxtacardiac pressure because these two forces act together to oppose the right atrium's balloonlike tendency to recoil inward. Therefore it is not surprising that all of these pressures (pleural, juxtacardiac, and right atrial) are influenced by the respiratory cycle.[6-8]

During spontaneous breathing, lung volume rises from FRC to end-inspiratory volume by expansion of the rib cage and descent of the diaphragm. This reshaping of the thorax stretches the lung, increasing its recoil tension, so pleural pressure and juxtacardiac pressure both become more negative (subambient). At any right atrial volume, this process reduces P_{ra}. Therefore spontaneous inspiration reduces pleural, juxtacardiac, and right atrial pressures. By the mathematical relationship in Equation 1, this augments venous return.[9] Over the course of passive spontaneous expiration, all three pressures return toward their values at FRC. It follows that intrathoracic pressure, during relaxed spontaneous breathing, is always least negative at end-inspiration and falls continuously throughout the rest of the respiratory cycle.

Right Ventricular Preload and Stroke Volume

Transmural pressure is the pressure difference across (inside to outside) a hollow structure. This pressure difference and the wall tension of the structure determine its radius. P_{ra} approximates the pressure within the right ventricle during cardiac filling. Juxtacardiac pressure approximates the pressure surrounding the ventricle. During spontaneous inspiration, systemic venous return to the right atrium and ventricle are augmented (Equation 1), and end-diastolic ventricular volume rises. P_{ra} falls, but not as much as juxtacardiac pressure falls. Transmural pressure is, therefore, increased by spontaneous inspiration. Despite the falling P_{ra}, right ventricular stroke volume normally rises during spontaneous inspiration; hence, there is a paradoxical inverse relationship between P_{ra} and right ventricular stroke volume over the spontaneous respiratory cycle (Figure 26-2).[10] If *transmural* P_{ra} is plotted against right ventricular stroke volume during various respiratory maneuvers, the expected positive slope is revealed (Figure 26-3).[11]

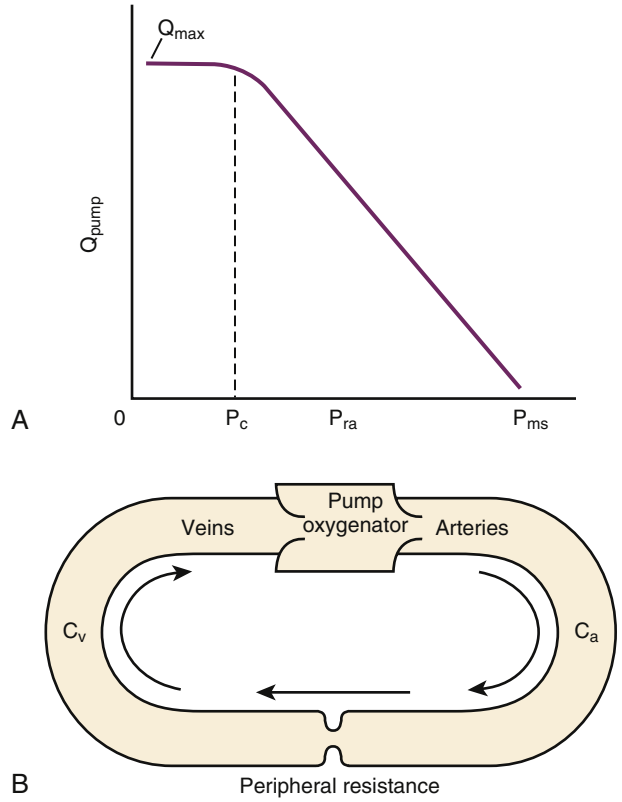

Figure 26–1. A, Systemic venous return curve. Flow (Q_{pump}) is plotted on the ordinate, but is treated as the independent variable. Right atrial pressure (P_{ra}), the dependent variable, is plotted on the abscissa. **B,** Circulation is treated as though a pump transferred blood from veins to arteries, generating arterial pressure sufficient to overcome peripheral arterial resistance. Arterial compliance (C_a) and venous compliance (C_v) determine the volume of blood distending arteries and veins at any Q_{pump}. When there is no flow, pressure equilibrates throughout the circulation at the mean systemic pressure of the circulation P_{ms}. As pump flow is progressively increased, venous pressure falls and arterial pressure rises because of the net transfer of blood from veins to arteries by the pump and because of the accumulation of blood before the peripheral resistance. When venous pressure falls to P_c, the critical closing pressure of the venous system, no further increase in pump flow is possible. *(Modified from Guyton AC: Determination of cardiac output by equating venous return curves with cardiac response curves, Physiol Rev 35:123, 1955.)*

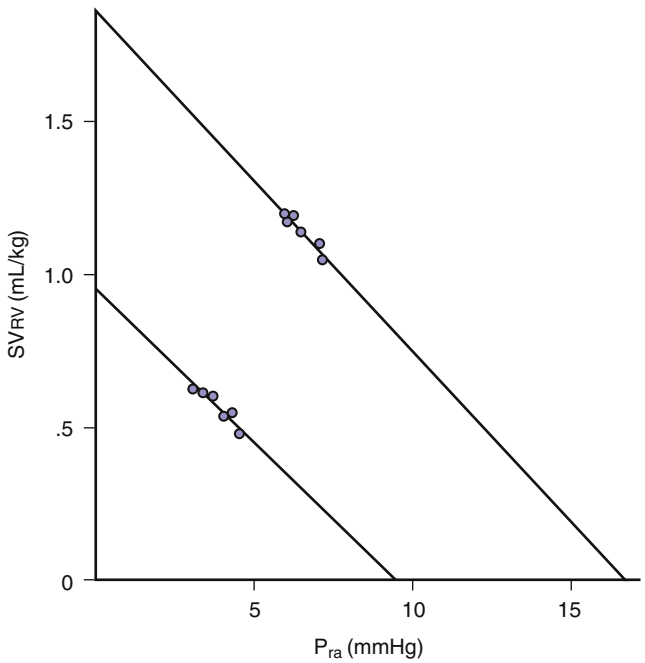

Figure 26–2. During spontaneous inspiration, right atrial pressure (P_{ra}) falls, but this decline is associated with an increase in right ventricular stroke volume (SV_{RV}). Shown at two different mean P_{ra}. *(From Pinsky MR: Instantaneous venous return curves in an intact canine preparation,* J Appl Physiol *56:765, 1984.)*

Positive Pressure Mechanical Ventilation and Right Ventricular Preload

The effects of positive pressure ventilation on pleural, juxtacardiac, and right atrial pressure are opposite those of spontaneous breathing. A common goal in the application of positive end-expiratory pressure (PEEP) is restoration of normal end-expiratory lung volume (normal FRC). All other things being equal, pleural pressure, which opposes thoracic recoil, should be the same at end-expiration whether breathing is spontaneous or mechanical. Pleural pressure is, after all, determined by thoracic volume.

During spontaneous inspiration, active reshaping of the thorax by the respiratory muscles and diaphragm inflates the lungs by reducing pleural pressure. In contrast, throughout positive pressure mechanical inspiration, pleural pressure rises because the passive thorax is pushed outward (from FRC to end-inspiratory volume) by the expanding lungs. Passive expiration restores pleural pressure to that of FRC. Averaged over the entire respiratory cycle, pleural pressure is higher during positive pressure breathing than it would be during spontaneous breathing (Figure 26-4). (This elevation of pleural pressure during positive pressure mechanical ventilation is generally called transmission of airway pressure to the pleural space.) Positive pressure ventilation, therefore, reverses the effects of spontaneous breathing on venous return[12] and right ventricular transmural pressure.

Positive pressure inspiration impedes venous return by raising P_{ra}. Right ventricular stroke volume declines over positive pressure inspiration because right ventricular transmural pressure is reduced. Averaged over the entire respiratory cycle, P_{ra} is raised and right ventricular stroke volume and cardiac index are reduced by positive airway pressure relative to their expected values during spontaneous breathing (Figure 26-5).

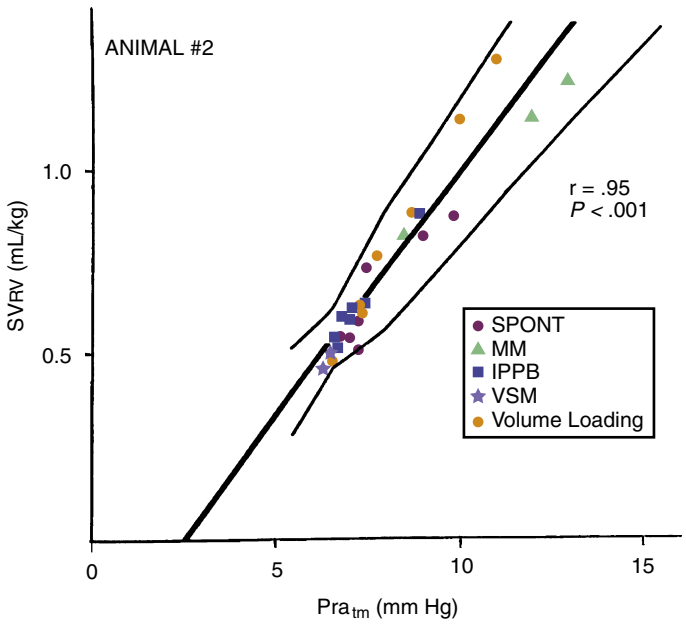

Figure 26–3. Over a wide range of respiratory maneuvers, right ventricular stroke volume (*SVRV*) varies directly with transmural right atrial pressure (Pra_{tm}). *IPPB,* Intermittent positive pressure breathing; *MM,* Müller maneuver; *SPONT,* spontaneous breathing; *VSM,* Valsalva maneuver. *(From Pinsky MR: Determinants of pulmonary arterial flow variation during respiration,* J Appl Physiol *56:1237, 1984.)*

It is easy to argue from these observations that positive pressure ventilation will invariably decrease venous return to the right heart, but this is not always the case. PEEP tends to elevate intrathoracic pressure over the entire respiratory cycle and opposes venous return. However, it may also displace blood from the pulmonary circulation and from the abdominal viscera (by descent of the diaphragm), thereby raising P_{ms}. Positive airway pressure may also have favorable effects on left heart function (see the section on left ventricular afterload). In patients whose left heart function improves, both left and right ventricular inflow pressures fall, enhancing venous return.

Critical Illness and Effects of Positive Pressure Breathing on the Right Heart

Among the effects of critical illness are capillary leak, chest wall edema, pulmonary edema, surfactant dysfunction, abnormal blood volume, and abdominal distension. Each modifies the effects of positive pressure breathing on the right heart. Capillary leak alters the compliance of the atrial and ventricular chambers, modifying the responsiveness of the heart to changes in preload. Sepsis and inflammation decrease cardiac

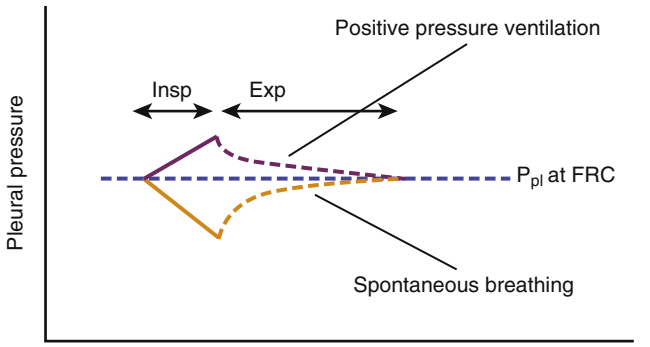

Figure 26–4. Over the course of the respiratory cycle, if spontaneous and positive pressure breaths both begin and end at the same functional residual capacity (*FRC*), spontaneous breathing takes place at lower pleural pressure than does positive pressure ventilation.

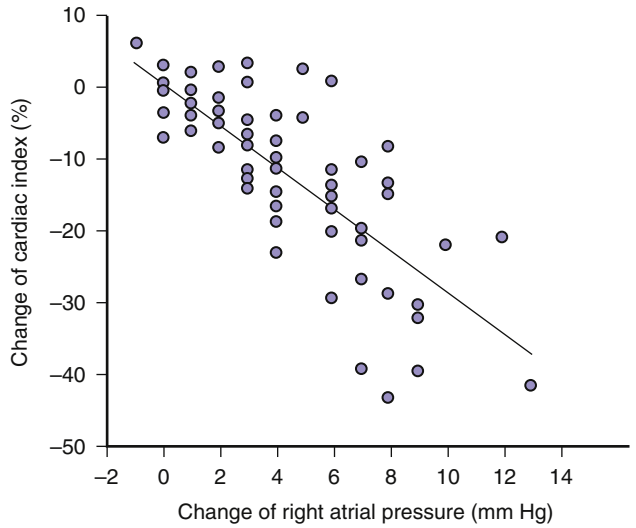

Figure 26–5. Relationship between the percentage change in cardiac index and the percentage change in right atrial pressure that was produced by the application of graded levels of positive airway pressure in adults. *(From Jellinek H, Krafft P, Fitzgerald RD, et al: Right atrial pressure predicts hemodynamic response to apneic positive airway pressure,* Crit Care Med *28:672, 2000.)*

contractility, directly altering the way the heart responds to changes in preload. Chest wall edema, pulmonary edema, surfactant dysfunction, and abdominal distension alter thoracic and pulmonary compliances, which in turn alter pleural and juxtacardiac pressures.

Reduced respiratory system compliance diminishes the transmission of alveolar pressure to the juxtacardiac space.[13] The change in intrathoracic pressure that occurs with a change in static airway pressure is essentially the same as the change observed in pulmonary artery wedge pressure,[14] which is readily measured. Recognizing this relationship in adults has made it possible to estimate percent transmission of airway pressure to the juxtacardiac space by measurement of respiratory system compliance (Figure 26-6).

Both abnormal blood volume and abnormal vascular compliance can change P_{ms} and thereby alter venous return. Vascular hypovolemia can exaggerate the adverse effects of positive pressure ventilation on preload.

Pulmonary Circulation

By modifying pulmonary vascular resistance (PVR), the effects of breathing on pulmonary circulation modify right ventricular afterload. The effects of breathing also can change the distribution of pulmonary blood flow within the lung. Both effects are significant.

Lung Volume

The alveolar septae are highly vascular (Figure 26-7). More than 90% of the alveolar surface makes contact with alveolar capillaries. These vessels can be separated into two categories according to their location or their response to lung inflation. Most alveolar vessels are capillaries and lie in septa, which separate adjacent alveoli. Other alveolar vessels are termed *corner vessels* because they are located at the intersection of alveolar septa. These corner vessels are generally larger and most likely will divide later in their course to become alveolar capillaries located in septa between adjacent alveoli. When the lung is stretched, either by spontaneous inspiration or by positive pressure distension, corner vessels are pulled open by radial traction and their resistance to blood flow is reduced. When alveolar septa are stretched, alveolar capillaries thin and restrict flow. The net effect of these factors is a U-shaped relation of PVR to lung volume (Figure 26-8)[15-18]; PVR is least at FRC and rises with either atelectasis or overdistension.

Alveolar Pressure

When alveolar pressure is greater than ambient, as it is during positive pressure ventilation, the vessels that course through alveolar septae between adjacent alveoli can be compressed.[19,20] This behavior is akin to that of a Starling resistor, a collapsible tube traversing a rigid housing (Figure 26-9). Flow (Q) is propelled through the tube by inflow pressure (P_i) and is opposed by outflow pressure (P_o). The tubing has some intrinsic resistance (R). If the housing is pressurized to a surrounding pressure (P_s), flow through the tube is determined as follows:

$$\text{For } P_s < P_o < P_i,\ Q = (P_i - P_o)/R \quad (2)$$

$$\text{For } P_o < P_s < P_i,\ Q = (P_i - P_s)/R \quad (3)$$

$$\text{For } P_o < P_i < P_s,\ Q = 0 \quad (4)$$

Except when $P_s < P_o$, alveolar pressure appears to modulate local pulmonary blood flow as though it surrounds the pulmonary capillary (Figure 26-10).

From this discussion, the degree to which P_s affects pulmonary blood flow is influenced by the magnitude of inflow pressure,

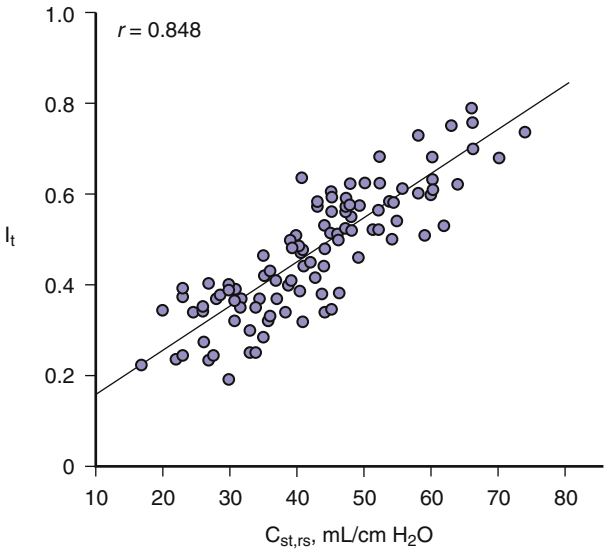

Figure 26–6. Relationship between the static compliance of the respiratory system ($C_{st,rs}$) and the index of transmission (I_t, decimal fraction) of a change in static airway pressure to the pulmonary circulation in adults. I_t values for pleural and juxtacardiac spaces are presumed to be comparable. *(From Teboul JL, Pinsky MR, Mercat A, et al: Estimating cardiac filling pressure in mechanically vented patients with hyperinflation,* Crit Care Med *28:3631, 2000.)*

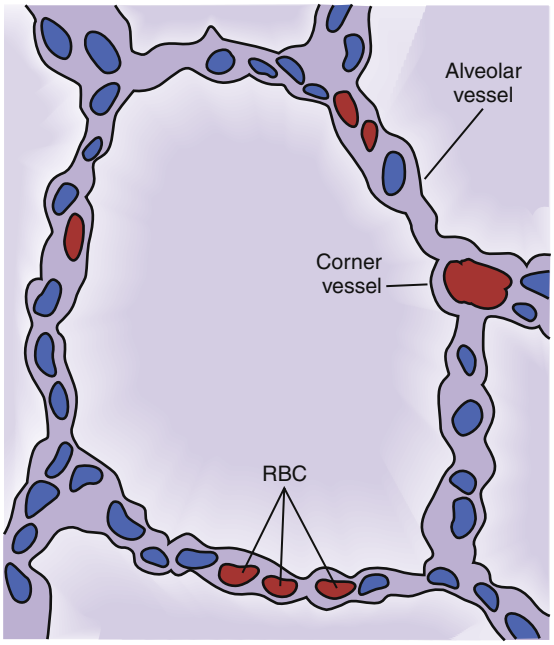

Figure 26–7. Alveolus is encased in a network of capillaries. Alveolar vessels are those that lie between adjacent alveoli. Corner vessels are those that lie at the intersection of alveolar septa. *RBC,* Red blood cell.

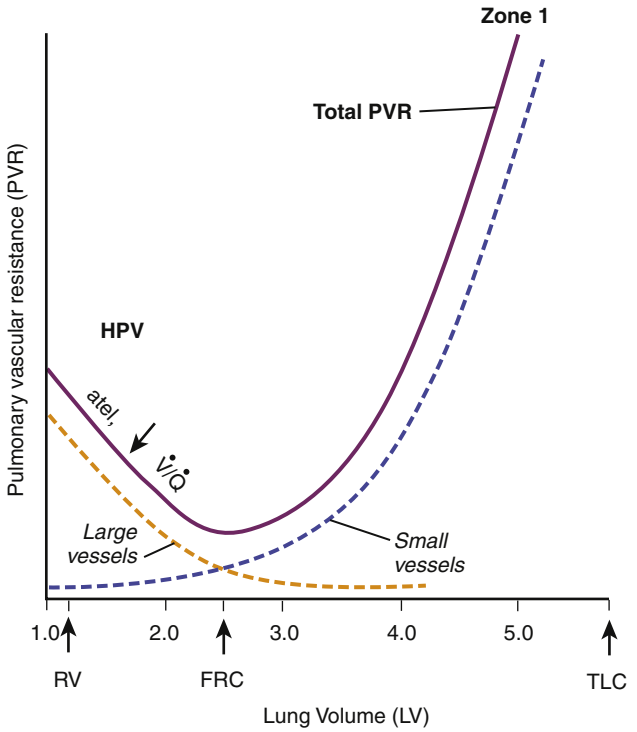

Figure 26–8. Effects of lung volume on pulmonary vascular resistance (*PVR*). As whole lung is distended from functional residual capacity (*FRC*) toward total lung capacity (*TLC*), PVR rises, predominantly by increasing resistance to flow through the small alveolar vessels that course between adjacent alveoli (alveolar vessels). As whole lung is collapsed from FRC toward residual volume, PVR rises, predominantly by effects on corner vessel that traverse the intersection of alveolar septa. *(Modified from Cassidy SS, Schwiep F: Cardiovascular effects of positive end-expiratory pressure. In Scharf SM, Cassidy SS, editors:* Heart lung interactions in health and disease, vol 42, Lung biology in health and disease, *New York, 1989, Dekker.)*

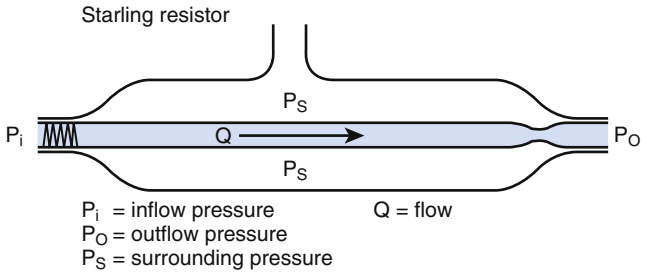

Figure 26–9. Starling resistor is a compressible conduit traversing a rigid housing, which is pressurized to a surrounding pressure (P_s). Flow (Q) traverses the conduit, propelled by inflow pressure (P_i) and opposed by outflow pressure (P_o) such that driving pressure is ($P_i - P_o$) for $P_s < P_o$. As P_s is increased, it begins to influence flow, but only after it exceeds P_o. At $P_s > P_o$, the driving force for flow becomes ($P_i - P_s$). *(Modified from Knowlton FP, Starling EH: The influence of variations in temperature and blood pressure on performance of the isolated mammalian heart,* J Physiol *44(3):206-219, 1912.)*

which, for the pulmonary capillary, must be adjusted for vertical height. Alveolar pressure causes greater reduction in flow at low pulmonary artery pressure than it does at high pressure. Pulmonary hypertension (high P_i) dampens this cardiopulmonary interaction, whereas hypovolemia (low P_i) accentuates it.

Hydrostatic pressure in the lung is a function of vertical height (see Chapter 20).[21] To estimate the hydrostatic inflow pressure of a pulmonary capillary, a pressure equivalent to

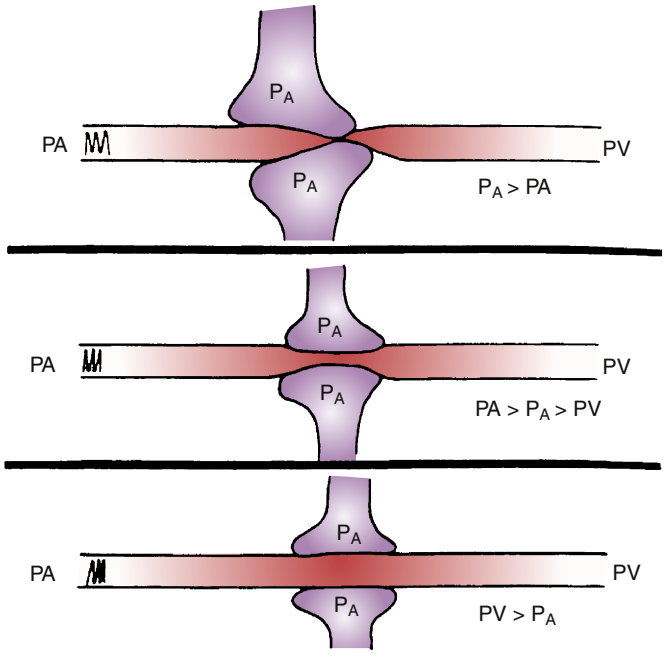

Figure 26–10. Pulmonary capillaries are, in essence, surrounded by gas-filled alveoli. The influence of alveolar pressure (P_A) on regional lung blood flow is similar to the influence of surrounding pressure on flow through a Starling resistor. At ambient values of P_A, pulmonary vein pressure (*PV*) opposes inflow. As P_A rises, it begins to oppose inflow only after $P_A > PV$. It modulates inflow until P_A reaches hydrostatic inflow pressure (*PA*), at which point flow ceases.

that exerted by a water column extending from the left atrium to the capillary must be subtracted from the pressure within the main pulmonary artery. The greater the vertical height of the pulmonary capillary, the lower its inflow pressure and the greater the attenuation of flow by alveolar pressure. This can produce areas of no flow, especially at peak inspiration, high in the supine lung. These high ventilation/perfusion ratio (Va/Q) alveolar capillary units waste ventilation and can cause hypercarbia (see Chapter 40). Vertical height (h) of the capillary also alters the backpressure to flow. At a left atrial pressure of 10 cm H_2O (7 mm Hg), for example, there is (10 − h) cm H_2O opposing flow up to a vertical height 10 cm above the heart. Above that, there is no back pressure, and P_i and P_s determine flow through the capillary. Compression of pulmonary capillaries is a local phenomenon. It can divert pulmonary blood flow away from normal lung segments toward consolidated or atelectatic lung segments whose airways do not effectively transmit airway pressure to the alveolus.[22] By this mechanism, the application of high PEEP in the presence of lobar pneumonia may increase blood flow through unventilated lung and worsen hypoxemia (Figure 26-11). From a more positive perspective, PEEP may relieve atelectasis and improve ventilation, thereby relieving alveolar hypoxic vasoconstriction. Whether PEEP benefits or impairs pulmonary blood flow may depend on the balance of its effect on atelectasis and its effect on alveolar capillaries.

Regulation of Pulmonary Vascular Resistance

The resistance to flow through a vessel is described by the following:

$$R = 8\,\eta l / \pi r^4 \qquad (5)$$

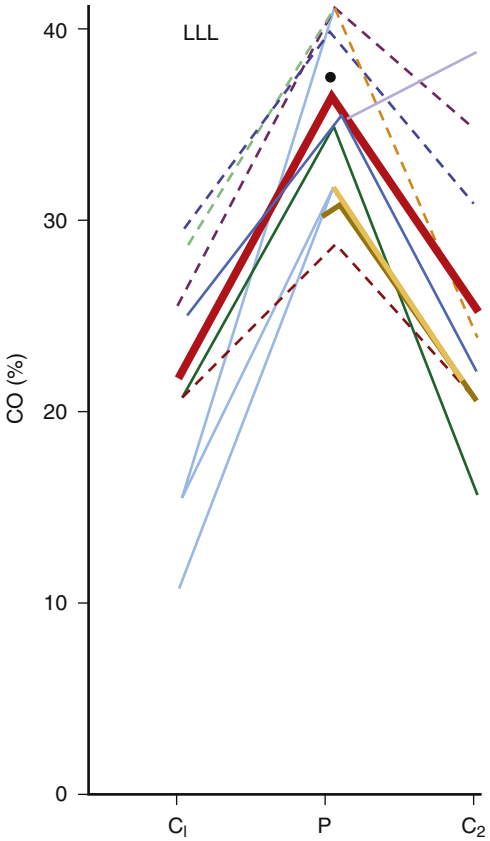

Figure 26–11. Blood flow to the left lower lobes (*LLL*) of dogs with LLL pneumonia, measured at zero positive end-expiratory pressure (*PEEP*) (C_1), 6–12 cmH_2O PEEP (*P*), and on cessation of applied PEEP (C_2). PEEP diverted blood flow away from more normal lung toward the consolidated LLL. *(From Mink SN, Light RB, Cooligan T, et al: Effect of PEEP on gas exchange and pulmonary perfusion in canine lobar pneumonia,* J Appl Physiol *50:517, 1981.)*

where η is viscosity, *l* is length, and *r* is radius. It follows that PVR can be effectively controlled by active changes in vessel radius. Mechanical ventilation may alter blood pH and alveolar oxygen tension (po_2), both of which influence vessel tone and radius (Figure 26-12).[23,24]

Hypoxic pulmonary vasoconstriction is a powerful mechanism for sustaining systemic oxygenation in the face of lung disease.[25-28] Relief of atelectasis and restoration of segmental ventilation not only increases the fraction of the lung that is ventilated but also restores blood flow to those segments by several mechanisms. Segmental alveolar hypoxia is relieved. Segmental volume is restored, which returns segmental vascular resistance toward its volume-dependent nadir. Gas exchange is also improved, favorably altering pH, pco_2, and po_2, and thereby reducing global PVR.

Direct Effects of Airway Pressure on Pulmonary Vascular Tone

Pulmonary vessels are stretched by lung inflation. The lung of infant lambs responds to abrupt changes in airway pressure with changes in vascular tone. Abrupt distension of one lung of the intact infant lamb increases the PVR of that lung alone.[29] The resistance change is sensitive to the waveform of the lung distension[30] and persists for some time after relief of distending pressure and return of lung volume to baseline.[31] This effect is calcium channel dependent[32] and resembles a myogenic reflex whereby direct vessel stretch causes constriction.

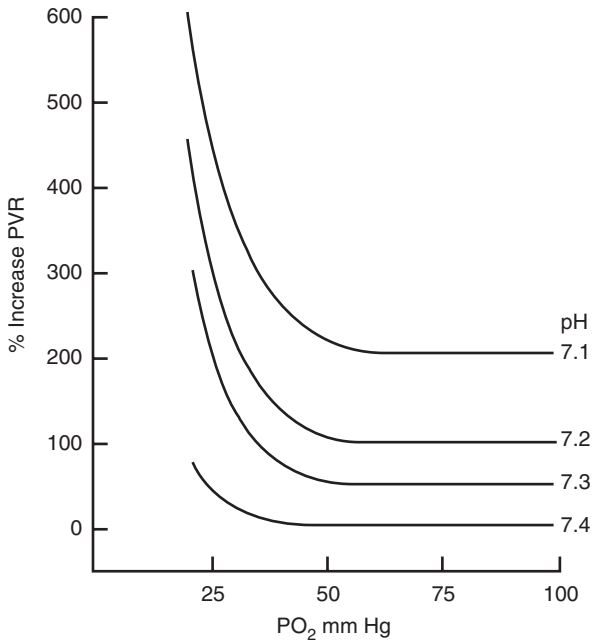

Figure 26–12. Pulmonary vascular resistance (*PVR*) is a function of both pH and arterial po_2. *(From Rudolph AM, Yuan S: Response of the pulmonary vasculature to hypoxia and H^+ ion concentration changes,* J Clin Invest *45:399, 1966.)*

Left Ventricular Preload

Positive airway pressure can impede left ventricular filling via several mechanisms. The first is impaired systemic venous return. Other mechanisms involve functional reduction in left ventricular compliance.

Decreased Venous Return

The reduction in venous return to the right heart seen at high airway pressure should directly reduce filling of the left heart. But there is a trap in this line of reasoning. Venous return, when averaged over several respiratory cycles, equals cardiac output. If other cardiopulmonary interactions and compensatory mechanisms restore cardiac output to normal, then right and left heart venous return will not be diminished.

Ventricular Interdependence

The right and left ventricles share a common muscle mass and pericardial space. It follows that compliance of either ventricle will be influenced by volume of the other chamber (Figure 26-13). Increased venous return to the right heart, as occurs during spontaneous inspiration and especially during execution of a Müller maneuver, tends to shift the interventricular septum to the left, reducing compliance of the left ventricle.[33] Similarly, excessive compression of the pulmonary circulation by positive airway pressure may impede right ventricular ejection, causing the right ventricle to dilate and encroach on the left. Reduced left ventricular compliance tends to diminish stroke volume by diminishing left ventricular muscle stretch and ejection force (by the Frank-Starling mechanism).

Ventricular interdependence may play a major role in cyclic changes in left ventricular stroke volume across single respiratory cycles. During spontaneous breathing, inspiration dilates the right ventricle by augmented filling. This pushes the interventricular septum to the left and makes the left ventricle less

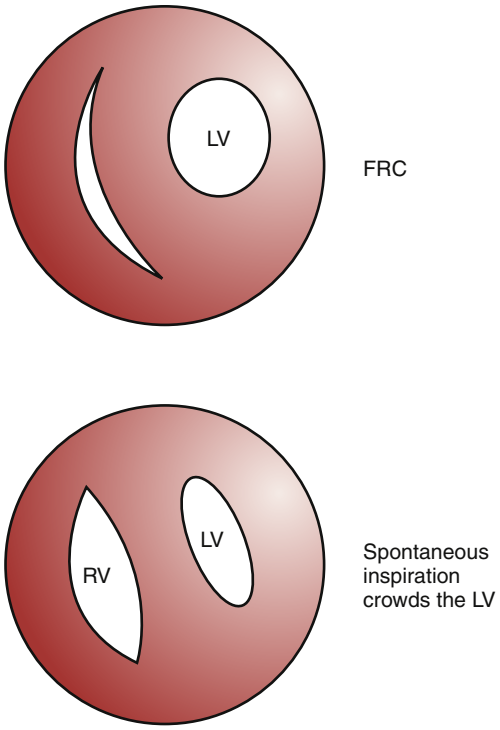

Figure 26–13. Increasing the diastolic volume of the right ventricle (*RV*) reduces compliance of the left ventricle (*LV*). *FRC,* Functional residual capacity.

compliant, reducing stroke volume, pulse pressure, and both systolic and diastolic pressures.[34]

During positive pressure inspiration, right ventricular filling may be reduced. The septum is displaced to the right, making the left ventricle more compliant. Stroke volume is augmented by increased left ventricular filling. Stroke volume, pulse pressure, and both systolic and diastolic pressures increase.

Cardiac Crowding

Overinflation of the lungs may crowd the cardiac fossa in which the heart resides. To the extent that this creates a mechanical barrier to cardiac filling, it may reduce left ventricular compliance, end-diastolic volume, and force of contraction.

Left Ventricular Afterload

The left ventricle ejects blood from within the thorax to the extrathoracic arteries and arterioles. Most of the resistance to this forward flow resides in the arterioles. From a practical point of view, the pressure in the extrathoracic arteries can be described by the following equations:

$$(P_{artery} - P_{ms}) = Q \times R_{arteriole} \quad (6)$$

or

$$P_{artery} = Q \times R_{arteriole} + P_{ms} \quad (7)$$

where Q is cardiac output, P_{artery} is inflow pressure before the arteriole, and P_{ms} is outflow pressure after the arteriole as defined for the venous return curve.

It follows that, at any given blood volume, arterial pressure is determined by forward flow and arteriolar resistance. These two parameters set the afterload opposing left ventricular ejection.

When the left ventricle contracts, it creates internal pressure against the closed aortic valve by generating tension in the myocardium that encircles the ventricular chamber. This "wall tension" causes ventricular pressure to rise until it reaches aortic diastolic pressure, opening the aortic valve and ejecting the stroke volume. Creation of wall tension and subsequent shortening of myocardial fibers perform the external mechanical work of the heart (see Chapter 19).

When the heart squeezes, it creates a pressure difference between the ventricle and the juxtacardiac space. In effect, the myocardium creates a transmural pressure to produce a ventricular pressure sufficient to open the aortic valve. Aortic diastolic pressure and external (juxtacardiac) pressure determine the myocardial wall tension needed to open the aortic valve. Both pressures represent afterloads to left ventricular ejection.[35,36]

An infusion of phenylephrine, by raising $R_{arteriole}$, increases the afterload of the left ventricle (Figure 26-14). It raises the pressure required to open the aortic valve. This increases the wall tension the heart must generate to eject blood.

The Müller maneuver, forced inspiration against a closed glottis, does the same thing. It reduces juxtacardiac pressure, thereby raising the transmural pressure required to open the aortic valve. Thus the Müller maneuver also increases the afterload of the left ventricle.

Positive pressure inspiration or application of PEEP may raise juxtacardiac pressure to such an extent that the wall tension required to open the aortic valve is diminished. Mechanical ventilation may, therefore, reduce the afterload of the left ventricle.

The net effect of positive pressure inspiration often is augmentation of left ventricular ejection. Stroke volume may consequently rise, cardiac output increase, and arterial pressure rise. Arterial pressure is commonly observed to rise during positive pressure inspiration, whereas it falls during spontaneous inspiration. These are effects of afterload on stroke volume.

Cardiac Contractility

Studies of the effects of positive airway pressure on left ventricular contractility have yielded conflicting results. Certainly changes in preload and afterload have secondary effects on stroke volume, but independent effects of positive airway pressure on left ventricular contractility have not been consistently demonstrated. Negative inotropic effects modulated by reflexes, mediators, or alterations in coronary blood flow have been described,[37-42] but most animal and human studies fail to show that positive airway pressure has any primary effect on myocardial contractility.[43-46]

It has been suggested that high levels of PEEP may compress coronary vessels, cause myocardial ischemia, and thereby impair ventricular function.[47-49] The left ventricular myocardium is perfused predominantly in diastole. To the extent that juxtacardiac pressure exceeds left ventricular diastolic pressure, such an effect is plausible. This assertion appears more compelling for patients in shock and for those with intrinsic coronary blood flow limitations than for otherwise normal individuals.

Right ventricular myocardial perfusion normally occurs in both systole and diastole. In systole, right ventricular coronary

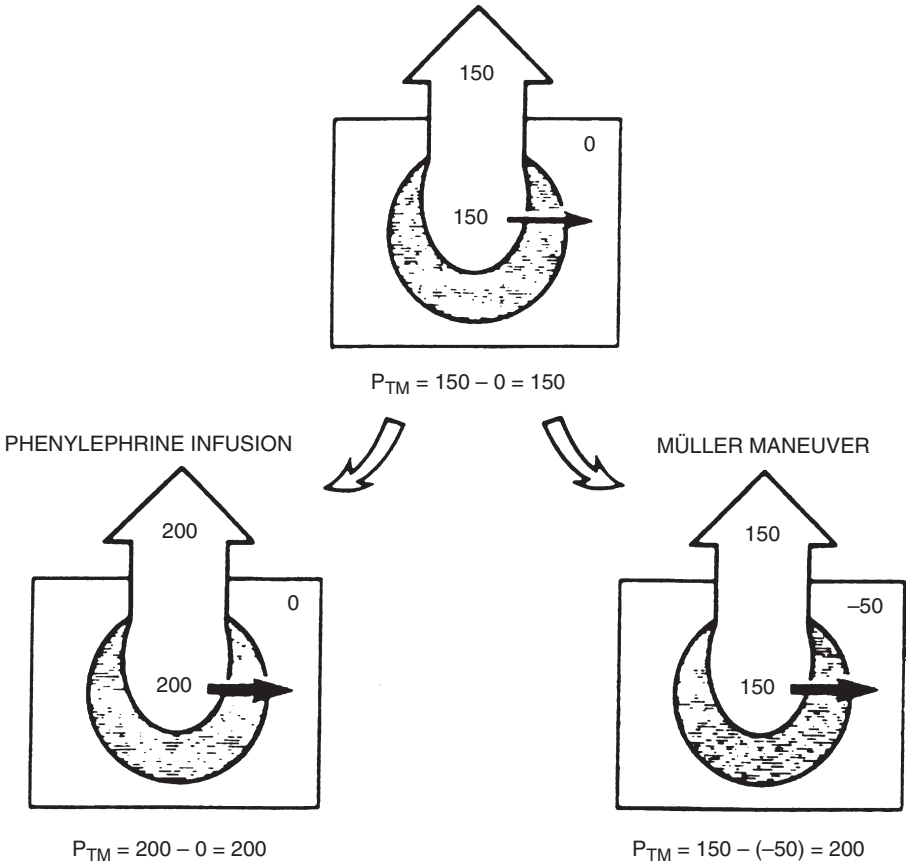

Figure 26–14. Negative pressure in the juxtacardiac space (Müller maneuver) increases the wall tension required to eject blood into the aorta. This respiratory maneuver acts like a phenylephrine infusion to increase left ventricular afterload. *(From Buda AJ, Pinsky MR, Ingels NB Jr, et al: Effect of intrathoracic pressure on left venticular performance,* N Engl J Med *301:453, 1979.)*

inflow pressure is aortic systolic pressure, and right ventricular coronary outflow (or surrounding) pressure is right ventricular or pulmonary artery systolic pressure. To the extent that positive pressure ventilation impedes pulmonary blood flow and increases pulmonary artery pressure, it may impede right ventricular systolic myocardial perfusion. Right ventricular diastolic myocardial perfusion may be subject to modulation by positive airway pressure as described for the left ventricle. Overall, it does not appear likely that judicious levels of positive airway pressure have much effect on myocardial contractility.

Preload Dependence Versus Afterload Dependence

The expected effects of an abrupt rise in airway pressure are as follows:

1. Decreased filling of the right ventricle acts to decrease right ventricular stroke volume.
2. Impaired pulmonary blood flow or increased right ventricular afterload acts to decrease right ventricular stroke volume.
3. Both diastolic displacement of the interventricular septum toward the left ventricle (with resultant crowding of the left ventricle) and crowding of the juxtacardiac space by the expanding lung reduce left ventricular compliance. Both of these factors act to decrease left ventricular stroke volume.
4. Reduced left ventricular afterload acts to increase left ventricular stroke volume.

Although these effects are not incompatible, they do make the aggregate effect of positive airway pressure on cardiac output less predictable.

In general, positive airway pressure has its most pronounced effect on right ventricular filling; therefore, positive airway pressure reduces cardiac output in most patients. Such patients may be thought of as "preload dependent" because the effect of positive airway pressure on cardiac output is dominated by its effect on right heart filling. This effect is greatest in patients who are hypovolemic because the driving pressure for systemic venous return ($P_{ms} - P_{ra}$) is more sensitive to change in P_{ra} when P_{ms} is low. In adults, the P_{ra} threshold (at zero PEEP) below which increasing airway pressure reduces cardiac output is approximately 12 mm Hg.[50] Furthermore, the rise in P_{ra} with positive airway pressure is mechanical and does not appear to be a function of blood volume, so the percent reduction in driving pressure is exaggerated in the hypovolemic patient.

Another definition of preload dependence is responsiveness to vascular volume infusion. By this definition, when the dominant effect of positive airway pressure is to impede right heart filling, vascular volume infusion raises cardiac output. Four measurable parameters (Figure 26-15) predict responsiveness to vascular volume infusion: variation over the respiratory cycle (Maximum − Minimum) in pulse pressure, arterial systolic pressure, P_{ra}, and pulmonary artery wedge pressure.[51] Of these parameters, the inspiratory increase in arterial pulse pressure is the most sensitive and specific predictor of

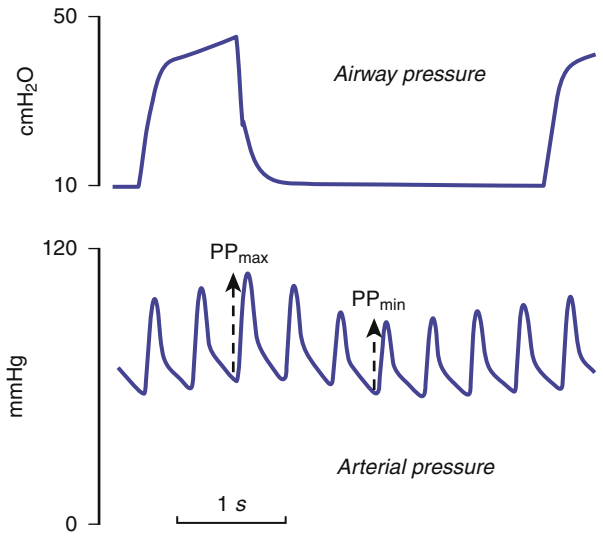

Figure 26–15. Positive pressure inspiration generally raises aortic pulse pressure (*PP*), systolic pressure (*SP*), and diastolic pressure (*DP*) as well as right atrial pressure, and pulmonary artery wedge pressure. *(From Michard F, Chemla D, Richard C, et al: Clinical use of respiratory changes in arterial pulse pressure to monitor the hemodynamic effects of PEEP,* Am J Respir Crit Care Med *159:935, 1999.)*

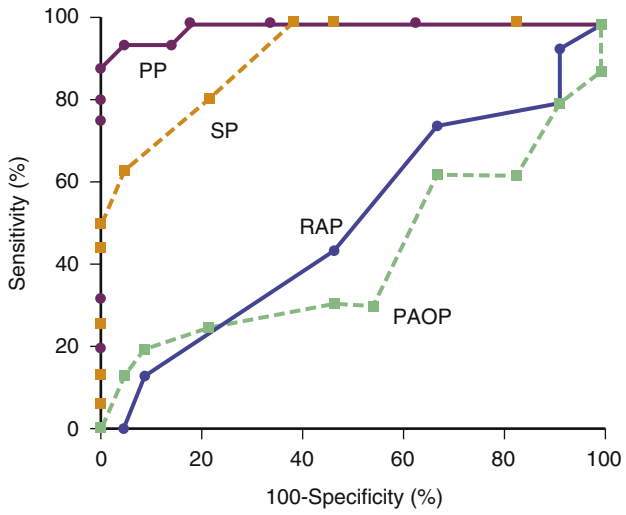

Figure 26–16. Septic patients on positive end-expiratory pressure were challenged by volume infusion. In response to volume loading, some patients had a greater than 15% increase in cardiac index. These responsive patients were deemed preload dependent. The sensitivity and specificity of variation in pulse pressure (*PP*) across the respiratory cycle as a predictor of responsiveness to volume loading yielded a near-perfect receiver operating characteristic curve. Greater than 15% inspiratory rise in PP appears to identify adults with preload dependence during positive pressure ventilation. *PAOP,* Pulmonary artery occlusion pressure; *RAP,* right atrial pressure: *SP,* systolic pressure. *(From Michard F, Boussat S, Chemla D, et al: Relation between respiratory changes in arterial pulse pressure and fluid responsiveness in septic patients with acute circulatory failure,* Am J Respir Crit Care Med *162:134, 2000.)*

"preload dependence" (by receptor operating characteristic curve) (Figure 26-16). Greater than 15% inspiratory rise in pulse pressure appears to identify adults with preload dependence during positive pressure ventilation.[52]

One might expect the converse also to apply. Reduced magnitude of the effects of positive pressure ventilation on right ventricular filling or augmented effects on left ventricular ejection may make the patient "afterload dependent." Patients who have high blood volume, such as those in congestive cardiac failure or those with chronic anemia, should have high P_{ms} and decreased sensitivity to changes in P_{ra}.[53] Moreover, the patient with poor left ventricular contractility may greatly benefit from the afterload reduction of positive pressure ventilation.[54] If positive airway pressure enhances the ejection of blood into the systemic circulation, this may directly reduce left atrial pressure. From these considerations, better cardiac output may also reduce P_{ra} by transferring blood from veins to arteries and reducing venous capacitance vessel blood volume (see Figure 26-1, *B*). When favorable effects on left ventricular ejection act to reduce right and left atrial pressures, cardiac output improves. Such a patient might be thought of as "afterload dependent."

Fluid Responsiveness During Positive Pressure Ventilation

In the intensive care unit, whether volume infusion will augment cardiac output or merely contribute to vascular volume overload is often a vital issue. In adults, about half of all hemodynamically unstable critical care patients are not volume responsive.[55] The traditional guides to volume resuscitation have focused on measurement of cardiac filling pressures and responses to fluid challenges. In critically ill patients and in normal subjects, the stroke volume response to vascular volume infusion is poorly predicted by measurement of either right arterial or pulmonary artery occlusion pressure.[56] Much recent interest has focused on minimally invasive estimation of likelihood of responding to fluid infusion.

The cardiopulmonary interactions described previously can be used to predict response to fluid challenge. The change in stroke volume over the course of the positive pressure respiratory cycle strongly predicts fluid responsiveness, the greater the percentage change in stroke volume the greater the response to volume infusion.[57] Similar relations have been shown between fluid responsiveness and respiratory variation in aortic blood flow velocity[58] and arterial pulse pressure.[50] Inspiratory collapsibility of the inferior[59] and superior[60] vena cavae have also been shown to predict volume responsiveness. The strong linear relationship of increase in cardiac index after fluid resuscitation to preinfusion pulse pressure variability over the respiratory cycle (ΔPP) is shown in Figure 26-17, which depicts data from 14 adults with acute lung injury.

This same parameter, change in arterial pulse pressure over the respiratory cycle, can be used to estimate the effect of PEEP on cardiac index. The strong linear relationship of ΔPP to PEEP-induced change in cardiac index is shown in Figure 26-18.

Changes in cardiac index induced by either fluid resuscitation or by application of PEEP appear to be predicted by measurement of ΔPP.[51] In general, in these patients, the greater the ΔPP, the more preload dependent the patient to PEEP and the more preload responsive to fluid resuscitation.

Elevated Work of Breathing and the Circulation

During quiet respiration, the heart has no difficulty satisfying the demand of the respiratory muscles for perfusion and muscle oxygen delivery. In respiratory failure, however, respiratory muscle perfusion may not be adequate. The diaphragm and the accessory muscles of respiration all are taxed to the limit by respiratory distress. Unlike cardiac muscle, respiratory

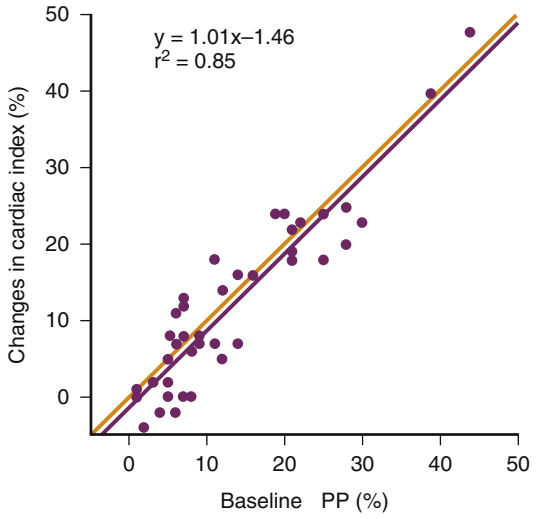

Figure 26–17. Relationship between ΔPP before volume expansion (baseline) and % change in cardiac index in 40 adult patients with septic shock during mechanical ventilation. Volume expansion comprised 500 mL 6% hydroxyethyl starch. ΔPP = 2 × (Peak arterial pulse pressure – Lowest arterial pulse pressure)/(Peak PP + Lowest PP). *(From Michard F, Boussat S, Chemla D, et al: Relation between respiratory changes in arterial pulse pressure and fluid responsiveness in septic patients with acute circulatory failure,* Am J Respir Crit Care Med *162:134, 2000)*

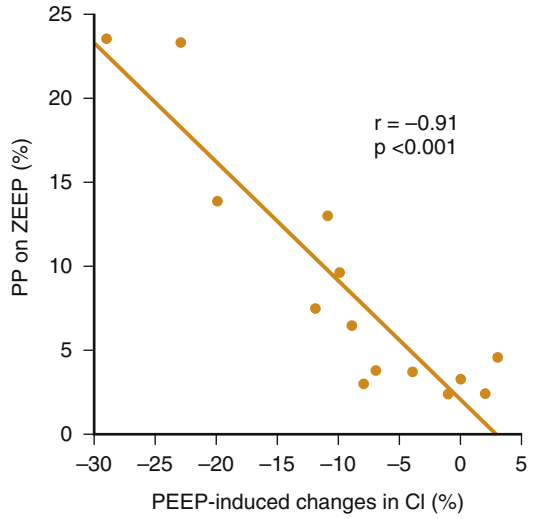

Figure 26–18. Relationship between ΔPP on zero PEEP and % decrease in cardiac index on application of 10 cm H_2O PEEP. ΔPP = 2 × (Peak arterial pulse pressure – Lowest arterial pulse pressure)/(Peak PP + Lowest PP). *(From Michard F, Chemla D, Richard C, et al: Clinical use of respiratory changes in arterial pulse pressure to monitor the hemodynamic effects of PEEP,* Am J Respir Crit Care Med *159:935, 1999.)*

muscles can accumulate a limited oxygen debt, but persistent hypoperfusion may interfere with their ability to perform the requisite work of breathing. In many clinical scenarios, including shock, congestive heart failure, and respiratory disease, the inability of the circulation to maintain adequate respiratory muscle blood flow causes weakness, respiratory muscle fatigue, and ultimate respiratory arrest.[61] Loaded breathing,[62] respiratory muscle failure, and impending respiratory arrest all pose a strain on the circulation, demanding greater cardiac output.

Mechanical ventilation is, therefore, a highly effective if not essential intervention in the patient with cardiac decompensation and respiratory distress.

Pulsus Paradoxicus in Respiratory Distress

Arterial pressure normally falls during spontaneous inspiration, which is best explained as a result of increasing left ventricular afterload at a time in the respiratory cycle when ventricular interdependence restricts left ventricular filling. It is well known that pericardial tamponade causes accentuation of the normal inspiratory decrease in systemic blood pressure, a phenomenon known as pulsus paradoxus. This finding has been attributed to accentuation of ventricular interdependence, which favors right over left ventricular filling, at the same time in the respiratory cycle when inspiration is raising left ventricular afterload.

During loaded spontaneous inspiration, as in the Müller maneuver or in the presence of inspiratory airway obstruction (e.g., croup), the inspiratory fall in juxtacardiac pressure is exaggerated, and left ventricular afterload is accentuated. Again, the result is pulsus paradoxicus, an accentuated drop in blood pressure during inspiration.

Blood pressure commonly rises during positive pressure inspiration, which is termed *reverse pulsus paradoxus*. This finding has been attributed to left ventricular afterload reduction by the rise in juxtacardiac pressure that occurs during positive pressure inspiration.[63] Reverse pulsus paradoxicus is a normal finding during positive pressure ventilation but may be accentuated in afterload-dependent states (e.g., left ventricular dysfunction) as discussed in the Preload Dependence versus Afterload Dependence section).

Effects of Breathing on Measurement of Hemodynamic Parameters

Because hemodynamic measurements vary with respiration, mechanical ventilation may complicate assessment of cardiac function. Yet it may not be advisable to discontinue PEEP or mechanical ventilation to assess hemodynamics. Measuring vascular pressures at a consistent time in the respiratory cycle usually is sufficient. End-expiratory measurements are generally used because airway pressures are least at that time and hemodynamic measurements most closely approximate those at FRC.

It should be understood that the effects of mechanical ventilation on the circulation are not merely artifactual. They are real. There is no greater accuracy of measurements made off the ventilator. Measurements performed after ventilator disconnect are subject to the effects of respiratory dysfunction and instability.

A special circumstance can occur when a balloon flotation catheter with its tip in zone I lung is used to measure pulmonary artery pressure and when such a catheter with its tip in zone I or II lung is used to measure pulmonary artery wedge pressure.[64] Under such circumstances, airway pressures that exceed vascular pressures may be erroneously reported as vascular pressures.

Effects of Cardiovascular Function on Respiration

Shock States and Respiratory Function

Shock of any cause diminishes perfusion of respiratory muscles and can lead to respiratory failure and respiratory arrest. It also causes metabolic acidosis, which constricts

pulmonary vessels and opposes lung blood flow.[65,66] Acidosis is a potent stimulus of respiratory effort and contributes to tachypnea and respiratory distress, which in turn worsen the demand on the heart. Shock is injurious to both heart and lung, and one final common pathway to recovery is the initiation of mechanical ventilation, which benefits both organ systems.

Hypovolemic shock can create extreme preload dependency.[67] In hypovolemic shock, diastolic blood pressure may fall during positive pressure inspiration, impairing coronary perfusion. This may cause myocardial ischemia and worsen cardiac function.

Cardiogenic shock, by reducing oxygen delivery to tissues, elevates tissue oxygen extraction from the blood. The resultant decline in venous oxygen tension has a paradoxical effect. It increases the efficiency of pulmonary blood flow by allowing greater oxygen uptake per unit of pulmonary blood flow. That is, the more desaturated the blood that enters the pulmonary circulation, the more new oxygen it can upload. This process requires that alveolar po_2 not limit the amount of oxygen available for uptake and is one reason to administer oxygen to patients suffering cardiorespiratory failure.

Congestive Heart Failure

All that has been said about shock is equally true of congestive heart failure (CHF). In fact, there is a continuum from CHF to cardiogenic shock. CHF elicits physiologic responses that restore cardiac output toward normal. As these homeostatic responses are exhausted, cardiac output declines and the patient develops obvious manifestations of cardiogenic shock and respiratory failure.

In addition to the impact of shock on respiratory function and reserve, CHF generally causes fluid retention and pulmonary edema. Treatment of cardiogenic shock by vascular volume expansion may, by augmenting cardiac filling pressures, improve cardiac output at the expense of pulmonary edema. The edematous lung is stiff, may have elevated airway resistance, and can have alveolar flooding, atelectasis, intrapulmonary shunt, and severe ventilation/perfusion mismatch.

When a premature infant has a large patent ductus arteriosus, the primary manifestation of cardiac volume overload may be respiratory embarrassment.

Again, mechanical ventilation addresses most of these issues. Furthermore, PEEP improves lung function and supplemental oxygen supports gas exchange. Treatment of CHF can itself dramatically improve lung function. In contrast to hypovolemic shock, cardiogenic shock generally causes elevated atrial pressures. When this is the case, venous return may be insensitive to airway pressures during positive pressure ventilation. The patient is then usually afterload dependent and responds favorably to the afterload reducing effects of positive pressure ventilation.

When treating the patient with CHF on positive pressure ventilation, there is a risk of worsening pulmonary edema during fluid resuscitation. It is wise to assess pulse pressure and systolic pressure and diastolic pressure because they vary across the respiratory cycle to predict volume responsiveness before fluid challenge.[68] These parameters may also prove useful in assessing the impact of changes in PEEP on cardiac index.[51]

Cardiac Disease as a Cause of Blood Gas Abnormalities

Cardiac disease can cause arterial hypoxemia or hypercarbia by several mechanisms. The most obvious cardiac cause of arterial hypoxemia is right-to-left intracardiac shunting of blood as seen in tetralogy of Fallot. This situation allows venous blood to directly reenter the arterial circulation, causing arterial desaturation. In admixture lesions, such as transposition of the great arteries, tricuspid atresia, or total anomalous pulmonary venous connection, there is obligatory mixing of the systemic and pulmonary circulations, which allows desaturated blood to reach the systemic circulation, causing hypoxemia.

Arterial oxygen tension in right-to-left shunt lesions is sensitive to the volumes of systemic and pulmonary venous return that enter the aorta. The greater the ratio of pink to blue blood, the greater the arterial saturation. When oxygen-enriched air is administered after an excessively large aortopulmonary shunt, arterial blood may become fully saturated as a result of oxygen dissolved at high po_2 in the torrential pulmonary venous return.

In transposition of the great arteries, arterial oxygenation may be inherently limited by the degree of mixing that can occur. Pulmonary blood flow may be enormous, yet little of the pink pulmonary venous return escapes to the systemic circulation. Only the pulmonary venous return that reaches the systemic circulation delivers oxygen to the tissues.

In hypoplastic left heart syndrome, which is an admixture lesion, supplemental oxygen may, by reducing PVR, dramatically divert blood flow to the pulmonary circulation at the expense of systemic blood flow. This can both dramatically drop blood pressure and raise arterial po_2. In this situation, the rise in po_2 can be attributed to the fall in cardiac output and to the increase in pulmonary blood flow. These two changes alter the ratio of pink to blue blood that admixes in the atria.

Cardiac disease can cause hypercarbia by several mechanisms.[69] CHF can cause pulmonary edema, which interferes with lung function. As discussed in the Shock States and Respiratory Function section of this chapter, it can weaken the muscles of respiration and thereby reduce minute ventilation during spontaneous breathing.

Certain cardiac defects (or their treatments) can create large-scale ventilation/perfusion (V/Q) abnormalities, which may include underperfusion of large volumes of lung. An example is branch pulmonary artery stenosis, which may accompany tetralogy of Fallot or follow its surgical repair. Another example is maldistribution of pulmonary blood flow caused by a surgical shunt, which predominantly perfuses only one lung. The resultant high ventilation/perfusion defect functionally wastes ventilation. The airflow to high V/Q (underperfused) segments does not contribute to carbon dioxide (CO_2) clearance (as the scanty perfusion carries little, if any, CO_2 to that region of the lung). This waste of ventilation functionally reduces effective minute alveolar ventilation, causing CO_2 retention. In contrast, the gas exhaled by high V/Q segments mixes with gas from perfused alveoli during expiration, lowering the end-tidal pco_2. The result is elevated arterial pco_2 and markedly lower end-tidal pco_2, an apparent high arterial-alveolar pco_2 gradient. This is also called elevated alveolar dead space.

One additional mechanism of hypercarbia in cardiac disease is extremely low pulmonary blood flow in the presence

of admixture or right-to-left shunting. In this situation, so little blood reaches the lung that the circulation cannot deliver to the alveoli as much CO_2 per minute as the body produces until venous pco_2 becomes quite elevated. This can occur in ductus-dependent cyanotic cardiac defects on ductus closure and presents the paradoxical findings of clear (underperfused) lung fields and hypercarbia despite adequate ventilation. When there is no right-to-left shunt, elevation of venous (and occasionally arterial) pco_2 can occur without cyanosis. This commonly occurs during cardiopulmonary resuscitation (or in severe shock) when circulation is inadequate.

Hypercyanotic Spells

One special scenario that warrants discussion is the hypercyanotic spell, often called a tetrad spell. In these episodes, pulmonary blood flow is inadequate to take up sufficient oxygen from the lung to meet the mitochondrial demand for oxygen. Mixed venous po2 progressively falls. In the presence of admixture or right-to-left shunting, this directly reduces arterial oxygen tension. Sometimes the cause of the spell is abrupt reduction in pulmonary blood flow, as occurs with worsening obstruction of the infundibulum of the right ventricular outflow tract in tetralogy of Fallot or increased right-to-left shunting because of systemic vasodilation. However, pulmonary blood flow need not fall for a hypercyanotic spell to occur. Oxygen demand may rise (e.g., because of crying, fever, or exertion), outstripping the capacity of pulmonary blood flow to take up oxygen from alveolar air. Blood loss or acute anemia can cause worsening hypoxia and acidosis in the presence of underlying cyanotic disease. Hypercyanotic spells can occur in any cyanotic heart defect or in the child with lung disease and cyanosis.

The cycle put in place by this abrupt inadequacy of pulmonary oxygen uptake includes acidosis, physical distress, exaggerated skeletal muscle work, respiratory distress, exaggerated respiratory muscle work, and a further increase in muscle oxygen utilization. The cycle can progress to death unless it is interrupted.

Although respiratory distress and tachypnea may suggest a pulmonary cause, the treatment is directed at restoration of pulmonary blood flow (volume expansion, squatting, propranolol, transfusion if there has been blood loss), assurance of adequate alveolar oxygen for uptake (supplemental oxygen), reduction of oxygen demand (calming, sedation, paralysis, intubation, and mechanical ventilation, propranolol), or ductus manipulation (prostaglandin E_1).

Glenn and Fontan Procedures

Hearts that cannot support two separate circulations after repair (univentricular hearts and hearts having one hypoplastic ventricle) often are palliated and then repaired by routing systemic venous return to directly perfuse the lung without a pump (Glenn and Fontan procedures). This procedure frees the one functional ventricle to support the systemic circulation.

After such a procedure, the pressure of venous return drives pulmonary blood flow. At low pulmonary artery driving pressures, gravitational and airway pressure-mediated changes in V/Q matching may be exaggerated. The pressure of alveolar gas impinging on alveolar capillaries mediates this effect during mechanical ventilation. High airway pressure (from high PEEP or high tidal volume) tends to create alveolar dead space and waste ventilation as described in the Alveolar Pressure section of this chapter. Use of high PEEP and large tidal volumes in Glenn and Fontan patients requires caution and attention to gas exchange, although low levels of PEEP are generally well tolerated.

One additional effect of elevated airway pressure in these patients is impaired venous return. The heart does not compensate for increases in right ventricular afterload following a Fontan procedure. It is predictable that venous filling pressure will rise in proportion to the rise in alveolar pressure, so a 5 cm H_2O rise in PEEP is expected to raise venous pressure by 4 mm Hg. This might reduce cardiac output in proportion to the reduction in venous return as described for the normal circulation.

The advisability of PEEP after a Fontan or Glenn procedure must take into account the heart's inability to compensate for any elevation of PVR that may accompany atelectasis or lung disease. After either one of these procedures, the disadvantages of PEEP must be weighed against the risks of low FRC lung dysfunction.

Pulmonary Hypertension

Pulmonary hypertension makes the pulmonary circulation less susceptible to gravitational and airway pressure (Starling resistor)-mediated changes in V/Q matching. In contrast, it raises the tension in pulmonary vessels and invariably leads to smooth muscle hypertrophy and increased vasomotor reactivity. Even the infant with pulmonary hypertension because of a large interventricular communication and large left-to-right shunt (low PVR) may be capable of intense pulmonary vasoconstriction after repair. The lung with pulmonary hypertension must be ventilated with special attention to blood pH, arterial pco_2, alveolar po_2, and probably degree of lung stretch, all of which alter PVR.

Pulmonary hypertensive crises can be transparent unless pulmonary artery pressure is monitored. They are only obvious in the presence of a right-to-left shunt. In the absence of such a shunt, an abrupt rise in PVR presents as a fall in cardiac output, sometimes associated with right ventricular ischemia, which may be evident on the electrocardiogram. Cardiovascular deterioration in a patient with underlying pulmonary hypertension should always direct attention to the patient's respiratory status.

There are numerous potential treatments of pulmonary hypertensive crises. Central to these is assurance of normal gas exchange and adequate (but not excessive) lung expansion. Oxygen, inhaled nitric oxide, selective phosphodiesterase inhibitors, calcium channel blockers, and other vasodilators have been used. Treatments that address oxygen demand also are essential.

Vascular Impingement on the Lungs

There are several recognizable cardiovascular syndromes of vascular impingement on airways.[70,71] The respiratory effects of these lesions are predictable from their location. Complete vascular rings may compress the trachea, causing airway narrowing, obstruction, and localized tracheomalacia. A pulmonary artery sling is origin of the left pulmonary artery from the right. The left pulmonary artery then wraps around the right

mainstem bronchus to pass between the trachea and esophagus on its course to the left lung. It may impinge on the right mainstem bronchus, often causing right lung air trapping and overdistension. In congenital cardiac defects, pulmonary hypertension and left atrial hypertension often occur together. In this situation, the left atrium may elevate the left mainstem bronchus and trap it against the hypertensive left pulmonary artery.[72] This situation often leads to left lung atelectasis. In tetralogy of Fallot with absent pulmonary valve, massive dilation of the main pulmonary artery may occur with impingement on the bifurcation of the trachea. Tracheobronchial malacia may cause critical respiratory problems in this lesion, even after successful repair of the cardiac defect.

Effect of Initiating Mechanical Ventilation

At the time of initiation of mechanical ventilation, the interactions between breathing and circulation are abruptly altered. Moreover, these changes are superimposed on simultaneous sedation, paralysis, other pharmacologic regimens, and instrumentation of the pharynx and airway. Whereas narcotics, paralytics, atropine, and other drugs have well-defined effects, the effects of initiation of mechanical ventilation on circulation are not as consistent.

In many cases, effects on right ventricular preload predominate. This is generally the case in patients who are hypovolemic, such as asthmatics who have not been taking enough oral fluids at home, patients who are dehydrated, and septic children who may be hypovolemic because of capillary leak syndrome. Air trapping, as occurs in asthma, may be worsened by positive pressure ventilation, high ventilator rates, or use of long inspiratory times,[73] with consequent amplification of effects on venous return. Vascular volume expansion should accompany intubation in these patients.[74] It is noteworthy that the decrease in stroke volume that is often caused by positive pressure ventilation is not generally accompanied by a compensatory rise in heart rate,[75,76] so hemodynamic embarrassment that occurs upon institution of mechanical ventilation is not generally signaled by tachycardia.

Patients with segmental lung disease may undergo redistribution of blood flow on initiation of positive pressure ventilation. Patients with lobar pneumonia or large segments of atelectasis may become more hypoxemic on institution of positive pressure breathing because of diversion of pulmonary blood flow away from normal lung toward low V/Q lung segments. In contrast, application of PEEP may quickly reexpand collapsed areas of lung, improving V/Q matching and enhancing oxygenation.

Patients with pulmonary vascular disease may benefit from restoration of normal blood gases and alveolar gas composition, because alveolar hypoxia, arterial hypercarbia, and acidosis all increase pulmonary vascular tone. Inadvertent overdistension of lung may, in contrast, cause a calcium channel mediated rise in PVR.[77]

Patients in congestive cardiac failure, especially those with elevated filling pressures, may benefit almost immediately from afterload reduction as described in the Left Ventricular Afterload section of this chapter. Relief of respiratory distress and diminished work of breathing can quickly benefit the circulation. Septic patients with myocardial depression also may show prompt improvement.

Myocardial Dysfunction, Ventricular Assist Devices, and Extracorporeal Life Support

Cherissa Hanson, Keith C. Kocis, and Ana Lía Graciano

PEARLS

- Advances in medical management, surgical techniques, and mechanical circulatory support for pediatric patients with congestive heart failure continue to improve patient outcomes.
- Indications for use of mechanical circulatory support continue to evolve.
- Patient size, expected duration of support, and goals of support (i.e., bridge to recovery versus bridge to transplant) must be considered in the choice of mechanical circulatory support device.
- Mechanical circulatory support is a life-saving therapeutic option for patients with advanced heart failure. Device options in children remain limited because of their size constraints.
- Selection of the appropriate mechanical circulatory device is critical to a successful outcome.

Myocardial dysfunction resulting in heart failure and low cardiac output syndrome (LCOS) is a common occurrence in the pediatric intensive care unit. The primary goal in the management of these patients is to ensure adequate tissue oxygen delivery, because an imbalance between oxygen delivery and consumption will result in further organ failure. Initial therapies to treat decompensated heart failure should target decreasing metabolic demands (i.e., work of breathing), heart rate and rhythm control, augmentation of preload, decreasing afterload, and augmenting cardiac contractility. Despite advances in medical therapy (e.g., milrinone and amiodarone),[1,2] a group of patients will continue to deteriorate or require excessive vasoactive and inotropic support. This group should be evaluated for mechanical circulatory support.

Mechanical circulatory support has become an essential component of pediatric cardiac intensive care units (ICUs). Results of mechanical cardiopulmonary support in infants, children, and young adults have steadily improved in the past decade. Novel and innovative forms of mechanical circulatory support are being developed while extended indications are currently being explored. Extracorporeal life support (ECLS) remains the most commonly deployed form of mechanical support.[3,4]

In this chapter we review the basics of myocardial dysfunction in children with an emphasis on LCOS and its treatment with regard to mechanical circulatory support. We outline the principles of appropriate use of ECLS along with its current indications and important technical aspects, including the use of ventricular assist devices (VADs). Finally, we outline indications, patient management, present research, and future directions of these technologies for use in pediatric patients.

Myocardial Dysfunction

Patients admitted to the pediatric intensive care unit for heart failure often demonstrate inadequate cardiac output to meet the metabolic needs of the body (i.e., shock). The etiology of heart failure in pediatric patients encompasses a broad spectrum of pathology that has environmental, structural, metabolic, and other origins.

Low Cardiac Output Syndrome

LCOS describes a clinical and biochemical state where there is inadequate systemic oxygen delivery (Do_2) to meet the metabolic demands of the patient. This condition has been described since the 1960s, and multiple studies have documented the predicted change in physiologic parameters. LCOS is frequently seen in patients with severe sepsis, myocarditis, and cardiomyopathies and after pediatric cardiac surgery.[5] Postoperative physiologic changes resulting from cardiopulmonary bypass, residual lesions, cardioplegia, ventriculotomy, changes in the loading conditions of the myocardium, or myocardial ischemia during aortic cross-clamping all may contribute to the development of LCOS. A variety of proinflammatory triggers are activated during cardiopulmonary bypass as a result of blood contact with foreign surfaces, ischemia, reperfusion, tissue trauma, and temperature changes. This complex inflammatory response includes complement activation, cytokine release, leukocyte and platelet activation, and the expression of adhesion molecules.[6] LCOS has been

reported to affect up to 25% of infants and children, typically occurs between 6 and 18 hours after cardiac surgery, and results in longer intensive care stay and increased mortality.[7] It is associated with elevated systemic and pulmonary vascular resistances, impaired myocardial function, and arrhythmias. When unrecognized or inadequately treated, LCOS can result in irreversible end organ failure, cardiac arrest, and even death. Prevention, early recognition, and optimal treatment are essential components for reversing its course.

Although detailed assessment of oxygen delivery in critically ill children is extremely challenging, numerous hemodynamic and biochemical parameters can help guide the bedside clinician. Arterial lactate and mixed or central venous saturation are important biochemical markers in patients with LCOS. An elevated lactate level on admission and one that rises at 0.9 μm per hour postoperatively is associated with major adverse events including death in infants after cardiac surgery.[8] Furthermore, lower mixed venous saturation may increase the predictive power of elevated arterial lactate levels for mortality after pediatric cardiac surgery.[9-13] The predicted changes in cardiac output have been systematically demonstrated in newborns following the arterial switch operation for transposition of the great vessels.[14] The median maximal decrease in cardiac index (32%) occurred approximately 6 to 12 hours after separation from cardiopulmonary bypass, and nearly a quarter of these newborns reached a nadir of cardiac index that was less than 2 L/min/m^2. The drop in cardiac index was coupled with a rise in the calculated systemic and pulmonary vascular resistance. Perfusion strategy with either low-flow bypass or circulatory arrest was not associated with postoperative hemodynamic or other nonneurologic postoperative events.[14]

Therapeutic Considerations

The treatment of LCOS aims at providing adequate oxygen delivery to meet the demands of end organs. Achieving a balance between O_2 supply and demand is essential and can be achieved by decreasing oxygen consumption (Vo_2) and/or increasing Do_2. Normally the ratio between Do_2 and Vo_2 is 5:1, and when Vo_2 increases according to increased metabolic demands, Do_2 readjusts by also increasing. When the rate of oxygen consumption exceeds Do_2, anaerobic metabolism begins. Mixed venous saturation is a reflection of the Do_2/Vo_2 ratio and can be an important indicator of O_2 delivery in critically ill patients. Management of patients with this malady should aim to decrease Vo_2 and increase Do_2.

Decreasing Oxygen Consumption

LCOS has been an active area of research, and multiple reviews of current therapies are available to guide the intensivist.[15-17] Vo_2 is determined by tissue metabolism and is increased during periods of increased muscular activity, infection, hyperthermia, or with increased levels of catecholamines. Supportive care for decompensated heart failure begins with strategies aimed at decreasing the child's metabolic demands. These strategies often include basic critical care therapies such as intubation and mechanical support for respiratory insufficiency, analgesia and sedation, and treatment of anemia (Figure 27-1). Likewise, temperature control is a routine but important part of intensive care, and even a modest increase in body temperature can result in major increases in systemic Vo_2 during the early postoperative period.[18]

Increasing Oxygen Delivery

Systemic oxygen delivery (Do_2) is defined as the amount of O_2 delivered to peripheral tissues each minute and is determined by cardiac output and the oxygen content of arterial blood as shown by the Fick equation (listed below), where Do_2 refers to oxygen delivery and CO to cardiac output. Arterial oxygen content (Cao_2) is determined by hemoglobin (Hb) concentration, the arterial oxygen saturation (Sao_2), and the partial pressure of oxygen in the arterial blood (Pao_2). CO is defined as the product of heart rate (HR) × stroke volume (SV).

$$Vo_2 = CO\,(Cao_2 - Cvo_2)$$

$$Do_2 = CO \times Cao_2$$

$$Cao_2 = (Hb \times 1.36 \times Sao_2) + (Pao_2 \times 0.003)$$

$$CO = HR \times SV$$

Oxygen delivery can be improved by oxygen therapy, red blood cell transfusions, intravenous fluids, and inotropic support. Mechanical respiratory support not only decreases metabolic needs by decreasing the work of breathing but also can improve the arterial oxygen saturation (by the administration of oxygen and positive end-expiratory pressure [PEEP]), thus increasing Cao_2. However, endotracheal intubation can be risky in these patients and requires a clear understanding of the patient's current pathophysiology. Cao_2 also can be increased by transfusing packed red blood cells to increase the hemoglobin concentration. Packed red blood cells can help ameliorate tachycardia caused by anemia, but risks of transfusion exist. A continuous assessment of the patient's volume status (preload) is needed to avoid hypovolemia or fluid overload with worsening pulmonary edema. Optimizing preload will allow for greater diastolic filling, perfusion of the coronary arteries, and increased stroke volume. LCOS has been traditionally managed using catecholamines or their analogues (i.e., epinephrine, dopamine, and dobutamine); however, these agents can be deleterious on global and myocardial Vo_2, and when used in high doses they can lead to increased mortality.

Pharmacologic Treatment of Pediatric Heart Failure

In contrast to adult patients, tremendous heterogeneity exists between the etiology and pathophysiology of congestive heart failure in pediatric patients. Despite these differences, treatment strategies for pediatric patients have traditionally followed the recommendations extrapolated from large, randomized, multicenter trials in adult patients because of a lack of pediatric clinical trials. Symptom management with digitalis and diuretics formed the basis of early therapy (~1970s) of pediatric patients with congestive heart failure. Angiotensin-converting enzyme inhibitors (ACEI) exert favorable effects on cardiac remodeling and survival in adults with congestive heart failure. Their role in children is less clear. A randomized, placebo-controlled trial in children evaluated the effect of ACEI in patients with a single ventricle by

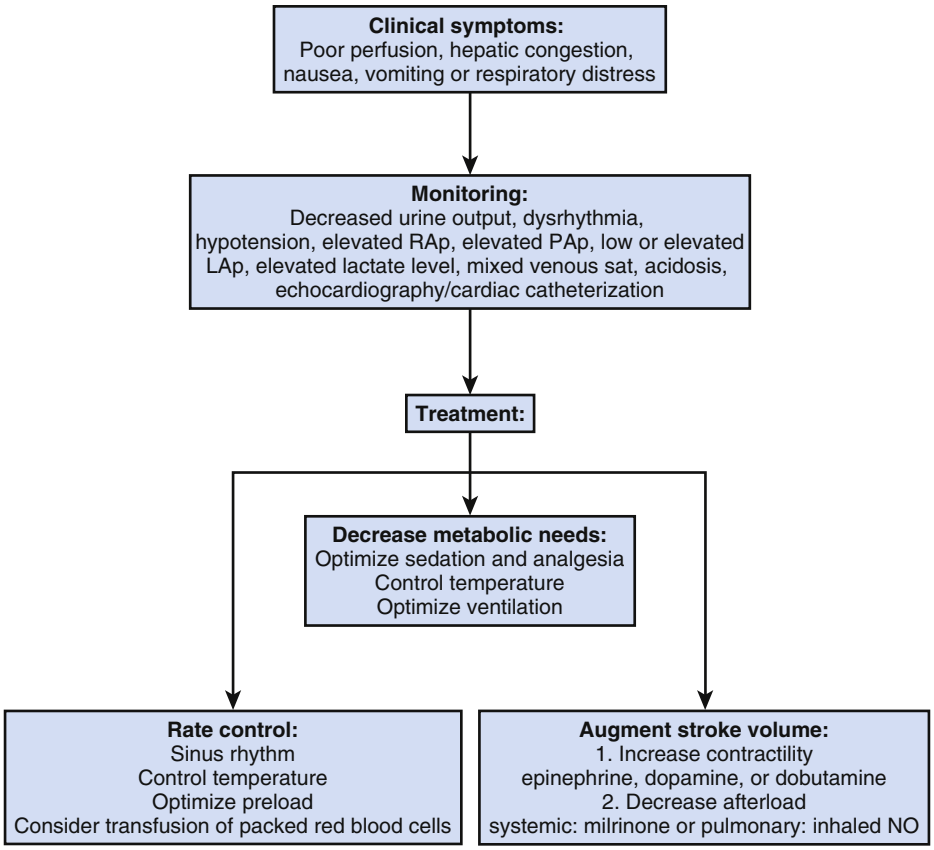

Figure 27–1. Algorithm for treatment of ventricular dysfunction. *NO,* Nitric oxide.

measuring exercise capacity, but this study failed to demonstrate a beneficial effect.[19]

β-Blockade utilization in pediatrics primarily has been extrapolated from the positive effects seen in adult trials that demonstrated a reduction in mortality and risk of hospitalization with the use of carvedilol.[20-21] A few reports have been made of the efficacy of propranolol in children with severe congestive failure as a result of left-to-right shunts[22] and of metoprolol in children with dilated cardiomyopathy.[23] Single-center trials have demonstrated both improved ejection fraction with the use of carvedilol in children awaiting heart transplantation with dilated cardiomyopathy[24,25] and a delayed time to transplantation or death.[25] However, the most recent and largest multicenter, randomized, double-blind, placebo-controlled trial of carvedilol for children and teenagers with symptomatic systolic heart failure failed to demonstrate an improved survival benefit.[26]

Milrinone, a phospodiesterase-3 inhibitor, has emerged as an important "inodilating" agent that is widely used in children after open heart surgery.[1-2,27-29] A landmark study showed that the prophylactic use of milrinone was associated with a decreased likelihood of LCOS in children after certain types of open-heart surgery.[28] This benefit is thought to result from both improved myocardial contractility as well as pulmonary and systemic vasodilatory effects.[2,28] Milrinone reduces right ventricular (RV) and left ventricular (LV) afterload through systemic and pulmonary vasodilatation and improves diastolic relaxation (lusitropy) of the myocardium through its enhanced cyclic adenosine monophosphate (cAMP)–dependent reuptake of calcium after systole.[30,31] A loading dose of 25 to 50 μg/kg generally is administered followed by a continuous infusion at doses between 0.25 to 0.75 μg/kg/min.

Calcium sensitizing agents (Levosimendan) have been shown to improve cardiac function and survival in adults with decompensated heart failure.[32] but pediatric data is scarce.[33-37] Nitric oxide is another therapy that may improve right heart failure.[38-39] Adult patients who undergo open heart surgery and receive triiodothyronine supplementation have demonstrated a dose-dependent increase in cardiac output that has been associated with an improved clinical outcome. However, a recent systematic review concluded that there is lack of evidence that triiodothyronine supplementation is beneficial in the prevention of morbidity and mortality in children undergoing cardiac surgery.[40]

Fenoldopam, a selective dopamine-1 receptor agonist, causes systemic vasodilatation and increased renal blood flow, with improved renal function.[41-43] Its use in critically ill adult patients with renal dysfunction has become routine. Two recent meta-analyses have concluded that the use of fenoldopam in critically ill adult patients at risk of acute kidney injury appears to decrease the development of acute tubular necrosis, the requirement for renal replacement therapy, overall patient mortality, and length of ICU stay.[44-45] One study also demonstrated a reduction in the time on mechanical ventilation.[44] However, few data exist regarding the use of fenoldopam in neonatal or pediatric patients. One retrospective study evaluated the use of fenoldopam in neonates after cardiopulmonary bypass with poor urine output despite conventional diuretic therapy and demonstrated a significant improvement in diuresis.[46] However, a subsequent prospective trial failed to demonstrate a beneficial effect.[47]

Terlipressin is a synthetic long-acting analogue of vasopressin with a higher affinity for vascular V1 receptors than vasopressin. Terlipressin has been used in adult patients to treat extremely low cardiac output,[5] but its application in children is limited. Terlipressin demonstrated an improvement in respiratory, hemodynamic, and renal indices in postoperative pediatric cardiac patients with refractory LCOS.[48-49] While these results are encouraging, further investigation with prospective randomized trials are needed to provide data regarding the efficacy and safety of terlipressin in infants and children.

Mechanical Circulatory Support

LCOS is a critical condition that requires prompt and aggressive treatment When medical treatment is ineffective, patients should be considered for mechanical circulatory support. Successful institution of this therapy can allow for recovery or be a bridge to heart transplantation. Mechanical circulatory support for cardiopulmonary failure refers to the use of mechanical devices to temporarily support (generally less than 30 days) heart or lung function (partially or totally) when maximal conventional medical treatment fails. Mechanical circulatory support can be provided by ECLS (via a roller or centrifugal pump) or via a VAD. The patient's underlying physiopathology, size, and expected length of support dictates which technique is best. In children, the majority of mechanical circulatory support continues to be achieved with ECLS.

Historical Perspective

Since 1953, when John Gibbon first utilized extracorporeal perfusion in the operating room, the indications and utilization of this therapy have continued to expand. Technological advances in ECLS have afforded support for thousands of patients per year with a variety of respiratory and/or cardiac indications. As of July 2009, a total of 37,092 pediatric and neonatal patients were registered patients within the Extracorporeal Life Support Registry.[50]

Early trials of ECLS were marked by mixed results. In 1985, Bartlett[51] reported the first successful use of ECLS in a newborn. Since then, neonates with diagnoses of meconium aspiration syndrome, persistent pulmonary hypertension, and congenital diaphragmatic hernia have been treated for severe respiratory failure that is unresponsive to conventional therapies.[52,53] ECLS was first used for cardiac support in the 1970s by Baffes, but it was not until the 1990s that ECLS became a common therapeutic technique for this patient population.[54-55]

In 1971, DeBakey reported the first successful use of a VAD in adults.[56] During the past 20 years, the favorable results seen in the adult population has prompted the adaptation of adult technology for pediatric patients. Two pulsatile paracorporeal devices were introduced for use in children, the Medos-HIA and the Berlin Heart. Worldwide experience with these devices to support the neonatal and infant population as a bridge to either recovery or transplantation is increasing.

Mechanical Support Devices

Mechanical support devices can be categorized according to the expected duration of support. Short-term devices are used to support the myocardium in the intensive care setting for hours to days but rarely beyond 30 days; long-term devices are suitable for extended periods of support. The basic classification of mechanical support devices according to the expected length of treatment provided is as follows: Short-term (less than 30 days) mechanical support devices include (1) ECLS, (2) centrifugal VADs, and (3) intraaortic balloon pumps (IABPs). Long-term (>30 days) mechanical support devices include (1) pulsatile and (2) rotary axial devices.

Short-Term Mechanical Support Devices

Extracorporeal Life Support

ECLS is primarily utilized for short-term support of patients with decompensated heart failure who are unresponsive to medical therapy. Adaptations to the traditional cardiopulmonary bypass circuit have resulted in the standard ECLS circuit (Figure 27-2). The ECLS cannulation is initiated by placement of vascular cannulas within the patient's circulatory system.

Venoarterial (V-A) ECLS provides both biventricular and typically pulmonary support. It is important to note that complete cardiac support cannot be provided by V-A ECLS because of incomplete drainage of the right heart. Routine cannulation for V-A ECLS occurs via one of three arterial and venous access points: (1) The transcervical approach places the venous cannula in the right atrium via the right internal jugular vein and the arterial cannula in the ascending aorta via the right carotid artery; (2) the transthoracic approach with direct cannulation of the right atrium and aorta through a median sternotomy is utilized for postoperative cardiac patients who either cannot be weaned from cardiopulmonary bypass or require mechanical circulatory assistance in the immediate post-operative period; and (3) femoral artery and vein cannulation is an option for older/larger children via the femoral artery and vein. The transcervical and transthoracic approaches are the preferred methods for small children. Figure 27-3 demonstrates a chest radiograph evaluation of cannula placement in a patient supported by V-A ECLS.

Venovenous (V-V) ECLS provides pulmonary support without cardiac support. In V-V ECLS a single cannula is placed in the right atrium through a transcervical approach. This cannula provides both inflow and outflow for the circuit. V-V ECLS can improve RV dysfunction as a result of oxygenated, pH-balanced blood flowing to the lungs, thus decreasing pulmonary vascular resistance and right heart afterload. In addition, improved filling of the LV can occur through decreasing RV overdistension. Likewise, the absence of an aortic cannula prevents the increase in LV afterload seen with venoarterial ECLS. However, at times the indirect cardiac effects of V-V ECLS do not adequately improve ventricular dysfunction and conversion from V-V ECLS to V-A ECLS is required. See Table 27-1 for a comparison of V-A versus V-V ECLS.

The no membrane oxygenator VAD is an adaptive technique to traditional ECLS that several centers have utilized. This form of ECLS eliminates the oxygenator from the standard circuit configuration. This technique allows for mechanical circulatory support while limiting both the harmful inflammatory effects of the oxygenator and reducing the initial need for anticoagulation.[57] It allows the ECLS device to be utilized as either an RV assist device, LV assist device, or a biventricular assist device.

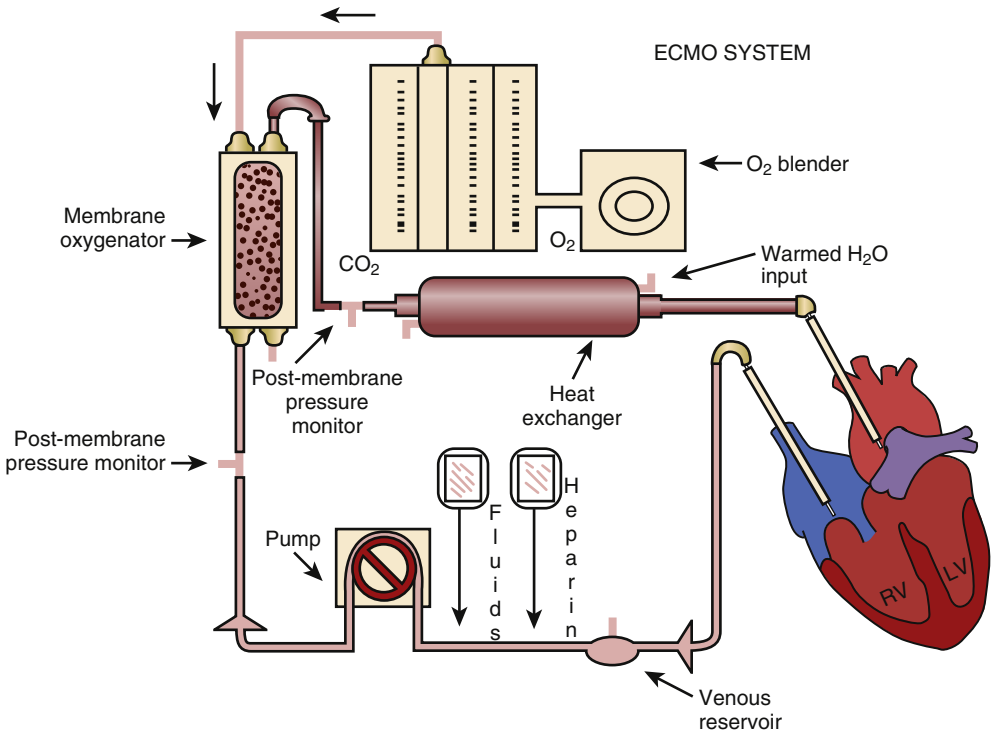

Figure 27–2. Extracorporeal membrane oxygenation circuit.

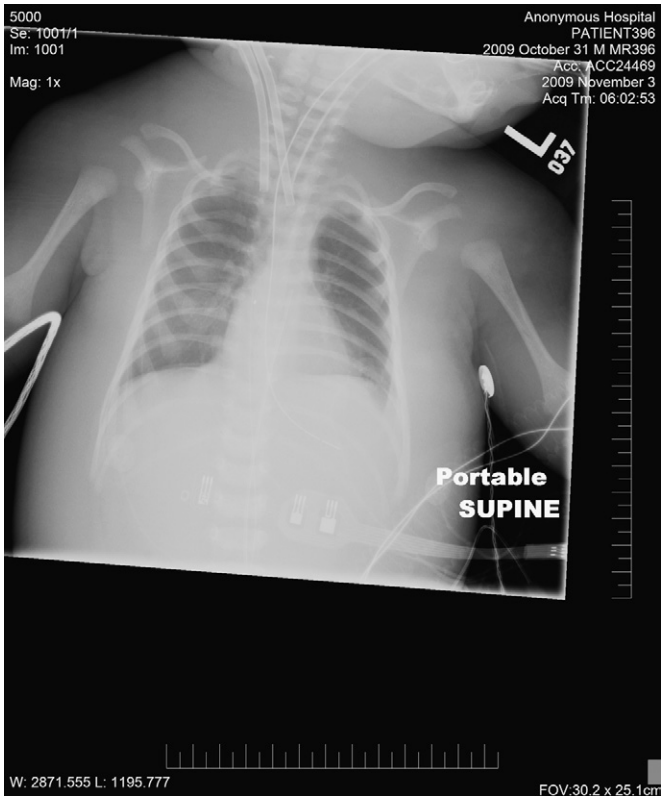

Figure 27–3. Chest radiograph showing extracorporeal membrane oxygenation cannulas.

Extracorporeal Life Support Circuit

Through either extrathoracic or transthoracic placement, the most common configuration involves placement of a venous drainage cannula in the right atrium where blood is passively drained from the patient to the venous reservoir. Blood then passes through a servoregulated roller-head or centrifugal pump that pumps blood through the remainder of the system. Gas exchange (O_2 addition and CO_2 removal) is provided through an artificial lung (oxygenator) where a sweep gas passes in counter current to the blood, allowing diffusion to occur. Blood temperature is controlled by a countercurrent heat exchanger. Finally, blood is pumped to the body into the aorta at systemic pressure. Additional components include ports for infusion of medications, a hemofilter for fluid control or dialysis, and monitoring systems that regulate gas exchange, flow, and pressure.

Extracorporeal Life Support Physiology

Patient circulatory physiology is altered by the initiation of mechanical circulatory support, and it is important to understand how ECLS affects these patients. Mechanical circulatory support affords recovery of myocardial function through a variety of mechanisms. Alteration of both RV and LV preload and afterload occurs to varying degrees based on which device is utilized and how it is utilized. Some of these alterations can be deleterious. Adequate decompression of the left heart decreases left atrial hypertension and reduces cardiac wall stress, cardiac work, and myocardial oxygen consumption, allowing for improved coronary perfusion. Mechanical circulatory support of the LV allows for reverse molecular remodeling with normalization of heart failure and apoptosis markers, normalized expression of genes involved in calcium homeostasis, cell growth, and differentiation, and up-regulation of structural proteins.[58] With adequate venous drainage, both right atrial and left atrial pressures are lowered. This effect is important to prevent complications such as pulmonary edema or hemorrhage, pleural effusions, ascites, superior vena cava syndrome, or stroke. Likewise, a low to normal central venous pressure is important for patients who have experienced

cardiac arrest and are at risk for ongoing cerebral ischemia as a result of cerebral edema and increased intracranial pressure.

Extracorporeal Life Support Indications and Contraindications

It is widely accepted that all patients considered for mechanical circulatory support should have either a reversible physiologic process or be a candidate for a bridge to transplant or a bridge to destination therapy. The time frame in which recovery is expected and the severity of cardiac and/or other organ failure is used to guide medical personnel regarding optimal selection of a mechanical circulatory support device. Appropriate patient selection and stabilization is vital to maximize survival and outcome with any mechanical circulatory support system. The ELSO Registry Outcomes as of July 2009 are listed in Table 27-2.

Myocarditis

The clinical course of patients with myocarditis is variable. Some patients present with subclinical disease, others have an indolent course that progresses to dilated cardiomyopathy, and a subset of patients demonstrate fulminant disease. Those with fulminant acute myocarditis often experience a rapidly progressive course leading to death. Without mechanical circulatory support, patients with a fulminant course had expected survival rates of only 25% to 50%.[59-61] With the aggressive utilization of ECLS as a bridge to transplantation or recovery (or VAD if a longer recovery time is anticipated), survival rates for patients with any form of myocarditis are now reported to be as high as 90% to 93%.[62-64] It has been suggested that the institution of ECLS may aid in the normalization of ventricular geometry, a phenomenon that is referred to as reversible remodeling. This process is thought to improve ventricular dysfunction because of favorable influences on the neurohormonal cardiovascular milieu and unloading of the LV.[65] For patients with the most severe disease, that is, end-stage dilated cardiomyopathy resulting from fulminant myocarditis, the use of mechanical circulatory support without transplantation has resulted in survival rates as high as 67% to 80%.[66-68]

Postcardiopulmonary Bypass

Failure to wean from cardiopulmonary bypass occurs in approximately 1% to 3.2% of pediatric congenital cardiac surgery cases.[69-71] Individual institutions have reported survival rates to hospital discharge between 32% and 54% for pediatric patients who require ECLS after cardiac surgery.[70-77] One small series has reported a survival rate as high as 80%.[69] However, the July 2009 ELSO registry report for postoperative cardiac surgery patients younger than 16 years reported an overall survival rate of only 40%.[50] All of these patients demonstrate LCOS refractory to medical management as detailed in prior sections. It has been demonstrated that in patients with decompensated heart failure, a rising blood lactate level >0.75 mmol/L/hour on serial measurements despite escalating inotropic support may accurately predict a poor outcome.[10] For this patient population, it is anticipated that cardiac arrest or end-organ dysfunction will occur. The use of mechanical circulatory support is a widely accepted tool to support the vital organs while allowing for myocardial recovery.[78-80] It is imperative that this group of postoperative cardiac patients be evaluated for residual cardiac defects before considering mechanical circulatory support. Diagnostic or interventional cardiac catheterization may guide treatment pathways or be therapeutic. On occasion a patient's condition may warrant immediate mechanical support in order to safely proceed with cardiac catheterization. In these instances it is feasible to obtain hemodynamic and angiographic data or to perform therapeutic interventions in the cardiac catheterization laboratory. Balloon valvuloplasty or angioplasty of aortic arch obstructions, device closure of residual atrial or ventricular septal defects, coiling of aortopulmonary collateral vessels, and/or balloon or blade atrial septostomy all may be crucial interventions to improve cardiac output and allow for separation from mechanical circulatory support. If these defects cannot be managed in the catheterization laboratory, prompt return to the operating suite will be required. Residual cardiac defects, if left untreated, have been shown to be nearly universally fatal for patients requiring mechanical circulatory support.[80]

The use of ECLS for postcardiotomy support in neonates and infants with single-ventricle physiology remains controversial and continues to be considered a relative contraindication in some centers. The 2009 ELSO report lists a 34% survival rate for ECLS use in patients following the stage I Norwood procedure,[50] which is lower than for other postcardiotomy patients.[50,81]

Extracorporeal Cardiopulmonary Resuscitation

In-hospital cardiac arrest in children continues to be associated with dismal outcomes despite advances in cardiopulmonary resuscitation (CPR). A prospective multicenter

observational study from the National Registry of Cardiopulmonary Resuscitation reported a good neurologic outcome for 73% of survivors of an in-hospital cardiac arrest, yet the rate of survival to hospital discharge was only 27%.[82] Another multicenter observational study from the Pediatric Emergency Care Applied Research Network reviewed in-hospital cardiac arrests that occurred during an 18-month period between 2003 and 2004. It also reported a good neurologic outcome for 76% for survivors and an improved (49%) rate of survival to hospital discharge with the utilization of extracorporeal CPR. Both reviews excluded out-of-hospital, do-not-resuscitate, or neonatal ICU patients.[83] However, while neurocognitive outcome has improved for survivors of cardiac arrest, the duration of CPR has been inversely proportional to survival. One center demonstrated that a witnessed in-hospital cardiac arrest of >30-minute duration was universally fatal without the utilization of ECLS.[84] This knowledge has led to an emerging interest in the use of ECLS for patients who have failed to reestablish a perfusing rhythm and adequate circulation with conventional CPR rescue techniques. The American Heart Association guidelines for in-hospital pediatric cardiac arrest now recommend consideration of ECLS during CPR if the conditions leading to the arrest are likely to be reversible or amenable to heart transplantation.[85] However, wide variability in patient selection and the ability to institute ECLS in a timely fashion (5 to 176 minutes) has led to variable success reports ranging from 0% to 100%.[86-95] Table 27-3 presents a summary of the current literature on ECPR. Thus large centers have increasingly dedicated resources for the rapid deployment of ECLS, utilizing a team that is immediately available to cannulate with a pre-primed circuit. The 2009 ELSO Registry for neonatal and pediatric patients supported with ECLS following cardiac arrest reported a survival to hospital discharge rate of 38%.[50]

Myocardial Failure: Bridge to Transplantation

While heart transplantation is the treatment of choice for patients with end-stage myocardial failure, many children die every year waiting for a suitable organ to become available.

As a result, mechanical circulatory support is now increasingly utilized as a bridge to heart transplantation. The most common indications for ECLS as a bridge to transplant include end-stage congenital heart disease, cardiomyopathy, and graft rejection after heart transplantation. To date, no randomized controlled trials have been performed in the pediatric age group to determine if mechanical circulatory support as a bridge to cardiac transplantation confers improved survival for patients with myocarditis. Children with myocardial failure resulting from myocarditis demonstrate increased short-term survival when treated with ECLS and transplantation,[67] however; long-term survival reports suggest that bridge to transplantation may only be indicated for patients with giant cell or the acute form of myocarditis but not those with the fulminant form.[62-63,96]

Factors that dictate which mechanical circulatory support device is used include patient size, the need for pulmonary support, and duration of wait time. Complications associated with ECLS generally limit the duration of support with this device to approximately 2 weeks, although support that lasts >4 weeks has been rarely reported. As long as complications precluding transplant have not developed, there should be no arbitrary cutoff for duration of support. A recent review of the United Network for Organ Sharing Database from 1995 to 2005 evaluated both clinical status at transplantation and risk factors for short- and long-term mortality of patients supported with various mechanical circulatory support devices. This study revealed that 30-day survival was significantly decreased for patients who received a bridge to transplant with ECLS versus VAD; long-term (10-year) survival was not affected. Not surprisingly, preoperative severity of illness also predicted early survival following cardiac transplantation. The overall 10-year survival rate was 56.8%.[97]

ECLS has been the mainstay of therapy for small children and neonates in the United States for short-term support (~2 weeks) because of a paucity of devices for this age group. The use of paracorporeal pulsatile assist devices (Berlin Heart and Medos HIA) for neonates in European countries has demonstrated early promising results.[98-100] The utilization of this technology is in its nascent stage in the United States. However, a retrospective review that compared survival outcomes of children supported with ECLS versus Berlin Heart to heart transplantation or recovery at Arkansas Children's Hospital favored the use of the Berlin Heart (57% vs. 86%).[101]

Malignant Dysrhythmias

Mechanical circulatory support is an essential therapy for patients with malignant dysrhythmia that is unresponsive to pharmacotherapy. A subset of patients with acute fulminant myocarditis presents with refractory LCOS and dysrhythmia that further compromises end-organ perfusion. If these patients do not rapidly respond to antiarrhythmic agents, many progress to cardiac arrest and death. In this scenario, mechanical circulatory support may be beneficial as a bridge to recovery or transplantation.[63] Several potentially lethal tachyarrhythmias, such as supraventricular tachycardia, junctional ectopic tachycardia, or ventricular tachycardia, can occur congenitally or are acquired in the postoperative period as a result of the ingestion of toxic substances or medications.[102-104] Again, ECLS can allow time for resolution of dysrhythmia, for medical treatment to take effect, and/or for recovery of cardiac function.

Refractory Respiratory Failure

Severe neonatal respiratory failure refractory to maximal medical therapy that requires ECLS is the most common indication for ECLS. Diagnoses include meconium aspiration syndrome, congenital diaphragmatic hernia, persistent pulmonary hypertension of the newborn, sepsis, respiratory distress syndrome, or other congenital lung abnormalities. Three randomized controlled trials involving neonates have been conducted and all reported that ECLS improved the survival rate.[53,105-107] It has been reported that of infants treated with ECLS, the proportion of infants with congenital diaphragmatic hernia has been increasing, whereas the proportion with respiratory distress syndrome, meconium aspiration syndrome, and sepsis has been decreasing.[108] However, the overall patient survival for this group remains at 75%.[1] A recent report, the first to perform a systematic comparison of neonatal ECLS practice patterns and respiratory failure deaths between countries, demonstrated distinct differences between the United States and the United Kingdom. It concluded that U.S. clinicians seem more willing to utilize ECLS for persistent pulmonary hypertension of the newborn and congenital diaphragmatic hernia. This difference in practice pattern was correlated with a decrease in the U.S. neonatal death rate from congenital diaphragmatic hernia in comparison with the United Kingdom.[109]

During the past 2 decades, successful treatment of pediatric patients with ECLS is increasingly being described in patient groups that would have been excluded in the past. ECLS is now considered for patients with trauma, immunosuppression, underlying bleeding disorders, sickle cell disease, status asthmaticus, pulmonary embolism, established multiple organ system failure, and more. However, reported survival rates are variable. For example, whereas a survival rate of 94% is reported in patients treated with ECLS for refractory status asthmaticus,[110] that of immunocompromised patient populations is only 31% to 36%.[111-112] Even of greater concern is that although case reports of survival with good neurologic outcome exist for the hematopoietic stem cell transplant population, review of the ELSO database demonstrates an almost universal fatal outcome for these patients.[113-114] The duration of ECLS required until successful decannulation is often longer for respiratory indications of use. This finding is likely due to the fact that parenchymal lung disease often requires a longer period of recovery than does myocardial dysfunction. The most common diagnosis in the pediatric respiratory ECLS group of patients is acute respiratory distress syndrome. Overall survival for this group of patients remains at 56%.[50] Although no randomized controlled trials for pediatric patients with refractory respiratory failure have been performed, a prospective, observational study with matched control subjects demonstrated improved survival of ECLS patients when compared with conventional support.[115]

Contraindications

If a patient has been selected as an appropriate candidate for consideration of mechanical circulatory support, then few absolute contraindications exist. While each institution may have slight variations of this list of contraindications, it is generally accepted that weight <2 kg, irreversible cardiac failure without the option for transplantation, severe neurologic dysfunction, severe intracranial or intraabdominal bleeding,

and lethal congenital abnormalities are all absolute contraindications. Technical limitations would include an inability to obtain vascular access as a result of thrombosis, abnormal anatomy, or prior surgery. As previously discussed, when considering a postoperative cardiac patient for mechanical circulatory support, it is prudent to rule out the possibility of a residual cardiac defect. Furthermore, cardiac arrest is not an absolute contraindication if rapid resuscitation is available and the underlying etiology is deemed to be reversible.

Critical Care Management During Extracorporeal Life Support

Patients who require mechanical circulatory support are critically ill, often with loss of multiple end-organ function. It is not surprising that complications occur with a greater frequency for this group of patients than for other critically ill pediatric patients. The basic management principles are discussed in this section. Table 27-4 will be referred to frequently throughout this section because it summarizes the most common reported complications for pediatric patients supported by ECLS as of July 2009.

Cardiac Output

When assessing the hemodynamic state of a patient, one must consider to what degree the patient is contributing to cardiac and or pulmonary circulation versus the ECLS device. The amount of flow provided by the ECLS device is easily obtained from circuit monitors, although least accurately from revolutions per minute (rpm)/circuit diameter calculations. For most cardiac ECLS patients, flow is initiated at 120 to 150 mL/kg/min. However, it is important to note that flow should be adjusted to fit the physiologic needs of each patient. Patients with single-ventricle physiology or sepsis may require higher flows approaching 200 mL/kg/min to support their metabolic needs. Assessment of the patient's intrinsic cardiac output is often unobtainable. However, indirect evaluation of the patient's cardiac output is possible through assessment of arterial systolic blood pressure, pulse pressure, heart rate, organ perfusion, mixed venous oxygen saturation, and lactic acid levels on a given flow rate. Comparisons of these variables over time allow the clinician to make decisions regarding the adequacy of circulatory support or the readiness to wean from support. An echocardiogram also can provide valuable information and help guide therapy. Mixed venous saturation is measured in the venous return portion of the circuit, with a goal of 65% to 80% in acyanotic patients. However, if a "left-to-right" shunt exists, such as a left atrial vent, the mixed venous saturation will be falsely elevated. In cyanotic patients an arterial venous oxygen saturation difference ($Sa\text{-}Vo_2$) of 20% to 25% is typically targeted. Serial lactate measurements often are a helpful aid in the assessment of total end-organ perfusion. A delay in clearance may occur in patients with

ongoing hepatic dysfunction, sepsis, low CO, and end-organ hypoperfusion. An approximation of the relative contributions of the patient and circuit pulmonary parameters is possible. This assessment is permitted through analysis of serial patient and circuit blood gas assays such as pH, Pco_2, and Pao_2, with consideration of the mechanical ventilation settings (includes fraction of inspired oxygen [Fio_2] and PEEP), circuit flow rate, CO_2 sweep rate, and circuit oxygen concentration.

Finally, "shunts" within the patient or the circuit must be taken into consideration. An example of a "right-to-left" patient shunt includes a patient with a patent ductus arteriosus and pulmonary artery hypertension, or an atrial septal defect or ventricular septal defect with pulmonary artery hypertension or RV outflow tract obstruction. Circuit "left-to-right" shunts are generally limited to a left atrial vent, the hemodialysis filter, and continuous arterial blood gas devices. Patient shunts that have the potential to be bidirectional, such as a patent ductus arteriosus or an intracardiac shunt, typically confound analysis. For these reasons an optimal cardiac repair with closure of residual "defects" should be performed prior to institution of mechanical circulatory support or early within the course of treatment. Therefore total blood flow for the patient on mechanical circulatory support requires the addition of ECLS circuit flow with the patient's native cardiac output minus any "shunt" within the system as a whole.

Troubleshooting

Hemodynamic compromise can continue despite mechanical circulatory support, and often low-dose inotropes and/or inodilators can aid cardiac contractility to augment native cardiac output and reduce afterload to both the RV and LV. The most commonly utilized agents are dopamine (3 to 5 μg/kg/min), epinephrine (0.03 to 0.05 μg/kg/min), dobutamine (5 μg/kg/min) and/or milrinone (0.25 to 0.75 μg/kg/min). High-dose catecholamine use is detrimental to cardiac recovery, and circuit flow should be increased to provide adequate circulation and allow for the lowest dosing possible. Tachyarrhythmias and pulseless electrical activity requiring cardiopulmonary resuscitation occurs in 3% of neonatal and pediatric extracorporeal membrane oxygenation (ECMO) runs (see Table 27-4).[50] Chemical/electrical cardioversion of any dysrhythmia to sinus rhythm should be attempted to promote recovery of cardiac function. Pacing often is utilized to maximize cardiac output as well.

Hypovolemia is a common occurrence during mechanical circulatory support for a variety of reasons. Inadequate venous drainage secondary to cannula malposition, cardiac tamponade, tension pneumothorax, or hemothorax may occur and generally result in hypotension that requires immediate correction (see Table 27-4).[50] Ongoing evaporative losses from the circuit and bleeding as a result of coagulopathy can contribute to hypovolemia. Initiation of ECLS activates a host of inflammatory mediators, resulting in capillary leak and hypovolemia.[6] Hypertension resulting from high renin levels is one of the most common and unavoidable cardiovascular complications of ECLS (see Table 27-4).[50] While hypertension has not been demonstrated to negatively affect survival, its potential deleterious effects such as bleeding and cardiac function recovery are a cause for concern.[116]

Cardiac Stun

The phenomenon of reversible global dyskinesia of the ventricle was coined "cardiac stun" by Braunwauld and Kloner in 1982.[117] Reversible cardiac dysfunction that results in a lack of LV ejection and thus no arterial pulsation and which resembles electromechanical dissociation also has been observed in patients following the initiation of ECLS.[116,118-119] Excluding conditions of physiologic tamponade from thoracic tissues, blood, or air, an infant on ECLS should have sufficient cardiac function to generate a minimal pulse pressure of 10 mm Hg. More recent evaluations of patients who experience cardiac stun upon initiation of ECLS defined this condition as the absence of aortic valve opening, equalizing of the patient and membrane Pao2 in the absence of a patent ductus arteriosus, and narrowing of the aortic pulse pressure to <5 mm Hg.[116] The etiology of cardiac stun is multifactorial and hypothesized to be the sequelae of acute ischemia followed by reperfusion.[117-118,120] The incidence of stun on ECLS is 5% to 12% in neonates and results in a significant increase in mortality for these patients[119-120] (see Table 27-4). Stun typically occurs during the first few hours of initiation of bypass and resolves within days. The patients in whom cardiac stun developed were reported to be more hypoxic, hypercarbic, and acidotic and were more likely to have had a cardiac arrest prior to initiation of ECLS.[119-120]

Diagnostic and Therapeutic Uses of Cardiac Catheterization

Initial diagnostic and hemodynamic assessment should be made by transthoracic echocardiography and Doppler. However, sometimes diagnostic transthoracic echocardiography is either suboptimal or suggestive of a significant lesion. Transesophageal echocardiography may improve the diagnostic accuracy but may not be possible because of bleeding risks. Cardiac catheterization is a useful tool for select sets of patients who fail to wean from ECLS. Diagnostic catheterization can provide a hemodynamic assessment that clinicians may use in their decision to utilize mechanical support.[96,121] Therapeutic interventions that might be performed in the catheterization laboratory include balloon or blade atrial septostomy to alleviate left atrial hypertension; balloon valvuloplasty or angioplasty of vascular obstructions; and device closure of residual atrial, ventricular, or aortopulmonary shunts. Correction of these defects in the catheterization laboratory or operating room often is required to allow for separation from mechanical circulatory support. In a recent review of 216 courses of ECLS for pediatric patients, 50 of 60 catheterizations performed led to an intervention either during or after the catheterization procedure.[122] Complications included left myocardial perforation in 2 infants each weighing less than 3.5 kg. Both were treated for the complication and survived the procedure. However, the risk of bleeding and death are not insignificant.

For patients with significant LV failure, it may be necessary to decompress an over- distended left atrium to prevent complications such as pulmonary edema or hemorrhage or mitral regurgitation and to improve coronary perfusion.[79,122-126] In this scenario, "venting" of the LV occurs through placement of a LV inflow cannula in the left atrial appendage in the operating room or creation of an intraatrial connection via balloon or blade septostomy. Improvement in LV function has been demonstrated after LV venting.

Patients with a Single Ventricle

The lower survival rates in patients with a single ventricle have in part been attributed to the added demands of balancing the systemic and pulmonary circulations while supporting

an increased volume burden on a postoperative patient with innately compromised single-ventricle physiology. When an imbalance between the two circulations exits, it places these patients at risk for impaired coronary perfusion resulting from diastolic run-off into the pulmonary bed. Despite the challenges presented, large centers continue to report improved outcomes with the accumulation of experience and the application of innovative new strategies. For example, initial efforts to balance the systemic and pulmonary circulations on ECLS included either completely or partially occluding the aortopulmonary shunt. However, this method has fallen out of favor because the lack of antegrade pulmonary blood flow that results from shunt occlusion has been demonstrated to increase mortality.[127-128] Also, smaller size shunts are now being placed during the initial surgery. Of note, higher mechanical support flows of ≥200 mL/kg/min may be required to provide adequate systemic and pulmonary support when the shunt is left open. Several centers have utilized an adaptive strategy to traditional ECLS that eliminates the oxygenator from the standard circuit configuration, instituting a VAD-like configuration that has been termed *NOMO-VAD* for "no membrane oxygenator-ventricular assist device." In patients who have hypoplastic left heart syndrome after undergoing a Norwood procedure, the shunt is left open and routine mechanical ventilation strategies are utilized as oxygenation is provided by the infant's own lungs.

Anticoagulation Strategies

Hemorrhagic and thrombotic complications are major concerns for patients during ECLS. Bleeding can manifest at surgical sites (arterial/venous cannulation sites) or covertly at areas such as the thorax, intracranial vault, or the gastrointestinal tract (see Table 27-4). Prevention strategies that target reduction of hematologic complications focus on maintenance of the hemostatic regulatory mechanisms as nearly normal as possible.[129] All forms of ECLS require some degree of anticoagulation to prevent thrombotic complications. The patient's age in conjunction with the ECLS device flow and mechanical properties will dictate which anticoagulation agents and strategies are used. Most commonly, a heparin infusion is utilized for patients receiving ECLS.

ECLS requires the most aggressive management of hemostasis and will be the focus of discussion. Apart from single-center experience, no well-defined consensus and/or protocol is available for pediatric and neonatal ECLS.[130-131] Platelets are consumed by surgical bleeding sites and sequestered by the membrane oxygenator, and routine transfusions are required to maintain counts greater than 100,000/mm^3. Administration of fresh frozen plasma to restore overall factor activity is the most routine procoagulation method utilized. Most centers measure platelet, hematocrit, prothrombin time/partial thromboplastin time, fibrinogen, specific factor levels, and activated clotting times (with a goal of an activated clotting time of 180-220 on full flows and of 160 if significant bleeding is present) to guide heparin infusion rates; however, considerable variability exists in management.[130] Treatment with Coumadin, aspirin and clopidogrel, and low molecular weight heparin can be selectively used with certain mechanical support devices. Newer treatment strategies include use of additional agents such as antithrombin III (AT III) in either bolus or infusion form to supplement anticoagulation.[131] AT III is an α_2-glycoprotein, a serine protease inhibitor, that inactivates a number of enzymes from the coagulation system, including the activated forms of factor II, VII, IX, X, XI, and XII. Replacement of AT III is required when its level is low (less than 30%) and heparin infusion rates are increased without an resultant increase in activated clotting time. Medical monitoring of both low molecular weight heparin administration through anti-Xa levels and of heparin administration through both quantitative heparin levels are utilized. Heparin-induced thrombocytopenia (HIT) is a rare but serious complication of heparin administration caused by antibodies binding to a complex of heparin and platelet factor 4 that leads to increased mortality.[132] A drop in platelet count by more than 50% of the highest previous value should raise suspicion of HIT and trigger investigation. In an evaluation of 9 patients supported by ECLS for severe acute respiratory distress syndrome with a greater than 50% drop in platelet count, HIT antibodies were found in three of the nine patients.[132] Treatment includes discontinuing heparin administration and initiating Argatroban if continued anticoagulation is needed.

Ventilation Strategies

Ventilator management during ECLS remains controversial. While data exist to guide clinicians regarding prevention of barotrauma, volutrauma, and oxygen toxicity for mechanically ventilated patients with acute respiratory distress syndrome in general, it is lacking for patients receiving ECLS support.[133] Lung collapse strategies used for respiratory support on ECLS are not utilized by most cardiac ECLS centers. Goals continue to target the prevention of atelectasis with utilization of appropriate PEEP in order to maximize oxygenation of nonbypassed blood returning to the left atrium, which then is ejected by the LV to perfuse the coronary arteries. This coronary blood flow also should be pH/P_{CO_2} corrected. In addition, providing modest ventilation can be achieved with either a pressure or volume limited mode of ventilation, setting the tidal volume at 8 to 10 mL/kg. Respiratory rates between 10 and 25 are set depending on the age and "rest" strategy being used and the degree to which the patient's lungs are required for gas exchange. Optimizing P_{aO_2} to the patient and circuit by blending F_{IO_2} to keep the F_{IO_2} less than 0.6 prevents free radical formation and ocular oxygen toxicity, thus providing adequate oxygenation to decrease pulmonary hypertension and optimize coronary O_2 delivery. Chest radiographs are routinely performed to assess and guide strategies to optimize lung volume so that volutrauma and barotrauma are avoided.

Fluid, Nutrition, and Renal Strategies

Fluid overload and electrolyte disturbances such as high or low serum levels of potassium, calcium, magnesium, and phosphorous (K, Ca, Mg, and PO_4) are common and need immediate correction. Most cardiac patients on ECLS receive total parenteral nutrition because of increased risk of gastrointestinal complications in patients with cardiac defects, umbilical artery catheters, poor perfusion, or other bowel abnormalities. A select subset of this population may tolerate trophic/full enteral feedings. Diuretics, commonly furosemide, often are used to provide optimal fluid balance in patients with significant capillary leak and fluid retention (see Table 27-4). Optimization of fluid status is essential to weaning and eventual separation from ECLS support. For anuric or oliguric patients, early placement of an in-line hemofilter into the ECLS circuit with or without countercurrent dialysate

is recommended. However, the management decisions that balance the use and timing of diuretics versus hemofiltration are controversial. The indications for initiation of dialysis are the same as for other critically ill patients with renal failure. Multiple retrospective reviews of patients supported by ECLS have found renal replacement therapy to be a risk factor for increased mortality.[70,72,81,92-93] No causal relationship has been identified, and further investigation in this area is warranted.

Analgesia and Sedation

Initially, adequate analgesia and sedation are essential for both safety, comfort, and to minimize metabolic demands in patients with circulatory compromise in the early postoperative recovery period. Typically an opiate in addition to a benzodiazepine class drug is utilized. Infusions may be used with cautious monitoring because toxicity from propylene glycol and other solvents have been reported with benzodiazepine use.[134-135] Neuromuscular blockade should be largely avoided to limit critical care myopathy, promote regular evaluation of the central nervous system, and limit soft tissue fluid accumulation. Central nervous system infarcts, hemorrhage, or seizures are all known complications of ECLS (see Table 27-4). For infants with an open fontanel, a daily head ultrasound should be performed early in the course of treatment and with any change in clinical neurologic status. For older patients, a significant change in their neurologic status has a high likelihood of heralding major intracranial pathology, which needs to be promptly diagnosed by computed tomography in order to guide treatment and proceed in determining patient viability.[136] For patients with VADs that are either fully implantable or paracorporeal, it often is possible to lighten analgesia and sedation following perioperative stabilization to permit extubation and mobilization. Some devices are truly portable with battery packs.

Infection

It is not surprising that patients receiving ECLS are at a high risk of the development of nosocomial bloodstream infections (BSI). Identified risk factors that increase the incidence of infection include duration of ECLS,[137-142] open versus closed chest cannulation,[138,142] presence of central venous lines,[139] and undergoing a major procedure just before or while on ECMO.[138,141-142] In July 2009, the ELSO reported an incidence of reported an incidence of 6.1% to 18.9% culture-proven BSIs. It appears that older patients receiving ECLS for respiratory failure may be at higher risk of health care–associated infection than are neonates or cardiac patients (see Table 27-4).[50] Bloodstream infections during ECLS support for both pediatric cardiac patients after cardiopulmonary bypass and neonates with cardiac or respiratory failure have been associated with a poor outcome.[140,143]

The diagnosis of sepsis is difficult for patients supported with ECLS. While variable degrees of leukopenia have been documented for neonates supported with ECLS, an increase in phagocytosis and intracellular killing by neutrophils also occurs.[144-145] Temperature is completely controlled by the circuit's heat exchanger, so infection generally is not manifested by fever in these patients. Hypotension or thrombocytopenia may occur for a variety of reasons. In view of this, the standard of care in many ECLS centers has been to perform both routine surveillance cultures and provide prophylactic antibiotics. However, management strategies to limit infectious risks continue to evolve. Because of a lack of proven benefit and concerns regarding the long-term impact of broad-spectrum antibiotics on local bacterial resistance profiles, an increasing number of centers now perform daily blood cultures without the routine use of prophylactic antibiotics.[137-138] Additional retrospective data may suggest that routine surveillance cultures may not be warranted.[139-140] Further investigation is warranted to determine the impact of prophylactic antibiotic use on incidence of BSI, local antimicrobial flora, length of stay, survival, and cost.

Intrahospital Transport

Crucial situations exist for patients supported with ECLS that require intrahospital transport. This can include mobilization from the intensive care unit to a variety of locations such as the catheterization laboratory, radiology, or the operating suite. Reluctance to perform essential diagnostic or therapeutic interventions often includes a fear of potential disastrous complications during intrahospital transport. These fears are not unfounded.[146-148] Guidelines designed to promote the establishment of an organized, efficient transport process supported by appropriate equipment and personnel have been recognized and are increasingly utilized in hospitals.[149] Intrahospital transport for patients who receive ECLS is a labor-intensive process that should be approached in a coordinated effort with specific focus on the preparatory phase, the transfer phase, and posttransport stabilization. However, with careful attention to these aspects, centers have demonstrated that intrahospital transport for patients who receive ECLS support can be carried out safely and without major complications.[136]

Ventricular Assist Devices

VADs are classified as extracorporeal (when the assist device is situated outside of the body), intracorporeal (when the assist device is fully implantable), or paracorporeal (when the assist device is situated adjacent to the body). Percutaneous VADs, which are devices placed by an interventional cardiologist in the catheterization laboratory, also have been developed.[150] Most VADS share similar basic principles. Cannulation depends on the type of support required. The right atrium (venous drainage) and pulmonary artery (arterial return) are cannulated for right ventricular assist device (RVAD), and the left atrium (venous drainage) and aorta (arterial return) are cannulated for left ventricular assist device (LVAD). A combination of both right and left ventricular assist devices is termed biventricular assist device (BiVAD). The pump is connected to a controller and power supply. Pumps have differences in modes of operation, size, and placement. A comparison of ECLS and VAD support is listed in Table 27-5.

Centrifugal Ventricular Assist Devices

Centrifugal ventricular assist devices pumps have been available since the late 1970s to support neonates and older children with postoperative cardiac failure and preserved lung function.[151] They have been an effective support for infants and children with myocardial failure from a variety of etiologies (i.e., acute myocarditis, dilated cardiomyopathy, acute transplant rejection, anomalous left coronary artery from the pulmonary artery, and others).[65,67] The most commonly used centrifugal pump VAD (Figure 27-4) is the BioMedicus centrifugal pump (Medtronic, Eden Prairie, Minnesota). The BioMedicus centrifugal pump can be utilized for cardiopulmonary

Table 27–5 Extracorporeal Life Support vs. Ventricular Assist Device

	ECLS	Centrifugal VAD	Pulsatile VAD
Oxygenator	Yes	No, but can be added	No
Anticoagulation	ACT 180-200	ACT 160-180	Aspirin/warfarin/LMWH
Support	Cardiac ± respiratory	Cardiac ± respiratory	Cardiac
Type of ventricular support	Biventricular	Univentricular or biventricular	Univentricular or biventricular
Ventricular decompression	May need LA "venting"	Via direct drainage cannula in LA or LV apex	Via direct drainage cannula in LV apex
Risk of air embolus	Low	Yes (especially with LVAD)	Yes (especially with LVAD)
Length of support	Short term	Short term	Long term
Cannulation site	Transthoracic or transcervical	Transthoracic	Transthoracic

ACT, Activated clotting time; *ECLS,* extracorporeal life support; *LA*, left atrial; *LV,* left ventricular; *LVAD,* left ventricular assist device; *LMWH,* low molecular weight heparin; *VAD,* ventricular assist device.

bypass, ECLS, or ventricular assistance. The pump consists of a polycarbonate cone built around several rotator cones. It is magnetically coupled to a driver that controls the RPM. The pump spins at an adjustable rate, generating a vortex continuous flow. This creates a negative pressure that allows blood to drain into the pump and redirects it out the top of the vortex ("tornado effect"). The BP-80 and BP-50 models have cone volumes of 80 and 50 mL, respectively, with maximal flows of 10 L/minute. The centrifugal pump output (flow) is proportional to the rotational speed of the pump (RPM), pump preload (patient's intravascular volume), and pump afterload (impedance to the outflow). Actual flow is measured with a flow probe on the arterial limb as RPM may not correlate accurately with flow. Heparin-bonded tubing can be used to minimize the need for aggressive anticoagulation. Mean arterial pressure is maintained by varying intravascular volume and adjusting rpm on the VAD console. Large negative pressures can be generated. If excessive negative pressure is generated, cavitation and hemolysis can occur. A VAD system can be used for temporary assistance of stunned myocardium of the LV. Although the system is designed for univentricular support (LVAD or RVAD), with two pumps connected in series it can provide biventricular support (BiVAD).

Advantages of this VAD over ECLS include its simplicity in design, ease of cannulation, small priming volumes, decreased hemolysis, reduction in the degree of systemic inflammatory response syndrome seen following initiation, and less anticoagulation (if an oxygenator or a heat exchanger are not used). Klotz and colleagues[152] compared the outcome of primary VAD implantation versus primary ECLS in 183 patients with LCOS after heart surgery. Primary VAD was performed in 20 patients, and 163 patients underwent ECLS. In the ECLS group, 13 patients were converted from ECLS to a VAD (ECLS-VAD). Thirty-day mortality rates were 50% (VAD), 75% (ECLS), and 46% (ECLS-VAD). Survival was best with VAD implantation within 1.2 days following onset of LCOS. The authors concluded that early VAD support promotes survival in patients with LCOS after heart surgery.[152]

The BioMedicus Pump is the most common centrifugal VAD system used in children in the United States. The centrifugal VAD requires a functional RV since the RV supplies preload to the LV supported by the pump. Complications of the centrifugal VAD system include occasional thrombus formation in the circuit, hemolysis, nonpulsatile blood flow, bleeding and infection. Duncan and colleagues[153] reported the outcomes of 29 pediatric patients supported with BioMedicus VADs; there was a survival rate of 71% among patients with anomalous origin of the left coronary artery arising from the pulmonary artery or with cardiomyopathy. In those who underwent heart transplantation after support, survival was 50%, and fewer instances of neurologic complications and hemolysis were seen than in the ECLS group reported in the same study.[153] Successful use of the centrifugal VAD as a bridge to implantable VAD and then to heart transplantation in a patient with single-ventricle physiology has been reported.[154]

The CentriMag VAD (Levitronix, Zürich, Switzerland) is approved as an investigational device in the United States. It belongs to a new class of magnetically levitated devices operating in a bearingless rotor that floats with a rotating magnetic field. Because of its contact-free environment and absence of seals or valves, this device minimizes blood trauma, virtually eliminating thrombus formation and hemolysis. It is capable of operating over a range of speeds up to 5500 RPM, generating flows up to 9.99 L/minute under normal physiologic conditions. The PediVas VAD (Levitronix) is capable of operating over a range of speeds up to 5500 RPM, generating flows up to 1.7 L/min under normal physiologic conditions. Other available centrifugal pumps VADs include the RotaFlow (Jostra, Hirrlingen, Germany) and Capiox (Terumo, Ann Arbor, Mich.).

Intraaortic Balloon Pump

Since their invention and introduction into clinical practice in the 1960s, IABPs have become a therapeutic tool for the management of refractory low cardiac output states in adults.[155-156] In 1980, Pollock[157] first described the use of an intraaortic balloon pump in pediatric patients with the advent of modified equipment and pediatric-sized balloon catheters. The IABP is a polyethylene balloon mounted on a catheter that is usually inserted into the aorta via the femoral artery. The balloon is guided into the descending aorta approximately 2 cm from the subclavian artery. The balloon pump works by inflating in the aorta during diastole (after aortic valve closure) for improved retrograde coronary flow augmentation; the balloon then deflates before systole to decrease LV afterload. Cardiac output may be augmented by as much as 40%, decreasing LV stroke work and myocardial oxygen requirements. The pump

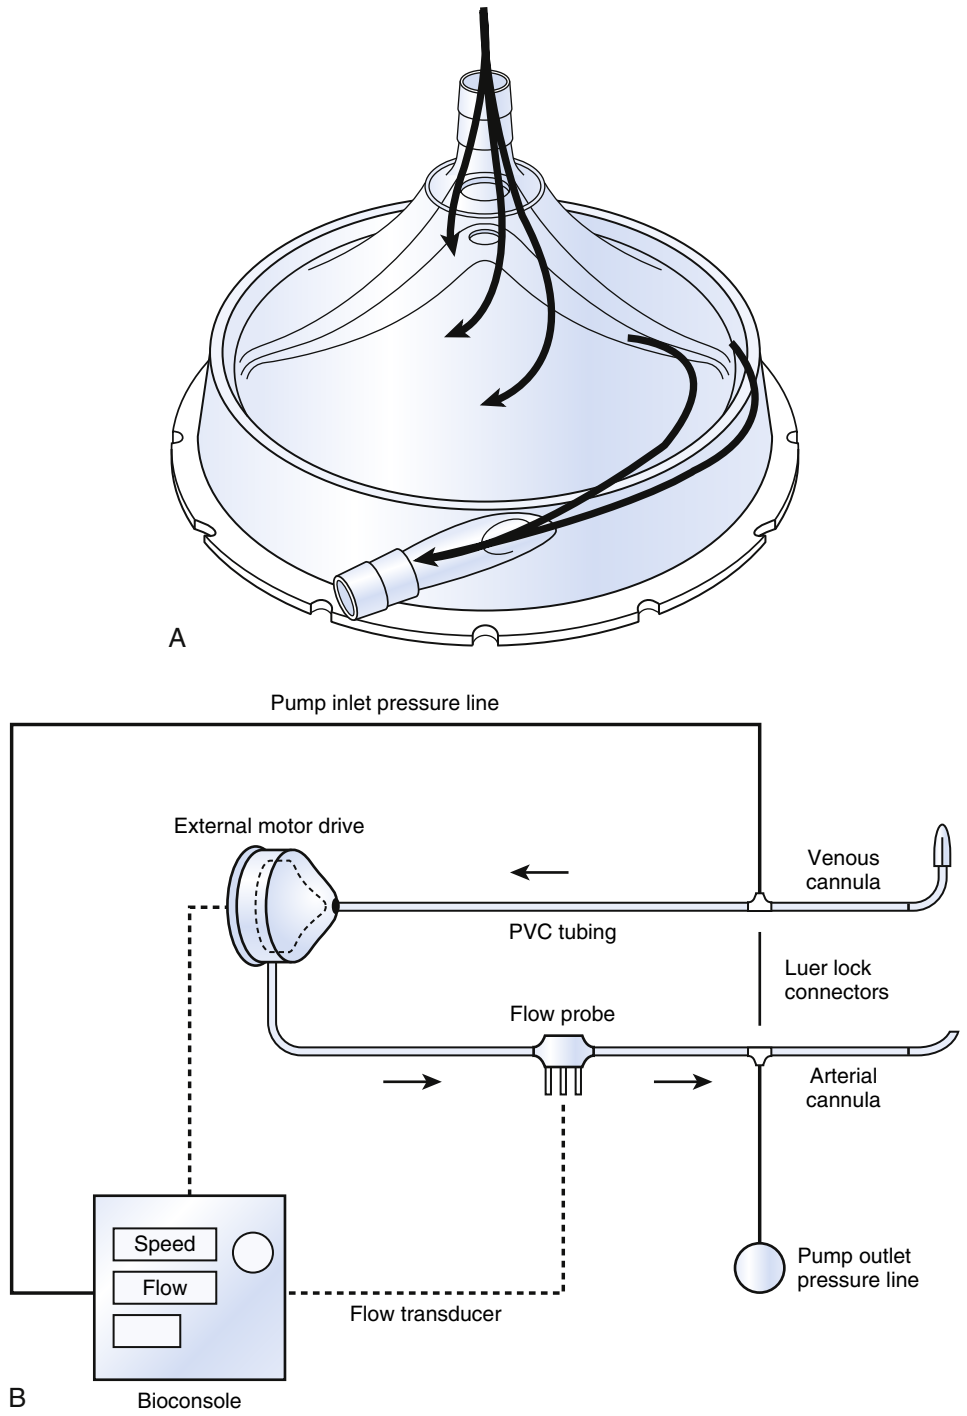

Figure 27–4. **A,** Schematic diagram of the BioMedicus centrifugal pump (Medtronic). Blood enters the cones via the apex of the cone, and the kinetic energy of the spinning cones is transferred to the blood leaving the side port. **B,** Centrifugal pump setup. (From Karl TR, Horton SB: *Centrifugal pump ventricular assist device in pediatric cardiac surgery. In Duncan BW, editor: Mechanical support for cardiac and respiratory failure in pediatric patients, New York, 2001, Marcel Dekker.*)

is available in a wide range of sizes (2.5 to 50 mL), and it is driven by an external console. A review of the use of IABPs to support 24 postoperative cardiac patients with LCOS despite optimal repair and maximal medical support was performed. The mean age was 5 years (7 days to 17.5 years), with a mean weight of 19 kg (3.5 to 59 kg). Eighteen of 24 patients (75%) were weaned off the IABP, with 15 long-term survivors (62%). Major complications associated with increased mortality included two patients with limb ischemia and one patient with both limb and mesenteric ischemia, which resulted in a fatal outcome. Additional complications included bleeding that necessitated reexploration of the chest and sepsis.[158] A similar review of 29 patients supported with IABP for medical, postoperative surgical, and bridge to transplant indications demonstrated survival to hospital discharge of 18 of 29 patients (62%).[158-159]

Advantages of IABP include its relative ease of use and its placement without surgical dissection. Disadvantages include infrequency of use, which is limited as an isolated LV support modality; contraindication with patients of a certain anatomy/physiology (e.g., patent ductus arteriosus or aortic insufficiency); and serious complications that include mesenteric ischemia and arterial injury. In children, failure to augment CO can occur because of a highly distensible aorta. The pediatric IABP catheters differ from adult catheters in a variety of ways. The catheter shafts are smaller (4 or 5 Fr) with balloon sizes of 0.75 to 10 mL. Early failed reports of the use of IABP in children were primarily due to the use of inappropriate sized balloons and failure to gate to the electrocardiogram at fast heart rates.[157,160] Adequate timing of the balloon inflation and deflation is essential; radial artery tracings were used in the past to aid timing of balloon inflation, but rapid heart rates led to significant timing errors.[161] The use of M-mode echocardiography to aid in timing of the balloon inflation and deflation with aortic valve opening and closing has significantly improved the efficiency of IABP therapy.[161] As a result of these difficulties, the use of IABP therapy in the pediatric population has remained limited to a small number of patients in a few institutions.

The Hemopump (Johnson & Johnson Interventional Systems, Rancho Cordova, Calif.) was the first device that showed the clinical feasibility of using high-speed, implantable rotary pumps for cardiac support. The Hemopump was initially studied at the Texas Heart Institute in 1988 as a short-term device for treatment of cardiogenic shock. The Hemopump included a tiny axial flow pump that provided up to 3.5 L/minute of circulatory support. Today the Hemopump is no longer used, but its design has served as the base for the development of other circulatory assist devices.

The Impella 2.5 (Impella Cardiotechnik AG, Aachen, Germany) is a minimally invasive, catheter-based cardiac assist device designed directly to unload the LV decreasing myocardial workload and oxygen consumption and increase CO and coronary and end-organ perfusion. The Impella 2.5 can be inserted into the LV in the catheterization laboratory via a standard guidewire through the femoral artery, into the ascending aorta, across the aortic valve, and into the LV. The tip of the catheter contains a "pigtail" that crosses the patient's aortic valve, rendering it open. This pump generates up to 2.5 L/min. A randomized trial is currently being conducted to compare the effectiveness of the Impella 2.5 versus IABP in patients with cardiogenic shock due to acute myocardial infarction.[162] The Impella 2.5 and a larger version, the Impella 5.0, are investigational devices.

Long-Term Mechanical Support Devices

The emergence of this newer type of device has provided a better range of equipment for mechanical support for children in the intensive care setting, but longer term mechanical support devices, especially for neonates and children, are still lacking. Much progress has been made since the early VAD initially described by Michael DeBakey.[56] Clinical experience with these devices in adults is extensive and includes patients with postcardiotomy failure, acute myocardial infarction, cardiogenic shock, ischemic cardiomyopathy, and even myocarditis.

The pediatric experience with long-term devices is limited. However, two important trials have shown the effectiveness of these devices in adults. The Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure trial in adult patients with severe heart failure who were ineligible for heart transplantation reported a significant improvement in quality of life and short-term survival in patients with severe heart failure with use of VADs as destination therapy (compared with optimal medical management).[163] The Harefield Recovery Protocol Study trial evaluated whether patients with advanced heart failure requiring VAD support can recover sufficient myocardial function to allow device removal (explantation). The Harefield Recovery Protocol Study combined the HeartMate XVE with conventional oral heart failure medications, followed by the novel β_2 agonist clenbuterol. The study reported that 73% (11 of 15) of patients who underwent the combination therapy regimen demonstrated sufficient recovery to allow explantation and avoid heart transplantation. Freedom from recurrent heart failure in surviving patients was 100% and 89% at 1 and 4 years after explantation, respectively.[164]

Various devices are indicated for single or biventricular assist depending on the patient's needs. Long-term devices (support longer than 30 days) have been placed in pediatric patients as a bridge to transplantation, a bridge to recovery, or destination therapy when permanent circulatory support is needed for patients who are not candidates for heart transplantation.[158,165-167]

Pulsatile-Type Devices

Pulsatile VADs function on the principle of "positive displacement" by trapping a fixed amount of blood and then forcing (displacing) that trapped volume into an exit cannula. Pneumatic pulsatile VADs have been available in pediatric sizes since 1992. Since the early report of pneumatic paracorporeal VADs in children, the pediatric experience with long-term pulsatile devices has been growing.[98] Advantages of these devices include the ability to provide long-term biventricular support (i.e., weeks to months) without an oxygenator, patient mobility out of the intensive care setting, the need for low-level anticoagulation heparin or warfarin with antiplatelet therapy, and, of course, their pulsatile flow nature. Disadvantages include a propensity for thromboembolic complications, high cost when compared with centrifugal VADs, the need for exteriorization of the cannulas, and size limitations usually suitable for patients with body surface area (BSA) 0.8 m^2 or greater, especially when biventricular support is needed. Infection is also a serious complication, although immobilization of the cannulas close to the exit site can decrease the incidence. Hypertension while on support is commonly seen and can be treated with different pharmacologic agents such as milrinone, calcium channel blockers, ACE inhibitors, β-blockers, α-antagonists, nitroprusside, or nitroglycerin. Thus far only the Berlin Heart EXCOR (Berlin Heart AG, Berlin, Germany)and the Medos HIA (Medizenintechnik, Berlin, Germany) pulsatile systems have proved successful in children of all ages and in children weighing as little as 2 kg. Both systems are paracorporeal. They have a special silicone system that connects the blood pump to the body; these cannulas are anastomosed to the right atrium and pulmonary artery for the RV (RVAD) and to the apex of the LV or more rarely to the left atrium and the ascending aorta for LV support (LVAD).[98,99]

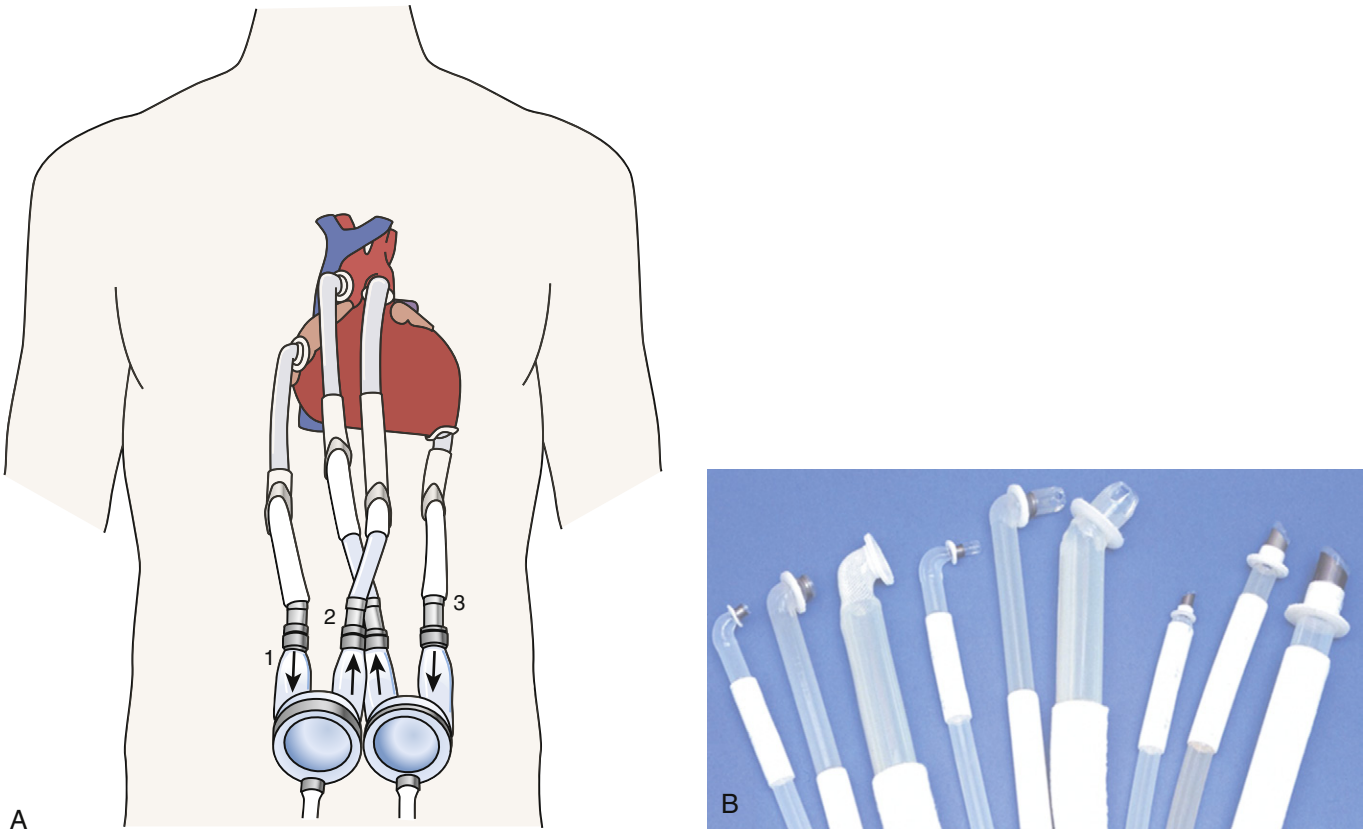

Figure 27–5. A, Schematic diagram of the Berlin Heart biventricular assist device showing apical cannulation, which allows better left ventricular unloading and decreased afterload to the right ventricle. *1,* Deoxygenated blood flows from the body into the right atrium. Since the right ventricle is unable to pump blood into the lungs, the blood goes into the device. *2,* The blood is pumped out from the device into the pulmonary artery. *3,* Once the blood is oxygenated in the lungs, it flows into the left atrium. Since the left ventricle is unable to pump, the blood goes into the device. *4,* The Berlin heart pumps blood into the aorta and systemic circulation. **B,** Set of cannulas available for the Berlin Heart assist device. The cannulas are available in different diameters, lengths, and tip configurations. *(Courtesy Berlin Heart AG, Berlin, Germany.)*

Berlin Heart Ventricular Assist Device or EXCOR

The Berlin Heart VAD or EXCOR is a paracorporeal pulsatile device that has been in use since 1988 and has been used in pediatric patients since 1992 (Figure 27-5 device and cannulas). The EXCOR pediatric VAD was specially designed and developed for pediatric patients. The pumps and cannulas are available in different sizes, making the system suitable for children a few days old to adolescents. The pump sizes vary between 10 mL to 80 mL. The 10-mL pumps are suitable for neonates and infants with body weight of up to 9 kg (BSA of 0.2 m^2); the 25-mL and 30-mL pumps can be used in children up to the age of 7 years (weight 30 kg and BSA of about 0.95 m^2); and adult-size pumps (50 and 60 mL) can be implanted in older children. All Berlin Heart EXCOR cannulas exit the body through the upper abdominal wall. The system is internally heparin coated. The Berlin Heart VAD can provide univentricular or biventricular support.

Hetzer and colleagues[99,100] reported a 15-year experience with the use of the Berlin Heart EXCOR pulsatile assist device in children aged 3 days to 15.5 years who had severe myocardial failure resulting from cardiomyopathy, fulminant myocarditis, end-stage congenital heart disease, or acute heart failure following surgery for congenital heart repair with a survival rate of 62%. Mean support was 17 days (range, 12 hours to 98 days).[99-100] Survival rates of up to 70% recently have been reported in small infants.[98] A recent North American single-center experience with the Berlin Heart EXCOR in a group of 17 children (13 LVAD and 4 BiVAD), in which six patients were supported by ECMO and one by a centrifugal pump prior to EXCOR placement, reported a survival to hospital discharge of 75%. Three children died on support while awaiting a transplant, 11 children were bridged to transplantation, 2 were explanted, and 1 was still on support at the time the study was published. The main complications were stroke in seven patients, two of whom eventually died, and bleeding or hematoma formation that required surgical intervention.[168]

The Medos Ventricular Assist Device

Since 1994, the Medos VAD pump chambers have been successfully implanted as a mechanical heart support system. The variety of available pump chamber sizes can accommodate adult, infant, and pediatric applications, providing a complete range of patient support. The Medos VAD system is a pneumatically driven paracorporeal VAD with three LV sizes (10, 25, and 60 mL maximum SV) and three RV sizes (9, 22.5, and 54 mL SV).

Survival with the Berlin EXCOR and the Medos VADs has been reported at 36% in children from 2 weeks up to age 16 years, including an infant with BSA less than 0.3 m^2. Diagnosis included fulminant myocarditis, dilated cardiomyopathy,

endocardial fibroelastosis, Ebstein anomaly, and status post redo aortic valve replacement.[169,170]

Thoratec Ventricular Assist System

The Thoratec Ventricular Assist System (Thoratec Corp, Berkeley, Calif.) is a pneumatically driven, polyurethane sac enclosed in a plastic housing designed for intermediate and long-term use (weeks to years). The Thoratec VAD has a stroke volume of 65 mL and can be operated at rates up to 100 beats/min, providing blood flow rates of almost 7 L/min. Patients require systemic anticoagulation for the duration of the VAD support. There are two Thoratec VAD systems, one paracorporeal (PVAD) and one implantable (IVAD). The Thoratec pneumatic PVAD is indicated as a bridge to transplantation or bridge to recovery. It can provide acute or intermediate univentricular or biventricular support. The external position of the pump allows device exchange in cases of malfunction, thrombus, or infection. Furthermore, it can be used in smaller patients who are poor candidates for implantable devices, with the smallest reported patient weighing 17 kg (BSA, 0.73 m^2). The Thoratec IVAD is a small, simple, and versatile intracorporeal device with the same features as the Thoratec PVAD except that it is used when longer support is anticipated. The device has been approved by the Food and Drug Administration (FDA) since 2004 for circulatory assistance as bridge to transplant or bridge to recovery. In a recent multicenter study (in the United States and Germany), the Thoratec PVAD was used in 19 children with a mean BSA of 1.09 m^2 (range, 0.73 to 1.29), a mean age of 10 years (range, 7 to 14), and a mean weight of 31 kg (range, 17 to 41). Indications for support were end-stage cardiomyopathy in eight patients, myocarditis in three patients, end-stage congenital heart disease in seven patients, and transplant graft failure in one patient. Mean duration of support was 43 days (range, 0 to 120). Survival through hospital discharge occurred in eight (72%) of 11 patients with cardiomyopathy or myocarditis; however, only one of seven patients with congenital heart disease survived. Neurologic complications were significant and predominant in the congenital heart disease group.[171] Neurologic complications in these pediatric patients seem to be higher when cannulation is performed in the left atrium versus the LV.[172]

The Abiomed BVS 5000 VAD

The Abiomed BVS 5000 VAD (Abiomed, Inc, Danvers, Mass.) was the first assist device approved by the FDA to be used in postcardiotomy patients. It is a pneumatically drive, pulsatile, extracorporeal pump that it is used in adults for short-term univentricular or biventricular support. The BVS 5000 can produce a stroke volume of 80 mL and flows up to 6 L/min. It has been used in patients with a BSA 1.2 m^2 or greater. It is usually used as a bridge to recovery in patients who have exhausted all other medical options.

Rotary/Axial-Type Devices

The rotary/axial-type devices are small, almost entirely implantable, continuous flow, rotary pumps with axial flow. The apex of the LV is used as the inflow cannulation site (to maximize flow conditions), and the ascending aorta has been used for the outflow graft. Thrombus formation has occurred when the graft was placed in the descending aorta. Advantages of the axial system include its relatively small size, relatively easy implant/explant procedures, noiseless system, lower infection risk, and continuous flow that not only provides unloading throughout the cardiac cycle but also minimizes stasis and thrombus formation. Disadvantages include a size limitation for pediatric patients with less than 1.5 m^2 BSA. The DeBakey LVAD (MicroMed Technology, Inc, Houston, Tex.), the Jarvik 2000 (Jarvik Heart, Inc., New York), and the HeartMate II (Thoratec) are described in the following section.

MicroMed DeBakey and HeartAssist 5

In the early 1990s, collaboration between the National Aeronautics and Space Administration (NASA), Dr. Michael DeBakey, and Dr. George Noon produced the MicroMed DeBakey VAD. In 1998, this effort culminated in the first clinical implant of an axial flow pump into a patient with heart failure. Since that time, more than 440 implants of this VAD technology have been performed in patients around the world. Recent design changes have been made to create the HeartAssist 5 (MicroMed) (Figure 27-6, *A* and *B*), which supports pediatric patients who weigh as little as 18 kg. It provides a wide degree of cardiac support, with blood flows from 1 to 10 L/min. The HeartAssist 5 Pediatric VAD provides precise blood flow as low as 1 L/min, and the entire implanted device weighs only 235 g. This is an implantable LVAD, intended for more than 3 months' support, focusing on bridge to transplantation. It represents the first miniaturized device, approximately one tenth the size of other currently marketed pulsatile VADs. The advantages of this device include small size; relative ease of implant and explant; decreased infection risk; and continuous flow, which unloads the ventricle throughout the cardiac cycle while minimizing stasis and the associated risk of thrombus formation. It can operate up to 8 hours on batteries. The long battery life allows for better patient mobility. Disadvantages include the rapid impeller speed, which leads to hemolysis. This device has been granted FDA "humanitarian device exemption" and is indicated for use as temporary left-sided mechanical circulatory support as a bridge to cardiac transplantation for pediatric patients (5 to 16 years old, with BSA greater than 0.7 m^2 and less than 1.5 m^2 who are in NYHA class IV end-stage heart failure refractory to medical therapy and who are [listed] candidates for cardiac transplantation). An adult version of the HeartAssist 5 is also available. The HeartAssist 5 Pediatric VAD is contraindicated in patients who have RV failure that is unresponsive to medical therapy; patients with a primary coagulopathy or platelet disorders; and patients with an allergy or sensitivity to heparin.[173-175]

Jarvik 2000

The Jarvik 2000 is an intraventricular assist device with a relatively small surface area measuring 1.8 cm in diameter by 5 cm in length. The device usually is implanted into the left ventricular apex via a left thoracotomy, and the outflow graft is placed into the descending aorta. Blood flow ranges from 2 to 7 L/min and is determined by impeller speed and systemic vascular resistance, with the usual setting at 9000 rpm (range, 8000 to 12,000 rpm). It offers several advantages over pulsatile flow pumps, including a smaller size that reduces the risk of infections, simpler implantation, fewer moving parts, absence of valves to direct blood flow, smaller blood-contacting surfaces, and reduced energy requirements that enhance simplicity and durability. The recent addition of sintered titanium microspheres on its intraventricular blood-contacting surface

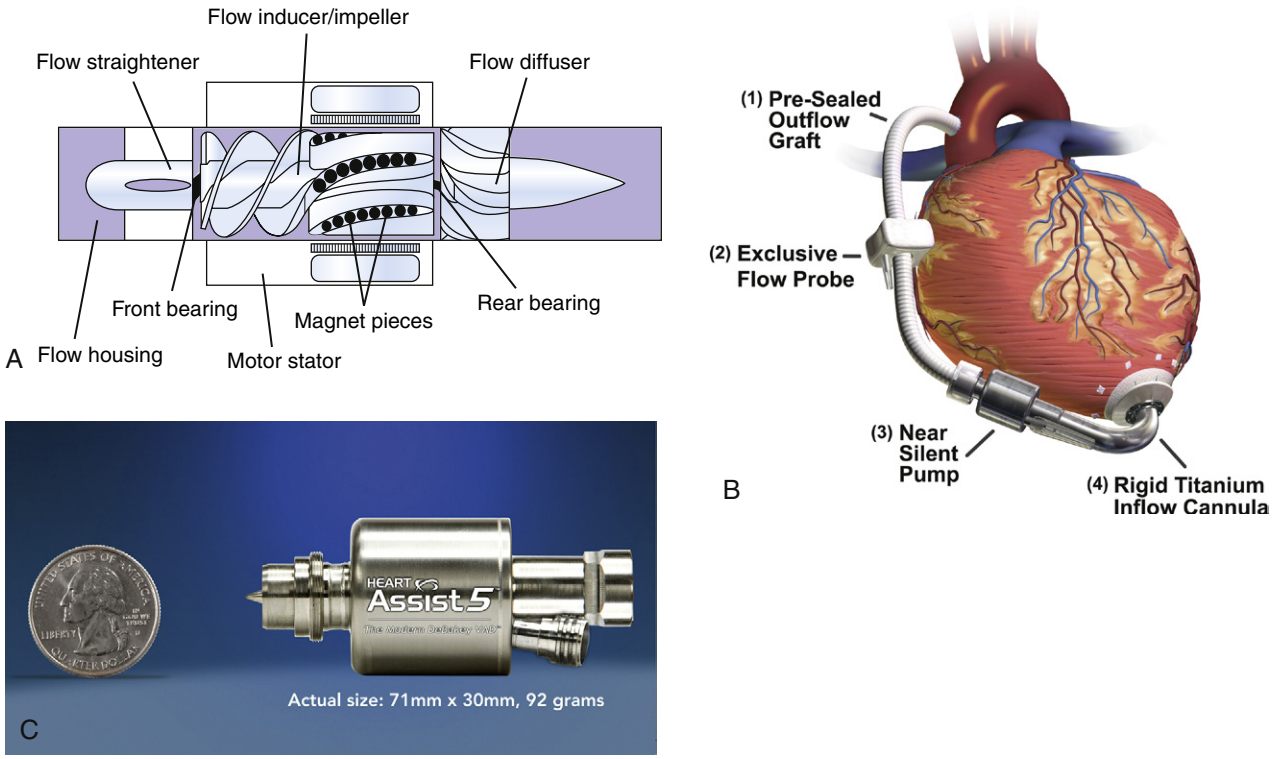

Figure 27–6. HeartAssist 5 pediatric ventricular assist device (modern DeBakey ventricular assist device). **A,** DeBakey ventricular assist device in a cutaway view. **B,** HeartAssist 5 with its position in the heart. **C,** HeartAssist 5 shown with a U.S. quarter for size comparison. *(Courtesy MicroMed Technology, Houston, Tex.).*

has decreased the incidence of thrombus formation. This device has an external speed control that can easily be adjusted according to the patient's physiologic needs. The Jarvik 2000 is FDA approved as an investigational device to be used for a bridge to transplantation. In Europe, the Jarvik 2000 is certified to be used as a bridge for both, transplantation and destination therapy. A pediatric Jarvik 2000 is under development.

HeartMate II

The HeartMate II is an axial flow rotary pump that utilizes blood-immersed mechanical bearings with textured blood-contacting surfaces. The transcutaneous version is totally implantable. The HeartMate II is a rotary pump that is smaller than the first-generation devices, principally because of the elimination of the sac or reservoir necessary in pulsatile pumps. This device has two cannulas (inflow and outflow) without valves. It has smooth surfaces in the outlet and inlet stators, but anticoagulation is still required. Clinical experience shows that the HeartMate II LVAD provides excellent support, with significant improvement in functional capacity. In a multicenter, prospective study, 42% of 133 adult heart transplant candidates supported with HeartMate II underwent transplantation within 6 months of support, with an overall 6-month survival of 75% and 1-year survival of 68%. More recently, an improved 6-month survival of 86.9% and 3% incidence of device malfunction with a mean duration of support of 6 months has been reported. The FDA has already approved its use as a bridge to transplant and for destination therapy. The HeartMate II has demonstrated great device reliability and significantly reduced device noise. It has low thrombogenicity and low thromboembolic risk, making it a good device option for destination therapy.

Total Artificial Heart

Total artificial heart (TAH) devices completely replace the patient's native ventricles and all four cardiac valves and are used as bridge to destination therapy. Because of their large size, these devices have very limited use in children.

CardioWest (SynCardia Systems, Inc, Tucson, Ariz.) is the modern version of the Jarvik 7, which was first implanted in 1982. The CardioWest temporary TAH is the only artificial heart in the world. The CardioWest TAH is used as a bridge for heart transplant for eligible patients dying from end-stage biventricular failure. The 70 mL CardioWest TAH is suitable for patients with a BSA 1.7 m^2 or greater; a 50-mL version of the device is under research investigation.

The AbioCor Replacement Heart is a new mechanical device that replaces the pumping function of the diseased heart. It is used as destination therapy in patients who are ineligible for heart transplant and have no other suitable treatment options. The AbioCor Replacement Heart has been granted FDA approval for Humanitarian Device Exemption.

Next Generation Levitated Devices

New generations of devices include centrifugal continuous-flow pumps with an impeller or rotor suspended in the blood flow path using a noncontact bearing design that uses either magnetic or hydrodynamic levitation. The levitation systems suspend the moving impeller within the blood field without any mechanical contact, thus eliminating frictional wear and reducing heat generation. This feature hopes to promise longer durability and higher reliability with low incidence of device failure and need for replacement. Usually, magnetic

levitation devices are larger because of the need for complex position sensing and control system. Examples of third-generation devices are the VentrAssist (Ventracor Ltd, Sydney, Australia), Levitronix CentriMag (Thoratec Corp.), DuraHeart (Terumo), the HVAD (HeartWare Corp, Framingham, Mass.), and the EVAHEART LVAS (Sun Medical Technology Research Corp., Nagano, Japan).

Ethics

Although advances in medical management, surgical techniques, and mechanical circulatory support for pediatric patients with cardiomyopathy or congenital heart defects continue to improve outcomes, the morbidity and mortality related to pediatric heart failure continue to exist.[15] The overall quality of life can be adversely affected in some patients because of therapy-related complications. In addition, the caregivers of these patients may experience significant burdens due to posttraumatic stress disorder, anxiety, depression, or poor physical health.

While the randomized controlled trial remains the most powerful tool for unambiguous comparison of various therapies, it is a well-recognized problem that such trials to compare either pharmacologic agents or mechanical circulatory support devices used to treat pediatric heart failure are lacking. Obstacles exist that limit the ability to perform research on pediatric patients with congestive heart failure. For example, invasive procedures are more difficult, noninvasive procedures in small children often require anesthesia to ensure adequate data collection, and consent to participate in research must be obtained by proxy requiring a greater level of preexisting evidence that the therapy being studied is safe and efficacious. Lastly, given the current level of observational data that exists to perform a randomized controlled trial, investigators must reconcile the ethical difficulty of allowing a patient to receive what is believed to be a less effective treatment in the interest of "objectively" evaluating therapeutic efficacy.[176] For example, a randomized controlled trial was never performed for ECLS in pediatric cardiac patients. All of these barriers impart a greater risk for performing research in children.

Future Directions

Several new mechanical support devices are under investigation. Options for circulatory support of pediatric patients younger than 5 years are still limited to short-term extracorporeal devices. The need for devices suitable for small patients has been recently addressed by the National Heart, Lung, and Blood Institute (NHLBI), which has funded research for the development of mechanical support devices in children from 2 to 25 kg with congenital heart or acquired cardiovascular disease. Five contracts were awarded to develop a family of devices that include (1) an implantable mixed-flow VAD designed specifically for patients up to 2 years of age, (2) another mixed-flow VAD that can be implanted intravascularly or extravascularly depending on patient size, (3) compact integrated pediatric cardiopulmonary assist systems, (4) apically implanted axial-flow VADs, and (5) pulsatile-flow VADs. These investigational devices include (1) the PediaFlow (World Heart Corporation, Oakland, Calif.),[177] (2) the PediPump (Foster-Miller Technologies, Albany, NY),[178] (3) the Pediatric Cardiopulmonary Assist System (pCAS) (Ension, Pittsburgh, Pa.),[179] and (4) the Penn State Pediatric Ventricular Assist Device (University Park, Pa.)[180] and (5) the Pediatric Jarvik 2000.[181] The NHLBI established the Pediatric Circulatory Support Program in 2004 by funding the development of these five novel circulatory support devices for infants and young children with congenital or acquired cardiovascular disease. In early 2010, the NHLBI awarded four contracts to begin preclinical testing of these devices. This 4-year program, called Pumps for Kids, Infants and Neonates (PumpKIN), is the next phase of NHLBI support for the clinical realization of these devices. The devices are supposed to support patients from 1 to 6 months of age, be sufficiently small and reasonable portable, and be routinely positioned and functioning in less than 1 hour. PumpKIN contractors are the University of Pittsburgh, Ension, Inc., the University of Maryland, and Jarvick Heart, Inc.

Conclusion

Principles of mechanical circulatory support require an individualized approach. Indications should include not only postpericardiotomy syndrome but pediatric patients with a variety of disease processes leading to LCOS such as myocarditis and septic shock. Short-term experience with mechanical devices had been limited to ECMO, but pediatric experience with VADs is growing, especially with centrifugal VADs. The pediatric experience with long-term devices is limited but evolving. With better clinical management and advances in technology, survival of pediatric patients with severe heart failure should continue to improve.

Chapter 28

Disorders of Cardiac Rhythm

Frank A. Fish, Prince J. Kannankeril, and James A. Johns

PEARLS

- Arrhythmias may result from ongoing therapies; ask, "What's the DEAL?"
  - — *D*rugs and drips
  - — *E*lectrolytes
  - — *A*irway and acid base
  - — *L*ines
- Appropriate diagnosis is key. Always attempt to document arrhythmia in multiple leads before instituting therapy.
- For ventricular fibrillation or pulseless ventricular tachycardia, begin cardiopulmonary resuscitation and defibrillate immediately.
- Involve a cardiologist before initiating (chronic) antiarrhythmic drug therapy.
- Whenever possible, use available means to document atrial rate to discern correct ventricular-atrial relationship.
- "Supraventricular tachycardia" is a nonspecific electrocardiographic pattern. Multiple types of supraventricular tachycardia exist, and appropriate therapy depends on appropriate diagnosis.
- Whenever possible, opt for therapies that maintain atrioventricular synchrony.

Cardiac rhythm disturbances (arrhythmias) are common in intensive care settings, where they may represent the primary disease process or occur as a complication of management (Table 28-1).[1,2] It is important to note that arrhythmias that might otherwise be well tolerated hemodynamically may be immediately life-threatening to the critically ill child. In addition, certain treatment strategies may be available in the critical care unit that normally might not be considered, particularly for serious but transient arrhythmias. Therefore response to arrhythmias in this setting should emphasize prompt restoration of hemodynamic stability concurrent with identification of the arrhythmia mechanism and predisposing factors. This chapter emphasizes the most common clinical scenarios and treatment approaches encountered in the intensive care setting while providing a broader overview of the array of arrhythmia mechanisms and their associated presentations in pediatric patients.

Classification of Arrhythmias

Arrhythmias are commonly classified according to rate, electrocardiographic (ECG) findings, and, when possible, the underlying electrophysiologic mechanisms. Electrocardiographically, arrhythmias can be characterized as bradycardias, tachycardias, or extrasystoles. Bradycardias are further subdivided into the level of dysfunction: sinus node or atrioventricular (AV) conduction. Extrasystoles and tachycardias are categorized as supraventricular or ventricular in origin. Tachycardias can be further characterized by the level of origin (supraventricular vs. ventricular) and functional mechanism: reentry, automaticity, or triggered activity. Whereas most treatment algorithms assume a reentrant mechanism, abnormal triggering and automaticity may be particularly important in the critically ill patient and may respond quite differently to given therapies, such as pacing or direct current cardioversion. Although differentiating between these mechanisms is sometimes difficult, it may be essential in guiding appropriate therapy, especially if initial therapies prove ineffective.

Bradycardias

Appropriate Versus Normal Heart Rate

Normal heart rate ranges vary tremendously during childhood as a function of age and autonomic tone. Thus in a given clinical situation, "appropriate" heart rate is a more useful concept than "normal" heart rate. Critically ill patients typically manifest some degree of sinus tachycardia in response to pain, sepsis, shock, fever, or adrenergic agonist infusions, and the degree of tachycardia also serves as a gauge of pain or hemodynamic instability. Thus inappropriately fast or slow rates for a given circumstance warrant evaluation for underlying factors affecting the sinus rate or the possibility of a nonsinus mechanism.

Sinus Bradycardia and Sinus Pauses

Sinus bradycardia may result from high vagal tone, hypothermia, acidosis, increased intracranial pressure, drug toxicities, or direct surgical trauma to the sinoatrial (SA) node. In otherwise well patients, intermittent sinus bradycardia or prolonged sinus pauses may be caused by intense vagal episodes, such as those occurring during neurocardiogenic syncope. Whereas vagal stimulation may produce profound bradycardia, pauses, or even asystole lasting for several seconds, transient bradycardia

Table 28–1 Classification of Arrhythmias by Type and Basis

Arrhythmia	Primary	Secondary
Ventricular premature beats and supraventricular premature beats	+++	+++
Sinus bradycardia, sick sinus syndrome	++	++
Incomplete AV block		
Mobitz I	++	+++
Mobitz II		++
Congenital third-degree AV block	+++	++
Acquired third-degree AV Block		++
Paroxysmal SVT (AV reentrant tachycardia, AV nodal reentrant tachycardia)	+++	
Ectopic atrial tachycardia	++	
Atrial flutter and intraatrial reentry	++	+++
Atrial fibrillation	+	+++
Chaotic atrial tachycardia		++
Junctional ectopic tachycardia	+	+++
Monomorphic ventricular tachycardia	++	++
Torsades des pointes	+	+
Ventricular fibrillation	+	++
Bidirectional ventricular tachycardia	++	+

AV, Atrioventricular; *SVT*, supraventricular tachycardia; +++, typical; ++, occasional; +, rare.

should not be construed as an absolute indication for pacing. However, in the hemodynamically tenuous patient, persistent or recurring bradycardias, whether attributed to sinus node exit block (periodic loss of sinus impulse) or sinus arrest, often warrant intervention with vagolytic, sympathomimetic, or pacing therapies. It is important to recognize that blocked premature atrial depolarizations (where premature P waves may be obscured in the preceding T wave) may also mimic sinus pauses or even sinus bradycardia when occurring in a bigeminal pattern. In cardiac patients, sinus node dysfunction may be the result of surgical injury or heterotaxy syndromes. Primary sinus node dysfunction in childhood is rare but has been described.[3]

Conduction Abnormalities

First-degree, second-degree, and third-degree AV blocks are characterized by conduction delay, intermittent interruption, or complete interruption in AV conduction. As with sinus bradycardia, AV conduction delay may be the result of intense vagal tone, metabolic derangements, drug toxicity, or direct injury to the AV node. Second-degree block can be further characterized: Mobitz type I, also called Wenckebach conduction, displays progressively prolonged AV conduction prior to a single nonconducted atrial impulse, whereas Mobitz type II occurs abruptly without such delay. Wenckebach conduction is best recognized by comparing the PR interval prior to block to the conducted PR immediately after the blocked beat. Mobitz I usually represents block in the AV node and is less likely to progress suddenly to high-grade block. In some settings, such as in well-conditioned athletes, a Mobitz I block may be benign. Mobitz type II, characterized by abrupt failure to conduct without prior lengthening of the PR interval, usually is attributed to block within the His conduction system and may indicate greater potential for sudden progression to complete AV block. As such, type II block may be more ominous and may require more aggressive intervention (i.e., pacing).

Higher grades of second-degree AV block can occur as a progression from either Mobitz I or Mobitz II block and are best characterized by the ratio of atrial to ventricular depolarizations (2:1, 3:1, 4:1, etc.). The level of block cannot be inferred and may even occur physiologically in the setting of atrial tachyarrhythmias, including atrial flutter, which often result in second-degree AV block in the presence of normal AV nodal function. Likewise, vagally mediated AV block may result in transient high-grade block (although the sinus rate usually slows concurrently).

Complete or third-degree AV block represents complete loss of AV conduction, usually with a junctional or idioventricular escape rhythm that is regular but may be quite slow. Periodic shortening of the RR interval may be the only clue to distinguish complete AV block from high-grade second-degree block with intermittent conduction (Figure 28-1) or from a junctional rhythm with slower atrial rate and intermittent AV conduction.

Bundle branch block patterns occur when impaired conduction in the specialized intraventricular conduction system results in delayed right or left ventricular depolarization, resulting in an aberrant widened QRS complex. Bundle branch block and AV block sometimes represent normal physiologic responses to abrupt shortening of the cycle length (as with premature atrial systoles or tachycardia initiation) or may result from drug effects, surgical injury, or primary disease within the specialized conduction tissue.

Escape Rhythms

In the presence of sinus bradycardia or AV block, escape rhythms typically emerge from AV nodal or Purkinje cells. These rhythms are slower than the appropriate sinus rate but may become accelerated with enhanced adrenergic tone and compete with the underlying sinus rhythm. It is important to distinguish these accelerated subsidiary rhythms from both pathologic tachycardias and escape rhythms resulting from AV block. Only rarely does an accelerated junctional or ventricular rhythm result in significant symptoms in a healthy child.[4] However, in the critically ill patient, the resultant loss of AV synchrony may warrant atrial pacing at a slightly faster rate if cardiac output is compromised.

Tachycardias

Classification by Mechanism

As discussed earlier, some degree of sinus tachycardia is expected in most critical care patients as an appropriate response to the primary illness. The degree of sinus tachycardia for age may provide important insights into the level of sedation, pain, or hemodynamic stress of a given patient. However, exaggerated or persistent sinus tachycardia must be distinguished from other tachycardia mechanisms that may appear similar electrocardiographically.

Most abnormal tachycardias encountered clinically are caused by abnormal impulse propagation in the form of reentry. This may represent reentry using an accessory AV

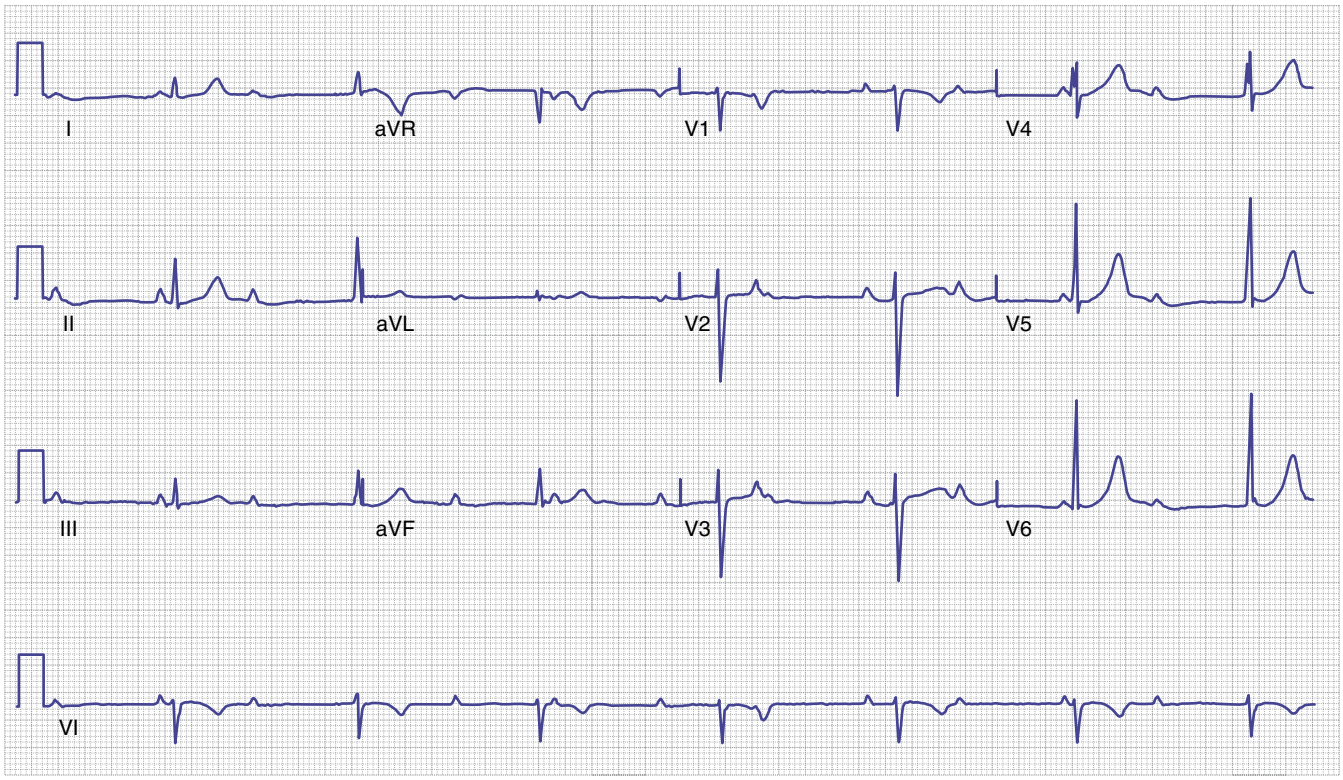

Figure 28–1. Complete AV block, presumably congenital, in an asymptomatic 9-year-old with slow resting heart rate. Note the regular RR interval, which confirms complete rather than incomplete (second-degree) AV block.

connection (AV reentry), the AV node and its adjacent tissues (AV nodal reentry), atrial myocardium (intraatrial reentry including atrial flutter and fibrillation), or ventricular myocardium (most ventricular tachycardias). Automatic tachycardias represent abnormal impulse formation arising from either ectopic foci or usual subsidiary pacemaker tissues (atrial, junctional, or ventricular) but at a significantly accelerated rate. These tachycardias may be due to an abnormally accelerated rate of depolarization of normally automatic tissues or to diseased atrial or ventricular myocardium with a propensity to abnormal spontaneous depolarization. Triggered tachycardias are thought to arise from abnormal secondary depolarizations (afterdepolarizations) following normal myocardial depolarizations, which may propagate to adjacent tissues. These tachycardias probably are important in several specific situations such as cardiac glycoside toxicity (delayed afterdepolarizations) and drug-induced long QT syndromes (early afterdepolarizations), and they also are important in many hereditary arrhythmias syndromes. Triggered activity is often dependent on the underlying heart rate, a feature that may sometimes be exploited therapeutically.

Classification by Site

Tachycardias usually are subdivided first according to the site of origin as supraventricular or ventricular. This anatomic distinction is the basis for most treatment algorithms. However, both supraventricular and ventricular tachycardias include a diverse group of arrhythmias with varying substrates, mechanisms, and electrocardiographic features that become increasingly important when simple treatment algorithms fail or when arrhythmias become recurrent and require repeated or ongoing therapies.

Supraventricular Tachycardias

"Supraventricular tachycardia" (SVT), "paroxysmal atrial tachycardia," and "paroxysmal supraventricular tachycardia" (PSVT) are descriptive but nonspecific terms commonly used interchangeably to describe tachycardias with a regular rate (usually in excess of 200 to 220 beats/min), normal QRS morphology, and P waves that either are not discernible or follow the QRS complex. This phenotype represents the most common form of SVT seen in otherwise healthy neonates and children and usually can be attributed to AV nodal reentry or AV reentry using an accessory connection (see next section). However, these typical ECG features can be produced by a more diverse array of tachycardia mechanisms.[5] Furthermore, intermittent AV block or QRS prolongation may be observed in certain types of "SVT," such that the ECG distinction of "SVT" from other atrial arrhythmias becomes obscured. Likewise, some tachycardias of supraventricular origin are associated with a widened QRS, either because of rate-related bundle branch block or anomalous antegrade conduction through an accessory connection. Therefore it is most useful to include among SVTs all tachycardias originating from the atrium, the AV node, or both, regardless of whether the ventricles participate primarily (i.e., AV reentry) or merely as a secondary consequence of AV conduction. This broad and inclusive definition appropriately allows inclusion of nonreciprocating mechanisms that need to be included in the differential diagnosis of "SVT," such as intraatrial reentry.

Atrioventricular Reciprocating Tachycardias

AV reciprocating tachycardias use one or more accessory AV connections to allow a reentrant circuit to develop involving both atrial and ventricular tissues. By definition, they display

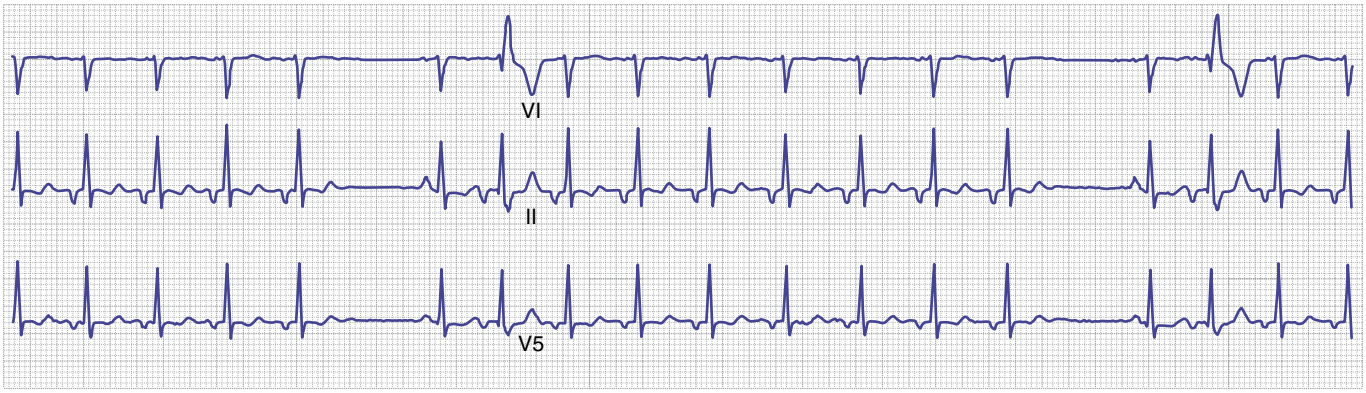

Figure 28–2. Supraventricular tachycardia resulting from the permanent form of junctional reciprocating tachycardia. Note the slow rate, long RP and short PR interval, and inverted P waves in ECG leads II and III. At rest, this rhythm often shows incessantly repetitive termination (with retrograde block), followed by immediate reinitiation (after single, isolated sinus complexes). With exercise, this rhythm often is faster and sustained, rendering it electrocardiographically indistinguishable from the atypical form of nodal reentry.

a fixed 1:1 AV relationship. *Orthodromic reciprocating tachycardia* (ORT) is the most common AV reentrant tachycardia and, in otherwise normal infants, also is the most common mechanism of SVT.[5,6] In ORT, antegrade conduction is over the AV node, whereas retrograde conduction to the atria occurs via an accessory AV connection. QRS morphology and duration usually are normal, with retrograde P waves often evident following each QRS complex. If the accessory connection conducts antegradely during sinus rhythm, ventricular preexcitation occurs prior to conduction over the AV node (Wolff-Parkinson-White [WPW] syndrome). The fusion of preexcited ventricular depolarization with the normal depolarization of the AV node and His-Purkinje system produces the characteristic short PR interval and Δ wave of WPW syndrome. Many patients experiencing ORT have normal QRS morphology during sinus rhythm. In these individuals the accessory pathway may only conduct retrogradely and is thus clinically evident only during tachycardia or during ventricular pacing.

Antidromic reciprocating tachycardia (ART) is a much less common AV reciprocating tachycardia in which the circuit is reversed: antegrade conduction occurs exclusively via the accessory connection and results in a "maximally preexcited" QRS. As a result, ART is not readily distinguishable from ventricular tachycardia by ECG features alone. Retrograde conduction occurs over the AV node (or a second accessory connection), producing a 1:1 ventricular-atrial (VA) relationship. By definition, patients with ART also have the ECG features of WPW syndrome during sinus rhythm. ART should be distinguished from ORT with aberrant conduction.

A specific form of antidromic AV reentry uses Mahaim fibers, which are accessory AV connections with decremental antegrade conduction. Most Mahaim fibers are located on the right ventricular free wall (atriofascicular connections), although some arise from the AV node itself (nodoventricular connections). *Tachycardia using a Mahaim fiber* should be considered in a young patient with a regular tachycardia and left bundle branch block QRS pattern. Typically, ART and tachycardia using Mahaim fibers have a 1:1 VA relationship. However, because retrograde conduction in either case may be supported over a second accessory connection, maneuvers typically resulting in AV nodal block may not terminate these tachycardias, further confusing clinical distinction between these wide QRS complex tachycardias and ventricular tachycardia.

Permanent junctional reciprocating tachycardia (PJRT) is a variant of ORT with retrograde conduction over a slowly conducting accessory AV connection that possesses decremental ("AV nodelike") conduction.[7] The relative conduction and refractory properties of the accessory connection and the AV node are such that the PR interval is short or normal and tachycardia is incessant. In a single-lead rhythm strip, PJRT may mimic sinus tachycardia, although a 12-lead ECG reveals atypical P wave morphology with P-wave inversion in the inferior leads. This tachycardia typically displays repeated spontaneous termination and prompt reinitiation, resulting in incessant tachycardia until it is adequately treated (Figure 28-2).

Atrioventricular Nodal Reentrant Tachycardia

AV nodal reentrant tachycardia (AVNRT) is the most common cause of SVT in older children and young adults without WPW syndrome or structural heart disease. It is seen less commonly in infants.[5,6] Occasionally it is precipitated for the first time by a serious illness or by other secondary factors associated with arrhythmias in the intensive care unit (ICU). This tachycardia can be attributed to so-called "dual AV nodal physiology." Conceptually, one functional "limb" of the AV node typically displays slow conduction and a short refractory period, whereas the other limb typically displays more rapid conduction but a longer refractory period. The differential conduction between the two "limbs" of the AV node (slow and fast pathways) provides the functional substrate for reentry. In actuality, these "limbs" represent differential conduction properties of the fibers inputting the AV node from upper and lower approaches of the atrial septum, representing so-called "fast" and "slow" inputs.

Classically, two electrocardiographically distinct forms of AVNRT may occur. In the "typical" form of AV node reentry, antegrade conduction during tachycardia is over the slow AV node inputs, and the P waves often are obscured by the preceding QRS complex. In the "atypical" form of AV node reentry, antegrade conduction is via the fast inputs of the AV node and retrograde conduction is over the slow limb. This conduction results in a long RP and short PR with an inverted P wave. The typical form of AVNRT can be difficult to distinguish from ORT in which P waves also are often obscured.

The atypical form of AVNRT may be indistinguishable from PJRT (see previous section), except that the tachycardia is paroxysmal rather than incessant. Like PJRT, atypical AVNRT must be carefully distinguished from other tachycardias with a normal PR interval, including sinus tachycardia, intraatrial reentry, or ectopic atrial tachycardias (see next section). Other atypical forms of AV nodal reentry using "intermediate" pathways can occur but are uncommon in children. Other variations of AVNRT can be characterized during the course of formal intracardiac electrophysiologic study.

Primary Atrial Tachycardias

Primary atrial tachycardias represent a diverse group of tachycardias originating solely from atrial tissue. They include tachycardias with discrete P waves (ectopic atrial tachycardia, intraatrial reentry), sawtooth flutter waves (atrial flutter), or disorganized atrial activity (atrial fibrillation, chaotic atrial tachycardia).[8] The ECG appearance alone may not adequately distinguish the underlying mechanism.

In all cases, conduction to the ventricles is over the AV node (except in patients with associated WPW syndrome). The resulting ventricular rate determines the degree of clinical compromise during these tachycardias. If conduction is rapid or occurs over an accessory connection, the QRS morphology may be aberrant and difficult to distinguish from ventricular tachycardias. However, interventions that slow or block AV nodal conduction usually allow the ongoing and faster atrial rhythm to be revealed. It is useful and often necessary to directly record atrial depolarization (via esophageal, epicardial, or intraatrial recordings) to discern atrial activation. Despite the potential ECG similarities of the various primary atrial tachycardias, the varying mechanisms confer important differences in clinical behavior.

Most atrial tachycardias encountered in the intensive care setting are reentrant in nature. Most commonly these atrial tachycardias occur either in neonates, where the classic sawtoothed pattern of atrial flutter is observed, or in postoperative cardiac patients. In patients with congenital heart disease (CHD), the patterns of intra-atrial activation may be quite variable and depend upon the surgical anatomy and resultant scar and conduction slowing. As such, the tachycardia, often referred to as *intra-atrial reentrant tachycardia* (IART), often displays a slower atrial rate with more discrete and sometimes normal-appearing P waves (rather than classic "flutter" waves). Because of the slower atrial rate, 1:1 AV conduction may be especially common. The administration of an AV node–blocking agent may slow AV conduction, and especially if 2:1 AV conduction results, ongoing tachycardia may be mistaken as sinus tachycardia with first-degree AV block. Thus this arrhythmia should be considered with any monotonous and seemingly inappropriate sinus rate with PR prolongation in a patient with CHD. Careful inspection of any transient irregularities that may result from variations in the AV conduction ratio may reveal the diagnosis.

Atrial fibrillation, a very common arrhythmia among the elderly, is far less common in pediatric patients. It may occur as the result of atrial myocarditis,[9] as a result of an underlying reentrant SVT,[10] or sometimes as the result of central venous catheters (Figure 28-3). In patients with WPW syndrome, rapid conduction over the accessory pathway may be life-threatening. When atrial fibrillation is seen, the underlying basis should be sought, because the long-term implications and treatment measures are much different than in adult patients.

Ectopic atrial tachycardia is an automatic arrhythmia that typically presents as an incessant and chronically elevated atrial rhythm that may be mistaken for sinus tachycardia,

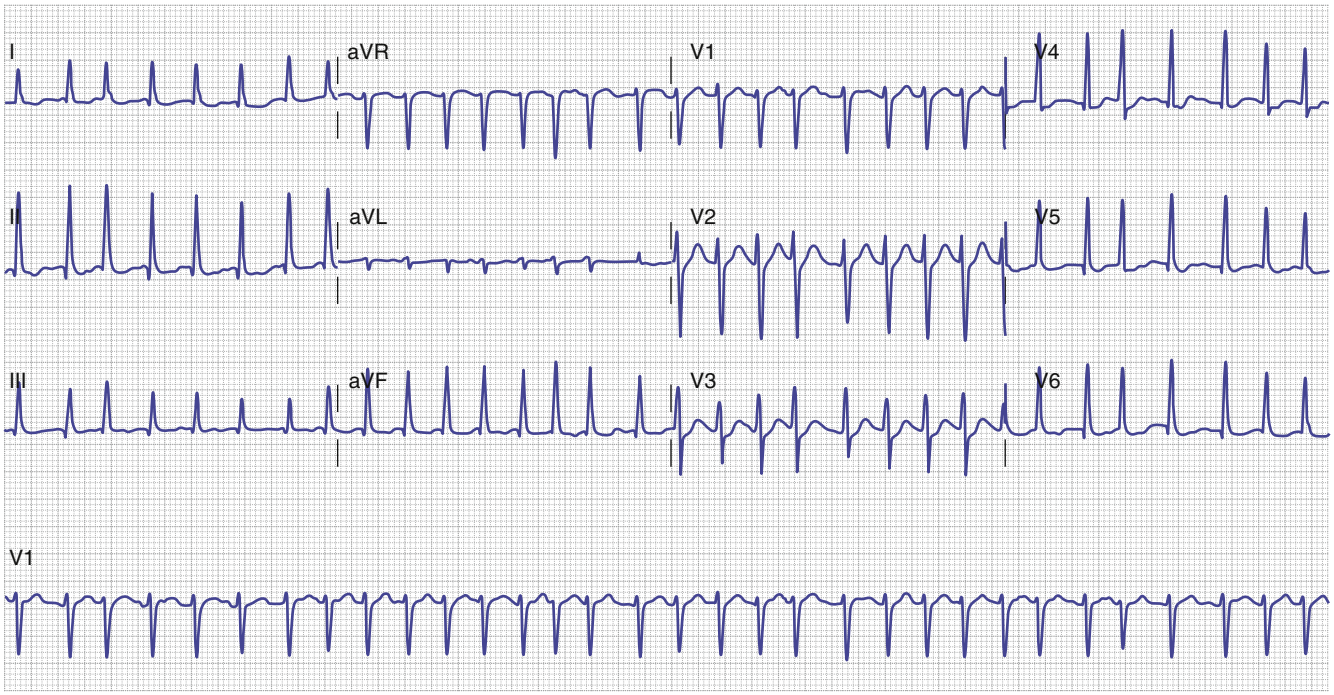

Figure 28–3. Sustained atrial fibrillation in a previously healthy 17-year-old placed on extracorporeal membrane oxygenation for pneumonia and acute respiratory distress syndrome. Review of stored telemetry revealed atrial ectopy soon after cannulation, eventually initiating atrial fibrillation. Following DC cardioversion to sinus rhythm, frequent ectopy persisted until the venous cannula was repositioned. Several months later, the patient remained free of further arrhythmias.

depending on the site of the automatic focus. First-degree AV block may be seen as a result of the inappropriate rate. Patients often experience no overt palpitations but rather present with ventricular dysfunction and sometimes frank congestive heart failure. In such cases, careful scrutiny of the P wave morphology and evaluation of any abrupt changes in rate (as the result of transitions between sinus and the tachycardia) are necessary to establish the diagnosis. Adenosine may inhibit the automatic focus, making this diagnosis especially difficult.

Chaotic atrial tachycardia is an uncommon arrhythmia that is usually observed in infants and toddlers, often in association with a viral respiratory illness.[11] The hallmark features are a rapid and irregular atrial rate, often exceeding 300 bpm, and presence of multiple P-wave morphologies. The resulting ventricular response is irregularly irregular, simulating atrial flutter. However, this rhythm is probably the result of multiple triggered foci within the atria, and thus acute termination measures (i.e., DC cardioversion, adenosine, or pacing) are of little benefit. Usually this arrhythmia resolves within weeks or months of presentation.

Junctional Ectopic Tachycardia

Junctional ectopic tachycardia (JET) probably arises from an abnormal automatic focus or a protected microreentrant circuit in the region of the AV node or proximal His bundle. Antegrade conduction usually is over the normal His-Purkinje system with a narrow QRS. Retrograde (VA) block or complete VA dissociation with a slower atrial rate aids in the recognition of this mechanism. Variants include a congenital form, the more common postsurgical form, and paroxysmal JET described primarily in adults.[12,13] As in primary atrial tachycardias, atrial depolarization may be obscure, and direct atrial recordings aid the diagnosis. Occasionally JET is associated with 1:1 VA conduction, in which case additional pacing or pharmacologic maneuvers are necessary to distinguish it from other mechanisms of SVT.

Ventricular Tachycardias

Ventricular tachycardias include all tachycardias that arise exclusively within the ventricle(s) and require neither the atrium nor the AV node for perpetuation. Because ventricular depolarization is aberrant, the QRS duration is always prolonged for a given age and heart rate. The QRS morphology may be either uniform or changing (bidirectional, polymorphic). Classically, ventricular tachycardias are associated with VA dissociation (atrial rhythm at a slower rate). However, in children, VA conduction over the AV node (or an accessory connection) may be sufficient to allow intermittent or even 1:1 VA conduction. Thus VA dissociation, when present, is helpful, but when it is absent (or uncertain) it does not exclude ventricular tachycardia as the underlying mechanism. The presence of periodic fusion complexes (QRS morphology intermediate between tachycardia morphology and sinus morphology) is virtually pathognomonic for ventricular tachycardia with VA dissociation.

Although often regarded as a homogeneous group of arrhythmias, ventricular tachycardias actually constitute diverse rhythms, representing each of the underlying tachycardia mechanisms (reentry, automaticity, and triggered activity) with important therapeutic implications.[14] Likewise, although they are sometimes lethal, they may range in complexity and severity from benign accelerated ventricular rhythm to rapid polymorphic ventricular tachycardia and ventricular fibrillation. Both the clinical setting and the QRS morphology during ventricular tachycardia may provide important clues to the mechanism and pathogenesis, anatomic origin or tachycardia focus (see incessant ventricular tachycardias), and treatment strategies, as discussed later.

Approach to Diagnosis

Monitoring and General Assessment

In the intensive care setting, there may be a tradeoff between precision of diagnosis and urgency of therapy. Even so, appropriate diagnosis remains key to ongoing therapy. When an arrhythmia develops, rapid assessment of hemodynamic stability dictates the extent to which diagnostic studies can be pursued relative to the urgency of treatment. This should include assessment of level of consciousness, ventilation, tissue perfusion, and blood pressure. If time allows, determination of acid-base balance or other indicators of tissue perfusion (e.g., mixed venous oxygen saturation and serum lactate levels) is helpful. Minimal initial diagnostic evaluation should always include a timely evaluation of available ECG rhythm strips and a rapid review of drugs being administered, potential toxic exposures, respiratory and acid-base status, and known associated illnesses. Electrolyte assessment (potassium, calcium, and possibly magnesium) and drug screening may provide valuable diagnostic clues and should be obtained. The history of surgical procedures for CHD and trauma (chest and cranial) should be quickly reviewed. Indwelling catheters should be surveyed on radiographs for potential intracardiac position. Concurrent with this brief survey, a differential diagnosis of the rhythm disturbance should be quickly established, followed by the most appropriate emergency therapy. If the patient is sufficiently stable, therapy may be deferred until the arrhythmia can be more precisely characterized.

Surface Electrocardiogram

The surface ECG remains the cornerstone of arrhythmia diagnosis. Certainly in patients with known cardiac abnormalities, and arguably in all patients admitted to the ICU, a baseline ECG should be obtained at admission. This ECG may provide a valuable baseline for later comparison in the event of an arrhythmia. Because these arrhythmias occur in a monitored environment, a strip should be available to assess the rate, regularity, QRS morphology and duration, and AV relationship (Table 28-2), which should provide an initial differential diagnosis (Figure 28-4). Ideally, multiple leads should be inspected. For sustained tachycardias, a full 12-lead ECG should be obtained whenever possible because diagnostic details, such as QRS aberrancy, atrial rate, and P-wave morphology, or hidden features, such as "flutter waves," may be evident only in selected leads (Figure 28-5). Most contemporary monitoring systems now have automatic arrhythmia detection and storage capabilities, allowing discrimination between a gradual versus abrupt change in rhythm or rate. Such distinctions may be key in discriminating between sinus and nonsinus tachycardias in the critical patient. Familiarity with the capabilities and limitations of the specific system available is therefore essential.

For bradycardias, the surface ECG usually is sufficient to characterize the arrhythmia and differentiate between an abnormality in sinus nodal function and AV block, based

Table 28–2 Electrocardiographic Patterns

Pattern	Description
AV BLOCK	
Mobitz I	Shortened PR of first conducted beat after block
Mobitz II	No change in PR before/after block
	Periods of high-grade block
Third-degree	Fixed, rather than variable, RR interval
SUPRAVENTRICULAR TACHYCARDIAS	
AV reentrant supraventricular tachycardia	P waves obscured or buried in ST segment
AV nodal reentrant supraventricular tachycardia	P waves obscured by terminal QRS
	"Pseudo" R′ in lead V_1 during tachycardia, not sinus
Junctional ectopic tachycardia	Narrow QRS tachycardia, VA dissociation
	RR periodically shortened because of sinus capture complexes*
Atrial ectopic tachycardia	Monotonous rate, inappropriately fast
	Abnormal P-wave morphology (may be subtle)
Intraatrial reentrant tachycardia	Inappropriately fast rate, discrete P waves, variable AV conduction in postoperative patient with congenital heart disease
Atrial flutter	Variable RR interval
	Rapid, sawtooth flutter waves (>280 beats/min)
Atrial fibrillation	Irregular ventricular rate
	Coarse baseline with no discernible P waves
Chaotic atrial tachycardia	Three or more P-wave morphologies, irregular atrial rate, variable AV conduction (periods or atrial flutter or fibrillation common)
VENTRICULAR TACHYCARDIAS	
Monomorphic	Wide QRS for age, different from baseline
	Slurred upstroke of QRS
	Variable VA conduction†
	Sinus capture complexes†
Idiopathic types	Left bundle branch block, inferior axis (right ventricular outflow tract origin)
	Right bundle branch block, left superior axis (left ventricular septal origin)
Bidirectional	Alternating QRS axis (beat-to-beat)
Torsades des pointes	Initiation with "short-long-short" sequence
	QT-interval prolongation prior to onset
	"Twisting" of QRS axis

AV, Atrioventricular; *VA,* ventriculoatrial.
*Junctional ectopic tachycardia may be associated with third-degree AV block.
†Helpful when seen; absent if 1:1 VA relationship.

on the ratio of atrial-to-ventricular rate. The diagnosis of tachycardias may not be feasible from the surface ECG alone. Nevertheless, a combination of surface ECG and simple diagnostic maneuvers, sometimes coupled with direct recording of atrial activation, should allow accurate determination of most tachycardias. As with bradycardias, the surface ECG should be inspected for the ventricular rate and regularity, QRS duration and morphology, and atrial-to-ventricular relationship. Too often the apparent atrial-to-ventricular relationship is not clearly reflected on the surface ECG, and direct atrial recording, either with temporary atrial pacing wires or an esophageal ECG, is necessary to facilitate the diagnosis (Figure 28-6).

Bradycardias

In the absence of AV block, bradycardias are characterized by the origin of the initiating impulse as sinus, atrial, junctional, or ventricular. It is important to distinguish junctional or ventricular bradycardia from sinus bradycardia with an underlying junctional or ventricular escape, respectively. Terms such as "nodal rhythm" and "dissociated" are imprecise and demand further characterization. When the atrial rate exceeds the ventricular rate, second-degree or third-degree AV block is present. In complete AV block, the resultant escape rhythm usually is regular; in second-degree AV block, the ventricular intervals vary (see Figure 28-1). Occasionally, sinus node disease and complete AV block coexist, so it is important in the setting of a slow atrial rate to note "sinus capture" complexes when appropriately timed P waves conduct to the ventricle. When atrial pacing is feasible (as in patients with recent cardiac surgery), temporary atrial pacing can be used to demonstrate normal AV conduction, and the maximum rate at which 1:1 conduction can be maintained can be easily determined and followed serially.

The distinction between bradycardia resulting from AV block and sinus nodal dysfunction may have important therapeutic implications. If AV nodal conduction is intact, it usually is most appropriate to pace the atrium only (see AAI mode) rather than perform dual-chamber pacing. In contrast, isolated AV block is best managed by sensing and tracking the intrinsic atrial rate (see DDD mode).

Extrasystoles

Extrasystoles, or premature beats, usually are defined as supraventricular (supraventricular premature beats or premature atrial complexes) or ventricular (premature ventricular complexes, ventricular premature beats [VPBs]) in origin. True junctional extrasystoles are uncommon. When the extrasystole results in an early QRS with normal morphology and duration, a supraventricular extrasystole may be presumed. Usually, an early P wave can be discerned, but it may be obscured by the preceding T wave in certain leads. The ensuing sinus beat usually is advanced by the atrial extrasystole, but entrance block can result in a "full compensatory pause," usually attributed to a ventricular extrasystole.

Isolated premature QRS complexes with prolonged QRS duration may represent either ventricular extrasystoles or aberrantly conducted atrial extrasystoles. Distinguishing the two may be difficult from a single rhythm strip. Premature P waves often may be obscured in a particular lead, or the ventricular extrasystole morphology may appear similar to the sinus QRS in one lead (but totally dissimilar in another). The ECG features favoring ventricular extrasystoles over aberrantly

Figure 28–4. Ventricular tachycardia in an 8-year-old with previous muscular ventricular septal defect repair. Note transient VA block *(arrows),* excluding a supraventricular mechanism with aberrant conduction.

Figure 28–5. Ventricular tachycardia following cardiac surgery. Note similarity between QRS complexes during sinus rhythm and ventricular tachycardia in two of three recorded leads.

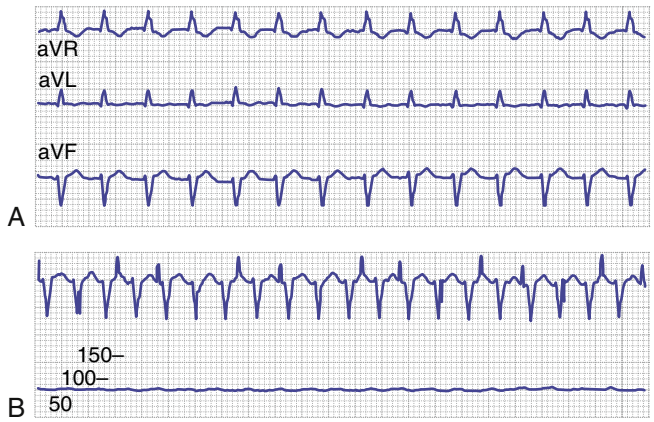

Figure 28–6. A, Narrow QRS tachycardia in an infant following a stage I Norwood operation. Possible AV dissociation is suggested, but P waves are not easily discerned on the surface electrocardiogram. **B,** Atrial recording from the same patient (after rate increased) using an epicardial atrial pacing wire. AV dissociation with faster junctional rate is demonstrated, typical of junctional ectopic tachycardia. Absence of clearly shortened RR intervals because of sinus capture might indicate associated AV block.

conducted atrial extrasystoles include (1) wide QRS morphology, (2) a full compensatory pause, (3) presence of fusion beats, and (4) absence of a discernible premature P wave. In the setting of ventricular preexcitation, variable fusion can occur as a result of exaggerated preexcitation with premature atrial depolarizations. As noted earlier, ventricular extrasystoles usually are followed by a full compensatory pause because the sinus node is not reset by the ventricular depolarization. However, an atrial extrasystole may sometimes fail to reset the sinus node (because of entrance block) or a ventricular extrasystole may occasionally reset the sinus node because of retrograde (VA) conduction. The simultaneous occurrence of both narrow QRS and wide QRS extrasystoles usually favors normally and aberrantly conducted atrial extrasystoles, particularly when the QRS width varies with the degree of prematurity (excluding fusion complexes).

The distinction of atrial versus ventricular extrasystoles may be somewhat academic in otherwise asymptomatic individuals because neither generally warrants therapy. However, either might be a harbinger for underlying myocardial irritability and should prompt a search for underlying causes. Occasionally, measures to suppress ectopy may appear to improve cardiac output by "regularizing" filling time in an otherwise tenuous patient. The relative advantages and risks of any such measure, whether achieved with medications or temporary pacing, need to be considered individually.

Tachycardias with Normal QRS

By definition, all tachycardias with normal QRS represent either sinus tachycardia or a form of SVT. It should be noted that the terms *supraventricular tachycardia, paroxysmal supraventricular tachycardia, and paroxysmal atrial tachycardia* often are used in reference to tachycardias with normal QRS, a regular rate in excess of 200 bpm, and no readily discernible P waves. In otherwise healthy infants, children, and adolescents, these features usually result from either AV reentrant tachycardia or AVNRT (Figure 28-7). Further distinction between

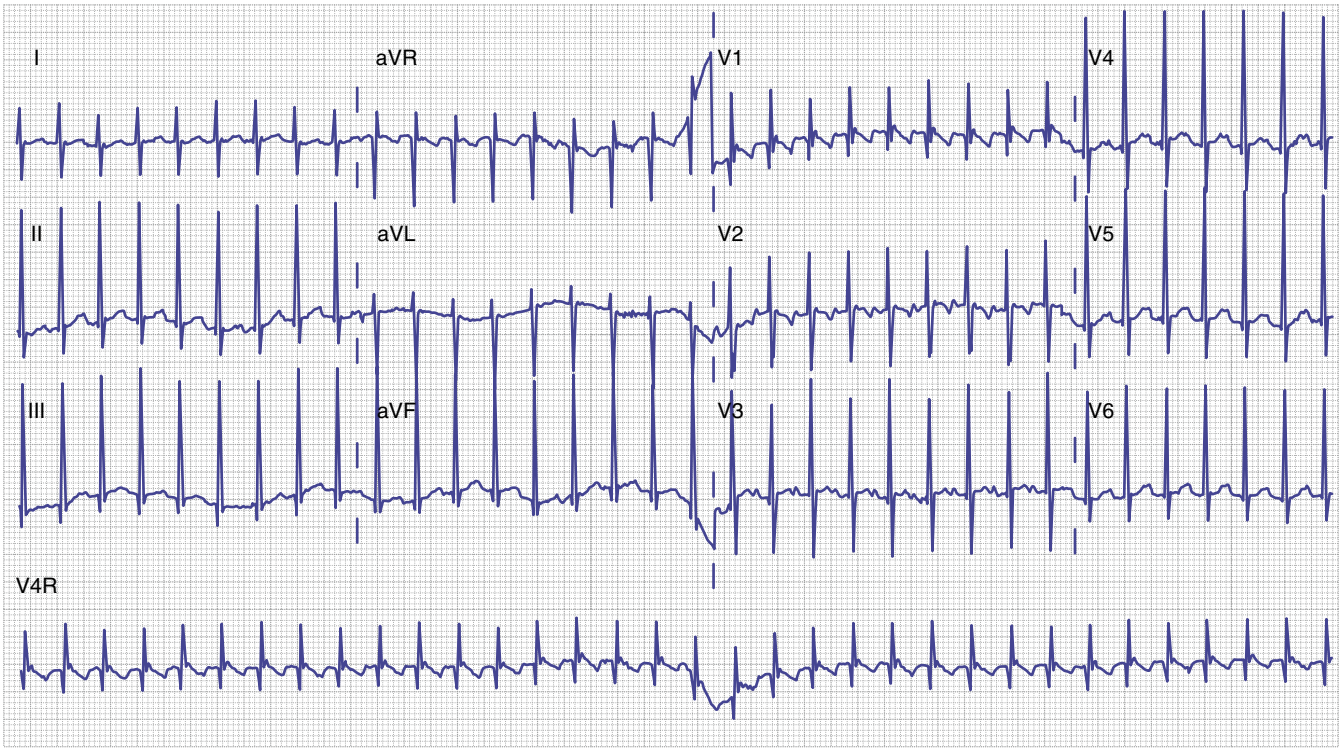

Figure 28–7. Supraventricular tachycardia resulting from AV nodal reentry in an infant. Although considerably less common than orthodromic reciprocating tachycardia in this age group, the P wave on the terminal portion of the QRS complex results in a "pseudo rSr′ pattern." During sinus rhythm, this terminal deflection on the QRS was absent, and the transesophageal recording confirmed the mechanism.

these two mechanisms has little impact on acute management. However, in the ICU setting, primary atrial tachycardias (including sinus tachycardia) and junctional tachycardias also must be considered (particularly following cardiac surgery). Abnormal P-wave morphology (determined by 12-lead ECG), PR interval greater than 50% of the RR interval, or completely obscured P waves favor a nonsinus mechanism. Finally, the QRS duration may appear normal by adult standards but be significantly prolonged for age.

In young patients, intraatrial reentry, atrial flutter, and atrial fibrillation usually are seen following surgical treatment for congenital heart defects involving the atrium (atrial septal defects, atrial repair of transposition of the great arteries, or the Fontan operation).[15] The sawtooth pattern typical of atrial flutter may be absent in these patients, and the term *intraatrial reentrant tachycardia* (IART) may be more appropriate when discrete P waves are present. Because the atrial rate often is relatively slow in comparison with "typical" atrial flutter, a high index of suspicion is required. In some cases, the atrial rate is slow enough that consistent 1:1 conduction (with discrete P waves) further obscures the diagnosis by simulating sinus tachycardia. Similarly, with 2:1 conduction, alternate P waves may be obscured by the T wave, giving the impression of sinus rhythm.

Distinguishing sinus tachycardia from various types of SVT may be difficult. The appropriateness and variation of the rate (or lack thereof) may be particularly helpful in differentiating sinus from nonsinus tachycardias. Observing the heart rate response to interventions such as volume expansion, analgesia, antipyretic agents, and catecholamine infusions often is helpful. Depending on the pattern of atrial activation, P waves may even simulate a normal sinus P-wave morphology during primary atrial tachycardias. In other cases, AV conduction may appear to be 1:1 on the surface electrocardiogram when, in fact, a second P wave is obscured by the QRS complex or T wave. Direct atrial recordings using transesophageal electrocardiography or temporary epicardial atrial pacing wires usually facilitate the diagnosis (see Figure 28-6, *B*). Vagal maneuvers or administration of adenosine to interrupt AV conduction transiently often helps characterize the true AV relationship and determine whether the AV node participates in the tachycardia mechanism.

Tachycardias with Prolonged QRS

Generally, tachycardias with prolonged QRS should be presumed to be ventricular tachycardias until or unless evidence of an alternative diagnosis is demonstrated. VA dissociation, the hallmark ECG feature of ventricular tachycardia, may not be seen in childhood because of rapid retrograde conduction over the AV node (see Figure 28-4). The distinction between ventricular tachycardia and SVT with aberrant conduction can be difficult and may require invasive electrophysiologic study. Prolonged attempts to differentiate the two at the bedside by noninvasive means often are fruitless and may delay treatment. The wrong conclusion may prompt inappropriate and potentially dangerous therapeutic maneuvers. In the acute setting, treatment based on a presumed diagnosis of ventricular tachycardia is rarely deleterious, even when the mechanism subsequently proves to be supraventricular. However, an erroneous presumption of "SVT with aberrant conduction" may have disastrous consequences. When feasible, a full 12-lead ECG may aid in the diagnosis, particularly when a baseline ECG in normal rhythm is available for comparison. Apparent hemodynamic stability should not be mistaken for evidence of SVT rather than ventricular tachycardia, whether in an otherwise healthy child or in a patient with known cardiac disease.

Monitoring of Atrial Depolarization

When the AV relationship during a tachycardia is unclear, sometimes it can be inferred indirectly by other available monitoring. Invasive arterial and venous pressure waveforms can help define atrial contractile action in some situations. For example, cannon A waves commonly are noted in patients with atrial flutter or JET.

Direct recording of atrial activity is necessary when the AV relationship cannot be determined from the surface ECG or otherwise inferred by the means described. Patients recovering from cardiac surgery frequently have temporary atrial epicardial pacing wires in place that can be used to record atrial electrograms directly while simultaneously recording the surface ECG (see Figure 28-6, *B*). Attachment of the atrial wires to a unipolar precordial lead ("V lead") on the monitor is an easy way to observe atrial activation. Otherwise, atrial activity can be readily recorded with a bipolar esophageal catheter inserted in the esophagus behind the left atrium.

Diagnostic Uses of Adenosine

Although most widely used as an acute therapy for terminating SVT that involves the AV node, adenosine administration also may yield important diagnostic clues to the underlying arrhythmia mechanism.[16] By producing transient block in the AV node during tachycardia, it often is possible to distinguish AV reentrant tachycardias and AVNRTs (either of which should terminate) from atrial tachycardias and ventricular tachycardias. However, adenosine's effects are not confined to the AV node. Ectopic (automatic) atrial and junctional tachycardias, intraatrial reentry, and certain ventricular tachycardias also may terminate with adenosine. Extreme caution should be taken when administering adenosine during wide QRS tachycardia. Adenosine produces vasodilatation, which theoretically can result in hemodynamic deterioration and tachycardia acceleration, or even fibrillation, if tachycardia fails to terminate. Ventricular fibrillation has been rarely observed when adenosine is administered in the setting of WPW syndrome, probably as a result of atrial fibrillation that then is conducted rapidly to the ventricles. Prompt defibrillation should always be readily at hand when administering adenosine for diagnostic or therapeutic purposes.

Treatment of Rhythm Disturbances

The approach to treatment of cardiac arrhythmias is influenced by the clinical setting, but several important considerations help guide therapy in any given situation. The first and most important concern is the degree of hemodynamic compromise associated with a particular arrhythmia. Minor rhythm disturbances may be more readily recognized in the intensive care setting than in other situations simply because of the level of monitoring and may prompt undue attention. In contrast, potentially life-threatening arrhythmias may best be treated by acute measures (e.g., cardioversion or temporary pacing) not readily available in other settings. Extracorporeal support and assist devices add another dimension to the equation. Extracorporeal membrane oxygenation support may serve as adjunctive therapy for refractory arrhythmias, whereas other modes of support (e.g., an assist device or balloon pump) may require a regular rhythm for appropriate coordination of the device with spontaneous cardiac activity.

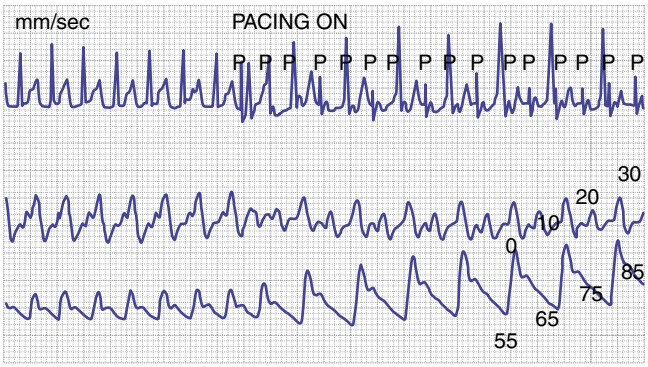

Figure 28–8. Junctional ectopic tachycardia with hypotension immediately improved with faster atrial pacing (in this case, resulting in 2:1 AV block and AV synchrony).

A second important consideration in critically ill patients, particularly those undergoing cardiac surgery, is to favor therapies that maintain appropriate AV synchrony. In the setting of marginal hemodynamics, an otherwise acceptable ventricular rate during arrhythmias such as atrial tachycardias and fibrillation, junctional tachycardia, or AV block may further compromise cardiac output as a result of loss of AV synchrony (see Figure 28-8).

A third consideration in the management of arrhythmias in this setting is the recognition that many arrhythmias in the ICU are iatrogenic. Even minor arrhythmias may herald more serious issues, such as electrolyte disturbances, acidosis, subendocardial ischemia, excessive catecholamine infusions, or increased intracranial pressure. It is important to identify and correct any such underlying causes because therapies directed at the rhythm itself may not protect from more serious rhythm decompensation.

Finally, whenever feasible, acute and short-term measures with limited potential to impair hemodynamics generally should be favored over chronic therapies. Thus nonpharmacologic therapies, such as pacing or cardioversion, or ultrashort-acting drugs, such as adenosine and esmolol, may be preferable to chronic antiarrhythmic therapy. Whether chronic therapy is warranted for a given arrhythmia is determined more by its underlying mechanism, clinical setting, and frequency than by the severity of the arrhythmias encountered in the intensive care setting. Before beginning chronic antiarrhythmic therapy, consultation with a cardiologist versed in the spectrum of arrhythmias seen in childhood is advisable. The impact of acute measures on chronic arrhythmia management becomes increasingly crucial with the emergence of amiodarone use in the ICU and the increasing availability of nonpharmacologic therapies such as radiofrequency catheter ablation and implantable defibrillators for a broader spectrum of arrhythmias and patient populations.[17,18]

Bradycardia Therapies
