Clinical signs and symptoms frequently associated with IEMs are listed in Box 76-1. The symptom repertoire of the critically ill infant is limited, and the clinical presentation of metabolic disorders often is nonspecific. It is for this reason that the diagnosis of an IEM may be easily missed. To maintain maximum diagnostic sensitivity for IEMs, the clinician must maintain a high level of suspicion and be willing to initiate screening metabolic laboratory studies with little provocation. As was true for appendectomies in the era prior to the advent of ultrasound-based diagnosis of appendicitis, a certain number of nondiagnostic metabolic laboratory workups in sick children must be performed to ensure ascertainment of individuals with inherited metabolic disorders. In particular, IEM should be a strong diagnostic consideration in any neonate who has become catastrophically ill following a period of normalcy. This presentation may be clinically indistinguishable from bacterial or viral sepsis, and the nonspecific supportive therapy provided to potentially septic infants (fluid and glucose administration) may alleviate the symptoms and

mask the presence of an IEM. Diagnostic metabolic laboratory studies are most likely to provide definitive information if performed on clinical samples obtained at initial presentation and before any therapy is initiated. Failure to obtain the necessary specimens at this time may miss an important diagnostic window of opportunity. Many children with IEM have been saved initially by intensive but nonspecific treatment but then suffered clinical relapse or even death in the absence of the correct diagnosis. Certainly, the possibility of an IEM should be considered in any child for whom the clinical picture suggests sepsis but the laboratory evaluation for sepsis is negative. Unfortunately, bacterial sepsis is often a complicating factor in critically ill children with IEM. For example, *Escherichia coli* infection (including pyelonephritis, bacteremia, or meningitis) is frequently detected at presentation in infants with galactosemia. The astute clinician remains ever vigilant for the signs and symptoms that may suggest an inherited metabolic disorder.

Recurrent episodes of vomiting and dehydration in response to fasting or intercurrent illness are an important clue to IEM in older infants and children. Feeding difficulties and failure to thrive are common chronic complications. Children with unexplained hypotonia, developmental delay, or movement disorder should be evaluated for possible IEM. Inherited neurodegenerative disorders, such as the lysosomal storage diseases, stereotypically cause developmental regression, specifically loss of previously attained developmental milestones. Several IEMs are associated with major physical anomalies (Table 76-1). When present, these anomalies are exceedingly valuable in suggesting a specific diagnosis and directing the diagnostic evaluation. More commonly, the child with IEM is morphologically normal, and the presenting symptoms are nonspecific. The clinician must then rely upon screening laboratory tests to evaluate the potential for IEM.

Table 76–1 Physical Anomalies Associated with Inborn Errors of Metabolism

Dysmorphic facial features	Peroxisomal disorders Glutaric aciduria type II Smith-Lemli-Opitz syndrome Menkes syndrome Lysosomal storage disorders
Structural brain anomalies	Glutaric aciduria type II (cortical cysts) Pyruvate dehydrogenase deficiency (cortical cysts, agenesis of the corpus callosum) Glycosylation disorders (cerebellar agenesis)
Macrocephaly	Glutaric aciduria type I (with subdural effusions) Canavan disease Alexander disease
Cataracts	Galactosemia Peroxisomal disorders Mitochondrial disorders Lowe syndrome
Lens dislocation	Homocystinuria Sulfite oxidase deficiency Molybdenum cofactor deficiency
Pigmentary retinopathy	Peroxisomal disorders including cherry red spots Lysosomal storage disorders Long chain 3-hydroxyacyl-CoA dehydrogenase deficiency
Renal cysts	Glutaric aciduria type II, Peroxisomal disorders Mitochondrial disorders
Ambiguous genitalia	Congenital adrenal hyperplasia Smith-Lemli-Opitz syndrome
Skeletal abnormalities	Menkes disease Homocystinuria Peroxisomal disorders Lysosomal storage diseases
Hair or skin abnormalities	Menkes disease Holocarboxylase synthetase deficiency Biotinidase deficiency Argininosuccinic aciduria Phenylketonuria

Laboratory Evaluation of Suspected Inborn Errors of Metabolism

Abnormal results of routine laboratory studies may provide clues to the presence and type of IEM (Table 76-2). Highly informative but sometimes subtle laboratory abnormalities are often overlooked, especially in a busy ICU or hospital ward. For instance, a clinically relevant newborn screening result may have been sent to the primary care provider or birth hospital but not efficiently communicated to the ICU, in a different hospital, to which the now critically ill infant has been admitted. It is imperative to verify the infant's screening results with the primary care provider or newborn screening laboratory (Box 76-2). Calculation of the anion gap, another example of a routine and highly informative result, is key to the differential diagnosis of metabolic acidosis. The absence of urine ketones in hypoglycemic children older than 2 weeks strongly suggests impaired ketogenesis as a consequence of either hyperinsulinism or fatty acid oxidation disorder. On the other hand, fatty acid oxidation and ketogenesis are incompletely developed in neonates. The presence of ketones in the urine of infants younger than 2 weeks is very unusual even during fasting or hypoglycemia and suggests the presence of an unusual keto acid, such as those excreted in maple syrup disease or the organic acidemias. Keto acids, organic acids, and sugars such as galactose or fructose increase urine specific gravity. Urine specific gravity greater than 1.020 in any neonate or in a well-hydrated older child suggests the unexpected presence of an osmotically active substance. Routine urinalysis at many hospitals may not include use of the Clinitest to detect reducing substances. Urine Chemstrips utilize a colorimetric glucose oxidase-based method to specifically detect glucose. This test does not react with any other sugar (galactose or fructose). However, some bedside glucose monitoring systems do react with galactose or fructose; inappropriately elevated capillary blood "glucose" accompanied by a normal venous glucose as measured by chemistry analyzer suggests the presence of a sugar other than glucose in the blood. A comatose infant with a blood urea nitrogen (BUN) level below the limits of detection may have an inherited defect in the urea cycle. Blood ammonia measurement is crucial to confirming that suspicion. Failure to check the blood ammonia level has caused missed diagnoses, failure to appropriately treat hyperammonemia, and further morbidity and mortality in comatose infants with urea cycle disorders

Table 76–2 Initial Laboratory Evaluation of Suspected Inborn Errors of Metabolism

Laboratory Test	Abnormality	Disorder
Complete blood count	Neutropenia Macrocytic anemia Pancytopenia	Organic acidemias Glycogenosis type 1b Cobalamin processing defects Congenital lactic acidoses
Serum electrolytes	Metabolic acidosis	Glycogenoses Organic acidemias FAO disorders MSUD Congenital lactic acidoses
Blood gas	Metabolic acidosis Metabolic alkalosis	Same as above Urea cycle disorders
BUN	Low or undetectable BUN (with hyperammonemia)	Urea cycle disorders
Transaminases (ALT, AST)	Liver dysfunction	Galactosemia Fructosemia Tyrosinemia α1-antitrypsin deficiency FAO disorders Organic acidemias Congenital lactic acidoses Congenital disorders of glycosylation
Total and direct bilirubin	Hyperbilirubinemia	Galactosemia Fructosemia Tyrosinemia α1-antitrypsin deficiency Congenital lactic acidoses
Serum uric acid	Hyperuricemia	Glycogenoses Purine disorders
Blood ammonia	Hyperammonemia	Urea cycle disorders FAO disorders Organic acidemias
Blood lactate	Lactic acidemia	Congenital lactic acidoses Glycogenoses Fructosemia Gluconeogenesis disorders
Urinalysis Odor Color pH Specific gravity Ketones Reducing substances	Unusual odor Inappropriately high specific gravity due to metabolites Ketosis Positive reducing substances	PKU, MSUD, organic acidemias Organic acidemias, galactosemia, fructosemia MSUD, organic acidemias Galactosemia, fructosemia

BUN, Blood urea nitrogen; *FAO,* fatty acid oxidation; *MSUD,* maple syrup urine disease.

or organic acidemias. Finally, bacterial sepsis and meningitis are more common causes of severe lethargy and coma in infants than is IEM, but bacterial infection may also be a complicating feature in severely ill infants with IEM. Infants with galactosemia, for example, are particularly prone to pyelonephritis, bacteremia, sepsis, or meningitis, often with *E. coli*, as noted above. Antibiotic therapy without diagnosis and specific treatment of the underlying disorder may be useful in the short term but does not mitigate long-term IEM-specific effects.

Box 76–2 Screening Metabolic Laboratory Studies for Children with Suspected Inborn Errors of Metabolism

- Plasma amino acid analysis
  Minimum 2 mL blood in a heparin tube
- Urine organic acid analysis
- Urine metabolic screen
  Minimum 10 mL urine

Suspicion of an IEM based upon clinical and routine laboratory findings should initiate specialized biochemical testing (Table 76–3). In the case of severely ill infants or when the clinical suspicion of IEM is very high, consultation with a biochemical geneticist, even if only by phone, is strongly advised to help direct the laboratory investigation and initial therapy. When the clinical presentation is nonspecific, that is, catastrophic illness in a previously well child without signs of any particular IEM, the "shotgun" diagnostic evaluation should minimally include plasma amino acid analysis, urine organic acid analysis by gas chromatography-mass spectrometry, and a so-called *urine metabolic screen*. The battery of qualitative assays included in a urine metabolic screen differs among laboratories, and the ordering clinician should be aware of which tests and disorders are included in the repertoire of the diagnostic laboratory chosen. Furthermore, although diagnostic laboratories in the United States must meet Clinical Laboratory Improvement Amendments requirements and often are accredited by the College of American Pathologists, the testing methodologies used, the quality of diagnostic testing for IEM, and more problematically, the availability of laboratory-associated consultants with experience in the diagnosis and treatment of IEM vary widely among laboratories. Although the ability of clinicians to direct clinical specimens toward specific diagnostic laboratories may be inhibited by contractual arrangements between the hospital and large referral laboratories, the critically ill patient is best served by diagnostic evaluation carried out in a timely manner by an experienced biochemical genetics laboratory, with laboratory staff available by phone for expert consultation on interpretation of test results.

The specific clinical presentation or specific screening laboratory findings may direct the intensivist or biochemical geneticist to order other more specialized metabolic tests (see Table 76-3). These analyses may provide diagnostic confirmation for specific disorders and supportive evidence alone for others. For several IEMs, confirmation of diagnosis may require enzyme activity analysis in tissue (red blood cells, lymphocytes, cultured skin fibroblasts, liver, or skeletal muscle depending upon the specific disorder in question) or molecular DNA testing for a specific gene defect. In general, these tertiary tests, which are often difficult, labor-intensive, and expensive, should be ordered following consultation with a biochemical geneticist. In some instances, confirmatory diagnostic biochemical or molecular tests are available only through specialized research laboratories.

Table 76–3 Biochemical Genetic Laboratory Studies

Specimen	Test	Disorder
Blood	Plasma amino acid analysis	Aminoacidopathies
	Plasma carnitine	Organic acidemias FAO disorders
	Plasma acylcarnitine profile	Organic acidemias FAO disorders
	Serum transferrin electrophoresis	Congenital disorders of glycosylation
Urine	Metabolic screen	
	Ketones	Organic acidemias
	Reducing substances	Galactosemia, fructosemia
	Ferric chloride	PKU
	Dinitrophenylhydrazine	PKU, MSUD
	2,4-nitrosonaphthol	Tyrosinemia
	Cyanide-nitroprusside	Sulfur-containing amino acids
	Mucopolysaccharide screen	Mucopolysaccharidoses
	Qualitative amino acid chromatography	Multiple amino aciduria s
	Organic acid analysis	Organic acidemias FAO disorders
	Acylglycine profile	Organic acidemias FAO disorders
	Quantitative mucopolysaccharide measurement and electrophoresis	Mucopolysaccharidoses
	Qualitative sulfites (Sulfitest) or quantitative sulfocysteine	Sulfite oxidase deficiency Molybdenum cofactor deficiency
	Quantitative succinylacetone	Tyrosinemia type 1
	Quantitative purines	Purine synthesis disorders

Postmortem Evaluation of a Child with Suspected Inborn Errors of Metabolism

Some IEMs, particularly those exacerbated by fasting, may present as sudden infant death. For many IEMs, acute metabolic compensation may be rapid and lethal despite intensive medical intervention. The time after clinical presentation but prior to death may be insufficient to execute an adequate metabolic evaluation. Disease diagnosis is still possible postmortem and is important for fully understanding the cause of death and determining recurrence risk in the family. A protocol for postmortem evaluation of an infant or child with suspected IEM is given in Box 76-3. Many of the biochemical genetic analyses recommended for acutely ill children are still valid on postmortem specimens. Valuable information may be learned from amino acid, carnitine, and acylcarnitine analyses in blood and from metabolic screening and organic acid analysis in urine. However, collection of blood and urine

Box 76–3 Postmortem Biochemical Genetic Evaluation

To be performed on any deceased infant <1 year of age for whom the cause of death is not apparent or any child with suspected IEM.

Analyses are most reliable if obtained within 6 hours after death.

1. Contact newborn screening laboratory for results of neonatal screening.
2. Obtain a 3-mm punch biopsy of skin or Achilles tendon for fibroblast culture.
   - A. Prepare skin with chlorhexidine (Hibiclens) or alcohol. Do not use Betadine because it may inhibit fibroblast growth.
   - B. Use sterile technique.
   - C. Store biopsy specimen in sterile RPMI culture media (if available) at room temperature. May be stored in sterile nonbacteriostatic saline for up to 24 hours prior to culture if culture media is not readily available.
   - D. Send to cytogenetics or biochemical genetics laboratory for culture, possible enzyme analyses, and frozen storage.
3. Collect blood via cardiac puncture (~5 mL per tube).
   - A. One red-top tube at room temperature. Collect and store serum at 70° C.
     - i. Comprehensive metabolic panel (potassium, lipids, uric acid may not be accurate postmortem)
     - ii. If hypoglycemic, insulin, growth hormone, and cortisol levels
   - B. One green-top (sodium heparin) tube at room temperature. Collect and store plasma at 70° C.
     - i. Plasma amino acid analysis
     - ii. Plasma carnitine levels
     - iii. Plasma acylcarnitine profile
   - C. One green-top (sodium heparin) tube at room temperature for cytogenetic (karyotype) analysis.
   - D. If storage disorder suspected, one green-top tube (sodium heparin) at 48° C (wet ice) for leukocyte isolation and diagnostic enzyme analyses.
   - E. One lavender-topp (EDTA) tube at room temperature for CBC.
   - F. One yellow-top (ACD) tube for DNA isolation and possible mutation analysis.
   - G. If infant is <1 year old, spot whole blood onto newborn screening filter paper card for repeat screen.
   - H. Blood lactate and ammonia may not be accurate postmortem.
4. Collect urine (10–20 mL) by suprapubic tap or by swabbing the bladder interior with cotton swab.
   - A. Urinalysis
   - B. Urine reducing substances
   - C. Urine metabolic screen
   - D. Urine organic acid analysis
   - E. If storage disorder suspected, quantitative urine mucopolysaccharide and oligosaccharide analysis
5. If urine is unobtainable, organic acid analysis may be performed on vitreous humor collected by needle aspiration from an eye. Freeze vitreous humor at –70° C.
6. If blood is unobtainable, collect bile (2–3 mL) via puncture of the gallbladder for acylcarnitine profile. Store at –20° C.
7. Collect several biopsies (2 g each) from skeletal muscle, cardiac muscle, kidney, and liver.
   - A. For routine histology, biopsies should be submitted fresh to the pathology laboratory.
   - B. For enzyme analyses, biopsies should be wrapped in aluminum foil, placed in a labeled small specimen container, and immediately frozen in liquid nitrogen. Store at –70° C.

Modified from Steiner RD, Cederbaum SD: Laboratory evaluation of urea cycle disorders. *J Pediatr* 138 (Suppl 1):S21-29, 2001.

may not be possible postmortem, especially if the autopsy is performed many hours after death. In these instances, metabolic testing may be obtained on alternative specimens such as vitreous humor or bile. In the event that screening biochemical studies suggest a specific diagnosis, disease confirmation by enzyme analysis in tissue is highly desirable. Many enzymes can be assayed in cultured fibroblasts; viable fibroblasts may be cultured from skin or Achilles tendon samples obtained as late as 24 hours after death. Biopsies of other organs may be necessary for analysis of certain other enzymes. Muscle, liver, and kidney specimens may be obtained postmortem for enzymatic analysis, but most enzymatic activities in solid organs deteriorate rapidly following death. Collection of specimens as soon as possible after death is critical for valid enzyme analyses.

Emergency Treatment of Children with Suspected Inborn Errors of Metabolism

Laboratory investigation of suspected IEM may require several days to complete, given that the biochemical genetics laboratory may be physically remote from the treating hospital and many of the tests involve complex specimen preparation and analysis. A general approach to the emergency treatment of children with suspected IEM, while awaiting diagnostic studies, is given in Table 76-4. For many IEMs associated with acute catastrophic illness, elimination of the offending metabolite is the key to therapy. Immediate cessation of oral feedings, to stop protein or fat intake, will begin to limit toxin production in disorders of amino acid or fatty acid metabolism. Adequate energy intake as carbohydrate must be supplied, usually parenterally, until a specific diagnosis and definitive treatment plan are available. Dextrose infusion at a high rate suppresses catabolism and reduces the consumption of endogenous protein or fatty acid stores. In extremely recalcitrant cases, insulin infusion drives anabolism and further decreases toxin production. Acute metabolic decompensation in some IEMs (e.g., maple syrup disease) is associated with mild peripheral insulin resistance. Insulin administration (often as little as 0.01 to 0.05 units/kg/hour given by continuous intravenous [IV] infusion or subcutaneous bolus injection) overcomes this resistance and has an immediate impact upon metabolic control. Some clinicians also use anabolic agents such as growth hormone or testosterone to acutely suppress protein and fat catabolism. In certain types of congenital lactic acidosis, particularly defects of pyruvate metabolism, carbohydrate infusion worsens lactic acidosis. Replacement of some carbohydrate with fat as an intralipid infusion may partly reduce blood lactate levels, but infants with this degree of sensitivity to glucose infusion often are difficult to treat and suffer high mortality. Severe hyperammonemia that does not respond to dietary protein restriction and dextrose infusion must be treated by hemodialysis. Ammonia clearance with exchange transfusion or peritoneal dialysis is insufficient to adequately decrease blood ammonia levels. If the results of specialized biochemical genetic diagnostic tests are expected within 2 to 3 days, then parenteral dextrose infusion alone should be adequate to maintain nutrition until a more definitive treatment plan is available. Beyond 3 days, developing essential amino acid and fatty acid deficiencies may induce catabolism of endogenous protein and fat. To prevent this occurrence, enteral or parenteral nutrition with minimal amounts of protein (0.5 g/kg body weight/day) and lipid (20% of total energy intake) should be considered. Empiric administration of cofactors such as the B vitamins is not harmful and may improve metabolite clearance, particularly in disorders caused by deficiency of enzymes that require specific cofactors. Carnitine is required for transport of long-chain fatty acids across the mitochondrial membrane and serves a secondary role in the disposal of excess and potentially toxic acyl-CoA species. Secondary carnitine deficiency is commonly associated with acute metabolic decompensation in organic acidemias and fatty acid oxidation defects. L-Carnitine administration prevents secondary carnitine deficiency and may improve clearance of toxic metabolites; it is lifesaving in specific inherited dilated cardiomyopathies.

Table 76–4 Emergency Treatment of Suspected Inborn Error of Metabolism

Goal	Action
Suppress toxic metabolite production	Discontinue oral feedings
Correct fluid imbalance and electrolyte abnormalities	Appropriate IV fluid management
Correct hypoglycemia	IV dextrose-containing fluid infusion
Correct metabolic acidosis	Intravenous hydration if pH >7.2 Add IV bicarbonate if pH <7.2 Sodium bicarbonate (1 mEq/mL solution), 1 mEq/kg IV push at <1 mEq/min May repeat ×3 until pH >7.2; maximum dose 7 mEq/kg/24 hr
Correct hyperammonemia	Suppress protein catabolism Hemodialysis
Treat infection	Appropriate infectious disease laboratory evaluation and antibiotic therapy
Suppress protein and lipid catabolism	Infuse D_{10}1/2NS at 1.5-2 × maintenance rate Add insulin infusion if hyperglycemic If severe, unrelenting acidosis, consider growth hormone or testosterone therapy to promote anabolism
Empiric cofactor administration	L-carnitine, 25-50 mg/kg/every 6 hours IV if organic acidemia suspected or cardiomyopathy present B vitamin complex, 100 mg each vitamin every day Vitamin B_{12}, 1 mg IM × 1 if macrocytic anemia
Maintain nutritional status (if without enteral feeds ×2 days and without diagnosis of a specific IEM)	Enteral feeds or parenteral hyperalimentation to include: Protein, 0.5 gm/kg/day only Lipid, 20% of total energy intake Carbohydrate to provide at least the minimum necessary energy intake

Classification of Inborn Errors of Metabolism by Clinical Presentation

As mentioned previously, the clinical presentation of IEM in neonates provides a paradigm for the suspicion and evaluation of potential IEM at all ages. The classification outlined

Table 76–5 Features of Group 1 Inborn Errors of Metabolism

Clinical Features	Laboratory Findings	Possible Diagnoses	Specialized Diagnostic Tests
Hepatosplenomegaly Coarse facies Macroglossia Fetal hydrops Macular cherry red spots Bone changes Hypotonia or hypertonia Chronic rhinorrhea Failure to thrive	Liver dysfunction No acidosis Normal ammonia Normal glucose	Neonatal onset: GM1 gangliosidosis Icell disease Sialidosis Galactosialidosis Niemann-Pick type A MPS VII CDG Later onset Tay-Sachs disease Krabbe disease Other MPS syndromes Niemann-Pick B or C	Urine mucopolysaccharides Urine oligosaccharides Serum transferrin electrophoresis Enzyme analysis in serum, lymphocytes or fibroblasts
Hepatomegaly Dysmorphic facies Severe hypotonia Large anterior fontanelle Seizures Epiphyseal calcific stippling on radiograph	Liver dysfunction No acidosis Normal ammonia Normal glucose Adrenal insufficiency	Peroxisomal disorders: Zellweger syndrome Neonatal adrenoleukodystrophy Others	Plasma very long chain fatty acid analysis Functional and genetic analysis of fibroblasts

MPS, Mucopolysaccharidosis; *MPS VII*, Sly syndrome; *CDG*, congenital disorders of glycosylation.

here is adapted and expanded to include late-onset disorders from a neonatal IEM classification system first described by Jean-Marie Saudubray and colleagues.[4,8]

IEMs can be classified into one of three groups by pathogenic mechanism. In group 1 IEMs, the production or catabolism of complex molecules is disturbed. The lysosomal storage and peroxisomal disorders are included in this group. The symptoms of these disorders include permanent and progressive somatic and neurologic abnormalities that develop in utero, are often clinically apparent at birth, and are unaffected by food intake. This group is often distinguished by the presence of somatic abnormalities such as dysmorphic features or hepatosplenomegaly. Typical clinical features, potential neonatal and late-onset diagnoses, and confirmatory diagnostic tests are listed in Table 76-5.

In group 2 IEMs, the symptoms are caused by defects in the production or utilization of energy. This group includes the congenital lactic acidoses, glycogenoses, gluconeogenic defects, and fatty acid oxidation disorders. In group 3 IEMs, clinical symptoms are caused by progressive intoxication in a previously well infant because of accumulation of toxic metabolites proximal to a metabolic block. Often, neonatal onset IEM in groups 2 and 3 can be distinguished by the time of clinical onset relative to birth. The symptoms of a block in energy production or utilization (group 2) may present within hours after birth, whereas symptoms of intoxication (group 3) develop over the first week of life with increasing food intake and accumulation of toxic metabolites. However, variants of many of these disorders may not become clinically apparent for several months or even years after birth.

Group 2 Inborn Errors of Metabolism

Systemic or tissue-specific impaired energy production from food substrates is the unifying feature of disorders classified in group 2. Generalized profound neurologic dysfunction, including severe central hypotonia, coma, and seizures, sometimes with peripheral spasticity or abnormal movements, typifies the clinical presentation. Children with these disorders present with similar clinical phenotypes but are easily separated into four subgroups (A through D) based upon associated results of routine laboratory studies (Table 76-6). Severe refractory generalized motor seizures, often beginning within the first hours after birth, sometimes even prenatally, are the hallmark of subgroup A. Routine laboratory studies (glucose, blood pH, electrolytes, ammonia) are generally normal unless the infant is near extremis, and secondary metabolic abnormalities are present. Several inherited disorders are associated with this phenotype; diagnostic differentiation depends upon clinical evaluation by an experienced pediatric neurologist or geneticist and the judicious use of specialized diagnostic laboratory tests.

The amino acid glycine is an abundant neurotransmitter within the central nervous system (CNS). Inherited deficiency of the glycine cleavage system, which removes glycine from its receptor in the neuronal synapse, causes severe unrelenting generalized seizures and profound developmental arrest. The only ubiquitous laboratory finding is an elevated cerebrospinal fluid (CSF/plasma glycine ratio).[9] Sulfite oxidase deficiency, either as a primary genetic defect or secondary to generalized deficiency of its molybdenum-containing cofactor, is another rare but important cause of neonatal-onset seizures. Recently, infantile-onset pyridoxine-dependent or folinic acid-dependent seizure disorders have both been found to be caused by recessively inherited deficiency of α-aminoadipic semialdehyde (α-AASA) dehydrogenase, an intermediate enzyme in the metabolism of the amino acid lysine.[10] Consequently, all neonates with refractory seizures should be screened for these treatable disorders either through measurement of α-AASA in urine or sequencing of the ALDH7A1 (antiquitin) gene. Profound neurologic dysfunction with seizures is one of many possible clinical presentations of infants with peroxisomal or respiratory chain disorders. Some subtypes of a still expanding list of congenital disorders of glycosylation present with seizures,[11] as do disorders of sterol production such as Smith-Lemli-Opitz syndrome,[12] but these diagnoses are often associated with stereotypic dysmorphic features and anomalies. Finally, disorders of neurotransmitter synthesis should be

Table 76–6 Features of Group 2 Inborn Errors of Metabolism

Clinical Features	Associated Laboratory Findings	Possible Diagnoses	Specialized Diagnostic Testing
SUBGROUP A			
Profound neurologic dysfunction Severe hypotonia Seizures	No acidosis Normal ammonia Normal glucose	Nonketotic hyperglycinemia Sulfite oxidase or molybdenum cofactor deficiency Pyridoxine- or folinic acid-responsive seizures Peroxisomal disorders Respiratory chain disorders CDG Cholesterol synthesis defects Neurotransmitter synthesis defects	Plasma and CSF amino acid analysis Urine sulfocysteine Urine oxypurines Urine α-aminoadipic semialdehyde *ALDH7A1* gene sequencing Plasma very long chain fatty acid analysis Blood and CSF lactate Plasma acylcarnitine Urine organic acids Serum transferrin electrophoresis Plasma sterols CSF neurotransmitters
SUBGROUP B			
Neurologic dysfunction Hypotonia Seizures With severe acidosis ± Liver dysfunction ± Dilated cardiomyopathy	Severe acidosis Lactic acidosis ± Ketosis ± Hypoglycemia ± Anemia	Congenital lactic acidoses Pyruvate dehydrogenase Pyruvate carboxylase Respiratory chain disorders	Blood and CSF lactate Plasma and CSF amino acid analysis Urine organic acids Diagnostic muscle biopsy to include histology, enzyme analysis
SUBGROUP C			
Neurologic dysfunction Vomiting Dehydration Hypotonia Coma ± Hepatomegaly, liver dysfunction ± Dilated cardiomyopathy Triggered by fasting or intercurrent illness	Hypoglycemia No ketones in urine Acidosis ± Hyperammonemia ± Lactic acidosis	Fatty acid oxidation defects: MCAD LCHAD VLCAD CPT II CAT MACD Ketogenesis defects: HMG-CoA lyase MCKAT SCOT	Urine organic acids Plasma carnitine Plasma acylcarnitine profile Diagnostic fasting study Fatty acid oxidation studies in cultured skin fibroblasts Gene-specific mutation analysis
SUBGROUP D			
Neurologic dysfunction triggered by short fast Hepatomegaly	Severe fasting hypoglycemia Lactic acidosis Normal ammonia ± Ketosis ± Hyperuricemia ± Hypophosphatemia	Glycogen storage: Glycogenosis 1 Glycogenosis 3 Fructose 1,6-bisphosphatase deficiency	Diagnostic fasting study Enzyme studies in liver Gene-specific mutation analysis

CDG, Congenital disorders of glycosylation; *MCAD*, medium chain acyl-CoA dehydrogenase; *LCHAD*, long chain 3-hydroxyacyl-CoA dehydrogenase; *VLCAD*, very long chain acyl-CoA dehydrogenase; *CPT II*, carnitine palmitoyltransferase II; *CAT*, carnitine acylcarnitine translocase; *MACD*, multiple acyl-CoA dehydrogenase deficiency (also known as glutaric aciduria type 2); *HMG-CoA lyase*, 3-hydroxy-3-methylglutaryl-CoA lyase; *MCKAT*, medium chain ketoacyl-CoA thiolase; *SCOT*, succinyl-CoA oxaloacetate transferase.

considered in any infant with idiopathic seizures and neurologic dysfunction, especially if a movement disorder, most commonly dystonia, is also present. Abnormal CSF neurotransmitter levels (5-methyltetrahydrofolate, 5-hydroxyindoleacetic acid, homovanillic acid, 3-methyl-DOPA) are the only associated laboratory diagnostic clue in this latter category of disease.

Severe persistent lactic acidosis is the hallmark of the disorders in subgroup B of early-onset energy deficiency diseases. The presence of metabolic acidosis with an elevated anion gap suggests the possibility of lactic acidosis (subgroup B) or an organic acidemia (see group 3, intoxication types); these are differentiated by measurement of blood lactate and urine organic acid analysis. Blood lactate is most reliably measured on arterial blood or a free-flowing sample drawn from an indwelling central venous catheter. Artifactual elevation of lactate in peripheral venous blood samples is nearly ubiquitous and should be confirmed by lactate measurement in a more appropriate sample. Secondary lactic acidosis resulting from asphyxia, poor tissue perfusion, or tissue necrosis is much more common and may be difficult to differentiate from the congenital lactic acidoses. Occult cardiac disease, intracranial hemorrhage, or bowel necrosis must be considered and ruled out in infants with severe lactic acidosis. Congenital lactic acidosis generally persists despite adequate life support measures, including fluid resuscitation and ventilatory assistance. In certain enzyme deficiencies, the blood lactate level may further increase with IV dextrose infusion. Simultaneous measurements of blood and CSF lactate and amino acids are useful for differentiating primary from secondary lactic acidoses. In congenital lactic acidosis, the CSF lactate level often is higher than the blood lactate level, while the CNS is relatively protected from systemic acidosis in secondary lactic acidemias. The

blood pyruvate level is elevated in some congenital lactic acidoses such as pyruvate dehydrogenase deficiency. However, accurate measurement of blood pyruvate is difficult and fraught with false-positive elevations. Elevated plasma alanine (which is measured as part of a plasma amino acid analysis) is a more stable and reliable indicator of pyruvic acidosis, as alanine and pyruvate are in equilibrium. Enzymatic analysis in cultured skin fibroblasts or mitochondria isolated from a fresh muscle biopsy often is necessary to confirm a specific enzyme deficiency.

Children with subgroup C defects present with hypoketotic hypoglycemia, triggered by fasting, metabolic stress, or intercurrent illness. In these disorders, utilization of fatty acids as fuel is impaired. The most common of the fatty acid oxidation defects is MCADD, which occurs in up to 1:10,000 white births. Although fatty acid oxidation and ketogenesis defects may present in the newborn period, particularly in the setting of delayed maternal milk production for exclusively breastfed infants, the first clinically significant episode may not occur for weeks to months or even years after birth. With extended fasting or intercurrent illness where metabolic demand exceeds available energy supply, severe lethargy acutely develops and then progresses to coma. Recurrent vomiting and consequent dehydration may be associated. Sudden infant death after an overnight fast is an all-too-frequent initial presentation in up to one third of infants with fatty acid oxidation defects. Infants who survive may suffer recurrent episodes of fasting or illness-induced coma, leading to progressive CNS damage and permanent disability. Metabolic acidosis (resulting from accumulation of partially oxidized fatty acids or secondary lactic acidosis), hyperammonemia, hepatomegaly and liver dysfunction, and hypertrophic cardiomyopathy may occur during acute metabolic decompensation episodes. Liver histology is typified by severe steatosis. Chronically affected children may exhibit recurrent vomiting, failure to thrive, developmental delay, and muscular hypotonia. Certain disorders that affect oxidation of long-chain fatty acids are frequently associated with recurrent rhabdomyolysis and myoglobinuria (long-chain 3-hydroxyacyl-CoA dehydrogenase [LCHAD] deficiency, trifunctional protein deficiency, very-long-chain acyl-CoA dehydrogenase [VLCAD] deficiency, or carnitine-palmitoyl transferase [CPT]-II deficiency) or pigmentary retinopathy and slowly progressive vision loss (LCHAD or trifunctional protein deficiency). Mothers of infants with fatty acid oxidation disorders (particularly LCHAD or trifunctional protein deficiency) may present with acute liver dysfunction during pregnancy with an affected fetus. This may manifest as acute fatty liver of pregnancy or maternal HELLP (hemolysis, elevated liver enzymes, low platelets) syndrome. In the affected infant, hypoglycemia (serum glucose <40 mg/dL) with inappropriately low or absent ketone production during a symptomatic episode is the key laboratory finding that leads to suspicion of a disorder in this subgroup. Differentiation of the specific defects requires analysis of urine organic acids and plasma acylcarnitine species. Between episodes, when the child is clinically well, the urine organic acid profile may be completely normal. Acylcarnitine profiles are more consistently abnormal, but both tests, if normal initially, should be repeated on samples obtained during a symptomatic period to absolutely rule out the possibility of a fatty acid oxidation defect. Carnitine is required for normal fatty acid oxidation; long-chain fatty acids are activated to fatty acyl-CoA, then esterified to carnitine by CPT-I on the outer mitochondrial membrane. These acylcarnitine esters are then transported into mitochondria to complete the oxidation process. In fatty acid oxidation defects, the metabolic block leads to accumulation of the fatty acyl-CoA substrate specific to the deficient enzyme; these species appear in blood as acylcarnitine esters. Analysis of plasma acylcarnitine profiles by tandem mass spectrometry often suggests a specific enzyme deficiency in children with suspected fatty acid oxidation disorders.[13] Diagnostic confirmation may require enzyme analysis in liver tissue or radiometric evaluation of fatty acid oxidation in cultured skin fibroblasts. For certain defects, molecular DNA analysis is clinically available. Two disorders, namely, MCADD[14] and LCHAD deficiency,[15] are associated with relatively common disease-causing mutations. Treatment of all disorders in this subgroup is based upon the provision of adequate nonfat calories and prevention of fasting. Generous IV glucose infusion is lifesaving and essential during acute episodes of metabolic decompensation. Chronic dietary therapy is tailored to the specific enzyme deficiency involved. Many practitioners prescribe carnitine supplementation, initially intravenously during an acute episode and later orally, but the efficacy of this intervention has not been formally investigated in any controlled clinical trial, and its use in disorders of long-chain fatty acid oxidation remains controversial.

Hypoglycemia following a short fast of only 4 to 6 hours is highly suggestive of a glycogen storage disease or a disorder of gluconeogenesis such as fructose 1,6-bisphosphatase deficiency. These disorders of energy deficiency are classified in subgroup D. These infants appear healthy while fed but quickly become obtunded and hypotonic with fasting hypoglycemia. Hepatomegaly is a prominent physical feature. During acute hypoglycemia, other biochemical derangements, including lactic acidosis, hypophosphatemia, hyperuricemia, and hypertriglyceridemia, are frequently present. Confirmation of the diagnosis may require a provocative fast under controlled conditions with continuous monitoring and, sometimes, measurement of glycogen content or enzymatic analysis on a liver biopsy specimen. Molecular DNA analyses are increasingly available for a less invasive approach to diagnostic confirmation in this class of diseases.

Group 3 Inborn Errors of Metabolism

Infants with group 3 IEMs display symptoms and a progressive clinical course suggestive of intoxication. In these infants, who appear completely healthy at birth and for the first few days of life, neurologic dysfunction appears as toxic metabolites accumulate with increasing food intake. Initial symptoms may include vomiting and lethargy that progress, perhaps over only a few hours, to complete coma or shock. This specific clinical presentation in particular suggests the possibility of bacterial or viral sepsis; evaluation for infectious disease is entirely appropriate. However, the clinician must remain alert to the possibility of an underlying IEM in a previously healthy infant suffering catastrophic illness within the first days of life. Group 3 IEMs can be subdivided into four subgroups (A through D) based upon specific clinical and laboratory findings (Table 76-7).

Maple syrup urine disease (MSUD), or branched-chain keto acid dehydrogenase (BCKD) deficiency, affects the catabolism of the branched-chain amino acids leucine, isoleucine, and valine and is the only disorder in subgroup A. Affected

Table 76–7 Features of Group 3 Inborn Errors of Metabolism

Clinical Features	Associated Laboratory Findings	Possible Diagnoses	Specialized Diagnostic Studies
Subgroup A			
Neurologic deterioration Coma Abnormal movements Hypertonia Sweet odor	Mild acidosis Normal lactate ± Ketonuria Normal ammonia + urine DNPH test	Maple syrup disease (branched-chain keto acid dehydrogenase deficiency)	Plasma amino acid analysis Urine organic acid analysis
Subgroup B			
Neurologic deterioration Coma Dehydration	Severe acidosis Severe ketonuria ± Hyperammonemia ± Lactic acidosis ± Hypoglycemia ± Neutropenia Negative urine DNPH test	Organic acidemias: Propionic acidemia Methylmalonic acidemia Isovaleric acidemia MCD deficiency Others	Urine organic acid analysis Plasma carnitine levels Plasma acylcarnitine profile Urine acylglycine profile Molecular DNA analysis
Subgroup C			
Neurologic deterioration Coma Seizures Hypotonia ± Liver dysfunction	Severe hyperammonemia No acidosis + Alkalosis Low BUN Normal glucose Normal lactate	Urea cycle disorders (CPS, OTC, ASS, ASL deficiencies) Triple H syndrome (hyperornithinemia-hyperammonemia-homocitrullinuria)	Plasma amino acid analysis Urine organic acid analysis Urine orotic acid Enzyme studies in liver or fibroblasts Molecular DNA analysis
Subgroup D			
Neurologic deterioration Hepatomegaly Liver dysfunction Cholestatic jaundice	Direct hyperbilirubinemia ± Hypoglycemia ± Acidosis ± Lactic acidosis ± Ketosis	Galactosemia Fructosemia Tyrosinemia type 1 Neonatal hemochromatosis Respiratory chain disorders	Urine reducing substances Plasma amino acid analysis Urine organic acid analysis Urine succinylacetone Enzyme studies Molecular DNA analysis

ASL, Argininosuccinate lyase; *ASS*, argininosuccinate synthetase; *BUN*, blood urea nitrogen; *CPS*, carbamyl phosphate synthetase; *DNPH*, dinitrophenylhydrazine; *MCD*, multiple carboxylase deficiency; *OTC*, ornithine transcarbamoylase.

infants present with coma; abnormal body movements including seizures; and, in contrast to many IEMs, hypertonia and opisthotonus. A severe burst-suppression pattern is the typical EEG abnormality. A sweet body odor, concentrated particularly in urine and cerumen, is often present. Mothers with previously affected children can often diagnose MSUD in a new infant by the presence of this odor. Routine laboratory studies may document mild metabolic acidosis and mild ketosis, but normal lactate and ammonia. The branched-chain keto acids that accumulate in MSUD react only slightly with the urine dipstick test for ketones but readily form a flocculent white precipitate with 2,4-dinitrophenylhydrazine (DNPH) in a urine metabolic screen. The presence and specific identities of branched-chain keto acids in urine are confirmed by urine organic acid analysis. Plasma amino acid analysis reveals tremendous elevation of leucine with lesser accumulations of valine and isoleucine. The neurologic symptoms associated with MSUD result entirely from leucine intoxication. Valine and isoleucine, which do not cross the blood-brain barrier as readily as leucine, seem to contribute little to the neurologic phenotype. Reduction of leucine levels in the body is the goal of MSUD treatment.[16] Emergency therapy during the initial clinical episode includes dietary protein restriction and IV infusion of dextrose-containing fluids. Hyponatremia is a common associated feature; IV hydration with hypotonic fluids easily exacerbates this problem. Additionally, leucine accumulates in CSF and brain and is strongly osmotically active. Rapid IV infusion of hypotonic solutions in several instances has led to acute cerebral edema and death. Dextrose solutions containing a minimum of 0.45% saline (one-half normal saline) are essential, but 10% dextrose with normal saline is preferred if the serum sodium concentration is greater than 135 mEq/L. With administration of IV dextrose, mild hyperglycemia secondary to insulin resistance may occur; inclusion of regular insulin (often only 0.05 units/kg body weight/hour) by either IV infusion or subcutaneous injection promotes anabolism, suppresses endogenous protein catabolism, and accelerates leucine clearance. The vitamin thiamine is a cofactor for BCKD; some individuals with BCKD deficiency (usually with a late rather than neonatal presentation) may respond clinically to thiamine supplementation. Oral thiamine (100 mg/day) is often given empirically to determine whether there is any effect on leucine levels. Once the diagnosis of MSUD is confirmed by plasma amino acid analysis, enteral feedings with a medical food that is free of branched-chain amino acids should be initiated, even if the infant is comatose and nasogastric feedings are necessary. Parenteral hydration should continue until results of urine ketone and DNPH tests are negative and full enteral feeds are reestablished. On this regimen, plasma valine and isoleucine levels plummet rapidly, but several days may be required before plasma leucine normalizes. The valine and isoleucine deficiencies that frequently develop on this regimen stimulate endogenous protein catabolism, which impairs reduction of blood leucine, prolongs neurologic impairment, and chronically may be associated with symptoms of protein insufficiency (hair loss, skin breakdown,

growth failure). Therefore valine and isoleucine supplementation (50 to 100 mg/kg/day) is required. Chronic lifelong therapy involves dietary protein restriction and provision of sufficient energy and amino acids in a leucine-free synthetic medical food. Despite this, infants who suffered prolonged severe leucinosis as neonates often exhibit significant developmental disability. Early diagnosis and appropriate therapy critically enhance neurodevelopmental outcome.

Severe ketoacidosis is the hallmark of IEMs in subgroup B, the organic acidemias. Methylmalonic, propionic, and isovaleric acidemias are the most common disorders in this subgroup. Infants with organic acidemia present with catastrophic episodes of vomiting, dehydration, and coma. Hypoglycemia, lactic acidosis, hyperammonemia, neutropenia, or pancytopenia may be associated findings depending upon the specific IEM. The urine dipstick test for ketones is strongly positive, but in contrast to MSUD, little precipitate forms following the addition of DNPH reagent to the urine. Identification of the specific offending organic acid is accomplished by urine organic acid analysis using gas chromatography-mass spectrometry. Diagnostic confirmation may require enzymatic analysis in tissues such as leukocytes, liver, or cultured skin fibroblasts. Molecular DNA analysis is increasingly available as a diagnostic modality as well. Cessation of protein intake, vigorous rehydration with dextrose-containing fluid, and management of acidosis with sodium bicarbonate infusion are the mainstays of emergency management. In severely acidotic patients, especially with associated hyperammonemia, hemodialysis may be useful for quickly removing both ammonia and the offending organic acid with the goal of minimizing CNS damage. IV infusion of L-carnitine (100 to 300 mg/kg/day) assists with the removal of the offending organic acid and prevents secondary carnitine deficiency. Oral L-glycine supplementation has a similar role in certain IEMs, most notably isovaleric acidemia. Chronic therapy is tailored to the specific enzyme deficiency but often involves dietary protein restriction and provision of a synthetic medical food supplying sufficient energy and amino acids. Recurrent episodes of life-threatening ketoacidosis and coma, generally triggered by fasting or intercurrent illness, are often the greatest long-term clinical difficulties.

Advancing dietary protein intake and normal protein catabolism during the first few days of life lead to severe hyperammonemia in infants with urea cycle and allied disorders (subgroup C). The clinical presentation is nonspecific, with progressive vomiting and neurologic dysfunction. Routine laboratory studies are generally deceptively normal, although the BUN often is below the limits of detection in infants who are unable to synthesize urea. No acidosis is present unless the infant is apneic or hypoperfused and secondary lactic acidosis has developed. Most severely hyperammonemic infants demonstrate respiratory alkalosis secondary to Kussmaul-like hyperventilation triggered by cerebral edema. Detection of hyperammonemia is the critical diagnostic key. The blood ammonia level must be measured in any child with acute-onset obtundation without a clear etiology such as trauma. Determination of the specific IEM involved requires analysis of blood amino acids and urine organic acids. Diagnostic confirmation is now often accomplished through molecular DNA analysis of specific genes involved in the urea cycle, but in rare instances, enzyme analysis in liver or for a few defects in cultured skin fibroblasts may yet be necessary if molecular testing is inconclusive. Provision of nonprotein energy and suppression of protein catabolism through IV dextrose infusion are essential, as in the organic acidemias, but emergency hemodialysis to rapidly decrease blood ammonia is absolutely required if any possibility of favorable neurodevelopmental outcome is to be preserved. Ammonia clearance by exchange transfusion or peritoneal dialysis is insufficient to accomplish this goal. Even with prompt hemodialysis, the metabolic derangement in some infants is so severe that little sustained decrease in blood ammonia is observed. Despite aggressive therapy, neonatal-onset urea cycle disorders are frequently lethal. The few infants exposed to hyperammonemia for a prolonged period who, because of extraordinary life-support efforts, survive are often profoundly neurologically impaired. On the other hand, clinical outcome is favorable in cases where blood ammonia levels rapidly correct on hemodialysis. This dichotomy in outcome presents a considerable dilemma to the intensivist faced with these critical treatment decisions. In practice, hemodialysis should be attempted as soon as possible after the discovery of hyperammonemia unless clinical signs of severe permanent CNS damage are already present. Disorder-specific therapy should continue for infants whose blood ammonia levels immediately normalize with hemodialysis. Aggressive life support measures should be limited for those infants with recalcitrant hyperammonemia. Following dialysis, generous IV hydration and provision of nonprotein calories should continue. The amino acid arginine, normally synthesized through the urea cycle, becomes an essential amino acid that must be provided exogenously in urea cycle disorders. L-Arginine hydrochloride is available for IV administration as 10% solution and should be added to the IV fluid bag to give 0.66 g arginine HCl/m^2/day (6 mL/kg/day in infants). The ammonia scavenging agents sodium phenylacetate and sodium benzoate are available as a combined IV solution (Ammonul, Ucyclyd Pharma). Administration of this solution dramatically improves ammonia clearance and is indicated for the acute management of the proximal urea cycle disorders, but it is associated with severe adverse effects including metabolic acidosis and erosive gastritis if administered inappropriately. Ammonul should be used only in consultation with a provider experienced with its administration and with careful monitoring. Long-term therapy is based upon dietary protein restriction and oral L-arginine or L-citrulline supplementation. Oral administration of sodium benzoate or sodium phenylbutyrate (Buphenyl, Ucyclyd) as ammonia scavengers is often prescribed. Episodes of fasting- or illness-induced hyperammonemic coma frequently recur. Management of recurrent hyperammonemia in a patient known to have a urea cycle disorder is similar to that outlined earlier but can be tailored to the specific defect. Liver transplantation is a viable treatment option for individuals suffering recurrent hyperammonemia and chronic clinical and developmental difficulties despite adequate nutritional and medical therapy.

Hepatomegaly, liver dysfunction, and cholestatic jaundice in association with neurologic deterioration are the central presenting features of IEM in subgroup D. For all of these disorders, the accumulating toxin is particularly damaging to hepatocellular function. Hypoglycemia, acidosis, and mild ketosis may be present. Bacterial infection, particularly urinary tract infection, bacteremia, or meningitis, often caused by *E. coli* or other gram-negative enteral flora, is a frequent occurrence in infants with galactosemia. The specific diagnosis is suggested by the clinical scenario and by the results of

screening laboratory studies. Infants with this clinical presentation who are breastfed or receiving cow's milk-based infant formula are at risk for symptoms of galactosemia, given that lactose (milk sugar) is a disaccharide of galactose and glucose. Infants receiving exclusively soy milk-based formula ingest little galactose. The predominant dietary carbohydrates in soy formula are fructose and glucose, so infants fed soy formula who have this clinical presentation are likely to have fructosemia rather than galactosemia. More typically, infants with fructosemia present clinically after the introduction of fruit to their diet. In either galactosemia or fructosemia, reducing sugars are detected in urine following ingestion of the offending sugar by the urine reducing substance test (Clinitest). Plasma tyrosine level is elevated, urine organic acid analysis displays metabolites from the tyrosine pathway, and succinylacetone is detected in the urine of children with tyrosinemia type I (fumarylacetoacetate hydrolase deficiency). Neonatal hemochromatosis can be diagnosed only on liver biopsy by staining for iron. Diagnostic confirmation differs for each disorder but may include further metabolite analyses, enzymatic analysis in tissue, or molecular DNA testing. Initial therapy is nonspecific: cessation of enteral feeding and IV infusion of dextrose-containing fluid. Once the exact diagnosis is known, a specific therapy plan can be developed. For the carbohydrate disorders, the offending sugar must be reduced or eliminated from the diet. Galactosemic infants are fed soy-milk based formulas only. After weaning, ingestion of dairy products, including baked goods prepared with dairy products, is strictly avoided. Similarly, fructosemic individuals must strenuously avoid any fructose-containing foods. In prior eras, cirrhosis and liver failure were the inevitable outcomes in children with tyrosinemia type I unless they received a liver transplant. Effective therapy that prevents liver degeneration in tyrosinemia has now been developed. The oral drug 2-(2-nitro-4-trifluoro-methylbenzoyl)-1,3-cyclohexanedione (NTBC) blocks tyrosine metabolism upstream from FAH and prevents accumulation of the intermediate metabolites that are toxic to hepatocytes.[17] This medication was highly successful in preventing cirrhosis in two separate clinical trials and has been approved by the United States Food and Drug Administration for general use. The long-term efficacy of NTBC therapy, particularly with regard to the incidence of hepatic adenoma, a common complication of tyrosinemia I, has yet to be proven.[18]

Summary

Most IEMs with symptom onset in the neonatal period emerge as one of the clinical presentations described. As mentioned previously, many of these IEMs have milder or late-onset forms that present with identical symptoms as described, but months or years after birth and often following the stress of fasting or intercurrent illness. These clinical scenarios provide a framework for the recognition, initial evaluation, and emergency treatment of infants with IEM. The remainder of this chapter focuses upon the differential diagnosis of select clinical situations encountered in the pediatric intensive care unit.

Metabolic Acidosis

The key to the differential diagnosis of metabolic acidosis is calculating the serum anion gap ($Na^+ - [Cl^- + HCO_3^-]$). This calculation, normally 10 to 15 mmol/L, represents the unmeasured negative ions, predominantly albumin, in blood. Normal anion gap acidosis (low serum HCO_3 but normal anion gap) is caused by excess bicarbonate loss from either the gut (diarrhea) or kidney (renal tubular acidosis). An elevated or so-called *positive anion gap* suggests the presence of another unmeasured anion. Incidentally, a low serum anion gap may be seen in extreme hypoalbuminemia, as occurs in nephrotic syndrome (see Chapters 68 and 71).

The differential diagnosis of positive anion gap metabolic acidosis in children is similar to that of adults (e.g., using a favorite mnemonic, such as MUDPILES or KETONES), but with the addition of another class of acidoses, the IEMs. Poisoning with methanol, ethanol, paraldehyde, isoniazid, or salicylates can be readily ruled out by history or drug screen. Uremia is also easily discovered by laboratory evaluation. The most common etiologies of a positive anion gap acidosis in children are ketosis, lactic acidosis, or a combination of the two. Extreme dehydration can cause both ketosis and lactic acidosis; these abnormalities are readily corrected with vigorous parenteral rehydration with dextrose-containing fluids. Persistent lactic acidosis suggests ongoing tissue damage from hypoxemia, hypoperfusion, or, more rarely, an inborn error of mitochondrial metabolism. It should be remembered that several organic acids, such as propionic and methylmalonic acids, react with the urinary ketones dipstick. These pathologic organic acids can be differentiated only from the more typical ketones, 3-hydroxybutyric and acetoacetic acids, by urine organic acid analysis. Severe positive anion gap metabolic acidosis that cannot be easily explained by the clinical context, especially if it occurs recurrently or is recalcitrant to parenteral fluid therapy, suggests an inborn error of organic acid metabolism and should be evaluated with a battery of screening metabolic studies, including plasma amino acid analysis, urine organic acid analysis, and urine qualitative metabolic screen.

Hypoglycemia

Hypoglycemia can be defined as a blood glucose concentration less than 40 mg/dL.[19] Low blood glucose may be present within the first few hours after birth, especially in preterm or low-birth-weight infants, but the capacity for effective gluconeogenesis and fatty acid oxidation is induced within the first day after birth. Therefore blood glucose less than 40 mg/dL is distinctly unusual after the first 24 hours of life, particularly in infants who have started feeding, and should be thoroughly investigated (Fig. 76-2). A review of hypoglycemia in infants and children along with a useful diagnostic algorithm have been published.[20] A detailed medical history and careful physical examination are essential to discovering the cause of hypoglycemia. The timing of hypoglycemia relative to feeding is a critical item of historical information. Persistent or postprandial hypoglycemia suggests hyperinsulinism. Hypoglycemia after a short fast (3 to 6 hours) along with permanent hepatomegaly suggests a glycogen storage disorder. Hypoglycemia following a longer fast (8 to 12 hours) suggests a defect in gluconeogenesis or a problem with utilization of fatty acids. The presence of ketones in urine (as measured qualitatively by urine dipstick) or in serum (quantitative measurement of 3-hydroxybutyrate or acetoacetate) is an important clue to the etiology of hypoglycemia. Ketosis during hypoglycemia demonstrates that insulin secretion is appropriately suppressed and that fatty acid mobilization and oxidation are

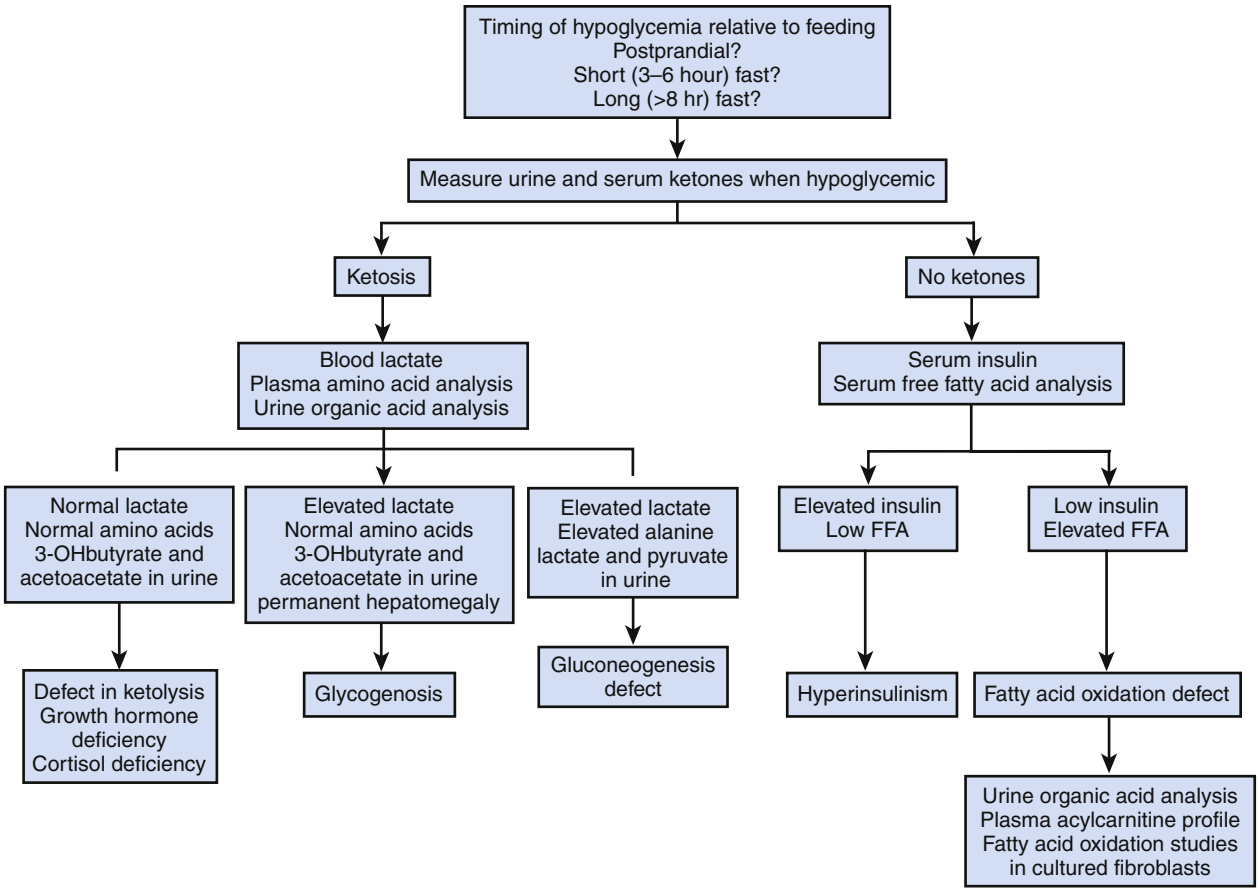

Figure 76–2. Algorithm for evaluation of hypoglycemia in children. *FFA,* Free fatty acid.

intact. Glycogen storage disorders, gluconeogenic defects, and defects of ketone utilization all are associated with ketosis. The absence of ketogenesis during hypoglycemia suggests that either insulin levels are inappropriately elevated or fatty acid oxidation is blocked. An important caveat to this rule is that infants younger than approximately 1 week cannot normally produce enough ketones during fasting to trigger a positive urine dipstick test for ketones. The absence of urine ketones in an infant younger than 1 week does not contribute to the differential diagnosis of hypoglycemia. On the other hand, serum ketones increase with fasting even in neonates, and this test provides a valuable result in the investigation of hypoglycemia. In hypoketotic hypoglycemia, measurement of total serum free fatty acids provides further useful diagnostic information. During fasting, insulin secretion normally is suppressed, free fatty acids are mobilized into circulation from peripheral adipose tissues, and ketones are produced by oxidation of fatty acids in liver. A low serum total free fatty acid level during hypoketotic hypoglycemia strongly suggests inappropriate insulin secretion, even if insulin levels do not appear to be dramatically elevated. Hypoketotic hypoglycemia in association with elevated serum total free fatty acids suggests a defect in fatty acid oxidation.

The importance of treating hypoglycemia cannot be overemphasized as affected individuals are at high risk for seizures and permanent brain damage.[21] After appropriate diagnostic studies are obtained, hypoglycemia should be treated with IV glucose administration at the rate of normal hepatic glucose production, approximately 10 mg glucose/kg body weight per minute or 150 mL/kg per day of a 10% solution until the underlying disorder is identified and more appropriate therapies can be initiated.

Hypoketotic hypoglycemia with low serum total free fatty acids suggests hyperinsulinism. Hyperinsulinism presenting in the newborn period may be caused by intrauterine exposure to elevated glucose levels (maternal diabetes mellitus), familial hyperinsulinemic hypoglycemia (defect in the sulfonylurea receptor), or hyperammonemia/hyperinsulinism syndrome (abnormality in regulation of insulin secretion secondary to mutation in glutamate dehydrogenase). Infants with hyperinsulinism often are obese and require glucose infusions greater than 10 mg/kg/min to maintain normoglycemia. Glucagon administration (0.03 mg/kg, up to 1 mg total dose) reverses hypoglycemia in hyperinsulinism. Oral diazoxide has not been shown to be efficacious in most neonatal cases; however, it can be effective in normalizing blood glucose levels in patients who have infantile forms of hyperinsulinism, including hyperammonemia/hyperinsulinism syndrome.[22] This usually is given at doses of 5 to 10 mg/kg/day divided into three doses. When initially administered, it is given along with glucose and glucagon. The efficacy of diazoxide is defined by demonstrating normal preprandial and postprandial glucose concentrations after overnight fasting and after having stopped IV glucose and any other medications for 5 consecutive days.

Hypoketotic hypoglycemia with elevated serum total free fatty acids, usually occurring following an extended fast (8 to 12 hours) or in association with an intercurrent illness, suggests a defect in fatty acid oxidation. The clinical presentation

of fatty acid oxidation disorders has been described. Although inherited deficiency of at least nine different enzymatic steps in the mitochondrial β-oxidation pathway has been described, the clinical presentation of infants and children with these diseases is stereotypically similar and can be differentiated only by appropriate metabolic testing. In all cases, vigorous hydration with dextrose-containing parenteral fluids is lifesaving. Fasting avoidance is key to long-term treatment and prevention of hypoglycemic episodes.

Infants and children with glycogen storage disorders present with hypoglycemia and permanent hepatomegaly. Hypoglycemia in these disorders is poorly responsive to glucagon administration. Enzymatic defects affecting glycogen synthesis, including glycogen synthase deficiency (GSD-0), as well as defects in glycogen breakdown, such as debranching enzyme deficiency (GSD-III), result in hypoglycemia. Glycogen synthase deficiency usually presents as severe morning hypoglycemia with hyperketonemia and low lactic acid and alanine. Debranching enzyme deficiency results in hypoglycemia secondary to limitation of glucose release from the outer branches of the glycogen molecule. Ketosis is present in GSD-III as the body attempts to generate fuel by increased fatty acid oxidation. Furthermore, the gluconeogenesis pathway is intact; thus hypoglycemia is much milder. In glucose 6-phosphatase deficiency (GSD-1a) and glucose 6-phosphate translocase deficiency (GSD-1b), hypoglycemia usually is apparent 2.5 to 3 hours postprandially as these disorders not only affect glucose release from glycogen but also disrupt gluconeogenesis. Individuals with these disorders have lactic acidosis, ketosis, and hyperuricemia in addition to hepatomegaly.

Hypoglycemia following a longer fast (8 to 12 hours) suggests a defect in gluconeogenesis, ketogenesis, ketolysis, or fatty acid oxidation. Fructose 1,6-bisphosphatase, a disorder of gluconeogenesis, presents as fasting hypoglycemia but also with metabolic decompensation following fructose ingestion. Ketonemia and lactic acidemia are major features, in addition to the hypoglycemia. The ketone synthesis defects that present with fasting hypoketotic hypoglycemia include 3-hydroxy-3-methylglutaryl-CoA synthase deficiency and 3-hydroxy-3-methylglutaryl CoA lyase deficiency. These patients have hypoglycemia in combination with normal blood lactate but no ketonuria. Infants with 3-hydroxy-3-methylglutaryl CoA lyase deficiency also are hyperammonemic. Defects in succinyl-CoA oxoacid transferase and methylacetoacetyl-CoA thiolase represent ketolysis defects. Although the consistent biochemical abnormality is severe ketoacidosis, hypoglycemia also can be seen. Blood lactic acid and ammonia concentrations usually are normal.

Cardiomyopathy and Inborn Errors of Metabolism

Cardiomyopathies, as a rule, are rare. Studies undertaken by the Pediatric Cardiomyopathy Registry have determined that the overall annual incidence is 11.8 per 1 million patient-years and that the incidence was higher in children younger than 1 year than in those between 1 and 18 years old.[23] In this regional study, 40% of cases were hypertrophic cardiomyopathies, 49% of cases were dilated cardiomyopathies, 3% of cases were restrictive or other types, and 8% were unspecified. Further study revealed that of cases of hypertrophic cardiomyopathy, 16% had an identifiable IEM as the underlying cause. These causes included disorders of glycogen metabolism (5%), mucopolysaccharide metabolism (4%), oxidative phosphorylation (5%), and fatty acid metabolism (2%). In the cases of dilated cardiomyopathy, 5% were found to be of a metabolic etiology with disorders of glycogen metabolism (1%), mucopolysaccharide metabolism (2%), and oxidative phosphorylation (2%) as the recognizable underlying cause. Thus it is important to consider IEM in the differential diagnosis of any child with dilated or hypertrophic cardiomyopathy. Because the prevalence of underlying metabolic disorders is so high, some authors have recommended that all children with cardiomyopathy undergo metabolic screening, including blood lactate, plasma amino acid analysis, urine organic acid analysis, urine metabolic screening (particularly for the detection of excessive urinary mucopolysaccharides), plasma carnitine levels, and plasma acylcarnitine profile (Box 76-4).[24] Additionally, serum creatine kinase (CK) should be measured to exclude muscular dystrophy.

Autosomal dominant hypertrophic cardiomyopathy has an incidence of 1:500 but demonstrates extremely variable penetrance. Mutations in genes encoding structural sarcomeric proteins are frequent causes of dominant hypertrophic cardiomyopathy. More than 140 mutations in 15 different genes have been identified.[25]

Cardiomyopathy may be a complicating feature of several IEMs (Table 76-8), but with a few exceptions, other associated symptoms or physical examination findings at the time of presentation point toward the appropriate diagnosis. Very broadly, the pathogenesis of cardiomyopathy in IEMs is either myocardial energy deficiency, as occurs in the dilated cardiomyopathy associated with several organic acidemias, or excessive storage of complex molecules in the heart, as occurs in the hypertrophic cardiomyopathy of mucopolysaccharidoses such as Hurler syndrome. Cardiomyopathy occurs as the sole initial clinical manifestation in a relatively restricted list of metabolic diseases, including autosomal recessively inherited deficiency of the cellular carnitine transporter, fatty acid oxidation disorders, glycogenosis types II and IX, and disorders of oxidative phosphorylation. The carnitine transporter defect is caused by deficiency of the sodium-dependent transporter OCTN2, which is responsible for transporting carnitine from the circulation into tissues including cardiac and skeletal muscle.[26] Dilated cardiomyopathy with symptoms of heart failure generally presents within the first years of life and is associated with severely low plasma total carnitine levels. Cardiac function improves dramatically after carnitine supplementation, and cardiomyopathy rarely recurs if carnitine is continued.

Hypertrophic cardiomyopathy resulting from myocardial steatosis may be an isolated presenting feature in several disorders of fatty acid oxidation, particularly those affecting

Table 76–8 Cardiomyopathy and Inborn Errors of Metabolism

Cardiomyopathy as the sole or key presenting feature	Carnitine transport defect
	Fatty acid oxidation defects including: VLCAD deficiency Mitochondrial trifunctional protein deficiency Carnitine palmitoyltransferase deficiency
	Glycogen storage disease type II (Pompe disease)
	Glycogen storage disease type IX (phosphorylase b kinase deficiency)
	Disorders of oxidative phosphorylation (mitochondrial myopathy)
Cardiomyopathy as a secondary feature	Organic acidemias, including: Propionic acidemia Methylmalonic acidemia 3-methylglutaconic aciduria D-2-hydroxyglutaric aciduria Biotinidase deficiency
	Glycogen storage disease type III
	Glycogen storage disease type IV
	Mucopolysaccharidoses
	Congenital disorders of glycosylation
	Congenital myotonic dystrophy
	Congenital muscular dystrophies

VLCAD, Very long chain acyl-CoA dehydrogenase.

long-chain fatty acid metabolism such as VLCAD or mitochondrial trifunctional protein deficiencies. Saudubray et al.[27] examined a series of 109 patients with fatty acid oxidation defects and found that cardiac involvement, including hypertrophic cardiomyopathy or arrhythmia, was apparent at presentation in 51% of cases. Fatty acid oxidation disorders are most reliably detected by analysis of plasma acylcarnitine profiles by tandem mass spectrometry. Long-chain fatty acids are activated to CoA derivatives and then esterified to carnitine prior to transport into mitochondria for β-oxidation. In fatty acid oxidation disorders, especially during acute metabolic decompensation, acylcarnitine species accumulate in plasma and provide a diagnostic profile that is specific to a given enzyme deficiency. Confirmation of the diagnosis may require enzymatic analysis in cultured fibroblasts or mutation analysis. Once the diagnosis of a long-chain fatty acid oxidation disorder has been established, restriction of dietary long-chain fat intake and provision of medium-chain triglyceride oil as an alternative fuel source for the myocardium often reverses cardiomyopathy. Cardiac support measures, including extracorporeal membrane oxygenation, may be necessary for as long as 1 to 2 weeks after presentation before heart function improves.

Glycogen storage disease type II (acid α-glucosidase deficiency; Pompe disease) is a disorder of lysosomal glycogen accumulation that frequently presents as hypertrophic cardiomyopathy, yielding the classic "boot-shaped" radiographic appearance of the cardiac silhouette. Skeletal myopathy manifesting as severe hypotonia may complicate the presentation. Confirmation of the diagnosis requires measurement of enzyme activity in skeletal or cardiac muscle or cultured fibroblasts. In the past, treatment has only been supportive, but enzyme replacement therapy is now available. IV infusion of recombinant acid a-glucosidase every other week has led to improved cardiac function, neuromuscular development, and survival in infants with Pompe disease.[28] However, antibody formation against the drug in some infants, with subsequently decreased treatment effectiveness, remains a clinical problem.

Myocardial function is highly dependent upon mitochondrial oxidative phosphorylation; up to 30% of the total myocardial volume is composed of mitochondria.[29] Dilated or hypertrophic cardiomyopathy is a frequent presenting feature in infants with severe defects of mitochondrial oxidative phosphorylation. Skeletal muscle myopathy, liver dysfunction, renal tubulopathy, bone marrow failure, or CNS abnormalities may occur. Chronic lactic acidosis, if present, is an important indicator of mitochondrial dysfunction. Screening metabolic laboratory studies demonstrate nonspecific abnormalities associated with chronic lactic acidosis. Definitive diagnosis requires histologic evaluation of skeletal muscle and measurement of respiratory chain enzyme activities. Isolated deficiency of cytochrome c oxidase (COX or complex IV) and reduced nicotinamide adenine dinucleotide (NADH)-ubiquinone oxidoreductase (complex I) of the mitochondrial respiratory chain are the most common oxidative phosphorylation defects presenting with cardiomyopathy. Although some protein subunits of complexes I and IV are encoded by mtDNA, most infant-onset isolated complex deficiencies probably are the result of autosomal-recessively inherited deficiency of nuclear-encoded respiratory chain subunits or of chaperone proteins that ensure proper assembly of functional complexes. For instance, hypertrophic cardiomyopathy caused by functional COX deficiency has been associated with mutations in nuclear COX subunit genes[30,31] or nuclear genes for COX associated-proteins SCO1 and SCO2.[32]

Cardiomyopathy may be seen in several other IEMs, but in these disorders, other physical or biochemical features are generally apparent at initial clinical presentation. For instance, dilated cardiomyopathy may complicate propionic acidemia during acute metabolic decompensation, but features of severe metabolic acidosis, vomiting, dehydration, coma, and possibly hyperammonemia are part of the initial clinical presentation.

Metabolic Myopathies and Rhabdomyolysis

Rhabdomyolysis is a clinical syndrome resulting from skeletal muscle injury and release of potentially toxic substances into the circulatory system. Acute onset of severe muscle pain associated with increased serum CK levels is the hallmark of the disorder. In extreme cases, massive myoglobinuria may cause acute renal insufficiency. Although trauma and direct muscle injury are by far the most common causes of rhabdomyolysis, inborn errors of muscle metabolism should be considered in the differential diagnosis of rhabdomyolysis occurring at any age. In the absence of a history of trauma, the differential diagnosis of acute rhabdomyolysis should include drug or toxin exposure, muscle hypoxia (often associated with seizures), temperature alterations, inflammatory diseases, and IEMs. Because muscle contraction depends upon adenosine triphosphate (ATP) generated by the mitochondrial electron

transport chain, it follows that any process that impairs muscle ATP synthesis or which results in energy expenditure that surpasses ATP production could lead to rhabdomyolysis. The clinical history should lead toward the appropriate diagnosis. A family history that includes rhabdomyolysis or a history in which more than one episode of exercise-induced rhabdomyolysis has been observed should induce suspicion of a metabolic disorder. Along with muscular dystrophy and endocrine etiologies (hypothyroidism, hyperthyroidism, diabetic ketoacidosis, pheochromocytoma), glycolytic defects, fatty acid oxidation disorders, purine biosynthetic disorders, and disorders of mitochondrial oxidative phosphorylation should be considered if historical elements do not direct toward the more common etiologies. As described previously, the fatty acid oxidation disorders can be detected by urine organic acid analysis and plasma acylcarnitine profile. Chronic lactic acidosis may be a clue to a disorder of oxidative phosphorylation. Measurement of blood lactate level before and after an exercise treadmill protocol may help detect a respiratory chain defect if the postexercise lactate level is severely elevated. Definitive diagnosis of a mitochondrial disorder requires histologic and enzymatic analysis of a fresh muscle biopsy. The glycolytic defects of phosphofructokinase and phosphoglycerate mutase deficiencies along with myophosphorylase deficiency (glycogen storage disease type V or McArdle disease) cause severe recurrent rhabdomyolysis; their detection requires enzymatic analysis of muscle tissue. Likewise, myoadenylate deaminase deficiency, a defect in purine catabolism, and CPT-II deficiency are also diagnosed by measurement of the enzyme activities in muscle.

Neonatal Screening for Inborn Errors of Metabolism

Newborn screening for IEMs was first introduced in the 1960s, with screening for phenylketonuria. Technological advances, most significantly the introduction of tandem mass spectrometry to mass screening, have greatly increased the number of disorders that can be identified by analysis of a dried blood spot on a filter paper card.[33] An expert review conducted by the American College of Medical Genetics led to the recommendation that 29 core conditions, including several aminoacidopathies, fatty acid oxidation defects, and organic acidurias detectable by tandem mass spectrometry, should be included in the panel of disorders screened.[34] As of 2009, all states in the United States and most of Europe have now adopted this recommendation. The cost versus benefits of expanded screening, whether to include specific very rare or poorly treatable disorders in the screening panel, and the availability of adequate follow-up resources continue to be debated, but a general consensus has emerged that expanded newborn screening is an effective tool for identifying IEMs early in life, allowing for the initiation of therapy, often before the infant becomes symptomatic, and for preventing morbidity and mortality associated with IEMs.[35] It must be remembered, however, that newborn screening is just that—a screen, and both false-positive and false-negative results are possible. Thus the astute clinician must remain cognizant of the fact that in an ill infant, a normal newborn screen is reassuring but should not be taken as absolute proof-positive that an IEM identifiable on newborn screen is not present. Appropriate screening laboratory evaluation and emergency treatment should be instituted if clinical signs and symptoms of an IEM are present in a sick child.

Conclusion

Inborn errors of metabolism are individually rare but collectively will make not-infrequent appearances in a busy pediatric ICU. The signs and symptoms of IEMs may be nonspecific and often overlap extensively with more common disorders. When clinical suspicion of an IEM arises, screening biochemical genetic laboratory studies must be ordered. Further confirmatory testing often is necessary if screening laboratory tests point toward a specific disease. Confirmatory testing and disease-specific therapy should be instituted following consultation with a biochemical genetics specialist. If detected and treated early, the clinical outcome for many IEMs can be favorable.

Common Endocrinopathies in the Pediatric Intensive Care Unit

Kalia P. Ulate and Jerry J. Zimmerman

PEARLS

- During stress, the endocrine system interacts synergistically with the neurogenic and inflammatory systems to mediate classic "fight or flight" responses.
- Cortisol, produced in the adrenal zona fasciculata, is a key mediator in directing the compensatory antiinflammatory response syndrome by modulating the transcription of thousands of genes, perhaps 20% of the entire genome.
- Critical illness–related corticosteroid insufficiency represents the most common cause of secondary adrenal failure seen in the intensive care unit. Critical illness–related corticosteroid insufficiency reflects a dynamic, typically reversible situation that is thought to result from both decreased cortisol production as well as tissue resistance to cortisol.
- Critical illness hyperglycemia is the result of inflammation-mediated increased endogenous glucose production and decreased utilization resulting from insulin resistance.
- Although the evidence regarding glycemic control and its benefits is controversial, it is difficult to ignore the convincing association that exists between hyperglycemia and morbidity and mortality, as well as the results of initial trials reporting a significant decrease in mortality when critically ill adult and pediatric patients were maintained in a euglycemic state.
- It is crucial that "critical" blood and urine samples be obtained prior to treating hypoglycemia unless one can be absolutely certain of the etiology of the hypoglycemia.
- Sick euthyroid syndrome, common among critically ill patients, is characterized by a rapid decrease in triiodotyrosine and a variable increase in reverse triiodotyrosine that appears to be proportional to the intensity of illness severity and concentration of TNF-α.

Functional Elements of the Stress Response

The stress response involves an integrated interaction between neurogenic, endocrine, and inflammatory systems, as indicated in Figure 77-1.[1-5]

Appendix materials for this chapter are available online at http://www.expertconsult.com.

A variety of afferent stimuli that include pain, sight, hearing, smell, pressure changes, chemical alterations, vascular stress receptors, as well as overt inflammation lead to two primary efferent responses: (1) increased sympathetic (and parasympathetic) nervous system activity, and (2) increased release of hypothalamus and pituitary hormones (counter-regulatory response). Catecholamine release inhibits insulin release and action and stimulates synthesis of glucagon, adrenocorticotropic hormone (ACTH), and antidiuretic hormone (ADH). Hypothalamic production of ADH facilitates water retention at the renal distal collecting tubule. Direct neuronal innervation of the kidney and changes in osmolality sensed at the juxtaglomerular apparatus result in activation of the renin-angiotensin-aldosterone axis, ultimately increasing systemic vascular resistance and facilitating sodium retention at the renal distal convoluted tubule, as indicated in Figure 77-2.

Hypothalamic-Pituitary-Adrenal Axis

Stressful stimuli lead to activation of the supraoptic and paraventricular nuclei of the hypothalamus, causing the release of ADH and corticotropic-releasing hormone, respectively.[3-5] Corticotropic-releasing hormone is transported via hypophysial portal capillaries to the anterior pituitary, facilitating the production of pro-opiomelanocortin, a 239 amino acid peptide that includes primary protein sequences for ACTH, β-lipotropin, β-endorphin, and melanocyte-stimulating hormone. ACTH is transported by the blood to the zona fasciculata of the adrenal gland, where it stimulates the de novo synthesis of cortisol. A schematic overview of the regulation of cortisol synthesis and secretion is provided in Appendix Figure 77-A (see http://www.expertconsult.com).[6]

Primary activation of the hypothalamic-pituitary-adrenal (HPA) axis in the intensive care unit (ICU) largely reflects the intensity of the systemic inflammatory response syndrome. Interleukin (IL)-6 has been shown to mediate lipopolysaccharide-induced ACTH secretion during infection and inflammation.[7]

IL-1 and IL-2 also stimulate cortisol production,[8,9] whereas tumor necrosis factor-α (TNF-α), macrophage inhibitory protein, and corticostatin (a peptide defensin with anti-ACTH activity) are believed to inhibit it. A general overview of

classic endocrinologic pathways affecting cortisol production is shown in Figure 77-3.

Cortisol Biochemistry

The starting point in all steroid hormone synthesis is the conversion of cholesterol into pregnenolone, which represents the rate-limiting step in cortisol production. It requires both mobilization of cholesterol from storage depots and its transfer to cytochrome P-450 located on the inner mitochondrial membrane that catalyzes side chain cleavage. Pregnenolone is then converted to 17-hydroxyprogesterone, and through the enzyme 21-β hydroxylase, it then is converted to 11-deoxycortisol. This process leads to a final key step in cortisol synthesis, the conversion of 11-deoxycortisol to cortisol by the enzyme 11-β hydroxylase, another specific cytochrome P-450 isoenzyme. Generation of a unique hydroxyl group at carbon 11 is essential for both the antiinflammatory and glucose homeostasis functions of cortisol. In addition, cortisol exhibits weak mineralocorticoid activity equivalent to approximately 1% that of aldosterone. A schematic overview of the biosynthesis of adrenal cortical hormones is summarized in Appendix Figure 77-B.[10]

A diurnal rhythm of cortisol production is noted among healthy individuals, with peak cortisol production typically between the hours of 8 and 9 AM and a nadir of cortisol production typically around midnight mediated by negative feedback mechanisms of the HPA axis. These regulatory mechanisms and diurnal variation are overridden during stress and critical illness because of the continued stimulus of ACTH secretion. Consequently a marked increase in cortisol levels is seen in critically ill patients with normal adrenal function. The physiologic adrenal production of cortisol is approximately 9 mg/m^2/day. Stress production of cortisol may reach 200 to 300 mg/day, resulting in a plasma total cortisol level occasionally exceeding 60 μg/dL. The mean and range of plasma cortisol concentrations as a function of age have been reported for normal children and may be found in Appendix Table 77-A.[11]

Although the plasma half-life for cortisol ranges from 80 to 115 minutes, biologic duration of action of cortisol is approximately 8 hours. Cortisol is catabolized by reduction of the steroid nucleus C4-C5 double bond, by reduction of the C3 ketone to a hydroxyl, by oxidation of the C11 hydroxyl group, or conjugation of the C11 hydroxyl group with either sulfate or glucuronic acid.

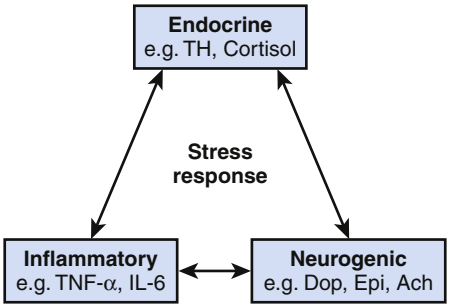

Figure 77–1. Neurogenic-endocrine-inflammation response to stress. *Ach,* Acetylcholine; *Dop,* dopamine; *Epi,* epinephrine; *IL-6*, interleukin-6; *TH,* thyroid hormone; *TNF-α*, tumor necrosis factor-α.

Actions of Cortisol

Cortisol is transported from the adrenal gland to various tissues via cortisol-binding globulins, namely transcortin, and albumin. Transcortin has a high affinity for cortisol but a low carrying capacity. The opposite is true for albumin.[12]

Cortisol diffuses through the plasma membrane by binding to the glucocorticoid receptor that is flanked by heat shock proteins (70, 90, and 56) for transport to the cell nucleus, where cortisol binds to glucocorticoid responsive elements. Once in the nucleus, cortisol modulates the transcription of thousands of genes, perhaps 20% of the entire genome.[13,14] Although the majority of corticosteroid action is related to changes in gene transcription, corticosteroids also decrease the stability of messenger ribonucleic acids, ultimately decreasing protein synthesis, including a number of inflammatory proteins.[13]

Cortisol affects three general areas of physiology, namely inflammation, hemodynamics, and metabolism.

Inflammation

Much critical illness is thought to be a product of a disturbance of the balance between systemic inflammatory responses (SIRS) versus compensatory anti-inflammatory responses.[15-17] Cortisol concentration is locally increased at sites of inflammation through degradation of transcortin by neutrophil elastase and by local up-regulation of 11 β-hydroxy steroid dehydrogenase, which converts cortisone to cortisol.

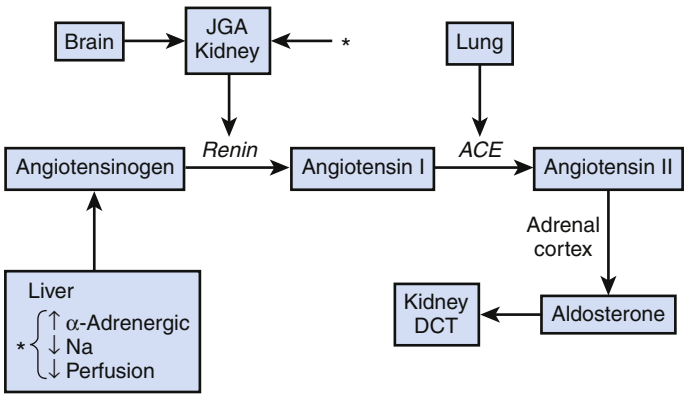

Figure 77–2. Renin-angiotensin-aldosterone axis. *ACE,* Angiotensin converting enzyme; *JGA,* juxtaglomerular apparatus.

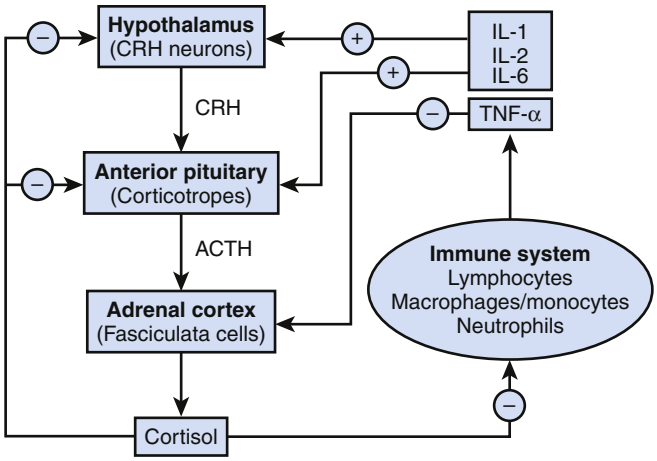

Figure 77–3. Signaling along the hypothalamic-pituitary-adrenal (HPA) axis. (+) Indicates stimulatory signaling and (–) indicates inhibitory signaling. In general, proinflammatory cytokines stimulate the HPA axis at the level of the hypothalamus and pituitary. It should be noted that TNF-α also inhibits cortisol production at the adrenal. Cortisol provides negative feedback relative to its own production, including its antiinflammatory action of inhibition of proinflammatory cytokines synthesis.

Cortisol plays a key antiinflammatory role. It inhibits the internalization of nuclear factor κB (NFκB) into the nucleus by increasing the synthesis of IkB, which traps NFκB in the cytoplasm and thus effectively thwarts the up-regulation and synthesis of a variety of proinflammatory genes and mediators. Similarly, cortisol blocks intranuclear NFκB binding to appropriate deoxyribonucleic acid promoter regions (Figure 77-4). Cortisol exhibits similar activity with nuclear transcription factor activator protein-1.

Furthermore, cortisol increases the production of annexin, which inhibits phospholipase A_2, resulting in an inhibition of both cyclooxygenase and lipoxygenase pathways and associated modulation of the synthesis of a variety of inflammatory lipids. In addition, cortisol decreases both B-cell and T-cell proliferation, increases apoptosis of both cell types, and inhibits inflammatory cell degranulation.

Less well recognized antiinflammatory effects of cortisol include the augmentation of macrophage inhibitory factor, activation of antiinflammatory acute phase proteins including IL-1 receptor antagonist, inhibition of inflammatory cell chemotaxis, down-regulation of adhesion molecules, and the inhibition of neutrophil adhesion and respiratory burst.

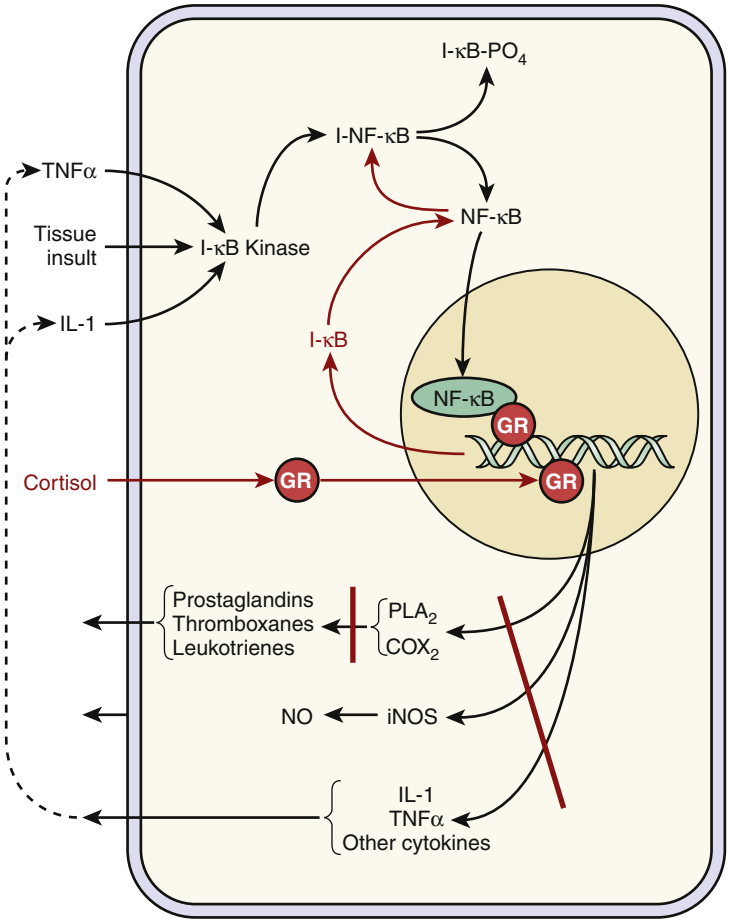

Figure 77–4. Antiinflammatory actions of cortisol. Cortisol facilitates the production of the inhibitor of NFκB (I-κB), which binds to NFκB and prevents it from entering the nucleus and activating target genes. Activated glucocorticoid receptor (GR) also interferes with NFκB binding to its response elements in deoxyribonucleic acid, thus preventing the induction of phospholipase A_2, cyclooxygenase 2 (COX2), and inducible nitric oxide synthase (iNOS). By blocking further production of proinflammatory cytokines such as tumor necrosis factor-α and interleukin-1, cortisol disrupts the positive feedback cycle involving these cytokines. *NO,* Nitric oxide. *(Modified from Goodman HM:* Basic medical endocrinology, *Boston, 2009, Elsevier, p 80.)*

Hemodynamics

Cortisol augments cardiac contractility, maintains vascular tone by inhibition of inducible nitric oxide (NO) synthase, ensures endothelial integrity, up-regulates vasoactive receptors, and increases catecholamine synthesis. These effects allow the maintenance of normal hemodynamics and are particularly important in the setting of sepsis, where proinflammatory cytokines mediate increased NO production, compromised endothelial integrity, systemic vasoplegia, and cytopathic dysoxia.

Metabolism

Cortisol promotes energy substrate mobilization through proteolysis, lipolysis, and gluconeogenesis. It exerts permissive actions on glucagon and is antagonistic to insulin. SIRS-activated and cortisol-facilitated lean muscle catabolism provides substrate for hepatic gluconeogenesis and synthesis of acute-phase reactants to cope with the adversity of critical illness but may be inexorably linked to significant corticosteroid adverse effects that may be life-threatening in the ICU. Increased cortisol concentration during stress represents a key mediator in hyperglycemia of critical illness, which will be discussed later. A schematic diagram of the effects of cortisol on metabolism is displayed in Figure 77-5.[10]

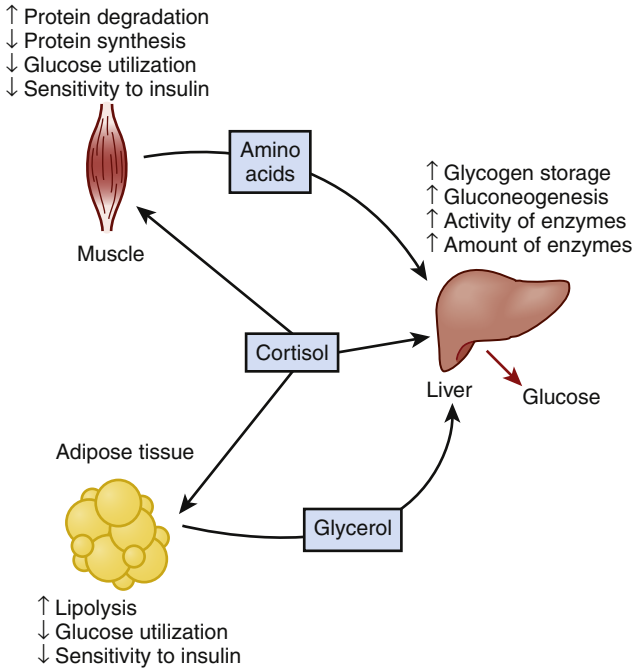

Figure 77–5. Schematic overview of metabolic actions of cortisol. *(Modified from Goodman HM:* Basic medical endocrinology, *Boston, 2009, Elsevier, p 76.)*

Assessing Adequacy of the Cortisol Stress Response

Historically, adrenal function during critical illness has been ascertained by random baseline plasma cortisol concentrations or by calculating the difference between a corticotropin-stimulated plasma cortisol concentration minus a baseline cortisol concentration. In the latter case a so-called δ value less than 9 μg/dL is considered evidence of inadequate adrenal reserve.[18] Depending on the cutoff value chosen (10, 15, 18, 20, or 25 μg/dL), critically ill patients may demonstrate a range of adrenal insufficiency occurrence when random baseline total plasma cortisol concentrations are evaluated.[19] Examples of cortisol testing are illustrated in Figure 77-6.

A normal total circulating cortisol concentration is typically in the range of 5 to 10 μg/dL. Patients with true adrenal insufficiency demonstrate concentrations below 5 μg/dL that do not increase with corticotropin or ACTH adrenal stimulation. In the setting of severe stress such as trauma, burns, or sepsis, a normal person typically increases circulating total cortisol twofold to fivefold, generally in the range of 25 to 50 μg/dL. Similarly, a normal person with adequate adrenal reserve will increase circulating total cortisol by at least 9 μg/dL following an exogenous dose of corticotropin. Traditionally, corticotropin stimulation testing has used a corticotropin dose of 250 μg or, alternatively, 145 μg/m^2 for children. It has been argued that such a pharmacologic dose of corticotropin may result in a nonsensitive stimulation test, and accordingly, a dose of 1 μg of corticotropin has been suggested.[20] However, the latter approach has not been scrutinized as rigorously as the higher dose. For example, more than 50% of a healthy adult cohort demonstrated a δ cortisol concentration less than 9 μg/dL with the low-dose corticotropin stimulation test.[21] A detailed evaluation of critically ill adults with sepsis indicated that patients with a high baseline plasma cortisol concentration but a δ

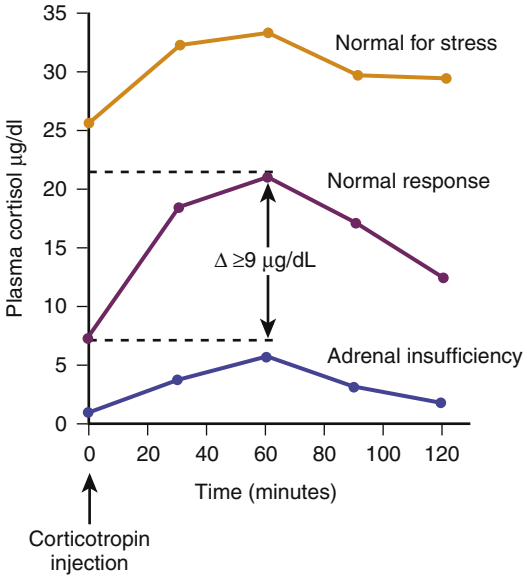

Figure 77–6. Cortisol testing in the pediatric intensive care unit. Normal serum total cortisol typically ranges from 5 to 10 μg/dL. Following intravenous corticotropin administration of 145 μg/m^2 (maximum 250 μg), cortisol concentrations between ~15 and 20 μg/dL are generally considered an appropriate response, which is a change from baseline of at least 9 μg/dL. Levels below 5 μg/dL are diagnostic of absolute adrenal insufficiency. Baseline cortisol concentration during severe stress should generally increase to levels exceeding 25 μg/dL.

cortisol concentration <9 μg/dL exhibited the highest risk for hemodynamic instability and mortality. In fact, a subsequent interventional trial of cortisol was designed based on these findings.[22]

Although the overnight metyrapone test is not generally applicable to critically ill patients, it has been used as a

gold standard in an attempt to identify a population with an apparent inadequate adrenal response to the stress of critical illness. Metyrapone administration will result in an increased ACTH and buildup of the cortisol precursor 11-β deoxycortisol. Among adult patients with severe sepsis, approximately 60% exhibited an abnormal cortisol stress response per the overnight metyrapone test. Best predictors of this situation included a baseline total cortisol concentration of ≤10 μg/dL, a δ cortisol concentration ≤9 μg/dL, or a free cortisol concentration <2 μg/dL.[18]

Free Cortisol

Although most cortisol is bound to transcortin or serum albumin, the free fraction comprising 10% to 15% of the total is actually responsible for the protean effects of cortisol. Accordingly, it has been suggested that perhaps free cortisol rather than total cortisol might be more reliable in terms of identifying a population that would most benefit from cortisol replacement therapy.[23] For most critically ill patients, cortisol-binding globulin is typically decreased and the percentage of cortisol as the free fraction is increased. Moreover, with corticotropin adrenal stimulation, the increase in the free cortisol concentration is greater than the increase in the total cortisol concentration.[24,25] Assessing total cortisol concentrations may be especially problematic in critically ill patients with low albumin concentrations.[23] Multiple limitations of corticotropin stimulation testing to assess total cortisol concentrations during critical illness have been summarized.[26] Free cortisol concentrations may be assessed in urine as well as in saliva,[27] but blood contamination of either specimen may limit this approach in the pediatric ICU (PICU). Recently it has been demonstrated that free cortisol concentrations may be determined among critically ill children in real time utilizing temperature-controlled centrifugal ultrafiltration and immunochemiluminescence assay.[28] However, what constitutes an adequate free cortisol response among critically ill patients, again with the intent of identifying a population who might benefit from cortisol supplementation, has not been ascertained.

Adrenal Insufficiency in the Intensive Care Unit

Adrenal insufficiency may be classified under two major categories: primary, where direct malformation or destruction of the adrenal glands occur, and secondary, where typically loss of HPA axis integrity occurs. The latter situation is most often encountered among critically ill patients.

Primary Adrenal Insufficiency

Thomas Addison first described primary adrenal insufficiency in his treatise, "On the Constitutional and Local Effects of Disease of the Suprarenal Capsules" in a manuscript published in London in 1855.[29] Addison's disease is more typically encountered in adult patients and is included in a group of disorders termed autoimmune adrenalitis.[30,31] Signs and symptoms of Addisonian crisis include intercurrent illness with a history of chronic weight loss and anorexia, dizziness, lethargy, and chronic pigmentation. Symptoms more likely to be associated with admission to the ICU include sudden hypovolemic shock, hyperkalemia, vomiting, diarrhea, abdominal pain, and coma. Other causes of primary adrenal failure include congenital adrenal hyperplasia, with approximately 95% of such cases secondary to 21 hydroxylase (CYP 21) deficiency. In this category, the next most common congenital inborn error of metabolism is 11 hydroxylase deficiency.[32] Primary congenital adrenal failure also can occur among infants with adrenoleukodystrophy associated with a metabolic defect in metabolism of very long chain fatty acids. Other causes of congenital adrenal failure include Wolman disease and familial unresponsiveness to ACTH.[33]

Because of its precarious circulation associated with a subcapsular arteriolar plexus, the adrenal glands are subject to hemorrhage and infarction, particularly in the setting of septic shock—the so-called *Waterhouse-Friderichsen syndrome*—initially described as adrenal apoplexy.[34,35] As indicated in Figure 77-7, a variety of drugs are known to inhibit various metabolic steps along the cortisol synthetic pathway.[6]

Prominent among these inhibitors of cortisol synthesis is etomidate, because it is increasingly being utilized as a sedative for endotracheal intubation to facilitate mechanical ventilation. In one study evaluating patients in an emergency department, more than 50% exhibited a δ cortisol concentration less than 9 μg/dL during a corticotropin stimulation test following etomidate sedation for endotracheal intubation.[36] Multiple other investigations report similar findings. In an observational cohort study of 60 children with meningococcal severe sepsis, it was noted that a single bolus of etomidate was associated with impaired adrenal function, specifically 11 β-hydroxylase activity.[37] Similarly, an important risk factor for adrenal insufficiency among adult ICU patients requiring mechanical ventilation was use of etomidate for sedation.[38] Some experts have advised eliminating the use of etomidate entirely from the ICU[39,40] because it may be an independent risk factor for mortality associated with acute adrenal insufficiency.

Secondary Adrenal Insufficiency

Secondary adrenal insufficiency in the PICU can be seen with pituitary disorders in which inadequate ACTH is produced in response to stress. Probably the most common example would be children undergoing surgical resection of a craniopharyngioma. In addition, long-term corticosteroid administration (e.g., among patients with recalcitrant asthma patients with oncologic or rheumatologic diagnoses, or transplantation patients) results in suppression of ACTH release, occasionally with resultant adrenal atrophy.

Probably the most common cause of secondary adrenal failure seen in the ICU is so-called *critical illness–related corticosteroid insufficiency* (CIRCI).[41] A seemingly inadequate adrenal response relative to the degree of stress characterizes CIRCI, which represents a dynamic, typically reversible situation that is thought to be a result of both decreased cortisol production as well as tissue resistance to cortisol. This resistance to cortisol may result from depletion of corticosteroid-binding globulins, activation of 11β-hydroxyl steroid dehydrogenase and other catabolic reactions, decreased glucocorticoid receptor density and activity, and elevated antiglucocorticoid compounds and receptors.[42-45] Currently CIRCI is thought to be best diagnosed by δ cortisol (following corticotropin stimulation) less than 9 μg/dL or a random total cortisol concentration of less than 10 μg/dL.[18,41]

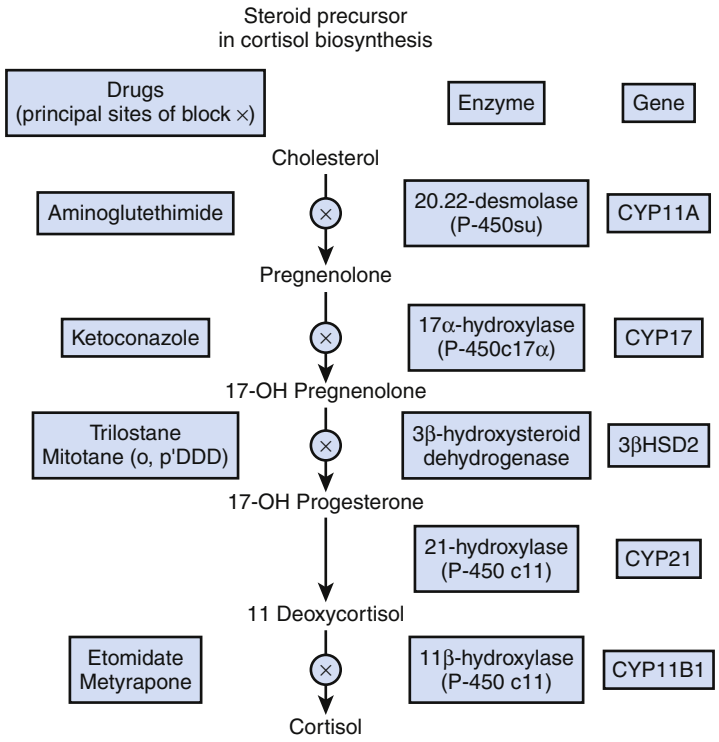

Figure 77–7. Inhibitors of cortisol synthesis. *(Modified from Belchetz P, Hammond P:* Diabetes and endocrinology, *London, 2003, Mosby Elsevier, p 286.)*

Multiple pediatric observational studies, most related to sepsis, have correlated random, baseline serum cortisol concentrations with various outcomes.[37,46-49] In summary, these studies indicated a loss of ACTH-cortisol circadian rhythm among children with sepsis. As critical illness severity increased (e.g., sepsis → septic shock → death from sepsis), proinflammatory mediators such as IL-6 and TNF-α, as well as ACTH, increased while cortisol concentrations decreased. Both serum cortisol and ACTH concentrations correlated with illness severity per pediatric risk of mortality and organ dysfunction scores, lactate, and C-reactive protein. Three pediatric observational studies also have examined corticotropin stimulation testing among children with severe sepsis.[50-52] These studies in general demonstrated that, like adults, an inadequate adrenal reserve is common among children with sepsis. For children with inadequate adrenal reserve, illness severity is increased, as is the requirement for vasoactive-inotropic resuscitation. Such children also more frequently demonstrate vasoactive-inotropic resistance shock and multiple organ dysfunction syndrome. Chronic illness, the degree of organ dysfunction at presentation, and an inadequate adrenal reserve (δ cortisol concentration <9 μg/dL) predicted risk of mortality.

Cortisol Replacement Studies

Adult Investigations

Most clinical investigations related to cortisol replacement therapy in the ICU have focused on patients with septic shock and unstable hemodynamic status despite both fluid and vasoactive-inotropic support. Several investigations examining high doses of methylprednisolone in the 1970s and 1980s found no benefit in terms of reduced mortality but increased risk of significant adverse effects. Subsequently, the notion of relative adrenal insufficiency or CIRCI emerged as a concept. Multiple investigations utilizing hydrocortisone instead of methylprednisolone administered at low stress doses consistently demonstrated hastened resolution from septic shock, and some investigations also reported reduced mortality with this alternative approach. A key hydrocortisone interventional trial was conducted among 19 adult ICUs in France.[53] In this investigation, 229 of 300 adult patients with septic shock (74%) demonstrated a δ cortisol concentration less than 9 μg/dL in a standard corticotropin adrenal stimulation test. Among this predefined group treatment, both low-dose hydrocortisone as well as fludrocortisones resulted in faster resolution of septic shock and reduced mortality. However, a follow-up trial, Corticosteroid Therapy of Septic Shock (CORTICUS, ClinicalTrials.gov number NCT00147004), which involved 499 adult patients with severe sepsis, did not confirm these findings. This investigation concluded that hydrocortisone did not improve survival among adults with septic shock but did hasten reversal of shock among patients in whom shock was reversed.[54]

Pediatric Investigations

Interventional clinical trials examining adjunctive corticosteroids for pediatric sepsis are sparse. Data regarding corticosteroid administration for pediatric Dengue fever are conflicting, and a Cochrane systematic review on this subject concluded no benefit from adjunctive corticosteroids for pediatric Dengue shock, summarizing four trials that enrolled a total of 284 subjects.[55] A retrospective descriptive investigation querying the Pediatric Health Information System concluded no benefit of adjunctive corticosteroids for pediatric sepsis, but this investigation was hampered by lack of illness severity data.[56] Subsequently a similar retrospective descriptive cohort study has been reported utilizing the database generated during the

Researching Severe Sepsis and Organ Dysfunction in Children: A Global Perspective (RESOLVE, F1K-MC-EVBP) trial of activated protein C for pediatric severe sepsis.[57] Among a cohort of 477 children with severe sepsis, baseline characteristics did not differ among children who did or did not receive corticosteroids. In particular, their mean pediatric risk of mortality III score and number of dysfunctional organs were similar. Indications for corticosteroid prescription (mostly hydrocortisone) were primarily therapeutic to address shock (89%). The 28-day mortality rate from all causes among children receiving and not receiving corticosteroids was 15% and 19%, respectively ($P = .30$). Similarly, no difference in mean days of vasoactive-inotropic infusion or mean days of mechanical ventilator support was found.

Current Guidelines for Corticosteroid Prescription in the Pediatric Intensive Care Unit

Septic Shock

The American College of Critical Care Medicine has provided updated recommendations for the diagnosis and management of corticosteroid insufficiency in critically ill adult patients.[41] Based on expert summary of six randomized controlled trials including a meta-analysis, they concluded that adults with recalcitrant septic shock may benefit from moderate doses of hydrocortisone (200 to 300 mg/day or a similar total daily dose administered by continuous intravenous infusion). Higher doses of corticosteroid equivalents appear to be associated with an increased incidence of adverse events.[41] Similarly updated clinical practice guidelines for hemodynamic support of children with septic shock recommend (albeit with no level I evidence) hydrocortisone replacement therapy if a child is at risk for adrenal insufficiency or HPA axis failure, for example, children with purpura fulminans, congenital adrenal hyperplasia, prior recent steroid exposure, and those who remain in shock despite high-dose vasoactive-inotropic and fluid resuscitation.[58]

Bronchopulmonary Dysplasia

Corticosteroids, typically dexamethasone, also have been utilized to decrease lung inflammation and the risk of subsequent bronchopulmonary dysplasia. In this setting a higher corticosteroid dose was associated with increased risk of neurodevelopmental impairment. Some authors have concluded that corticosteroids should not be administered to neonates with a low risk for bronchopulmonary dysplasia because there appears to be no "safe" window for corticosteroid administration among extremely low birth weight infants.[59]

Neonatal Hypotension

Hydrocortisone is also commonly used to treat hypotension among neonates. However, this practice may be associated with a higher incidence of intraventricular hemorrhage, periventricular leukomalacia, and death.[60] A meta-analysis demonstrated that hydrocortisone increases blood pressure and reduces vasoactive-inotropic requirements among hypotensive preterm neonates. However, the actual long-term clinical benefits of this practice remain unclear.[61] Long-term sequelae of hydrocortisone administered to hypotensive neonates are yet to be fully elucidated. Similarly, corticosteroids have been used to improve hemodynamic stability following neonatal/pediatric cardiac surgery. Variable practice precludes generalizations regarding the long-term benefits of this intervention.[62-64]

Acute Lung Injury/Acute Respiratory Distress Syndrome

Five randomized studies enrolling more than 500 adults have evaluated the role of corticosteroid treatment among patients with acute lung injury and acute respiratory distress syndrome (ARDS). These interventional trials consistently reported that corticosteroid treatment was associated with significant improvement in Pao_2/fraction of inspired oxygen (Fio_2) ratio, reduction in markers of systemic inflammation, duration of mechanical ventilation, and length of ICU stay. It has been recommended that moderate-dose corticosteroids be considered in the management strategy of adults with early severe ARDS and before day 14 in patients with unresolving ARDS.[41] Both methylprednisolone and hydrocortisone also have been used in this regard. Best available evidence suggests optimal initial administration of methylprednisolone as a continuous infusion with a total dose of 1 mg/kg/day.[41] Similar data are not currently available regarding children with acute lung injury/ARDS.

Postextubation Stridor

A Cochrane systematic review of 11 trials examining corticosteroids for the prevention and treatment of postextubation stridor in neonates, children, and adults (summarizing 2301 subjects) concluded that the prescription of corticosteroids to prevent or treat stridor after extubation has not been proven to be effective overall for neonates or children. However, this intervention merits further study, particularly for patients at high risk of having the extubation procedure fail. Studies of high-risk adults found multiple doses of corticosteroids initiated 12 to 24 hours before extubation to be helpful.[65]

Corticosteroid Adverse Effects

Relative to the relative balance of SIRS versus compensatory antiinflammatory response syndrome, excessive steroid administration has been associated with increased risk for hospital-acquired infection among adult patients with septic shock,[54] among children receiving hydrocortisone following surgery for congenital heart disease,[66] and among adults with trauma treated with corticosteroids.[67,68] Subjects enrolled in the CORTICUS trial who received hydrocortisone also exhibited a higher risk of both sepsis and septic shock.[54]

Dissolution of lean body mass mediated by both endogenous and exogenous corticosteroid administration is common in stress states. Although this response may be beneficial in the short term as previously noted, prolonged steroid-mediated muscle catabolism can be associated with prolonged ICU weakness and hyperglycemia. An overview of corticosteroid-mediated proteolysis is displayed in Figure 77-8.[69]

Prolonged ICU weakness has been associated with prolonged neuromuscular weakness and the need for continued mechanical ventilation even in the setting of resolved lung

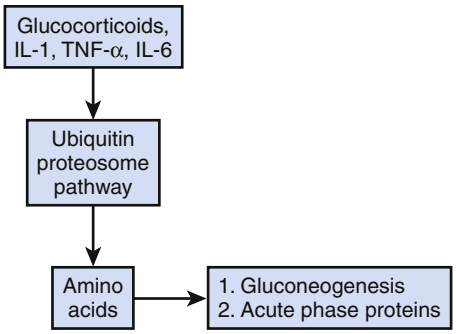

Figure 77–8. Proteolysis in catabolic states. Glucocorticoids, tumor necrosis factor-α, interleukin-1, and interleukin-6 stimulate the ubiquitin proteosome pathway, which causes proteolysis and amino acid release that are used as precursors of gluconeogenesis or in the synthesis of acute phase reactant proteins. *IL,* Interleukin; *TNF,* tumor necrosis factor.

disease,[70-73] whereas hyperglycemia has been associated with a variety of adverse events in the PICU, as detailed in the section of this chapter in which hyperglycemia is discussed. Additional important clinical consequences of protein catabolism that may be exaggerated by exogenous corticosteroid administration include impaired wound healing, hypoalbuminemia, disordered coagulation, and impaired gut function with bacterial translocation.[74]

In the CORTICUS trial,[54] transient hypernatremia also was noted among patients receiving hydrocortisone. Although gastrointestinal hemorrhage represented an important adverse effect in previous clinical trials examining the potential utility of high-dose methylprednisolone as adjunctive therapy in patients with sepsis, this adverse effect has not been problematic in later investigations utilizing low-dose hydrocortisone.

Long-term exposure to excessive corticosteroids results in Cushing's syndrome. In the absence of obvious exogenous steroid administration, Cushing's syndrome is diagnosed as a high 24-hour urine-free cortisol concentration that is not suppressed by administration of dexamethasone. Clinical characteristics of Cushing syndrome include hypertension, hypokalemic alkalosis, proximal myopathy, hyperglycemia, osteoporosis, opportunistic infections, psychiatric problems, and central obesity with characteristic striae.

Alterations of Glucose Homeostasis

Normal Glycemic Regulation

Euglycemia occurs when the rate of glucose utilization parallels the rate of glucose production or absorption. Following a glucose load, the body assumes an absorptive state, and its metabolic profile is primarily regulated by insulin. Insulin binds to a tyrosine kinase receptor on cell membranes and triggers a complex series of events that lead to insulin receptor substrate binding, recognition of the activated insulin receptor substrate by intracellular signal transducing proteins, and activation of postreceptor signaling pathways. This action activates phosphatidylinositol-3 kinase and nuclear gene expression modulating proteins. These in turn stimulate glycogen synthesis and inhibit glycogenolysis in liver and muscle, increase glucose uptake by increasing glucose transporter (GLUT)-4 on the cellular membrane, and downregulate the expression of phosphoenolpyruvate carboxykinase (PEPCK) and inhibits fructose 1,6 biphosphatase, the key rate-limiting steps of hepatic gluconeogenesis (Figure 77-9). Insulin also exerts lipogenic and antilipolytic effects.

During the fasting or postabsorptive state, glucagon is secreted. Glucagon opposes the effects of insulin on enzymes involved in glycogen mobilization and storage, thereby increasing glycogenolysis and decreasing glycogen synthesis, increasing gluconeogenesis through upregulation of PEPCK gene expression, and increasing ketogenesis. This oppositional action of glucagon toward insulin is shared by cortisol, epinephrine, and growth hormone and are all grouped together as counter-regulatory hormones.

Hormone release in response to serum glucose is regulated by the hypothalamus. It modulates autonomic efferent activity through signals received from peripheral (gustatory, intestinal, and hepatic) and central glucoreceptors. A glycemic rise activates the parasympathetic system and suppresses the sympathetic system, increasing insulin secretion through vagopancreatic stimulation. A drop in blood glucose produces the opposite response, thereby inhibiting insulin secretion and increasing counter-regulatory hormone secretion.[75] Euglycemia is maintained not only by a carefully orchestrated and dynamic combination of neuroendocrine mechanisms but also by hepatic autoregulation,[76] in which the liver controls hepatic glucose output in response to circulating glucose concentration.[77]

Glucose Uptake and Metabolism

Glucose enters the cell through GLUT-4 in insulin-dependent tissues (i.e., adipose tissue and cardiac and skeletal muscle) and through GLUT-1, GLUT-2, and GLUT-3 in non–insulin-dependent tissues. GLUT-1 and GLUT-3 have a high affinity for glucose and ensure its entry even during episodes of relative hypoglycemia. GLUT-1 and GLUT-3 are present in the brain, nerves, kidneys, and red blood cells. GLUT-2 is a low-affinity transporter present in the liver that captures excess glucose primarily for storage and ensures bidirectional flow for glucose output from the liver. Once glucose enters the cell, it is either stored as glycogen or metabolized for energy production or lipid synthesis.

Hyperglycemia

The American Diabetes Association defines hyperglycemia as a fasting glucose level more than 125 mg/dL. As many as 86% of patients admitted into a PICU were found to exhibit hyperglycemia at some point during their stay.[78] Once thought to simply represent an alteration of carbohydrate metabolism in response to severe stress,[79] hyperglycemia in critically ill adults and children has more recently received greater attention because of its association with increased morbidity and mortality.[80-84]

Etiology of Critical Illness Hyperglycemia

During the acute stages of illness there is an increase in glucagon, cortisol, growth hormone (GH), and catecholamine secretion. The resultant increase in gluconeogenesis and glycogenolysis raises serum glucose to levels that would, under physiologic circumstances, be enough to cause a decreased secretion of counter-regulatory hormones and an increase in

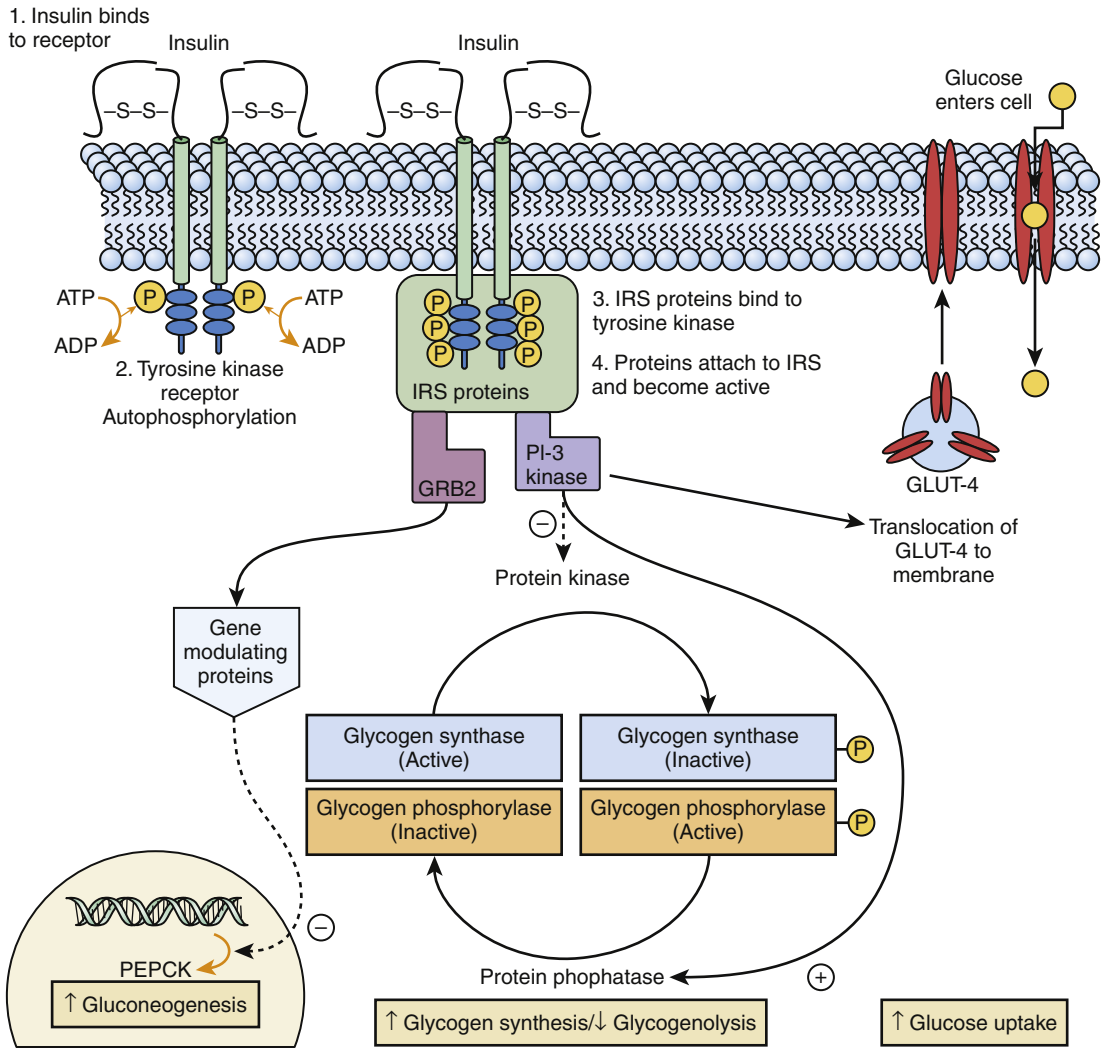

Figure 77–9. Insulin receptor signaling pathways. After insulin attaches to the receptor, it activates tyrosine kinase activity, causing it to autophosphorylate. Insulin receptor substrate (IRS) protein binds to the now active tyrosine kinase receptor. IRS then serves as a loading dock for several different proteins. Growth factor receptor-bound protein 2 (GRB2) is one of the proteins involved in signal transduction and will activate gene modulating proteins that inhibit phosphoenolpyruvate carboxykinase (PEPCK) expression in the nucleus, thereby decreasing gluconeogenesis. Phosphatidylinositol-3 kinase also becomes active after attaching to IRS and leads to inhibition of protein kinases and stimulation of protein phosphatases; this results in increased glycogen synthesis and decreased glycogenolysis. Phosphatidylinositol-3 kinase also leads to translocation of glucose transporter 4 (GLUT-4) to the membrane, therefore increasing glucose uptake.

insulin secretion. In critical illness, however, hyperglycemia is accompanied by persistently elevated levels of proinflammatory cytokines and stress hormones. Normal-to-high insulin levels fail to normalize blood glucose, which reflects insulin resistance. Recent evidence suggests that pediatric patients with cardiovascular and respiratory failure have an absolute rather than a relative insulin deficiency.[85] However, it is still unknown whether this deficiency is the result of a primary pancreatic β cell dysfunction in this subset of patients or β cell exhaustion resulting from severe insulin resistance.[86]

Critically ill patients may demonstrate hepatic and peripheral insulin resistance. In hepatic insulin resistance, high insulin levels fail to inhibit PEPCK expression, and gluconeogenesis continues in the presence of hyperglycemia. The mechanism by which insulin fails to dominantly inhibit PEPCK expression is not known. Although the mechanisms leading to peripheral insulin resistance in critically ill patients are not yet completely elucidated, evidence indicates that the defect lies primarily in the insulin-mediated glycogen synthesis pathway in skeletal muscle[87] and not in glucose oxidation.[88] Increased levels of counter-regulatory hormones, catecholamines, and inflammatory cytokines, particularly TNF-α, IL-1, and IL-6, have all been linked to the occurrence of insulin resistance.[89,90] TNF-α leads to decreased glycogen synthesis and glucose uptake by muscle cells in vitro by impairing insulin postreceptor signaling pathways.[89] Additionally, TNF-α induces peripheral resistance to GH,[91] leading to decreased insulin-like growth factor-1 levels and reduced inhibition of GH secretion through negative feedback, therefore markedly increasing the release of GH during acute stress. The combination of insulin resistance with high circulating levels of counter-regulatory hormones mediates a catabolic state previously discussed. Concomitant lipolysis causes an increase in free fatty acids (FFAs) that further exacerbates insulin resistance[92,93] by altering postreceptor signaling pathways and aggravates the inflammatory response.[94]

In summary, critical illness hyperglycemia is the result of inflammation-mediated increased endogenous glucose production and decreased utilization resulting from insulin resistance. Conditions that are unique to each patient, such as underlying comorbidities (e.g., hepatic dysfunction, obesity, and pre-existing insulin resistance), exogenous administration of glucose through the oral or parenteral route in the form of nutrition or dextrose diluted drugs, dialysate that contains dextrose, and exogenous corticosteroid and catecholamine administration also play an important role in the development of hyperglycemia in critically ill children.

Hyperglycemia and Outcomes

The association between hyperglycemia and adverse outcome measures has been well documented in adults admitted to ICUs.[81,95] More recently, the link between hyperglycemia and increased morbidity and mortality in critically ill children has been the target of investigation. Hyperglycemia has been associated with increased mortality in a variety of pediatric populations including children and neonates with respiratory failure,[96] congenital cardiac defects (following surgery),[97,98] septic shock,[99,100] severe burn injuries,[101] necrotizing enterocolitis,[102] and traumatic brain injuries and general critical illness.[78,103,104] The intensity and duration of hyperglycemia[78,97,98,104] and glucose variability[104,105] have all been found to be associated with poor outcomes among critically ill children, including increased rates of renal failure, liver dysfunction, adverse central nervous system events (e.g., hemorrhage, strokes, and seizures) and hospital-acquired infections.

Hyperglycemia Pathogenesis

The association between hyperglycemia and organ dysfunction or death might be as simple as the relationship between a surrogate marker of severity of illness or stress and the expected outcome. However, clinical and laboratory evidence suggests that hyperglycemia is more than an epiphenomenon.[106] Studies have shown that hyperglycemia adversely modulates both endogenous and pharmacologically induced cardioprotective signal transduction pathways,[107] increases myocardial infarction size, impairs endothelial function, and adversely affects coronary microcirculatory regulation.[108] Hyperglycemia also has been shown to increase systemic vascular resistance, decrease stroke volume, impair cardiac output in rats,[109] and promote cardiomyocyte damage and apoptosis.[110,111] In addition, hyperglycemia has been shown to contribute to renal mesangial cell apoptosis,[112] increase the risk of infection,[113,114] and worsen cerebral injury by adversely affecting the blood-brain barrier and augmenting ischemic injury.[115,116] Despite peripheral insulin resistance, stress increases whole body glucose uptake, which occurs at the expense of non–insulin-dependent tissues, especially those involved in the immune response.[117] Cytokines have been shown to up-regulate the expression of GLUT-1 and GLUT-3,[118,119] placing non–insulin-dependent tissues at risk for direct glucose toxicity in the presence of elevated plasma glucose levels.

Normally a small amount of superoxide is generated from the mitochondrial electron transport chain that is then cleared by manganese superoxide dismutase. In the presence of a cellular glucose overload, the rate of production of superoxide exceeds the enzyme's capacity to clear it. Superoxide then interacts with NO within the mitochondria to produce peroxynitrite. Production of peroxynitrite is further increased in critical illness because of increased NO availability resulting from a cytokine-induced activation of inducible NO synthase. Peroxynitrite has been shown to induce apoptosis in rodent cardiomyocytes,[120] thymocytes,[121] renal cells,[122] and neurons.[123] Furthermore, its production in the endothelium rapidly consumes NO and leads to endothelial dysfunction.[124]

Hyperglycemia has important effects on the immune system as well. It facilitates activation of NFκB, which governs inflammatory gene expression.[125] The effect hyperglycemia has on neutrophil chemotaxis, phagocytosis, and reactive oxygen species generation is controversial.[113] Hyperglycemia may hinder migration of neutrophils and macrophages to an infectious focus because of decreased microvasculature dilation and decreased blood flow to the area as a result of an impaired NO response to bradykinin. Additionally, by causing an increased expression of adhesion molecules on the endothelium, hyperglycemia decreases the number of free leukocytes available for migration.[126] Hyperglycemia also can impair complement fixation by IgG, and by attaching to the active site of C3, it can disenable complement binding to the microbial surface for opsonization.[113]

Management of Critical Illness Hyperglycemia

Clinical Trials

An initial landmark trial of intensive insulin therapy (IIT) was conducted in an adult surgical ICU.[83] Patients were randomly assigned to an IIT group to maintain blood glucose levels between 80 and 110 mg/dL or to a conventional treatment group in which administration of insulin was begun if glucose levels exceeded 215 mg/dL, and insulin was then titrated to maintain glucose levels between 180 and 200 mg/dL. A total of 1548 patients were enrolled in this study. IIT resulted in a decrease in the ICU death rate from 8.0% to 4.6% ($P < .04$), resulting in a 42% drop in ICU mortality and a 34% drop in overall in-hospital mortality. A reduction occurred in the incidence of bloodstream infections, acute renal failure requiring dialysis or hemofiltration, median number of red blood cell transfusions, critical illness polyneuropathy, and duration of mechanical ventilation and ICU length of stay in the IIT group.

A similar trial was subsequently conducted in the medical ICU of the same institution enrolling adult patients who were predicted to require at least 3 days of intensive care.[95] A total of 1200 patients were enrolled and randomized to IIT or conventional therapy in the same manner as the previous trial. Only 767 patients remained in the ICU for at least 3 days. In the intention to treat analysis, IIT did not significantly reduce in-hospital mortality. In fact, mortality was increased in patients in the IIT group who had an ICU length of stay of less than 3 days. However, in the patients who remained in the ICU for 3 or more days, in-hospital mortality was reduced from 52.5% to 43.0% ($P = .009$). Morbidity also was reduced in the IIT group, reflected as a reduction in newly acquired kidney injury, earlier weaning from mechanical ventilation, and shorter ICU and hospital lengths of stay. Hypoglycemia occurred more frequently in the IIT group and was identified as an independent risk factor for death by logistic regression analysis.

Subsequent studies have yielded conflicting results. A multicenter randomized trial, Volume Substitution and Insulin

Therapy in Severe Sepsis (VISEP), that examined the effect of insulin therapy in severe sepsis was terminated early after the first safety analysis because of a significantly increased number of hypoglycemic events in the IIT group compared with the conventional insulin therapy group.[127] No difference in morbidity or mortality was found between the IIT and conventional therapy groups. Another recent large randomized multicenter trial examined the effects of IIT on outcomes of 6104 critically ill adult patients admitted to surgical or medical ICUs.[127a] Only patients thought to require at least 3 days of intensive care were enrolled in the study. IIT (glycemic target: 81 to 108 mg/dL), was not associated with a significantly different ICU or hospital length of stay, duration of mechanical ventilation, need for renal replacement therapy, incidence of infection, rate of red blood cell transfusion, or new single or multiple organ failures when compared with a conventional treatment group (glycemic target <180 mg/dL). In addition, IIT was not only associated with a higher incidence of hypoglycemia but also with a higher mortality than was conventional glycemic control.

To date two meta-analyses have been published evaluating the effects of glycemic control on outcomes in critically ill adults.[128,129] In the first study, strict glycemic control did not confer any survival benefit over conventional therapy and placed patients at a significantly higher risk of hypoglycemia. The subsequent meta-analysis reported similar results but differed in that IIT was associated with decreased mortality in critically ill adult surgical patients. In this study, the incidence of hypoglycemia also was found to be higher among patients in the ITT group and did not vary by type of ICU or insulin dose.

Few similar pediatric studies have been published. In a neonatal multicenter trial, very low birth weight infants were randomly assigned to an early insulin group and a control group.[130] Patients in the early insulin group were assigned a fixed insulin dose with additional dextrose to maintain euglycemia from 24 hours from birth until 7 days of age. Patients in the control group only received additional glucose or insulin in the setting of hypoglycemia or hyperglycemia, respectively. Although hyperglycemia and weight loss during the first week was significantly less frequent in the early insulin therapy group, mortality at 28 days was significantly higher in this group than in the control group. Hypoglycemia was significantly more frequent in the early insulin therapy group compared with the control group (29% vs. 17%). This trial was prematurely stopped because of increased mortality rates and increased incidence of intraventricular hemorrhages and brain parenchymal lesions in the insulin therapy group.

Most recently a randomized control trial studied the effect of strict glycemic control on outcomes of critically ill children.[131] Seven hundred patients were randomly assigned to IIT and control groups. Patients assigned to the IIT group were targeted to maintain blood glucose levels at age-adjusted fasting normoglycemic levels. Patients in the control group were treated with insulin if blood glucose level exceeded 214 mg/dL on two occasions and was then targeted to maintain glucose levels between 180 mg/dL and 214 mg/dL. Patients in the IIT group had significantly lower mean glucose concentrations and a higher incidence of hypoglycemia (25% in the IIT group vs 1% in conventional group; $P < .0001$). When compared with the control group, patients in the IIT group had shorter lengths of ICU and hospital stay and an attenuated inflammatory response, as per reduction in C-reactive protein levels. Mortality was significantly lower in the IIT group (3%) compared with the control group (6%).

Although intensive glycemic control has become ubiquitous to many adult ICUs and recommendations to implement glycemic control in this setting have been issued by the American Diabetes Association and American Association of Clinical Endocrinologists,[132] currently insufficient evidence exists to adopt glycemic control as the standard of care for critically ill children, and accordingly at this time no professional organizations have issued position statements regarding glycemic control for critically ill children.

The Ideal Glycemic Target

As glycemic control strategies are permeating into pediatric intensive care practice, the ideal glycemic target for our patients is still subject to debate. However, it is very likely that the same glycemic control targets used for critically ill adult patients might not be appropriate for the entire pediatric age spectrum. One must take into consideration that strict glycemic control trials have been set to maintain normal fasting glucose levels for patients, or, as in the most recent pediatric trial, to maintain levels within age-adjusted fasting normoglycemic ranges. However, most patients in the critical care setting are not truly fasting. Patients generally receive some form of nutrition through intravenous or parenteral routes. A fasting glucose level therefore may not be the ideal target for these patients, especially when one considers the increased incidence of hypoglycemia seen in the IIT groups of the existing pediatric trials of glycemic control. Hypoglycemia can have serious repercussions, particularly in the developing brain,[133,134] and it has been associated with increased morbidity and mortality in pediatric patients.[104] Observational studies suggest that glycemic ranges not strictly in the euglycemic range may accrue a mortality benefit[135] and be associated with a lower incidence of hypoglycemia.[136]

Recently, a protocolized approach to identify and manage hyperglycemia in critically ill patients was successfully and safely implemented in a PICU and in pediatric postoperative cardiothoracic surgery patients, in which a glycemic target of 80 to 140 mg/dL was safely maintained.[137,138] However, because the protocol was applied to all patients in that unit, it is unknown whether any benefit was obtained from maintenance in this range. To date no pediatric randomized controlled trials have been performed to examine the potential benefit of a more permissive target.

Summary

Hyperglycemia is common in PICUs and is a result of a combination of insulin resistance, conditions that are unique to each patient, and iatrogenic effects from various therapies. Although the evidence on glycemic control and its benefits is controversial, it is difficult to ignore the convincing association that exists between hyperglycemia and mortality and the results of initial trials reporting a significant decrease in mortality when a euglycemic state was maintained for critically ill adult and pediatric patients. Studies that refute this evidence have demonstrated an increased incidence of hypoglycemia in their study patients, which makes it difficult to discern whether glycemic control has not led to improved outcomes or whether its benefit is obscured by the deleterious effects of hypoglycemia. The practice of glycemic control in pediatrics behooves further study. Large pediatric randomized control trials need to be performed

to confirm a benefit from ITT and to refine its practice so that children may reap the potential benefits of strict glycemic control without being placed at increased risk of harm.

Hypoglycemia

Definition

The definition of hypoglycemia has been controversial. Historically its diagnosis was made upon satisfaction of the Whipple's triad, which includes presence of clinical manifestations of hypoglycemia, a low blood glucose concentration coincident with the timing of the manifestations, and the resolution of the signs and symptoms when normoglycemia is reestablished. The triad dates back to the 1930s, when in the absence of current imaging and laboratory diagnostic techniques, criteria were developed to minimize unwarranted surgical intervention for insulinoma. These criteria have fallen out of surgical favor and instead are now applied as the classic definition of symptomatic hypoglycemia and are used by many practitioners to guide therapy for hypoglycemia. This triad, although very helpful in other clinical settings, is of little value in the ICU, where the signs and symptoms of hypoglycemia may not be evident in patients who often are sedated and undergoing neuromuscular blockade.

Although the determination of which glucose levels represent hypoglycemia is controversial, a glucose level less than 40 mg/dL is generally accepted to be in the hypoglycemic range. However, this concentration is well below the level at which counter-regulatory responses occur. As plasma glucose levels reach 80 to 85 mg/dL, insulin secretion decreases, and as levels approximate 65 mg/dL, glucagon, epinephrine, cortisol, and growth hormone are released.[139] In addition, a decrease in mental efficiency may be seen when levels fall below 50 to 60 mg/dL.[140] Because a delay in the recognition and management of hypoglycemia may lead to long-term neurologic sequelae,[141] it is important to make a distinction between the laboratory diagnosis of hypoglycemia (<40 to 50 mg/dL) and an interventional threshold at which therapies to raise serum glucose will be applied. Setting the interventional threshold at a level similar to that which elicits counter-regulatory responses seems appropriate, and as such, treatment should be offered for hypoglycemia when levels fall below 60 mg/dL to prevent complications, especially in young children. An even higher interventional threshold (<70 mg/dL) is warranted for children who are at increased risk of hypoglycemia.

Pathogenesis

Imaging studies of infants who sustained neonatal hypoglycemic brain injury display diffuse cortical and subcortical white matter damage that is most prominent in the parietal and occipital lobes. This pattern differs from the neuroimaging features of other neonatal insults, including hypoxic-ischemic encephalopathy.[142] Interestingly this pattern does not resemble the glucose uptake pattern of neonatal brains by positron emission tomography,[143] which may indicate that neuronal damage is not simply due to cerebral deprivation of its primary substrate for energy production. Evidence indicates that hypoglycemia activates receptors for excitatory amino acids within the brain and causes cell depolarization, with subsequent cellular edema and apoptosis.[144] Slow correction of hypoglycemic coma[145] and induced hypothermia prior to glucose reperfusion[146] were shown to be protective in animal models by reducing reperfusion-associated superoxide production and by decreasing cerebral metabolism. Thus neuronal injury might occur not only during the hypoglycemic event but during glucose reperfusion, which triggers neuronal death. Studies of its kind have not been performed in humans and likely would be impractical, yet we should consider careful correction of hypoglycemia to avoid large, sudden swings in blood glucose levels because glucose variability has also been associated with mortality in critically ill patients.[146a]

Clinical Manifestations

Diaphoresis, tremor, tachycardia, anxiety, weakness, hunger, nausea, and vomiting are all autonomic manifestations caused by an adrenergic stress response that occurs with a rapid decline in blood glucose levels. Other symptoms that are associated with hypoglycemia are a result of a deficiency of the brain's primary energy substrate and as such are known as neuroglycopenic symptoms. These symptoms include headache, visual disturbances, lethargy, restlessness, irritability, dysarthria, confusion, somnolence, stupor, coma, hypothermia, seizures, and motor and sensory disturbances. The glycemic ranges at which these symptoms manifest vary, and in many cases they may be asymptomatic or masked by sedatives and muscle relaxants.

Fasting Adaptation

Consumption of glucose is largely dependent on the brain-to-body ratio. This phenomenon explains the reduced fasting tolerance of infants whose glucose utilization rate (approximately 6 mg/kg/min) is much greater than that of older children and adults (1 to 2 mg/kg/min). This reality places younger patients at increased risk of hypoglycemia. In addition, their ability to maintain euglycemia through glycogenolysis and gluconeogenesis is reduced because glycogen stores and muscle bulk are small, thus having a smaller pool of available gluconeogenic substrates. Fasting tolerance increases rapidly in the first days of life. Neonates may fast up to 18 hours after 1 week of age. By 1 year a 24-hour fast is tolerated, and by 5 years a child may fast for up to 36 hours without experiencing hypoglycemia.[147]

Understanding fasting physiology is crucial to the logic and methodologic approach that is required for diagnosing the etiology of hypoglycemia. Normally in the postabsorptive state, metabolism is governed primarily by counter-regulatory hormones. In the first 4 hours of a fast in infants or in the first 8 hours in older children, glucagon is released and euglycemia is maintained primarily by glycogenolysis. Following glycogen store depletion, gluconeogenesis gains importance in the maintenance of normal glucose levels (Figure 77-10).

Muscle provides amino acids, particularly alanine and glutamine as gluconeogenic substrates. Glycerol 3-phosphate derived from triglyceride hydrolysis is also a gluconeogenic precursor. Fatty acids resulting from triglyceride hydrolysis are transported to the liver where they are oxidized to generate acetyl coenzyme A and ketones. The latter may then be used as alternative fuel by skeletal and cardiac muscle to help ensure availability of glucose to the brain and to erythrocytes that are strictly dependent on glucose for energy production. The brain also may utilize ketones as an alternative fuel source, but it does so only during a prolonged fast.

Hypoglycemia that occurs early during fasting should be a clue regarding a hormonal imbalance or a primary disorder of glycogenolysis. Disorders of gluconeogenesis will not manifest

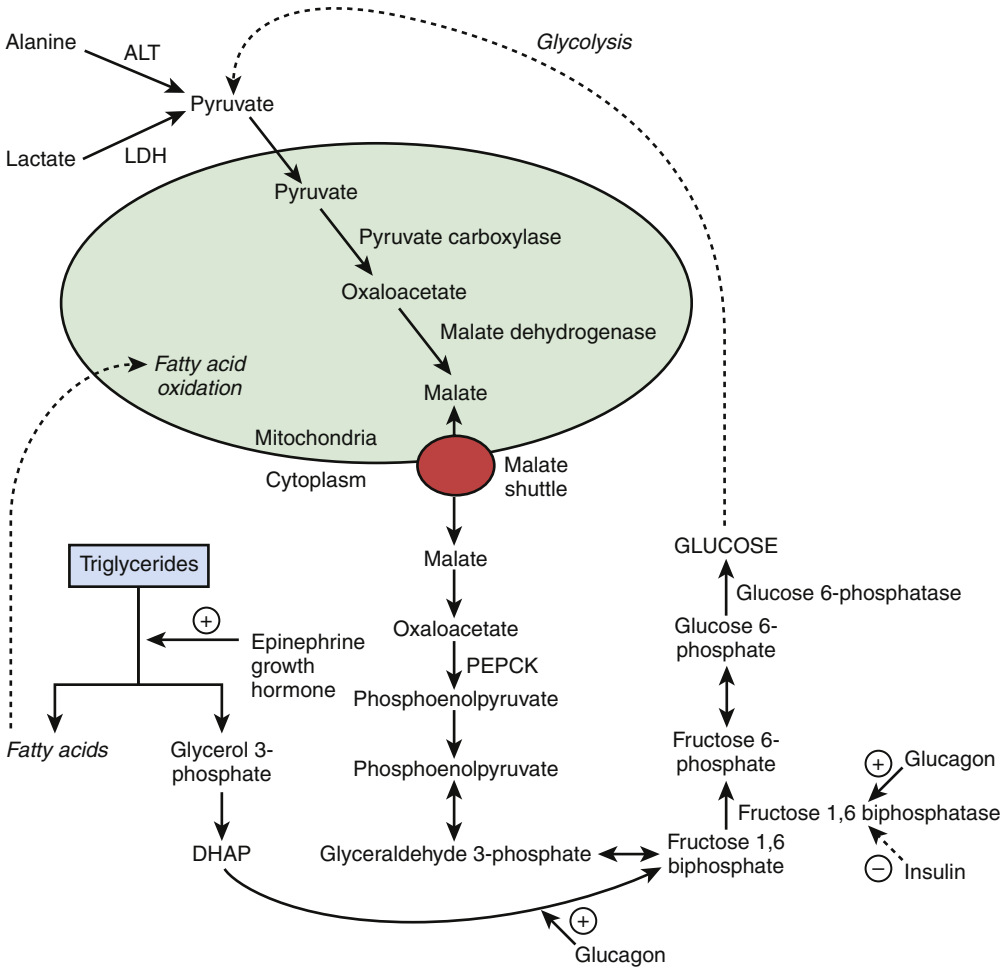

Figure 77–10. Schematic overview of gluconeogenesis. Pyruvate is generated from glycolysis, lactate, or alanine through pyruvate kinase, lactate dehydrogenase (LDH), and alanine-amino transferase (ALT), respectively. Pyruvate enters the mitochondria freely and is converted into oxaloacetate, which is then converted into malate in order to enter the malate shuttle and cross the mitochondrial membrane into the cytoplasm, where it is again converted into oxaloacetate and through phosphoenolpyruvate carboxykinase (PEPCK) is converted into phosphoenolpyruvate that goes through the series of enzymatic-driven reactions depicted and is finally converted into glucose. Note that one of the rate-limiting steps of gluconeogenesis is the conversion of fructose biphosphate into fructose 6-phosphate and is regulated by the actions of glucagon (stimulates) and insulin (inhibits) on fructose 1,6 biphosphatase. Triglycerides also contribute to gluconeogenesis by their breakdown into fatty acids and glycerol 3-phophate, which is then transformed into dihydroacetone phosphate and then into fructose 1,6 biphosphate to follow the rest of the gluconeogenic pathway and result in the generation of glucose.

after an early fast. They become apparent only after glycogen stores have been depleted; hence typically they present later in infancy once feeding intervals become increasingly prolonged. The same is true for fatty oxidation disorders. These disorders generally require a more prolonged fast to manifest, nearing 12 to 18 hours in infants and 18 to 24 hours in older children.

Diagnostic Approach

The history at presentation and the timing of hypoglycemia in relation to the last meal help differentiate disorders of glycogenolysis that present in the immediate postprandial period from disorders of gluconeogenesis, fatty acid oxidation defects, and hormonal imbalances that have a later onset. Physical examination also may suggest the diagnosis. Large-for-gestational-age neonates suggest hyperinsulinism. Midline defects, microphallus, and optic nerve atrophy are suggestive of hypopituitarism. Some glycogen storage disorders are associated with marked hepatomegaly. Ambiguous genitalia in an infant or hyperpigmentation in an older child suggest adrenal insufficiency. Abnormal neuromuscular signs may indicate adrenal leukodystrophy or a fatty acid oxidation defect. However, although a thorough history and physical aid in the diagnosis, physical examination findings often are absent or subtle, and even when they are present and clearly suggestive of a diagnosis, confirmatory laboratory testing is necessary. Therefore it is crucial that "critical" blood and urine samples be obtained prior to treating hypoglycemia unless one can be absolutely certain of the etiology of the hypoglycemia. If the etiology is uncertain, these samples must be obtained and tests performed as outlined in Figure 77-11.

This testing is the most valuable step in the evaluation of the hypoglycemic child. It will quickly point toward a particular pathway of glucose homeostasis that is dysfunctional, help guide further work-up, and may eliminate the need to do a formal diagnostic fast study with its inherent risks. One of the most important differentiations to be made in the work-up of a hypoglycemic child is whether hypoglycemia is accompanied by acidosis.

In an intact gluconeogenic pathway, all gluconeogenic substrates must be exhausted prior to the onset of hypoglycemia;

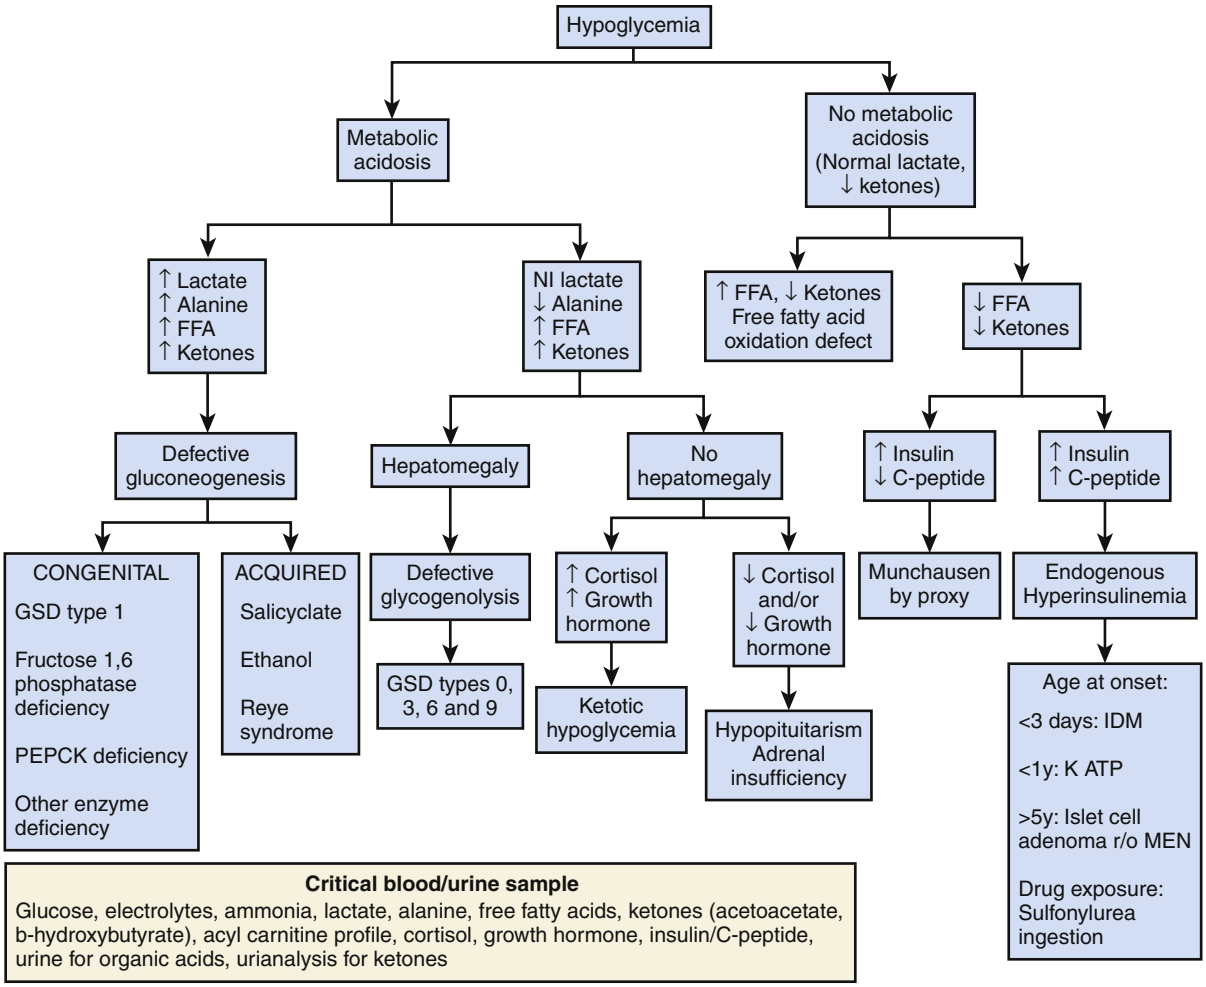

Figure 77–11. Algorithmic approach to hypoglycemia. *FFA,* Free fatty acids; *GSD,* glycogen storage disease; IDM, infant of diabetic mother; *MEN,* multiple endocrine neoplasia; *PEPCK,* phosphoenolpyruvate carboxykinase; K_{ATP}, potassium adenosine triphosphate channel hyperinsulinism, persistent hyperinsulinemic hypoglycemia of infancy.

therefore, lactic acid should not be elevated. The presence of lactic acidosis suggests a defect of gluconeogenesis if no other causes for increased lactic acid, such as shock, are present. On the other hand, the presence of ketoacidosis with a normal lactate points toward a defect of glycogenolysis, ketotic hypoglycemia, or a hormonal deficiency. In these conditions lactate and alanine are low, reflecting normal gluconeogenesis. As the body turns to fat as the primary source of substrate for energy production, increased ketone production occurs. A rise in free fatty acids without an associated elevation in serum ketones during a hypoglycemic event points toward a fatty acid oxidation defect. Decreased FFAs strongly suggests endogenous or exogenous hyperinsulinism because of the antilypolytic effect of insulin.

Defects of Gluconeogenesis

Deficiencies of pyruvate carboxylase, PEPCK, and fructose 1,6 biphosphatase are two of the major enzymatic defects responsible for inadequate gluconeogenesis. Glucose 6-phosphate deficiency (glycogen storage disease [GSD] type 1) is a combined defect of gluconeogenesis and glycogenolysis, because this enzyme is the common final step of both processes. Although most disorders of gluconeogenesis typically manifest after a 4- to 8-hour fast, GSD type 1 presents after an extremely brief postprandial period because of the combined gluconeogenic and glycogenolytic impairment. Its clinical presentation is that of severe hypoglycemia, hepatomegaly, hyperlipidemia, hyperuricemia, and hyperketonemia. Inadequate availability of gluconeogenic substrate and inability to utilize these substrates appropriately are seen with inborn errors of metabolism such as hereditary fructose intolerance (fructose 1-phosphate aldolase deficiency) and galactosemia (see Chapter 76). Gluconeogenesis also may be impaired by drugs such as alcohol[148] and aspirin[149] and may be associated with profound hypoglycemia.

Defective Glycogen Storage and Mobilization

GSDs are, for the most part, defects not in the storage of glucose in the form of glycogen but rather in the "un-storage" of glucose from glycogen. Only glycogen storage disease 0 (glycogen synthase deficiency) represents a defect of glycogen synthesis, and it is rare. Other disorders that are classified as GSDs reflect defects of glycogen breakdown. With the exception of GSD type 1, all other GSDs are associated with minimal to no hypoglycemia because gluconeogenesis usually can maintain normoglycemia in these patients. GSD types III (glycogen debranching enzyme), VI (hepatic glycogen phosphorylase),

and IX (phosphorylase kinase deficiency) are associated with mild hypoglycemia and usually present with associated liver enlargement.

Ketotic Hypoglycemia

In a normal person who is allowed to fast long enough hypoglycemia will develop along with increased ketones. Similar symptomatology develops in patients with this diagnosis, but typically after a short fast, in some cases as short as a few hours. Metabolic pathways are generally intact. Ketotic hypoglycemia is rare before the age of 6 months, subsides before puberty, and is common in children with a low body mass index.[150] It is generally considered a benign condition because sequelae are rare. A lower substrate pool due to decreased muscle mass,[150] insufficient ketone body use, and unrecognized hepatic glycogen synthase deficiency[151] have all been proposed causes, although the definite etiology remains unclear. The low alanine levels during fasting suggest that a limited gluconeogenic supply could be responsible, although some investigators propose that ketotic hypoglycemia represents the end of the Gaussian curve for normal fasting tolerance.[152]

Hormonal Deficiencies

Deficiencies in any of the counter-regulatory hormones can lead to hypoglycemia. Hypopituitarism with isolated GH deficiency and panhypopituitarism with decreased ACTH release typically present during infancy. The latter usually occurs in association with an intercurrent illness that unmasks an impaired cortisol response to stress. Adrenal insufficiency from other causes should be considered in the differential diagnosis of a critically ill child with hypoglycemia because, as previously discussed, multiple factors place such patients at increased risk for CIRCI. Measurement of hormonal levels during the hypoglycemic event will demonstrate inappropriately normal or low levels of these hormones.

Fatty Acid Oxidation Disorders

An increase in FFAs without increased ketonemia suggests a dysfunction in the oxidation of FFAs and conversion into ketones, either as a problem related to transport of these acids into the mitochondria or because of a metabolic defect in the β-oxidative process (see Chapter 74). These problems generally manifest after a 12-hour fast or after a shorter fast if it is associated with an intercurrent illness that places the patient in a catabolic state. Patients may present with encephalopathy and increased ammonia levels, and if it is unrecognized, the condition may be fatal. Fatty acid oxidation defects may be diagnosed by analysis of an acylcarnitine profile and urine for organic acids and by genomic profiling. Carnitine transport deficiency may present with cardiomyopathy, and carnitine supplementation may be life saving.[153] Treatment includes avoidance of fasting and quick reversal of hypoglycemia. Of note, valproic acid may interfere with fatty acid oxidation and mimic these disorders, leading some experts to recommend carnitine supplementation in infants treated with this anticonvulsant agent.[154]

Hyperinsulinism

An elevated insulin level in the presence of hypoglycemia is an inappropriate response to fasting and is diagnostic of hyperinsulinism. The high insulin levels cause an inhibition of gluconeogenesis and lipolysis. Therefore these patients have normal lactate and low FFA and ketone levels in their serum. Measurement of C-peptide differentiates between exogenous hyperinsulinism as seen in Munchausen by proxy and endogenous hyperinsulinism. When endogenous hyperinsulinism presents in the first 3 days of life, it is generally explained by persistently elevated insulin secretion in the neonate after being accustomed to a hyperglycemic environment in utero, as is the case among infants of diabetic mothers or among infants subject to perinatal stress. More than 90% of patients in whom hyperinsulinism persists have K_{ATP} channel hyperinsulinism, formerly known as persistent hyperinsulinemic hypoglycemia of infancy. Potassium flow through this channel regulates insulin secretion. When glucose enters the β cell and undergoes glycolysis, the generation of ATP causes closure of the K_{ATP} channel and stops potassium efflux from the cell. This phenomenon generates a positive membrane potential, and cell depolarization occurs, which in turn causes calcium channels to open, and insulin granules are released. When intracellular glucose levels are low, ATP is decreased and K_{ATP} channels open, allowing potassium to leave the cell and maintain a negative potential, causing closure of calcium channels and inhibiting glucose release. Genetic mutations that cause loss of function of the K_{ATP} channel cause it to remain closed and allow for a constant positive membrane potential and persistent insulin release despite low glucose levels and decreased ATP production[155] as schematically depicted in Appendix Figure 77-C.

Different modes of inheritance exist, with autosomal recessive inheritance operative in the most severe form. Other modes of inheritance are another homozygous form with a single recessive paternal gene mutation with loss of the normal maternal allele (focal adenomatosis), and a milder autosomal dominant form. Treatment consists of diazoxide, but it may be ineffective. Octreotide is an alternative. If hypoglycemia persists despite medical management, pancreatectomy may be necessary.

When hyperinsulinism presents after infancy, insulinoma and multiple endocrine neoplasia enter into the differential diagnosis. Sulfonylurea, quinine, and pentamidine also may augment insulin secretion and mediate hypoglycemia in cases of intentional or accidental ingestion. A detailed history about medications in the home must be obtained in all patients presenting with hypoglycemia.

Hypoglycemia and Critical Illness

Hypoglycemia has been observed in association with a variety of diagnoses, including sepsis,[156] congestive heart failure,[157] renal failure,[158] liver failure,[159] and pancreatitis,[160] and it has been associated with increased mortality among critically ill children.[136,161] Critically ill patients are at risk of hypoglycemia, not only because of their underlying illness but because of factors unique to their hospitalization, such as muscular atrophy from prolonged immobilization and gluconeogenic substrate depletion, undernutrition often resulting from the limitation of caloric intake because of fluid restriction, increased glucose consumption, adrenal insufficiency, loss of intravenous access or inadvertent disconnection of infusion lines, or iatrogenic factors related to drugs and therapies, including the practice of strict glycemic control.

Hypoglycemia Treatment

After obtaining the "critical" blood/urine samples, the administration of 2 mL/kg of 10% dextrose water solution is indicated for patients with hypoglycemia. An intravenous maintenance

fluid regimen should be initiated to provide a glucose infusion rate of 8 mg/kg/min. Serum glucose should be rechecked 15 minutes after the initial bolus, and if hypoglycemia persists, a repeat bolus of 5 mL/kg of 10% dextrose water and an increase in the glucose infusion rate by 50% is recommended. If the amount of fluid to be administered in order to maintain a glucose infusion rate that will maintain blood glucose levels at greater than 70 mg/dL is excessive, a fluid with a higher dextrose concentration should be used to prevent fluid overload. Glucagon (0.03 mg/kg) can reverse hypoglycemia in patients with adequate glycogen stores and normal glycogenolytic pathways. Definitive treatment will depend on the underlying etiology. Avoidance of long fasts for patients with fatty acid oxidation defects, appropriate supplementation for patients with hormonal deficiencies, and continuous gavage feedings for patients with severe fasting intolerance may be needed.

Summary

Hypoglycemia is a manifestation of iatrogenesis, intentional or accidental drug ingestion or administration, or the manifestation of an underlying disorder. All critically ill patients with hypoglycemia should raise a high index of suspicion because many defects that cause hypoglycemia remain silent until an intercurrent illness or stress overwhelm the compensatory capacity of the individual. Unless certitude of the etiology of the hypoglycemia exists prior to therapy, a "critical" blood/urine sample should be obtained whenever possible prior to correction of the hypoglycemia to guide diagnosis and further management. Prompt recognition and treatment are necessary to prevent neurologic injury. A multidisciplinary approach is often necessary.

Alterations of Thyroid Hormone in Critical Illness

Classic Thyroid Endocrinology

Thyroid-stimulating hormone (TSH), which is derived from the anterior pituitary, is a pleiotropic hormone that affects basically all aspects of thyroid hormone synthesis. TSH action within the thyroid follicular cells facilitates the sodium iodide symporter, resulting in iodide trapping in the thyroid gland; it increases the synthesis of thyroglobulin (the site of tyrosine residues destined for derivation of thyroid hormones) and activates thyroid peroxidase, resulting in so-called *organification* or iodination and coupling of tyrosine residues. It is important to note that autoantibodies may bind to TSH receptors and stimulate a response similar to TSH, resulting in a hyperthyroid state.

Thyroid Hormone Biochemistry

An overview of thyroid hormone biosynthesis and secretion is provided in Figure 77-12.[10] In this schematic diagram, iodide is transported into the thyroid follicular cell

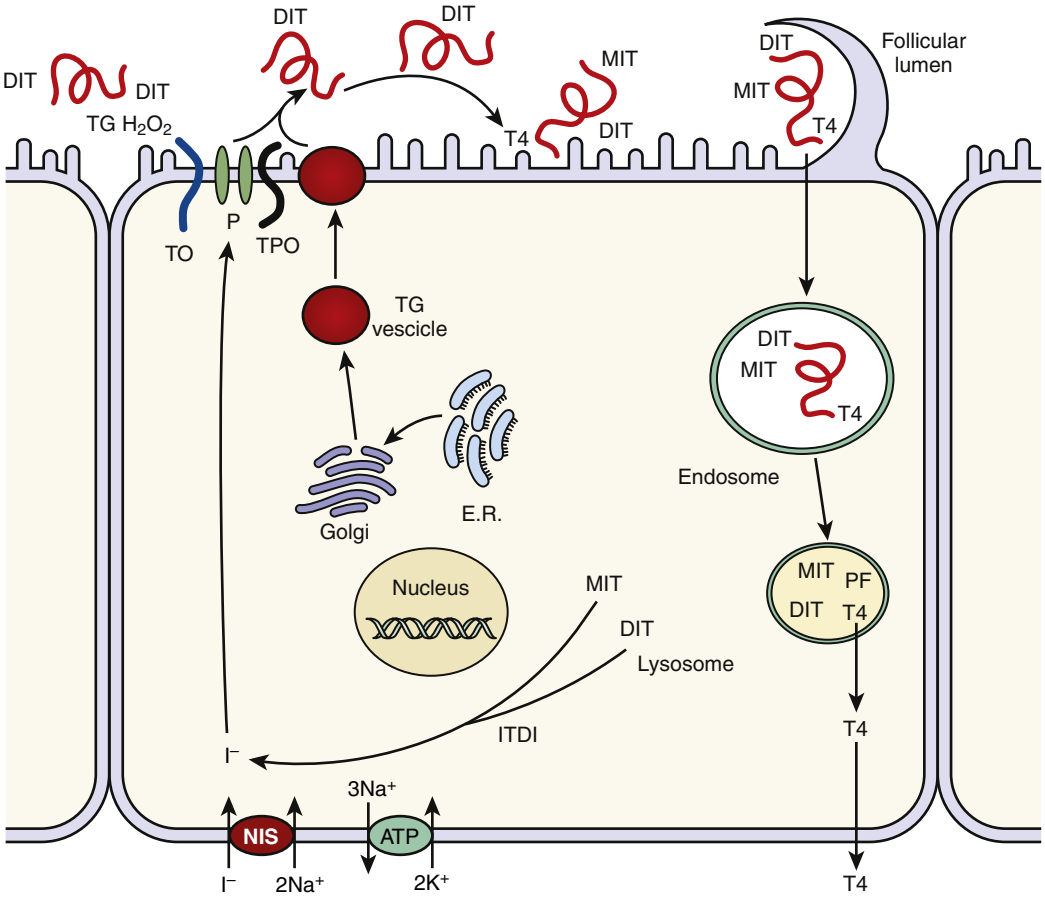

Figure 77–12. Thyroid hormone biosynthesis and secretion. *(Adapted from Goodman HM:* Basic medical endocrinology, *Boston, 2009, Elsevier, p 45.)*

by the action of the sodium-iodide symporter. Subsequently this iodide diffuses passively through the iodide channel, termed pendrin. Thyroglobulin (TG) is synthesized within the rough endoplasmic reticulum and subsequently is packaged by the Golgi apparatus into TG secretory vesicles that are released into the follicular cell lumen. Thyroid oxidase produces hydrogen peroxide that is subsequently utilized by thyroid peroxidase to oxidize iodide to iodine. Iodine then reacts with the tyrosine residues within TG to produce monoiodotyrosine and diiodotyrosine residues within the TG peptide.

Thyroid peroxidase also catalyzes coupling of adjacent iodotyrosines to form thyroxin (T4), as well as lesser amounts of triiodothyronine. Secretion of T4 from the thyroid follicular cell begins with TG phagocytosis and formation of TG endosomes that then fuse with lysosomes containing proteolytic enzymes capable of digesting TG into peptide fragments, as well as monoiodotyrosine, diiodotyrosine, and tT4. T4 is released from the cell at the basal membrane, and both monoiodotyrosine and diiodotyrosine are deiodinated by iodotyrosine deiodinase and recycled.

T4 is transported to peripheral tissues via the transport hormones T4-binding globulin, transthyretin, and albumin. Because all of the T4 transport proteins are of at least moderate size, T4 is not filtered by the kidney. In peripheral tissues, T4 is metabolized to triiodotyrosine (T3) and reverse T3 (rT3) by the action of various isoforms of iodotyrosine deiodinases. Transcription and translation of this enzyme is highly dependent upon cytokine stimulation. If monodeiodination occurs on the outer tyrosine ring the product is T3, and if the monodeiodination occurs on the inner tyrosine ring the resultant product is rT3 (Figure 77-3).[10]

In peripheral tissues, T3 binds to thyroid hormone receptors that can bind to specific nucleotides sequences termed *thyroid responsive elements* within promoter regions of genes that they regulate, whether or not the thyroid hormone is present. The presence or absence of T3 on the thyroid receptor dictates a corepressor or coactivator activity.[162]

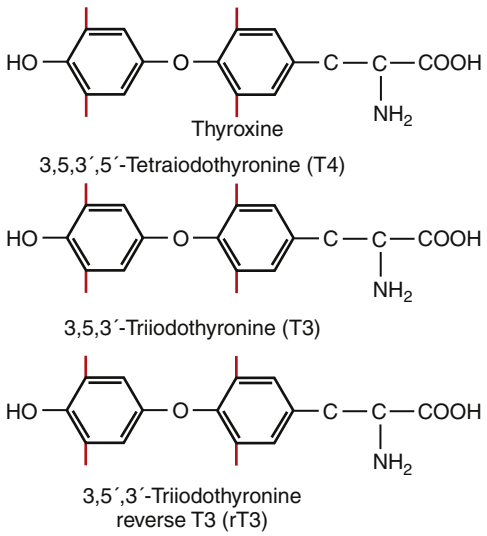

Figure 77–13. Thyroid hormone chemical structures. *(Adapted from Goodman HM:* Basic medical endocrinology, *Boston, 2009, Elsevier, p 40.)*

Thyroid Hormone Actions

Box 77-1 summarizes the effects of thyroid hormone on metabolism.[163]

Thyroid hormone significantly affects skeletal and central nervous system growth and maturation. Unrecognized hypothyroidism in infancy results in marked physical, motor, and mental delay, termed *cretinism*. Hemodynamically, thyroid hormone is known to increase β-adrenergic receptor density and activity, as well as up-regulation for genes encoding calcium channels (ryanodine receptor) and sodium potassium adenosine triphosphatase. In a general way, thyroid hormone provides gain control for carbohydrate and lipid metabolism and significantly accelerates both protein synthesis and degradation. Through its effects on uncoupling of ATP production, thyroid hormone can significantly affect oxidative metabolism as well as heat production.

Hyperthyroidism

Manifestations of thyrotoxicosis reflect increased thyroid hormone concentration. Box 77-2 summarizes signs and symptoms characteristic of thyrotoxicosis.

Grave's disease is probably the best known example of hyperthyroidism and classically is associated with a diffusely enlarged thyroid gland (goiter), exophthalmos, and cardiac palpitations. Pathophysiology of Grave's disease involves thyroid-stimulating autoantibodies that bind to TSH receptors. Hypertrophy and hyperplasia of the thyroid accompanying Grave's disease is typically associated with lymphocytic infiltration.[164] Grave's disease typically occurs in adults and chronically is associated with nervousness, fatigue, tremor, heat intolerance, and weight loss.[165] Hyperthyroidism also may occur via increased production of TSH resulting from a pituitary adenoma. Painful thyroiditis (de Quervain thyroiditis) can occur following a viral illness and may be

Box 77–1 Thyroid Effects on Metabolism

1. Increased oxygen consumption
2. Enhanced thermogenesis
3. Accelerated amino acid and lipid metabolism
4. Facilitated and water and ion transport
5. Enhanced tissue growth and development
6. Altered cortisol and insulin catabolism
7. Modulated growth hormone and parathormone activity
8. Enhanced respiratory response to hypoxia and hypercarbia
9. Increased β-adrenergic receptor affinity and responsiveness to catecholamines

Box 77–2 Signs and Symptoms of Thyrotoxicosis

1. Hyperactivity, tremor, agitation, hyperreflexia
2. Sinus tachycardia, palpitations, arrhythmias, systolic hypertension, heart failure
3. Perspiration
4. Abdominal pain, diarrhea
5. Bulging eyes (exophthalmos)
6. Thirst
7. Proximal myopathy
8. Apathy, stupor, coma

associated with hyperthyroidism.[166] A more likely presentation of hyperthyroidism in a teenager is likely to be caused by Hashimoto's thyroiditis. Amiodarone can be associated with either hyperthyroidism or hypothyroidism because its chemical structure is similar toT4.[167] Neonatal thyrotoxicosis is similar to Grave's disease and involves transplacental passage of TSH-like autoantibodies from the mother to the fetus. Thyrotoxicosis is more common among patients with Down syndrome, diabetes mellitus, and McCune-Albright syndrome.

Patients admitted to the ICU with hyperthyroidism typically will exhibit either sinus tachycardia or supraventricular tachycardia, nausea, vomiting and diarrhea, and weakness, as well as confusion, delirium, or even coma. Classic findings of a diffusely enlarged thyroid with a overlying bruit or murmur may not be present.

Thyroid storm is the most severe manifestation of hyperthyroidism. It is an exaggerated state of thyrotoxicosis that generally follows an acute stressor, is of sudden onset, and may progress to extreme hyperthermia, cardiovascular collapse, coma, and, if left untreated, to death. Treatment of thyroid storm involves a four-pronged approach: (1) provide supportive measures such as antipyretics, anxiolytics, and volume resuscitation as needed; (2) block T3 activity in peripheral tissues by utilizing thionamides, iopanoic acid, or β-adrenergic blockage with an esmolol infusion and subsequently with propranolol (1 to 2 mg/kg/day) and corticosteroids; (3) control thyroid gland production of T4 utilizing thionamides such as propylthiouracil (20 mg/kg/day in four divided doses) or methimazole, which interfere with thyroid peroxidase iodination (iodide administration in large doses to exceed 0.1 mg/kg/day [Lugol solution 5 to 10 drops orally every 8 hours] interferes with the transport of iodide in the thyroid and thyroid hormone release); and (4) identify and treat identifiable precipitating antecedents. With adequate management, clinical improvement is seen within 24 hours. In severe cases of recalcitrant thyroid storm, plasmapheresis with charcoal hemoperfusion has been used to reduce circulating T4. Occasionally, subtotal thyroidectomy may be required for chronic thyrotoxicosis. Anticipated postsurgical complications in such patients include recurrent laryngeal nerve damage, hypocalcemia with tetany secondary to inadvertent parathyroid gland resection, and hypothyroidism.

Hypothyroidism

The most common cause of hypothyroidism is iodine deficiency, which affects approximately 800 million people worldwide. The signs and symptoms of congenital hypothyroidism include prolonged neonatal jaundice, coarse features, protruding tongue, apathy, poor feeding, umbilical hernia, and eventual mental retardation. For this reason, unrecognized neonatal hypothyroidism is of particular concern. Patients with Down syndrome are especially at risk of the development of hypothyroidism. Thus hypothyroidism should be suspected in children with trisomy 21 with unstable hemodynamics following cardiovascular surgery. True hypothyroidism resulting from thyroid gland failure or maldevelopment will manifest with an elevated TSH concentration, although this response may be blunted in the ICU by malnutrition, dopamine, and corticosteroids. Levothyroxine constitutes the primary treatment for hypothyroidism.

Sick Euthyroid Syndrome in Critical Illness

The sick euthyroid syndrome occurs in the setting of illness, malnutrition, and surgery including pediatric cardiac surgery patients.[168,169] The syndrome is characterized by a rapid decrease in T3 and variable increase in rT3 that appears to be proportional to the intensity of illness severity and concentration of TNF-α. In addition, a decline in various thyroid hormone–binding proteins is evident. Conversion of T4 to T3 is suppressed as a result of decreased 5′-deiodinase activity. Because of decreased thyroid-releasing hormone gene expression in the hypothalamus, thyroid-releasing hormone is decreased with a resultant reduced TSH messenger ribonucleic acid. Laboratory finding characteristics of sick euthyroid syndrome are summarized in Table 77-1.[170]

The significance of sick euthyroid syndrome in critical illness remains controversial. Evidence indicating overt pathology in this setting is sparse. Some persons argue that this scenario reflects an effort of the body to conserve energy expenditure during stress. Thyroid hormone alterations characteristic of sick euthyroid syndrome would also be expected to modulate protein catabolism.[171] Sick euthyroid syndrome should be differentiated from true hypothyroidism. The latter can occur occasionally among patients to whom dopamine and high-dose corticosteroids are administered, both as a result of inhibition of TSH. Various drug effects on thyroid hormone metabolism are summarized in Table 77-2.

Table 77–1 Sick Euthyroid Syndrome Laboratory Data

Variable	Value
Free T4	Normal
T4 →T3 conversion	Decreased
T3	Markedly decreased
rT3	Variable
TSH	Normal

rT3, Reverse triiodotyrosine; *T3,* triiodotyrosine; *T4,* thyroxin; *TSH,* thyroid-stimulating hormone.

Table 77–2 Effects of Various Drugs on Thyroid Hormone Metabolism

Drug	Effect
Dopamine	Blunts TSH response to TRH
Corticosteroids	Suppresses basal and TRH-stimulated TSH release
Iodinated contrast agents	Decreases hepatic conversion of T4 to T3
Amiodarone	Decreases hepatic conversion of T4 to T3, and decreases servo feedback T3 binding at the pituitary
Phenytoin	Enhances T4 to T3 conversion (low free T4 and low total T4)

T3, Triiodotyrosine; *T4,* thyroxin; *TRH,* thyroid-releasing hormone; *TSH,* thyroid-stimulating hormone.

Thyroid Hormone Supplementation in the Pediatric Intensive Care Unit

Patients with true hypothyroidism should receive replacement T4. Treatment of patients with sick euthyroid syndrome is more controversial. Although the basis for the observation is not clear, adult investigators have previously demonstrated that low serum T3 levels represent the single most significant predictor of cardiovascular mortality and mortality resulting from all causes among adults with heart disease.[172] Triiodothyronine replacement in adults with impaired left ventricular function resulted in improved left ventricular function, as well as restored cardiomyocyte gene expression to euthyroid levels.[173] Among adult patients with heart failure, infusion of T3 for 72 hours resulted in normalization of serum T3 levels with concomitant improvement in stroke volume as well as left ventricular end-diastolic volume compared with pretreatment levels.[174] Such findings have stimulated interest in thyroid hormone pathophysiology among children with cardiovascular disease. Thyroid function, as well as clinical outcomes, were assessed serially among children undergoing cardiac bypass surgery. All subjects demonstrated defined nonthyroidal illness syndrome characterized by reduced TSH, total T3, free T3 index, and T3 uptake. These changes were correlated with prolonged need for mechanical ventilation, degree of organ dysfunction, and vasoactive-inotropic scores.[175]

One interventional trial has reported the effect of T3 supplementation among children undergoing cardiovascular surgery. In this investigation, replacement dosing of T3 following cardiopulmonary bypass resulted in increases in plasma T3 concomitant with measures of improved myocardial performance, particularly among children exhibiting low postoperative cardiac output.[176] Currently other interventional studies assessing the potential benefits of T3 supplementation during and following pediatric cardiac surgery are in progress (e.g., a study of Triostat among infants during heart surgery: ClinicalTrials.gov:NCT00027417).

Chapter 78

Diabetic Ketoacidosis

Catherine Pihoker, Ildiko H. Koves, and Nicole S. Glaser

PEARLS

- Diabetic ketoacidosis (DKA) results either from absolute insulin deficiency or from relative insulin deficiency in the setting of high levels of counter-regulatory hormones stimulated by infection or other illness.
- DKA is characterized by hyperglycemia, ketosis, and acidosis.
- Treatment of pediatric DKA involves insulin administration and intravenous fluid administration to correct dehydration, and replacement of electrolyte deficits.
- Cerebral edema is the most frequent serious complication of DKA in children and is the most frequent cause of morbidity and mortality resulting from DKA.
- See Box 78-1 for more information about DKA treatment in children and adolescents.

Etiology, Definition, and Presentation

Diabetic ketoacidosis (DKA) occurs when serum insulin concentrations are very low in relation to concentrations of glucagon and other counterregulatory hormones (epinephrine, norepinephrine, cortisol, and growth hormone). This situation occurs most commonly in new onset of type 1 diabetes and in patients with known diabetes during infections or other illnesses, or with insulin omission (see the following section). In the setting of low insulin concentrations in relation to counterregulatory hormone concentrations, the normal physiological mechanisms responsible for maintaining adequate fuel supply during fasting and physiological stress are exaggerated, resulting in hyperglycemia, ketosis, and acidosis. A diagnosis of DKA can be made when the serum glucose concentration is greater than 200 mg/dL (>11 mmol/L) and venous pH is less than 7.30 (or the serum bicarbonate concentration is less than 15 mmol/L) in the presence of elevated urine or serum ketone concentrations.

In a child with new onset of type 1 diabetes, declining insulin production results from autoimmune destruction of pancreatic beta cells. The concentration of insulin is decreased relative to glucagon causing excess hepatic glucose production and decreased peripheral glucose uptake in muscle and adipose tissue.[1,2] When the serum glucose concentration rises above approximately 180 to 200 mg/dL, the renal threshold for glucose reabsorption is exceeded causing glycosuria, which leads to osmotic diuresis and compensatory polydipsia. Low insulin concentrations also stimulate the release of free fatty acids (FFA) from adipose tissue to fuel ketogenesis.[3] This, in combination with activation of the hepatic β-oxidative enzyme sequence resulting from relative excess of glucagon in relation to insulin, results in markedly increased hepatic ketone production.[2-4]

Progressive dehydration and increasing acidosis eventually stimulate additional release of the counterregulatory ("stress") hormones, cortisol, catecholamines, and growth hormone, which accelerate hepatic glucose output and ketone production.[5,6] Infection or other illness or injury can likewise contribute to this process by stimulating release of counterregulatory hormones. Elevated cortisol concentrations augment FFA release from adipose tissue and decrease peripheral glucose uptake. Increased epinephrine concentrations directly increase glycogenolysis and stimulate release of gluconeogenic precursors from muscle.[7,8] Both epinephrine and norepinephrine also stimulate lipolysis and β-oxidation of FFAs.[9,10] Catecholamines may also directly inhibit insulin secretion, thereby accelerating DKA in those with endogenous insulin capacity, such as a new diagnosis of type 1 diabetes or those with type 2 diabetes.[11,12] Growth hormone also decreases peripheral glucose uptake, and enhances ketone production by increasing FFA release.[13] Elevated concentrations of counterregulatory hormones thus result in increased acidosis, hyperglycemia, and dehydration. This in turn stimulates further counterregulatory hormone release thereby creating a "vicious cycle" resulting in rapid worsening of DKA (Figure 78-1).

During DKA, intestinal ileus results from potassium depletion, acidosis, and diminished splanchnic perfusion, causing abdominal pain and vomiting and thereby limiting fluid intake. Progressive dehydration eventually leads to diminished tissue perfusion sufficient to cause accumulation of lactic acid, enhancing acidosis.[14] In addition, poor perfusion may result in diminished renal function, limiting the capacity for clearance of glucose and ketones. Ongoing osmotic diuresis and ketonuria in the setting of acidosis also results in urinary losses of electrolytes (potassium, sodium, chloride, calcium, phosphate, and magnesium).

Classical symptoms of DKA include polyuria, polydipsia, polyphagia, weight loss, abdominal pain, nausea, and vomiting. Abdominal tenderness, absence of bowel sounds and guarding are frequent and may even mimic an acute abdomen.[15] Tachycardia and signs of hypoperfusion, such as delayed capillary refill time and cool extremities, are also common as well as dry mucous membranes, absence of tears, and poor skin turgor. Despite substantial volume depletion, however, hypotension

Box 78–1 DKA Treatment in Children and Adolescents

Fluids

- Most children require an initial fluid bolus of 10 mL/kg of isotonic fluids (0.9% saline or lactated Ringer's). Additional fluid boluses may be administered if necessary to restore perfusion.
- Subsequent fluid administration should replace the remaining fluid deficit (typically ~70–90 mL/Kg) plus maintenance fluids over 36–48 hours using 0.45%–0.9% saline. 0.9% saline may be used initially with a transition to 0.45% saline after several hours.

Insulin

- After initial fluid bolus(es), begin insulin administration at 0.1 U/kg/hr.
- An initial insulin bolus dosage is not necessary.
- Insulin should be administered 0.1 U/kg/hr until ketoacidosis resolves (pH >7.30, HCO_3 >15, normalization of anion gap).
- To prevent hypoglycemia, glucose-containing intravenous fluids should be used after the plasma glucose concentration declines below ~250–300 mg/dL.

Potassium and other electrolyte replacement

- Potassium replacement is required, and should begin immediately in patients with hypokalemia. Potassium replacement should begin concurrent with insulin treatment in all others. For patients with hyperkalemia, potassium replacement should be based on the serum potassium measurements and given only after adequate renal function is verified.
- Potassium administration should begin at 40 mEq/L of intravenous fluids (excluding rare patients with significant hyperkalemia). Subsequent potassium administration should be adjusted according to serum potassium concentrations.
- Calcium, magnesium, and phosphate concentrations should be monitored during therapy. Phosphate concentrations typically decrease during treatment and replacement of phosphate by using potassium phosphate in combination with potassium chloride can be considered. Replacement of calcium and magnesium is rarely required.

Correction of Acidosis

- Bicarbonate treatment should not be used routinely.
- In rare circumstances (symptomatic hyperkalemia, cardiovascular instability caused by severe acidosis), bicarbonate treatment should be considered.

Monitoring

- Vital signs should be measured hourly.
- Continuous cardiac monitoring is recommended.
- Fluid intake and output should be recorded hourly.
- Blood glucose concentrations should be measured hourly. Electrolytes, serum urea nitrogen, creatinine, venous pH, and P_{CO_2} should be measured every 2–4 hours. Calcium, magnesium, and phosphate should be monitored approximately every 6 hours. More frequent electrolyte measurements may be necessary in patients with abnormal or rapidly changing electrolyte concentrations.
- Mental status should be assessed hourly. More frequent assessment may be necessary for patients with headache or other symptoms or signs of cerebral edema.

Modified from Glaser NS: Pediatric diabetic ketoacidosis and hyperglycemic hyperosmolar state. *Pediatr Clin North Am* 52:1611-1635, 2005.

is unusual in children with DKA and occasional children may present with hypertension. Kussmaul breathing and tachypnea are the result of metabolic acidosis and respiratory compensatory mechanisms. Fruity breath odor (acetone) may be present. Hypothermia has also been described.[16]

Although hyperglycemia is part of the definition of DKA, in rare cases, the serum glucose concentration may be nearly normal, so called "euglycemic DKA." This situation has been reported most frequently in pregnant women.[17-19] Normal glucose concentrations or even hypoglycemia despite ketosis may also occur in children with known diabetes who administer insulin to treat DKA prior to arrival in the emergency department. In general, however, the persistence and severity of hyperglycemia reflects the severity of dehydration. In the absence of preexisting renal disease or unusually high carbohydrate intake just before presentation, blood glucose concentrations in excess of 500 to 600 mg/dl imply that dehydration is of sufficient severity to diminish the glomerular filtration rate and thereby diminish the capacity for renal clearance of excess glucose.[20]

Concentrations of ketone bodies (beta-hydroxybutyrate [βOHB] and acetoacetate [AcAc]) are elevated in DKA resulting in acidosis. Hyperchloremic acidosis frequently coexists with increased anion-gap acidosis, and the anion gap reflects the combination of these processes.[21] The ratio of βOHB:AcAc (typically 1:1 in the normal state) is increased during DKA and may be as high as 10:1.[22] During treatment, this ratio returns to normal. The nitroprusside reaction used to test urine ketone concentrations detects only AcAc and not βOHB. As a result, nitroprusside urine testing cannot be relied on to determine DKA severity or treatment response. Bedside blood ketone meters provide a rapid means for measuring βOHB, and may be useful in place of or in addition to urine testing particularly in patients with anuria or oligoria who produce insufficient amounts of urine for ketone testing.[23] Blood ketone measurements are also useful for determining the timing of transition from intravenous to subcutaneous insulin administration. Urine ketones may be present even when blood ketones have normalized as a result of urine stagnating in the bladder.

Hyperglycemia results in fluid shifts from the extravascular to the intravascular space and a decrease in the serum sodium concentration. This decrease can be calculated as an approximately 1.6 mEq/L decrease in sodium concentration for every 100 mg/dl increase in serum glucose higher than 100 mg/dl or $Na_{corrected} = Na_{actual} + (\text{glucose in mmol/L} - 5.5 \text{ mmol/L})$}.[24,25] Hyperlipidemia may also contribute to a decrease in measured serum sodium concentrations.[26] Typically, serum

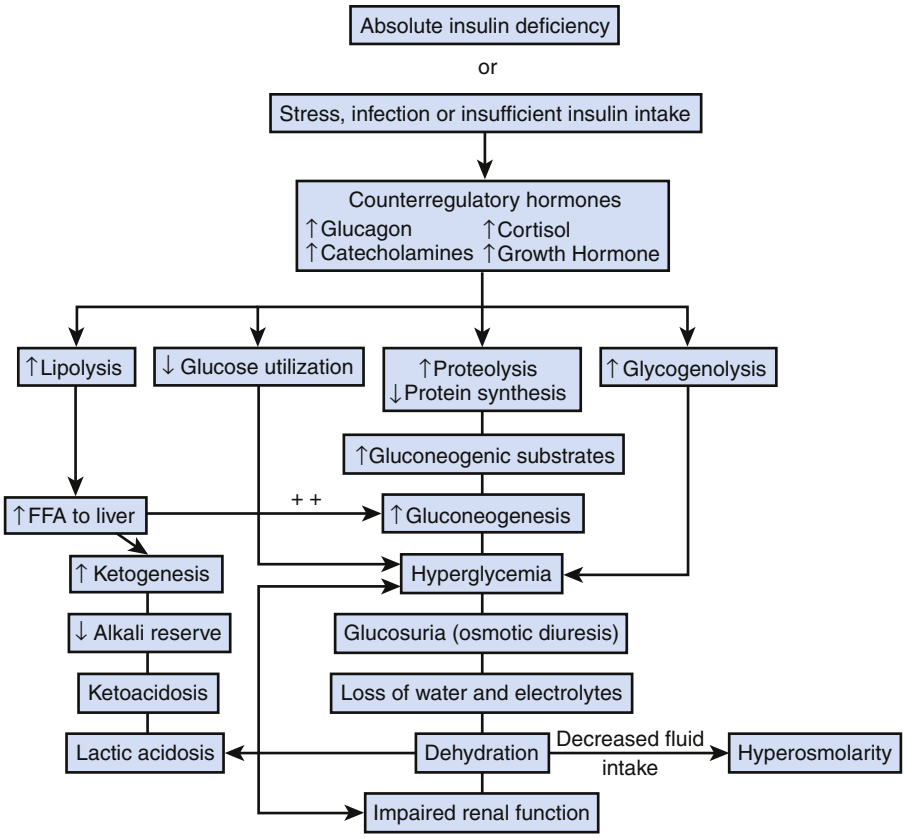

Figure 78–1. Pathophysiology of DKA. *(From Wolfsdorf J, Glaser N, Sperling MA: Diabetic ketoacidosis in infants, children, and adolescents: a consensus statement from the American Diabetes Association,* Diabetes Care *29[5]:1150-1159, 2006.)*

potassium at presentation is in the high-normal range as a result of redistribution of potassium ions from the intracellular to the extracellular space. Several processes are responsible for intracellular potassium depletion including direct effects of low insulin concentrations, intracellular protein and phosphate depletion, and buffering of hydrogen ions in the intracellular compartment.[27] Intracellular potassium stores may be profoundly depleted and the serum potassium concentration typically declines rapidly with insulin treatment. Serum phosphate concentrations similarly decrease during treatment.

Leukocytosis is frequent in children with DKA, likely resulting from elevated concentrations of catecholamines and proinflammatory cytokines. In children, new onset of type 1 diabetes or insulin omission are far more common causes of DKA than infection. [28] Therefore, an elevated or left-shifted white blood cell count need not prompt a search for an infectious process in the absence of fever or other symptoms or signs of infection. However, in the presence of fever, careful history, physical examination, and laboratory evaluation to assess for infection is prudent.

Epidemiology

Frequency of Diabetic Ketoacidosis at Diagnosis

The frequency of DKA at diagnosis varies widely by geographic region, with an overall estimated frequency of approximately 20% to 67%. In the population-based US study, SEARCH for Diabetes in Youth, data were collected from self-reported health questionnaires and medical record review. In this study, 25.5% of children and adolescents presented at onset of diabetes in DKA.[29] A similar frequency was observed in Germany, with 26.3% of children under the age of 15 presenting in DKA at diagnosis of diabetes. In a collaborative study from Germany and Austria, the Diabetes Patienten Verlausdokumentation (an electronic documentation system for children with diabetes), the frequency of DKA at presentation was 21.1%.[30] Younger age (<5 years) and female sex were associated with higher likelihood of presenting in DKA.[31,32] A delay in diagnosis is associated with a higher likelihood of DKA, and two factors contributing to this are patient age and provider experience. Regions with a higher prevalence of type 1 diabetes generally have a lower frequency of DKA,[33] attributed to heightened awareness in providers and thus earlier detection. The non-specific nature of individual symptoms, such as polyuria, tachypnea, and altered mental status, may cause such symptoms to be misconstrued as urinary tract infection, pneumonia, or meningitis, respectively.[34] Mallare et al.[35] reported a frequency of DKA of 33% in children and adolescents at the initial visit, and almost double (59%) in those in whom the diagnosis of diabetes was missed at the initial visit. The diagnosis of diabetes was more likely to be missed in very young children (34% of children ≤5 years of age compared to 8.5% in those greater than 10 years of age),[35] particularly when these very young children are evaluated by family practitioners rather than pediatricians.[36]

Frequency of Diabetic Ketoacidosis in Children and Adolescents After Diagnosis

Although there are several population-based studies reporting the frequency of DKA at presentation, fewer data are available describing the incidence of DKA in children and adolescents with established diabetes. Reported frequencies range from 1 to 10 per 100 patient years.[37] In the Diabetes Control and Complications Trial, the incidence of DKA in adolescents treated with intensive management regimens was 2.8 per 100 patient-years, significantly lower than the incidence in those treated conventionally (4.7 per 100 patient years). Although this is an older study, it was a time and resource-intensive study, and represents a more idealized situation than often encountered in the overall pediatric diabetes population.[38] In a more recent study from the Barbara Davis Center for Childhood Diabetes in Denver, Colorado, the overall incidence of DKA was 8 per 100 person-years. In that study, factors associated with higher incidence included older age, higher HbA1C (relative risk [RR] of 1.68 per 1% increase in HbA1C in younger children, RR of 1.43 in older children), higher reported insulin dose, DSM4 psychiatric diagnoses, and "underinsurance" reflecting lower socioeconomic status.[39] DKA is also observed more often in children and adolescents on continuous subcutaneous insulin infusion therapy (CSII) than on subcutaneous injections, particularly in the first year of initiation of CSII.[40] However, lower rates of DKA are achievable for those on CSII with adequate training and resources.

Over the past two decades T2DM has been occurring with increasing frequency in older children and adolescents. Certain racial/ethnic groups in the United States are disproportionately affected including Native Americans, Hispanics, and African Americans. DKA can be the clinical presentation for T2DM in youth estimated at 5% to 10%.[41] Youth with T2DM may also present with hyperglycemic hyperosmolar state (HHS), also referred to hyperosmotic hyperglycemic non-ketotic coma (HHNK, described more fully in the following section).

Morbidity and Mortality Associated with Diabetic Ketoacidosis

Mortality in children presenting with DKA is approximately 0.25% to 0.30%.[37] Most of the mortality in DKA occurs in children with cerebral edema, accounting for 57% to 87% of deaths. Neurologic sequelae of DKA are described in the section on DKA-associated complications. Other causes of morbidity and mortality include sepsis and secondary infection, electrolyte abnormalities (e.g., hypokalemia), arrhythmias, rhabdomyolysis, thrombosis, pneumomediastinum, subcutaneous emphysema, and pulmonary edema.

Management Guidelines

Fluids

Restoration of adequate peripheral perfusion and hemodynamic stability with bolus administration of intravenous fluids (0.9% saline or other isotonic fluids) should begin as soon as possible. Typical patients require an initial fluid bolus of 10 ml/kg that may be repeated if ongoing hemodynamic instability is present. Studies have shown that clinical assessments of dehydration severity in children with DKA tend to be inaccurate (Figure 78-2).[42] The average degree of dehydration for most patients is approximately 7% to 9% of body weight and this figure should be used as a basis for determining the total volume of fluids to be replaced.[42,43] The estimated fluid deficit, along with maintenance fluid requirements, should be replaced over 36 to 48 hours using 0.45% to 0.90% saline, generally initially with 0.9% saline, then transitioning to 0.45% saline after several hours assuming serum Na is not falling. Replacement of ongoing urinary fluid losses is usually unnecessary because osmotic diuresis typically resolves rapidly after beginning insulin infusion. However, in circumstances of persistently high urine output, or profuse vomiting or diarrhea, replacement of ongoing losses may be considered.

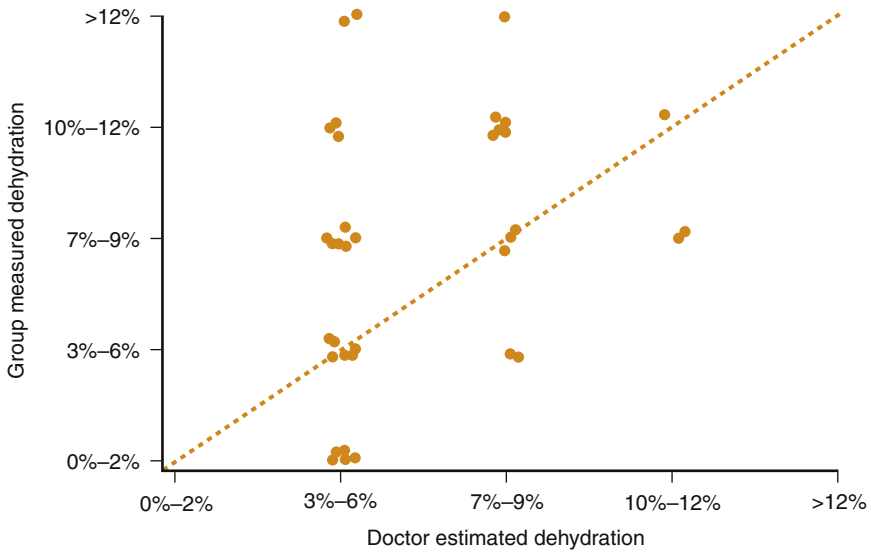

Figure 78–2. Estimated versus measured dehydration in children with DKA. *(From Koves IH, Neutze J, Donath S, et al: The accuracy of clinical assessment of dehydration during diabetic ketoacidosis in childhood,* Diabetes Care *27[10]:2485-2487, 2004.)*

Insulin

Insulin should be administered intravenously at a rate of 0.1 units/kg/hour. Insulin administration results in resolution of acidosis and hyperglycemia via suppression of ketogenesis, and hepatic glucose output and promotion of peripheral glucose uptake. An initial bolus or loading dose of insulin is not recommended. Maximal suppression of ketogenesis is achieved rapidly with an insulin infusion (0.1 unit/kg/hour).[44,45] Even in the absence of insulin administration, the serum glucose concentration usually decreases substantially with initial rehydration, reflecting improvements in renal perfusion and decreased counter-regulatory hormone concentrations.[14] This decline in glucose concentration during the initial period of rehydration should not be interpreted as indicating excessive insulin administration.

Serum glucose concentrations typically normalize before ketosis and acidosis resolve. To continue insulin administration at dosages sufficient to allow resolution of ketosis, dextrose should be added to the intravenous fluids. Transition to dextrose-containing fluids should occur when the serum glucose concentrations decline below approximately 250 mg/dl. The "two-bag system" for dextrose administration allows a rapid response to changes in serum glucose concentration and is cost-effective.[46] Two bags of intravenous fluids with identical electrolyte content, but varying dextrose content (0% and 10%) are administered simultaneously with the relative rates of administration frequently adjusted to increase or decrease the dextrose concentration while maintaining a constant overall rate of administration of fluid and electrolytes.

Electrolytes

Serum potassium concentration often declines rapidly during treatment and potassium replacement is mandatory. Typical patients require potassium administration at concentrations of 30-40 mEq (occasionally up to 80 mEq) per liter of intravenous fluids. Potassium chloride may be used alone or in combination with other potassium salts (potassium phosphate or potassium acetate), permitting lower chloride administration. Adequacy of renal function should be considered before administration of potassium.

Phosphate replacement in children with DKA is controversial. Theoretically, low 2,3-diphosphoglycerate levels in red blood cells may occur in association with hypophosphatemia leading to decreased tissue oxygen delivery.[47,48] However, clinical relevancy of this supposition has not been demonstrated. Although the risk of hypocalcemia during DKA treatment is increased with phosphate replacement, symptomatic hypocalcemia is very uncommon when phosphate is administered slowly and in the more modest concentrations recommended in most DKA treatment protocols.[49,50] Severe hypophosphatemia during DKA has been shown to be associated with rhabdomyolysis and hemolytic anemia, suggesting that monitoring of serum phosphate concentrations is necessary and treatment of severe hypophosphatemia is essential.[51,52]

Hypomagnesemia and hypocalcemia may also occur during DKA treatment but are generally mild, rarely requiring treatment. Monitoring of serum calcium and magnesium concentrations, however, is recommended.

Correction of Acidosis

Routine bicarbonate administration is contraindicated in children with DKA as acidosis generally corrects rapidly with insulin and fluid administration, and hemodynamic instability resulting from acidosis is rare. However bicarbonate administration is associated with several possible adverse effects including an increase in the risk of hypokalemia and a theoretical increase in tissue hypoxia resulting from a leftward shift in the hemoglobin-oxygen dissociation curve.[47,53] Paradoxical acidosis of the cerebrospinal fluid has also been documented with bicarbonate administration, likely resulting from diminished respiratory drive and a rise in the partial pressure of CO_2, which readily crosses the blood-brain barrier augmenting CSF acidosis.[54,55] Bicarbonate administration has also been associated with an increased risk of DKA-related cerebral edema.[56] In very rare circumstances (severe hemodynamic instability not responding to standard measures or potentially life threatening hyperkalemia), bicarbonate administration may be considered.

Monitoring

Intensive monitoring is essential for children with DKA and most should be treated in a pediatric intensive care unit (PICU) or other unit with similar capacities.[57,58] Blood glucose concentrations are typically measured hourly and electrolyte concentrations every 2 to 4 hours. Determinations of serum pH (every 2 to 4 hours) are helpful, particularly because serum bicarbonate concentrations may not increase during the first several hours. Venous blood gas samples generally are sufficient and arterial samples are rarely needed. Failure of acidosis to improve during treatment should prompt evaluation of the adequacy of insulin infusion, fluid balance, presence of non-anion gap hyperchloremic acidosis and a search for other causes such as renal failure, sepsis, or even appendicitis.

All fluid intake and output should be accurately recorded. Consideration of fluids and other management that may have occurred prior to admission to a PICU is important. Vital signs and mental status should be monitored hourly. One study showed a high frequency of prolonged QT interval corrected for heart rate in children with DKA and arrhythmias have been described in rare cases.[59] Therefore, cardiac monitoring is recommended.

Diabetic Ketoacidosis–Associated Complications

Cerebral Edema

Cerebral edema (CE) has been recognized as a complication of diabetes mellitus in children since 1936. It is essentially a clinical diagnosis, based on deterioration of mental state during resuscitation for DKA. Signs and symptoms that should prompt consideration of CE include inappropriate slowing of heart rate, hypertension, severe headache, recurrence of vomiting, irritability, lethargy, or other mental status changes.[60] Some patients progress to coma, respiratory arrest, and cerebral herniation. Most episodes of CE occur several hours after initiation of DKA treatment; however, 5% to 20% of cases occur at the time of presentation, before the initiation of therapy. Cerebral edema remains the leading cause of death

and morbidity in children with type 1 diabetes mellitus. The frequency of CE associated with DKA remains unchanged despite clinical efforts to the contrary.[32]

Reported mortality from CE varies widely and is in part dependent on the criteria used to define CE. Rates as high as 50% to 90% have been reported, but more recent studies[56,61] report lower rates of 21% to 24%. Overall, the incidence of CE is approximately 0.7% to 0.9% within DKA presentations. In other words, approximately 1 in 400 children with DKA die as a result of CE. Morbidity is significant; in particular, debilitating neurologic sequelae occur in 21% to 26% of children with DKA-related CE.[56, 61] Although frank CE is uncommon, there are substantial data to suggest that sub-clinical or asymptomatic CE occurs in many children with DKA, perhaps even in the majority. Limited data suggest that subtle brain injury may also be associated with DKA, even in the absence of clinically apparent CE.[62]

The pathophysiology of CE remains enigmatic. Several causative theories have been proposed for the occurrence of CE during DKA. Idiogenic, osmotically active substances that regulate cell volume have been thought to play a role in causing DKA-related CE. Taurine (2-aminoethane sulfonic acid), in particular, is thought to mediate a critical role in neuroosmoregulation during DKA.[63] Alternatively, cerebral hypoperfusion (caused by volume depletion) before DKA treatment and the effects of reperfusion during DKA therapy have been hypothesized to result in CE and cerebral injury.[64,65] Direct effects of ketone bodies and inflammatory cytokines on blood-brain barrier function have also been hypothesized to play a role.[66,67] To date, however, the precise pathophysiology of CE remains unresolved and multiple factors may be involved.

Epidemiological studies of risk factors for CE show that children with higher initial blood urea nitrogen concentrations, lower initial PCO_2 concentrations and greater acidosis at the time of presentation of DKA seem to be at greatest risk for CE.[56,65,68,69] A blunted rise in measured serum sodium concentration during DKA treatment has also been associated with increased risk of CE as has treatment with bicarbonate.[56] Early administration of insulin (within the first hour) was also associated with increased CE risk in one study.[68] Studies evaluating the impact of variations in fluid administration protocols on risk of CE have yielded conflicting results. As yet, there is no clear association between any aspect of fluid treatment and increased risk of CE.

After the diagnosis of CE is made, treatment is a matter of urgency and should not be delayed while awaiting imaging studies or further testing. Intravenous mannitol (0.25-1 g/kg) should be administered immediately. Recent reports suggest the use of 3% saline in boluses or as a continuous infusion for treatment of CE, but data demonstrating beneficial effects are limited to case reports.[70,71] Ongoing intensive care unit monitoring is essential. Pulmonary support by means of endotracheal intubation is likely to be required because of severe alterations in mental status, impaired airway reflexes, and altered respiratory drive. Therapeutic hyperventilation in intubated patients, however, has been associated with poorer outcomes.[72] Therefore, decreasing P_{CO_2} below the patient's own compensation for metabolic acidosis should be avoided in children with DKA except where absolutely necessary to treat impending cerebral herniation. A reasonable approach would be to initially maintain the patient's current P_{CO_2} level and then gradually allow the P_{CO_2} to increase as acidosis corrects. If the patient's respiratory drive remains intact, utilization of support rather than mandatory ventilation modes, permits the patient to determine rate and depth of breathing. Central nervous system imaging in patients with suspected CE is recommended to exclude other etiologies of altered mental status such as central nervous system thromboses or infarction.

Neuropsychologic Sequelae

Adverse neurodevelopmental outcomes in children with diabetes have in large part been attributed to recurrent hypoglycemia, and this area has been extensively investigated. More recently, hyperglycemia and hyperglycemic extremes such as occur with DKA have been attracting increasing attention and interest for resultant potential neuropsychological sequelae. Short-term effects on neurocognitive performance involving complex skills, such as inhibiting an overlearned response and learning of complex novel information have been described.[73] Long-term deficits in memory have been found to be associated with DKA.[62] Rapid and significant variability in blood glucose levels may have further impact, particularly on the developing brain and may be more neurotoxic than sustained hyperglycemia.[74]

Thrombotic Complications

Thrombotic complications are common in children with DKA and central venous catheters are particularly prone to thrombosis.[75,76] Cerebral thromboses and pulmonary emboli have also been described. Hyperosmolarity may result in direct osmotic disruption of endothelial cells leading to release of tissue thromboplastins.[77] Higher levels of vasopressin stimulated by hypertonicity and decreased vascular volume may also contribute to enhanced coagulation.[78] Prophylaxis with low dose heparin should be considered for children with central venous lines.

Other Complications

Rhabdomyolysis[79,80] is potentially life threatening. It is characterized by elevated serum creatine kinase, lactate dehydrogenase, and amino alanine transferase concentrations due to muscle injury. Rhabdomyolysis may result in renal failure, compartment syndrome, severe hyperkalemia and other electrolyte disorders leading to arrhythmias. Hyperosmolarity has been thought to be one causative factor and the risk is higher in children who have DKA complicated by features of HHS.[79]

Acute pancreatitis has been described in case reports of both children and adults with DKA, but occurs rarely. Far more frequent are benign elevations in serum amylase and/or lipase occurring in 24% to 40% of children with DKA. These elevated pancreatic enzyme concentrations typically normalize rapidly with DKA treatment and are not associated with clinical features of pancreatitis.[81]

Although neurological deterioration in children with DKA is most frequently caused by cerebral edema, cerebral infarctions with and without hemorrhage and cerebral thromboses have also been described.[82] Other rare complication of DKA in children include pulmonary edema,[83] cardiac arrhythmias,[84] renal failure,[85] intestinal necrosis,[86-88] and rhinocerebral mucormycosis.[89,90]

Hyperglycemic Hyperosmolar Syndrome

HHS is characterized by extreme elevations in serum glucose (>600 mg/dL) and hyperosmolarity (serum osm >330 mOsm/kg) in the absence of significant ketosis or acidosis

(urine ketone concentration <1.5 mmol/L and serum bicarbonate >15 mEq/L). Although HHS is defined as a condition separate from DKA, 30% of cases occur in combination with substantial ketosis and acidosis meeting criteria for both HHS and DKA. Until recently, HHS was thought to occur infrequently in pediatrics. A recent increase in case reports of HHS in children suggest that the frequency may be increasing.[91,92] As in adults, HHS in children has a relatively high mortality of 10% to 35%.[93,94] The majority of HHS reports in children include acanthosis nigricans, obesity, African-American race, and family history of type 2 diabetes. Most cases of HHS are the initial presentation of diabetes, and most of these youth will subsequently have a clinical diagnosis of type 2 diabetes.

Occurrence of HHS during DKA poses challenges in terms of recognition and treatment. Generally, dehydration is more profound than the clinical assessment would suggest, reflecting difficulties in clinical evaluation due to obesity and relative preservation of intravascular volume because of hyperosmolarity. Electrolyte losses similarly exceed those of DKA as a result of more prolonged osmotic diuresis. Patients who meet criteria for both DKA and HHS require more prolonged and aggressive fluid and electrolyte replacement therapy than typical children with DKA. Replacement of ongoing urinary losses may be necessary. Frequent reassessment of circulatory status and fluid balance is critical. A high frequency of thromboses has been described in children with HHS as well as rhabdomyolysis and a malignant hyperthermia-like syndrome.[95,96] Cerebral edema appears to be a rare complication of HHS, with only one case reported.[97]

Health Care Costs Associated with Diabetic Ketoacidosis

Health care costs for DKA vary by geographic regions in the United States, and comparing costs is often complicated by variations in health care systems, methods of reporting costs (e.g., hospital costs versus payer costs), and contractual arrangements. One strategy to decrease the frequency of DKA is to promote awareness in the general population, in communities, and among providers. A successful campaign to heighten awareness of signs and symptoms of DKA took place in Parma, Italy. In the Parma campaign, simple messages regarding signs and symptoms of diabetes were provided to practitioners and schools, and free access to care arranged. Compared with neighboring regions where the frequency of DKA at the time of diagnosis was quite high at 78%, the Parma region observed a very low frequency of 12.5% during the 8 years of the campaign. Of note, the campaign was relatively inexpensive, the costs $23,000 for the 8 years of the campaign.[33]

Another more targeted strategy is linked to recognition of diabetes risk. In children enrolled in prevention studies, which are mostly siblings of probands with type 1 diabetes, the frequency of DKA is far less than that of the general population; less than 4% for those participating in the Diabetes and Prevention Trial-1 presented in DKA, and 63.3% were asymptomatic.[98] For children and adolescents with diagnosed diabetes, multidisciplinary and intensive team management approaches have been shown to decrease the frequency of DKA. Unfortunately, obtaining sufficient reimbursement for intensive case management in the United States has been challenging, despite demonstrated savings to the health care system. In a relatively small study, the costs for emergency and hospital visits for those not involved in intervention more than exceeded (125%) the costs of intensive case management.[99] This included only hospital charges and did not include additional societal costs, such as missed days of work and school, patient and family worry and anxiety, and impact of recurrent DKA, possible cerebral edema, and poor diabetes control on long-term health. In a larger, longer study of multisystemic home-based psychotherapy for adolescents with poorly controlled diabetes, admissions for DKA were reduced by almost half compared with the control group over a 2-year period, resulting in a estimated cost savings of $23,886 to 72,226 (range reflecting hospital costs and third party costs, respectively).[100] These examples emphasize the need for preventative rather than crisis-based approaches to the pediatric diabetes population.

Very young children with diabetes remain the most likely to present in DKA with CE, and comprise the age group with the most rapid rise in incidence of diabetes. Taken together, these data suggest that there are very important opportunities for prevention strategies in this age group. Major efforts are needed to address health care disparities overall in children with diabetes, and prevention of DKA is no exception.

Structure and Function of Hematopoietic Organs

Seth J. Corey and Julie Blatt

PEARLS

- Hematologic intervention is one of most frequent therapeutic modalities in the intensive care unit setting.
- The blood system is frequently affected by severe illnesses, and its failure contributes to morbidity and mortality.
- Normal ranges for blood cell numbers or function depend on the age of the patient.
- The degree of hematopoiesis in a given bone varies with age and must be considered for successful bone marrow aspiration or biopsy.
- For major invasive procedures such as surgery or placement of arterial lines or endotracheal, platelet count should be maintained at 50,000/μL.

The hematopoietic system responds quickly to changes in oxygen tension, bleeding, or infection. When stressed, as in a very ill child, hematopoiesis and blood cell function may be insufficient. The extensive use of red blood cell (RBC) or platelet transfusions, and antimicrobials support the importance of the blood system as a vital organ affected in the pediatric intensive care unit setting. This chapter reviews the anatomy and physiology of the hematopoietic system to provide a basis for understanding the repercussions of primary hematological abnormalities, as well as hematopoietic manifestations of nonhematological diseases. Aspects that are of practical importance to the intensivist are emphasized. The structure and function of the coagulation system are discussed in Chapters 81 and 82 and that of the immune system (particularly B and T lymphocytes and macrophages) in Chapter 90.

Structure and Function of the Bone Marrow

During embryogenesis and fetal development, hematopoiesis shifts from the yolk sac to the liver and, after the twentieth week of gestation, to the bone marrow.[1] Although hepatic erythropoiesis may persist for several weeks after birth, in the term infant hematopoiesis takes place almost entirely in the bone marrow. A defining feature of hematopoietic stem cells is their ability to home to the bone marrow. This homing occurs via chemoattractants such as stromal cell-derived factor-1 and its cognate chemokine receptor on the stem cell, as well as interaction between a variety of stem cell adhesion molecules and their ligands on stroma and endothelial cells. The hematopoietic stem cell may be identified by the presence of cell surface markers, such as CD34 or by properties to exclude Hoeschst dye 33342, via a multidrug transporter.[2]

Grossly, two types of bone marrow can be recognized in normal individuals: yellow marrow, so called because of the predominance of fat cells, and red marrow, in which blood cells predominate. White marrow, consisting predominantly of stromal cells and intercellular matrix, may result from atrophy or starvation. Red marrow proportionately is a much greater component of body weight and volume in the infant than in the adult (Figure 79-1).[3] Early in life, it is contained in the medullary cavities of the long bones, which gradually fill with fat such that by late puberty, the adult distribution of hematopoiesis (sternum, pelvis, vertebrae, cranium, ribs, epiphyses of long bones) is achieved. That the degree of hematopoiesis in a given bone may vary with age is an important consideration in selecting a site for bone marrow aspiration or biopsy; for example, although the anterior and posterior iliac crests can be used at any age, the tibia can be used only until the age of 2 years. In disease states characterized by excessive destruction of blood cells, such as some severe hemolytic anemias, hematopoiesis may increase twofold to eightfold. Active sites of hematopoiesis may expand, and extramedullary hematopoiesis may be found, particularly in the liver and spleen.

Microscopically, the marrow is a network of vascular channels (sinuses) separating islands of fat, hematopoietic cells, and rare osteoblasts and osteoclasts (which are important for bone remodeling).[4,5] The vasculature and cells are joined by a reticulin (fiber) network or scaffolding. By light microscopy, bone marrow aspirate specimens demonstrate hematopoietic elements; however, a bone marrow biopsy provides a more accurate measure of cellularity. Reticulin can be seen by light microscopy when special histochemical stains are used.

The blood vessels that feed the marrow are branches of those that feed the surrounding bone.[6] Large central arteries run longitudinally within the marrow and send radial branches that penetrate the endosteum and form capillaries in the Haversian and Volkmann's canals of the bony cortex.[7] These capillary systems drain into the bone marrow sinuses, which in turn drain into a central sinus or vein. Because the marrow circulation interconnects with the general circulation

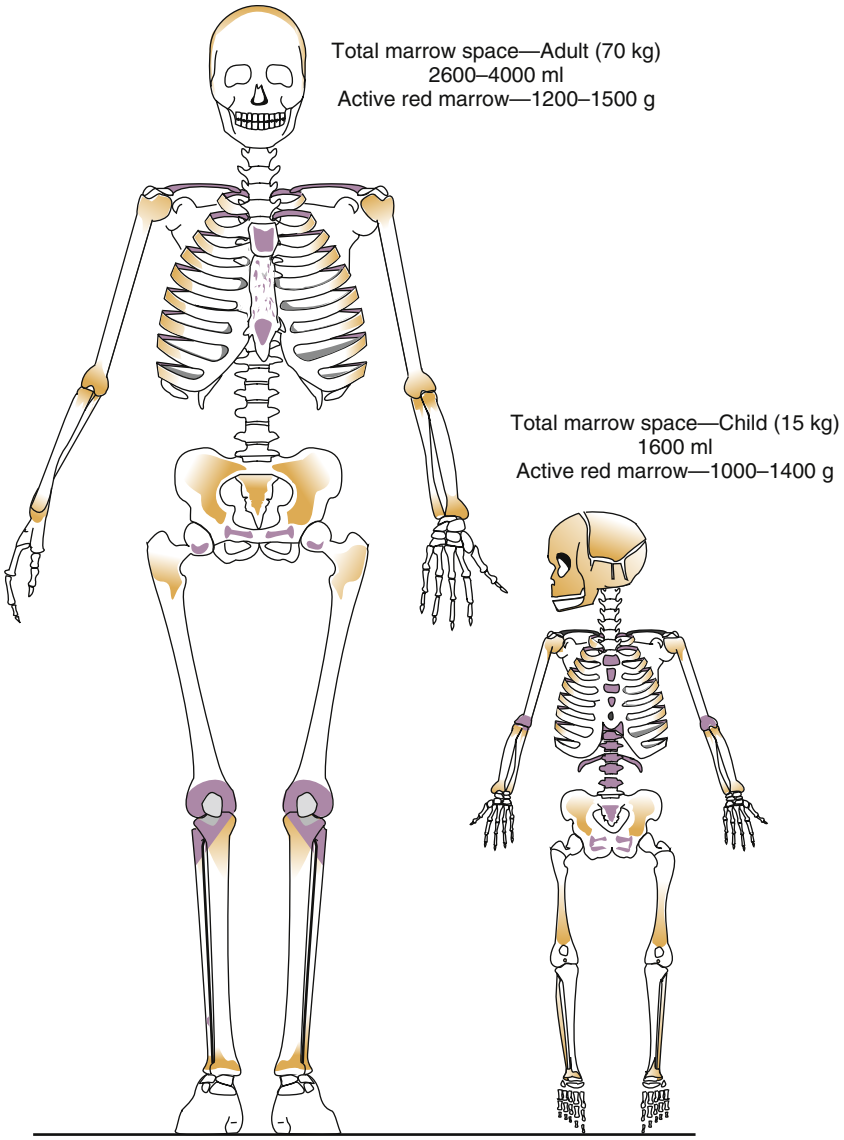

Figure 79–1. Comparison of active red marrow–bearing areas in the child and the adult. Note the almost identical amount of active red marrow in the child and adult despite a fivefold discrepancy in body weight. *(Modified from MacFarlane RC, Robb-Smith AHT:* Functions of the blood, *Oxford, 1961, Blackwell.)*

in this fashion, fluids and medication injected in bone marrow are absorbed as rapidly as through intravenous routes. Unlike peripheral veins, intramedullary vessels supported by their bony shell do not collapse in shock; therefore, intraosseous (either tibial or iliac crest) infusion is appropriate when standard intravenous access is not available.[8] It is also noteworthy that the interconnection between the marrow and general circulation provides the mechanism by which bone marrow may embolize to the lung after osseous trauma or fracture. This has not been demonstrated to be of clinical significance in the case of intraosseous infusion.[9]

The concept of the stem cell has expanded recently,[10] and its ex vivo manipulation has raised much interest by a wide group of physicians and scientists studying nonhematologic systems. One essential feature of the stem cell is its plasticity.[11] Provocative studies have shown that stem cells isolated from the bone marrow can be driven to differentiate to muscle, liver, cardiac, or neuronal tissue. This raises the possibility that the marrow may be a convenient and ethically less challenging source of stem cells for stem cell engineering and tissue replacement. Although the clinical applications to nonhematologic tissues remain distant, the use of hematopoietic stem cells to replace a diseased marrow is a common practice (i.e., stem cell transplantation). Alternative sources of hematopoietic stem cells have been found peripheral blood following growth factor–induced mobilization or from placental cord blood.

Hematopoiesis

Cells within the hematopoietic island include the RBCs, granulocytes (neutrophils, eosinophils, basophils), monocytes and macrophages, platelets, lymphocytes, and their precursors. The earliest precursors, or stem cells, are thought to look like small lymphocytes and are not usually distinguishable from them by microscopy. Their existence was best confirmed by in vitro culture assays in which nucleated cells from bone marrow aspirate specimens plated onto tissue culture dishes layered with methylcellulose generate colonies (aggregates

of cells) of one or more lineages. Now, immunophenotyping provides rapid identification of cell lineage and stage of development.[12] The first morphologically identifiable precursor cells are the proerythroblast, myeloblast, monoblast, megakaryoblast, and lymphoblast. These committed precursors and their terminally differentiated counterparts sit within the hematopoietic islands. Megakaryocytes (which make up <1% of hematopoietic cells) generally are located next to marrow sinusoids and shed platelets (fragments of megakaryocyte cytoplasm) directly into the lumen. Erythroblasts also are produced near the walls of the vascular sinuses in clusters with macrophages called erythroblast islets. As the erythroblasts develop, they extrude their nuclei, which are phagocytosed by the macrophages. In contrast, granulocytes (most numerous of the hematopoietic cells), monocytes, and lymphocytes are produced throughout the marrow away from vascular sinuses. The mature white blood cells (WBCs) are motile and migrate to the sinuses.

Within the peripheral circulation, the number of cells of each type is maintained in a narrow range in the normal individual. Adults and post-pubertal adolescents have approximately 5000 granulocytes, 2000 lymphocytes, 500 monocytes, 5×10^6 RBCs, and 150,000 to 300,000 platelets per microliter of whole blood. Age-dependent values for younger children are shown in Table 79-1.[13] To a lesser extent, values also are a function of race and sex, so that African Americans (especially males) normally may have granulocyte counts less than 1500/μL. Normative values for Latinos are less clear, but have been reported to be closer to those of Caucasians.[14] As summarized elsewhere, under normal conditions the rate of production of each cell type equals the rate of destruction. Because the life span of mature RBCs in adults is 100 to 120 days, 5×10^4 RBCs/μL are produced daily. The average platelet life span is 7 to 10 days so that approximately 2×10^4 platelets/μL are produced daily. With less than a 12-hour life span, granulocytes production occurs at a rate of 10^4 cells/μL. The very slow rate of production of lymphocytes reflects their long life span, measured in years.

The mechanisms that regulate this steady state are incompletely understood. However, evidence strongly suggests the existence of a pluripotent stem cell that is capable of self-renewal, from which progenitor cells committed to hematopoiesis (RBCs, granulocytes, megakaryocytes, and monocytes) and to lymphopoiesis develop (Figure 79-2).[13] The "trilineage myeloid" stem cell has been designated *colony forming unit-stem* (CFU-S) on the basis of bone marrow culture assays and experiments in which the spleens of lethally irradiated mice infused with donor marrow cells are found to contain colonies each consisting of precursors of RBCs, granulocytes, monocytes, and megakaryocytes.[16] The existence of CFU-S in human beings is further deduced from chromosomal studies in myeloproliferative disorders. Lymphoid development appears to arise from a separate progenitor. Although the CFU-S is found predominantly in the bone marrow, there probably are small numbers of circulating pluripotent stem cells because marrow of lethally irradiated animals can be reconstituted by using peripheral blood.[3]

The numbers of committed progenitor cells that differentiate in any time period is dependent on feedback from humoral regulators that are produced within the marrow microenvironment and by extramedullary sources, including T cells, macrophages, endothelial cells, and fibroblasts. These hematopoietic growth factors are cytokines, known by a variety of names. Many of the cytokines have overlapping functions.

Table 79–1 Normal Values for Hematology

Age	Hemoglobin (g %)	Hematocrit (%)	Mean corpuscular volume (fl)	MCHC (g/%RBC)	Reticulocytes (%)	WBC/μL × 100 range (avg)	% Neutrophils	Platelet (10^3/μL)
28-week gestation	14.5	45	120	31	5–10	—	—	275 ± 60
32-week gestation	15.0	47	118	32	3–10	—	—	290 ± 70
1 day*	16.8–21.2	57–68	110–128	29.7–33.5	1.8–4.6	7–35 (18)	45–85	310 ± 68
1 week*	15.0–19.6	46–62	107–129	30.4–33.6	0.1–0.9	4–20 (10)	30–50	
1 month*	11.1–14.3	31–41	93–109	33.3–36.5	0.1–1.7	6–18 (10)	30–50	
3-5 months	10.4–12.2	33	80–96	31.8–36.2	0.4–1.0	6–17 (10)	30–50	300 ± 50
6-11 months	11.8	35	77	33	0.7–2.3	6–16 (10)	30–50	
1 year	11.2	35	78	32	0.6–1.7	6–15 (10)	30–50	
2-10 years	12.8	37	80	34	0.5–1.0	7–13 (9)	35–60	
11-15 years	13.4	39	82	34	0.5–1.0	5–12 (8.5)	40–60	
Adult								300 ± 50
Male	16.0 ± 2.0	47 ± 7	91	34	0.8–2.5	4.3–10 (7)	25–62

Factors in variability, statistical studies, *Am J Dis Child* 93:486, 1957; Matoth Y, et al: Postnatal changes in some red cell parameters, *Acta Paediatr Scand* 60:317, 1971; Wintrobe MN: *Clinical hematology,* ed 7, Philadelphia, 1974, Lea & Febiger; Mauer AM: *Pediatric hematology,* New York, 1961, McGraw-Hill; Oski FA, Naiman JL: *Hematologic problems in the newborn infant,* Philadelphia, 1972, WB Saunders; and Nathan D, Oski F: *Hematology of infancy and childhood,* Philadelphia, 1981, WB Saunders.

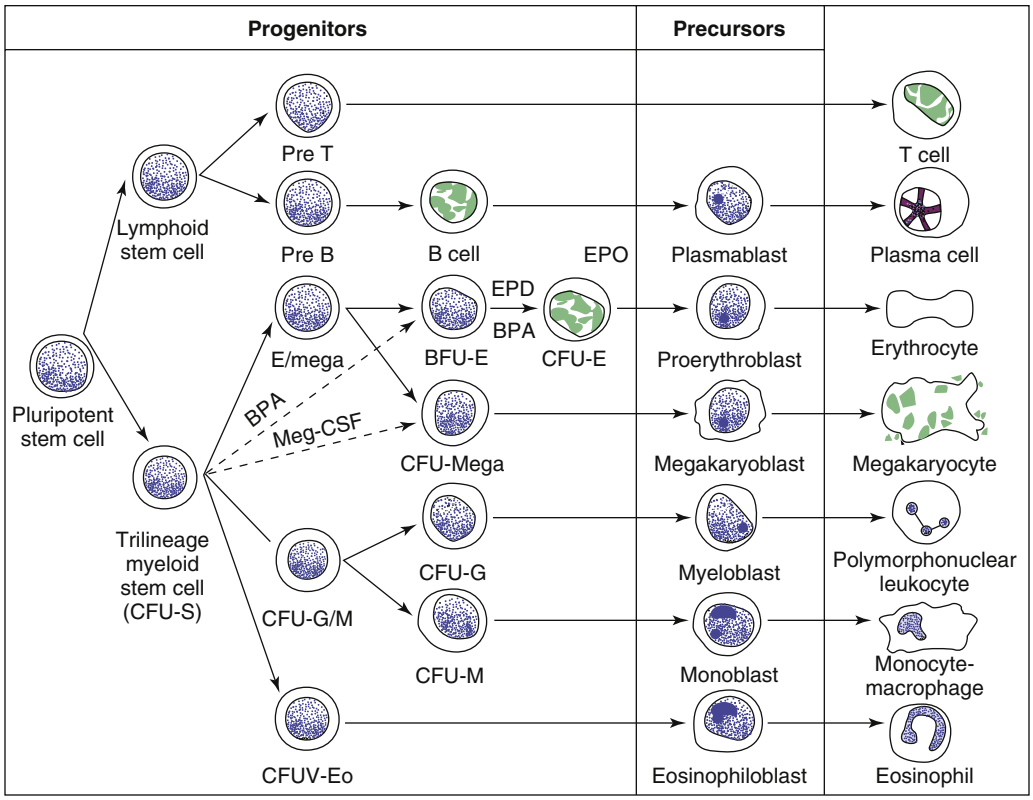

Figure 79–2. A schematic outline of the progenitor basis of hematopoiesis. Not shown in this outline is the process of self-renewal of fractions of the progenitor cell populations, particularly the immature progenitors. Also not shown is the progressive amplification of progenitors and precursors as they mature and differentiate. The bipotential erythroid-megakaryocyte progenitor shown in this drawing has been demonstrated in the mouse, but not definitively in humans. *Dotted arrows* indicate an alternative scheme. *(Modified from Nathan DG: Introduction: hematologic diseases. In Wyngaarden JB, Smith JH, editors:* Cecil's textbook of medicine, *Philadelphia, 1988, WB Saunders.)*

However, gene targeting in the mouse ("knockout mouse") of cytokines or their receptors has identified the essential nonredundant functions for several hematopoietic growth factors. Mice deficient in erythropoietin (Epo), thrombopoietin (Tpo), and granulocyte colony-stimulating factor (G-CSF) suffer from severe anemia, thrombocytopenia, or neutropenia, respectively.

Although the list of cytokines and small molecules that regulate hematopoiesis continues to grow, clinical application has been chiefly limited to Epo and G-CSF. Chemical modification of Epo and G-CSF has resulted in two longer-acting forms, darbepoetin alpha, and pegfilgrastim, respectively. Their primary advantage is longer half-lives. Recently, two platelet-stimulating agents, romiplostim and eltrombopag, have been Food and Drug Administration–approved for use in adults with chronic immune thrombocytopenic purpura (ITP).[15] Characteristics of specific hematopoietic growth factors, discussed in the following sections, are summarized in Table 79-2.

Table 79–2 Recombinant Hematopoietic Growth Factors

CSF	Target	Clinically Available
SCF	HSC, mast cells	No
IL-3	HSC	No
Epo	Erythroid progenitors	Yes
G-CSF	Granulocytes and their precursors	Yes
GM-CSF	Phagocytes and their precursors, dendritic cells	Yes
M-CSF	Monocytes and their precursors	No
Tpo*	Megakaryocytes	Yes*
IL-11	Megakaryocytes	Yes

Epo, Erythropoietin; *G-CSF,* granulocyte colony-stimulating factor; *GM-CSF,* granulocyte-macrophage colony-stimulating factor; *HSC,* hematopoietic stem cells; *IL,* interleukin; *M-CSF,* macrophage colony-stimulating factor; *SCF,* stem cell factor; *Tpo,* thrombopoietin.
*Thrombopoietin-like peptides have been approved.

Erythropoiesis

On its way toward RBC maturation (see Figure 79-2), the CFU-S sequentially differentiates into burst-forming units-erythroid (BFU-E) and colony forming units-erythroid (CFU-E), which are identifiable experimentally on the basis of growth characteristics in culture. These phases of development, which involve amplification of cell number, are extensively reviewed elsewhere.[16] As noted earlier, the proerythroblast is the earliest morphologically identifiable precursor and presumably is the successor to the CFU-E. The subsequent sequence of RBC production normally takes 3 to 4 days in the marrow and involves multiple cell divisions with increasing differentiation, characterized chiefly by globin messenger RNA, cytoplasmic synthesis of hemoglobin, and

ultimately extrusion of the RBC nucleus. The enucleated cell is large and, because it contains residual RNA, stains deeply by the Wright-Giemsa technique (i.e., polychromatophilic macrocyte). Normally at this stage the erythrocyte is released into the circulation where it can be demonstrated as a reticulocyte. In newborns younger that 1 week of age, reticulocytes in the blood can comprise more than 5% of the total RBCs. At any older age, the normal reticulocyte count is less than 2%. From this uncorrected reticulocyte count, the absolute reticulocyte count can be calculated by multiplying by the RBC count. The normal absolute reticulocyte count would be 0.02 to 5×10^6 RBC/μL. Alternatively, a corrected reticulocyte is used: multiplying the reticulocyte percentage by the observed hematocrit divided by the normal hematocrit. If the corrected reticulocyte count is less than 1%, one must suspect bone marrow failure or insufficiency. Because the reticulocytes lose their RNA within 24 to 30 hours, their quantitation provides a rough estimate of the rate of erythropoiesis during the past 24 hours. This can be more accurately measured by ferrokinetic studies, which are not readily available. The proportion of erythroid precursors in a bone marrow aspirate also provides a more convenient estimate of total erythropoiesis that is valid if a cellular specimen is obtained and if granulopoiesis is normal. In the older child or adult, erythroid precursors normally are one third as plentiful as myeloid precursors (i.e., the myeloid/erythroid ratio is about 3:1). Approximately 10% of erythroid precursors do not produce circulating RBCs (ineffective erythropoiesis).

Maturation of RBC precursors is regulated by a number of humoral and nutritional factors. Epo appears to act predominantly by increasing proliferation of CFU-E (see Table 79-2 and Figure 79-2). Its production is stimulated by hypoxemia or acute hemorrhage. During fetal development, it is mainly produced in the liver, but this site shifts later to the juxtamedullary region in the kidneys. Humoral factors less well characterized than Epo that are derived from multiple sources (spleen cells, peripheral blood monocytes, and mononuclear bone marrow cells) appear to act at an earlier stage of differentiation to amplify the number of progenitors committed to Epo responsiveness. Among these are burst-promoting activity, which enhances production and proliferation of BFU-E. Within the marrow, normal RBC maturation requires both folate and vitamin B_{12}; a deficiency of either results in abnormal nucleic acid synthesis and the production of an abnormal precursor, the megaloblast. Iron is required for hemoglobin synthesis, and deficiency results in poorly hemoglobinized small (hypochromic, microcytic) RBCs.

Once in the peripheral blood, the life span of the normal RBC in the adult or older child is 100 to 120 days. In the term newborn the RBC life span is about 60 days, which grows progressively shorter with increasing prematurity.[14] Presumably these differences in age-dependent RBC longevity reflect differences in membrane stability and oxidative metabolism. Removal of RBCs from the circulation is not a random process. Senescent RBCs are removed selectively from the circulation by the macrophages of the reticuloendothelial system. Although this is primarily a function of the spleen (see the following section), asplenic patients with normal RBCs accomplish this process in the liver and other sites and do not exhibit an increased RBC life span. In subjects with hemolytic anemias who undergo therapeutic splenectomy, the red cell life span increases, but not to normal levels.

The primary function of the circulating RBC is to carry O_2 from the lungs to the tissues. Hemoglobin (Hb) must be packaged within the RBC membrane to prolong its plasma half-life. Interference with the reversible binding of O_2 by Hb can occur by several mechanisms, including (1) methemoglobinemia, the inability to maintain ionic iron within the Hb molecule in the reduced state; (2) the presence of abnormal hemoglobins, among which are the methemoglobins which have an abnormal affinity for O_2; (3) age- or disease-related differences in the percentage of structurally normal HbF, which has a high affinity for oxygen; and (4) changes in the microenvironment that alter the intracellular concentration of 2,3-diphosphoglycerate (2,3-DPG).[17] The oxyhemoglobin interaction also is complicated by the Bohr effect (at a lower pH, Hb binding of O_2 with less affinity) independent of 2,3-DPG concentration. Patients with severe acidosis have low concentrations of 2,3-DPG, which results in an oxygen dissociation curve that shifts to the left. However, the in vivo curve may be normally placed because the Bohr effect counterbalances the reduction in red cell 2,3-DPG. If metabolic acidosis is rapidly corrected, the prompt rise in blood pH is reflected in a proportional increase in oxygen affinity (the Bohr effect). However, there is a lag of several hours before the red cell 2,3-DPG increases to normal. During this time, there is a shift to the left in both the in vivo and the in vitro O_2 dissociation curves. This phenomenon may compromise tissue oxygenation in patients who have diminished cardiovascular reserves.

Premature infants with respiratory failure may have a left-shifted O_2 affinity curve both because of the high levels of HbF and because of an acidosis-induced decrease in 2,3-DPG levels. Exchange transfusions with fresh adult blood have been found to reduce mortality, perhaps by providing blood with "normal" O_2 affinity.[18] Other reasons for impaired O_2 delivery are decreased RBC mass (anemia, which leads to a compensatory increase in 2,3-DPG) and decreased blood flow, either because of vascular anatomical abnormalities or because of increased blood viscosity (e.g., in sickle cell disease). In addition to Hb-bound O_2, the oxygen dissolved in plasma (which normally amounts to less than 2% of the total oxygen carried in the blood) increases linearly with increases in PO_2. For this reason, very anemic patients, although they have insufficient Hb with which to carry O_2, benefit from administration of O_2. Extensive research into the design of artificial blood has focused both on "red blood" (repackaged Hb from senescent RBCs or of Hb produced with genetic engineering) and "white blood" or perfluorocarbons (emulsions that dissolve large amounts of O_2), but their use is still limited and investigational. For now, RBC transfusions ameliorate anemia acutely, otherwise Epo may be used to elevate Hb over several weeks. Although antibody-mediated Epo-associated pure red cell aplasia is infrequent,[19] familiarity with possible Epo toxicity should accompany its use.

Granulopoiesis

As shown in Figure 79-2, in addition to BFU-E, CFU-S also gives rise to several other distinct cell populations. The best characterized of these are the CFU-GM (which in turn generate both CFU-G [granulocyte colony-forming units] and CFU-M [monocyte-macrophage colony-forming units]) and the CFU-Eos (eosinophil colony-forming units). As with the

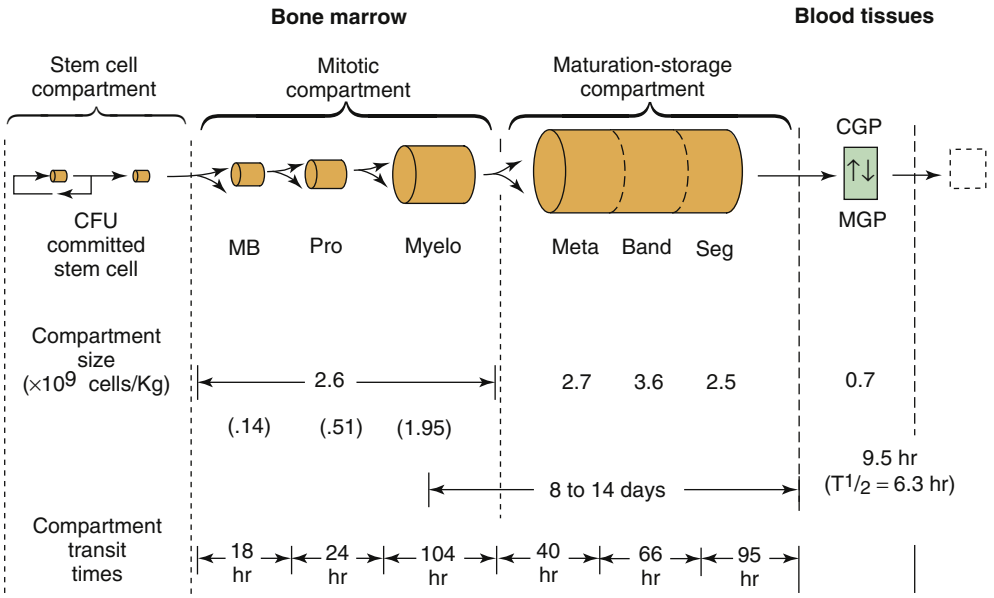

Figure 79–3. Model of the production and kinetics of neutrophils in humans. The marrow and blood compartments have been drawn to show their relative sizes. The compartment transit times, as derived from $DF^{32}P$ studies are shown on the next to last line. Values derived from tritiated thymidine studies are shown on the last line. *(Modified from Wintrobe MN et al:* Clinical hematology, *ed 8, Philadelphia, 1981, Lea & Febiger.)*

CFU-E, these are not morphologically recognizable and probably masquerade in the bone marrow as small lymphocytes. They are identified on the basis of growth characteristics in in vitro bone marrow culture assays.

Subsequent stages of granulocytic (neutrophilic, eosinophilic, and basophilic) and monocytic differentiation can be visualized by routine histochemical stains of bone marrow aspirates.[20] In the neutrophilic polymorphonuclear (PMN) series, the transition from myeloblast to mature PMN involves an overall decrease in cell size; coarsening, indentation, and ultimately separation of nuclear chromatin, with loss of nuclear chromatin, with loss of nucleoli; and replacement of azurophilic granules (whose contents include myeloperoxidase [MPO]), prominent in promyelocytes, by the specific granules (containing a number of secretory factors important for neutrophil function, but not MPO) in mature PMNs. Other structural changes during the course of PMN maturation include the disappearance of certain surface antigens, which can be identified by specific monoclonal antibodies and the appearance of receptor sites for complement (C3) and for the Fc portion of the immunoglobulin molecule. These stages in development are accompanied by functional changes, including increases in cell motility, responsiveness to chemoattractants, deformability, and phagocytic capabilities.

Parallel morphologic and functional changes occur with eosinophilic granulocyte differentiation. It is noteworthy that the peroxidase in eosinophil granules is different from that in neutrophils or monocytes, so that congenital deficiencies of myeloperoxidase in the latter cells leave eosinophil function intact. The blood basophil (which histologically is similar to the tissue mast cell) also is presumed to arise in the bone marrow from the CFU-GM (also known as *granulocyte macrophage progenitor cell*). In contrast to the CFU-Eos, there is no evidence as yet for a separate basophil CFU. DNA labeling studies have demonstrated the kinetics of neutrophil development within the bone marrow. As shown in Figure 79-3 there is a mitotic pool (myeloblast and myelocyte) that allows for amplification of cell number, and a storage or reserve pool (metamyelocyte and PMN) that in older children and adults contains roughly 100 times the number of granulocytes normally found in the peripheral blood.[21] This reserve is mobilized and leads to mature neutrophilia at times of stress (e.g., sepsis, exercise, tachycardia, and pregnancy) or on administration of pharmacological doses of corticosteroids or exposure to endotoxin. In neonates, the storage pool is only two to three times the circulating pool of PMNs and can be depleted, for example, by overwhelming sepsis.[22] Sepsis-related neutropenia may be due to apoptosis of neutrophils and their progenitors as well as a block in their maturation.[23] Thus, sepsis results in both neutropenia and neutrophilia.

Eosinophilic granulocytes also have mitotic and storage pools in the marrow that are about 300 times that seen in the periphery. After less than a week, they are released from the marrow in response to hypoxia and eosinophilic factors (e.g., heparin, histamine). In contrast to their effects on neutrophils, corticosteroids and epinephrine block mobilization of eosinophils from the marrow. The effect of epinephrine can be blocked by propranolol, suggesting mediation by β-adrenergic receptors. Little is known about basophil development in the bone marrow. Monocyte development, which, as previously suggested, is closely related to myelopoiesis, is also poorly understood. However, there does not appear to be a storage pool.

The mature neutrophil escapes from the marrow into the circulation by migration through reversible gaps between the endothelial cells lining the sinuses and capillaries. Factors known to influence this process include chemoattractants, such as products of the serum complement system. Those factors noted previously that mobilize the storage pool may cause an egress of less mature granulocytes with a resultant "shift to the left" in the peripheral blood. Once in the periphery, approximately half of the polymorphs adhere to the endothelium of blood vessels as the marginating pool while the other half actually circulate. Stress and epinephrine release the

marginating cells and therefore double the absolute granulocyte count. Eosinophils have a similar arrangement of circulating and marginating cells, whereas the marginating pool of monocytes is three times that of the circulating pool.

The life span of the neutrophil once in the periphery is 6 to 12 hours and can be less in the presence of inflammation, fever, or infection. Neutrophils are irreversibly removed from the circulation into the liver, lungs, bowel, or bladder, back to the bone marrow, or to sites of infection where they contribute to the acute inflammatory response. Their extravascular half-life also is on the order of hours. Although the circulating half-life of eosinophils is comparable with that of neutrophils, eosinophils can persist in the tissues for many days. Under pathological conditions, eosinophils may cycle back and forth between the tissues and circulation. Monocytes also have a circulating half-life measured in hours. Once in the tissues, however, they can persist for months or years and undergo the histological (larger), biochemical (increased lysozymes and ectozymes), and functional (enhanced endocytosis) changes associated with tissue macrophages. The precise changes depend on the organ of residence; for example, in the liver they are identified as Kupffer cells and in the lung as alveolar macrophages.

The CSFs that regulate myelopoiesis are diverse, and their biological specificities may overlap.[24] Cytokines such as interleukin (IL)-1, tumor necrosis factor, granulocyte-macrophage colony-stimulating factor (GM-CSF), and G-CSF expand the PMN precursor compartment and mobilize them by promoting their diapedesis from the marrow and from vascular endothelium. Endotoxin promotes the host inflammatory response by stimulating endothelial cells, macrophages, and fibroblasts to produce cytokines.

Both GM-CSF and G-CSF prime PMNs for enhanced phagocytosis and superoxide production in vitro, modulate cell surface expression of adhesion receptors, inhibit apoptosis, and promote antibody-dependent cellular cytotoxicity. However, GM-CSF inhibits chemotaxis, whereas G-CSF promotes it. G-CSF acts only on the granulocytic lineage. GM-CSF affects macrophages and eosinophils, which accounts for its side effects of eosinophilia and, at high doses, capillary leak syndrome. Because of stickiness and margination along vascular endothelium, a transient drop in O_2 saturation may occur within minutes after administration. GM-CSF can result in transient fever. Bone pain may occur with administration of either drug, if marrow production is high. WBCs must be monitored, and the drug typically is discontinued when the absolute neutrophil count exceeds 1500 to 10,000/μL. When it is discontinued, the number of circulating PMNs decreases. Multiple trials have demonstrated the efficacy of growth factors in decreasing the time interval of profound neutropenia or length of antibiotic coverage and hospitalization; their use has not changed overall survival. Clinical uses of G-CSF and GM-CSF are given in Table 79-3. Although nonhematopoietic tumor cell lines can display receptors for GM-CSF or G-CSF, administration of these drugs has not led to an appreciated increase in relapse or progressive disease. There has been some concern over erythroid stimulating agents in stimulating cancer growth.[25] Although these agents can be given to patients with myeloid leukemias or myelodysplastic syndromes without adverse effects, caution should be exercised.

As in the case of RBC and platelet development, normal myelopoiesis also requires the presence of vitamin and mineral growth factors. One hallmark of megaloblastic anemia (vitamin B_{12} and folate deficiencies) is the hypersegmented PMN. The hypochromic microcytic anemia of copper deficiency is characteristically associated with neutropenia. Among the non-lymphoid WBCs, clinical sequelae of quantitative or qualitative deficiencies of neutrophils have been particularly well studied. Systemic or mucocutaneous bacterial infections (gram-positive and gram-negative organisms) are frequent. They occur with an incidence that increases with the degree and duration of neutropenia and in the presence of indwelling catheters, intravascular lines, and endotracheal tubes.

Recommendations for prevention of infections in neutropenia include strict handwashing, changing sites of percutaneous lines as often as every 48 hours, and use of recombinant CSFs in limited situations (as noted previously). The use of prophylactic antibiotics and reverse isolation is controversial, and will vary among centers and divisions within centers. In addition to clearing bacteria and fungi, monocytes secrete a variety of inflammatory cytokines.

Table 79–3 Comparison of GM-CSF and G-CSF

Factor	Additional Uses	Starting Dose
G-CSF	Chemotherapy-induced suppression, severe congenital neutropenia, peripheral stem cell harvest, drug-induced neutropenia	5 μg/kg/d SQ or IV
GM-CSF	Autologous BMT, enhanced antigen presentation, drug-induced neutropenia	250 $\mu g/m^2$/d SQ or IV

BMT, Bone marrow transplantation.

Megakaryocyte and Platelet Production

The CFU-S gives rise to a committed megakaryocyte progenitor, the CFU-Mega (see Figure 79-2) identifiable in in vitro clonogenic assays and by the presence of platelet glycoprotein surface antigens. Unlike RBC and granulocyte differentiation in which cell division keeps up with mitosis, the next phase of development of megakaryocytes is characterized by endoreduplication, a process of mitosis without cell division that leads to increased DNA content up to a ploidy of 32N (where 2N is a diploid cell). With increasing ploidy comes increased cell volume, degree of nuclear lobulation, and granules containing factors that influence platelet function. A system of "demarcation membranes" identified by electron microscopy separates the megakaryocyte cytoplasm into several thousand anucleate platelets, which are shed into the lumens of the marrow sinusoids. The entire process takes about 5 days. Although megakaryocytes can be visualized on bone marrow aspirates and biopsy specimens, their quantitation by these techniques is approximate and correlates only loosely with platelet production. Factors controlling platelet shedding have not been studied extensively. With exceptions, however, large platelets or megathrombocytes (increased mean platelet volume) are seen in thrombocytopenia caused by increased platelet destruction. Normal platelet volume occurs more frequently in thrombocytopenia resulting from decreased platelet production.

Some platelets go directly from the marrow to the blood, where they remain; others go temporarily to the spleen, which possibly contributes to their further maturation. Normally one third of the total body platelet mass is sequestered there, although the number can go as high as 90% in pathological states. Once in the peripheral blood, platelets have a life span of about 10 days. Chromium studies, useful to assess platelet life span, have severe limitations in estimating the extent of organ-specific uptake of platelets and response to splenectomy.

Tpo is the critical growth factor for the production of platelets.[26] Whereas IL-3, GM-CSF, Epo, IL-11, and IL-6 stimulate CFU-Mega growth in vitro, none of these factors has proved to be highly effective in increasing platelet counts in clinical trials. Clinical trials are beginning in pediatrics and these agents may be available on a compassionate basis for older children. Thrombopoietin potently stimulates the expression of CFU-Mega and megakaryocytes, resulting in an increased platelet mass. Because knockout mice have been created that lack the gene for the thrombopoietin receptor but still produce some platelets, other cytokines must contribute to platelet production. These factors, such as IL-3 and IL-11, most likely synergize with thrombopoietin. Whether Epo itself has thrombopoietic activity is controversial. Although iron deficiency anemia is often associated with thrombocytosis, increases in Epo may not be the immediate mechanism, and not all disease states associated with elevated Epo levels are characterized by increased platelet number. As with the other cell lines, megakaryopoiesis is also dependent on vitamins; severe megaloblastic anemia may be associated with thrombopenia and bizarre platelet and megakaryocyte morphology.

Spontaneous bleeding is unlikely unless there are fewer than 20,000 normally functioning platelets/μL. However, for major invasive procedures such as surgery or placement of arterial lines or endotracheal tubes, the platelet count should be maintained at a level more than 50,000/μL or even 100,000/μL. The minimum platelet count for performing a spinal tap is less clear, but most clinicians would ask that the platelet count be at least 30,000/μL. Other indications for platelet transfusions are discussed in Chapter 73. In the rare patient with idiopathic thrombocytopenic purpura and intracranial hemorrhage, optimum control of bleeding requires cooperation between neurosurgery, general surgery, hematology, and intensive care clinicians and some combination of splenectomy, high-dose gamma globulin, steroid therapy, and platelet transfusions.

Lymphopoiesis

The bone marrow and thymus are the primary lymphoid organs, the site of lymphocyte production. The secondary lymphoid organs, to which the B and T cells migrate, include the spleen, lymph nodes, and gut-associated lymphoid tissue (tonsils, appendix, and Peyer's patches of the small intestine).

The Spleen

The spleen is enclosed in a thick, fibromuscular capsule. Numerous trabeculae spring from the capsule to divide the interior pulp into lobules, within which is a scaffolding of reticular cells and fibers. Unlike the thymus, the spleen has a hilum through which the splenic artery and its branches enter and then branch further to course along the trabeculae. Collaterals from the gastric artery enter through the splenic capsule so that splenic artery ligation does not result in infarction. The branches of the splenic artery pass into the parenchyma to form central arteries that are surrounded for much of their length by a dense sheath of T lymphocytes and macrophages. Lymphoid follicles, some with germinal centers containing B cells from the bone narrow (as noted previously), are also present in the periarterial lymphatic sheath. Together the B cell– and T cell–dependent areas comprise the white pulp of the spleen. The rest of the splenic parenchyma is the red pulp. It contains radial branches of the central arteries that carry hemoconcentrated blood (plasma is skimmed off and runs in other arterial branches), well-defined endothelial lined venous sinuses that ultimately drain into the splenic vein, and an anatomically separate reticulin network, the splenic vein, which function as endothelial lined blood vessels. Most of the circulation runs from the arterial system into the cords and then into the venous system, probably by squeezing through gaps in the endothelium. After the neonatal period, a marginal zone of the red pulp that abuts the white pulp becomes more prominent. It contains antigen-processing macrophages that are needed for B-cell function. It is believed to be the initial site of interactions between antigen and lymphocytes. Small numbers of efferent lymphatic vessels lie at the proximal end of the central arteries and leave the spleen through the trabeculae.

Normally the spleen is found in the left-upper quadrant of the abdomen. Its weight increases linearly with body weight until puberty, after which it shrinks somewhat. A spleen tip is palpable in 10% of normal children. On the basis of data from splenectomy cases, small accessory spleens occur in almost 20% of individuals. Generally they are located near the hilum of the main spleen, with which they share their vascular supply.

The spleen has many functions. The red pulp filters damaged and old RBCs from the systemic circulation by several mechanisms. (1) The cells are distorted and disrupt as they pass through the small lumens of the arterial capillaries or between the endothelial cells of the sinuses: in particular, cells with HbS undergo increased sickling, and cells with abnormalities of glycolytic metabolism or senescent cells become increasingly fragile in the face of decreased O_2 tension with lactic acidosis and decreased adenosine triphosphate production. (2) Cells are entrapped in the viscous blood within the fine mesh reticulin. (3) Cells undergo antibody-mediated (especially immunoglobulin G) hemolysis or phagocytosis, as seen in some autoimmune hemolytic anemias. Damaged cells or their debris produced by any of these mechanisms are removed by macrophages of the red pulp or may escape back into the circulation. Rigid inclusions such as Howell-Jolly bodies may be pitted without destroying the parent RBC on passage through the sinus endothelium. Therefore the presence of even small numbers of Howell-Jolly bodies is a subtle indicator of impaired splenic function except in the term and especially in the premature neonate, where they also are seen and thought to be a normal developmental stage.

As mentioned earlier, the spleen also is a temporary reservoir for platelets and to a small extent for WBCs. Thus after splenectomy there is a usually transient thrombocytosis that resolves within 3 to 6 months. In children it does not appear to carry a predisposition to thrombosis even with platelet counts as high as 10^9/μL. In the presence of antiplatelet or anti-WBC

antibody (some synthesized by the spleen) and in hypersplenism without antibody, the spleen may also function as a filter and result in thrombopenia and neutropenia, which may be reversible by surgical or pharmacological (steroids, high-dose gammaglobulin) splenectomy (see section on platelet production).

The spleen, predominantly the white pulp and marginal zone, also plays a number of roles in host defense, elegantly and elaborately discussed elsewhere.[8,15] In short, splenectomy has been associated with an increased incidence of serious infections with encapsulated bacteria, intraerythrocytic parasites, and possibly leukemia in patients who have splenectomy as part of the management of Hodgkin disease. Most clinicians recommend use of *Haemophilus influenzae* type b, meningococcal, and pneumococcal vaccines 1 to 2 weeks before splenectomy (in previously unimmunized individuals), with boosters against pneumococcal disease every 5 to 10 years, and prophylactic antibiotics for variable times, but at least through adolescence. Although it is not a site of hematopoiesis beyond fetal life under normal conditions, in certain disease states the spleen can reactivate its hematopoietic potential. These states include some congenital hemolytic anemias and acquired diseases, such as myeloid metaplasia. All are associated with splenomegaly and usually with hepatomegaly, signifying a more general expansion of hematopoiesis. The liver can fulfill some of these functions so that in functionally or literally asplenic patients RBC life span, for example, is not increased. However, the liver is less effective at other functions, including pitting and host defense.

Lymph Nodes

Like most of the rest of the lymphoreticular system, lymph nodes are surrounded by capsules and have architecturally distinct cortices and medullary zones, functionally distinct B cell– and T cell–dependent areas, and macrophages—all compartmentalized by a reticular meshwork. Many of the small lymphocytes, especially the T cells, continually are recycled through the systemic circulation by the thoracic duct. They function primarily as a site of interaction between the immune system and invading antigens. Mediastinal lymph node enlargement as a result of invasion by lymphoid or nonlymphoid tumors or from endogenous antigenic stimulation may compromise the airway and present anesthetic risks.

Thrombosis in Pediatric Intensive Care

John Roy and Paul Monagle

PEARLS

- Vascular access devices are the most common cause of thromboembolic disease in children, and every attempt should be made to limit their use based on real clinical need.
- Thrombophilia is rarely the major cause of thrombosis in critically ill children, and multiple tests to identify thrombophilic states are rarely useful to patient management.
- For reasons that remain uncertain, heparin-induced thrombocytopenia is rarely seen in children.
- Care must be taken in the diagnosis of thrombosis in children, as assumptions made in adult diagnostic strategies may not be true in children.
- Unfractionated heparin is the most useful anticoagulant in critically ill children; however, dosing errors are common, and pediatric intensive care units should spend considerable resources on training and systems to ensure safe management of heparin.

Dramatic improvements in pediatric intensive care have led to the improved survival of critically ill children, and to the emergence of previously rare complications. In order to achieve this improved survival, there has been a dramatic increase in the invasiveness of supportive care. The use of central venous access, invasive arterial monitoring, and circulatory support including ventricular assist devices (VAD) and extracorporeal membrane oxygenation (ECMO), as well as processes such as hemofiltration and hemodialysis that are performed through large-bore vascular access devices, increases the likelihood of vascular endothelial damage or direct vascular obstruction. These insults to the vascular system are often combined with prolonged hypotension, systemic inflammatory states, and infection, all of which may alter endothelial and vascular responsiveness. Finally, there are a multitude of drugs and fluids administered during the periods of critical illness, which can impact directly on plasma proteins and endothelial function, or which may lead to dilution of critical plasma proteins involved in the coagulation system. Not surprisingly, therefore, thromboembolism is an increasingly common problem faced in the pediatric intensive care setting, and contributes significantly to morbidity and mortality.

This chapter describes key issues related to thrombosis in the pediatric intensive care unit. Developmental hemostasis is a crucial concept both to the understanding of the etiology of thrombosis in children, and to the application of diagnostic and therapeutic strategies. The etiology, epidemiology, clinical features, diagnosis, and management of the major types of thrombosis encountered in children in the intensive care unit (ICU) will be discussed. However, thrombosis of the central nervous system (CNS), including arterial ischemic stroke and cerebral sinovenous thrombosis are beyond the scope of this chapter (see Chapter 63). As in many areas of pediatrics, high-level evidence is often lacking; however, best-available evidence will be drawn upon where possible. Extrapolation from adult studies resulting in suboptimal treatment outcomes in children highlights the need for pediatric-specific trials and guidelines.

Developmental Hemostasis

The hemostatic system is a dynamic, evolving entity that not only likely affects the frequency and natural history of thromboembolic disease in children, but also the response to therapeutic agents.[1-5] The concept of developmental hemostasis was first coined in the late 1980s and is now uniformly accepted. Not only are the plasma levels of many individual coagulation proteins different in pediatric patients from adults, but the global functioning of the coagulation system appears to be quite different. In additional to quantitative differences, there is evidence (mostly from animal models) of qualitative differences in many coagulation proteins, especially in neonates.[6,7] Finally, again from animal models, data would support significant differences in the antithrombotic properties of the blood vessel wall, with altered concentrations of active glycosaminoglycans.[8,9] Although ongoing research in this area is desperately needed, current knowledge regarding the differences between adults and children in plasma proteins most likely to impact on anticoagulation therapy is as follows.

Plasma concentrations of antithrombin (AT) are physiologically low at birth (~0.50 U/mL) and do not increase to adult values until 3 months of age. Sick premature neonates frequently have plasma levels of AT of less than 0.30 U/mL. Fetal reference ranges are now available and show that AT levels range from 0.20 U/mL to 0.37 U/mL at gestational ages of

19 to 38 weeks. This likely has a profound effect on the action of heparin, whose antithrombotic activity is dependent on catalysis of AT to inactivate specific coagulation enzymes, in particular thrombin. Some studies suggest children in pediatric intensive care units have markedly reduced AT levels compared to age-matched controls, potentially further enhancing this effect (Figure 80-1). The capacity of plasmas from neonates to generate thrombin is both delayed and decreased compared to adults, and is similar to plasma from adults receiving therapeutic amounts of heparin.[10] Following infancy, the capacity of plasmas to generate thrombin increases but remains approximately 25% less than for adults throughout childhood.[11] Both an increased sensitivity and an increased resistance to unfractionated heparin's anticoagulant activities have been reported in vitro in plasma from neonates. Increased sensitivity to unfractionated heparin is observed in systems based on assays dependent on thrombin generation (e.g., activated partial thromboplastin time [APTT]). The in vitro effects of unfractionated heparin (0.25 U/mL), on neonates, children, and adults were compared recently, and thrombin generation was delayed and reduced in children compared to adults, and virtually absent in neonates.[12] Resistance to unfractionated heparin is observed in systems based on assays that measure the inhibition of exogenously added Factor Xa or thrombin and that are dependent on plasma concentrations of AT.

In vitro, thrombin generation is similar in adults and children at the same concentration of low-molecular-weight heparin (LMWH). However, at 0.25 U/mL LMWH, thrombin generation was delayed and reduced by approximately half in newborns compared to adults. These differences were matched by reductions in rates of prothrombin consumption.[12]

The vitamin K–dependent clotting factors are the most extensively studied group of factors in infants. Physiologically low levels of clotting factors (II, VII, IX, and X) were measured in infants who received vitamin K prophylaxis at birth. The levels of the vitamin K–dependent factors and the contact factors (Factors XI and XII, prekallikrein, and high-molecular-weight kininogen) gradually increase to values approaching adult levels by 6 months of life. For children receiving vitamin K antagonists, the capacity of their plasmas to generate thrombin is delayed and decreased by 25% compared to plasmas from adults with similar INRs.[13]

Whether the overall activity of the protein C/protein S system varies with age is unknown. However, at birth, plasma concentrations of protein C are very low, and they remain decreased during the first 6 months of life. Although total amounts of protein S are decreased at birth, functional activity is similar to that in the adult because protein S is completely present in the free, active form because of the absence of C4-binding protein.[14,15] Furthermore, the interaction of protein S with activated protein C in newborn plasma may be regulated by the increased levels of α_2-macroglobulin. Plasma concentrations of thrombomodulin are increased in early childhood and decrease to adult values by late teenage years. However, the influence of age on endothelial cell expression of thrombomodulin has not been determined.[16]

Total tissue factor pathway inhibitor (TFPI) levels in newborns are reported as being similar to levels in older children or adults. Free TFPI is reported as being significantly lower in newborns.[17]

Despite the changes in individual protein levels and in global tests of coagulation, the hemostatic system in neonates and children does not seem disadvantageous compared to the "normal" coagulation system as measured in adults. There is no data to support either an increased bleeding or thrombotic risk during infancy and childhood for any given stimulus and on the contrary, one could argue that the hemostatic system in neonates and children is protective against bleeding and thrombotic complications compared to adults. This is despite the fact that when considering individual proteins, many proteins exist at levels during stages of infancy that would be associated with disease in adults. There clearly remains much to be learned about the evolution of the coagulation system with age, and this is an area in which there is much ongoing active research. As a better understanding of the neonatal and child coagulation system is achieved over coming years, thinking may change regarding many aspects of thrombosis development and management in this patient population.

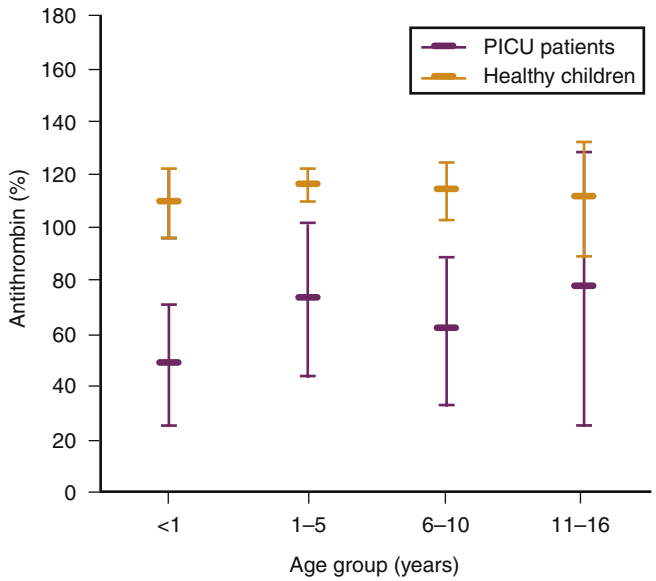

Figure 80–1. Antithrombin levels by age group in samples obtained from children in a pediatric intensive care unit (PICU) compared to age-matched controls. Note the reduction in antithrombin levels in sick children. *(Courtesy P. Monagle.)*

Etiology and Epidemiology

While there has been much published recently on a variety of factors that may contribute to the etiology of thrombosis, perhaps the most useful concept for the clinician to understand remains Virchow's triad[18]. Virchow's triad recognizes that three factors are involved in the development of thrombosis, those being the blood vessel wall, the blood constituents, and blood flow[19] (Figure 80-2). Patients in the pediatric ICU (PICU) often demonstrate abnormalities in one, two, or all of these factors, and in the consideration of each patient, it is important to determine which of these abnormalities may be predominant, as this can be a useful guide to therapy. For example, in a patient with a cardiac lesion, either primary or postsurgical, where there is extremely poor blood flow in one part of the cardiovascular system, the optimal management is to improve the blood flow. While anticoagulation may well have an important role, progressively increasing the intensity of anticoagulation will significantly increase the risk of bleeding and yet may not substantially further reduce the risk of thrombosis, which is being driven

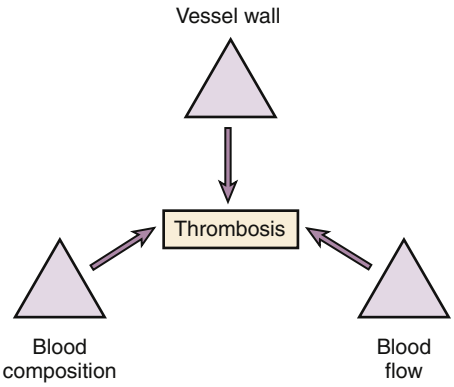

Figure 80–2. Virchow's triad, highlighting the importance of each factor in contributing to thrombosis formation.

primarily by flow. Alternatively, patients with disseminated intravascular coagulation (DIC) have a marked perturbation of function of the vascular endothelium (blood vessel wall) and anticoagulation alone is unlikely to prevent thrombotic complications, which will only be avoided by treatment of the primary illness and subsequent resolution of the DIC.

Combinations of these factors are important in many instances. For example, central venous access is a common precipitant of thrombosis most commonly through interruption to flow (especially in small infants where the catheter-to-vein diameter ratio is close to 1:1), and through disruption of the vessel wall at the insertion site. However, thrombosis is seen more commonly when there is an additional abnormality in the blood constituents as well, for example in protein-losing states like nephrotic syndrome or enteropathy, or through inflammatory or septic conditions, or via drugs such as oral contraceptives. Additional scenarios that reduce blood flow further, such as hypotension, may also increase the risk of thrombosis. Consideration of the etiological factors in this way often enables clinicians to make some attempt at risk stratification and to modify care to reduce some of the multifactorial drivers of thrombosis on an individual basis, even though there may not be clear numerical data from large studies on the actual level of risk.

Table 80-1 summarizes the epidemiology and known risk factors for most etiologies of common non-CNS thrombosis seen in critically ill children. The most important risk factors for thrombosis in the pediatric intensive care unit remain the presence of vascular access devices and recent cardiac surgery. Two additional risk factors worth discussing, although they are not often particularly relevant in children are thrombophilias and heparin-induced thrombocytopenia.

Central Venous Access Devices

The most common risk factor for venous thrombosis in children appears to be the presence of a central venous catheter (CVC) although most children have several concomitant risk factors.[20]

Over 50% of venous thromboembolisms in children occur in the upper venous system secondary to the use of central venous catheters (CVCs). Three types of CVC-related thrombosis are described in the literature: clots at the tips of CVCs that impair infusion or withdrawal of blood; fibrin sleeves that are not adherent to vessel walls but may occlude CVCs; and CVC-related thrombi that adhere to vessel walls, with partial or complete obstruction of vessels where the CVC is located. This discussion refers to this third type of thrombosis only; that is, obstructive CVC-related thrombosis. There are a number of mechanisms that may be contributory to the development of CVC-related thrombosis, including damage to the vessel wall by the CVC or by substances infused through the CVC (total parenteral nutrition [TPN], chemotherapy), disrupted blood flow due to the presence of the CVC, and thrombogenic catheter materials. Use of CVCs occurs most commonly in children who require short-term intensive care, hemodialysis, or long-term supportive care (TPN or chemotherapy).[21]

The incidence of CVC-related thrombosis reported in the literature varies, reflecting differences in underlying conditions, diagnostic tests, and index of suspicion. For example, the incidence of CVC-related thrombosis in children receiving long-term TPN varies from 1% based on clinical diagnosis,[22] to 35% based on ventilation-perfusion scans or echocardiography, to 75% based on venography.[23] In a prospective cohort, 18% of children in an intensive care setting with CVCs in place for at least 48 hours developed CVC-related thrombosis.[24] The recently completed Prophylactic Antithrombin Replacement Therapy in Kids with ALL Treated with L-Asparaginase (PAARKA) study reported a venographically proven CVC-related thrombosis incidence of 37% among asymptomatic children with acute lymphocytic leukemia receiving L-asparaginase therapy,[25] In many patient populations, the incidence is not accurately known.

Arterial Access

The most common type of arterial thrombosis in children occurs as a result of placement of arterial catheters. Non–catheter-related arterial thrombosis may be congenital (familial hyperlipidemia and hyperhomocysteinemia) or acquired (Takayasu arteritis, Kawasaki disease, congenital heart disease, and arterial thrombosis in transplanted organs). There are, in general, three types of arterial catheterizations that are used in children that may result in arterial thrombosis: umbilical arterial catheterization in neonates (will not be discussed in this chapter), cardiac catheterization, and peripheral catheterization. Arterial occlusion causes tissue ischemia resulting in tissue necrosis if the vascular occlusion persists. Organ and tissue damage at remote sites may result from embolic events occurring due to fragmentation of the original thrombus.

Often, in the PICU, short-term femoral artery access will be required, or emergency femoral artery puncture will be performed, or alternatively, the femoral artery will be inadvertently accessed during attempts at femoral venous access. In terms of understanding the implications of this, one can only really extrapolate from the cardiac catheterization literature, recognizing that diagnostic and therapeutic cardiac catheterization via the femoral artery have some significant differences in terms of thrombosis risk.

Adverse events occurring as a result of femoral artery puncture include arterial spasm and arterial thrombosis. Clinically, vascular spasm and thrombosis are indistinguishable in the initial phases of presentation with the following symptoms: decreased or absent pulses, pale or mottled limb, and decreased capillary refill. Arterial spasm usually resolves within a few hours in the absence of therapy while arterial thrombosis usually requires therapy. The incidence of femoral artery thrombosis following cardiac catheterization without thromboprophylaxis is approximately 40%. The incidence is inversely proportional to patient age and weight, with infants

Table 80–1 Summary of the Epidemiology, Clinical Features, Diagnosis, and Complications of the Most Common Types of Non-CNS Thromboembolism in Children

	Type/Location	Age/Sex	Incidence	Underlying Illness or Risk Factors	Clinical Features	Diagnosis	Complications
Spontaneous VTE	Lower limb	M = F Teenagers	1.2 per 10,000 hospital admissions		Leg, inguinal, or abdominal pain Leg swelling or discoloration	Doppler US	Immediate: PE Cardiac extension Chylothorax SVC syndrome Long-term: Recurrent VTE PPS
	Axillary	M = F Teenagers	Very rare	Mass lesion Thoracic inlet obstruction New sport involving arms	Arm swelling, pain, and discoloration	Doppler US	
CVAD-related VTE	Line tip thrombosis	Higher in neonates		Cancer, sepsis, trauma, surgery, immobility, long-term lines, congenital heart disease, burns, cardiac catheterization	Inability to flush or draw from line	Linogram Echocardiogram if tip in RA	Variceal hemorrhage
	Fibrin sleeve				Asymptomatic	Linogram, venography	
	CVAD-related DVT Iliofemoral, IVC, jugular, subclavian		Catheter material		Asymptomatic Limb or facial swelling, pain, discoloration SVC syndrome, chylothorax	Doppler US for neck, limb, and abdominal TE Venography (radiograph, CT, or MR) for intrathoracic TE	
PE			Up to 30% children with CVC-related DVT	CVAD-related DVT RA thrombus, cancer, CHD, cardiomyopathy, burns, sepsis, trauma, nephrotic syndrome, APLA, transplantation	Asymptomatic (up to 50%) Tachycardia Chest pain Respiratory distress Increased oxygen requirements Acute right heart failure Collapse Sudden death	V/Q scan Pulmonary angiography Plain radiography, CT, MR ECG Autopsy most common diagnostic test in children	Death Pulmonary hypertension and heart failure Recurrence
Arterial TE	Peripheral arterial catheter Radial artery, occasionally foot arteries			Peripheral arterial catheter	Acute limb ischemia: blanching, pallor, diminished pulses/CR Loss of patency	Doppler US	Ischemia (hand)
	UAC Celiac, mesenteric, renal, and lower limb arteries			Umbilical arterial catheter	Loss of patency Lower limb ischemia NEC/organ ischemia	Doppler US Contrast angiography	Organ Ischemia NEC Lower limb TE CNS TE (via PFO)
	Cardiac catheter Femoral artery	Increased in younger children	Up to 10%	Repeated manipulations, balloon dilatations, raised hematocrit	Limb ischemia	Doppler US	Reduced limb growth Claudication Loss of future access

	Congenital and acquired arterial disease Coronary, cerebral, peripheral arterial disease	Rare		Hyperlipidemia, homocysteinuria, acquired arteritis (Takayasu, Kawasaki)	Xanthomata Features of vasculitis or underlying disease	Echocardiography Doppler US Angiography	Myocardial infarction Stroke
	Cardiac valve				Murmur, valvular dysfunction	Echocardiography Angiography, CT, MR	Stroke Limb TE PE
	Cardiac shunt including Fontan		19% post-Fontan patients	Mechanical heart valves Shunts including Fontan	Acute loss of pulmonary blood flow		
Renal vein thrombosis	Neonates: Unilateral, 70% Bilateral, 30%	M = 64%		Asphyxia, polycythemia and dehydration, sepsis, cyanotic CHD, infant of diabetic mother	Flank mass Hematuria, Proteinuria Thrombocytopenia Renal failure	Doppler US (CT, MRI)	Adrenal hemorrhage Renal failure Hypertension
	Older children			Nephrotic syndrome, burns, SLE, transplant	Diarrhea and vomiting Dehydration, hypovolemia		
Portal vein thrombosis				Neonates: UVC Children: Liver transplant, abdominal sepsis, splenectomy, sickle cell disease, APLA Up to 50% idiopathic	Acute abdomen Portal hypertension- GI bleeding, splenomegaly	Doppler US MRI/MRA CT	Death Portal hypertension and variceal hemorrhage
Hepatic artery thrombosis					Asymptomatic	Pulsed Doppler + real time US Angiography CT/MRI	
Renal artery thrombosis					Anuria, renal failure Other signs of acute rejection	Doppler US	

APLA, Antiphospholipid antibody; *CHD,* congenital heart disease; *CNS,* central nervous system; *CR,* capillary return; *CT,* computed tomography; *CVAD,* central venous access device; *CVC,* central venous catheter; *DVT,* deep vein thrombosis; *ECG,* electrocardiogram; *F,* female; *IVC,* inferior vena cava; *M,* male; *MR[I/A],* magnetic resonance [imaging/angiography]; *NEC,* necrotizing enterocolitis; *PE,* pulmonary embolus; *PFO,* patent foramen ovale; *PPS,* postphlebotic syndrome; *RA*, right atrium; *SLE,* systemic lupus erythematosus; *SVC,* superior vena cava; *TE,* thromboembolism; *UAC,* umbilical arterial catheter; *UVC,* umbilical venous catheter; *US,* ultrasound; *V/Q,* ventilation/perfusion; *VTE,* venous thromboembolism.

at highest risk.[26] The frequency of femoral artery thrombosis in PICUs is unclear. Similarly with peripheral arterial catherization, the mechanism of injury is endothelial damage and blood vessel occlusion. The exact frequency of peripheral arterial occlusion in the PICU remains unknown.

Cardiac Surgery

Children with congenital heart disease constitute a major proportion of children seen in tertiary hospitals with thrombosis. Recent data shows that almost 50% of infants less than 6 months old and 30% of older children who suffer venous thromboembolic disease have underlying cardiac disorders. Similarly, almost 70% of infants (less than 6 months) and 30% of children who suffer arterial thrombosis have underlying cardiac defects. In addition, the majority of children receiving primary anticoagulant prophylaxis are being treated for complex congenital heart disease or severe acquired cardiac illness.[26] Presumably, the mechanisms underlying this increased risk of thrombosis are alterations to blood flow (for example, following Fontan surgery, where venous return is driving the pulmonary blood flow), and disturbances of the vascular endothelium related to intravascular sutures or vascular manipulation. Whether a postsurgical inflammatory state induces changes in the blood constituents that predispose to thrombosis is also unknown. Two classic examples of cardiac surgery-related thrombosis are the Blalock Taussig (BT) shunt, and the Fontan procedure.

The natural history of BT shunts has been assessed using angiography. Godart et al.[27] assessed BT shunt growth and development of stenosis and distortion in 78 patients at a mean follow-up time of 51 months. They found that growth of the pulmonary arteries occurred but did not exceed the normal growth of the pulmonary arterial tree. However, a shunt procedure could cause distortion and stenosis of the pulmonary artery that might have important implications for future corrective surgical intervention. Risk factors for patency and stenosis include the age of the patient and graft size.[28,29]

The incidence of thrombotic occlusion of BT shunts in the literature ranges from 1% to 17%.[28-42] This risk might be increased in children having first-stage Norwood surgery, as these children are small and unstable and often have labile blood pressures as well.

There have been a number of recent reviews regarding anticoagulation after Fontan surgery.[43,44] The Fontan procedure, or a modified version, is the definitive palliative surgical treatment for most congenital univentricular heart lesions. Thrombosis remains a major cause of early and late morbidity and mortality. Reported incidences of venous thrombosis and stroke ranged from 3% to 16% and 3% to 19%, respectively, in retrospective cohort studies where thrombosis was the primary outcome, and from 1% to 7% in retrospective studies assessing multiple outcomes. Thrombosis may occur anytime following Fontan procedures, but often presents months to years later. No predisposing factors have been identified with certainty, although this may be due to inadequate power and the retrospective nature of the studies.

Thrombophilia

Congenital thrombophilia is usually defined as having the following features: (1) positive family history, (2) early age of onset of thromboembolism, (3) recurrent disease, and (4) multiple or unusual thrombosis locations. Clinically, the most significant inherited prothrombotic conditions are deficiencies of antithrombin (AT), protein C (PC), and protein S (PS), because of the large increase in relative risk these deficiencies confer. Activated protein C resistance/factor V Leiden (FV-R506Q) and prothrombin G20210A (IIG20210A) polymorphism, while having less impact on individual risk, are significant because of their frequencies in certain populations. A large number of other candidate genes have been proposed as risk factors for congenital thrombophilia.[45] However, most of these candidates have not undergone careful segregation or population studies to define their pathogenic role. In fact, some of the seemingly obvious candidates such as abnormalities in fibrinolysis do not appear to confer thrombotic risk.[46] These latter studies are, however, hampered by the low prevalence of most of these inherited abnormalities in the general population.

Recent reports demonstrate an increased risk for thrombosis in families with a second genetic abnormality.[47] Most reports have described a combination of FV-R506Q with abnormalities of PC, PS, or AT. These findings begin to shed light on the marked variability in clinical expression of these syndromes. The effect of more severe deficiencies has long been evident from the severely affected neonates with homozygous PC and PS deficiency. Apart from the well-defined homozygous cases, the risk and severity of thrombosis appear to vary with the type and number of underlying genetic abnormalities.[47-50]

The role of these congenital prothrombotic states in childhood thrombosis remains controversial. Despite recent meta-analysis suggesting that thrombophilia is a significant risk factor in childhood thrombosis, there are serious limitations to the published literature on which these meta-analyses are based. [51]

The reported incidence of congenital prothrombotic disorders in children with venous thrombosis varies from less than 1% to over 60%.[48-50,52-84] If one considers the deficiencies of AT, PC, and PS in addition to the Factor V Leiden and prothrombin gene mutations, large family studies found negligible rates of thrombosis in children less than 15 years.[85] A number of cohort studies have failed to identify AT deficiency in children with both arterial and venous thrombosis.[70,71,75,76] Those studies that reported higher frequencies of AT deficiency did not distinguish between acquired and inherited deficiency.[57] In children with cancer and venous thrombosis, the reported incidences of thrombophilias are 3%.[75,86] The variability in incidence reported in all these studies reflects small sample sizes, variability in study design, differing definitions of prothrombotic disorders, and different patient selection criteria.[87] A prospective study of an unselected cohort of children with venous thrombosis found that with the exception of teenagers with spontaneous thrombosis, inherited thrombophilic markers did not contribute significantly to the pathogenesis of venous thrombosis in children.[88]

Screening for congenital prothrombotic disorders in children with venous thrombosis is of unproven benefit, regardless of the presence or absence of acquired risk factors. At this time, uniform screening of children with major illnesses, and/or those who require CVCs, for congenital prothrombotic disorders in order to provide prophylactic therapy cannot be recommended. The contribution of congenital prothrombotic disorders to venous thrombosis in pediatric patients remains to be clarified. Few children develop thrombosis due to a heterozygote congenital prothrombotic condition, without also having an acquired risk factor.[45,68,69,89-96]

In summary, the data supporting inherited thrombophilia as a major factor in thrombosis in childhood is conflicting. In the PICU, it is likely that the dominant factors are clinical risk factors for thrombosis and that, if it contributes at all, thrombophilia may act as an additional hit in a multi-hit pathogenesis. However, there remains no evidence to support routine screening for thrombophilia, and there are certainly no data to support primary prophylaxis of children with inherited heterozygous thrombophilia. Further, there is no evidence that the presence or absence of thrombophilia changes acute treatment once a thrombosis is diagnosed. Given the inherent difficulties in interpreting at least the functional assays of protein levels in acutely sick children, there seems little role for thrombophilia testing in the PICU.

Heparin-Induced Thrombocytopenia

Heparin-induced thrombocytopenia (HIT) occurs in approximately 3% to 5% of adults exposed to unfractionated heparin (UFH) and is typically associated with a reduced platelet count, occurrence 5 to 10 days after heparin exposure, and an increased risk of thrombosis despite the thrombocytopenia. HIT is the result of a complex antigen-antibody interaction, and the most important therapeutic intervention once HIT is diagnosed is the immediate withdrawal of all heparinoid anticoagulants, and substitution with non-heparinoid drugs until the risk of thrombosis is ameliorated.[97]

A number of case reports of pediatric HIT have described patients ranging in age from 3 months to 15 years.[98-102] UFH exposure in these cases ranged from low-dose exposure during heparin flushes used in maintaining patency of venous access devices, to supratherapeutic doses given during cardiopulmonary bypass and hemodialysis. Studies specifically examining the frequency of HIT in children have varied in their reported results, likely related to differences in patient inclusion and laboratory techniques.[103-108] Reported rates vary from almost nonexistent in unselected heparinized children[106] up to 2.3% in children in the PICU.[107] However, HIT appears to occur far less frequently in children than in adults and the rationale for this is unclear.[106] Many patients in the neonatal intensive care unit/PICU who are exposed to UFH have multiple potential reasons for thrombocytopenia and/or thrombosis, and recent papers confirm that many positive HIT tests are in fact false positives.[109] Danaparoid, hirudin, and argatroban are alternatives to UFH in children with HIT;[100-102,110-113] however, these drugs have significant risks in children.[114] Until such time as the true clinical incidence of HIT in children is understood, the diagnostic tests have higher sensitivity and specificity, and there are safe and reliable alternatives to heparin therapy in acutely sick children, the diagnosis of HIT in children should be made with caution. Careful attention to the diagnostic criteria, exclusion of other causes, and rationale use of test results are all required.

Clinical Features

The clinical symptoms and complications of venous thrombosis in children can be classified as acute or long-term. The acute clinical symptoms include loss of CVC patency; swelling, pain, and discoloration of the related limb; swelling of the face and head with superior vena cava syndrome; and respiratory compromise with pulmonary embolus (PE). The long term complications include prominent collateral circulation in the skin (face, back, chest, and neck as sequelae of upper venous thrombosis, and abdomen, pelvis, groin and legs as sequelae of lower venous thrombosis), repeated loss of CVC patency, repeated requirement for CVC replacement, eventual loss of venous access, CVC-related sepsis, chylothorax, chylopericardium, recurrent thrombosis necessitating long-term anticoagulation and its risk of bleeding, and post-thrombotic syndrome.

In adults, asymptomatic thromboses are not necessarily treated and thrombosis experts argue that these thrombi are probably inconsequential. Symptomatic thrombi are treated to prevent embolism and extension. However, in children, asymptomatic thrombosis that is radiographically detected (and which constitutes a large proportion of the thrombosis diagnosed in children), is of clinical importance for a number of reasons. First, there is increasing evidence supporting the relationship between CVC-related sepsis and CVC-related thrombosis.[115] Second, PE in children is frequently not diagnosed during life due to the subtle symptoms and the presence of other illnesses, but can cause sudden respiratory compromise. However, PE most commonly results from CVC-related thrombosis and can cause death.[116] Third, in a child with a patent foramen ovale (or some other cardiac right-to-left shunt) and venous thrombosis, stroke may occur as a result of the right-to-left intracardiac connection. Fourth, the long-term consequences of CVC-related thrombosis may be significant and include death and loss of venous access. Sudden death has been described in a few case reports from rupture of an intrathoracic collateral vessel thought to have resulted from previous CVC placement years earlier. Loss of venous access is a devastating complication of CVC-related thrombosis in children requiring vascular access for organ transplant, lifelong TPN, or dialysis.

The clinical presentation of pulmonary embolus in children is often masked. In critically ill children, sudden cardiorespiratory deterioration can be due to a multitude of causes, and the difficulty in performing appropriate imaging to confirm the diagnosis of PE often means the diagnosis is either not considered, or unable to be substantiated. Further, previously healthy children tend to tolerate large pulmonary embolus remarkably well, so often shortness of breath or dyspnea is transient, and the resolution of symptoms betrays the significance of the underlying pathology. Many children with substantial PE have no symptoms at all, until they demonstrate those of chronic venous hypertension, or a subsequent further PE has fatal consequences. Clinical suspicion for PE must be high in all critically unwell children, especially those with central venous access devices in situ.

The clinical presentation of arterial thrombosis in children is often more straightforward, with cold, pale, pulseless limbs acutely related in time to the placement of an arterial catheter. However, other systemic arterial thrombosis, for example, emboli to abdominal organs, may present with vague and nondiscriminatory symptoms. Arterial thrombosis related to transplanted vessels may present as sudden graft loss.

Diagnosis

Venous Thrombosis

Little is known about the precision and accuracy of the noninvasive imaging techniques that are commonly used to make the diagnosis of venous thrombosis in neonates. There are

few studies comparing currently used diagnostic tests. The low pulse pressure and small vessels in premature newborns can make ultrasound more difficult to interpret. Similarly, the presence of CVCs makes compressibility difficult to assess and, accordingly, greatly reduces the sensitivity of ultrasound. In neonates with umbilical vein catheters, Doppler ultrasound was shown to be poor compared to contrast venography in detecting asymptomatic thrombi.

The exception is renal vein thrombosis (RVT), where ultrasound is the radiographic test of choice because of its sensitivity in detecting an enlarged kidney, as distinct from the ability to detect intravascular thrombosis. In the first week after RVT, the affected kidney swells and becomes echogenic with prominent echo-poor medullary pyramids. Subsequently, the swelling decreases and the kidney becomes heterogeneous, with loss of corticomedullary differentiation. Ultimately, depending on the degree of recovery, ultrasound may demonstrate focal scarring or atrophy. Color Doppler ultrasound may demonstrate absent intrarenal and renal venous flow in the early stages of RVT. Magnetic resonance imaging (MRI) and computerized tomography (CT) have also been used for RVT, but have no apparent advantages over ultrasound.

In summary, in neonates with suspected venous thrombosis, venography remains the gold standard where possible. Clinicians will often be forced to use a combination of clinical assessment and suboptimal imaging to make clinical decisions, because the gold standard is practically unachievable. This must be factored into progressive decision-making.

In older children, there is a little more data about diagnostic strategies. A well-designed substudy of the PAARKA investigation compared venography versus ultrasound for the diagnosis of asymptomatic upper venous system CVC-related venous thromboembolism. Ultrasound was demonstrated to have a sensitivity of 20% for intrathoracic thrombosis, yet diagnosed jugular thrombi that were missed on venography.[25] The Lineogram, Ultrasound, and Venogram (LUV) study compared linogram, ultrasound, and venography for the diagnosis of symptomatic upper venous system CVC related thrombosis.[117] Most of the thrombi in this study were located in the jugular veins and diagnosed by ultrasound (80% sensitivity) but not venography.[118] Another study compared magnetic resonance venography (MRV) to ultrasound and linogram in 25 children with multiple CVC insertions who were suspected of having major central venous thrombosis.[118] Linogram consistently underestimated the extent of thrombosis. Ultrasound detected only seven of 18 thromboses seen on MRV, and underestimated the extent of four of the seven. In all cases, ultrasound identified jugular thrombosis but failed to identify more central thrombosis. Further, MRV identified a patent vein for reinsertion of CVC in 22 of 25 children. At operation, venous patency was confirmed in 20 patients (91%). There are no studies determining the sensitivity and specificity of diagnostic testing for lower venous system CVC-related thrombosis in children.

In summary, for children with suspected upper system thrombosis, a combination of ultrasound (jugular veins) and bilateral upper limb venography (subclavian and central veins) is recommended. The temptation to extend ultrasound imaging below the clavicles should be resisted. MRV may be a viable alternative to formal venography depending on local expertise. For children with suspected lower system thrombosis, ultrasound is a reasonable alternative for veins distal to the groin, based on adult experience. As in adults, serial ultrasound may be required to exclude thrombosis in specific circumstances. For more proximal veins, venography or MRV should be considered. Of importance, while there is considerable literature about the value of sensitive D-dimer assays in excluding DVT in adults, there is no such data in children. Furthermore, given the preceding medical and surgical therapies that most children with DVT have received, D-dimer is unlikely to be of use. At this time, D-dimer is not part of the recommended diagnostic strategy for venous thrombosis in children.

Pulmonary Embolus

There are no studies determining the sensitivity and specificity of diagnostic testing for PE in children. However, literature would support that PE is significantly underdiagnosed in children, especially those in intensive care settings. A number of potential difficulties with interpreting ventilation/perfusion (V/Q) scans in children at risk from PE have been identified. This is particularly the case in children following specific cardiac surgeries such as Fontan surgery, where total pulmonary blood flow may not be assessed by isotope injected into an upper limb. The true impact of these difficulties on diagnostic accuracy remains to be determined. In addition, there are concerns about the safety of perfusion scanning in children with significant right-to-left cardiac shunts, as it is likely that significant amounts of macroaggregated albumin will lodge in the cerebral circulation, and the impact of this is unknown.[119] Ventilation-perfusion scanning remains the recommended first-line investigation for PE in neonates and children. Pulmonary angiography remains the gold standard. Clinicians will frequently need to make a presumptive diagnosis based on clinical findings and the presence or absence of source thrombosis. CT pulmonary angiography may be an alternative, especially in the specific populations in whom V/Q scanning is more worrisome (e.g., large right-to-left shunts), but CT may miss small peripheral pulmonary emboli. Further, repeated CT angiogram may cause significant radiation exposure to breast tissue in young female patients.[116]

Arterial Thrombosis

There is little specific information related to diagnostic strategies in neonates. Contrast angiography remains the gold standard. Peripheral arterial thrombosis is usually diagnosed clinically. Ultrasound remains unproven, although serial measurements may provide useful information. Aortic thrombosis, usually secondary to umbilical artery catheterization, requires radiological diagnosis. Contrast angiography is rarely feasible in critically ill newborns. Noninvasive imaging techniques have not been validated. In fact, in one of the only comparative studies, ultrasound failed to visualize aortic thrombosis in four patients, three of whom had complete aortic obstruction by contrast angiography. Thus clinicians must often use clinical findings and suboptimal imaging to make clinical decisions.

In older children, many arterial thromboses are diagnosed on clinical grounds alone, for example, after femoral artery puncture. False negatives are reported using ultrasound to diagnose spontaneous femoral artery thrombosis in children. False-positive magnetic resonance angiography has been reported for chronic femoral artery obstruction when compared with formal angiography. In suspected peripheral artery thrombosis, clinicians should consider the possibility

of intramural or external hematoma causing arterial compression as a differential diagnosis, and for peripheral arteries, ultrasound may be sufficiently sensitive to exclude this phenomenon.

Other important arterial thromboses are those that occur in the arterial supply to transplanted organs. For hepatic artery thrombosis after liver transplant, serial testing with pulsed Doppler combined with real-time ultrasound of the liver parenchyma has a sensitivity of approximately 70%. Both false-positive and false-negative results occur, such that angiography is usually required to confirm the diagnosis. Computerized tomography of the liver may be of aid in equivocal cases. Spiral CT has been shown to be sensitive and specific in adults. The value of MRI is yet to be fully determined.

Intracardiac Thrombosis

Three studies have specifically compared transthoracic echocardiography (TTE) to transesophageal echocardiography (TEE) in the diagnosis of intracardiac thrombosis following Fontan surgery.[120-122] Stumper et al.,[122] in a cross-sectional survey of 18 patients, found three intracardiac thromboses using TEE, only one of which was detected by TTE. Fyfe et al.,[121] in a similar study, found six thrombi in four pediatric patients using TEE, only one of which was detected by TTE. Balling et al.[120] performed a cross-sectional study of 52 patients after Fontan surgery. Seventeen patients (33%) had thromboses seen on TEE, only one of which was identified on TTE. Several other publications reported intracardiac thromboses diagnosed by TEE or angiography that were not detected using TTE. Thus transthoracic echocardiography is likely insufficient to exclude intracardiac thrombosis in children after Fontan surgery, although the studies published had a number of design flaws.

The validity of transthoracic echocardiography in other clinical situations is unknown, and clinicians should consider the local expertise, availability of TEE, and the clinical situation before determining the diagnostic approach in any individual child.

Management

Overall, the management of thrombosis in children is based around anticoagulation. There are a multitude of reasons why anticoagulation therapy in children is more difficult to manage than anticoagulation therapy in adults, and some of these are listed in Table 80-2.[123] The indications for surgical intervention or thrombolysis are few and far between. A limited drug arsenal exists in terms of drugs for which there is experience in children. No anticoagulants are formally approved for use in children and so all anticoagulants are used off label. In critically unwell children, there are often multiple relative or even absolute contraindications to anticoagulation, and the balance of risk versus benefit is difficult to ascertain due to the lack of well-designed studies. In general, anticoagulation is best managed by a pediatric hematologist experienced in thrombosis and anticoagulation, in consultation with the critical care team. At all times, the overall management of the child's underlying condition must be kept in perspective versus the management of an individual thrombosis.

In terms of specific guidelines for managing thrombosis in children, the American College of Chest Physicians regularly publishes evidence-based guidelines and the reader is referred to the most up-to-date version of these guidelines as the best overall guide to antithrombotic therapy in children.[123]

Table 80–2 Factors that Increase the Complexity of Anticoagulant Therapy in Children Compared with Adults

Factor	Impact
Epidemiology of thrombosis	Increased proportion of sick children with multiple comorbidites
Developmental hemostasis	Affects response to therapeutic agents
Pharmacokinetic differences	Volume of distribution, binding, and clearance of drugs vary with age
Concurrent illnesses	Increased frequency of intercurrent infections (and hence medications) in children
Less diagnostic certainty	Requirement for general anesthetic to perform diagnostic studies impairs ability to investigate and monitor thrombosis in children
Limited vascular access	Delivery of intravenous therapy and monitoring of anticoagulant therapy more difficult
Drug formulations	All anticoagulants are "off label" in children and there are no specific pediatric preparations, making accurate dosing difficult
Dietary differences	Formula-fed versus breast-fed infants have vastly different responses to certain drugs (e.g., vitamin K antagonists)
Compliance	Age significantly affects ability to understand and cooperate with therapy
Parental supervision	Children in dysfunctional families present special management issues not seen in adults

The most common drug used is critically unwell children is unfractionated heparin. Of all currently available anticoagulants, it is the only intravenous preparation with short half-life and rapid onset and offset for which there is a known antidote. Low-molecular-weight heparins such as enoxaparin, tinzaparin, and dalteparin are all indicated for subcutaneous use in children. While there are many situations in which LMWH are advantageous, their long half-life and lack of reversibility with protamine usually make them poor anticoagulants for critically unwell children. Oral anticoagulation with coumarin derivatives such as warfarin are suitable for long-term anticoagulation, but the need for oral administration, slow onset of action, and long half-life make them unsuitable for acute anticoagulation of critically unwell children. There are a multitude of newer anticoagulants available for use in adults, and their use in children has been reviewed recently.[114] To date, the outcome of these newer drugs when used in children has been poor. The lack of antidote for most of them is an important limitation when considering their use in critically ill children. Thus until further research identifies an alternative anticoagulant that has the advantageous properties of UFH, UFH will remain the anticoagulant of choice in pediatric intensive care units.

Unfractionated Heparin in Children

UFH can be used as a first-line intervention to treat arterial and venous thromboses in infants and children. In addition, UFH also has numerous indications for primary thromboprophylaxis in infants and children, including cardiac angiography, artificial circuits (e.g., cardiopulmonary bypass, hemodialysis, extracorporeal membrane oxygenation), arterial cannulation, and venoocclusive disease prevention during bone marrow transplantation. The short half-life of UFH makes it the ideal antithrombotic agent for use in critically ill children who are at greater risk of bleeding complications but who nonetheless require antithrombotic therapy.[124]

Unfractionated heparin is a complex glycosaminoglycan capable of binding to many circulating proteins as well as to the vascular endothelium.[125-129] The anticoagulant effect of therapeutic doses of UFH is largely limited to its interaction with two naturally occurring anticoagulants: antithrombin and tissue factor pathway inhibitor. Antithrombin is a natural inhibitor of all serine proteases except factor VIIa and protein C, although the majority of its anticoagulant effect is mediated through thrombin and factor Xa.[130,131] Unfractionated heparin binding to AT occurs via a unique pentasaccharide sequence present in approximately one third of UFH molecules.[127,129] The UFH:AT complex produces a thousandfold increase in AT inhibition of coagulation protein activity compared to AT alone.[130,131] Following intravenous administration of UFH, TFPI release from the vascular endothelium increases in a dose- and concentration-dependent manner.[132] Unfractionated heparin is believed to increase the antithrombotic effect of TFPI by increasing its affinity for factor Xa by simultaneously binding to both proteins (Table 80-3).[134,135]

The monitoring of UFH therapy in the PICU is a major problem. For many indications, there is no clear therapeutic range, and certainly no clinical outcome data in pediatrics to support any particular therapeutic range. In addition, each of the monitoring tests available has significant limitations, particularly in children. Clearly, global measures of hemostasis such as the APTT will always be limited by confounding variables that affect results. Direct measurement of UFH's ability to inhibit specific coagulation proteins (e.g., factor Xa), while producing definitive values, only represents one component of UFH's inhibitory effect on in vivo coagulation. Protamine titration has been viewed as the gold standard with respect to the measurement of UFH; however, the lack of automation renders protamine titration less clinically practical. A summary of the available tests for monitoring UFH and their shortcomings in pediatrics is presented in Table 80-4.

The most important adverse effect from heparin therapy in children is bleeding. One cohort study reported bleeding in 1.5% (95% CI, 0.0% to 8.3%) of children treated with UFH for DVT/PE.[136] However, many children were treated with subtherapeutic doses of UFH (compared to the target APTT) in this study.[136] A more recent single-center cohort study reports a major bleeding rate of 24% in children in pediatric intensive care receiving UFH therapy.[137] Further studies are required to determine the true frequency of UFH-induced bleeding in optimally treated children. There are only three case reports of pediatric UFH-induced osteoporosis. In two of these, the patient received concurrent steroid therapy.[138-140] The third received high-dose intravenous UFH therapy for a prolonged period.[141] However, given the convincing relationship between UFH and osteoporosis in adults, clinicians should avoid long-term use of UFH in children when alternative anticoagulants are available. HIT has been discussed previously in this chapter.

Table 80–3 Factors in Children that Affect the Action of Unfractionated Heparin

UFH Factor	Age-Related Difference
UFH acts via AT mediated catabolism of thrombin and factor Xa	Reduced levels of AT [3,4,142] Reduced capacity to generate thrombin[10,11] Age-related difference in anti Xa/anti IIa activity[143]
UFH is bound to plasma proteins, which limits free active UFH	Alterations in plasma binding[144,145]
Endothelial release of TFPI	Age-related differences in amount of TFPI release for same amount of UFH[145]

When considering bleeding as an adverse effect of UFH, clinicians frequently view this complication as a consequence of trying to manage the balance between bleeding and clotting in critically ill children. However, in reality, one of the most common reasons for heparin-associated bleeding is due to accidental overdose of UFH. This often occurs in children who are receiving low-dose UFH flushing of vascular access devices, intended, for example, to be 50 units UFH/5 mL. Errors in vial selection and failure of bedside checking procedures result in 5000 units UFH/5 mL being injected, and in small infants this results in a massive overdose of UFH. While reports of such events rarely occur in the medical literature, and in fact there are no specific reports of this in the literature for over 20 years, the popular press is littered with reports of medicolegal activity and deaths of children due to such errors. A Google search of heparin overdose in children will highlight many recent incidents, many with fatal outcomes. Figure 80-3 summarizes the range of heparin preparations found in a typical PICU. It is not hard to see how such errors occur in busy units that operate 24 hours per day. Units should actively manage the choices of UFH preparations available to their staff to minimize the risk of confusion. Staff should be educated in the dangers of UFH, and encouraged to be vigilant at all times when administering a drug that consistently ranks in hospital lists of the drugs most commonly involved in medication errors.

Another adverse event from UFH only recently reported has been anaphylaxis, which in 2007-2008 accounted for over 80 deaths due to an unintended contaminant introduced in the manufacturing process. Again, while there is almost nothing in the medical literature describing these events, the FDA released a number of warning statements, and one impact of this has been changes to the labeling of UFH. The potential for contamination of drug products made from biological sources will always be real. An important mechanism to minimize this risk is to ensure that children only receive UFH when the risks are clearly outweighed by the benefits. UFH has been described as being ubiquitous in PICUs, and clinicians should actively minimize unnecessary exposure.

In summary, anticoagulation in children in PICU is common, and UFH is the most common agent currently utilized. While there remain many concerns about the potential adverse

Table 80–4 Assays Used in the Monitoring of UFH Therapy

Assay	Common Uses	Advantages	Disadvantages in Children
APTT F-Clot	Coagulation screening assay Therapeutic UFH monitoring	Low cost Easy to perform Widely available	Baseline APTT often prolonged in children Wide variability in reagent sensitivity to age-related differences Nonphysiologic measure of UFH effect No validation of therapeutic ranges in children
TCT F-Clot	Coagulation screening assay Therapeutic UFH monitoring (rarely)	Easy to perform	Patients previously exposed to topical thrombin may have antibodies causing prolongation of the clotting time Optimal concentration of thrombin used for the assay is unknown No validated reference range for UFH in children
ACT F-clot	CPB, extracorporeal circuits	Easy bedside whole blood test Extensive experience in most PICUs	Does not correlate with any specific measures of heparin activity Analyzer dependent
Anti-Xa F-Ch	Calibration of APTT reference ranges Therapeutic UFH monitoring	Direct measure of UFH inhibition of Xa Easy to perform	Not as widely available as APTT and costs significantly more Does not measure other mechanisms of UFH effect (e.g., Anti-IIa) and assumes constant ration of effect, which is not true in children Some kits have exogenous AT, others have dextran sulphate, both of which will introduce in vitro error in small children for different reasons
Protamine Titration Q	Not used clinically Used by reference laboratories	Only assay that directly measures UFH concentration Low cost	Not widely available Automated methods have not been validated for management of therapeutic UFH and manual methods labor intensive

F-Clot, Functional, clot-based assay; *F-Ch,* functional, chromogenic assay; *Q,* quantitative assay

Figure 80–3. Preparations of UFH commonly found on an Australian pediatric ward. Note the minimal differences in packaging, and the significant differences in UFH concentration, such that there is potential for a 100-fold overdose should a selection error be made.

effects of UFH, there are currently no real alternative anticoagulant agents available for intravenous use in sick children. Many adverse events are related to dosing errors, and it is likely that PICUs can significantly improve the safety of UFH by developing systems to prevent medication errors. In addition, there is emerging evidence that our understanding of the pharmacokinetics of UFH in children and of the assays used to monitor UFH in children is far from ideal. Urgent research is required to improve the safety and utility of UFH in critically ill children.

Conclusions

Thromboembolic disease is now a major cause of mortality and morbidity in critically ill children, in the context of children having marked differences in the hemostatic system compared to adults, which appear to be age related. There remains much to be learned about the etiology and clinical presentations of thrombosis. Diagnostic strategies are mostly extrapolated from adult studies, but are likely suboptimal. Similarly, management strategies and the use of anticoagulants in children for either treatment or primary prophylaxis are guided by minimal evidence, and there is a desperate need for further research. In the meantime, clinical decisions must be made, and for the time being, these decisions require considerable consideration of the individual risk-benefit ratios for each individual patient.

Hematology and Oncology Problems in the Intensive Care Unit

Francois P. Aspesberro, Joan S. Roberts, and Thomas V. Brogan

PEARLS

- Proactive treatment measures for tumor lysis syndrome include hydration with hypotonic or isotonic saline solution, alkalinization, use of allopurinol or urate oxidase, avoidance of exogenous potassium, close monitoring of fluid status, and frequent monitoring of serum potassium, sodium, chloride, bicarbonate, calcium, phosphorus, uric acid, blood urea nitrogen, and creatinine concentrations.
- Clinically significant hyperleukocytosis occurs with white blood cell count greater than 200,000/μL in acute myeloid leukemia and greater than 300,000/μL in acute lymphocytic leukemia.
- Concurrent thrombocytopenia and hyperleukocytosis increase risk of morbidity including intracranial hemorrhage and death. Aggressive therapy to correct coagulopathy with fresh-frozen plasma and vitamin K and to maintain platelet count greater than 20,000/μL is critical.
- Oxygen consumption may become delivery dependent when the hemoglobin concentration falls below 5g/dL or less.
- Signs of significant cardiovascular compromise may not become evident until the child has acutely lost at least 25% of total blood volume.
- Neutropenic patients have a decreased ability to manifest a coordinated proinflammatory and immunoregulatory response against infectious pathogens. Restoration of adequate intravascular volume and broad-spectrum antibiotic therapy are the most important therapeutic intervention for neutropenic patients in septic shock.
- In the absence of other hemorrhagic risks, platelet counts 10,000/μL and greater are associated with little risk of serious bleeding.
- Gastrointestinal bleeding is an important cause of morbidity and mortality in patients with end-stage renal disease.
- Intravenous administration of desmopressin acetate at a dosage of 0.3 μg/kg over 30 minutes improves platelet dysfunction caused by uremia within 1 hour, and the effect is maintained for 4 to 8 hours.
- Childhood mediastinal masses produce few symptoms until they have occluded a substantial portion of the cross sectional area of the trachea or main-stem bronchi or the superior vena cava. Diagnosis should be established with the least invasive means available, because these patients are at significant risk for anesthetic complications.
- Spinal cord compression most frequently occurs as metastatic disease and requires emergent treatment with 1 mg/kg of dexamethasone over 30 minutes.
- Hemophagocytic lymphohistiocytosis (HLH) produces severe illnesses that may be confused with other forms of systemic inflammatory response syndrome, such as sepsis. Appropriate diagnosis is tantamount as untreated HLH is almost always fatal.

A variety of hematologic and oncologic disorders may cause critical illness resulting in admission of a child to the intensive care unit (ICU). Hematologic abnormalities arising from other conditions or their treatment may pose a challenge to physicians caring for the critically ill child. This chapter addresses the more frequently encountered problems. Chapter 84, "Hemoglobinopathies," addresses the complications of sickle cell anemia. Chapter 83, "Critical Illness Involving Children with Hematopoietic Stem Cell Transplantation," addresses the complications related to hematopoietic stem cell transplantation.

Hematologic Emergencies

Anemia

Anemia results from a deficiency in the oxygen carrying capacity of the blood. The deficit may be in the number of red blood cells (RBCs), the RBC hemoglobin concentration, or both. Because hemoglobin serves as the primary transport molecule for oxygen, anemia may affect the delivery of oxygen (O_2) to the tissues with wide-ranging potential complications.

O_2 delivery is the product of cardiac output and arterial O_2 content (Cao_2). Hemoglobin concentration and the percentage of O_2-hemoglobin binding (% saturation) are the primary determinants of Cao_2. Oxygen dissolved in the plasma normally contributes a negligible amount to overall O_2 delivery. Cardiac output is a product of stroke volume and heart rate. Abnormalities in any of these parameters may impair tissue oxygenation.

Under steady-state conditions, oxygen consumption remains constant and is independent of oxygen delivery until it falls below a critical level, which varies for each organ system. When the hemoglobin concentration decreases to approximately 5 g/dL or less, oxygen delivery and consumption may be altered.[1] Below this level, O_2 consumption becomes delivery dependent.

The body responds to acute, normovolemic anemia by increasing cardiac output, through increases in stroke volume, heart rate, or both. As the hematocrit falls, blood viscosity diminishes, thus increasing venous return and augmenting preload. In the patient with chronic anemia, increases in cardiac output are supplemented by increased levels of 2,3-diphosphoglycerate shifting the oxyhemoglobin curve to the right and augmenting O_2 delivery at the tissue level.

Anemias generally are classified either by the mechanism resulting in the hemoglobin deficit—decreased production, accelerated destruction, or loss of erythrocytes—or by the morphologic appearance of the erythrocyte (Box 81-1).[2] Decreased RBC production may result from a variety of causes, including congenital defects, such as Fanconi anemia and Diamond-Blackfan anemia, or from postnatal causes, including acquired aplastic anemia, erythropoietin deficiency associated with renal disease, bone marrow suppression secondary to drugs or infectious agents, nutritional deficiencies, and bone marrow infiltration.

RBC loss may stem from enhanced destruction as seen with erythrocyte membrane defects, (e.g., hereditary spherocytosis); with deficits in RBC enzymes such as glucose 6-phosphate dehydrogenase; and with microangiopathic processes, including hemolytic uremic syndrome, thrombotic thrombocytopenic purpura, and disseminated intravascular coagulation (DIC). Antibody-mediated red cell destruction, whether autoimmune, alloimmune, or drug related, may result in profound anemia. Blood loss secondary to trauma, surgery, hemorrhage, or even frequent phlebotomy may also lead to severe anemia.

Morphologic classifications of anemia are based on either erythrocyte size, as defined by mean corpuscular volume and mean corpuscular hemoglobin concentration, or by abnormalities in the erythrocyte shape (Box 81-2).[2] The normal values for mean corpuscular volume and mean corpuscular hemoglobin concentration vary with the child's age. A wide variety of conditions, some intrinsic to the erythrocyte and others related to extrinsic factors, may result in abnormal RBC morphology.

The more common causes of profound anemia encountered in the pediatric intensive care setting are reviewed below. These causes include hemorrhagic anemia, decreased RBC production, and hemolytic anemia. Chapter 84, "Hemoglobinopathies," provides a discussion of sickle cell anemia, other hemoglobinopathies, and their complications.

Box 81–1 Physiologic Classification of Anemia

A. Disorders of Red Cell Production in Which the Rate of Red Cell Production Is Less than Expected for the Degree of Anemia

1. Marrow failure
   - a. Aplastic anemia
     - (i) Congenital
     - (ii) Acquired
   - b. Pure red cell aplasia
     - (i) Congenital
     - (ii) Diamond-Blackfan syndrome
     - (iii) Aase syndrome
     - (iv) Acquired
     - (v) Transient erythroblastopenia of childhood
     - (vi) Other
   - c. Marrow replacement
     - (i) Malignancies
     - (ii) Osteopetrosis
     - (iii) Myelofibrosis
     - (iv) Chronic renal disease
     - (v) Vitamin D deficiency
   - d. Pancreatic insufficiency-marrow hypoplasia syndrome
2. Impaired erythropoietin production
   - a. Chronic renal disease
   - b. Hypothyroidism, hypopituitarism
   - c. Chronic inflammation
   - d. Protein malnutrition
   - e. Hemoglobin mutants with decreased affinity for oxygen

B. Disorders of Erythroid Maturation and Ineffective Erythropoiesis

1. Abnormalities of cytoplasmic maturation
   - a. Iron deficiency
   - b. Thalassemia syndromes
   - c. Sideroblastic anemias
   - d. Lead poisoning
2. Abnormalities of nuclear maturation
   - a. Vitamin BI; deficiency
   - b. Folic acid deficiency
   - c. Thiamine-responsive megaloblastic anemia
   - d. Hereditary abnormalities in folate metabolism
   - e. Orotic aciduria
3. Primary dyserythropoietio anemias (types I, II, II, IV)
4. Erythropoietic protoporphyria
5. Refractory sideroblastic anemia with vacuolization of marrow precursors and pancreatic dysfunction deficiency

C. Hemolytic Anemias

1. Defects of hemoglobin
   - a. Structured mutants
   - b. Synthetic mutants (thalassemia syndromes)
2. Defects of the red cell membrane
3. Defects of red cell metabolism
4. Antibody mediated
5. Mechanical injury to the erythrocyte
6. Thermal injury to the erythrocyte
7. Oxidant-induced red cell injury
8. Infectious agent-induced red cell injury
9. Paroxysmal nocturnal hemoglobinuria
10. Plasma lipid-induced abnormalities of the red cell membrane

Box 81–2 Classification of Anemias Based on Red Cell Size

A. Microcytic Anemias
1. Iron deficiency (nutritional, chronic blood loss)
2. Chronic lead poisoning
3. Thalassemia syndromes
4. Sideroblastic anemias
5. Chronic inflammation
6. Some congenital hemolytic anemias with unstable hemoglobin

B. Macrocytic Anemias
1. With megaloblastic bone marrow
   a. Vitamin B_{12} deficiency
   b. Folic acid deficiency
   c. Hereditary orotic aciduria
   d. Thiamine-responsive anemia
2. Without megaloblastic bone marrow
   a. Aplastic anemia
   b. Diamond-Blackfan syndrome
   c. Hypothyroidism
   d. Liver disease
   e. Bone marrow infiltration
   f. Dyserythropoietic anemias

C. Normocytic Anemias
1. Congenital hemolytic anemias
   a. Hemoglobin mutants
   b. Red cell enzyme defects
   c. Disorders of the red cell membrane
2. Acquired hemolytic anemias
   a. Antibody mediated
   b. Microangiopathic hemolytic anemias
   c. Secondary to acute infections
3. Acute blood loss
4. Splenic pooling
5. Chronic renal disease (usually)

Hemorrhagic Anemia

Bleeding may be either acute or chronic. Chronic bleeding generally causes anemia through depletion of iron stores.[3] In response, patients adapt mechanisms to increase O_2 delivery and to avoid hypovolemia permitting them to tolerate hemoglobin levels well below the normal range, with mild clinical findings. Signs and symptoms of acute hemorrhage result from poor end-organ perfusion, with consequent diminished O_2 delivery. However, diagnosis of the presence and degree of blood loss may be difficult in an otherwise healthy child. Signs of impending shock, such as pallor, anxiety, and tachypnea, may be subtle.[4] Signs of significant cardiovascular compromise may not become evident until the child has lost at least 25% of total blood volume. Patients who have lost more than 25% of blood volume usually manifest age-related systolic hypotension.[4] Initial management should include achieving hemostasis, establishment of a secure airway, maintenance of ventilation, and initiation of volume replacement via an adequate intravenous catheter.[5] Either crystalloid or colloid solutions are effective in restoring circulating volume, but an important debate currently exists over appropriate fluids and timing of resuscitation in acute traumatic hemorrhage that is beyond the scope of this chapter.

RBC transfusion should be given if O_2 delivery to the end organ is impaired.[6] Either whole blood or packed RBCs can be used, but the former has many difficulties related to storage and transport. If packed RBCs or plasma-poor red cells are used to correct O_2-carrying capacity during massive blood loss, deficits of coagulation factors develop earlier than during transfusion of whole blood. Hypofibrinogenemia generally develops first, followed by deficits in other clotting factors and later by thrombocytopenia. Fresh-frozen plasma should be used to treat coagulopathy that develops during replacement of massive blood loss with RBCs. Transfusion of platelets should be guided by serial platelet counts.[7]

Central venous pressure should be monitored to allow for rapid administration of RBCs and volume replacement while decreasing the risks of hypervolemia. Blood and other fluids may be administered very rapidly until central venous pressure rises to between 6 and 7 mm Hg. Chapter 29 discusses the diagnosis and management of shock.

Anemia Secondary to Bone Marrow Failure

Several hematologic diseases are associated with diminished blood cell production. Acquired aplastic anemia, characterized by pancytopenia and hypocellular or acellular bone marrow, is defined by at least two of the three following: granulocytes less than 500/μL, platelets less than 20,000/μL, and anemia with a corrected reticulocyte count less than l%, in conjunction with markedly hypocellular bone marrow.[8] The majority of cases have no definable cause but the pathophysiology appears related to immune mediated with destruction of blood-forming cells by lymphocytes. Excessive production of interferon-γ, tumor necrosis factor, and interleukin-2 has been noted.[9] Altered immunity results in CD34 cell death and in intracellular pathways leading to cell cycle arrest.[10] A minority of cases follows chemical or drug exposure. Post-hepatitis aplastic anemia typically occurs in young males, with pancytopenia presenting several weeks after severe liver inflammation.[11] Serologic testing for known hepatitis viruses generally reveals no pathogen.[12]

Acquired aplastic anemia can be distinguished from bone marrow failure resulting from Fanconi anemia by specific assays for chromosomal susceptibility to chemical cross-linking agents that characterize Fanconi anemia.[13] Other constitutional syndromes may be suspected based on the presence of a pedigree of typical physical stigmata. Cytogenetic studies usually are normal in aplastic anemia, whereas aneuploidy or structural abnormalities are relatively common in myelodysplasia.[10] Myelodysplasia may evolve in patients treated for aplastic anemia. Some patients with paroxysmal nocturnal hemoglobinuria develop bone marrow failure; conversely, paroxysmal nocturnal hemoglobinuria may evolve years after aplastic anemia is diagnosed.[10] In paroxysmal nocturnal hemoglobinuria, flow cytometry shows a deficiency of CD59 on erythrocytes and leukocytes.

Irrespective of the etiology of bone marrow failure, life-threatening complications may arise from blood cytopenias. The most common causes of death are bacterial sepsis and fungal infection secondary to refractory granulocytopenia.[14] Broad-spectrum antibiotics should be used to treat suspected infection in the granulocytopenic patient. Historically, gram-negative organisms were the most frequent cause of fulminant

infection in this patient population. With the increased use of central venous catheters, gram-positive organisms now predominate.[15] Antifungal therapy should be instituted in patients who fail to defervesce within 3 to 5 days of treatment with antibiotics. Persistent, unexplained fever requires thorough evaluation to look for evidence of invasive fungal infection.

Platelet transfusions should be used judiciously in an effort to avoid alloimmunization to platelet antigens, generally being reserved for episodes of active bleeding. Similarly, RBC transfusions should be reserved for patients whose oxygen delivery may be compromised as a result of profound anemia. The patient should not receive blood products donated by family members to avoid sensitization to leukocyte and platelet antigens of potential bone marrow donors. All blood products should be irradiated and leukodepleted to decrease the risk of graft-versus-host disease.[15] Treatment of severe acquired aplastic anemia involves either the use of immunosuppressive therapy or replacement of bone marrow through stem cell transplantation. The patient and immediate family members should undergo human leukocyte antigen typing. The treatment of choice, bone marrow or peripheral blood stem cell transplantation from a histocompatible sibling, produces long-term survival rates of 75% to 80%.[16] Unfortunately, up to 70% of patients may lack a suitably matched sibling donor. Stem cells are harvested from matched unrelated donor, or umbilical cord blood, produce poorer outcomes because of the higher rate of graft-versus-host disease. For these patients, immunomodulation, which usually includes a combination of antithymocyte globulin, cyclosporin, and corticosteroids, often with use of hematopoietic growth factors, has resulted in response rates of 70% to 80%.[17,18] Not all responders achieve a complete remission, however; late relapses, as well as evolution to myelodysplasia and leukemia, are reported.[19]

Hemolytic Anemia

Hemolysis, the destruction of RBCs with liberation of hemoglobin, may occur either within the blood vessels (intravascular hemolysis) or the reticuloendothelial system (extravascular hemolysis). Anemia results when the rate of RBC destruction exceeds new RBC production in the bone marrow.[20] Laboratory findings in patients with hemolytic anemia usually include increased reticulocyte count and elevated serum concentrations of unconjugated bilirubin and lactate dehydrogenase. Intravascular hemolysis usually results in decreased serum haptoglobin concentrations.

Premature destruction of RBCs may result from intrinsic RBC abnormalities, such as hemoglobinopathies or red cell membrane defects, or from a variety of extrinsic factors (Figure 81-1).[2] Numerous hemoglobin variants resulting in shortened RBC survival have been identified. Individuals with sickling hemoglobinopathies may suffer a variety of complications that require treatment in an ICU (see Chapter 84). Abnormalities in the structure of the RBC membrane, as in hereditary spherocytosis, or decreased quantities of RBC enzymes, as in G6PD deficiency, also decrease red cell survival. Hemolysis in these settings occurs primarily extravascularly. Mechanical disruption of the red cell membrane secondary to factors extrinsic to the RBC may lead to macroangiopathic hemolytic anemia, as with turbulent flow around a prosthetic heart valve, or microangiopathic hemolytic anemia, caused by

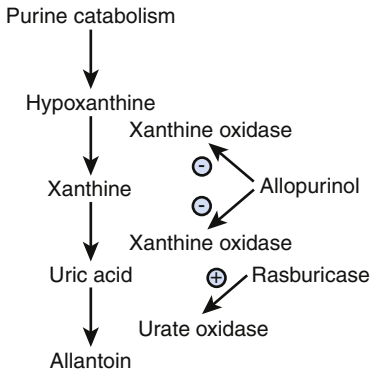

Figure 81–1. Causes of premature destruction of the red blood cell. *CU*, Copper; *DIC*, disseminated intravascular coagulation; *G6PD*, glucose 6-phosphate dehydrogenase; *HS*, hereditary spherocytosis; *PK,* pyruvate kinase; *PNH*, paroxysmal nocturnal hemoglobinuria.

fibrin deposition in the microvasculature. The latter process is seen in consumptive disorders, including DIC, hemolytic uremic syndrome, and thrombotic thrombocytopenic purpura.[21] In these entities, hemolysis is primarily intravascular. Schistocytes are characteristically seen on the blood smear.

The hemolytic processes that result from abnormal interactions between erythrocytes and the immune system are known collectively as autoimmune hemolytic anemia (AIHA).[2] AIHA can be classified as either primary, in which there is no identifiable systemic illness except possibly a history of a recent viral-like illness, or secondary, in which the hemolytic anemia is present in the context of another illness. AIHA has been reported as a manifestation of autoimmune disorders (e.g., lupus erythematosus), immunodeficiency disorders, malignancies, specific infections, or as a drug reaction (Box 81-3).[21] AIHA also may be classified by the thermal sensitivity of the autoantibodies. The most common form is the result of warm-reactive immunoglobulin (Ig) G autoantibodies directed against RBC membrane proteins. Extravascular hemolysis occurs, with sensitized erythrocytes cleared primarily in the spleen. Cold-agglutinin disease, the second most common form of AIHA, most frequently occurs with *Mycoplasma pneumoniae* infections, but it also is associated with other infectious agents, including Epstein-Barr virus, cytomegalovirus, and mumps virus. In this disorder, IgM autoantibody binds to the RBC and fixes complement. The erythrocytes may undergo intravascular hemolysis, or they may be cleared by the reticuloendothelial system, primarily in the liver. Paroxysmal cold hemoglobinuria, a rare variant of AIHA in which an IgG autoantibody binds at cold temperature to the P-antigen of the erythrocyte, fixing complement (the Donath-Landsteiner antibody) and producing intravascular hemolysis. It usually follows a viral illness.[21] Although drug-induced autoantibodies occur uncommonly in children, they may follow exposure to some antibiotics, including penicillins and cephalosporins.[22,23] Mechanisms of drug-induced hemolysis may include autoantibody formation and adsorption of the drug onto the red cell membrane, with immune complex formation with IgG or IgM.[24]

Patients with AIHA usually present with pallor, jaundice, and splenomegaly on physical examination. The reticulocyte count is generally elevated, although initially it may be low or normal. Spherocytes and polychromasia are present on the peripheral blood film, and nucleated RBCs are frequently seen.

Box 81–3 Classification of Autoimmune Hemolytic Anemia in Children

A. Primary AIHA*
1. Warm-reactive autoantibodies, usually IgG
2. Paroxysmal cold hemoglobinurla, usually IgG
3. Cold-agglutinin disease, usually IgM

B. Secondary AIHA†
1. Systemic autoimmune disease (e.g., lupus)
2. Malignancy (Hodgkin and non-Hodgkin lymphoma)
3. Immunodeficiency
4. Infection (*Mycoplasma*, viruses)
5. Drug induced

*Occurs in the majority of affected children and often follows a nonspecific viral-like syndrome, but in the absence of another systemic illness.
†Occurs in association with another systemic process.
AIHA, Autoimmune hemolytic anemia; *IgG*, immunoglobulin G.

RBC agglutination may be present in cold-reactive AIHA. The direct antiglobulin test (Coombs test) demonstrates the presence of antibodies or complement on the red cells. The indirect antiglobulin test measures the presence of unbound antierythrocyte antibodies in the patient's serum.

Therapy depends on the type of AIHA and the severity of clinical symptoms. Profound anemia, usually with a hemoglobin level of less than 5 g/dL, may result in cardiovascular compromise and requires erythrocyte transfusion to increase O_2-carrying capacity. The presence of autoantibodies often makes cross-matching blood difficult, and the patient may require transfusion with "least incompatible" blood.[25] Significant hemolytic transfusion reactions are infrequent.[25] However, severe hemolysis occurs on rare occasions, with hemoglobinemia and hemoglobinuria resulting in renal failure. Therefore transfusions should be started at a slow rate, and both plasma and urine samples should be checked regularly for free hemoglobin.[21] Patients with cold-reactive antibodies should be kept warm, and a blood warmer should be used for the transfused blood.[26] Even in the absence of transfusion, significant intravascular hemolysis may occur in patients with cold-reactive antibodies. Maintaining good renal blood flow and careful monitoring of urine output in this setting may help obviate renal injury.[27] Corticosteroids appear to slow the hemolytic process, particularly in patients with IgG autoantibodies, in whom they appear to inhibit Fc receptor-mediated clearance of sensitized erythrocytes.[28] The usual dosage is 1 to 2 mg/kg methylprednisolone given intravenously every 6 hours until the patient is clinically stable. The patient then can be switched to oral prednisone (2 mg/kg/day for 2 to 4 weeks, followed by a slow taper over 1 to 3 months).[21]

Corticosteroids may also be effective in cold agglutinin disease, although the response is less predictable.[29] High-dose intravenous γ-globulin (IVIG, 1 g/kg/day for 5 days), produces response in approximately one third of patients with warm-reactive disease.[30] Plasmapheresis and plasma exchange may be beneficial, particularly in patients with IgM autoantibodies.[31] The overall prognosis for children with AIHA is good. Cold-reactive AIHA generally resolves completely. Some patients with warm-reactive antibodies have a chronic course, marked by remissions and exacerbations.[21]

Thrombocytopenia

Thrombocytopenia may be secondary to either decreased platelet production or increased platelet destruction. Decreased platelet production may result from primary bone marrow failure states or from bone marrow infiltration by malignant cells as in leukemia, lymphoma, and metastatic solid tumors. Bone marrow suppression, a common side effect of antineoplastic therapy including both chemotherapy and radiotherapy, frequently leads to periods of thrombocytopenia. Thrombocytopenia or platelet dysfunction may result in bleeding, usually involving the skin and mucous membranes. Clinical manifestations include petechiae and purpura, epistaxis, gastrointestinal bleeding, hematuria, and menorrhagia. Intracranial hemorrhage is an infrequent manifestation of thrombocytopenia.

Indications for platelet transfusion in these settings vary with the underlying cause of thrombocytopenia and the patient's clinical status. Patients with primary bone marrow failure, who likely will experience prolonged thrombocytopenia, generally receive transfusions only for active bleeding because of the risk of alloimmunization. In addition, exposure to multiple platelet donors may jeopardize the success of bone marrow transplantation by increasing the risk of graft rejection.[32] In the absence of other hemorrhagic risks, platelet counts of 10,000/dL or greater usually carry little risk of bleeding.[33] The threshold for transfusion may need to be set higher in patients with sepsis, decreased humoral coagulants, or other risk factors. In the perioperative setting, platelet counts should be maintained at higher than 50,000/dL and greater than 100,000/dL for neurologic or ophthalmologic surgery.[34] Use of ABO-compatible donors and leukoreduction diminishes the risk of platelet alloimmunization.[33] Single-donor apheresis units reduce donor exposure compared with pooled platelet concentrates, but whether such usage reduces the incidence of platelet alloimmunization remains unclear.[35]

Immune Thrombocytopenia

Immune platelet destruction may be caused by autoantibodies, drug-dependent antibodies, or alloantibodies. Alloantibodies result from exposure to polymorphic epitopes expressed on foreign platelets to which the patient has been exposed (see previous section). Drug-induced thrombocytopenia may be suggested by the patient's medication history. Laboratory tests for specific drug-associated antiplatelet antibodies are available.

In immune thrombocytopenia purpura (ITP), autoantibodies to platelets may be associated with other autoimmune disorders or immune deficiency states, or after viral illness or immunization.[36] The incidence of childhood ITP was found to range from 5 to 7 per 100,000 per year, with 25% of the children subsequently developing chronic ITP.[37] Frequently, no predisposing condition is identified (idiopathic thrombocytopenia purpura). Regardless of cause, the reticuloendothelial system removes antibody-coated platelets, with the bulk of the destruction occurring in the spleen. These children typically present with petechiae, purpura, and bleeding from mucous membranes and isolated thrombocytopenia. The bone marrow responds with increased platelet production. The rapid turnover in platelets results in younger, somewhat larger, platelets entering the blood. Hence, serious bleeding rarely

occurs because of the increased effectiveness of platelets.[38] In a recent retrospective review, a low admission mean platelet volume value (<8 μL) and a history of viral prodrome were found to be independent prognostic variables that predicted durable remission.[39]

The primary goal of therapy in children with ITP is to limit bleeding especially from the central nervous system. Therapy does not appear to affect the natural history of the illness. There is no consensus regarding the management of acute ITP and the need for intervention in the absence of significant hemorrhage remains the subject of debate.[40] Intracranial hemorrhage remains rare, and there are no data that treatment actually reduces the incidence of intracranial hemorrhage. Therapy is directed at slowing clearance of sensitized thrombocytes in the spleen and reducing antibody production. Initial medical management usually involves the use of corticosteroids (prednisone 2 mg/kg/day) or IVIG (1 g/kg/day for 1 to 2 days).[41,42] High-dose methyl-prednisolone (30 mg/kg/day intravenously for 3 days) also is effective.[43,44] Bone marrow evaluation to rule out malignancy before corticosteroid therapy should occur. Infusion of anti-Rh(D) immunoglobulin (50 to 75 μg/kg) for individuals who have Rh(D)-positive RBCs prolongs survival of antibody-coated platelets in patients with ITP. As with IVIG, the major mechanism appears to include blockage of Fc receptors on reticuloendothelial cells.[45] Use of these agents usually halts bleeding and raises platelet counts to safe levels within a few days, although evidence indicating their influence on the course of the disease remains lacking.

Intracranial hemorrhage, the most devastating complication of ITP, although rare requires immediate intervention. Consequently, patients presenting with headaches, persistent vomiting, or neurologic symptoms require emergent computed tomography (CT) scan of the head. Therapy for intracranial hemorrhage usually includes, IVIG, corticosteroids, and emergency splenectomy.[46] Platelet transfusions in ITP rarely result in an increase in the platelet count because of rapid consumption of transfused platelets. Nevertheless, intermittent (2 to 4 IU/m^2 every 6 to 8 hours) or continuous (0.5 to 1 IU/m^2/hr) platelet transfusions have been administered for life-threatening hemorrhage, with decreases in bleeding reported.[47,48] Plasmapheresis may be beneficial in patients who do not respond to these interventions.[49] A splenectomy should be performed if a craniotomy is required, to maximize the perioperative platelet count.[47]

Nonimmune Thrombocytopenia

DIC occurs when generalized activation of the plasma coagulation pathways occurs within small blood vessels with formation of fibrin and depletion of circulating levels of humeral clotting factors and platelets. DIC usually follows a systemic insult, most often sepsis or shock. Treatment should be directed to the underlying cause. Hemorrhage frequently occurs at platelet counts greater than 10,000/μL because of concomitant depletion of clotting factors. Control of bleeding may necessitate platelet and plasma transfusions. DIC had been thought to be the etiology of much of the multiorgan system failure in ICU patients, with formation of a large number of microthrombotic foci leading to organ microcirculation failure and subsequent failure of the organ itself.[50] More recently, some studies have suggested that vascular endothelial damage induced by humeral mediators is the primary cause of thrombocytopenic multiorgan system failure.[51] In these instances, thrombocytopenia may be a marker of poor prognosis rather than a cause of ICU mortality.[52]

Increased platelet consumption with resultant thrombocytopenia occurs in diseases associated with extensive vascular endothelial damage, including hemolytic uremic syndrome and thrombotic thrombocytopenic purpura.[53,54] Aggregates of activated platelets become trapped in small blood vessels, causing a microangiopathic hemolytic anemia. Schistocytes usually are present on the peripheral blood film. Platelet transfusions should be given only for life-threatening bleeding because they may worsen the thrombotic process.[55]

Thrombocytopenia caused by splenic sequestration develops in individuals with massive splenomegaly. The etiology of splenomegaly includes infectious, infiltrative, neoplastic, obstructive, and hemolytic causes. The Kasabach-Merritt syndrome is an association of a giant hemangioma with localized intravascular coagulation causing thrombocytopenia and hypofibrinogenemia. Rare congenital thrombocytopenic syndromes include congenital amegakaryocytic thrombocytopenia, thrombocytopenia-absent radius and Wiskott-Aldrich syndrome.

Bleeding in Uremia

Hemorrhagic manifestations in patients with renal failure are characterized by purpura and bleeding from mucous membranes and puncture sites. Gastrointestinal bleeding may contribute to morbidity and mortality in patients with end-stage renal disease.[56] Concurrent hypertension increases the risk of subdural hematoma. The hemostatic defect in uremia is multifactorial, resulting in part from altered metabolism of platelets and vascular endothelial cells and from abnormal interactions between platelets and vascular endothelium.[57]

When uremia is present, clinical bleeding may be increased relative to the degree of thrombocytopenia resulting from secondary platelet dysfunction. Intravenous administration of desmopressin acetate (0.3 μg/kg over 30 minutes) improves platelet dysfunction caused by uremia within 1 hour with a duration of the effect for 4 to 8 hours.[58] Tachyphylaxis may occur after two to three doses. Intravenous conjugated estrogens or oral estrogens cause slower but more sustained improvements in bleeding time.[56] Dialysis results in improved platelet function through reduction of azotemia.

When severe anemia is present, platelets travel closer to the midstream and are less likely to interact with the vascular endothelium. In addition, RBCs exert metabolic effects on platelets by enhancing adenosine diphosphate and thromboxane A2 release. Therefore use of red cell transfusions or erythropoietin to increase the hematocrit to 30% helps to correct the bleeding time.[59] Further increase in hematocrit increases the risk of thrombosis, particularly of arteriovenous shunts and the extracorporeal hemodialysis circuit.

Oncologic Emergencies

Tumor Lysis Syndrome

As the name suggests, tumor lysis syndrome (TLS) results from the death of tumor cells resulting in the rapid extravasation of intracellular contents into the blood.[60] The release of intracellular contents may cause metabolic derangements and/or produce end-organ damage. Careful monitoring and

rigorous attention to organ function may help to obviate the majority of complications from this syndrome.

Although the lysis of malignant cells usually begins after the institution of chemotherapy, spontaneous TLS occurs.[61] Important considerations in TLS include the level of tumor burden and the sensitivity of the cells to the antitumor agents.[62] In children, hematologic malignancies such as acute lymphoblastic leukemia (ALL), acute myelogenous leukemia (AML) and Burkitt lymphoma provide the majority of cases of TLS.[63] TLS usually occurs with new-onset disease, preexisting renal dysfunction, when nephrotoxic drugs are used and with dehydration. Diagnosis of TLS generally requires some combination of hyperkalemia, hyperphosphatemia, hyperuricemia, and hypocalcemia in the face of a tumor. Yet no definitive classification or grading system exists although some differentiate between laboratory and clinical TLS.[64] The value of the classifications that have been published has not been established.

Pathophysiology

Tumor cells possess normal or supranormal quantities of many intracellular contents that pour into the circulation on cell death.[60] Potassium is the primary intracellular cation but cells have abundant nucleic acids, inorganic phosphates, and proteins. The metabolism of nucleic acids results in the production of uric acid. With high tumor burden, the release of these chemical may overwhelm normal homeostatic mechanisms, threatening the patient with hyperkalemia, hyperphosphatemia, hyperuricemia, and end-organ damage.

Hyperkalemia can acutely threaten cardiovascular status by altering cardiac rhythm. Levels of potassium greater than 6.5 to 7 mmol/L may lead to widening of the QRS complex and peaked T waves that can progress to disorganized ventricular rhythms and severe cardiac dysfunction. Other symptoms include irritability, fatigue, muscle weakness and cramps, paresthesias, nausea, emesis, and diarrhea. Hyperkalemia must be addressed emergently.

In addition to potassium, tumor cells possess substantial quantities of phosphates, often much higher than nonmalignant cells, which bind avidly to calcium depleting serum calcium levels.[65] The resultant calcium phosphate may precipitate in the renal tubules. High levels of phosphate, which are often exacerbated by renal dysfunction, may produce fatigue, lethargy, weakness, nausea, and emesis. Hypocalcemia may also result in muscle cramps as well as tetany, seizures, and dysrhythmia. Counterintuitively, low levels of calcium must be addressed by treating the elevated phosphate rather than by administering intravenous calcium.

Uric acid, the final product of purine nucleotide metabolism, is excreted in the urine but has low solubility, especially in acidic urine.[66] Production of uric acid depends on the enzyme xanthine oxidase. High levels of uric acid may injure renal tubules especially in the context of dehydration and administration of nephrotoxic medications. Increasing serum uric acid levels have been associated with increasing risk for TLS.

Uremia may also occur in patients at risk for TLS either from TLS itself or from preexisting renal injury or a combination of these factors. In TLS, the most common cause of renal injury results from precipitation of uric acid crystals in the renal tubule but can be due to calcium phosphate or xanthine crystals, nephrotoxic drugs, tumor infiltration, or obstruction and infection.[65]

Therapy

The key concepts in therapy include hydration to assure adequate end-organ perfusion, especially of the renal vascular bed, and some hemodilution. Additionally, altering the production of uric acid and the use of ion binders/antagonists help to protect end organs.

Hyperkalemia is a medical emergency, especially when the level exceeds 6.5 to 7.0 mEq/dL. Therapy includes oral and/or rectal cation exchange resins, intravenous calcium (gluconate or chloride) to antagonize the action of K^+ on the cardiac myocyte, and sodium bicarbonate to correct acidosis and increase the gradient of K^+ into the cells. Insulin and glucose encourage the movement of K^+ into cells. Diuretic therapy or, in the face of renal dysfunction, dialysis may help the excretion of K^+.

Therapy to obviate complications of elevated uric acid includes alkalinization of the urine, which increases the solubility of uric acid, to limit or avoid precipitation of uric acid crystals in renal tubule. Allopurinol, a xanthine analogue, inhibits the conversion of xanthine and hypoxanthine to uric acid by competitively blocking the enzyme xanthine oxidase.[67,68] Allopurinol decreases the formation of uric acid and reduces the incidence obstructive uropathy caused by uric acid in patients at risk for TLS. Allopurinol cannot, however, lower elevated uric acid levels that may precede therapy. Also inhibition of xanthine oxidase may increase the levels of xanthine and hypoxanthine, the former of which may produce renal tubular damage. Furthermore, allopurinol blocks the metabolism of purine-based chemotherapeutic agents (azothiopurine, 6-mercaptopurine) employed in the treatment of leukemias, rendering these agents less effective.[69]

Elevated levels of uric acid represent a difficult problem beyond the reaches of allopurinol. Urate oxidase, a nonhuman proteolytic enzyme, cleaves uric acid to allantoins, which are highly soluble at urinary pH decreasing the risk of renal injury. Rasburicase, a recombinant form of the enzyme, has high costs but appears to be effective at lowering uric acid levels, decreasing serum creatinine and phosphorus levels, and preventing the need for dialysis, permitting early institution of chemotherapy.[70] The decreased need for dialysis and other ICU therapies appear to render Rasburicase, when used in the initial management of high-risk patients cost effective as well.[71] Rasburicase is contraindicated in patients with a known G6PD deficiency (certain patients of African-American, Mediterranean, or Southeast Asian descent) and in pregnant or lactating females.[70]

Elevated levels of serum phosphates result in an initial increase in urinary excretion and decreasing tubular reabsorption, but this mechanism has its limits. The ability to excrete phosphates will be impaired by renal injury. Hyperphosphatemia may result in precipitation of calcium phosphate crystallizes causing or worsening renal dysfunction. This crystallization appears to increase when the calcium-phosphate multiple exceeds 70 and when the urine has been alkalinized.

Hyperleukocytosis

Hyperleukocytosis, defined as a white blood cell (WBC) count greater than 100,000/μL, is seen in 5% to 20% of children diagnosed with leukemia, most often in patients with ALL.[73] Clinically significant hyperleukocytosis usually occurs with

WBC count greater than 200,000/μL in AML, greater than 300,000/μL in ALL, and greater than 600,000/μL in chronic myeloid leukemia.[74] Myeloblasts and monoblasts, which tend to be larger and more rigid than lymphoblasts and granulocytes, are more likely to obstruct vessels, even in smaller numbers. Other benign causes of hyperviscosity include leukemoid reaction, polycythemia vera, and accumulation of abnormal hemoglobin in sickle cell disease.

As WBC counts increase, the viscosity of the blood raises dependent both the leukocyte and erythrocyte volumes as well as the deformability of the cells.[75] Substantial increases in WBC counts produce aggregation of leukocytes which may obstruct small blood vessels.[75] Leukostasis results in local hypoxia as well as invasion of the blood vessels by leukemic cells, producing organ and vascular damage and/or hemorrhage. Leukemic cells adhere to the endothelium, a process mediated by cytokines interleukin-1 and tumor necrosis factor-α released by the blasts themselves, and then migrate into the perivascular space. The adhesion molecules expressed by leukemic blasts and their chemotactic response to cytokines may be as important as cell number in causing leukostasis.[68] This may explain the variability in clinical presentation among patients with a range of peripheral blast counts and why some patients but not others develop leukostasis.

Children with hyperleukocytosis have higher rates of mortality and morbidity including neurologic complications (intracranial hemorrhage), pulmonary leukostasis, and tumor lysis syndrome than other children with leukemia. The most dramatic concern includes intracranial parenchymal hemorrhage, which typically is limited to the white matter, centered at intravascular microscopic leukemic nodules. Symptoms may include headache, mental status changes, seizures, or visual disturbance. Respiratory symptoms found with pulmonary leukostasis may include hypoxemia, respiratory failure, and adult respiratory distress syndrome. Arterial measurement of oxygenation should be promptly obtained rather than relying on pulse oximetry because elevated met-hemoglobin concentration may be present.[71] Chest radiograph findings of pulmonary leukostasis may be normal or reveal diffuse interstitial infiltrates. Immediate cytoreduction is indicated when excessive O_2 metabolism of leukocytes causes tissue hypoxemia. Elevated serum lactate levels have been described as an early sign of microcirculatory failure.[72]

Children with AML and hyperleukocytosis have a higher risk of early morbidity and mortality than patients with non-hyperleukocytotic AML or with ALL and hyperleukocytosis, but the true incidence of these complications is not well elucidated.[76] Central nervous system hemorrhage with high WBC counts occurs in 5% to 33% of patients with AML and hyperleukocytosis, usually correlating with the degree of hyperleukocytosis.[75] Complications of leukostasis in ALL patients commonly occur when WBC counts exceed 400×10^9/L and at presentation.[75] The frequency of CHS hemorrhage appears to be much lower in patients with ALL and hyperleukocytosis. In one study, nearly half of children with AML and WBC of 100×10^9/L or greater developed complication before or during the first 14 days after initiation of chemotherapy.

Therapy for hyperleukocytosis has not undergone rigorous analysis. Diuretic therapy and packed red cell transfusion both increase viscosity and are best avoided. Concurrent thrombocytopenia and hyperleukocytosis increase risk of death from bleeding complications. Aggressive therapy with fresh frozen plasma and vitamin K to correct coagulopathy and maintenance of platelet count greater than 20,000/μL are critical.[73] Hydration, alkalinization, and allopurinol have been used in patients with WBC counts higher than 100,000/μL.[74] More aggressive therapies must be considered for symptomatic patients, those with laboratory evidence of hypoxia or ischemia, or in certain patients depending on malignancy type and WBC. Both exchange transfusion and leukapheresis can be used to rapidly lower WBC. No randomized trials of cytoreduction have been performed, and although a reduced incidence of electrolyte abnormalities has been shown, no improvement in pulmonary status, central nervous system outcome, or mortality has been demonstrated.[77] Complications of leukapheresis include difficulty with vascular access, rapid rebound of WBC count, and need for anticoagulation. Cytoreduction by leukapheresis, exchange transfusion, or other methods may modulate cell-cycle distribution and nucleoside transporters in leukemic cells by increasing the fraction of the S-phase. No beneficial role has been demonstrated for use of steroids or emergency cranial radiation.[75] After leukapheresis, the blast counts often rebound rapidly unless cytoreductive medications are initiated.

Spinal Cord Compression

Compression of the spinal cord by malignancy occurs uncommonly but still represents an important cause of morbidity in children, affecting between 2.7% to 5% of children with cancer. Most frequently, compression occurs as metastatic disease spread rather than primary spinal cord tumors themselves. Ewing sarcoma, neuroblastoma, and primitive neuroectodermal tumors appear to be the most frequent diagnoses although compression may be found with Hodgkin lymphoma, nephroblastoma, and germ cell tumors.[76,78]

Most cord compression results from epidural compression due to extension of paravertebral tumor through the intervertebral foramina, or, less commonly, extension of the tumor in the vertebral column. Compression of the vertebral venous plexus by epidural tumor causes vasogenic cord ischemia, edema, venous hemorrhage, and myelin loss.[79] The spinal cord compression usually localizes to the dorsal and lumbosacral regions (42% each). Patients frequently develop back pain, motor dysfunction, sphincter abnormalities, and alteration in sensation. Such findings represent harbingers of potential permanent loss of neurologic function, necessitating emergent evaluation including magnetic resonance imaging.

Confirmation of tumor compression of the spinal cord requires emergent medical action. A history of progressive spinal cord dysfunction and focal deficit or percussion tenderness of the spine requires 1 mg/kg dexamethasone intravenously over 30 minutes. Treatment of a cord-compressing lesion next mandates a decision between immediate surgical decompression, radiation therapy, or chemotherapy. This decision is influenced by a number of factors, including presence of a histologic diagnosis, likelihood of response to chemotherapy or radiotherapy, as well as degree and rate of progression of neurologic deficit. Although controversy exists, decompressive laminectomy is indicated for tumors without a diagnosis, patients with small cell tumors with very rapid neurologic deterioration or complete loss of motor function, and sarcoma, with the exception of osteogenic sarcoma.[76] However, laminectomy in children often leads to scoliosis,

kyphosis, and anterior subluxation. Consequently, the decision must be made with this issue in mind as laminectomy patients often require subsequent treatment for orthopedic sequelae.[81] Among children with complete sensory and motor loss below the level of spinal cord compression, 30% to 60% of treated children experience neurologic recovery.[76,78,82]

Acute Airway Compromise in Anterior Mediastinal Tumors

Superior Vena Cava Syndrome

Childhood mediastinal masses pose difficult diagnostic and therapeutic challenges. Such masses often produce few symptoms until they have occluded a substantial portion of the trachea or main-stem bronchi or the superior vena cava. Complete airway occlusion in these children represents a potentially fatal complication the risk of which increases at the time of sedation for diagnostic procedures. An estimated 9% to 15% of pediatric patients with anterior mediastinal masses and airway obstruction have been reported to develop life-threatening complications with anesthesia.[83-85] Over the past two decades, increased awareness of the potential for airway or cardiovascular collapse in pediatric patients with anterior mediastinal masses has led to improved management. Major airway complications are now more likely to occur in the postanesthetic care.[86] Superior vena cava syndrome, left atrial compression, and pericardial effusion may lead to a state of fixed cardiac output.

Mediastinal masses are classified by their anatomical compartment and anterior mediastinal masses represent 46% of all such masses in children.[87] The most common tumors found in the anterior mediastinal compartment include hematological malignancies: T-cell lymphoblastic leukemia, Hodgkin disease, and T-cell lymphoblastic non-Hodgkin lymphoma.[88-90] Children with anterior mediastinal mass often present with nonspecific findings including orthopnea, dyspnea, cough, pleural effusion, wheezing, superior vena cava (SVC) syndrome, pain, and stridor.[90-92] Mediastinal masses are far more common in older children and teenagers than in children younger than 5 years. Barking cough and stridor in an older child or teenager rarely occurs with croup and therefore needs further investigation

Important risk factors for airway compromise include computed tomography findings of more than 50% decrease in across-sectional area of the trachea, peak expiratory flow less than 50% of predicted value, anterior mediastinal mass, tracheal compression, main-stem bronchus compression, larger median mediastinal mass ratio, lymphoma, vena cava syndrome, pericardial effusion, pleural effusion, history of recurrent chest infections, stridor, orthopnea, cough, wheeze, and shortness of breath.[83,84,91,93] The predictive value of these risk factors remains controversial, however. Unfortunately, compression at the level of the carina or bronchi may contribute appreciably to respiratory compromise, even in patients with a cross-sectional area above 50% of predicted.[90] A computed tomography scan will provide evidence of airway compression at a tracheal and/or bronchial level as well as the existence of exacerbating factors such as pleural effusion that may limit a patient's physiological reserve.

The preoperative evaluation of patients with critical airway from compression by an anterior mediastinal mass should include an experienced multidisciplinary pediatric team of oncologist, anesthesiologist, interventional radiologist, surgeon, and intensivist.[83,91] Computed tomography provides the most useful, rapid test for airway compromise. Unfortunately, severe or rapid progressive symptoms may preclude lying supine for the scan. In such, cases diagnostic procedures under local anesthesia with ultrasound guidance or commencement of therapy before a cellular diagnosis may be required. Such use of empirical treatment can distort the histopathological appearance, hinder the making of a correct diagnosis, and lead to inappropriate treatment although in one study an accurate diagnosis was made in 95% of patients receiving steroids.[88] Bone marrow or lymph node biopsy and pleural fluid analysis may be helpful in patients who are not unstable. Complete blood count and α-fetoprotein, β-human chorionic gonadotropin, and lactate dehydrogenase levels should be obtained. Image-guided needle biopsy performed under local anesthesia for mediastinal mass or lymph node by skilled interventional radiologist remains the diagnostic test of choice.[90]

SVC syndrome encompasses the signs and symptoms related to compression or obstruction of the SVC, which in childhood most commonly results from anterior mediastinal mass, middle mediastinal lymph nodes, or occlusion of the SVC itself.[94] SVC obstruction may be accompanied by compression of other mediastinal structures, large airways, pulmonary vessels, and aorta. SVC syndrome is most often caused by lymphoid malignancy, including non-Hodgkin lymphoma, acute lymphocytic leukemia, and Hodgkin disease. In addition to malignancies, indwelling catheters, previous cardiac surgery, previous extracorporeal life support.[95] right-sided congenital diaphragmatic hernia,[96] and ventriculoperitoneal shunts are other causes of SVC syndrome in pediatric patients.

In children, respiratory symptoms usually predominate; air hunger, dyspnea, wheezing, and anxiety occur, particularly with position change. The gradual development of SVC syndrome may manifest with periorbital edema, conjunctival suffusion, facial swelling, dizziness, syncope, and cough. SVC syndrome may occur in conjunction with spinal cord compression (Rubin syndrome), where significant venous obstruction usually develops before the spinal cord compression. Patients with SVC syndrome and back pain should be evaluated with magnetic resonance imaging of the vertebral spine when their condition is stable.

Evaluation of anterior mediastinal mass is described previously. As in airway compression, SVC syndrome places a patient at significant risk for anesthetic complications during diagnostic procedures. CT should be pursued without sedation and may require prone positioning because compression of the great vessels may occur despite a patent airway, resulting in profound hypoxia and reduced cardiac output. In addition, echocardiography can evaluate cardiac motility and the degree of venous return. In one study, 16% of children with anterior mediastinal masses and SVC syndrome developed potentially life-threatening airway compromise, although all survived without sequelae. Seven percent required chemotherapy or radiotherapy before successful extubation. The authors conclude that general anesthesia should be performed only when spontaneous ventilation can be preserved.

Diagnosis should be established with the least invasive means available, with empiric anticancer therapy required if no histologic sample can be obtained safely. Tissue for definitive diagnosis should be obtained as soon as the patient's

clinical status allows to decrease the likelihood that empiric therapy will permanently obscure the diagnosis.

Septic Shock in Pediatric Oncologic Patients

Septic shock poses a grave threat to immunocompromised children. The need for early diagnosis and rapid, thorough treatment cannot be exaggerated.[97-99] In childhood cancer patients, shock most commonly occurs with bacterial sepsis but distributive shock may also occur in the context of an addisonian crisis among children who have received high dose steroid therapy in the prior 6 months.

Risk factors for sepsis in pediatric cancer and hematopoietic stem cell transplant patients include neutropenia, impaired mucosal barriers, preexisting end-organ failure, and graft-versus-host disease. Neutropenic patients have a decreased ability to manifest a coordinated proinflammatory and immunoregulatory host response against infectious pathogens. Prolonged neutropenia worsens infectious complications and mortality rates.[100]

Clinically children may present without fever, particularly those with neutropenia or receiving corticosteroids. Cardiovascular insufficiency may result in tachycardia, decreased blood pressure and altered pulse pressure, signs of poor perfusion, and signs of respiratory insufficiency (e.g., respiratory distress, increased work of breathing). Other signs of inadequate end-organ perfusion include altered level of consciousness, diminished urine output, and lactic acidosis. Blood cultures should be obtained from all lumens of vascular catheters without impeding treatment. Other cultures should be obtained based on clinical suspicion. A chest radiograph should be obtained in all patients. The presence of pulmonary infiltrates should prompt consideration of a computed tomography scan and/or bronchoscopy for microbiologic diagnosis.

Early goal-directed fluid resuscitation has been shown to improve outcome in children and adults with severe sepsis and septic shock.[97,99,101] Restoration of adequate intravascular volume improves tissue oxygen delivery and attenuates the inflammatory response. Inaccuracy in assessing shock state severity and delay of adequate fluid resuscitation increases mortality. Surviving Sepsis Campaign guidelines recommend that intravenous antibiotic therapy should be started within the first hour of recognition of severe sepsis[102] because this may be the most important therapeutic intervention for patients in septic shock.[98] Chest radiograph infiltrates should prompt coverage for community-acquired pneumonia and possible invasive fungal infections. Progression to multiple organ failure may necessitate more complex therapies including granulocyte-colony stimulating factor, mechanical ventilation, inotropic support, and renal replacement therapy.

Pediatric ICU mortality of septic shock in pediatric oncologic patients ranges from 38% to 77%,[103-107] affected by a number of factors including diagnosis, numbers of failed organs, and need for nonhematologic organ support.[103,104] Fiser et al.[108] reported in a recent large retrospective review of severe sepsis in pediatric oncology patients a 30% mortality for pediatric hematopoietic stem cell transplant patients and 12% mortality for non–hematopoietic stem cell transplant patients. But pediatric ICU mortality reached 64% when those patients required mechanical ventilation and inotropic support. Fungal pathogens were responsible for 63% of pediatric ICU mortality.

Hemophagocytic Lymphohistiocytosis

Hemophagocytic lymphohistiocytosis (HLH) describes a syndrome of conditions rather than a specific disease entity that is marked by hyperinflammation resulting from riotously elevated circulating cytokines.[109] HLH represents an emergency because it shares many clinical features with the severe inflammatory response syndrome (SIRS) or sepsis syndrome rendering diagnosis difficult but it requires a much different treatment algorithm.[110] Inadequately treated HLH results in very poor outcome; indeed, HLH has been seen in a variety of clinical scenarios, including inherited defects as well as acquired conditions.[111]

HLH arises because of defects, acquired or inherited, in cytotoxic activity, which diminishes elimination of cellular targets and impairs downregulation of the immune response.[109] All HLH defects appear to arise from abnormalities involving the process by which cytotoxic vesicles migrate to contact site of the target cell, attach, fuse, and release their contents. Familial HLH results from inherited abnormities in one of three protein involved in the activity of cytotoxic vesicles.[109] Perforin, a cytotoxic protein stored in secretory granules of cytotoxic cells, acts as an effector molecule for the cytotoxic function of natural killer cells and CD8+ cytotoxic lymphocytes as well as contributing to lymphocyte homeostasis. MUNC 13-4 has a crucial role in cytolytic granules. The final mutation discovered thus far is in the syntaxin-11 believed to be involved in cytotoxic granule release or trafficking. In addition to these syndromes, several immune deficiency syndromes (Chediak-Higashi syndrome, Griscelli syndrome and X-linked lymphoproliferative syndrome) place patients at risk for HLH.[109,112,113]

HLH may be acquired under a variety of circumstances, but the mechanism of impairment of natural killer cells and cytotoxic lymphocytes in secondary HLH remains unclear but occurs in all age groups.[109] These defects occur more commonly than genetic HLH but incidence data are lacking. Secondary HLH appear to be caused most frequently by infections, autoimmune disease, and malignant diseases. Less common causes include Kawasaki disease, metabolic disease such as lysinuria protein intolerance, multiple sulfatase and Wolman's disease. Macrophage activation syndrome, first described in 1985, appears to be a special form of HLH occurring in patients with underlying autoimmune disorders, most commonly rheumatoid arthritis.[114]

Patients typically present with signs and symptoms of systemic infection or SIRS including prolonged fever (usually unresponsive to antibiotics), hepatosplenomegaly, and cytopenias.[109] Because HLH often mimics other conditions, a high index of suspicion remains paramount. Fortunately, diagnostic guidelines exist (Box 81-4), but again must be considered because of the substantial overlap with other severe sepsis, SIRS, and multiple organ dysfunction syndrome. In some patients, neurologic symptoms, seizures, and cranial nerve palsies may occur.

Laboratory study often aids in diagnosis but may not be obtained routine in patients who may have provisional diagnoses such as sepsis syndrome. Diagnostic criteria require a ferritin level higher than 500 ng/mL, but the levels are usually much higher, exceeding 10,000, unlike in sepsis where

Box 81–4 Diagnostic Criteria for HLH

A. Familial Disease/Known Genetic Defect

B. Clinical and Laboratory Criteria (5 of 8 Criteria)

1. Fever
2. Splenomegaly
3. Cytopenia ≥2 cell lines
4. Hemoglobin <90 g/L (below 4 weeks <120 μg/L)
5. Platelets $<100 \times 10^9$/L
6. Neutrophils $<1 \times 10^9$/L
7. Hypertriglyceridemia and/or hypofibrinogenemia
   a. Fasting triglycerides >3 mmol/L
   b. Fibrinogen <1.5 g/L
8. Ferritin >500 lg/L
9. sCD25 = >2400 U/mL
10. Decreased or absent natural killer cell activity
11. Hemophagocytosis in bone marrow, CSF or lymphnodes

serum ferritin is elevated but appears to be generally below 2000. Serum triglycerides are elevated. Soluble interleukin-2 receptor (sCD 25) soluble FAS (CD178) are elevated. Hemophagocytosis may be absent early in the disease and can also be missed on bone marrow aspiration.

Treatment depends on whether HLH is primary or secondary. Initial treatment is meant to suppress hyperinflammation using immunosuppressive and cytostatic treatment with corticosteroids, cyclosporine A, or etoposide.[109] Identification of infection should prompt immediate treatment. Unfortunately, in cases of HLH appropriate antimicrobial therapy does not usually alter the hyperinflammation. Patients with primary HLH or underlying immune deficiency may require stem cell transplantation. Evidence of macrophage activation syndrome should prompt rheumatologic consultation.[114]

Anthracycline-Induced Cardiogenic Shock

The anthracyclines daunorubicin, doxorubicin, epirubicin, and idarubicin are used for a wide variety of solid tumor and hematopoietic malignancies of childhood.[115-117] Unfortunately, 15% of all pediatric cardiomyopathies occur in patients treated for childhood or adolescent malignancies.[118] In one prospective study, after anthracycline treatment, 5% of the children developed heart failure and 19% presented abnormal left ventricular function.[119] Shortening fractions declined proportionately to cumulative dose. Furthermore, differential susceptibility to cardiotoxicity became apparent early in treatment. Hence, patients at high risk of risk of important anthracycline cardiotoxicity may be identifiable early in treatment by regular echocardiography. Pediatric age and female gender are known risk factors for anthracycline cardiotoxicity.[120,121]

Anthracycline-induced acute myocardial injury is a rare form of cardiotoxicity that may occur immediately after a single dose or after a course of anthracycline therapy, with clinical symptoms usually occurring within a week of treatment.[115,116,122-124] Acute cardiotoxicity ranges from relatively benign arrhythmias to serious conditions such as fatal ventricular arrhythmias, myocardial ischemia/infarction, congestive heart failure, and cardiomyopathy.[122,123,125]

The pathophysiology of anthracycline-induced cardiotoxicity may include free-radical–mediated myocyte damage, adrenergic dysfunction, intracellular calcium overload, and release of cardiotoxic cytokines.[121,126] The myocardium appears susceptible to free radical damage from low levels of superoxide dismutase, catalase, and glutathione peroxidase activity.[127] Cardiac mitochondria contain a unique enzyme (reduced nicotinamide adenine dinucleotide dehydrogenase) in their inner membrane that reduces anthracyclines to their semiquinones, producing severe oxidative damage to mitochondrial DNA, reductions in cellular energy production and myocyte apoptosis.

Prevention of cardiotoxicity remains the ultimate goal. There is evidence that dexrazoxane reduces the cardiotoxicity associated with some anthracyclines without affecting the efficacy of anthracycline therapy.[128] The antioxidant CoQ10 is an integral component of the mitochondrial respiratory chain and has successfully been used in the treatment of cardiac failure.[129]

The outcome of anthracycline-induced cardiogenic shock during chemotherapy remains poor. The myocardium has limited regeneration ability.[117] The mortality rate related to anthracycline-associated heart failure is substantial; heart transplantation is often the only option for long-term survival.[115] Supportive treatment including mechanical support (e.g., extracorporeal life support or ventricular assist devices) may stabilize patients while decisions about longer-term care can be made.[116,129-132]

Chapter 82

Transfusion Medicine

Jacques Lacroix, Marisa Tucci, Alan Tinmouth, France Gauvin, and Oliver Karam

PEARLS

- The decision to prescribe the transfusion of any blood product must be based on individualized indications and must take into account specific health problems.
- Acute severe anemia (hemoglobin concentration <5 g/dL) can lead to death in some severely ill patients.
- There is no evidence that a red cell transfusion is beneficial in stable critically ill children if their hemoglobin concentration is greater than 7.0 g/dL. A hemoglobin concentration of 7.0 g/dL or higher may be required in unstable critically ill children and in pediatric intensive care patients with heart disease, particularly those with cyanotic heart disease, but the best threshold is unknown.
- Plasma can be useful to treat multiple coagulation factors deficiencies. It should not be used as a volume expander.
- Platelets can be useful to treat bleeding caused by low platelet counts and/or platelet dysfunction.
- In pediatric intensive care units, most transfusion-related adverse events are linked to immuno-mediated effects of blood products rather than to transfusion-transmitted infectious diseases.

In this chapter, the authors will review the rationale for the transfusion of red blood cells (RBC), plasma, and platelets in pediatric intensive care units (PICU). In addition transfusion reactions are discussed at the end of the chapter.

Red Blood Cells

RBCs contain hemoglobin (Hb), which binds and carries oxygen (O_2) to cells, thus facilitating efficient adenosine triphosphate (ATP) production via cellular respiration. Because energy expenditure is high in critically ill patients, it would seem rational to maintain their Hb level in the normal range. Anemia is observed in 74% of critically ill children.[1] RBC transfusion is the only effective way to rapidly increase the Hb level. However, the safety of RBC transfusion has been questioned in recent years. Infections transmitted by blood products were the most important concern in the 1980s. In the 1990s, nosocomial infections and multiple organ dysfunction syndrome (MODS) observed in critically ill adults who received an RBC transfusion have become a cause of concern.[2] Also transfusion-related immune modulation (TRIM),[3] and transfusion reactions like transfusion-related acute lung injury (TRALI) and transfusion-associated cardiac overload (TACO)[4] have become significant concerns. There are few data on these adverse events in PICU. Actually, the impact of RBC transfusion on risk/benefit and the cost/benefit ratios among critically ill children is not well characterized.

In the following sections, the authors will discuss anemia and O_2 delivery (DO_2), review evidence on the effectiveness and usefulness of RBC transfusion in the intensive care setting, and discuss the recommendations found in guidelines on RBC transfusion in critically ill children.

Red Blood Cell Transfusion: Why and Why Not

Anemia and O_2 Delivery

O_2 Delivery in the Critically Ill. Anemia decreases the capacity of blood to deliver oxygen because of lower hemoglobin content. Global DO_2 is dependent on cardiac output and the arterial concentration of O_2 (CaO_2): DO_2 = cardiac output (stroke volume × heart rate) × CaO_2. Arterial concentration of O_2 (CaO_2) is defined by the formula:

$$CaO_2(\text{mL } O_2 / 100 \text{ mL}) = (\text{Hb} \times SaO_2 \times 1.34) + (0.003 \times PaO_2)$$

In this formula, the Hb level is expressed in grams per deciliter, arterial O_2 saturation (SaO_2) is expressed as a fraction rather than a percentage, and PaO_2 is expressed in mm Hg or torr. Because global DO_2 is directly linked to the Hb concentration, the most rapid and effective way of increasing DO_2 (within minutes) is by increasing the Hb concentration, and this represents the most common rationale underlying RBC transfusion in critically ill patients. More modest augmentation in global DO_2 can be attained by increasing cardiac output and/or SaO_2. Indeed, a prospective study conducted in 2005 involving 30 North American PICUs showed that about 50% of critically ill children received at least one transfusion of packed RBC unit during their PICU stay.[1]

Adequate O_2 delivery to cells does not imply necessarily that O_2 consumption (VO_2) is adequate, and that cells produce enough energy. The formula used to calculate global VO_2 is:

$$VO_2 = (CaO_2 - CmvO_2) \times \text{Cardiac output}$$

in which $CmvO_2$ is the mixed venous O_2 concentration. VO_2 depends on substrate availability and on metabolic demands; it can be amplified by increasing cellular O_2 extraction rate (O_2ER), or by increasing DO_2 if there is VO_2/DO_2 dependence (Figure 82-1).

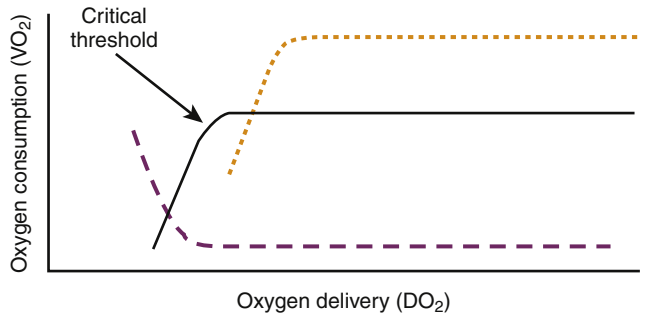

Figure 82–1. This figure illustrates the relationship between oxygen delivery (DO_2) and oxygen consumption (VO_2) in normal patients (black full line), of DO_2 and blood lactate level in normal patients (blue dashed line), and of DO_2 and VO_2 in critically ill patients with sepsis (red dotted line). Under the "critical threshold" marked by an arrow, VO_2 and blood lactate level diminishes if DO_2 decreases. Over this threshold, a fall in DO_2 does not cause a drop in VO_2 because it is compensated by an increase in oxygen extraction rate. In critically ill patients, the VO_2 is frequently higher than normal and the DO_2/VO_2 curve is shifted upwards to the right (red dotted line).

The relationship between O_2 delivery and consumption is characterized by two phases: a directly linear relationship between VO_2 and DO_2 up to a "critical threshold" (often referred to as the critical DO_2), and a flat section above this threshold (see Figure 82-1). Below the threshold, VO_2 diminishes if DO_2 decreases. Above this threshold, a fall in DO_2 does not cause a drop in VO_2 because it is compensated by mechanisms such as an increase in O_2ER; these mechanisms are limited though, which explains why there is a critical threshold of DO_2 under which O_2ER cannot increase any further, and under which VO_2 begins to fall.

The stress of critical illness increases metabolic rate and VO_2, and shifts the critical level of DO_2 to the right and up. Moreover, the compensatory mechanisms are limited. Thus, the critically ill patient rapidly finds himself or herself in a situation in which O_2ER can increase no further and in which other adaptive mechanisms are maximal, thus resulting in a situation where a higher DO_2 is critical to allow for energy requirements to be met.

Adaptive Mechanisms to Anemia

Anemia significantly decreases blood O_2 carrying capacity. However, in the normal host, the amount of O_2 delivered to tissues exceeds resting O_2 requirements by a two- to fourfold factor.[5] When the Hb concentration falls below 10 g/dL, several adaptive processes maintain VO_2. These processes include (1) increased O_2ER; (2) increased heart rate and stroke volume, which increase cardiac output; (3) redistribution of blood flow from nonvital organs toward the heart and brain, at the expense of O_2 delivery to less vital vascular beds, such as the splanchnic vasculature; and (4) rightward shift of the oxy-Hb-dissociation curve, which decreases affinity between Hb and O_2, thereby increasing the amount of O_2 released to cells.

Increasing O_2ER is an important way to adapt to anemia. The upper range of normal O_2ER is 30%; O_2ER increases if O_2 requirements are not met. Higher O_2ER is frequently observed in severely ill patients, which translates into low $SmvO_2$ and $ScvO_2$ (central venous O_2 saturation). When maximal O_2ER is attained and other adaptive mechanisms are overwhelmed, VO_2/DO_2 dependence appears and may result in O_2 debt, with is associated with mortality. The O_2 requirements of patients with sepsis and MODS is increased while they may have impaired left ventricular function and abnormal regulation of their vascular tone, which can restrict DO_2 and disturb redistribution of blood flow to local tissues; this may increase O_2 debt even more.

A number of host characteristics specific to children and infants may also impair their adaptive mechanisms. An increase in cardiac output can compensate for anemia. Because myocardial compliance is decreased during the first weeks of life, there is a significant impairment in diastolic filling, which limits stroke volume increase. In addition, an elevated heart rate at rest in newborns (about 140 ± 20/min) and infants (about 130 ± 20/min) also limits the ability to increase cardiac output. Congenital heart disease is frequently observed in PICU patients, and could also directly impair DO_2. Energy requirements in young infants are much higher than in adults. This difference is mostly attributable to growth and implies a greater need for substrates including O_2. In addition to increased metabolic demands, there are also major differences in O_2 transport between adults and children in the first years of life. The proportion of fetal Hb is significantly higher during the first months of life, causing a leftward shift of the oxy-Hb saturation curve. Physiologic anemia is normal during this period, and explains at least partly why the normal Hb concentration range is broad in the newborn and the infant. Moreover, the health status of children before ICU entry is generally better than that of adults, and might in part explain the lower PICU mortality rates seen in children. All these characteristics specific to critically ill children may alter their capacity to cope with a lower Hb concentration; further studies are needed to determine their clinical consequences.

O_2 Kinetics in the Critically Ill

Tissue hypoxia from low DO_2 may be due to low Hb concentration (anemic hypoxia), low cardiac output (stagnant hypoxia) or low Hb saturation (hypoxic hypoxia).[5] A significant number of intensivists use RBC transfusion to increase DO_2 in critically ill children.[6] RBC transfusion indeed increases DO_2, but there is no clear evidence that RBC transfusion improves tissue VO_2 in ICU patients.[2] Many mechanisms may explain why VO_2 does not always increase in such instances. Mitochondrial dysfunction is frequent in critically ill patients; this may prevent O_2 utilization (see Chapter 74).[7] Moreover, O_2 delivery to tissue is impaired in ICU patients, and there is some evidence that RBC transfusion may worsen that problem.

Regulation by Red Blood Cells of DO_2 to Tissue

Although RBC transfusion certainly increases systemic DO_2 in the central circulation, it does not mean that local O_2 delivery to tissues is improved. There is indeed evidence that RBC transfusion may disturb local DO_2. For example, Kiraly et al.[8] showed that tissue SO_2 (StO_2) in critically ill patients who received a transfusion of RBC units stored more than three weeks declined from about 89% to 81%, whereas this did not happen in controls. However, data on local DO_2 are inconsistent, their clinical significance remains to be determined, and the mechanisms are not well characterized; blood viscosity, microcirculatory flow, local DO_2, and cellular respiration may be involved.

Erythrocyte transfusion increases blood viscosity. Higher viscosity of blood can lead to microcirculatory stasis and impaired DO_2 to tissues. In the sickle cell literature, a Hb of 10 g/dL or hematocrit of 0.3 is often discussed as the level above which blood viscosity starts to increase. However no hard data indicate that blood viscosity is a clinically important problem unless the Hb is higher than 20 g/dL.

Activation of white blood cells (WBC) in packed RBC units and cytokine generation in the supernatant of transfused RBC units may also have a microcirculatory effect: some cytokines can mediate vasoconstriction or thrombosis of small vessels and cause local ischemia.[9] However, most packed RBC units are now prestorage leukocyte-reduced, which significantly decreases cytokine levels in the supernatant.[10] The clinical impact of cytokines in the supernatant of prestorage leukocyte-reduced packed RBC units remains to be determined.

There is evidence that RBC transfusion can cause vasoconstriction of small blood vessels via a mechanism involving an interaction between the Hb in RBC and the nitric oxide released by small vessels. With local tissue hypoxia, Hb in the microvasculature releases nitric oxide and triggers local vasodilatation; conversely, if there is sufficient O_2 in the microvasculature, Hb binds nitric oxide resulting in vasoconstriction. This regulatory mechanism is almost immediately lost once RBCs are stored: it has been shown that in vitro exposure of blood vessels to RBC units stored 3 hours or more causes vasoconstriction.[11] However, the level of nitric oxide increases rapidly after transfusion.[12] Although the clinical significance of these observations is not clear yet, these findings nonetheless suggest that local DO_2 can be disturbed by RBC transfusion.

Packed RBC units undergo several changes during storage, which are generally referred to as "storage lesion."[13] For example, the level of 2,3-diphospho- glycerate (2,3-DPG) in stored RBC decreases over time and can induce a leftward shift in the oxy-Hb dissociation curve, which impedes O_2 release to tissues even if DO_2 is increased. In addition, RBC deformability decreases after 2 or 3 weeks of storage, which may alter their capacity to pass through the capillary bed. Furthermore, hemolysis in older packed RBC units releases substantial amounts of free Hb ranging from 0.5 mg/dL in a 1-day-old RBC unit to 250 mg/dL in a 25 day-old unit[14]; free intravascular Hb has the ability to bind nitric oxide and therefore likely mediates vasoconstriction.[15]

Thus, whereas RBC transfusions certainly increase systemic DO_2, some available evidence suggests that impaired microcirculatory flow and O_2 availability can occur, which may have adverse effects on tissue oxygenation and cellular respiration.

Transfusion of Red Blood Cells: Indications (When)

Blood is clearly indicated for the treatment of hemorrhagic shock.[2] In such instances, the decision to prescribe RBC transfusions should be based on the physiologic state, the estimated amount of blood loss, and risk of ongoing hemorrhage, not on the Hb concentration.

RBC transfusion is more questionable if the hemorrhage is not clinically significant or if there is no hemorrhage. Pediatric intensivists have stated in two surveys that their decision to prescribe a RBC transfusion would be based on reasons such as a low DO_2 or VO_2, cardiovascular insufficiency, respiratory failure, or use of certain specific technologies such as extracorporeal membrane oxygenation (ECMO), hemodialysis, hemofiltration, plasmapheresis, or exchange transfusion; nonetheless, the most frequent reason to transfuse RBCs was reported to be a low Hb concentration.[1,6] The Hb level that should prompt a pediatric intensivist to prescribe RBC transfusion remains a matter of debate, but there is some evidence in the medical literature that can guide practitioners.

Evidence-Based Medicine: Clinical Studies

Four case series are applicable to critically ill children: two in children with septic shock,[16,17] another in postoperative cardiac surgery patients,[18] and the last in children with cyanotic heart disease undergoing elective cardiac catheterization.[19] These studies assessed hemodynamic parameters before and after a 0 to 20 mL/kg packed RBC transfusion; all reported a significantly increased Hb level as well as a greater DO_2 after transfusion, but only one study reported an increase in VO_2.[16] These findings support the hypothesis that RBC transfusion increases systemic DO_2, but does not necessarily increase VO_2.

There is evidence that severe anemia increases mortality and morbidity among severely ill children. In two studies involving patients who refused blood products for religious reasons, the risk of mortality increased significantly with a postoperative Hb level less than 4 g/dL in healthy adults[20] and less than 10 g/dL in adults with heart disease.[21] There are three prospective descriptive studies addressing this issue in pediatrics. Lackritz et al.[22] followed 2433 African anemic children younger than 12 years among whom 20% received a RBC transfusion. They reported that RBC transfusion was beneficial if the Hb level was below 4.7 g/dL and if the patient presented some respiratory distress. Lackritz et al.[23] subsequently published another prospective study examining 1223 consecutively hospitalized children in Kenya. Local guidelines suggested that an RBC transfusion should be given to all children with an Hb level less than 5 g/dL. The Hb level was less than 5 g/dL in 303 cases; 116 (38%) did not receive a transfusion, mostly because packed RBC units were not available. Each child with severe anemia was paired with the next child hospitalized with an Hb greater than 5 g/dL. The death rates were: 19.5% in 303 patients with Hb greater than 5 g/dL who were not transfused, 21.4% in 187 patients with Hb less than 5 g/dL who were transfused, and 41.4%% in 116 patients with Hb less than 5 g/dL who were not transfused. English et al.[24] completed a prospective cohort study of 1269 children with malaria hospitalized in Kenya; they reported that RBC transfusion decreased mortality if anemia was severe (Hb level <4 g/dL), or if a Hb level less than 5 g/dL was associated with dyspnea. These three studies suggest that the risk of mortality increases significantly in severely ill children requiring hospitalization if their Hb concentration is lower than 5 g/dL particularly if respiratory symptoms are present.

Two randomized clinical trials evaluated RBC transfusion strategies in children. The first trial was performed in Africa in 106 children with malaria crisis (hematocrit: 12% to 17%); RBC transfusion did not improve mortality rate (1/53 vs. 2/53) in patients without respiratory or cardiovascular compromise.[25] In the TRIPICU study, a large multicenter international randomized clinical trial involving 637 stable critically ill children with Hb level lower than 9.5 g/dL, 320 patients were allocated to a RBC transfusion threshold of 7 g/dL of Hb (restrictive group) and 317 to a threshold of 9.5 g/dL (liberal group). A statistically significant noninferiority

was found: 38 and 39 patients respectively developed new or progressive MODS, and there were 14 deaths in both strategy groups within 28 days postrandomization. The conclusion of this study was that a restrictive strategy is as safe as a liberal strategy in stable critically ill children. Moreover, given that 174 patients (54%) in the restrictive group received no RBC transfusion compared to 7 (2%) in the liberal group (P <.0001) and that patients in the restrictive group received 54% fewer RBC transfusions, the findings supported adopting a restrictive transfusion strategy for stabilized critically ill children.[26] Subgroup analyses were subsequently undertaken in patients with sepsis[27] and those having undergone noncardiac surgery[28]: both showed trends very similar to those reported in the original TRIPICU study.

Red Blood Cell Transfusion: Current Recommendations

Guidelines from many organizations emphasize that the decision to administer RBC should not be determined solely by an Hb value, but should be based on sound clinical judgment.[2,29,30] RBC transfusion in PICU is indeed associated not only with a low Hb level, but also with admission for cardiac disease (odds ratio [OR], 8.07; 95% confidence interval [CI], 5.14 to 14.65), higher severity of illness (PRISM score >10: OR, 4.83; CI, 2.33 to 10.04), and presence of MODS (OR, 2.06; CI, 1.18 to 3.57).[31] In a survey,[6] pediatric intensivists declared that they might consider prescribing a RBC transfusion based on the following markers: Hb concentration, low SaO_2, low PaO_2, low cardiac output (poor DO_2), high blood lactate level, low $ScvO_2$ or $SmvO_2$, poor VO_2, high severity of illness, active bleeding, and emergency surgery. However, how these determinants of RBC transfusion interacted with each other was unclear.

Many physicians advocate "goal-directed transfusion therapy."[32,33] Although it is theoretically rational to base the decision to transfuse RBCs on physiologic need, it is still a matter of debate what parameters best determine that need. It has been suggested that a RBC transfusion is indicated for patients with symptomatic anemia, but most critically ill children are unable to report these symptoms. Some have suggested it would be better to use global markers of oxygenation deficit, such as systemic VO_2, VO_2/DO_2 dependence, blood lactate level, $ScvO_2$, $SmvO_2$, or O_2ER.[34] Others propose the use of measurements that reflect local, regional, or tissue oxygenation deficit, such as brain tissue O_2 pressure ($PbtO_2$),[35] gastric tonometry[36] StO_2 measured by near-infrared spectroscopy[8] or digital O_2 extraction rate measured by noninvasive devices. Actually, it is presently not known what markers are best suited for this purpose and what cutoff values should be used to determine the need for RBC transfusion in critically ill children. The concept of goal-directed transfusion therapy is laudable, but is presently vaguely defined, and not supported by hard data. Recommendations specific to goal-directed transfusion therapy remain undetermined at the present time.[32]

In practice, a low Hb concentration remains the most frequent and the primary justification for pediatric intensivists to prescribe a RBC transfusion.[1] Therefore it makes sense that the Hb concentration be the first parameter assessed when a RBC transfusion is considered. Given the available evidence, RBC transfusion is recommended for all critically ill children who present with a Hb concentration below 5 g/dL. In stable patients, including septic patients,[27] patients having undergone noncardiac surgery,[28] and severely burned children,[37] it is suggested by experts to consider a RBC transfusion if the Hb concentration is lower than 7 g/dL, but a transfusion is not recommended if the Hb concentration is above this level.[2] These thresholds are not so far from current practice: Goodman et al.[38] have reported that all critically ill children with a Hb ≤5.3 g/dL and that 93% of those with a Hb of 6.4 g/dL or less received at least one RBC transfusion. However, determinants other than the Hb concentration must be considered including age, severity of illness or evidence of organ dysfunction or O_2 dependency, such as a high blood lactate level or low $ScvO_2$. For example, it would seem appropriate to consider a higher threshold and a more aggressive RBC transfusion strategy in unstable patients, but the optimal and safe lower limit of the transfusion threshold has not been established for such patients. Moreover, any recommendations made must also factor in specific considerations for disorders such as sickle cell disease, hemolytic uremic syndrome, and some cardiac diseases.

Many experts in the field of pediatric cardiology and cardiac surgery believe that the optimal Hb concentration for patients in the postoperative phase of cardiac surgery should be significantly higher, and advocate levels as high as 14 to 18 g/dL in cases of uncorrected cyanotic congenital cardiopathy.[39,40] Few clinical studies have addressed RBC transfusion in cyanotic heart disease. Experience with bloodless cardiac surgery for congenital heart disease in children whose families refuse transfusion for religious reasons seems to suggest that a lower Hb level may be well tolerated. This is supported by a randomized clinical trial involving 59 children with bidirectional Glenn or Fontan procedures. In this trial, patients were randomized either to a restrictive or liberal transfusion strategy (respective Hb concentration thresholds of 9 or 12 g/dL). The mean postoperative Hb was 11.1 ± 13 and 13.9 ± 0.5 g/dL, and the mean number of RBC transfusions was 0.47 ± 0.6 and 2.03 ± 1.2 per patient in the restrictive and liberal groups. No difference was found with respect to outcomes like peak blood lactate level (3.0 ± 1.5 vs. 3.1 ± 1.3 mmol/L), ventilator or pressor duration, ICU or hospital length of stay, or survival. More data are required before implementing a restrictive transfusion strategy in patients with cyanotic heart disease.[41] Beekman's 1985 statement that "The optimal Hb concentration for children with cyanotic heart disease has yet to be determined" remains true today.[19]

On the other hand, there is some evidence that a 7 g/dL threshold may be safe in the postoperative care of noncyanotic congenital heart disease in stabilized patients older than 28 days.[42] Willems et al.[43] analyzed a subgroup of 125 postoperative cardiac patients enrolled in the TRIPICU study after a cardiac surgery. No significant difference was found between the restrictive and liberal groups in new or progressive MODS (12.7% vs. 6.5%; P = .36), PICU length of stay (7.0 ± 5.0 vs. 7.4 ± 6.4 days) or 28-day mortality (two vs. two deaths). The British Society of Haematology[30] supports the acceptance of a postoperative hemoglobin level of 7 g/dL in children when there is good postoperative cardiac function unless there is a cyanotic heart lesion persisting. The Society of Thoracic Surgeons makes a similar recommendation for all cardiac surgery patients.[44] Data reported by Willems et al.[43] support these recommendations.

There is a debate on the usefulness of blood transfusion as a preventive measure. Some evidence suggests that this may be appropriate in critically ill children who have certain forms of congenital anemia (for example, sickle cell disease,[45] and in patients who require ECMO (a Hb threshold of 13 to 15 g/dL is suggested[46]) or surgery.[47] However, there are few hard data to support such recommendations in the latter two groups.

Prevention of Red Blood Cell Transfusion

"Bloodless medicine" is a popular concept in many American hospitals; it refers to all the strategies that can be used to provide medical care without allogeneic RBC transfusion, including blood conservation.[48] There are indeed many strategies that can prevent and/or significantly decrease the need for RBC transfusions and exposure to a transfusion. Adopting a restrictive RBC transfusion strategy in stable critically ill children is one of them; other possible means range from raising the Hb concentration before an elective surgery to using blood products only when necessary, limiting blood losses and administering the patient's own blood.

Bloodless medicine begins before surgery. Among the possible strategies in the preoperative period, the use of erythropoietin and iron supplementation to optimize the preoperative Hb level, collection of autologous donations to prevent some allogeneic transfusion,[49] avoidance of any medication that increases the risk of bleeding, including herbal medicine (e.g., garlic, ginseng, ginger[33]), and optimal control of any existing coagulation disorders just prior to surgery should be considered.

During surgery, maximal attention should be given to limiting blood loss[50] and ensuring good hemostasis and rapid control of all bleeding. In some instances, desmopressin,[51] fibrin sealants, or antifibrinolytic agents such as aprotinin or tranexamic acid[48] may be used to stop a hemorrhage. Recombinant activated factor VII (rFVIIa) is also advocated by some practitioners, but it is associated with a significant risk of thrombosis; the cost/benefit ratio of rFVIIa in children is not well evaluated and its use should be limited to situations with uncontrolled bleeding that is life-threatening.[52] The safety and cost-effectiveness of intraoperative blood conservation strategies such as normovolemic hemodilution,[53] autologous blood cell salvage modalities,[54] intraoperative autotransfusion, and deliberate hypotension[50] remain to be determined in children.

Postoperative and ICU management of anemia and bleeding is also important. A restrictive transfusion strategy is in line with the concept of "permissive anemia" supported by the British Committee for Standards in Haematology Transfusion Task Force.[30] A prospective study reported that 73% of blood loss in PICU is attributable to blood draws.[1] The number and the frequency of blood tests must be limited, and the amount of blood collected reduced. Many devices can help to minimize blood loss, including the use of loop sampling, pediatric blood collection tubes, microanalysis techniques requiring small volumes of blood, and in-line measurement of parameters such as blood gases and Hb concentration.[55-57] The erythropoietin response to anemia is blunted[58] and poorer than expected in critically ill patients.[59] In spite of this, there are data suggesting that erythropoietin can prevent anemia in critically ill adults,[60] in low-birth-weight preterm infants[61-63] and in the postoperative care of neonates.[64] In critically ill children, there are no data to support the use of erythropoietin as a preventive measure because most RBC transfusions are administered within 2 or 3 days after PICU admission,[1,65] a period of time too short to allow for a response to erythropoietin that generally requires several days.[66] The standard use of erythropoietin is presently not recommended in PICU.[65,67] In addition, iron supplementation is not indicated because most critically ill patients are not iron depleted.[59]

An RBC transfusion should be administered only if the anticipated benefit outweighs the potential risk. A threshold Hb concentration of 7 g/dL is adequate in most stable critically ill children.[68] The optimal Hb concentration or transfusion threshold above which the benefits outweigh the risks and costs remains to be determined in unstable patients and in patients with congenital heart disease.

Types of Packed Red Blood Cell Units

Many types of RBC units are available: standard, washed, irradiated, cytomegalovirus (CMV) negative, autologous and directed.

Standard Packed RBC Units

Storage of RBC units is made possible by refrigeration at about 4° C and by storage in preservative anticoagulant solutions that contains dextrose, sodium citrate, citric acid, and sodium diphosphate. Erythrocytes use dextrose and phosphate to generate ATP, which is essential for their survival. Citrate blocks coagulate by chelating calcium; it is also transformed into bicarbonate, which stabilizes the stored RBC unit pH above 6.4. Citrate-phosphate-dextrose (CPD) solution can be stored up to 28 days. Citrate-phosphate-dextrose-adenine (CPDA-1) contains more dextrose (2 g vs. 1.6 g/63 mL) and more adenine (17.3 mg/63 mL) than CPD; it can be stored up to 35 days because the level of ATP remains normal after 21 days of storage and is about 50% after 35 days. Packed RBC units are prepared by removing 200 to 250 mL of plasma from one unit of whole blood by centrifugation. To support the nutrient needs of RBCs after plasma is removed, additive solutions were developed, such as AS-1 (Adsol), AS-3 (Nutricel), and AS-5 (Optisol), and saline-adenine-glucose (SAG) or SAG-mannitol (SAGM)[69]; these additive solutions further decrease RBC lysis and allow for storage up to 42 days.[70]

The volume of a CPDA-1 unit is about 250 mL, including 63 mL of preservative solution; it must be diluted with 75 mL of NaCl 0.9% before transfusion (final volume: 325 mL). The volume of an AS-3 unit is about 350 mL and the volume of a SAGM unit is about 300 mL; both include approximately 100 mL of preservative solution and do not require any dilution.

Other Types of Packed Red Blood Cell Units

Whole Blood. The use of whole blood has been advocated mostly for first-line therapy in hemorrhagic shock as it contains RBCs, coagulation factors, and platelets. However, it is generally not available. Additionally, refrigeration in storage solution for even several hours results in decreased levels of coagulation factors, oxygen-carrying capacity, as well as platelet function. In practice, component therapy is standard practice and it is usually easier to give one or more packed RBC units diluted with normal saline along with plasma and/or

platelets. Whole blood units are also used by some for neonatal exchange transfusions, and in small children when priming for cardiac bypass procedures or continuous hemoperfusion. Whole blood is not recommended in normovolemic patients because it can cause a cardiac overload. The volume of a typical whole blood unit is about 450 mL.

Leukocyte-Reduced Packed Red Blood Cell Units. Packed RBC units contain some nonviable platelets, small amounts of coagulation factors, and WBCs that can release proinflammatory and antiinflammatory mediators during storage. Prestorage leukocyte reduction is a standard procedure for all blood components in many countries, such as Australia, Canada, and the United Kingdom; it can decrease the number of WBCs in packed RBC units from 1×10^9 to less 1×10^6 per product, and it decreases the concentration of cytokines in the supernatant, as well as some T cells that regulate immunomodulation.[71] In 2005, 88% of packed RBC units given in American PICUs were leukocyte-reduced at collection.[1] Transmission of intracellular viruses such as CMV and herpes is less frequent if there are fewer WBCs.

Washed Packed Red Blood Cell Units. RBCs can be washed with sterile saline; the process removes not only 98% of the plasma, but also up to 20% of the RBC. Erythrocyte washing increases the hematocrit up to 0.8, but the procedure takes up to 2 hours; thus it is impossible to use washed packed RBC units on an emergency basis unless they are prepared in advance. Washed units must be used within 24 hours after processing. Multiple wash cycles are required. The procedure may not reduce the proteins enough to prevent hypersensitivity reactions (e.g., hypersensitivity to immunoglobulin [Ig]A). The overall volume of a washed RBC unit is significantly decreased (about 200 mL rather than 350 mL for an AS-3 RBC unit), making them sometimes useful to limit the volume administered in some patients. Washed RBC units can also be considered for patients with severe, recurrent allergic reactions to blood and some patients with anti-IgA deficiency. Washed RBC units should not be considered leukocyte reduced.

Irradiated Packed Red Blood Cell Units. Some WBCs remain in RBC and platelets units, even in prestorage leukocyte-reduced units. The objective of irradiation is to induce enough DNA damage to prevent leukocyte proliferation.[72] Irradiation destroys the ability of transfused lymphocytes to divide and therefore to respond to host foreign antigens, thereby decreasing the risk of developing transfusion-associated graft versus host disease (TAGVH) in susceptible recipients. However, irradiation is not without some drawbacks. For example, it can damage the RBC membrane causing the release of significant amount of free Hb and potassium. Moreover, the shelf life of irradiated RBC units is reduced from 42 to 28 days.[73]

Irradiated RBCs are indicated for all children with congenital or acquired cellular immune deficiency (for example, allogeneic stem cell transplant recipients, certain hematologic malignancies, myeloablative chemotherapy recipients) to prevent TAGVH. Because diGeorge syndrome is not rare among infants with congenital heart disease undergoing cardiac surgery, these patients should receive irradiated units. Irradiation is also indicated in patients receiving directed donation from family members. Irradiation is not mandatory for most solid tumors, routine immunosuppressive therapy (corticosteroids), solid organ transplants, non-myeloablative chemotherapy recipients, or humoral immunodeficiency.

Cytomegalovirus-Negative Packed Red Blood Cell Units. A large proportion (30% to 70%) of blood donors are CMV positive. Most CMV infections are of little clinical consequence, but CMV can be fatal in patients with immunodeficiency. Fresh frozen plasma is not known to transmit CMV infection, but RBC units are. Although it would be ideal to administer only CMV-negative RBC units to CMV negative patients, the high prevalence of CMV infection among donors does not permit this.[74] Nevertheless, prestorage leukocyte reduction of blood products decreases transmission of CMV to 1% to 2% (similar to the rate of infection following the transfusion of CMV negative units) compared to standard products for which transmission is 13% to 37%. Administration of a CMV positive RBC unit is generally not an issue for immunocompetent patients. Established indications for CMV-negative units include CMV-negative recipients of organ or bone marrow transplants from CMV-negative donors, CMV-negative bone marrow transplant recipients, and intrauterine transfusions. Less well-established indications include CMV-negative patients who are potential candidates for autologous or allogeneic bone marrow transplant, CMV-negative patients undergoing splenectomy, potential seronegative donors for bone marrow transplant and CMV-negative patients with HIV.

Directed Packed Red Blood Cell Units. Directed blood is donated by family members or friends. Parents frequently believe that giving their own blood decreases the risks of transfusion, which, in practice, is not the case. A small increase of transfusion-transmitted infectious diseases has been reported.[46] Moreover, the risk of contracting a TAGVH is increased even in immunocompetent patients. In spite of this, directed blood donation remains popular; good clinical studies are warranted to better estimate the risk/benefit ratio of this practice. All directed RBC units must be irradiated pretransfusion.

Autologous Packed Red Blood Cell Units. Older healthy children can give their own blood a few weeks before elective surgery. It is frequently believed that autologous RBC units are free of risk, but this is untrue. These units are usually quite old by the time transfusion is required, which raises significant concerns with respect to RBC unit length of storage.[75] Moreover, autologous RBC units are not leukocyte-reduced, at least in Canada. The risk/benefit ratio of autologous RBC units remains to be determined.

RBC substitutes and other alternatives to RBC transfusion

Hemoglobin-based oxygen carrier solutions (semisynthetic or synthetic preparations of Hb) and perfluorocarbon derivatives can carry O_2.[76,77] Both were developed as alternatives to RBCs, but there are serious concerns about their safety and usefulness. None can be recommended presently.

Transfusion of Packed Red Blood Cells: How

Erythrocyte transfusion is the best way to rapidly increase the Hb concentration. The practitioner must address a few questions after a decision is made to prescribe a RBC transfusion:

what type of RBC unit (see the previous section), what blood type, how much (volume), how the unit is infused and what monitoring must be performed.

Blood Types

Table 82-1 describes the compatibility of different blood products. A completed cross-match is mandatory before any transfusion is given, with few exceptions. Transfusion of group O Rh negative RBC and/or group AB Rh positive plasma can be lifesaving, but this must be reserved for very severe and acute situations. It takes 15 to 20 minutes to complete ABO and Rh typing of a patient. If there are no RBC antibodies, fully compatible blood or immediate spin cross-match may be issued quickly. In the case of RBC antibodies or other anomalies, a full serologic cross-match is required, which will take more time. The risk of severe reaction to typed, but not cross-matched blood RBC units, is about 1 in 1000 if the patient has never received a transfusion; the risk is decreased by tenfold if a cross-match is done. If the patient has received at least one transfusion, the risks are respectively 1 in 100 with no cross-match and 1 in 1000 if a cross-match is done. It was recommended that similar units be used until patient recovery if a patient receives more than 20% of his blood volume with uncross-matched packed RBC units. However, this practice is a little outdated, as there is very little plasma in AS-3 and SAGM RBC units. If anti-A/B antibodies are detected on blood typing then antigen negative blood should be provided; otherwise ABO-identical units should be used when they become available. Repeat verification that the correct blood unit has been delivered to a given patient is essential because blood mismatch is the most important cause of severe transfusion reaction.

For high-risk elective procedures, type and cross-matching performed before bleeding event allows for compatible RBC units to be reserved for the patient. If an unforeseen emergency transfusion is required within minutes for an actively bleeding patient, it is impossible to deliver RBC units that are typed and cross-matched within a reasonable time frame and group O Rh negative RBC units must be administered. STAT ordering a transfusion means that it must be started within a few minutes after the prescription; STAT ordering is usually not required, unless the patient is actively bleeding.

Table 82–1

Blood Product	Receiver	Donor
Packed RBC unit and whole blood	A, O	
	B	B, O
	O	O
	AB	AB, A, B, O
	Rh^+	Rh^+ or Rh^-
	Rh^-	Rh^-
Plasma or platelets	A, AB	
	B	B, AB
	AB	AB
Platelets	Rh^+	or Rh^-
	Rh^-	Rh^- or Rh^{+*}

*Give as an anti-D vaccine (Win Rho SDF) if the receiver is Rh^- and the platelet concentration is Rh^+.

Volume and Number of Units

Prescribing the right volume of packed RBC units is important as this prevents cardiac overload and limit exposure to several donors. An easy to remember, albeit simplistic, rule of thumb suggests that administration of 10 mL/kg of packed RBC units should increase the blood Hb level by 2 to 3 g/dL. If the Hb concentration is stable in a patient that is not actively bleeding, it is more precise to calculate the difference between the Hb concentration observed before transfusion and the targeted Hb level. The following formula can be used to calculate more precisely the volume of packed RBCs that should be given:

$$\text{Volume(mL)} = [(\text{Hb}_{\text{targeted}} - \text{Hb}_{\text{observed}}) \times \text{Blood volume}] / \text{Hb}_{\text{RBC unit}}$$

where $Hb_{targeted}$ is the Hb concentration targeted posttransfusion (e.g., 10 g/dL), $Hb_{observed}$ is the most recently measured Hb concentration of the patient (g/dL), and $Hb_{RBC\ unit}$ is the average Hb concentration in the packed RBC units (g/dL) delivered by the blood bank. Hb concentration in RBC units may vary from one center to another and with different preservative solutions. For example, the hematocrit of RBC units with AS-3 (Nutricel) is approximately 0.55, and $Hb_{RBC\ unit}$ concentration is about 19.5 g/dL (range, 18-21 g/dL); the hematocrit of CPDA-1 is 0.75 to 0.65, and the $Hb_{RBC\ unit}$ is about 25 g/dL. The blood volume can be calculated according to the following formula:

$$\text{Total body blood volume} = \text{Weight} \times \text{Blood volume}$$

where weight is expressed in kilograms, and blood volume is in liters per kilogram (0.08 L/kg for a child younger than 2 years, 0.07 L/kg for child aged 2 to 14 years). For example, if the $Hb_{observed}$ in a 2-week-old baby weighing 3 kg is 6.5 g/dL, his blood volume is 0.24 L (0.08 L/kg × 3 kg), and the $Hb_{RBC\ unit}$ is 19.5 g/dL (AS-3), and if the physician targets a Hb concentration ($Hb_{targeted}$) of 10 g/dL, the volume of RBC unit to be transfused would be:

$$\text{Volume} = [(10\ \text{g/dL} - 6.5\ \text{g/dL}) \times 0.24\ \text{l}] / 19.5\ g/\text{d} = 0.043\ \text{L} = 43\ \text{mL}$$

If the volume needed to reach the $Hb_{targeted}$ is greater than the volume of one unit of packed RBCs, blood should be transfused one unit at a time to minimize exposure to multiple donors. Before the administration of additional packed RBCs, the Hb concentration should be measured after allowing at least 30 minutes posttransfusion for Hb and hematocrit values to equilibrate.[78] The transfusion can be completed with another unit or partial unit if a reasonable Hb level is not attained.

If the volume of packed RBCs required is less than one unit, a partial unit can be given. Whole packed RBC units can be subdivided in half (standard division) or in small pediatric 75 mL transfer packs (Pedi-Pak). Partial units should be prepared sterilely where possible. Partial units prepared nonsterilely expire 24 hours after the preparation. On the other hand, partial units prepared sterilely can be kept as long as the original unit (up to 42 days for AS-3). A small volume of packed RBC unit placed in a syringe must always be administered within 24 hours.

Length of Storage

Regulatory agencies and scientific societies such as the Food and Drug Administration and the American Association of Blood Banks mandate that packed RBC units can be stored up to 42 days based on the premise that at least 75% of transfused RBC will be alive 24 hours posttransfusion.[46,79] However, a "storage lesion" occurs over time, which raises many concerns.[13] These changes are associated with a number of biochemical and biomechanical changes including RBC ATP depletion, low 2,3-DPG levels, membrane phospholipid vesiculation and loss, protein oxidation, lipid peroxidation of RBC membranes, and RBC loss of deformability.

Prolonged storage changes the supernatant as well as the RBCs themselves. In the storage medium, studies have noted the generation of cytokines and other bioreactive substances,[80] including histamine,[81] complement activators, O_2 free radicals, lyso-phosphatidyl-choline species, and microvesicles containing lipids shed by RBCs. These bioactive substances may stimulate pro-inflammatory pathways and perhaps change flow patterns in the microcirculation.[11] The latter observation might explain the effect of RBC transfusion reported by Kiraly et al.[8] on StO_2 in critically ill trauma adults. A significant decline in StO_2 was observed in 17 patients who received RBC units stored since more than 21 days in the posttransfusion period compared to baseline. This was not observed in 15 patients who received fresher blood, nor in 16 patients who were not transfused.

Other well-documented time dependent changes in the storage medium are described, including a progressive fall in pH, an increase in plasma potassium and release of free Hb from lysed RBCs. On the other hand, fresh blood products stored for less than a week are not without risk and can be associated with transmission of certain intracellular viruses as well as TAGVH.[82,83]

There is presently controversy regarding the impact of RBC storage time in critically ill patients, both adult and pediatric. Some descriptive studies suggest that the outcome in critically ill adults is better if they receive fresher RBC units, while other studies do not support this.[84] Two prospective descriptive studies undertaken in critically ill children suggest that outcome is less favorable with transfusion of packed RBC units stored for more than 2 or 3 weeks.[85,86] On the other hand, a large retrospective study conducted in neonates undergoing cardiac surgery suggests that fresh blood may be more detrimental.[87]

The societal impact of implementing a "fresh RBC strategy" can be enormous: presently, RBC unit wastage is less than 1%; it is estimated that wastage would approach 30% if the allowable length of storage is decreased from 42 to 21 days.[79] Thus it is unethical to implement a fresh RBC transfusion strategy without strong evidence to support its usefulness. Whether the length of storage of RBC units really affects outcome in critically ill children remains to be determined by randomized clinical trials. The ABLE study (ISRCTN44878718) is such a trial and has been enrolling adults since 2009, whereas a pediatric trial is in preparation. Until hard evidence is available, the use of fresh rather than "old" blood cannot be recommended for PICU patients.

Perfusion, Warming, and Filtration

A RBC transfusion must be completed within 4 hours after the unit is delivered by the hospital blood bank. A packed RBC unit is usually given over 1 to 3 hours, but it might be given more slowly (up to 4 hours) or divided in two transfusions if there is some risk of cardiac overload.[46]

The viscosity of packed RBC units is high, which implies it is preferable to use larger bore needles to administer them.[88] No drugs should be given in the line used for packed RBC unit perfusion. It is also inappropriate to mix RBC units with dextrose or hypotonic solutions (risk of hemolysis), with Ringers lactate (risk of coagulation), or calcium.

Packed RBC units must be warmed before administration to diminish the viscosity of the blood product and to avoid hypothermia. Blood viscosity decreases by about 7% for each 1° C increase, thus reducing resistance and making it easier to administer blood products through catheters. Erythrocyte units are stored at 1 to 6° C and could cause significant hypothermia if given to a patient without warming. All blood products are warmed to room temperature (about 20° C) before delivery to the bedside. Warming to body temperature (37° C) may be required for patients weighing less than 10 kg or if large amounts need to be given corresponding to more than 20% to 30% of the circulating blood volume. Standard blood-warming devices must be used to raise the temperature of whole blood or packed RBC units, not microwave ovens that can cause severe hemolysis.

Because all packed RBC units (even prestorage leukocyte-reduced RBC units) contain fibrin, platelets, and WBC aggregates, a filter (with 80, 179, or 260 μm pores) must always be used to bind these aggregates before they are administered. Although their cost-usefulness has not been determined, filter with 20 to 40 microns micropores are more effective, and some evidence suggests that they can prevent some cases of TRALI. Filters with smaller micropores are not considered standard treatment.

Monitoring and Reporting Adverse Events

Patients should be monitored closely while receiving a transfusion. Vital signs should be taken before transfusion as well as within the first 15 minutes and every hour up to four hours after the transfusion.

Plasma

Plasma is separated from the RBC after collection of whole blood or it is collected using an apheresis machine; it is then frozen for storage to preserve the levels of coagulation factors. It is named "fresh frozen plasma" if the unit is refrigerated within 8 hours of collection, and "frozen plasma" within 24 hours of collection. There is a slight reduction in factor VIII levels in frozen plasma, but in clinical practice these two types of plasma are essentially interchangeable.[89] The acronym FP (frozen plasma) is used in this section to designate both of them.

Frozen plasma units are collected from a single donor, whereas units of solvent detergent (SD) plasma (Octaplas, Octapharma) is constituted from a pool of frozen plasma collected from approximately 700 donors and is processed using the SD process for inactivation of lipid-enveloped viruses. SD plasma is not currently licensed in the United States, but it is licensed and available in Europe. In some countries, only FP may be available, but in many countries including the United States fresh FP is still available in the year 2010.

FP units are systematically leukocyte-reduced by filtration before storage in many countries, but not in the United States. FP volume is about 200 to 250 mL/unit,[46] whereas the volume of SD plasma is about 200 mL/unit. On average, FP contains 1 unit/mL of all coagulation factors, but there is significant variability among individual units, which is attributable to

biological variation in factor levels among individual donors, and differences in processing, storage and preparation for transfusion.[90] The levels of coagulation factors in SD plasma are more standard with little variation among units as it is a pooled plasma product. FP is stored at −18° C up to one year after collection. Solvent detergent plasma can be stored for up to 48 months.

Transfusion of Plasma: Indication (When)

Generally, FP is transfused to correct multiple coagulation factor deficiencies (or single-factor deficiencies when no recombinant or plasma-derived coagulation factor concentrates are available) to patients with active bleeding or before invasive procedures when no alternative therapies are available or appropriate. Common coagulopathies for which FP may be given include liver disease and symptomatic disseminated intravascular coagulation (DIC). However, the use of plasma to treat disseminated intravascular coagulation is controversial because thrombosis is frequently a component of this disorder.[46] Frozen plasma can also be given for the emergency reversal of warfarin or vitamin K deficiency when prothrombin complex concentrates are not available.[91] Guidelines suggest transfusing FP only when the international normalized ratio (INR), the prothrombin time (PT), or the activated partial thromboplastin time (aPTT) is more than 1.5 times normal as coagulation factors are generally adequate for hemostasis below this level. However, some data suggest that FP is not very effective at normalizing mild abnormalities of coagulation tests, like an INR below 1.85,[92] and the potential clinical benefit of FP transfusion seems minimal when the INR is less than 1.7.[93]

Frozen plasma may also be administered during massive transfusion of packed RBC units. Some experts advocate early replacement of FP in a 1:1 ratio with RBC units in trauma patients with massive transfusion, whereas others suggest that FP transfusions should be guided by the presence of abnormal coagulation test results as previously listed or of whole blood: it should be administered in patients who have received more than 1.5 their circulating blood volume, even if there is no bleeding, or in patients who have received more than one circulating blood volume and who have clinical evidence of oozing or microvascular bleeding.[29,91,94]

Other indications for FP transfusion include plasma exchange for thrombotic thrombocytopenic purpura (TTP).[91] Some physicians advocate transfusion of plasma to treat cases of hemolytic uremic syndrome and to restore the blood volume of patients in shock, but there is no hard evidence to support such uses.

There is no evidence that FP should be given in prophylaxis to nonbleeding patients. Plasma should not be used as a volume expander; crystalloids, synthetic colloids, or purified human albumin solutions are preferred. Solvent detergent plasma has lower levels of protein C and S, which may contribute to increased thrombotic events and therefore should be used with caution in patients with severe liver disease, including liver transplant patients.

Transfusion of Plasma: How

One milliliter of FP contains about 1 unit of each of the coagulation factors. For most deficiencies, 30% of normal factor activity is enough to ensure hemostasis. Surgical hemostasis may be achieved with factor II levels 5% to 50% of normal, factor V approximately 30% of normal, factor VII 25% of normal, and factor VIII 30% to 60% of normal.[33] Practitioners usually administer 10 to 20 mL/kg of plasma initially; this should increase the level of the individual coagulation factors above 30%. As the levels of coagulation factors vary among units, the response to FP is not consistent. Therefore, the effectiveness of FP transfusion should be estimated by clinical judgment of ongoing bleeding and, if necessary, repeat coagulation testing. Additional doses of FP may be required for ongoing bleeding with persistently elevated coagulation tests. However, normalization of coagulation tests often does not occur and, therefore, should not be used as the only guide for additional FP transfusions.[95]

Frozen plasma transfusions should be ABO compatible but are not required to be identical. In contrast to RBC, group AB-positive plasma is the universal plasma donor and can be given in emergency situations when a blood group is not available. Cross-matching is not required because FP units are screened for antibodies against non-ABO and Rh antibodies, which may cause hemolytic reactions.

FP must be thawed (20 to 30 minutes) before transfusion. Warming FP can be shortened to 7 minutes using microwave ovens specifically constructed for this task (standard microwave oven can disable coagulation factors). A thawed unit of FP is ideally transfused within 4 hours, but thawed plasma can be relabeled and stored for up to 5 days in some countries including the United States (AABB Technical Manual). The clinical indications for thawed plasma are similar to FP but there is some decrease in the labile coagulation factors (factor V and VIII). A 80 or 170 μm pore filter must be used.

Platelets

The prevalence of thrombocytopenia, defined by a platelet count less than 150,000/μL (<150 × 10^9/L), is 17.3% on admission into PICU; 25.3% of children are thrombocytopenic at some point during their PICU stay.[96] Thrombocytopenia arises from decreased platelet production, increased platelet destruction, and dilutional or distributional causes.[97] In PICU, most thrombocytopenia is caused by sepsis, disseminated intravascular coagulation, MODS, or hemolytic uremic syndrome; however, heparin-induced thrombocytopenia,[98] massive transfusion,[99] and reactive hemophagocytic syndrome are not so rare.[100] In critically ill children, thrombocytopenia at PICU entry is associated with increased mortality (17.6% vs 2.5%)[96], bleeding complications, thrombosis, and prolonged PICU and hospital length of stay.

Platelet dysfunction is also observed quite frequently in PICU. Rarely platelet dysfunction can be caused by hereditary disease (e.g., Bernard-Soulier disease, etc.), but, more commonly, it is caused by specific treatments (hypothermia, pentastarch, and hetastarch,[101] etc.) or antiplatelet drugs (e.g., low-dose aspirin. nonsteroidal antiinflammatory drugs).

Standard Platelet Concentrates

Different methods can be used to obtain platelet concentrates: they may be whole blood derived platelets, either by the platelet-rich plasma (United States and United Kingdom) or the buffy-coat method (Europe and Canada) or by apheresis (single-donor) platelets (United States, Europe, and Canada). For

whole blood-derived platelets, platelet concentrates are often pooled (up to 6 units) for a single platelet transfusion.

Maximum platelet lifespan is 10.5 days.[102] Each platelet unit contains about 55×10^9 platelets. When stored at 20° C to 24° C and gently agitated in a continuous manner, platelets can be used up to 5 days after they were collected, but will become active only 4 hours after transfusion to the recipient. If they are stored at 4° C, they are active immediately, but cannot be stored for more than 48 hours. In practice, most platelets units are stored at 20° C.

Special Platelet Concentrates

Leukocyte-Reduced Platelets

A platelet concentrate must contain les than 8.3×10^5 WBCs to be labeled leukocyte reduced.[46] Prestorage leukocyte reduction is a standard procedure in many countries. Bedside leukocyte reduction filter should not be used when prestorage leukocyte reduction was done because it is useless and it can decrease the number of platelets.

Irradiated Platelets

The risk of TAGVH is increased in patients who receive HLA-compatible platelets. Therefore pretransfusion irradiation is mandatory for all human leukocyte antigen (HLA)-compatible platelet concentrates. Irradiation is also recommended for intrauterine transfusion and infants at risk of TAGVH.[46]

Cytomegalovirus-Negative Platelets

Platelet concentrates can transmit CMV. The indications for CMV-negative platelet and RBC are similar.

Platelets Substitutes

There is no alternative to platelets transfusion. However, cryoprecipitate can be used to treat platelet dysfunction caused by uremia if therapy like dialysis is not successful.[46]

Transfusion of Platelets: Indication (When)

Over 1.5 million platelet products are transfused in the United States each year.[103] Platelet transfusions are indicated for the prevention or treatment of bleeding in patients with thrombocytopenia or platelet dysfunction. As platelet transfusions will only result in modest elevations for 1 to 3 days in patients with persistent thrombocytopenia, the purpose of platelet therapy is not to eliminate all bleeding, but to prevent or stop major hemorrhagic events.

Therapeutic platelet transfusions are given to treat clinically significant bleeding associated with a low platelet count. There is evidence that correction of thrombocytopenia reduces mortality of critically ill patients,[96,104] but a platelet transfusion should be considered only if the platelet count in an actively bleeding patient is less than 50,000 to 100,000/μL.

More than 50% of platelets transfusions are given to prevent bleeding, even though the need for prophylactic transfusions has not been conclusively proven. There is insufficient evidence to support a particular threshold for prophylactic platelet transfusion in children. Most recommendations come from guidelines developed for adults, based on expert opinion. For patients with hypoproliferative thrombocytopenia (e.g., chemotherapy induced), a platelet transfusion threshold of 10,000/μL is recommended.[46] This is based on clinical trials in adults, which showed no increases in bleeding rates when comparing platelet transfusion thresholds of 10,000 vs. 20,000/μL.[102]

In the ICU, higher platelet transfusion thresholds are usually employed. Intensivists prescribe platelets for patients on ECMO if their platelet count is less than 100,000/μL; the same threshold is frequently used when a central nervous system procedure is undertaken. When the platelet count is less than 50,000/μL, platelets are usually given just before an invasive procedure (surgery, insertion of central venous catheter); it can also be considered in mechanically ventilated patients because the risk of pulmonary hemorrhage is significant. A threshold of 10,000 or 20,000/μL is recommended for lumbar puncture.

The platelet count must be monitored closely if a large amount, more than one blood volume, of crystalloids, and/or packed RBC units is given because this can significantly dilute the circulating platelet volume.[105]

The platelet count is not the only element to consider when deciding whether to administer platelets: increasing the threshold that triggers platelet transfusion may be appropriate if a rapid decrease in the platelet count is observed, if the risk of bleeding is higher, or if platelets are dysfunctional. Platelets are contraindicated in patients with thrombotic thrombocytopenic purpura and heparin-induced thrombocytopenia because of the increased thrombotic risk.

The capacity of platelets to stop a hemorrhage is not only related to their number, but also to their function. Many tests can be used to estimate platelet function: thromboelastogram, Sonoclot coagulation analyzed, Plateletworks analyzer, Hemostatus platelet function test, Platelet function analyzer, VerifyNow (Ultegra) System, and so on.[33] However, the results of these tests are not available on an emergency basis in most hospitals. Measurement of platelet mass may be a practical alternative. There is evidence that larger platelets exhibit increased hemostatic activity.[106] The results of a randomized clinical trial conducted in a neonatal ICU suggest that using platelet mass (Platelet count × Mean platelet volume) rather than platelet count to trigger a platelet transfusion may reduce the number of transfusions.[107] Nevertheless, it must be underlined that the clinical usefulness of all these tests remains undetermined in PICU.

There is significant diversity in the stated practice pattern with respect to platelet transfusions.[108] Most guidelines are based on experts' opinion, and not on hard data.[29,30] Significant work needs to be done to better determine when platelets should be administered in critically ill children.

Transfusion of Platelets: How

A simple rule of thumb suggests giving 1 or 2 platelet units per 10 kg, but not more than 6 units per transfusion. For children weighing less than 10 kg, the platelet dose can be 5 to 10 mL/kg of pooled or apheresis platelet unit. Transfusion of one platelet concentrate per m^2 of body surface generally increases the platelet count by 7000 to 11,000/μL. By body weight, the administration of one unit per 10 kg should increase the platelet count by 30,000 to 50,000/μL. However, a clinical trial, where platelet dose was estimated

by body surface area, evaluated low (1.1×10^{12} platelets/m^2), medium (2.2×10^{12} platelets/m^2), and high (3.3×10^{12} platelets/m^2) dose prophylactic platelet transfusions and did not find any differences in bleeding among adult or pediatric patients.[109] Platelet units must be used within 4 hours after they are delivered by the blood bank, but there is some evidence that the platelet count raises more if the unit is given within an hour. A filter with 80 or 170 micron pores must be used to remove aggregates that can form between harvesting and transfusion.

The volume of a platelet-rich unit is about 50 to 70 mL, whereas that of an apheresis platelet unit ranges from 200 to 300 mL; 90% to 95% of this volume is plasma. It is important to note that this plasma is not an adequate source of coagulation factors because their concentration drops rapidly during platelet storage. Platelet units can be volume reduced (removal of plasma) before transfusion, but this process can decrease the platelet count by 15% to 20%, shortens the storage time to 4 hours and delays platelet release from the blood bank by approximately 1 hour. Volume reduction can only be considered if there is a risk of severe cardiac overload, but is not recommended as a standard procedure because it can activate platelets.[46]

Unlike RBC units, ABO compatibility is not mandatory with platelets. However, it is better to use ABO compatible platelet unit in young patients with small blood volumes. Moreover it is recommended to deliver ABO compatible platelets when inventory and time permit, unless the plasma component has been substantially reduced. On the other hand, Rh compatibility is desired because all platelet units contain some RBCs. Transfusion of a Rh-positive unit to a Rh-negative patient can cause Rh alloimmunization; an anti-D immunoglobulin (Win Rho SDR) should be administered within 48 hours to prevent this complication when Rh positive platelets are given to an Rh-negative patient, particularly in female patients.[103]

The percent platelet increment (difference between post- and pretransfusion on pretransfusion platelet count) should be higher than 20% if the dose is adequate and if a repeat platelet count is performed 10 to 60 minutes posttransfusion; it should be higher than 10% if measured 18 to 24 hours posttransfusion.[103] Platelet refractoriness can occur because of nonimmune factors such as disseminated intravascular coagulation, in which platelet consumption can be high, acquired hemophagocytic syndrome, drugs such as amphotericin or heparin, or immune factors involving antiplatelet antibodies, and so on.[100,103,110] Treatment of the underlying problem is mandatory in such instances, for example stopping heparin administration. Patients with anti-IgA antibodies should receive washed platelets or platelets collected from IgA deficient donors.

Cryoprecipitate

Cryoprecipitate is a concentrated source of fibrinogen, factor VIII, factor XIII, and von Willebrand factor. It is stored at a minimum of −18° C for a maximum of 1 year. It is used in patients with congenital or acquired hypofibrinogenemia and patients with coagulopathy and significant bleeding. It is also used in patients with von Willebrand disease and hemophilia A only if specific factor concentrates are not available. The dose is 1 or 2 IU/10 kg (maximum, 12 units), which should increase fibrinogen level about 60 to 100 mg/dL (46). A blood filter (80 or 180 μm) should be used. The recommended rate of delivery is 30 minutes (maximum, 4 hours).

Transfusion Reactions and Complications

Transfusions of labile blood products (RBC, plasma, platelets) can cause immediate or delayed transfusion reactions and various complications. Immediate reactions usually occur during the transfusion or within six hours after the end of the transfusion. Delayed reactions can occur after a few days, weeks, or even years.

Red Blood Cells, Plasma, and Platelets

Immediate Transfusion Reactions

The incidence of typical immediate transfusion reactions to RBC, FP, and platelets is reported in Table 82-2. Acute transfusion reactions are probably underdiagnosed in critically ill children. In a study conducted in the PICU of Sainte-Justine Hospital, all transfusions between February 2002 and February 2004 were prospectively monitored.[111] A total of 2509 transfusions were administered to 305 patients; 40 acute transfusion reactions (1.6%) occurred: 24 nonhemolytic febrile reactions, 6 minor and 1 major (anaphylactic shock) allergic reactions, 4 isolated hypotensive reactions, 3 bacterial contaminations, 1 hemolytic reaction, and 1 TRALI.

The SHOT report on transfusion reactions observed in children in the United Kingdom from 1996 to 2005 estimated the incidence of adverse outcomes to be 18 per 100,000 RBC units issued for children less than 18 years, 37:100,000 for infants less than 12 months, and 13:100,000 for adults.[112] Among the 321 adverse reports in children, 82% were instances of incorrect blood component transfused, and 50 cases (14%) were acute transfusion reactions. The most important acute transfusion reactions are described below.

Respiratory System

TRALI is one of the most dangerous transfusion reactions. Two pathophysiologic mechanisms are currently proposed.[113,114] (1) According to the antibody hypothesis, TRALI is caused by an antigen-antibody reaction.[115] The antibodies (granulocyte antibodies and/or HLA class I or II antibodies) are present in the donor plasma and react with the recipient's WBC antigens (or rarely vice versa). The administration of such antibodies can directly injure the lung or can activate neutrophils, monocytes, and complement, creating an inflammatory reaction that may result in pulmonary damage.[115] (2) According to the "two-hit" or "neutrophil priming" hypothesis, recipients must first have a predisposing factor that "primes" their neutrophils, such as a septic state; then, the recipient's neutrophils are activated by donor plasma that contains leukocyte antibody or pro-inflammatory molecules like cytokines and bioactive lipids.[116]

The diagnosis of TRALI is made on the basis of clinical signs and symptoms, chest X-ray suggestive of pulmonary edema, and time relationship with transfusion (onset per-transfusion or within 6 hours posttransfusion). Causes of pulmonary edema other than TRALI should also be excluded, such as

Table 82–2 Incidence of Transfusion Reactions in Canada (Adults and Children)

	Risk per 1 Unit of Blood Component*

TRALI, Transfusion-related acute lung injury; *FP,* frozen plasma; *RBC,* red blood cell; *TACO,* transfusion-associated circulatory overload.
*Reported in 2003.
†Risk per pool of 5 units of platelet.
‡Hypotension can be caused by allergic or hemolytic reactions, septicemia, citrate toxicity, reaction to leukocyte reduction filters, and bradykinins in the supernatant of blood products.
§One retrospective study involving 143 critically ill adults with sepsis or septic shock reported more atrial fibrillation ($P = .04$), cardiac arrest ($P = .03$), and "all cardiac events" ($P = .001$) in recipients of packed RBC units.[153]
¶Metabolic complications include hypothermia, metabolic alkalosis,[4] hypocalcemia,[155] hypomagnesemia,[4] hyperkalemia,[155] hyponatremia,[12] and hyperglycemia.[156]

fluid overload or cardiac dysfunction. A panel of experts suggested a consensus definition of TRALI in 2004[117]; the list of diagnostic criteria advocated by these experts is detailed in Box 82-1. The experts defined TRALI as a new ALI for which no other risk factor than the transfusion can be found. They suggested to use the term "possible TRALI" if another risk factor can be temporally related to the ALI. TRALI is a clinical syndrome, and no laboratory test is pathognomonic of TRALI, but the presence of HLA and/or neutrophil antibodies in the donor plasma is highly suggestive[113]; however, the absence of such antibodies does not exclude a typical case of TRALI.

The diagnostic criteria advocated by the panel of experts in 2004 exclude the possibility that a TRALI appears in a patient who already presents an ALI or an ARDS, a frequent occurrence in PICU. There is indeed some evidence that a TRALI should also be considered in some patients with ALI/ARDS before a transfusion if their respiratory dysfunction deteriorates significantly during or after a transfusion. Marik at al.[118] suggested expanding the definition of TRALI in ICU to ALI/ARDS observed within 72 hours after the transfusion of a blood product: they reported that such "delayed TRALI syndrome" occurred in up to 25% of critically ill adults receiving a blood transfusion. Church et al.[119] also reported an association between the transfusion of plasma and/or packed RBC units and ALI/ARDS. The bioactive substances contained in packed RBC and plasma units can cause or add to the severity of cases of ALI/ARDS.[119,120] Further investigation is required to better characterize the epidemiology, the mechanisms and the clinical impact of transfusion-related ALI/ARDS in PICU.

All blood products that contain plasma, even in minute quantities, can cause a TRALI. When such reaction occurs, the transfusion must be stopped immediately and supportive treatment administered with oxygen (in 100% of the cases) and mechanical ventilation (in 70% of the cases). The associated hypotension may be unresponsive to fluid administration and may require use of inotropes/vasopressors.[121] Diuretics are not useful; they are contraindicated in hypotensive patients.[122] All suspected TRALI reactions must be reported to the blood bank, because the donor's other blood products have to be withdrawn.

The prognosis of cases of TRALI is usually good if the patient survives, but mortality rate of 6% is reported. In survivors, resolution is usually rapid (within 96 hours) and there are no long-term sequelae.[122]

Box 82–1 Diagnostic Criteria of TRALI and Possible TRALI[117]

TRALI*

Diagnostic criteria of ALI:
- Acute onset
- Hypoxemia: PaO_2/FiO_2 ≤300 or SpO_2 <90% on room air
- Bilateral infiltrates on frontal chest radiograph
- No evidence of left atrial hypertension (i.e., no circulatory overload)

No preexisting ALI before transfusion
Onset during or within 6 hours posttransfusion
No temporal relationship to an alternative risk factor of ALI (see list of factors below)

Possible TRALI

ALI
No preexisting ALI before transfusion
Onset during or within 6 hours posttransfusion
A clear temporal relationship to an alternative risk factor for ALI:
- Risk factors of direct lung injury: aspiration, pneumonia, toxic inhalation, lung contusion, near drowning
- Risk factors of indirect lung injury: severe sepsis, shock, multiple trauma, burn injury, acute pancreatitis, cardiopulmonary bypass, drug overdose

*All criteria must be present.

Cardiovascular System

TACO figures among the most frequent potentially severe adverse events attributable to RBC transfusion.[123] Its incidence in PICU is not well characterized. It is most commonly associated with a rapid or massive transfusion that causes pulmonary edema secondary to heart failure.[124] Reduced cardiac reserve, chronic and severe anemia (Hb <5 g/dL), and age (infants and elderly patients) are risk factors. The main symptoms are respiratory distress, hypoxemia, tachycardia, and hypertension. When a TACO is suspected, the transfusion must be stopped and supportive treatment with oxygen and diuretics administered. Slow transfusion (≤1 mL/kg/h) in at-risk patients can prevent TACO.

Isolated hypotensive reactions are increasingly recognized,[125] but their etiology remains uncertain. They are probably attributable to bradykinin generation, which can happen when a blood product is exposed to negatively charged surfaces (e.g., filters). The risk of hypotensive reaction is increased in patients receiving angiotensin-converting enzyme inhibitors or with diminished bradykinin metabolism.[126] Hypotensive reactions are more frequently associated with platelets than with RBC and plasma. The hypotension may happen alone or with some flushing; it occurs rapidly after the transfusion begins. The treatment is straightforward: the transfusion must be stopped and supportive treatment (i.e., fluid bolus) should be undertaken.

Other Acute Transfusion Reactions

Nonhemolytic febrile reaction is the most frequent and benign acute transfusion reaction. In addition to fever, it can be accompanied by chills, discomfort, headache, nausea, or vomiting.[127] The symptoms usually occur toward the end or soon after a transfusion. These reactions are mediated by pyrogenic substances that accumulate during storage, or by recipient's antibodies that bind with leukocytes from the donated blood, which allow activation of the complement system and production of cytokines.[80] Acetaminophen can be used to minimize fever, but premedication with acetaminophen, diphenhydramine, or steroids is not useful.[128,129] A decrease in the incidence of these reactions is reported with prestorage leukocyte reduction.[130,131]

Acute hemolytic reactions may be much more serious. They are caused by lysis or accelerated destruction of RBC from immunological incompatibility between donor and recipient blood.[132] The mortality rate associated with transfusion errors is less than 10%.[133] ABO mismatch is the most frequent and most severe of the blood group incompatibilities, with hemolysis (1 in 60,000) and death (1 in 600,000) as the results.[29] In most instances, the patient received a packed RBC unit that was prepared for another patient. The risk that such error happens is obviously higher in an emergency setting and its prevention warrants careful verification by medical staff of all blood products administered. The reaction is characterized by fever, chills, discomfort, diffuse pain, and hemoglobinuria; hypotension, shock, renal failure, and disseminated intravascular coagulation are also observed in some cases. When such reaction is suspected, the transfusion must be stopped immediately and supportive treatment must be administered. To avoid these hemolytic reactions, the donor and recipient's compatibility must be thoroughly checked (ABO and Rh types, unit identification number) and the recipient must be properly identified (name and medical record number) when the sample is taken for pretransfusion analyses as well as before the transfusion is started.

Nonimmune hemolysis can be caused by mechanical trauma to RBCs, rapid administration through a small catheter, excessive warming or freezing, or contact with hypotonic solution.

Allergic transfusion reactions result from the interaction between donor allergens and recipient antibodies (IgE) that provokes a type I hypersensitivity reaction.[134] Other possible mechanisms are: preexisting class-specific anti-IgA in patients with IgA deficiency, preexisting antibodies to polymorphic forms of other serum proteins (e.g., IgG, albumin, haptoglobin) that the patient is lacking, transfusion of allergens to which a patient is presensitized, (drugs, chemicals, etc), and passive transfer of IgE antibodies to transfused patients.[134] The reaction can be minor (e.g., isolated urticaria) or major (e.g., hypotension, anaphylactic shock, respiratory distress, digestive disorders). A severe reaction usually occurs quickly, whereas a benign reaction may occur up to 4 hours after the transfusion is completed. When an allergic reaction is suspected, the transfusion must be stopped and supportive treatment undertaken with antihistamines, steroids, and epinephrine if required. Prevention must be considered. Premedication of patients with antihistamines is suggested if they have already presented two minor episodes. In patients with major reactions, premedication can be used with steroids and antihistamines. Washed RBC and platelets units can also be used. Patients with anti-IgA antibodies must receive blood products from donors with IgA deficiency or products that have been washed several times. Leukocyte reduction does not offer any benefit.

Bacterial contamination is more frequent with platelets than with RBC units or plasma since platelet concentrates are stored at 20° C to 24° C. Contamination may be due to unsuspected bacteremia in the donor, skin flora when taking a blood sample from the donor or the environment, and product handling.[135] The most common germs are: gram-negative bacteria such as *Klebsiella pneumoniae*, *Serratia marcescens*, and Pseudomonas species, and gram-positive such as *Staphylococcus aureus*, *Staphylococcus epidermidis*, and *Bacillus cereus*. The reaction is characterized by fever and chills and may lead to septic shock. Symptoms usually appear during or within 4 hours after transfusion. When a bacterial contamination is suspected, the transfusion must be stopped immediately, wide spectrum antibiotics must be given (third-generation cephalosporin or beta-lactam in combination with aminoglycoside) and supportive treatment administered. The blood bank must be informed immediately, as other blood products from the same donor may need to be withdrawn.

Delayed Transfusion Reactions

Among the 321 adverse events reported in children by SHOT in UK from 1996 to 2005,[112] there were five cases of severe delayed transfusion reactions, including two cases of TAGVH disease. Transfusion-associated graft versus host disease is rare but very serious.[82,83] It may occur when viable lymphocytes from a donor are infused to a recipient who is unable to reject them because of immuno-suppression or partial HLA matching (closed donor genetic profile). Donor leukocytes can then persist in the recipient; because these lymphocytes recognize the recipient's HLA antigens as foreign, an immune reaction is triggered. Signs and symptoms (generalized skin rash, diarrhea, abnormal liver function, or fever) appear 8 to 10 days after transfusion.[136] Associated complications are aplastic anemia with pancytopenia, which may lead to hemorrhage and severe infections. The mortality rate is 90%. The risk of TAGVH is 1 in 700 after cardiopulmonary bypass in some immunocompetent adult populations.[137] The risk is also high in premature babies and if a patient with a congenital or acquired immunodeficiency receives a nonirradiated RBC unit or if the blood was a directed donation collected from a relative. Neoplasia (e.g., leukemia, solid tumors), chemotherapy and transplantation (stem cell, bone marrow, solid organ),[138] intrauterine transfusions, and exchange-transfusions are other risk factors. No effective treatment is recognized. Prevention can be accomplished by irradiating blood products that will be transfused to at-risk patients or that result from directed donations.

Delayed (extravascular) hemolytic reactions result from the interaction between recipient irregular alloantibodies and donor RBCs. They involve either antibodies that were present before transfusion, but were missed because they were undetectable by cross-matching, or antibodies that appear after the transfusion. Involved antibodies are usually E, Jk^a, c, Fy^a, and K.[139] These reactions occur 3 days to 2 weeks after the transfusion. Symptoms include anemia and jaundice. The outcome is usually good except in some patients with sickle cell anemia. There is no specific treatment, but using only appropriate RBC units can prevent cases.

Posttransfusion purpura is characterized by dramatic, sudden, and self-limiting thrombocytopenia. The pathogenesis is unclear, but it is presumably related to the development of platelet-specific antibody following transfusion. The platelet count drops below 10,000/μL 5 to 10 days after a transfusion was given to a patient with a history of sensitization by pregnancy or prior transfusion.[140] Purpura and diffuse hemorrhages (mucosal, gastrointestinal, urinary, cerebral) may be observed. The thrombocytopenia is refractory to platelet transfusion. The mortality rate is 8%. Treatment includes steroids, plasmapheresis, and immunoglobulins.

Complications Related to Massive Red Blood Cell Transfusion

Massive transfusion is defined by giving more than one circulating volume of blood within 24 hours, or more than 50% of the circulating blood volume in three hours or less, or 10 RBC units in adults.[99] A number of complications may occur: (1) coagulopathy and dilutional thrombocytopenia, which may trigger bleeding[141]; (2) hypothermia due to a rapid infusion of cold blood products, which can lead to arrhythmias, platelet dysfunction, and cardiac dysfunction; (3) citrate toxicity that may trigger hypocalcemia, hypomagnesemia, and metabolic alkalosis[142]; and (4) hyperkalemia. These complications can be avoided by implementing the following precautions: use a blood heater if the transfusion rate exceeds 50 mL/kg/h; monitor the coagulation profile and transfuse platelets, plasma or cryoprecipitate to maintain a platelet count greater than 50,000/μL, an INR less than 1.5 to 2.0, and fibrinogen level greater than 0.1 g/dL; monitor hypocalcemia, and administer $CaCl_2$ if necessary.[138]

Transfusion Transmitted Infections

In the United States, blood donation is tested at least for the following infectious agents: hepatitis A, B and C, human immunodeficiency virus (HIV), human T-cell lymphotropic virus (HTLV), West Nile virus (seasonal), and syphilis.[46] These tests and better donor selection leads to a significant decrease in the risk of transfusion-transmitted infectious diseases. However, there will always be some residual risk, attributable to the "window period" (time from the beginning of an infection to the time when tests can detect the infection) and to false-negative results. Table 82-3 lists the risks of contracting specific infections with transfusion.

Transfusion-Related Immunomodulation

There is strong evidence that transfusions might generate and/or enhance both anti- and proinflammatory reactions. Clinically important immune suppression is described in recipients of RBC units. For example, transfusions of packed RBC units have been reported to improve renal and cardiac allograft survival. This immune suppression might explain the increased rates of nosocomial infections reported in transfused critically ill adults.[143,144]

On the other hand, many proinflammatory molecules are found in RBC units, and may initiate, maintain, or enhance an inflammatory process.[13] The WBC and these substances may trigger or maintain a systemic inflammatory response syndrome in the recipients of RBC units. Administering a RBC transfusion to a critically ill patient with systemic inflammatory response syndrome may stimulate their inflammatory syndrome and constitute a "second hit," which can cause additional organ dysfunction, contribute to MODS,[145] and

Table 82–3 Transfusion-Transmitted Nonbacterial Infectious Diseases in Canada

Infection	Risk per Units of Blood Component*
HIV (AIDS)†	<1:4 million
Hepatitis B†	1:82,000 to 1:275,000
Hepatitis C†	<1:2.8 million
HTLV type I/II†	<1:1 million
Parvovirus B19†	1:5000 to 1:20,000
Cytomegalovirus†	Rare
Other infections‡	Low

HIV, Human immunodeficiency virus; *HTLV,* human T-cell lymphotropic virus.
*Most transfusion-transmitted infections are attributable to RBCs. However, there is historic evidence that the following infectious agents can be transmitted by plasma-derived products: HIV, hepatitis B and C, HTLV, and parvovirus B19—but not cytomegalovirus or parasites.[152]
†Reference 152.
‡Many other agents can be transmitted by a transfusion, such as West Nile virus, insect-borne zoonoses (e.g., malaria,[157] babesiosis,[158] *Bartonella quintana,*[159] and variant Creutzfeld-Jacob disease[160]).

perhaps ultimately result in higher mortality rates.[143] Some clinical data suggest that these risks decrease significantly if the packed RBC unit is leukocyte-reduced before storage.[68,146] However, in vitro data suggest that some inflammatory mediators are active even in leukocyte-reduced packed RBC units.[147] There are presently no data on this issue in pediatrics. The clinical impact of RBC transfusion on the immunological responses of critically ill children remains to be determined.

Complications Specific to Plasma Transfusion

Overall, the noninfectious and infectious complications associated with FP are similar to those of RBC transfusions, excluding hemolysis. The most notable risks associated with FP transfusion are TRALI and TACO. There are antibodies and other biologically active substances in plasma, but data suggest that SD plasma may be associated with a reduced incidence of TRALI. Frozen plasma is known to have immunomodulative properties,[148] which may explain why plasma is associated with an increased risk of MODS, ALI/ARDS,[119,149] and nosocomial infections.[150] Additionally the large volumes of FP transfused can result in TACO. Allergic reactions are also relatively common with FP transfusions (1% to 3%).

The risk of transfusion-transmitted viral infections is the same for FP and RBC units. Solvent detergent plasma has a reduced risk of infection related to enveloped viral pathogens, but the risk for nonenveloped viruses is not affected and the risk could be higher with regard to emerging nonenveloped viruses.

Complications Specific to Platelet Transfusion

The overall risk of clinically symptomatic adverse transfusion reactions attributed to a platelet transfusion was 10.9 per 100 pooled units in Canada.[123] Major allergic reactions and bacterial contamination are the most frequent severe complications associated with platelet transfusion.[123] Serious noninfectious complications of platelet transfusion are similar to those reported with plasma and RBC with the exception of hemolytic transfusion reactions. Rarely, hemolytic transfusion reactions can be seen after the transfusion of non-ABO identical platelets, which contain anti-A or anti-B antibodies. Platelet transfusion may also be associated with specific adverse effects including platelet refractoriness due to HLA alloimmunization. Prestorage leukocyte-reduced platelet products are available in most North American blood banks, which significantly decrease the risk of HLA alloimmunization and platelet refractoriness, nonhemolytic febrile reactions, and CMV transmission.

The most important infectious complication associated with platelet transfusion is bacterial infection. As platelet concentrates are stored at room temperature, the incidence of bacterially contaminated platelet products is higher than with RBCs. The risk of bacterial infection can be significantly reduced, but not eliminated, by bacterial testing (e.g., routine culture). The risk of other transfusion-transmitted infections is similar for platelets and other blood components.

Treatment of Transfusion Reactions

The following symptoms and signs suggest that an acute blood reaction occurred: fever, shivering (rigors), pain, anxiety, agitation, dyspnea, hypotension, hypertension, hemorrhage, shock, and hemoglobinuria (pink or red urine).

If a transfusion reaction is suspected, the transfusion must be stopped immediately, an intravenous access with NaCl 0.9% must be maintained, all measures to insure patient stability must be undertaken, verification that the patient received the correct unit must be done, a visual inspection of the unit must be done and described in the patient hospital chart, clinical data on the event must be detailed in the hospital chart, and the patient should be monitored for at least a few hours. In many centers, the unit that was being transfused, the filter and the tubing being used, and the remaining blood product are returned to the blood bank. A workup must be done to assess for infection as well as to measure antibodies, antigens, free Hb, and sometimes other markers of metabolic disturbance (acidosis, hyperkalemia, hypocalcemia, etc.). For example, collecting blood samples from the patient, including cultures, is mandatory if bacteremia is suspected, and it can be useful to measure antibodies, antigens, free Hb, or other markers of metabolic disturbance (acidosis, hyperkalemia, hypocalcemia, etc.). All possible transfusion reactions must be reported to the appropriate blood agency, which is the blood blank in many hospitals.

Conclusion

A transfusion can save a life, but it can also cause significant problems. The risk of death attributable to the transfusion of a labile blood product is low: only 1 death over 2,845,459 blood component units was reported in the United Kingdom during year 2008.[151] However, serious reactions and severe complications can happen. A transfusion is a serious matter: it should be prescribed only if deemed necessary. Closed monitoring of the recipient is mandatory while a transfusion is given.

Critical Illness Involving Children Undergoing Hematopoietic Progenitor Cell Transplantation

Jennifer A. McArthur, Barbara Bambach, Christine Duncan, Julie-An Talano, and Robert T. Tamburro Jr.

PEARLS

- Patients undergoing allogeneic hematopoietic progenitor cell transplant (HPCT) experience prolonged immune dysregulation and are at risk for both opportunist infection and graft-versus-host disease (GVHD).
- HPCT patients experiencing respiratory symptoms including a new oxygen requirement deserve prompt evaluation by the critical care team as they are at risk for rapid development of respiratory failure.
- Outcomes for HPCT patients requiring intensive care unit care have improved over the past decade.
- Patients who develop GVHD are at high risk for developing other transplant related toxicities.

Hematopoietic progenitor cell transplantation (HPCT) has evolved as treatment for a variety of congenital and acquired malignant and nonmalignant disorders. Over the years the name of this procedure has changed in an attempt to be more accurate. Throughout the literature, it has been referred to as bone marrow transplant or HPCT and now is sometimes referred to as hematopoietic progenitor cell transplant (HPCT).

The first successful human bone marrow transplant occurred in pediatrics for severe combined immunodeficiency. Reported in 1968, the patient received marrow from a human leukocyte antigen (HLA)-matched sibling.[1] Presently, in adults and children, the majority of allogeneic transplants are performed for the treatment of malignant disorders such as leukemias and lymphomas, although the field continues to expand to include nonmalignant disorders such as autoimmune disorders, metabolic diseases, immune deficiencies, and hemoglobinopathies. Since its inception, the field of pediatric HPCT has demonstrated vast improvements in morbidity and mortality related to transplantation; however, there are still many hurdles that we need to overcome. The major barriers that still contribute significantly to the morbidity and mortality of allogeneic transplantation are relapse of disease, toxicity from treatment, infection, and graft-versus-host disease (GVHD).

Sources of Hematopoietic Progenitor Cells and Identification of Donors

HPCT involves transplanting hematopoietic progenitor cells from a donor source into a recipient. These stem cells are capable of self-renewal and terminal differentiation that ultimately give rise to myeloid cells, lymphocytes, erythrocytes, and platelets (Figure 83-1). The donor source of these stem cells can be from the patient/recipient themselves (autologous) or from another individual (allogeneic). The source of the donor (autologous vs. allogeneic) is generally dependent on the indication for which the transplant is being performed. Autologous transplants can be used for the treatment of nonhematologic malignant diseases, whereas allogeneic transplants are used for hematologic malignancies and marrow failures or dysfunction. Traditionally, HPCT has been performed using stem cells obtained from bone marrow. However, stem cells can be mobilized into the peripheral blood by the use of cytokines (e.g., granulocyte-colony stimulating factor [G-CSF]) or upon recovery from chemotherapy. These peripheral blood stem cells (PBSCs) allow for faster hematopoietic recovery and possibly less tumor contamination than bone marrow for autologous transplantation. However, there may be more side effects in the allogeneic setting (increased incidence of graft versus host disease).[2] Umbilical cord blood has also been shown to contain large numbers of stem cells capable of reconstituting hematopoiesis. The first HPCT using cord blood was performed in 1988 on a 5-year-old child with Fanconi anemia using the patient's HLA-identical sibling.[3] Since then, unrelated cord blood stem cells have been used and numerous public cord blood banks have been established worldwide. In circumstances in which there is no matched unrelated donor or cord blood found in a timely fashion, a haploidentical transplantation can be performed using a parent or a sibling. Histoincompatibility barriers of a mismatched transplantation are overcome by using mega-doses of stem cells. However, for this to be successful, a majority of the T cells have to be removed from the graft to prevent severe GVHD. Unfortunately, this increases the

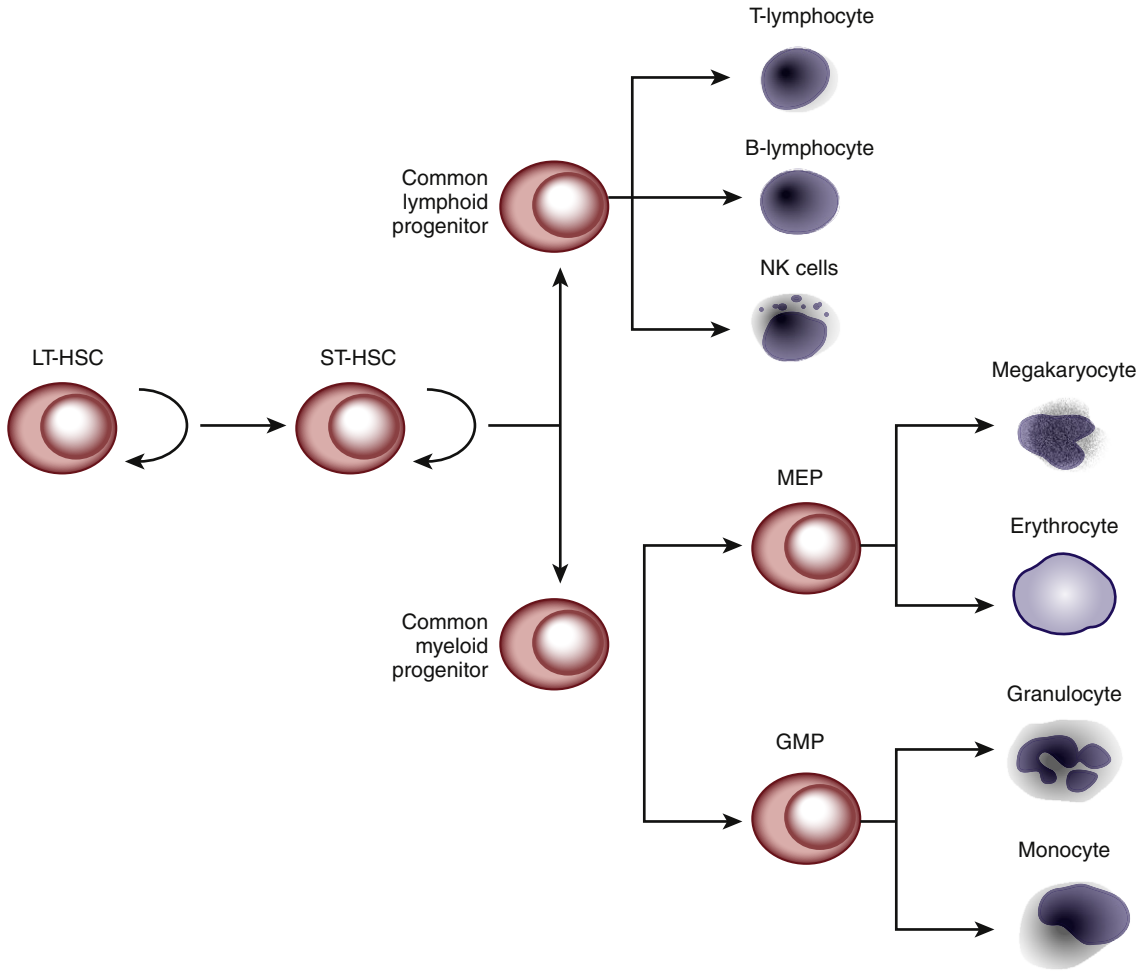

Figure 83–1. As hematopoietic stem cells divide, they give rise to common lymphoid and common myeloid precursor cells that eventually generate all mature blood lineages of the body. *GMP,* Granulocyte-monocyte precursors; *LT-HSC,* long-term hematopoietic stem cells; *MEP,* megakaryocyte-erythrocyte precursors; *NK,* natural killer; *ST-HSC,* short-term hematopoietic stem cells. *(Modified from Leung AYH, Verfaillie CM: Stem cell model of hematopoiesis. risk for severe infection and relapse of the patient's original disease.[4,5]

HLAs are expressed on the surface of various cells, in particular white blood cells (WBCs). These antigens are also known as the major histocompatibility complex with relevant genes on the short arm of chromosome 6.[6] This genetic region has been divided into chromosomal regions, called classes. Classes I and II are important in transplantation.

Class I is made up of HLA-A, HLA-B, and HLA-C and class II is made up of HLA-DR, HLA-DP, and HLA-DQ, as well as variations on these genes. Traditionally, the loci critical for matching for a bone marrow donor are HLA-A, HLA-B, and HLA-DR. HLA-C and HLA-DQ have recently gained importance and are now considered in determining the best available donor.[6,7] Ideally a matched sibling donor is the best donor for a patient. However, only 25% of patients with siblings are fortunate to have a matched sibling donor. If there is no sibling donor, an alternative donor is identified using the National Marrow Donor Program (NMDP) that has approximately 9 million potential donors and nearly 150,000 cord blood units available for patients who need a hematopoietic cell transplant (bone marrow, PBSC, or cord blood transplant).[8] As the degree of mismatch between patient and donor increases, so do the risks of complications from transplant, especially GVHD and rejection of the graft.

Indications and Outcomes

HPCT has been used for a variety of diseases. Autologous transplantation has traditionally been used to treat nonhematologic malignant diseases by escalating the doses of chemotherapy to myeloablative doses to hopefully eradicate the cancer. Recently, successive (two or three) autologous transplants have been performed with nonmyeloablative doses of chemotherapy particularly in brain tumors. The rationale of giving hematopoietic stem cells after the chemotherapy is completed is to minimize the period of neutropenia that will hopefully reduce the number of infections.[2]

Allogeneic HPCT has been performed for hematologic cancers that in children are most commonly leukemias including acute lymphoblastic leukemia and acute myelogenous leukemia. It has also been used to treat hematologic diseases including sickle cell anemia, thalassemias, and severe aplastic anemia. A variety of immune deficiencies and metabolic disorders have been cured by allogeneic transplant including severe combined immune deficiency and hemophagocytic lymphohistiocytosis (Table 83-1).[2]

Survival from HPCT has improved in the recent years. Typically for autologous transplantation the incidence of treatment related mortality is less than 10%; however, the majority

of failures of transplant are due to recurrent disease. Specifically the event-free survival rate for autologous HPCT for high risk neuroblastoma ranges from 33% to 57%.[9-11] For recurrent or refractory non-Hodgkin lymphoma the event-free survival in autologous HPCT ranges from 27% to 59%.[12] In relapsed or refractory Hodgkin disease the event-free survival ranges from 20% to 62%.[12] The NMDP and the Center for International Bone Marrow Transplantation Research data from 1998 to 2006 for acute lymphocytic leukemia shows the probability of survival at 5 years in matched sibling allogeneic HPCT for early or intermediate disease is approximately 50% versus 25% for advanced disease.[13] For unrelated donors the 5-year survival for pediatric patients is significantly increased for patients in first complete remission (CR1) (54%) and second complete remission (CR2) (49%) compared with patients with advanced disease (26%) (log-rank $P < .0001$).[14] Advanced disease is defined as third complete remission or refractory disease. For acute myelogenous leukemia the 5-year survival for pediatric patients (<18 years of age) transplanted for acute myeloid leukemia with unrelated donors is significantly increased for those patients transplanted in CR2 compared with those transplanted in CR1 or with advanced disease. However, a greater percent of patients transplanted in CR1 had poor-risk cytogenetics compared to those patients who were transplanted in CR2 (log-rank $P < .0004$). The 5 yr survival rates are 31% for CR1, 51% for CR2, and 29% for advanced disease.[15] However, the data for pediatric patients with AML in CR1 with a matched sibling shows a survival rate at 5 years of 65%.[16]

For patients with Fanconi anemia and severe aplastic anemia, the 5-year survival is 55% for allotransplants with unrelated donors facilitated by the NMDP in children younger than 18 years.[17] Pediatric survival rates after matched sibling HPCT for SAA are now excellent, 85% and even higher in some series.[18] In Wiskott-Aldrich disease and severe combined immune deficiency, the 5-year survival is approximately 75% to 80%.[19,20] For inherited metabolic disorders, the overall survival of pediatric patients with adrenoleukodystrophy/metachromatic leukodystrophy is approximately 50% and for Hurler syndrome is approximately 60% when using unrelated donor transplants facilitated by the NMDP from 1998 to 2006 (Table 83-2).[21]

Transplant Procedure

Conditioning Regimen

Patients undergoing HPCT are subjected to a treatment regimen referred to as a conditioning regimen or preparative regimen prior to infusion of the hematopoietic progenitor cells. The purpose of this preparative regimen is multifold. In cases of malignant disorders, it provides cytoreduction and/or eradication of disease. In addition, the preparative regimen must be immunosuppressive in allogeneic transplantation to allow the donor cells infused to establish themselves in the marrow cavity and overcome host rejection. The precise conditioning regimens can include chemotherapy alone or in combination with radiation. Numerous regimens have been explored and are dependent upon the disease for which the transplant is required and the research interests of the institution performing the transplant.

Stem Cell Harvesting/Collection/Cryopreservation

Stem cells can be collected or harvested from either bone marrow or peripheral blood. For patients or donors undergoing bone marrow harvest, general anesthesia or regional anesthesia is given with the patient in the prone position. Bone marrow is generally aspirated using special bone marrow harvest needles percutaneously from the posterior iliac crests using numerous passes. The amount of marrow taken is based on the size of the recipient. If there is a significant size discrepancy between the donor and the recipient (recipient larger than the donor), the donor may lose a significant amount of blood because bone marrow is well perfused with blood. Donors can be placed on iron therapy after harvest, or they can electively store autologous blood ahead of time. A newer technique allows for the collected marrow to be processed with removal of red blood cells (RBCs) (particularly necessary in cases of major ABO incompatibility between donor and recipient), and these RBCs can be transfused to the donor postoperatively.

Peripheral blood stem cells can be mobilized in patients recovering from chemotherapy (autologous) or by giving allogeneic donors cytokines such as G-CSF. Their stem cells then can be collected using an apheresis machine in an outpatient setting. Collection of sufficient cells for transplantation may require several apheresis procedures. Stem cells for allogeneic transplantation usually are collected on the day they are anticipated to be reinfused into the patient. Autologous collection

Table 83–2 Survival Rates for Pediatric Diseases Undergoing Hematopoietic Progenitor Cell Transplantation

		Survival Rate		
			Allogenic Transplantation	
	Stage	Autologous Transplantation	Sibling Donor	Unrelated Donor
Acute lymphocytic leukemia	Complete response (CR1 to CR2)	NA	50%	49%–54%
	Advanced disease	NA	25%	26%

of stem cells requires cryopreservation of the cells until the day of reinfusion. Dimethyl sulfoxide is added to the collection product to ensure cell viability, and the cells are frozen in liquid nitrogen until needed.

Stem cells can be collected from umbilical cord blood. After delivery of the infant, sterile umbilical venous access is obtained and the blood is collected into anticoagulated tubes. This can be done either before or after delivery of the placenta. A sample of this cord blood is used for HLA typing and infectious disease testing; the remainder is cryopreserved.

Reinfusion

The day of stem cell reinfusion is referred to as day 0 for the transplant period. Cryopreserved stem cells are thawed in a water bath under sterile conditions and may be washed to remove the dimethyl sulfoxide cryopreservant. Stem cells then are infused into the patient though the indwelling central venous catheter. These cells are capable of migrating into the bone marrow on their own. Blood transfusion–like complications can occur with reinfusion of stem cells, and patients are generally placed on cardiac monitors with emergency medications available at the bedside during the infusion. The infusion procedure is generally short, lasting anywhere from approximately 10 minutes to 4 hours, depending on the volume of cells infusing.

Recovery Period

After the reinfusion of stem cells, patients wait for count recovery to occur and receive treatment for any toxicities they have developed. Allogeneic transplant patients receive immunosuppressive medicines to prevent GVHD. Most patients are hospitalized for the entire transplant procedure, starting with the conditioning regimen. However, there is a trend toward outpatient HPCT, particularly in the autologous setting. A typical hospitalization for HPCT is 4 to 6 weeks, but it may be prolonged if umbilical cord blood is used or shortened for autologous transplants.

Complications

Patients undergoing HPCT are at high risk for complications that may require a stay in the pediatric intensive care unit (PICU). In one series, 19% of pediatric HPCT patients required a PICU admission.[22] In other published series, 6% to 25% of pediatric HPCT patients required mechanical ventilation.[23,24] Because of the high use of critical care services by HPCT patients, it is beneficial for the pediatric intensivist to be familiar with their complications.

The reasons for these patients being at such high risk for critical illness are multifactorial. Many of these patients are undergoing HPCT for an underlying disease that places them at risk for critical illness such as malignancies, severe immunodeficiencies, and metabolic disorders. To make room for the new hematopoietic progenitor cells, patients are given conditioning regimens with high doses of toxic chemotherapy and/or radiation. This makes them severely immunocompromised; placing them at high risk for opportunistic infections. The conditioning agents themselves cause significant oxidative stress, and may be the common denominator behind many of these complications.[25]

While mortality rates for HPCT patients requiring ICU care are quite high in comparison to the general ICU population, they appear to be improving. Data from the 1980s showed mortality rates for mechanically ventilated pediatric HPCT patients to be near 90%.[24,26] However, more recent data indicate the mortality rates to be closer to 60%.[24,27,28] In a single institution report, HPCT patients requiring vasopressor or inotropic support due to sepsis had PICU mortality rates of 30%. In the subgroup of septic patients requiring both inotropic and/or vasopressor support and mechanical ventilation, mortality rates were 74%.[29] Some of the improvements seen in outcomes over the years may be due to differing characteristics of the patients, as very few studies reported severity of illness scores.[26] In any case, no series reporting on mortality of pediatric HPCT patients was able to predict with 100% certainty that a given patient would not survive. Therefore it remains up to the critical care team in conjunction with the transplant team to use their best judgment when making recommendations to families regarding appropriateness and duration of critical care services for this complex patient population.

Cardiac Complications

Cardiac complications following HPCT can occur acutely during the immediate transplant period or as a late sequelae in survivors. The heart may be injured during the transplant

process from a variety of pathophysiological etiologies.[30,31] First, previous cardiotoxic treatments and therapies such as anthracyclines and iron overload from frequent red cell transfusions may predispose the heart to subsequent injury during transplantation. In addition, cardiotoxic therapies such as cyclophosphamide and irradiation used as part of the preparative regimen may further injure the recipient heart.[32,33] Moreover, hyperhydration therapies, blood product transfusions, and impaired renal function may place further stress on the heart. Finally, sepsis, that commonly affects the HPCT patient, has been found to decrease cardiac contractility.[34]

Despite these potential cardiac problems, cardiac complications are relatively rare in the early posttransplant period after HPCT. In an analysis of 2821 adult and pediatric patients, only 26 (0.9%) experienced a major or fatal cardiac complication in the first 100 days after transplant.[35] Seven of the 26 cardiac complications occurred in children, and given the median age of 22 years in that trial, an incidence of approximately 0.5% may be inferred for pediatric HPCT recipients. Among the 26 patients with significant cardiac complications, 11 had evidence of heart failure, 5 had pericardial tamponade, and 10 had dysrhythmias.[35] All 11 patients with heart failure died compared with only one each with tamponade or a dysrhythmia. All cases of heart failure occurred between day −6 and day +35. Four of the seven pediatric patients had heart failure. In another report, the Associazione Italiana Ematologia Oncologia Pediatrica-BMT Group described their transplant-related toxicity in 636 pediatric patients transplanted for acute leukemia.[36] In their experience, the incidence of moderate or severe cardiac toxicity in the first 90 days posttransplant varied by the type of transplant with autologous recipients experiencing an incidence of 1.9% (4 in 216, two deaths) and allogenic recipients of a compatible related donor experiencing a comparable incidence of 2.4% (7 in 294, four deaths). However, recipients of an allogeneic alternative donor experienced a 6.4% rate of these cardiac complications (8 in 126) with all eight experiencing an early death. In that study, the presence of moderate or severe cardiac toxicity increased the relative risk of an early posttransplant death more than ninefold (relative risk, 9.1; 95% confidence interval, 2.8 to 29.6), and more so than any other organ system toxicity.

The manifestations of the cardiac disease are varied and include myocardial ischemia, dysrhythmias, pericardial effusion, pericarditis, and progressive congestive heart failure. An accepted scoring system based on previously published grading of cardiac toxicities following stem cell transplantation consists of the following.[35]

Grade I: (1) cardiomegaly on chest radiograph without symptoms, (2) mild electrocardiogram changes not requiring treatment, (3) asymptomatic pericardial effusion

Grade II: (1) moderate electrocardiogram changes requiring and responding to medical intervention, (2) congestive heart failure requiring and responding to afterload reduction, diuretics, and digitalis, (3) pericarditis

Grade III: (1) severe electrocardiogram abnormalities with no or only partial response to medical intervention, (2) congestive heart failure requiring inotropic support, (3) cardiogenic shock, (4) a decrease in QRS voltage by more than 50%, (5) pericardial tamponade

Grade IV: fatal toxicity

Late cardiovascular toxicity occurring a year or more after HPCT is also being reported.[37,38] Late cardiovascular complications following HPCT include heart failure, dysrhythmias, hypertension, and cerebrovascular accidents. Several pathologic mechanisms of late congestive heart failure have been offered including those of acute heart failure such as previous cardiotoxic agents (anthracyclines, alkylating agents, thoracic irradiation) in conjunction with cyclophosphamide and total body irradiation during conditioning regimens. However, other factors such as the presence of chronic GVHD and patient characteristics such as age, size, and gender may play a role in late congestive heart failure. In one report of 155 long-term pediatric survivors of HPCT with a median length of follow-up of 9 years, 14 were found to have hypertension, 4 were found to have abnormal asymptomatic electrocardiograms, and 4 were found to have abnormal asymptomatic echocardiograms.[38] All patients in that report had a left ventricular shortening fraction greater than 30%. In another report of 112 children who received an allogeneic HPCT and survived at least 1 year, 11 had abnormal echocardiographic findings, 8 had hypertension, and 2 had cerebrovascular accidents.[39] The probability of developing a cardiovascular complication at 10 years was 11% ± 3% in that report. Moreover, among patients who developed a cardiac complication, all had received total body irradiation. Total body irradiation both alone, and in conjunction with pretransplant anthracycline use, was also associated with a negative impact on cardiac function 5 years after transplant in a cohort of 162 pediatric patients who underwent allogeneic HPCT for both malignant and nonmalignant diseases.[40] In that study, 14 (12%) of the 119 patients with pretransplant echocardiograms were found to have abnormal shortening fractions at the time of transplant. The cumulative incidence of shortening fraction abnormalities increased to 26% by the fifth year of follow-up in that report. In another study, assessing cardiac function during cardiopulmonary exercise testing revealed a significantly decreased maximal cardiac index in 33 children who had undergone HPCT in longitudinal follow-up.[41] Although no patient experienced a dysrhythmia or had electrocardiographic evidence of ischemia, four patients were found to have a shortening fraction less than 28%. Based on the finding of a decreased maximal cardiac index and a normal peak heart rate, the authors concluded that this provided evidence of long-standing subclinical cardiac dysfunction in this patient population.

In summary, cardiac toxicity appears to be an uncommon, although serious, complication following HPCT. It may present as an acute finding in the immediate posttransplant period with evidence of progressive heart failure, dysrhythmias, and pericardial effusions with tamponade. Late cardiovascular complications are also being studied. Although clinically evident late cardiac complications are being reported, there appears to be a number of subclinical findings detected by more involved testing. The importance of these subclinical findings is likely to be better understood as these children age further.

Pulmonary Complications

In adults the incidence of pulmonary complications after HPCT ranges from 30% to 60%.[42] The incidence in children is reported between 12% and 25%.[43,44] The need for mechanical ventilatory support is the most frequent reason for admission of HPCT patients to the PICU.[22,28]

Pulmonary complications can be divided into early and late complications (Table 83-3). Early complications occur within the first 100 days after transplant. The division into

Table 83–3 Pulmonary Complications of Hematopoietic Progenitor Cell Transplantation

Complications	Characteristics	Treatment
EARLY-ONSET PULMONARY COMPLICATIONS		
Infection	Positive test for infection	Antimicrobials
Diffuse alveolar hemorrhage	Progressive bloody return on BAL	Corticosteroids, FFP, plasmapheresis
Idiopathic pneumonia syndrome	Diffuse noninfectious lung injury	Etanercept
Engraftment syndrome	Periengraftment pulmonary edema	Corticosteroids
LATE ONSET PULMONARY COMPLICATIONS		
Bronchiolitis obliterans	Obstructive lung disease	Corticosteroids, macrolides
Bronchiolitis obliterans organizing pneumonitis	Restrictive lung disease	Corticosteroids
Idiopathic pneumonia syndrome	Diffuse noninfectious lung injury	Etanercept
Pulmonary veno-occlusive disease	Pulmonary hypertension	Sildenafil, prostacyclin, defibrotide

BAL, Bronchoalveolar lavage; *FFP,* fresh frozen plasma.

early and late complications is not absolute but may help the clinician in developing a differential diagnosis. Early complications include infection, diffuse alveolar hemorrhage (DAH), engraftment syndrome causing pulmonary edema, and idiopathic pneumonia syndrome.[45] Late-onset complications occur beyond 3 months after HPCT and include bronchiolitis obliterans (BO), bronchiolitis obliterans organizing pneumonia (BOOP), and idiopathic pneumonia syndrome (IPS).[46]

Early Pulmonary Complications

Engraftment Syndrome

Engraftment syndrome occurs just as patients begin to show signs of neutrophil recovery. This syndrome is likely caused by pulmonary leukoagglutination and inflammatory cytokines. Patients may develop fever, rash, fluid retention, capillary leak, and pulmonary edema. In severe cases patients can develop multiorgan involvement.[47] Engraftment syndrome may be related to a graft-versus-host response or in some cases a host-versus-graft response. In mild cases, no treatment is necessary.[47] In more severe cases, particularly if there is lung involvement, corticosteroids can be very beneficial.[47-49]

Diffuse Alveolar Hemorrhage

Alveolar hemorrhage may be infectious or noninfectious in etiology. However, the term DAH in an HPCT patient generally refers to a noninfectious etiology. The reported incidence ranges from 1% from 21% of HPCT patients. It usually occurs in the early posttransplant period and is characterized by widespread alveolar injury, absence of infection, and progressively bloodier return of BAL fluid during bronchoscopy.[50] The exact etiology of DAH is unknown but like other noninfectious pulmonary complications it is associated with GVHD and engraftment.[51-53] Endothelial injury from chemotherapy and radiation, inflammation, undiagnosed infections and immune mediated damage related to GVHD have all been postulated as the cause.[50,52]

Successful use of high dose corticosteroids has been reported in case reports of DAH.[50,54] However no prospective studies have proven the benefit of this therapy.[50,52] Fresh frozen plasma transfusions and plasmapheresis have been tried but are of uncertain benefit.[50] Aminocaproic acid used in conjunction with corticosteroids has been described in a series of eight patients with DAH refractory to corticosteroids. The overall 100-day mortality for these eight patients was 44%, an improvement over those treated with steroids alone where the overall 100-day mortality was 83%.[55]

Idiopathic Pneumonia Syndrome

Incidence and Diagnosis. The incidence of IPS in pediatric HPCT patients has been reported between 2% and 11.8%.[44,46,56] IPS is usually considered an early complication of transplant, but has also been described as a late complication of transplant. The diagnosis is made by meeting the diagnostic criteria set by an expert panel convened by the NIH in 1993. Patients must show evidence of widespread lung injury as evidenced radiographically by bilateral lung disease, signs and symptoms of pneumonia (cough, dyspnea or rales), abnormal lung function (increased alveolar to arterial oxygen gradient, pulmonary function testing with restrictive lung disease), and absence of an infectious etiology.[57]

The term IPS is often used interchangeably with idiopathic pneumonitis and interstitial pneumonitis in the literature. However, interstitial pneumonitis is the histopathologic description in some cases of IPS. Other cases of IPS will show histopathologic findings consistent with DAH or BOOP.[57] In any case, IPS, interstitial pneumonitis, DAH, BOOP, and BO are all considered noninfectious pulmonary complications of transplant. As prevention and treatment of infectious pulmonary complications have improved, these noninfectious complications are now the more troublesome.[42]

The literature continues to be confusing regarding the nomenclature of these noninfectious pulmonary complications of transplant. It is important for the critical care physician at the bedside to treat their patient appropriately without becoming anguished over the particular name of the disease. Though steroids and etanercept (tumor necrosis factor-alpha [TNF-α] receptor antagonist) may prove to be beneficial, at the present time no large clinical trials have shown any therapy to be effective for any of these noninfectious pulmonary complications. Therefore, paying close attention to fluid balance and utilizing lung protective strategies during mechanical ventilation are likely the most important aspects of care we can provide.

Etiology of Idiopathic Pneumonia Syndrome. Inflammation likely plays a significant role in the development of IPS. GVHD is known to be associated with high levels of inflammatory cytokines. GVHD has consistently been shown to be associated with IPS.[46,56,59] Because of this association, there is debate in the literature if IPS actually represents GVHD of the lung.[57]

In the mouse models of IPS when TNF-α knockout mice are used as recipients, the mice develop IPS like wild type mice. However, when TNF-α knockout mice are used as donors for wild type recipients, the severity of IPS is significantly less. In this model, TNF-α is derived from donor T-cells.[60] This animal model fits the clinical observation that patients who receive T-cell-depleted grafts have a lower incidence of pulmonary complications.[58,61]

Some cases of IPS may be caused by an unidentified infection. A retrospective study of stored BAL samples from HPCT patients with pulmonary complications detected human metapneumovirus in 5 (3%) of 163 patients. Three of the five patients were diagnosed with IPS. On review of these patient's medical records, they initially presented in the first 40 days after transplant with typical upper respiratory symptoms: fever, cough, nasal congestion, and sore throat. Four of the five patients died of rapidly progressive acute respiratory failure. Three of the five had DAH.[62]

Treatment of Idiopathic Pneumonia Syndrome. Because of the role of inflammation in IPS, corticosteroids have been used as therapy but have not been shown to be efficacious.[46,63] Therefore, since TNF-α has been shown to be an important mediator in mouse models of IPS, the soluble TNF-α-binding protein, etanercept has been used in recent years. It is currently under investigation in a large multicenter trial of both pediatric and adult patients who develop IPS from HPCT. Preliminary results look promising with 10 of the first 15 patients reported to have a complete response. The 28-day survival rate is 73% thus far.[64] This is a significant improvement from previous reported mortality rates approximating 50%.[46,58,64]

Continuous veno-venous hemofiltration has also been used in patients with acute lung injury after chemotherapy and HPCT. In a series of 10 patients, seven had a noninfectious lung injury. Four of these 7 were HPCT patients. All patients were mechanically ventilated and met criteria for ARDS. Three of the four HPCT patients with noninfectious lung injury survived to extubation.[65]

Lung transplantation has been reported in four children who have developed chronic respiratory failure as a complication of HPCT. Of the four patients reported, two are alive without significant complications 2 and 7 years after lung transplant.[66]

Calfactant (calf lung-derived surfactant) may play a role in the treatment of acute lung injury after HPCT. A post hoc analysis of a multicenter trial of calfactant in mechanically ventilated pediatric patients with acute lung injury showed possible benefit in the subgroup of immunocompromised patients. Twenty-seven of the 52 immunocompromised patients analyzed had undergone HPCT. In this subgroup analysis, patients who received calfactant had a 50% mortality rate, whereas those receiving placebo had a 60% mortality rate.[67] A trial of calfactant in pediatric patients with acute lung injury with leukemia, lymphoma, or history of HPCT is currently underway.

Extracorporeal membrane oxygenation (ECMO) has infrequently been used as a heroic measure for HPCT patients with severe lung injury. In a recently published review of the Extracorporeal Life Support Organization database there were no ECMO survivors with a history of recent HPCT.[68] However, there is one case report in the literature of an 8-month-old girl with SCIDS who was transplanted while symptomatic with bronchiolitis. ECMO was used successfully as a bridge to engraftment.[69]

Late Pulmonary Complications

Bronchiolitis Obliterans/Bronchiolitis Obliterans Organizing Pneumonia

BO and BOOP are late onset noninfectious pulmonary complications of HPCT. Both of these complications are associated with chronic graft-versus-host disease.[61,70] Patients with BO have an obstructive pattern on pulmonary function testing. On high resolution chest computed tomography (CT) both high and low attenuation areas are seen as are bronchial dilatation, bronchial thickening, vascular attenuation, and expiratory air trapping. Biopsy specimens show submucosal bronchiolar fibrosis and luminal narrowing and obliteration.[70]

Patients with BOOP have patchy air space disease on chest radiograph. High-resolution chest CT shows ground-glass opacifications, areas of consolidation, and pulmonary nodules.[70] As opposed to patients with BO, pulmonary function testing in BOOP shows a restrictive lung disease pattern. Biopsy specimens of BOOP show granulation tissue in the distal airways, alveolar ducts and peribronchial alveolar space.[42,71]

For both BO and BOOP it is recommended that patients undergo bronchial alveolar lavage to rule out infection. BO may be diagnosed on clinical grounds to avoid open lung biopsy and its associated risks. The diagnosis of BOOP generally requires biopsy. However, unlike BO, a transbronchial specimen is often sufficient.[70]

The number of patients with BO or BOOP reported in the literature is small. Therefore, it is difficult to make firm recommendations regarding treatment or prognosis. However, these complications may respond better to steroids than other noninfectious pulmonary complications of HPCT.[42,46] Macrolide therapy may be of benefit in patients with BO after HPCT but requires further study.[72] Other therapies such as inhaled cyclosporine, etanercept, infliximab and extracorporeal photochemotherapy have been described in case reports for BO.[70]

Pulmonary Veno-occlusive Disease

Case reports of pulmonary veno-occlusive disease (PVOD) in HPCT patients have been infrequently described. Patients have presented both early and late after HPCT. Patients present with increasing dyspnea and signs of right heart failure. Cardiomegaly and pulmonary edema are seen on chest x-ray. Pulmonary hypertension is seen on echocardiogram. In patients who have undergone cardiac catheterization, high right atrial pressure, right ventricular pressure, and pulmonary artery pressures are seen, whereas the pulmonary artery wedge pressure is frequently normal. Pathologic specimens show fibrosis of the venules and small pulmonary veins, whereas the larger pulmonary veins are typically normal. Because the resistance to flow in the pulmonary veins is typically normal in PVOD, the pulmonary artery wedge pressure appears normal despite having increased resistance through pulmonary venules and small pulmonary veins. Pulmonary

arterial intimal fibrosis and hypertrophy may also be seen. Steroids, other immunosuppressive agents, and anticoagulation have been used without notable benefit. Sildenafil with prostacyclin has been reported to be of some benefit in treating the pulmonary hypertension. Defibrotide may be beneficial given its efficacy in hepatic VOD, but there are no available reports of its use in patients with pulmonary VOD.[73,74]

Dilemmas in the Diagnosis of Pulmonary Complications

As HPCT patients with pulmonary complications are frequently tenuous, placing these patients at risk for complications from diagnostic procedures is a difficult decision. Although it is difficult to treat these critically ill patients without a firm diagnosis, it is also unpalatable to worsen the patient's condition while performing a diagnostic procedure that does not result in a diagnosis. Therefore, the debate continues in the literature and at the bedside regarding the risk/benefit ratio of invasive diagnostic procedures such as bronchial alveolar lavage (BAL) and lung biopsy.

St. Jude Children's Hospital recently published data regarding the diagnostic yield of BAL at their institution.[75] BAL identified the cause of respiratory symptoms in 53 (67.9%) of 78 of their allogeneic patients and 7 (63%) of 11 autologous patients. The most common finding diagnosed on BAL was bacterial infection (52%). The patients tolerated the procedure well with complications noted in less than 20%. In their series, transbronchial biopsy added additional information in only two of seven patients. They also noted that 14 of 16 patients who underwent open lung biopsy already had a positive BAL. The authors concluded that BAL had a beneficial risk/benefit profile and was useful in identifying patients who had an infectious etiology to their lung injury. However, biopsy did not add significantly more information but carried an unacceptable morbidity rate of 47%.

In contrast, a second study from Taiwan looked at the diagnostic yield of open lung biopsy versus BAL in a cohort of both pediatric and adult BMT patients with diffuse pulmonary infiltrates.[76] They found open lung biopsy resulted in a change in clinical management in 63% of their patients while BAL only offered a diagnosis in 30.7% of patients. This series found a shorter duration of intubation in patients who underwent open lung biopsy as opposed to BAL. The authors concluded this was due to a more accurate diagnosis leading to appropriate treatment in the open lung biopsy patients. In this cohort of patients the most common diagnoses were idiopathic interstitial pneumonitis and cytomegalovirus (CMV) pneumonitis as opposed to the St. Jude cohort where bacterial pneumonia was the most common. The difference in underlying diagnoses could explain the differences seen in the utility of BAL versus open lung biopsy.

Hepatic Complications

Hepatic complications of HPCT include infectious hepatitides (viral, fungal, bacterial), cholestasis, drug toxicity, VOD, and GVHD.

Viral hepatitis can be caused by any viral pathogen, including hepatitis C, CMV, Epstein-Barr virus, hepatitis B, adenovirus, herpes simplex, and varicella zoster. The diagnosis of these pathogens is based on clinical manifestations, with identification of the virus determined (1) histologically, (2) by culture of blood or tissue, or (3) by the presence of viral antigen or deoxyribonucleic acid within serum or liver tissue. Treatment is dependent upon identification of the viral pathogen. Herpes simplex and varicella zoster are treated with acyclovir, whereas CMV is treated with ganciclovir or foscarnet. Epstein-Barr virus-induced donor lymphocytes have been used *to treat* Epstein-Barr virus-associated lymphoproliferative disorders after allogeneic bone marrow transplantation.[77]

Fungal involvement of the liver is often seen in conjunction with widespread dissemination. There may be granulomas, abscesses, cysts, fungus in biliary ducts, or infarcts from vascular occlusion. Typically, Candida species are seen; however, any fungal pathogen can occur. Ultrasound or CT scan may help identify a lesion. Ultrasound-guided fine-needle aspiration can confirm the diagnosis. Bacterial infections of the liver occur less commonly but present similarly.

Gallbladder stones from poor oral intake, cytoreductive therapy causing exfoliation of gallbladder mucous-containing cells, and increased biliary excretion of precipitable material (cyclosporine A [CSA], antibiotics) all contribute to a 70% incidence of gallbladder sludge.[78,79] Numerous medications required for HPCT can have direct toxicity on the liver, including antibiotics, fluconazole, and CSA. Histologically, drug effect should be suspected when there is significant hepatocellular necrosis and minimal inflammation.

VOD after allogeneic HPCT was first reported in 1979[80] and now is recognized as a major cause of morbidity and mortality in the first 100 days of transplant. The pathogenesis is believed to result from hepatic venule and sinusoidal endothelial injury.[81] Histologically, subendothelial edema, endothelial cell damage with microthrombosis, fibrin deposition, and expression of factor VIII and von Willebrand factor within venular walls is seen.[82] Hepatic necrosis occurs, and collagen deposition in the sinusoids, venular wall sclerosis, and collagen deposition in the venular lumen is seen as the disease progresses.[83] Risk factors can include elevated transaminases before the conditioning regimen,[84-86] use of methotrexate for GVHD prophylaxis,[87] presence of oral mucositis,[88] interstitial pneumonitis,[89] or transfusional iron overload.[90] Certain preparative regimens have also been found to have a higher incidence of VOD, including those with high doses of total body irradiation, higher doses of cyclophosphamide, or the combination of busulfan and cyclophosphamide, or etoposide and carboplatin.[85,86,91,92] A recent trial of adults undergoing HPCT using everolimus and sirolimus for GVHD prophylaxis was terminated prematurely because of an unacceptably high rate of severe VOD and thrombotic microangiopathy.[93] The authors felt that busulfan use in conditioning may have been a contributing factor.

Clinically, VOD presents with hyperbilirubinemia, painful hepatomegaly, and fluid retention. The incidence varies based on risk factors and the criteria used but reportedly are as high as 55%,[84] with mortality rates ranging from 3% to 67%.[94] Significant variability in mortality results from differing conditioning regimens and definitions of VOD. Two sets of criteria have been used for VOD. Jones et al.[85] first described VOD and modified this criterion as hyperbilirubinemia greater than 2 mg/dL with at least two of three other findings: hepatomegaly, ascites, or 5% or greater weight gain.[85] McDonald et al.[84] in Seattle defined VOD in their series as two of the following criteria occurring within 20 days of transplant: hyperbilirubinemia greater than μg/dL, hepatomegaly or right upper quadrant pain, or sudden weight gain greater than 2% of body weight.[84]

Clinically, most patients with VOD develop symptoms between day 6 and 7 after transplant; peak around 10 days after onset; and return to baseline, if they are going to recover, 10 days later.[85] Multiorgan failure is seen more frequently in patients with VOD.[84,86] Pulmonary dysfunction, pleural effusions, hepatorenal syndrome, sodium retention with subsequent edema, and congestive heart failure all can occur and contribute to the high mortality rate. Liver ultrasound with Doppler study showing reversal of portal flow is a late finding in VOD.[95]

In some patients it is difficult to differentiate between VOD and hepatic GVHD and more invasive procedures are needed. Transvenous liver biopsy and hepatic venous pressure gradient measurement can be performed safely,[97] and have been found in a limited setting to have predictive value, with hepatic venous pressure gradient greater than 30 Hg associated with poor outcome.[96] Hepatic venous pressure gradient levels greater than 10 mm Hg have been shown to be highly specific for diagnosis of VOD.[98,99]

Given that the pathogenesis is thought to involve endothelial injury and coagulation factor deposition, attempts have been made to reduce the hypercoagulable state with several agents, including heparin, prostaglandin, and bile salts. Use of heparin as a continuous infusion has been explored most extensively with conflicting results, although randomized studies to date have not shown any benefit.[100-102] Ursodiol in historical studies and randomized trials has been shown to cause mild to moderate reduction in VOD occurrence.[103,104] Fresh frozen plasma and antithrombin III have been used as prophylaxis, both showing potential benefit in small nonrandomized studies.[105,106] Three separate nonrandomized trials using defibrotide as VOD prophylaxis have been reported. All three trials showed a reduction in incidence and severity of VOD, but used historic controls for comparison.[107-109]

Thrombolytic therapy with recombinant tissue plasminogen activator has been used successfully.[110,111] Pediatric dosing has been with low-dose recombinant tissue plasminogen activator at 0.25 to 0.5 mg/kg for 4 days.[111] Careful monitoring for bleeding complications is required because these patients already are at high risk with thrombocytopenia and hepatic dysfunction. Defibrotide appears promising with recent phase II trials showing 30% to 60% remission rates, even in patients with severe VOD.[112] N-acetylcysteine, a thiol antioxidant, and nitric oxide have been tried in anecdotal reports.[113,114]

Hepatic GVHD usually occurs when GI GVHD is present. Clinically, cholestatic jaundice with increased serum alkaline phosphatase and hyperbilirubinemia occur. Hepatocellular dysfunction with ascites and coagulopathy are unusual unless there is multiorgan end-stage disease. Histologically, portal inflammation is the hallmark feature. Treatment includes increase or change in immunosuppressant medications, although normalization of liver test results may take weeks or months.

Myelosuppression and Hematologic Complications

Myelosuppression and Immune Dysregulation

Stem cell transplant conditioning results in an extended period of neutropenia, anemia, and thrombocytopenia. Neutrophil engraftment is typically defined as an absolute neutrophil count of greater than or equal to $0.5 \times 10^3/\mu L$ on 3 consecutive days. The duration of time from stem cell infusion to engraftment depends on the intensity of conditioning, the type of transplant, the stem cell source and dose, the type of graft-versus-host disease prophylaxis used, and the degree of HLA matching. Neutrophil engraftment occurs 2 to 4 weeks following stem cell infusion. Factors associated with more rapid neutrophil engraftment include autologous transplant, the use of reduced intensity conditioning regimens, T-cell depleted transplantation, peripheral blood stem cell source, full HLA matching, and higher stem cell dose.[115] When peripheral blood progenitor cells are used engraftment typically occurs 1 to 6 days sooner than when bone marrow is used as the stem cell source.[116] Engraftment occurs slower when umbilical cord blood is used compared to PBSC and bone marrow.[117] Granulocyte stimulating factors are commonly used following autologous HPCT and umbilical cord blood transplant to reduce the time to stem cell engraftment.[118] Platelet engraftment generally occurs 1 to 2 weeks following neutrophil engraftment, but can take weeks to months. A platelet count less than 100,000 on day 100 following transplant is associated with poor outcome.[119]

Neutrophil engraftment does not signify the reconstitution of a fully functional immune system. It is crucial to remember that engrafted post-HPCT patients remain significantly immunocompromised and are at risk for life-threatening opportunistic infections. The restoration of normal immune function can take as long as a year in patients without significant post-HPCT complications and longer in patients with chronic GVHD.[120] Typically, natural killer cell recovery takes approximately one month and T-lymphocyte recovery takes 6-12 months.[121] Restoration of normal B-cell function takes approximatey 3 to 6 months post-HPCT in the absence of GVHD.[122]

Infectious Complications

Patients undergoing HPCT have increased susceptibility to many infections because of a combination of (1) neutropenia, (2) breakdown of physical barriers (mucositis, indwelling venous catheters), and (3) defects in cellular and humoral immunity as a result of the conditioning regimen and immunosuppressive therapy needed. The susceptibility to any particular organism varies over the course of the transplant period. During the first 2 to 4 weeks of the transplant, while the patient is neutropenic, bacterial infections account for approximately 90% of the infections. Enteric gram-negative bacilli (e.g., *Escherichia coli*, *Klebsiella, Enterobacter, Pseudomonas aeruginosa*) can cause rapid hemodynamic instability. The gram-positive infections (*Staphylococcus* and *Streptococcus*) are frequent causes of infections, due to the presence of central venous catheters. Therefore empiric antibiotic coverage for fevers during this time must be broad spectrum and provide adequate coverage for these organisms. Monotherapy with cefipime or imipenem is effective, simple, and has little toxicity.[123-125]

Fungal infections are increasing in frequency with better treatment and prophylaxis of bacterial and viral infections, particularly after allogeneic transplantation. Fungal pathogens in HPCT patients include the yeasts (e.g., *Candida* spp., *Cryptococcus neoformans*), molds (e.g., *Aspergillus, Fusarium, Mucormycosis*), and dimorphic fungi (e.g., *Coccidioides, Histoplasma, Blastomyces*). Of these, *Candida* and *Aspergillus* are most common. *Candida* spp. colonize the gastrointestinal

tract in more than half of healthy people,[126] but they become opportunistic infections in HPCT patients.

Candidal infections can occur as superficial mucosal infections (e.g., thrush) or deeply invasive (hepatosplenic candidiasis). Esophageal candidiasis is associated with dysphagia and retrosternal pain. This may be difficult to distinguish from chemotherapy or radiation-induced mucositis or herpetic mucositis. Endoscopy may be necessary to diagnose and appropriately treat. Candidemia may present with fever and systemic symptoms and is frequently not associated with tissue involvement. Because most HPCT patients receive fluconazole prophylaxis, candidemia should be treated with amphotericin B. Patients with documented candidemia or persistent/recurrent fevers should undergo evaluation for multiorgan involvement, including CT or magnetic resonance imaging (MRI) of the brain and chest abdomen/pelvis, and an ophthalmologic examination.

Aspergillus spores are routinely inhaled and in immunocompromised or HPCT patients can cause invasive infections. Neutropenia and GVHD with immunosuppressive treatment are risk factors for this. Outbreaks of Aspergillus can occur in areas of construction or with contaminated ventilation. Invasive aspergillosis occurs most commonly in the lungs with fever, cough, dyspnea, and ultimately hemoptysis as the disease progresses. The characteristic radiographic appearance is a cavitary lesion, but nodular infiltrates and bronchopneumonia are also seen. BAL should be performed initially. However, up to 50% of patients have a negative BAL and open-lung biopsy should be considered in this case.[127]

CMV is one of the most problematic viral infections for HPCT patients posttransplant. CMV emerges in the allogeneic patient between 1 and 3 months posttransplantation if either the patient or donor were CMV positive before transplant. CMV lays dormant after the initial clinical infection. However, in immunosuppressed patients, this virus can reactivate and result in interstitial pneumonitis, enteritis, or bone marrow suppression. CMV infection is defined as the identification of CMV from any site or the seroconversion to CMV positivity. CMV disease is defined as the clinical manifestations seen in the presence of CMV infection. The use of CMV-negative blood products and leukofiltration of blood products has helped reduce the risk of CMV infections in patients undergoing transplant. Interstitial pneumonitis from CMV presents with hypoxia and fever and an interstitial pattern on chest x-ray film. Untreated, there is an 80% mortality rate.[128] Ganciclovir and intravenous (IV) immunoglobin is the recommended treatment for CMV interstitial pneumonitis.[129] Ganciclovir is dosed at 10 mg/kg daily for 21 days followed by 5 mg/kg/day 5 days per week until day 180 posttransplantation. IV immunoglobin is given at 500 mg/kg every other day for 21 days, followed by 500 mg/kg weekly until day 180. With this regimen, survival is 80%. For patients resistant to ganciclovir, foscarnet may be given at 60 mg/kg three times daily for 7 days, then 90 mg/kg/day until day 180.[130,131] Ganciclovir can cause neutropenia, and growth factor (e.g., G-CSF, granulocyte macrophage–CSF) should be given if the absolute neutrophil count falls below 1000/ul. If the absolute neutrophil count falls below 500/μL, the drug should be held. In addition, renal adjustment may be necessary because both ganciclovir and foscarnet can be renal toxic.

CMV enteropathy presents with dysphagia, abdominal pain, nausea, vomiting, diarrhea, or gastrointestinal bleeding. These symptoms can be seen with GVHD as well, and endoscopy should be performed to aid in the diagnosis. Treatment is similar to that of CMV pneumonia.

Prophylaxis of CMV with ganciclovir is prohibited by its marrow-suppressive effects. However, monitoring of CMV now is available with improved antigenemia testing and polymerase chain reaction, allowing for preemptive therapy if results of these tests become positive before onset of clinically apparent disease. Ganciclovir then is given at 5 mg/kg twice daily for 7 to 14 days, then 5 mg/kg/day until day 120 posttransplantation.[132]

Graft Rejection

Primary graft rejection is an uncommon, potentially lethal complication of HPCT. It is defined as failure of the stem cell graft to recover hematopoietic function by day 30, though some patients successfully engraft later than day 30. The risk of graft rejection is increased with HLA-disparity between donor and host and when transplant is done for a nonmalignant hematologic condition. It is rare in sibling donor transplants. Graft rejection is an emergency as the risk of death increases with the duration of neutropenia and because there are few effective therapies.

Hematologic Complications

Patients require frequent blood product transfusions during the acute transplant phase due to conditioning-associated myeloablation and potentially increased consumption of platelets and RBCs. For most patients, the need for blood product transfusions declines rapidly following hospital discharge. However, some patients need transfusion support for months after transplant. All blood products should be gamma-irradiated to rid the product of competant donor T-cells that can cause transfusion associated-GVHD.[133] Additionally, blood products must be CMV negative to prevent transmission of the virus to nonimmune patients. This can be achieved by using blood from CMV seronegative donors or with leukofiltration.[134]

There is no commonly accepted standard transfusion parameter for either packed RBCs or platelets. Recent studies have investigated the use of a platelet transfusion threshold of 10,000. Most studies have found the use of this lower trigger safe for nonbleeding patients, but it is not supported in all studies.[135-137] A Cochrane review of the prophylactic transfusion at thresholds of $10 \times 10^3/\mu L$, $20 \times 10^3/\mu L$, and $30 \times 10^3/\mu L$ was recently reported.[138] The review found no difference in mortality rate or severe bleeding events between the groups. Similar studies are needed to assess RBCs transfusion parameters. Although transfusion parameters can be clinically useful, they do not replace clinical judgment.

Donors and recipients who are HLA matched are not necessarily ABO matched. ABO matching is not required for successful transplant and is a secondary consideration when choosing a donor. However, ABO mismatching puts the recipient at risk for immune-mediated hemolytic anemia. The risk for and severity of the potential hemolytic anemia depends on the degree of compatibility and is divided into four groups: (1) ABO-matched; (2) minor ABO mismatch, in which there is potential for hemolysis of the recipient RBCs by donor isoagglutinins; (3) major ABO mismatch, in which case the

recipient isoagglutinins are directed against donor/graft RBCs and donor RBCs after engraftment; and (4) bidirectional mismatch, which combines minor and major ABO mismatch.[139] When there is a major or bidirectional mismatch, the stem cell product must be RBC-depleted or the patient must have the offending isoagglutinins removed by pheresis prior to infusion to prevent a hemolytic reaction. Minor incompatibility, in which the recipient RBCs are incompatible with components of the donors plasma (e.g., donor is O and the recipient is B), puts the recipient at risk for an immune mediated transfusion reaction. Plasma depletion of the product prior to infusion reduces the risk. Even when plasma depletion is used mild hemolysis can exist for weeks to months due to antibody production from newly produced B-lymphocytes against residual recipient RBCs.

There are many described late hemolytic complications of transplant and most are uncommon. Autoimmune hemolytic anemias, thrombocytopenia, and neutropenias from post-HPCT immune dysregulation can occur months to years after transplant and are typically managed with immune suppression, immune modulation, or IV immunoglobin.

Post-HPCT thrombotic microangiopathic processes include hemolytic uremic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP).[140,141] Both are reported with increased frequency in patients who received cyclosporine as part of the GVHD prophylaxis regimen.

HUS is a potentially life-threatening, uncommon post-HPCT complication. It presents with hemolysis and mild to moderate renal dysfunction or with additional symptoms of seizures and severe hypertension at a median time of 5 months post-HPCT.[142] Many cases of post-HPCT HUS gradually self-resolve, although patients may be left with residual renal dysfunction. Post-HPCT TTP classically presents earlier than HUS with thrombocytopenia, schistocytes on the peripheral blood smear, and elevated LDH. Endothelial damage from transplant conditioning, GVHD, and calcinerin inhibitors are thought to contribute to the development of post-HPCT TTP.[143] It differs from classic TTP of childhood in that ADAMTS13 deficiency is not present.[141,143] Additionally, standard therapies for idiopathic TTP, such as plasma exchange, do not appear to be effective for the treatment of post-HPCT treatment.

Iron Overload

Iron overload is increasingly recognized as an important posttransplant complication. HPCT patients are at risk for increased iron burden due to repeated blood transfusions pre- and post-HPCT and disturbed iron metabolism.[144] Adverse effects from iron overload include increased susceptibility to infection, VOD, chronic liver disease, and cardiac dysfunction.[1,107,145] Studies show that iron overload has an adverse impact on survival in patients undergoing HPCT for beta-thalassanemia major and hematologic malignancies.[144,146,147]

There are multiple ways to diagnose iron overload posttransplant. Liver biopsy remains the gold standard, but frequently the diagnosis is made with imaging and laboratory studies. The serum ferritin is elevated in iron overload. However, ferritin is a nonspecific marker of inflammation that makes this a sensitive, but not specific indicator of iron overload. Serum iron studies are useful adjuncts for diagnosis and are often used when monitoring the efficacy of therapy. MRI can provide a quantification of organ specific iron burden.[148]

Phlebotomy is the standard treatment for post-HPCT iron overload.[149,150] Iron chelation is effective, but limited by the practical considerations in the case of deferoxamine infusion and potential toxicities of the treatments.[151]

Graft-Versus-Host Disease

GVHD is the most common complication of allogeneic HPCT. GVHD develops when donor T-lymphocytes respond to proteins on recipient cells.[152] Activated donor T-lymphocytes, monocytes, and macrophages triggers a self-propogating cycle of cytokine production and inflammation. GVHD was historically categorized as acute if symptoms developed before day 100 after transplant or chronic if the presentation was after day 100. The traditional definitions of acute and chronic GVHD have evolved. The current National Institutes of Health consensus recommends classification based on the clinical presentation rather than posttransplant day.[153] This classification recognizes two main categories of GVHD (acute and chronic), each with subcategories. Acute GVHD includes classic acute GVHD that develops within 100 days after transplant and persistent, recurrent, or late-onset acute GVHD that clinically resembles acute GVHD, but occurs greater than 100 days after transplantation. Chronic GVHD includes classic chronic GVHD with manifestations that are specific to chronic GVHD. The chronic GVHD category includes an overlap syndrome, which has features of chronic GVHD and features typical of acute GVHD.[153]

The skin, gastrointestinal tract, and liver are the most common involved systems in acute GVHD. The cutaneous presentation is typically an erythematous maculopapular rash, although there are a wide variety of possible skin findings. Diffuse bullous lesions with skin sloughing are the most severe manifestation of cutaneous GVHD. Acute gastrointestinal GVHD is characterized by diarrhea that is often bloody and may contain tissue. Hepatic acute GVHD typically presents with a cholestatic pattern of elevated bilirubin and alkaline phosphatase. Isolated transaminase elevation is uncommon. Less common presentations of acute GVHD are oral inflammation with possible ulceration and ocular inflammation. Acute GVHD is graded according to severity of the systems involved (Table 84-4).

The clinical presentation of chronic GVHD is more varied. The skin is the most commonly involved system. Patients may have persistent erythematous rash, severely dry skin, atrophy, changes in skin pigmentation, hair loss, or nail changes. The most severe clinical presentation of chronic cutaneous GVHD is scleroderma. Chronic hepatic GVHD is clinically similar to acute hepatic GVHD. The differential diagnosis includes viral infection and medication toxicity. A liver biopsy can aid diagnosis, but must be performed with caution in patients with increased bleeding risk.

The diagnosis of chronic pulmonary GVHD is controversial as there are no pathologically defined criteria for GVHD of the lungs. Bronchiolitis obliterans may represent the pulmonary equivalent of GVHD. This is an uncommon complication of transplant characterized by irreversible pulmonary obstruction. Post-HPCT bronchiolitis obliterans has a high mortality rate.[154] Steroid-resistant disease has an especially poor prognosis. Gastrointestinal tract chronic GVHD may present as anorexia, nausea, vomiting, diarrhea, or weight loss. Other manifestations of chronic GVHD are sicca syndrome, oral

Table 83–4 Consensus Criteria for Clinical Staging and Grading of Acute Graft-Versus-Host Disease

	Skin	Liver	Gut
STAGE			
1	Rash* <25% or persistent nausea†	Bilirubin 2–3 mg/dL‡	Diarrhea >500 mL/day§
2	Rash 25%-50%	Bilirubin 3–6 mg/dL	Diarrhea >1000 mL/day
3	Rash >50%	Bilirubin 6–15 mg/dL	Diarrhea >1500 mL/day
4	Generalized erythroderma with bullae	Bilirubin >15 mg/dL	Severe abdominal pain with or without ileus
GRADE‖			
I	Stage 1-2	None	None
II	Stage 3 or	Stage 1 or	Stage 1
III	—	Stage 2–3 or	Stage 2–4
IV	Stage 4 or	Stage 4 or	Stage 4¶

From Przepiorka D, Weisdorf D, Martin P, et al: 1994 consensus conference on acute GVHD grading, *Bone Marrow Transplant* 15:825-828, 1995.
*Use "rule of nines" or burn chart to determine extent of rash.
†Persistent nausea with histologic evidence of graft-versus-host disease in the stomach or duodenum.
‡Range given as total bilirubin. Downgrade one stage if an additional cause of elevated bilirubin can be documented.
§Volume of diarrhea applies to adults. For pediatric patients, the volume of diarrhea should be based on body surface area. Downgrade one stage if an additional cause of diarrhea has been documented.
‖Criteria for grading given as degree of organ involvement required to confer that grade.
¶Grade IV may include lesser organ involvement with Karnofsky performance status <50%, so patients with stage 4 gut GVHD usually are grade IV.

scarring with salivary gland scarring, fasciitis, and genitourinary scarring. Immune dysfunction independent of immunosuppressive medications is characteristic of chronic GVHD. Patients with chronic GVHD have abnormal splenic function and often need prophylaxis against encapsulated bacteria.

GVHD prevention regimens differ between institutions. Agents commonly used for prevention include cyclosporine, tacrolimus, methotrexate, rapamycin, and corticosteroids. Corticosteroids are the mainstay of treatment for GVHD. Other upfront treatments that specifically target affected systems are oral dexamethasone and tacrolimus rinses and corticosteroid or tacrolimus topical therapies. There are many available second-line agents and treatment strategies for steroid refractory GVHD, but none are considered standard. The choice of second-line therapy depends on the individual clinical situation. Due to prolonged treatment with corticosteroid some patients with chronic GVHD are adrenally insufficient. When a patient with chronic GVHD needs intensive care one should consider the use of stress dose corticosteroid.

Neurologic Complications

Neurologic complications contribute significantly to the morbidity and mortality following HPCT and are much more common following HPCT than in nontransplant oncology patients.[36,155-157] Seizures appear to be the most common clinical manifestation following HPCT occurring in approximately half of the reported cases.[155,156] Other symptoms include encephalopathy, motor function deficits, cranial nerve palsies, visual disturbances, and impaired coordination.[36,155-157] In one report, encephalopathy was reported in 26 (6.4%) of 405 pediatric patients following allogeneic HPCT.[157] In that report, the encephalopathy developed within the first 100 posttransplant days in all but one patient. Leukoencephalopathy was commonly reported in that study and others.[156-159]

Leukoencephalopathy primarily occurs in HPCT patients who receive cranial radiation and/or intrathecal chemotherapy before and after transplantation. Clinically, this condition manifests days to months after transplantation and may present with dysarthria, ataxia, dysphasia, confusion, or decreased sensorium in severe cases. The white matter changes can be detected with either CT or MRI. Peripheral nervous system neurotoxicity also occurs posttransplantation as an immune-mediated complication. Inflammatory degenerating polyneuropathy, myasthenia gravis, and polymyositis have all been described posttransplant.[160-162] These conditions present with muscle flaccidity, hypoactive deep tendon reflexes, and absence of extensor plantar reflexes.

Depending on the complications assessed, the length of follow-up time, and the patient population studied, clinical analyses report a wide range of neurologic complications in pediatric HPCT patients with more recent studies reporting a range of 10% to 24%.[36,155,156,158,163,164] However, an autopsy study of both children and adults (age range, 1 to 48 years; average, 23.7 years) demonstrated neuropathological abnormalities in more than 90% of patients who died after HPCT.[165] In one pediatric report, 11 (10%) of 133 children experienced a life-threatening neurologic complication within the first 3 months following HPCT.[163] In a more recent analysis, 40 (24%) of 165 pediatric HPCT patients were found to experience neurologic complications.[156] In that study, neurologic complications were categorized as either (1) transient and nonrepetitive symptoms lasting less than 24 hours and without abnormalities on MRI or on CSF analysis or (2) persistent (lasting more than 24 hours) or repetitive symptoms associated with radiographic cerebral imaging and/or CSF analysis abnormalities. Nineteen (12%) of the 165 patients satisfied the criteria of the second group approximating the incidence of the earlier study.

In that report, neurologic complications occurred most commonly in children who had undergone unrelated allogeneic transplantation (39%), more than related allogeneic transplants (21%) or autologous transplantations (11%). The finding of neurologic complications occurring more commonly in allogeneic rather than autologous HPCT recipients has been

previously noted.[158,166,167] These data support the finding that neurologic complications following HPCT are related to the presence of GVHD and immunosuppression.[156,158,163,168-170] GVHD and the need for prolonged immunosuppression are clearly associated with many of the etiologies of neurologic complications in this patient population. Common etiologies of neurologic complications in these children include CNS infections, intracranial hemorrhage and stroke, metabolic disturbances, medication toxicity, and CNS involvement of the underlying disease.[155-157]

CNS infections are a consequence of neutropenia and immunosuppression. Depending on the time period after transplant, patients may develop bacterial meningitis, aspergillus invasion of the brain parenchyma and vessels, cerebral toxoplasmosis, or viral encephalitis. These CNS infections contribute significantly to the morbidity and mortality following HPCT.[171] In addition to the association of GVHD with CNS infections, the medications used to treat GVHD are common causes of neurologic complications in this patient population. Neurotoxicity from CSA or tacrolimus, used for GVHD prophylaxis or treatment, can include tremor, seizures, headaches, cortical blindness, neuropathy, or mental status changes. Frequently, these symptoms are observed with levels above the therapeutic range, but this is not always the case. These effects usually are reversible with elimination of the drug. These medications may also be associated with the posterior reversible leukoencephalopathy syndrome.[156] As many as 5% to 6% of HPCT patients taking CSA may experience seizures.[172,173] Phenytoin, phenobarbital, or carbamazepine, that may be used to treat seizures, can alter cytochrome P-450 activity and interfere with CSA or tacrolimus levels. Valproic acid may be a better alternative in this situation.[174] Several other chemotherapy agents that may be used in the HPCT conditioning regimen can have neurotoxicity. High-dose carmustine, frequently used for autologous transplants for Hodgkin disease or lymphomas, has been associated with seizures. Busulfan, usually used in allogeneic transplants, can also cause seizures and epileptiform activity on electroencephalogram. In fact, phenytoin is given prophylactically during busulfan administration. Glucocorticoids used for immunosuppression can be associated with mood swings, dysphoria, agitation, or frank psychosis.

CSA, tacrolimus, and chemotherapeutics may also cause renal wasting of magnesium resulting in hypomagnesemia and lowering of the seizure threshold. In addition to hypomagnesemia, other metabolic abnormalities may occur in this setting contributing to seizures. Moreover, metabolic derangements resulting in encephalopathy has been considered the most common neurologic complication following HPCT with an incidence estimated to be as high as 37%.[175] A more recent pediatric analysis suggests that metabolic derangements remain a significant cause of encephalopathy after HPCT, but with a much lower incidence (14%) than this earlier study.[157] Hypoxia, ischemia, hepatic failure, electrolyte imbalance, or renal failure have all been found to be etiologies of these metabolic derangements resulting in encephalopathy. Clinically, patients are delirious or have a depressed mental status and no focal neurologic signs. Idiopathic hyperammonemia can occur in patients after high-dose chemotherapy, as in the transplant conditioning regimen. Altered mental status and respiratory alkalosis with elevated plasma ammonia occur acutely. Left untreated, irreversible cerebral edema may result.

Neurovascular complications are not uncommonly reported as one of the neurologic toxicities associated with HPCT. Thromboembolic episodes, subdural hemorrhages, and intracerebral hemorrhages are common examples. Thrombotic thrombocytopenic purpura has also been reported as a cause of encephalopathy following pediatric HPCT.[157] In a recent report, two (10%) of 21 children with a definitive diagnosis of encephalopathy following HPCT were found to have TTP and one other (5%) had evidence of a stroke.[157] In that report, one (5%) of the 22 children with intracranial imaging was found to have a subdural hematoma and two (10%) were noted to have infarctions. In another report, two (11%) of the 19 children with persistent neurologic symptoms (>24 hours) after HPCT were diagnosed with intracranial hemorrhage.[156] In a study of patients receiving HPCT or conventional chemotherapy alone in a pediatric oncology center, nine (12%) of the 76 patients who experienced a neurologic complication were found to have a vascular event.[155]

In terms of prognosis, neurologic complications appear to portend a poor prognosis. Nearly 60% of the children with persistent/repetitive symptoms and either radiographic or cerebrospinal fluid abnormalities following HPCT died; more than a third of them as a result of their neurologic complication.[156] In another study of 113 pediatric allogeneic HPCT patients, children with a neurologic complication following HPCT were significantly more likely to die than those who did not experience such a complication.[163] Thirty-three (32%) of 102 patients without a neurologic complication had died at 6 years of follow up as compared with 10 (91%) of the 11 patients with a neurologic complication ($P < .001$). In another study, neurologic complications were also associated with a higher mortality among pediatric HPCT patients, but only in the early post-transplant period.[158] Similarly, in the Associazione Italiana Ematologia Oncologia Pediatrica prospective study of 636 pediatric patients transplanted for acute leukemia, CNS toxicity was associated with early treatment-related death.[36] In that report, severe CNS toxicity was related to a threefold increase in the risk of treatment-related death as compared with absent or mild toxicity ($P = .02$). However, in a logistic regression model of all organ toxicities, the relationship between CNS toxicity and early treatment-related death was not statistically significant (relative risk, 2.2; 95% confidence interval, 0.8 to 5.5; $P = .11$). Finally, in a study of encephalopathy after pediatric HPCT, 17 (65%) of 26 patients died; 12 never recovered from their encephalopathy.[157] In that report, only four (15%) of the 26 patients experienced a full recovery of their encephalopathy.

Late Effects

A complete discussion of the late effects of HPCT is beyond the scope of this chapter. However, some potential late effects are relevant to intensive care providers. Patients who have been treated with total body irradiation or focal lung radiation and some chemotherapeutic agents are at risk for chronic lung disease including pulmonary fibrosis, obstructive lung disease, and restrictive changes.[38] Post-HPCT cardiac late effects include cardiomyopathy, congestive heart failure, or arrhythmia. Anthracycline chemotherapy is primary cause of cardiomyopathy. Anthracycline-related cardiomyopathy is dose dependent and treatment given before transplant contributes largely to the risk of developing cardiac dysfunction. Cardiac

late effects related to radiation include fibrosis, arrhythmia (related to fibrosis), and restrictive cardiomyopathy. Children who received radiation are at increased risk for myocardial infarction and congestive heart failure.[176]

Nutritional Support in the Critically Ill Hematopoietic Progenitor Cell Transplantation Patient

HPCT patients may begin their course malnourished that could put them at risk for the development of micronutrient deficiencies during transplant.[177,178] Deficiencies of micronutrients including magnesium, phosphorus, zinc, selenium, vitamin E, vitamin D and β-carotene have been described during conditioning.[177,179-182] HPCT patients are also at significant risk for development of severe mucositis and vomiting, making oral enteral nutrition difficult. However, enteral nutrition may be the preferred method of nutrition when possible as there is evidence that patients who are enterally fed are at decreased risk for developing GVHD.[183-185]

A few studies have shown an association between micronutrient deficiencies and transplant complications. Low zinc levels during the transplant course were associated with more febrile episodes, longer duration of febrile episodes, and more positive blood cultures.[186] Persistently low vitamin D levels were associated with more severe GVHD.[182]

Biochemical markers of oxidative stress during conditioning have been seen in HPCT patients. Decreased glutathione and α and γ-tocopherol levels have been documented during conditioning.[187] Increased serum Fe levels and a decreased total radical trapping antioxidant parameter of plasma (measure of antioxidant reserve) and linoleic acid concentrations have also been documented in HPCT patients.[188]

There is also increasing evidence for oxidative stress in critically ill patients with sepsis, systemic inflammation and lung injury; all common reasons for ICU admission of HPCT patients.[189-195] Therefore it is likely that the critically ill HPCT patient who has recently undergone conditioning may be under a significant amount of oxidative stress.

To date three trials examining antioxidant supplementation during HPCT have been published, only one in the English language. The single trial published in English came from Children's Hospital of Boston. Thirty-seven pediatric HPCT patients were given ursodeoxycholic acid, vitamin E, folinic acid, and total parenteral nutrition with traditional amounts of vitamins, minerals, and trace elements. There was no control group. They designed the study with the main outcome being feasibility of patients taking oral supplements. Most patients tolerated the oral medications well and the authors were able to prove feasibility. In these patients they also noted less mucositis, less hepatic toxicity, and a shorter time to engraftment in comparison to a historical control group.[196]

Although common sense dictates that some type of nutrition is good and prolonged lack of any nutrition would lead to death, little is known about the optimal nutrition for critically ill pediatric HPCT patients.[197] Critical illness and HPCT cause significant oxidative stress. Therefore, it is possible that critically ill HPCT patients may benefit from specialized nutritional strategies that optimize antioxidant capacity. This is a field that begs for further study.

Hemoglobinopathies

M.A. Bender and Katie R. Nielsen

PEARLS

- The pathophysiology of sickle cell disease is multifactorial, involving hemoglobin polymerization, oxidative damage to cell membrane proteins, white blood cell activation and inflammation, activation of the clotting cascade, and chronic hemolysis resulting in disturbances in nitric oxide metabolism.
- Acute chest syndrome is responsible for up to 25% of deaths in sickle cell disease, and its management should include antibiotic therapy with both a cephalosporin and a macrolide, oxygen to maintain saturations greater than 94%, prevention of atelectasis with incentive spirometry or biphasic positive airway pressure, diligent fluid resuscitation, adequate pain control, and bronchodilators.
- The default should always be to trust a patient's self-assessment of sickle cell pain.
- Up to 30% of patients with sickle cell disease have pulmonary hypertension and the threshold to treat must be lower than for other etiologies as even mild elevations in positive airway pressure (30 mm Hg) correlate with a significantly increased risk of death.
- The major cause of death in thalassemia major is cardiac failure secondary to iron overload; therefore, a thalassemic patient presenting in cardiac failure must be assessed for cardiac iron content and if present, undergo continuous chelation therapy.

Perspective

The evolution of animals is dependent on high concentrations of hemoglobin in red cells unattainable by most biochemists. This relies on the extraordinarily robust and coordinated synthesis of the α- and β-like globin polypeptide chains, and iron containing heme rings. Each has a highly evolved structure essential for optimal pairing of α- and β-like chains, as unpaired peptide initiates cellular damage. The resultant $\alpha_2\beta_2$ hemoglobin heterodimers play a critical role in the transport and regulation of carbon dioxide, pH, and nitric oxide (NO) in addition to O_2. Thus hemoglobin synthesis is a high stakes process in which any mutation may affect hemoglobin production, stability, function, or result in unpaired globin chains leading to devastating downstream effects. The approach to any hemoglobin alterations must consider the qualitative effects (i.e., how the plethora of hemoglobins' functions is altered), and quantitative effects (i.e., the amount of hemoglobin and unpaired globin chains).

Hemoglobinopathies are plentiful as many provide a protective effect to malaria. Although 5% of humans have hemoglobin variants, an estimated 300,000 affected homozygotes are born annually.[1] Contrary to popular beliefs, hemoglobinopathies do not provide resistance to infection, but rather diminish the chance of death once infected, allowing the development of partial immunity. Although sickle cell and thalassemia trait increase fitness, homozygotes in malaria endemic areas often do not survive into their teens. Although this strong protective effect resulted in a high incidence of hemoglobinopathies in the equatorial malaria zones, the slave trade and more recent voluntary migrations has led to the worldwide distribution of these conditions.

The Globin Gene Loci

The α- and β-like genes reside within multigene loci and are transcribed at unparalleled levels in both tightly tissue specific, and developmentally specific patterns.[2] This, and their involvement in human disease, has made these loci paradigms for gene regulation and pathophysiology. The β-globin gene was the first sequenced, and sickle cell was the first molecularly defined and diagnosed disease. Most forms of mutation (e.g., point, splicing, deletion, gene rearrangement) are observed in thalassemia, making these the quintessential teaching loci. This high variety and incidence of mutations result in frequent compound heterozygotes with a wide spectrum of clinical manifestations.

The five genes of the β-globin locus reside in a cluster on chromosome 11. The genes are expressed in an erythroid, and developmentally stage-specific manor; the ε, Aγ and Gγ, and δ and β genes being expressed primarily during the embryonic, fetal, and postnatal periods, respectively. At birth 95% of β-like chains are γ, with the rest being β. This ratio gradually inverts during the first year of life, explaining why phenotypes limited to the β-globin gene such as sickle cell and most β-thalassemias do not manifest until several months of age. Expression of the chromosome 16 based α-like genes differs; the embryonic ζ-gene parallels the expression of ε, but the twin α-genes are expressed from the fetal period onward. Thus α abnormalities manifest in utero, potentially with devastating consequences (e.g., hydrops fetalis). The resultant hemoglobin α-, β-heterotetramers (HbS) are developmentally

Appendix materials for this chapter are available online at http://www.expertconsult.com.

expressed; embryonic: Hb Gower1 (ζ_2,ε_2), Hb Gower2 (α_2,ε_2), and Hb Portland (ζ_2,γ_2); fetal: HbF (fetal) (α_2,γ_2) and adult: HbA2 (α_2,δ_2) and HbA (Adult) (α_2, β_2) (Appendix Figure 84-A). Although many suggest HbF, with its higher oxygen affinity, evolved to aid the fetus in "stealing" oxygen from the mother, this is not supported experimentally, the advantage of HbF may in fact lie in differential transport of NO or carbon dioxide. Unfortunately, despite the intensive study, multiple Nobel prizes and the clinical importance of the globin loci, little of the molecular understanding of the loci has been translated to clinical care. The holy grail of manipulating expression from the β-locus remains elusive. Inhibiting adult sickle or thalassemic genes, while concomitantly activating expression from the normal fetal genes would alleviate most disease, obviating the need for this chapter.

Sickle Cell Disease

Molecular Description and Epidemiology

Sickle cell disease (SCD) is a group of single gene, autosomal recessive disorders common in people originating from specific regions of Africa or India and in those of Hispanic descent. SCD encompasses a group of disorders characterized by the presence of a single nucleotide change in the adult β-globin gene, and a second abnormal allele allowing the sickle hemoglobin to polymerize. Substitution of an adenine (A) for a thymidine (T) in codon 6 results in replacement of a hydrophilic glutamic acid residue with a hydrophobic valine residue. The allosteric changes in hemoglobin structure occurring with deoxygenation leads to exposure of a destabilizing valine-containing pocket. The high concentration of hemoglobin in erythrocytes (MCHC) allows for the alignment of these pockets, leading to polymerization and transition to the classic sickle cell morphology (Figure 84-1) and the initiation of downstream events leading to pain and chronic end-organ damage. The presence of HbA in sickle trait, or HbF in the newborn, attenuate polymerization, diminishing the clinical consequences of HbS. In the United States, approximately 1 in 14 and 1 in 400 African Americans have sickle trait and SCD, respectively, with approximately 100,000 cases and approximately 1000 new births per year (in contrast to approximately 1 million births per year in Africa). With increased ethnic mixing, compound heterozygous forms of SCD are increasingly being observed (e.g., S/β-thalassemia or HbS/E). Sadly, though simple public health measures have dramatically decreased mortality rates in the United States, the countries with the highest incidence of SCD often lack such resources and children with SCD often do not reach their teens.

Sickle Cell Trait

Once the presence of HbS has been confirmed, the differential diagnosis consists of severe forms, less severe forms, and carrier states. Sickle cell trait (SCT) is distinguished from SCD by the presence of a normal β-globin allele and more HbA than HbS (typically 40% HbS) (Table 84-1). SCT does not result in the classic spectrum of sickle-related complications or alter red cell indices, but can lead to clinical abnormalities. Impaired renal concentrating abilities and intermittent microhematuria is common. Although of unclear clinical significance, this damage may interact with other pathophysiology in the African-American population (e.g., diabetes), explaining the high risk of chronic renal disease. In addition, there may be an increased risk of venous thromboembolism.[3] Most controversial is the concern that extremes of physical exertion, dehydration, and/or altitude may induce sickle cell vaso-occlusive events in some individuals with sickle cell trait.[4] This is particularly relevant to student athletes for whom no formal activity restrictions are recommended, but empirically, aggressive hydration during extremes of physical exertion is generally recommended.

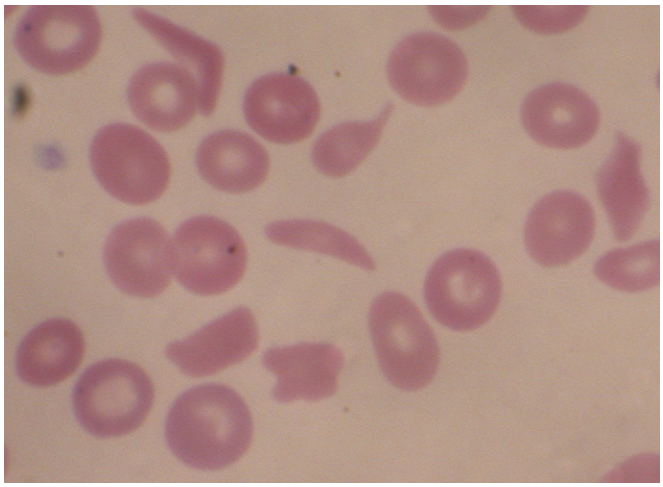

Figure 84–1. Morphology of sickled cells. Note that although a subset of cells has a high degree of polymerized HbS and has taken on the classic sickle shape, that the majority of cells maintain normal morphology. *(Courtesy Dr. Min Xu, Seattle Children's Hospital.)*

Spectrum of Sickle Cell Disease Genotypes

Although homozygous sickle cell (Hb S/S, often called *sickle cell anemia*) is most common, it is essential to be aware of additional genotypes that result in a similar spectrum of disease (see Table 84-1). That said, once in the intensive care unit (ICU), the form of SCD plays little role in decision-making. In HbS/β^+-thalassemia and HbSβ^0-thalassemia, the lower the expression of β-like chains from the thalassemic allele, the lower the hemoglobin concentration (Hgb) and MCV, and the higher the percentage of HbS and polymerization, resulting in a more severe clinical phenotype. In contrast, when HbS is expressed in conjunction with HbC, HbD, or Hb O-Arab or several other variants, near normal amounts of hemoglobin are made, but these forms are less able to attenuate HbS polymerization than HbA and result in milder sickle syndromes.

Natural History

The clinical manifestations of SCD result from intermittent episodes of vascular occlusion leading to tissue ischemia/reperfusion injury and variable degrees of hemolysis, both of which contribute to multiorgan dysfunction. The severity of disease manifestations varies widely in individuals with the same genotype and is affected by (1) known genetic modifiers, e.g., α-thalassemia that lowers the MCHC; (2) genetic modifiers of additional pathways contributing to the pathophysiology of SCD (below); (3) behavioral and environmental factors, (e.g., family and community support, racial disparities and access to health care); and

Table 84–1 Hematologic Characteristics of Sickle Hemoglobinopathies

Diagnosis*	Predominant Hemoglobins After Age 1 Year†	Phenotype‡	Hematologic Studies After Age 1 Year§		
			Hgb	MCV‖	HbA_2 (%)¶
HbA	A	nl	nl	nl	nl
HbA/S (trait)	A > S[a]	nl[b]	nl	nl	nl

(4) psychological factors, (e.g., coping with chronic disease, recurrent pain, and a high rate of depression). The spectrum of manifestations changes with age, and is beautifully described in Gill et al.[5] Previously, median survival in the United States for those with SCD was 42 years for men and age 48 years for women[6]; however, considerable improvements in longevity have been suggested.[7,8] The main causes of death are infection, acute chest syndrome, pulmonary artery hypertension, and cerebrovascular events.[9,10] What is not fully appreciated by pediatricians is that this increased lifespan is often associated with significant morbidity related to chronic organ damage.

Laboratory and Diagnostics

Though all newborns in the United States are now tested for SCD, states vary in when testing was initiated and the status of most immigrants is unknown, thus a need for testing in the ICU remains. Limitations in the acute setting include the lack of definitive SCD testing on an emergent basis, and that screening tests lack sensitivity and specificity. The prominence of HbS in conjunction with diminished or absent HbA defines SCD. Cellulose acetate electrophoresis or high pressure liquid chromatography laboratory diagnostics are most often used, but are rarely available on an emergent basis. HbS screening tests (e.g., Sickledex, Sickleprep, or Sicklequick) making use of the relative insolubility of deoxygenated HbS are available emergently; however, results must be interpreted with extreme caution as they lack sensitivity and specificity. In particular: (1) they do not distinguish SCD from sickle trait; (2) high levels of HbF may cause false-negative results, particularly important in neonates; (3) profound anemia can result in false negatives; (4) lipemia can cause false-positives results; and (5) some clinically significant forms of SCD can be missed (e.g., HbS/C). Although imperfect, screening tests in conjunction with a complete blood count, smear, and measure of iron status (e.g., zinc-protoporphyrin) help distinguish between SCD and SCT. Therefore in the setting of significant clinical suspicion of a hemoglobinopathy, consultation with lab medicine and hematology is recommended.

Pathophysiology

Although unable to fully provide the elegant details of the rapidly evolving insights into the multifaceted pathophysiology of SCD, this chapter outlines key pathways with direct relevance to management basics. While the initial era of understanding pathophysiology focused on HbS polymerization and red cell "sickling," this was followed by an awareness of the critical role of endothelial interactions and inflammation and later, of hemolysis and perturbations of NO metabolism (Figure 84-2).[11-14]

Hemoglobin Polymerization

Exposure of the hydrophobic pocket of deoxyhemoglobin leads to polymerization. Crystallization is enhanced by a high hemoglobin concentration (MCHC), low pH, and low temperature, whereas HbA and HbF attenuate it. A key determinant of sickling is the capillary transit time (CTT). The longer a red cell is exposed to the relatively deoxygenated, cold, and acidotic environment of the capillary and post-capillary venule, the more time exists for HbS polymerization to occur. This drives the basics of patient education, prevention and medical management including hydration, warmth, avoiding acidosis and vasoconstriction, ambulation, and assuring oxygenation. It also is the rationale for inducers of HbF and agents to prevent cell dehydration.

Red Cells, Inflammation, and the Endothelium

Crystallization leads to deformation of erythrocytes and oxidative damage to cell membrane proteins, leading to the activation of pathways contributing to the stimulation of white cells and inflammation, endothelial damage and the initiation of the clotting cascade and platelet aggregation. Membrane damage triggers movement of phosphatidylserine to the outer leaf of the red cell membrane where it acts as a substrate for factor V and VIII binding, promoting the clotting cascade.

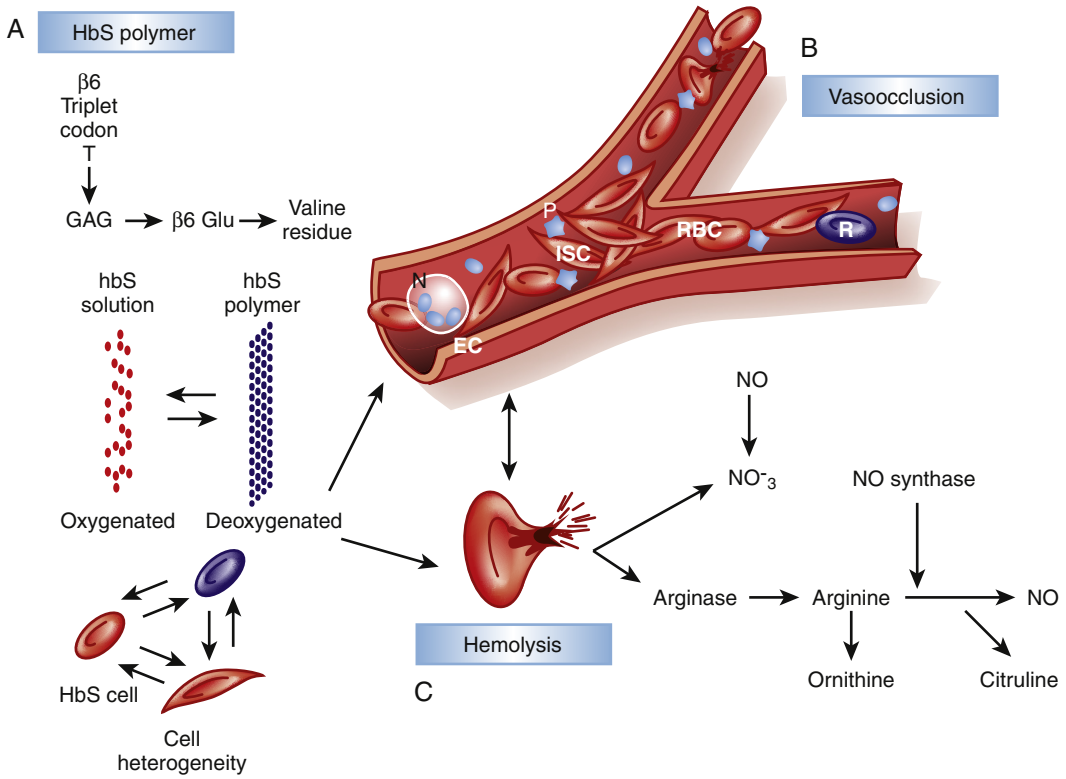

Figure 84–2. Summary of multiple interacting steps contributing to the pathophysiology of sickle cell disease. While an oversimplification and additional pathways are involved, the three predominant pathophysiologic steps are summarized. **A,** Polymerization of HbS. A single nucleotide change results in HbS, which polymerizes on prolonged deoxygenation, leading to sickled cells. **B,** Red cells, inflammation, and the endothelium. Activation of adherence receptors, coagulation, platelet aggregation, and inflammatory pathways lead to slowed flow, sickling of red blood cells, and eventual occlusion of blood flow *N,* Neutrophil; *EC,* endothelial cell; *ISC,* irreversibly sickled cell; *RBC,* red blood cell; *R,* reticulocyte; *P,* platelet. **C,** Hemolysis and NO homeostasis. Hemolysis releases free hemoglobin, which breaks down NO, whereas release of arginase converts the substrate for NO, arginine, to ornithine. Thus less NO is generated and more is destroyed. *(Modified courtesy Dr. Martin Steinberg, Boston University School of Medicine.)*

Reticulocytes and sickled cells expose increased adherence proteins, slowing flow and increasing CTT and enhancing binding to other cell types. Binding to platelets leads to platelet activation and aggregation, whereas binding to neutrophils stimulates the oxidative burst, damaging endothelium and exposing tissue factor, further promoting coagulation, platelet aggregation, and clot formation. In addition, bound white cells release cytokines, increasing inflammatory cell recruitment and division, perpetuating the process. Thus, sickle cell represents an activated, inflammatory state in which the CTT is easily compromised. This increases the likelihood of additional cells sickling and blood flow becoming further compromised, resulting in ischemic damage, inflammation, and propagation of the cycle. This activation and integration of multiple pathways explains the tremendous clinical heterogeneity observed in people with the same hemoglobin genotype, as well as why patients can show rapid clinical decline. The clinical importance of these paths in SCD is re-enforced by an elevated white blood cell (WBC) count being a risk factor for pain episodes, acute chest syndrome, and early death.[6,15] This also explains why infection and trauma are frequent triggers for sickle related pain, and why granulocyte-colony stimulating factor (G-CSF) has led to death in SCD.[16] Therapeutically, this points to the importance of nonsteroidal anti-inflammatory drugs (NSAIDs) in affecting the underlying pathophysiology as well as providing analgesia, and why clinical response to hydroxyurea is best correlated with a decrease in WBC.[17,18] Finally the identification of these interacting pathways identifies potential targets for new therapies affecting inflammation and cell-endothelial interactions.

Hemolysis and Nitric Oxide Homeostasis

In contrast to the vaso-occlusive complications that correlate with a high WBC and diminished HbF, recently a subset of complications including pulmonary hypertension, skin ulcers, and priapism were found to correlate with increased lactate dehydrogenase and bilirubin and reticulocyte count.[12-14] This defines a hemolytic phenotype arising from disturbances in NO hemostasis, and as described at the end of this section, this may be responsible for the inverse association of hemolysis and pain. Hemoglobin accelerates destruction of NO several thousand-fold. Normally laminar flow positions red cells centrally in vessels sequestering hemoglobin away from the endothelium where NO is synthesized and utilized. Hemolysis releases hemoglobin (Fe^{++}) that is now free to diffuse and reduce NO to nitrate with resultant formation of methemoglobin (Fe^{+++}). In addition, hemolysis releases erythrocyte arginase, resulting in arginine depletion, the precursor for NO synthesis. Thus chronic hemolysis leads to decreased NO synthesis and increased destruction, resulting in altered NO

hemostasis and increased tone of small vessels, slowing flow and increasing sickling. Optimal management of hemolysis related pathophysiology remains uncertain. Hemolysis prevention with hydroxyurea is appropriate and well accepted, and agents to prevent cellular dehydration (e.g., Mg^{++} or ICA-17043) are being investigated, but neither is appropriate for acute management. NO metabolism is directly modified with class 5 phosphodiesterase inhibitors (e.g., sildenafil) or by administering NO or related metabolites, and both approaches are being actively investigated for both acute and chronic use. Endogenous sulfur compounds may be tightly integrated with NO pathways, thus a therapeutic role of sulfur compounds may emerge.

In an exciting new paradigm for understanding SCD pain suggested by Gladwin and colleagues,[19] NO has been found to affect the processing of nociceptive signals, that may explain why patients with more severe hemolytic disease have fewer vaso-occlusive events (VOE). NO and resultant cGMP signaling increase the hyperexcitability of nociceptive neurons.[20] Thus as hemolysis depletes NO, it potentially attenuates pain signaling. Conversely, this may explain why SCD patients with fewer markers of hemolysis have more VOE. The implications of this biochemical pathway on pain management in SCD and other states of high hemolysis such as cardiac bypass are not known (see "Pain" below).

Clinical Manifestations

Although a summary of clinical problems and management are listed in the following section, the reader is referred to the National Heart Lung and Blood Institute standard of care guidelines[21] for more details: www.nhlbi.nih.gov/health/prof/blood/sickle/sc_mngt.pdf.

Pain

See Appendix Table 84-A for a detailed care plan, and Appendix Figures 84-B, C, and D for overviews of pain management.[22] Vaso-occlusive events, defined as the acute onset of severe pain secondary to ischemic tissue injury, are a hallmark of SCD. The complexities of SCD pain are best summarized by Shapiro and Ballas: "Vaso-occlusion is a physiological process, but the resultant pain is a biopsychosocial phenomenon. Psychosocial issues such as coping skills, social context, personality, mood, and interactions with the health care system mingle with the biologic factors and contribute to the expression of the illness."[23] SCD pain can be acute, recurrent and/or chronic, and is complicated by co-existing chronic disease as well as social and racial overlays. The need for aggressive and rapid treatment is critical and well documented in guidelines of the American Pain Society and British Society of Hematology and should be consulted.[24,25] Although aggressive intervention is essential for humane care and physiologic improvements (e.g., improving respiratory mechanics when having rib infarct pain), too often racial attitudes and concerns of drug seeking prevent sufficient delivery to patients in excruciating pain.[26] Pain is the most common reason for hospitalization in SCD. The impact of pain is extremely heterogenous in SCD, likely because of differences in genetic background affecting the pathways described above, environment and psychosocial and behavioral variables. In one cooperative study, 80% of patients sought care once or less per year, whereas 5% of patients accounted for one third of hospitalizations.[27] Recent daily pain diary assessments suggest these prior studies underestimate the routine pain many experience.[28] Risk factors for pain include a high Hgb, high WBC, coexisting alpha thalassemia, and increased levels of cell free DNA, whereas HbF is protective.[27,29,30]

Pathophysiology, Diagnosis, and Presentation. Pain can start spontaneously but common precipitating factors relate to the pathophysiology and include weather changes (especially cold), dehydration, inflammation, and infections, all of which increase CTT. Occlusion results in ischemic/reperfusion injury and the release of multiple inflammatory mediators that activate nociceptors, evoking a pain response. Pain may involve any part of the body though most commonly affecting the back and long bones. The unpredictability of the pain contributes to the psychological component of pain, potentially interfering with coping mechanisms.[31] Recurrent and chronic pain contribute to a decreased quality of life, decreased function, depression and suicidal ideations.[28,32,33] Diagnosis is based on a qualitative description, typically biting or gnawing, throbbing, and fatiguing; and quantitative description, that must be trusted (Figure 84-E). The description is essential to help rule out other etiologies of pain, because no physical exam, laboratory, or radiographic studies can confirm or negate this subjective complaint. Physical findings can include swelling, warmth, erythema and tenderness, but exams can be normal and critically, it must be re-enforced that patients can appear without distress. The role of laboratory and radiologic studies is to rule out other etiologies of pain; particularly important for sickle mesenteric pain that must be distinguished from other causes of abdominal pain (e.g., ultrasound to rule out appendicitis or cholecystitis, or tapping a joint to rule out infectious bone or joint processes). Serial quantitative assessments with a developmentally stage specific pain scale is standard of care, though fraught with problems.

Management. See Appendix Table 84-A for a detailed care plan, and Appendix Figures 84-B to 84-D for overviews of pain management.[22] An effective management strategy addresses the underlying tissue damage, nociception, history of pain episodes, and doses of medications required to achieve acceptable analgesia, baseline pain medications, history of tolerance, and how people process pain and coexisting depression. Although many are tempted to begin with analgesic medications, there are several other key components to management, such as the following: (1) environmental manipulation. A dark, calm, quiet environment with supportive interactions supports pain reduction. (2) Complementary methods. Many benefit from distraction, prayer, biofeedback, self-hypnosis and similar modalities. (3) Addressing pathophysiology and triggers. Fluids to maintain euvolemia, warmth and NSAIDs decrease CTT and promote conditions less likely to result in vaso-occlusion. (4) Adjuncts. Physical therapy, ambulation, and incentive spirometry should be encouraged to maintain blood flow and prevent atelectasis and acute chest syndrome (ACS). Additional adjuvants such as massage and acupuncture have been tried. After these have been addressed, providers may focus on analgesic medications.

Patients with SCD are the experts in their own pain management. Ideally patients and staff have agreed on individualized, predefined guidelines for pain management taking

into account the patient's degree of opiate tolerance, and side effect profile, and these are documented online or on a patient identification card. Early initiation of NSAIDs is essential, although the choice of NSAID is controversial (e.g., ibuprofen is a better anti-inflammatory, whereas ketoralac is a better analgesic). Notably, half of children will have resolution of pain with intravenous ketorolac.[34] For severe episodes, rapid and repeated doses of opiates (dosed every 20 minutes), followed by transition to patient controlled analgesia (if developmentally appropriate) is the accepted standard.[35] Although no consensus on the opiate of choice exists, many controversies remain. There are conflicting reports regarding an increased incidence of acute chest syndrome with morphine, with some suggesting decreased rates when nalbuphine is used.[36,37] Many avoid meperidine due to concerns of increased seizures and neuroexcitation.[38] The goal of opiate use is to balance providing sufficient pain relief to allow one to rest and perform incentive spirometry, while avoiding oversedation, which contributes to the development of pulmonary processes. Certain subsets of patients may benefit from regional anesthesia including epidural,[39] dexmedetomidine,[40] clonidine, gabapentin, ketamine, and intranasal diamorphine[41]; although few data exist evaluating their efficacy. One additional promising agent is low molecular weight heparin, which targets the prothrombotic and inflammatory state in SCD, Notably a recent trial reported fewer days of severe pain and length of stay with this intervention.[42]

As mentioned in the discussion of the pathophysiology of SCD, hemolysis leads to depletion of NO and this may attenuate nociceptive signaling through modulation of cGMP signaling.[19] This has substantial implications for SCD where, as described in the following section, modulators of NO metabolism are being increasingly employed therapeutically. Expected outcomes are not obvious as additional signaling pathways modulate cGMP activity, and NO and cGMP production can decrease pain under some conditions.[20] Some of this complexity is explained by the differential effects of modulating distinct sets of NO synthase genes and proteins.[20] Thus, ultimately agents that specifically modulate distinct arms of these pathways in specific regions of the body (e.g., periphery versus central nervous system) will be required to extract the full clinical benefits of NO metabolism manipulation for SCD while maintaining the benefit of NO deletion on chronic pain.

Sepsis

See Appendix Figure 84-F for a detailed care plan.[22] Sepsis is a major cause of morbidity and mortality in SCD. Strikingly, in the 1970s, 20% of SCD patients in the United States died before age 6 years, primarily from sepsis with encapsulated organisms, particularly *Streptococcus pneumoniae.*[5] Many patients were diagnosed with SCD when presenting with sepsis, and diagnosed families often did not appreciate that fever in a toddler was an emergency. This led to newborn screening programs and the development of comprehensive care programs focused on education and immunizations. As expected, this did not affect the incidence of sepsis, but deaths from sepsis plummeted,[43,44] and further decreased with the initiation of prophylactic penicillin in those younger than 6.[45] Widespread use of pneumococcal and Hib vaccines further decreased severe pneumococcal disease to 2.3 events per 100 patient-years, with ages 6 to 36 months being the highest risk group.[46,47]

Pathophysiology and Etiology. The developmental timing of sepsis risk correlates with decreased splenic function because of infarcts leading to functional asplenia, which can be observed as early as 3 months. The resultant defects in cellular immunity, the alternate complement pathway and decrease in memory cells and opsonizing antibodies reduces clearance of encapsulated organisms. Together these lead to a lessened response to the 23-valent polysaccharide vaccine requiring routine reimmunization and results in a 100 to 400 times increased risk of bacteremia with encapsulated pathogens. SCD patients have shown a strong response to the conjugated PCV-7 vaccine, resulting in a two-thirds reduction in invasive pneumococcal disease.[48] Serotypes not covered by the PCV-7 are increasing in prevalence, prompting the development of the PCV-13 vaccine. Although *S. pneumoniae* accounts for the majority of invasive infections other major pathogens include *Haemophilus influenzae* type b, *Escherichia coli* urosepsis, and *Salmonella* and *Staphylococcus* osteomyelitis.[49]

Management

See Figure 84-F for a detailed care plan.[22] Although the pathophysiology, diagnosis, and management of sepsis are presented in Chapter 103, several aspects are unique to SCD, including (1) a focus on prevention with aggressive vaccinations with PCV-13, the conjugated 23-valent vaccine (and recurrent boosters from falling titers), Hib, and meningococcus[50]; (2) prophylactic penicillin given through age 6 years; (3) the critical role of family and provider education in seeking medical care and parenteral antibiotics emergently for fevers higher than 38.3° C. Pneumococcus has doubling time of 20 minutes; thus a 2-hour delay can result in a 50-fold increase in bacterial burden; (4) antibiotic choice should be driven by clinical presentation, but for empiric therapy ceftriaxone is preferred over cefotaxime and cefuroxime due to increasing resistance of pneumococcus; and (5) possible transfusion if cardiovascularly unstable. Evolving care practices will need to account for (1) the influence of hydroxyurea, (2) increasing antibiotic resistance, and (3) the recent release of the PCV-13 vaccine. (Hydroxyurea can result in regrowth of splenic tissue, and early use in young children may prevent autoinfarction, but how this correlates with preservation of immune function and resistance to encapsulated organisms is unknown.)

Acute Chest Syndrome

See Appendix Table 84-B for a detailed care plan.[22] ACS is clinically heterogeneous and its definitions vary in the literature, making comparisons of studies difficult. The most general definition is a new nonatelectatic infiltrate on chest radiograph in a patient with SCD, though others add requirements for fever or respiratory symptoms (Figure 84-3). ACS is the second leading cause of hospitalization in SCD. ACS can progress in hours resulting in a mortality rate of 1% in children (vs. 4% in adults), with most deaths occurring in children younger than age 3 years.[51] ACS accounts for 25% of deaths.[51] Risk factors include a history of asthma, high baseline Hgb and low HbF. Factors associated with mortality include a prior episode of ACS, development of respiratory failure within 48 hours of presentation, sepsis, and simultaneous presentation with pain.[51] Etiologies vary by age and included bacterial infections with typical and atypical organisms, viral infections, fat emboli, and pulmonary hemorrhage

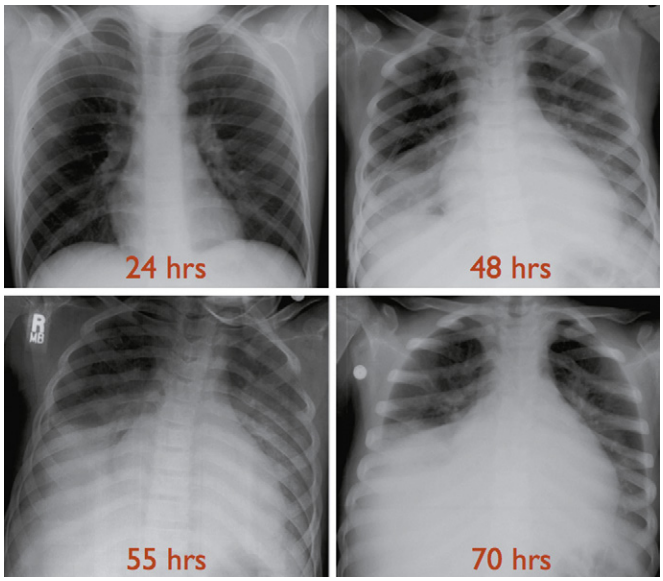

Figure 84–3. Rapid progression of acute chest syndrome. Serial chest radiographs of a 13-year-old male with homozygous sickle cell disease admitted for pain. Hours from admission are noted. Notably acute chest syndrome typically presents 2 to 3 days into an admission for a vaso-occlusive events.

and multiple etiologic factors are often present (see also Appendix Figure 84-G).[52]

Presentation. ACS frequently occurs 2 to 3 days into a VOE. Consistent with the variety of etiologies, presenting signs and symptoms are variable and vary with age (e.g., young children are more likely to present with fever while older adolescents are more likely to present with chest pain).[51] Notably, no single or pattern of signs and symptoms predicts ACS, and up to 35% of patients will have a normal pulmonary exam.[51] Therefore there should always be a low threshold to obtain a chest radiograph. Infiltrates are most common in the lower lobes, and pleural effusions are more common in adults.[51,52] Leukocytosis and significant drops in hemoglobin and platelets are common.[51] Significant morbidity is associated with ACS including pneumothorax and empyema and 14% of patients developed respiratory failure in one study.[52] Risk factors for respiratory failure include (1) extensive lobar involvement, (2) platelet count less than 199,000/μL and (3) history of cardiac disease.[52]

Management

See Appendix Table 84-B for a detailed care plan.[22] Management of ACS can be addressed in stages; initial conservative interventions are followed by transfusion for clinical decline or if severely ill and finally biphasic positive airway pressure (BiPAP) or ventilatory support if needed. Initial care should consist of (1) antibiotics: a cephalosporin to cover encapsulated organisms, particularly *S. pneumoniae*, and a macrolide because *Mycoplasma* and *Chlamydia* are the most common infectious pathogens; (2) oxygen to maintain saturations more than 94%; (3) judicious fluid resuscitation to maintain euvolemia while avoiding overly aggressive fluid resuscitation that may worsen cardiac and respiratory status due to a combination of severe anemia and decreased cardiac function; and (4) prevention of atelectasis. Incentive spirometry (IS) has been shown to prevent progression, and chest physiotherapy and ambulation may be of benefit.[53] Although IS is often limited by chest pain and patient compliance, use of a positive expiratory pressure (PEP) device has been shown to be as effective and better tolerated.[54] The use of BiPAP or continuous positive airway pressure (CPAP) as a preventive measure is untested but appropriate as early intervention may prevent the need for intubation. (5) Opiates should be carefully titrated to minimize splinting and allow IS, while minimizing respiratory depression (small opiate boluses before IS may be helpful). Pain relief can improve respiratory mechanics, improving clinical status. (6) Bronchodilators are indicated as asthma is common in SCD and its presence increases the risk of ACS, and a subset of patients respond independent of documented wheezing.[55] (7) The use of corticosteroids remains controversial. Although a randomized trial showed a decrease in hospital stay and transfusion, a subsequent retrospective review revealed a higher readmission rate, independent of a history of asthma.[56,57]

Transfusion has been shown to significantly improve oxygenation and clinical status in ACS.[52] Although transfusion is usually effective at reversing ACS, because of the risks, including alloimmunization, transfusion not part of initial management unless severely ill. For most patients serial observations, with a low threshold for repeat chest radiographs is appropriate; reserving transfusion for progression despite conservative management. The decision of when to transfuse is contentious and data have been lacking. Promising studies suggest elevated secretory phospholipase A2 (sPLA2) levels predict the development of ACS in SCD.[58] sPLA2 cleaves phospholipids, releasing free fatty acid, and is increasingly being associated with cardiovascular and pulmonary damage, including meconium aspiration. A randomized trial suggests early transfusion guided by sPLA2 levels, can prevent ACS.[58] Though promising, sPLA2 assays are not routinely available and their role in management remains to be determined.

Although 20% to 70% of patients with ACS are transfused, views differ on performing a simple transfusion targeting a Hgb of approximately 10, or an exchange transfusion targeting the same Hgb while lowering the HbS to under 30%.[51,52] Although both approaches improve oxygenation and are safe and effective, exchange transfusion requires exposure to more donors, increasing allo-immunization, is more time consuming, and may require central access in this population with increased thrombotic risk. Thus a simple transfusion is recommended for most situations.[59,60] The decision between direct and exchange transfusion in worsening ACS patients with a high Hgb (>9 g/dL) remains unclear as a minimal amount of red cells can be transfused.

Although lacking formal studies, the use of BiPAP or CPAP in an attempt to stave off intubation makes sense pathophysiologically. There is no consensus as to when to intubate or the optimal ventilation strategy in ACS, thus patients are often treated as children with acute lung injury or ARDS. For those patients with refractory hypoxemia, both high-frequency oscillatory ventilation and venovenous extracorporeal membrane oxygenation have been successful.[61-63] Several promising approaches to ACS including improving NO metabolism with inhaled NO or oral arginine, a precursor of NO; and inhibitors of sPLA2.[64]

Patients with ACS have developed plastic bronchitis. A review of 29 children hospitalized with ACS found 72% had plastic bronchitis, one requiring mechanical ventilation, suggesting there may be a role for intratracheal DNase.[65,66]

Stroke

See Appendix Table 84-C for a detailed care plan and Appendix Figure 84-H for a diagnostic approach.[22] One of the most debilitating and under-appreciated complications of SCD is a cerebrovascular accident (CVA), or the acute disruption of cerebral blood supply resulting in loss of brain tissue function lasting longer than 24 hours.[67] In contrast, transient ischemia attacks resolve within 24 hours, and usually less than 1 hour. This section will focus on CVA related to SCD; a detailed discussion of stroke can be found in Chapter 63. Before screening and prevention programs, 11% of children with HbS/S or HbS/β-thalassemia developed overt strokes (peak, 2 to 9 years), with another 17% having silent infarcts.[68,69] Risk factors include anemia, moya moya, history of CVA, and high velocities upon transcranial Doppler (TCD) ultrasound.[70] Additional risks for ischemic stroke include ACS and hypertension, whereas leukocytosis is a risk for hemorrhagic stroke. Patients with HbS/C disease and other compound heterozygotic states do not have such a significantly increased risk. Strokes are heterogeneous, being due to ischemia, hemorrhage, or thromboembolic events and involving large, medium, and small vessels. The type of CVA varies by age, with ischemic events more common in the first decade and hemorrhagic events more common after age 20 years. Pathophysiology varies tremendously depending on the type and site of stroke, for example anemia is associated with watershed infarcts, whereas thrombus formation and emboli affect more midsize to small vessels, and hemorrhagic strokes likely result from intimal hyperplasia and dilation at the site of previous insults.

Natural History. The natural history of overt ischemic infarcts has changed dramatically with screening TCDs and chronic transfusions. If untreated, 67% of patients have a recurrent infarct within 9 years, and this is reduced to 10% with chronic transfusions targeting a HbS of under 30%.[71-73] Screening TCDs using a standardized approach identifies patients with high cerebral vessel flow, associated with an excessively high stroke risk within 3 years.[74] This can now be decreased to 10% with chronic transfusions.[75] Although physical manifestations often show significant improvement after a stroke, persistent neurocognitive abnormalities are common. A subgroup of patients have moya moya, multiple constrictions of large arteries leading to collaterals at high risk of hemorrhage, aneurysm and clot (see Appendix Video 84-1). This group may have particularly severe disease and may represent some of the 10% resistant to chronic transfusions. The natural history of hemorrhagic infarcts varies in large part with their severity at presentation and location, because these dictate possible neurosurgical or radiology-guided interventions. Silent infarcts can result in difficulties with academic attainment and achievement and cognitive dysfunction similar to that in overt strokes.[76] Executive function deficits are most common, having a tremendous effect on a patient's function in society, and ability to navigate the health care system.

Diagnosis. See Appendix Figure 84-H for a diagnostic approach.[22] While diagnosis is suggested by a history of acute neurologic changes and abnormalities on neurologic physical exam, magnetic resonance imaging (MRI) and magnetic resonance angiogram confirm it. Notably, headache and signs of increased cranial pressure are more common in hemorrhagic stroke (see Chapter 59). Neurosurgical intervention for a hemorrhagic lesion should never be delayed; thus an emergent noncontrast CT is obtained to immediately rule out any surgically amenable lesions and MRI may be deferred, potentially until after therapy has been initiated (see Appendix Figure 84-H).[77] Other etiologies of childhood stroke must be considered and ruled out including infection, thrombosis (thrombosis panel and anticardiolipin antibodies), cardiac embolic disease, masses and trauma with vascular damage.

Management. See Appendix Table 84-C for a detailed care plan.[22] Acute care and monitoring is similar to that for other children with CVAs except exchange transfusion is suggested. Careful attention to signs of increased intracranial pressure and urgent neurosurgical consult in the setting of hemorrhagic stroke, assuring oxygenation, treating fevers to decrease metabolic demands, maintaining adequate cerebral perfusion pressure and monitoring blood sugars and electrolytes are discussed in detail in Chapter 63). Seizures should be treated, but there is no role for prophylaxis. Although tissue plasminogen activator (t-PA) has a role in non-SCD stroke, t-PA or anticoagulant therapy is not recommended in children, in part due to the different pathophysiology. While no studies have assessed the need for acute transfusion, the prevention of secondary events with a chronic transfusion program and the underlying pathophysiology has led to acute transfusion with a goal of maintaining a HbS under 30% being standard of care.[77] This is most efficiently done with exchange transfusion with a final Hgb of 10g/dL. Care must be taken to avoid hypotension with blood withdrawal during the exchange. Once stabilized, extensive evaluation by physical, occupational, and speech therapy, as well as a neurocognitive evaluation are essential to define new postevent baselines and guide future needs.

Aplastic Crisis

See Appendix Figure 84-I for a detailed care plan.[22] An acute worsening of baseline anemia (by 1 to 2 g/dL of Hgb) associated with decreased reticulocyte count (typically <1%), suggests aplastic crises and is caused by acute infection such as parvovirus B19. Sickle RBCs survive 10 to 14 days (vs. 60 to 100 days for normal cells); thus patients are dependent on a threefold to fivefold increased reticulocyte production and any decrease can lead to a transient red cell aplasia with rapid development of a profound anemia. Monitoring of Hgb (both absolute and compared with the individual's baseline), reticulocyte count, and cardiovascular status are essential. Most parvovirus B19 will spontaneously resolve, however, intravenous gammaglobulin should be considered to hasten viral clearance if reticulocytopenia persists. Transfusion may be necessary if cardiovascularly unstable or if the hemoglobin acutely falls more than 2 g/dL. Profound anemia or cardiac compromise may require a slow transfusion (2 mL/kg/hr), diuretics, or even exchange transfusion to avoid congestive heart failure.

Splenic Sequestration

See Appendix Figure 84-I for a detailed care plan.[22] Sequestration is characterized by an acutely enlarging spleen with a Hgb more than 2 g/dL below an individual's baseline value. Mild to moderate thrombocytopenia may also be present. Splenic

sequestration occurs in 10% to 30% of children with SCD, most commonly between the ages 6 months and 3 years, often following a febrile illness. Abdominal pain, nausea, and vomiting are common, and severe episodes of sequestration may progress rapidly to cardiovascular collapse and death. Transfusion is indicated when signs of cardiovascular instability are present and, as with aplastic crises, caution should be taken to avoid contributing to congestive heart failure. Though rare, emergent splenectomy may be required. Elective splenectomy is indicated for recurrent episodes of sequestration with cardiovascular compromise.

Pulmonary Hypertension

Despite being a major cause of death in SCD, pulmonary hypertension (PHTN) is underappreciated, in part due the uniquely high morbidity associated with mild elevations in pulmonary artery pressures (PAP).[78] Adults with estimated PAPs greater than 30 mm Hg or a tricuspid regurgitation velocity jet velocity (TR jet) of greater than 2.5 m/sec have a strikingly higher mortality rate; thus it is essential to have a significantly lower threshold for aggressive intervention for PHTN in the hemoglobinopathy patient than in others.[78] Pulmonary hypertension in children (defined as a PAP greater than 25 mm Hg at rest or greater than 30 mm Hg with activity) is present in approximately 30% of children, as well as adults, with SCD. With approximately 100,000 SCD patients in the United States, this translates to 30,000 cases, making SCD the leading cause of PHTN. Despite this, there is little awareness of this relationship in the hematology and cardiology communities.

Pathophysiology and Etiology. Assessment and management is complicated as multiple etiologies and risk factors contribute (see Chapter 48). Unlike most PHTN in childhood in which there is a single dominant cause (e.g., congenital malformation), multiple pathways contribute to the manifestation of PHTN in SCD and each must be addressed for optimal management. Pulmonary hypertension is more common in SCD patients with a "hemolytic phenotype" associated with priapism and leg ulcers, but independent of VOE. Thus patients often have a high LDH, bilirubin, and reticulocyte count, and low HCT which are associated with decreased NO production and increased NO destruction, that result in a NO resistant state. Frequently confounding factors in SCD include (1) hypoxic PHTN due to the high incidence of enlarged tonsils, obstructive sleep apnea, asthma, and chronic lung disease; (2) arterial obstructive PHTN secondary to increased coagulation and embolic disease; and (3) pulmonary venous hypertension due to cardiomyopathy. Contributing to the high morbidity in SCD are the protean manifestations of mild pulmonary hypertension (30 to 44 mm Hg). The majority of patients with SCD and PHTN will be asymptomatic or have mild decreases in exercise tolerance (e.g., 6-minute walk) yet have a 10-fold increased risk of death.[78] Adults with PHTN may not experience significant effects until pressures become moderate to severe, which for SCD portends a high mortality not observed in other patient populations with comparable pressure. The dilemma is that while mild PHTN is a major risk for death in adults, the natural history in children is unknown, and a recent study suggested no increased risk of death within three years of diagnosis.[79] Thus it is not clear how aggressively to treat children with SCD and PHTN.

Diagnosis. Though cardiac catheterization is the gold standard for determination of PAP, the indications for catheterization are debated within the sickle cell community. Noninvasive quantitation of the TR jet by echocardiography is most commonly used as it correlates with catheterization data. Catheterization is reserved for a subset of the patients initiating PHTN specific therapies.

Management. Though no consensus has been reached, a three-part approach to treatment is reasonable. (1) Optimization of SCD care, with the goal of decreasing the hemolysis fueling NO imbalance. Hydroxyurea and chronic transfusions are typically used though these are not acute interventions. (2) Aggressive diagnosis and treatment of confounding factors (e.g., tonsillectomy and adenoidectomy, BiPAP or CPAP, and nighttime O_2. (3) PHTN specific interventions, discussed in detail in Chapter 48. The mainstay of treatment of PHTN in the ICU is inhaled NO (iNO), which provides both direct vasodilation of the pulmonary vasculature and simultaneous reversal of the underlying disruption in NO metabolism. The major challenge with iNO is the development of rebound PHTN on discontinuation of therapy and difficulty in administration, thus driving a focus on alternative therapies. The phosphodiesterase (PDE)-5 inhibitor sildenafil is effective in facilitating weaning from iNO and in decreasing PAP over time in non-SCD PHTN[80,81]; however, a recent trial of sildenafil for PHTN in SCD was discontinued because of increased rates of VOE. Additional therapies that deserve consideration include (1) intravenous prostacyclin (epoprostenol), which reduced PAP in a small number of patients with SCD undergoing cardiac catheterization[82]; (2) endothelin receptor antagonists (e.g., bosentan and ambrisentan), which reduced PAP and improved 6-minute walk in adults with SCD and PHTN[83]; (3) inhaled iloprost, a prostacyclin analogue used in Europe, that has shown promising results in idiopathic PHTN, but its safety and efficacy in SCD has not been determined; and (4) oral arginine therapy, which reduced PAP within 5 days of therapy in a small number of patients with SCD and PHTN.[84]

Multiorgan Failure

Multiorgan failure syndrome is defined as severe pain associated with failure of at least two of the following organs: liver, lung, and kidney. It is often associated with severe pain in patients with previously mild disease and a relatively high Hgb.[85] Widespread vaso-occlusion is thought to be responsible, though data is lacking. Patients present with an atypically severe VOE, fever, and sudden deterioration including a drop in Hgb and platelets, diffuse encephalopathy, and rhabdomyolysis. Death has been reported in up to 25% of patients.[86] Exchange transfusion should be considered early, and can result in rapid recovery of organ function as well as survival. Antibiotics are often used, though many patients are culture negative. There are isolated reports of success with NO or plasma exchange in those with transfusion resistant disease.

Priapism

See Appendix Table 84-D for a detailed care plan.[22] Priapism is common in males with SCD, often starting in childhood and frequently occurring during the early morning hours. Stuttering priapism is intermittent episodes lasting fewer than 2 to 4 hours, and is often recurrent and may precede a more

severe episode. Severe episodes, lasting over 2 to 4 hours, need rapid intervention as they may result in permanent tissue damage and impotence.[87] Initial interventions include hydration, warmth, micturition, activity, and analgesia. Pseudoephedrine can be used for prevention and treatment though no efficacy data is available. If these measures fail to lead to detumescence in 4 to 6 hours aspiration and irrigation with a dilute α-agonist (e.g., epinephrine, phenylephrine) by a urologist has been shown to be effective if done within 24 hours.[88] Prevention with PDE-5 inhibitors is being investigated.

Skin Ulcers

Though rarely discussed, lower extremity ulcers are a major cause of morbidity, affecting comfort, ambulation, and increasing the risk for depression. Although no standard of care has been established, ulcers can be resistant to conventional therapies. As a result exchange transfusions and experimental interventions such as topical G-CSF, endothelin inhibitors and fetal cell transplants are under investigation.

Cholelithiasis

The prevalence of "stones" increases with age, and many centers suggest screening ultrasounds. Though often asymptomatic, cholecystectomy should be considered as soon as stones become symptomatic; avoiding the risk of infection or emergent surgery. Cholecystectomy is the most common general surgery procedure in SCD and is increasingly done laparoscopically, increasing operating room time, but decreasing recovery time.

Renal Conditions

Passage through the vasa recta exposes red cells to hypoxia, acidosis, and hypertonicity, which are extreme enough conditions to make some trait cells sickle, and causing damage to the renal medulla. This can lead to multiple complications that can affect fluid balance and renal function including (1) Hyposthenuria, an inability to concentrate urine. It is critical to remain aware of this in the ICU as the production of dilute urine cannot be used as a marker for being euvolemic, and, patients are prone to dehydration, leading to pain episodes. This results in enuresis being common and worsened in the ICU by continuous intravenous fluids and opiates. (2) Hematuria: This can range from micro-, to gross hematuria associated with papillary necrosis. Conservative management with bed rest and maintenance of high urine output to avoid the development of clots usually suffices. Vasopressin has been used with some success, as has ε-amino caproic acid, though the latter should be used with caution as it can lead to clot. If recurrent transfusions are required or bleeding becomes life-threatening, resection of the involved region may be indicated. (3) Tubule dysfunction including an incomplete renal tubular acidosis worsened by the hyposthenuria, and hyperkalemia associated with the use of potassium-sparing diuretics, angiotensin-converting enzyme inhibitors, or β-blockers. (4) Chronic renal failure associated with glomerular injury and proteinuria and can progress to nephrotic syndrome. End-stage renal disease develops in 40% of patients with nephrotic syndrome, thus persistent proteinuria is an indication for an in-depth evaluation. Risk factors include hypertension, hematuria, proteinuria, and worsening anemia. Although there is no clear cure, angiotensin-converting enzyme inhibitors can reduce the proteinuria, and NSAIDs should be avoided. Worsening anemia can be treated with erythropoietin, though patients often need higher doses than others. Alternatively, transfusions can be done, keeping in mind the increased risk of fluid overload. Kidney transplantation is appropriate, and outcomes are similar to that of African Americans, albeit less than other Americans. Current success using combined hematopoietic stem cell and kidney transplants in a canine model raise the exciting possibility of curing both the hemoglobinopathy and renal failure simultaneously.[89]

Ocular Conditions

Retinal arteriolar occlusions are thought to lead to ischemia and damage, resulting in release of vascular growth factors, causing a proliferative retinopathy. The goal is to treat with laser photocoagulation (or other techniques) before the development of severe disease. If untreated, retinal detachment and vitreous hemorrhage can occur, and may require retinal microsurgical intervention. Interestingly, whereas HbS/C tends to be less severe, the risk of retinopathy and avascular necrosis are both higher.

Avascular Necrosis

Occlusion of endarterial vessels can lead to necrosis of juxta-articular bone. This occurs disproportionately in patients with concomitant α-thalassemia or HbS/C disease. Avascular necrosis can lead to significant pain and decrease in function. Conservative management with NSAIDs, opiates, and reduced weight bearing can allow for limited function while boney remodeling occurs, though with age this is less successful and progressive destruction leads to degenerative arthritis. Targets relate to size and weight bearing, with the hips, knees, and shoulders being most affected. In an attempt to avoid hip replacement, surgical core decompression had been promoted, but a specific, aggressive physical therapy program has been shown to be as effective.[90] For severe cases, hip replacement is indicated.

Iron Overload

Unlike thalassemia, the iron overload of sickle cell is purely related to transfusion. Whereas sickle cell and thalassemic patients may show different patterns of iron deposition, the acute management in the ICU is similar, and is discussed in the thalassemia section.

Sleep Conditions

SCD patients are at increased risk for sleep-disordered breathing and obstructive sleep apnea, though the importance of this remains under debate.[91,92] It has been suggested sleep disturbances increase the risk of VOE and pulmonary hypertension, though data is inconsistent. The etiology is not clear, but notably, SCD patients tend to have enlarged tonsils and adenoids and children with SCD have more severe nocturnal desaturations and hypercapnia than others with obstructive sleep apnea. Tonsillectomy and adenoidectomy often leads to resolution. Alternatively, auto-CPAP has been well tolerated in SCD and shown to improve sleep and cognitive function.[93]

Depression and Suicide

With recurrent pain and complications that can occur without warning, it is not surprising that anxiety and depression are increased in SCD.[94,95] Interestingly, rates are higher than in cystic fibrosis, spina bifida, or diabetes, with 49% having anxiety symptoms in one study, and the risk of suicide in adults being increased.[33,95-97]

Table 84–2 Indications for Transfusion in Sickle Cell Disease

	Duration	Consensus	Method	Goal*
Stroke, acute	Single	+	Ex	HbS <30%
Stroke, ongoing care	Chronic	+	Either	HbS <30%
High-velocity TCD	Chronic	+	Either	HbS <30%
ACS, initial episode	Single	+	Dir > Ex	Hgb 10
ACS, recurrent	6–12 months	+	Either	
PHTN	Chronic	+	Either	
Multiorgan failure	Single	+	Ex	
Major surgery	Single	+	Dir	Hgb 10
Acute anemia	Single	+	Dir	
Recurrent spleen sequestration	Chronic	+		
Sepsis/meningitis	Single	+	Dir	
Severe chronic pain	6–12 months	+		
Congestive heart failure	Chronic	+		
Silent infarct with abnormal neuropsychology	Chronic	–		
Pregnancy		–		
Anemia/renal failure	Chronic	–		
Leg ulcers	6–12 months	–		
Severe growth delay		–		
Severe eye disease		–		
Priapism		–		

Dir, Direct; *Ex,* exchange; *Hb,* hemoglobin type; *Hgb,* hemoglobin concentration; +, consensus reached; –, consensus not reached.
*Goal of transfusion if a consensus has been reached.

Surgery and Anesthesia

See Appendix Table 84-E for a detailed care plan.[22] Major surgery in sickle cell is associated with increased perioperative risks including VOE pain, acute chest syndrome, and death, but these can be minimized with specific perioperative care. Preoperative transfusion was thought to provide benefit, leading to a randomized trial in which perioperative care was standardized and direct transfusion targeting a Hgb of 10 was compared with exchange transfusion targeting a Hgb of 10 with a HbS less than 30%.[98] Outcomes for both arms appeared better than observed historically, and the two groups were equivocal except the exchange arm was exposed to more units of blood and had more alloimmunization. Thus a direct transfusion is preferred as it minimizes exposure to blood. Communication and coordination between anesthesia, surgery, and hematology is essential, and institutions are encouraged to have a standard perioperative care plan for SCD. Most patients are admitted overnight for O_2, aggressive IS and observation, even if cleared to return home from a surgical standpoint. Because of poor compliance with incentive spirometry the use of BiPAP in the immediate post-operative period may be of use.[99] Specific recommendations should be followed (Appendix Table 84-E), though some feel that with modern improvements in perioperative care, that routine transfusion is no longer needed.[99,100]

Therapies and Interventions

The impact of public health policy and family education focused on prevention, early detection, and early intervention cannot be overstated. Morbidity, mortality, and quality of life have all improved. Although specific therapies were listed above, additional management guidelines follow. Increasingly treatments target specific mechanisms involved in the pathophysiology of SCD (see Appendix Figure 84-J for an overview).

Hydroxyurea

Although hydroxyurea is not an acute intervention, the intensivist should be aware that many SCD patients are (or should) be prescribed hydroxyurea, as it can decrease pain, ACS episodes, and transfusion need while increasing hemoglobin and lifespan.[10,101] Originally used in SCD to stimulate HbF production, the primary clinical benefits may stem from the relative leukopenia induced by this oral chemotherapeutic (see "Pathophysiology" above). Although good data exist for its use in adults, its role in children, especially the very young is an ongoing research question, but looks promising.[102] Clinicians should remain aware that in addition to cytopenias, hydroxyurea can lead to a red cell macrocytosis and should not be alarmed by MCVs greater than 115.

Transfusion

Though a mainstay of therapy, guidelines for transfusions in SCD are complex and vary by indication (Table 84-2).[103-106] See Chapter 82 for general information regarding blood transfusion. SCD specific issues follow.

Choice of Product. Packed RBCs should be leukodepleted to minimize febrile reactions and alloimmunization. Although transfusion from sickle trait donors is safe and effective, HbS negative blood should be requested to allow accurate

determination of posttransfusion HbS levels if needed. Due to racial, and therefore antigenic, differences between patients and the primarily white U.S. donor pool, alloimmunization is common, even after a single transfusion. This can significantly hinder the ability to provide future transfusion support. An extended cross-match for antigens of clinical significance that vary between racial groups should always be requested and should include Rh (Cc, D, Ee), and Kell in addition to ABO.[105] The intensivist must be aware that this matching, or finding compatible units for highly immunized patients, may take considerable time, thus a type and cross should be sent well before blood is needed, and in some emergencies extended matching may need to be forgone. Unlike patients with hematologic malignancies there is no need for blood product irradiation or CMV negative selection.

Type and Goals of Transfusion. Transfusion increases O_2 carrying capacity while decreasing the percent of HbS and different modes of transfusion affect these differentially. Few clinical trials are available but for several acute indications direct and exchange transfusions provided similar benefit, thus in these instances direct transfusion is preferred to minimize alloimmunization. The decision in chronic transfusion is more difficult as exchange transfusion results in less iron overload at the cost of increased exposure to blood. Manual exchange transfusions can be initiated rapidly with a single intravenous infusion, but are laborious and time consuming. Automated exchange (erythrocytapheresis) is rapid but not universally available, requires two large-bore intravenous infusions or a central pheresis-specific catheter and cannot be done in small children because of the significant volume and pressure shifts (size limits vary with the machine used). The target hemoglobin concentration or HbS percentage varies with indication (see Table 84-2) but in most cases the final Hb should never be higher than 11. Studies suggest higher Hb increase oxygen carrying capacity, but O_2 delivery falls. Formulas for calculating blood volumes for routine and exchange transfusions are available (Appendix Figure 84-K).

Indications. The reflective tendency to transfuse SCD patients should be avoided. Because of alloimmunization and other risks, attempts should be made to avoid transfusion unless there is a clear clinical indication. Transfusions may be one-time, or chronic, the latter not being an ICU issue. Table 84-2 summarizes guidelines and additional information is in specific sections.[103,104,106]

Hematopoietic Stem Cell Transplantation

Hematopoietic stem cell transplantation (HSCT) remains the one cure for SCD and is recommended for young patients with severe disease and a suitable donor. This is not appropriate in the acute setting, and there is debate over what defines a young patient and suitable donor, as well as what the optimal conditioning regime is. The major role of the ICU is supportive care post-transplant (see Chapter 83). Pediatric patients receiving a matched sibling transplant after a myeloablative conditioning regime had an 85% event-free survival and an approximately 94% overall survival with approximately 10% graft failure (reverting to their endogenous marrow) and 12% to 20% significant GVHD.[107,108] Attempts to adapt a less toxic, nonablative "mini transplant" regimen have been hampered by a high incidence of graft failure, potentially contributed to by a long history of exposure to donor antigens in transfusions. Initial attempts have found current regimes overly toxic to adults, presumably due to the accrued end-organ damage from SCD before transplant. Currently multiple SCD research transplant studies are available and address optimizing the conditioning regime and extending transplants to older patients, and to using alternate donors (unrelated, cord blood, haplo-identical).

Gene Therapy

Modification of autologous HSCs to correct the sickle mutation or add a normal gene avoids many of the problems of routine HSCT but remains experimental with limited number of clinical trials (see "Thalassemia" below).

Nitric Oxide

SCD often results in a NO resistant state. Both hemolysis related and vaso-occlusion related complications may directly benefit from NO-related therapies. Because NO is incredibly labile, multiple modes of delivery are being investigated, including providing substrate (e.g., arginine), providing cofactors for its generation (e.g., 6R-BH4), providing NO or direct metabolites intravenously or by inhalation, or modulating the effects of NO (e.g., sildenafil).[109]

Induction of β-like Chains

Many agents have been used to induce fetal globin genes with variable success. Refer to this topic in the "Thalassemia" section below for a more detailed discussion.

Antioxidants

SCD is associated with increased reactive oxygen species, RBC membrane damage, and depleted antioxidant stores. As a result multiple antioxidants are being investigated including L-glutamine and a variety of herbal or natural products.

Endothelial Protectants

As SCD results in endothelial disruption and inflammation, statins are being investigated including simvastatin and atorvastatin.

Thalassemia

Molecular Description and Epidemiology

In contrast to a single mutation being responsible for sickle cell, and the mutant peptide directly leading to the pathophysiology, a broad spectrum of mutations lead to thalassemia and it is the residual unpaired phenotypically normal globin chains that incite damage. The hallmark of thalassemia is an imbalance in the ratio of α- and β-chains, not a deficiency in chains. The distinction becomes important when one considers α-/β-thalassemia compound heterozygotes, or duplicated (excess) globin genes. The broad spectrum of mutations responsible for thalassemia truly represents a textbook compendium of mechanisms of mutation, but common to all is an altered level of chain production. Gene deletions account for the majority of α-thalassemias, leading to quantum incremental changes in phenotype depending on whether 1, 2, 3, or all 4 adult α-globin genes are missing. In contrast to α-thalassemia, a broad range of mutations lead to β-thalassemia, resulting in a continuum of clinical phenotypes. As with sickle cell trait, thalassemia trait is thought to provide increased fitness in malaria zones.

It is estimated that 1.5% of humans are heterozygous for a thalassemia, with about 0.05% having clinically significant disease. Because of the coexistence of α-/β-thalassemia in the same regions compound heterozygotes are common, leading to a huge spectrum of disease and complicating diagnostics.

Laboratory and Diagnostics

Although the sine quin non of diagnostics is the demonstration of an α- to β-globin chain imbalance, this is not practical for routine testing, thus most clinical laboratories rely on a variation of a thalassemia screen. The screen distinguishes thalassemia from iron deficiency, and α- from β-thalassemia. Due to the wide range of defects, and frequent mixed α- and β-thalassemia patients, it is impossible to state absolutes for diagnostic interpretation, and there should be a low threshold to consult with hematology. Components of the screen include (1) a complete blood count where emphasis is placed on the MCV which is decreased in proportion to hemoglobin production, the RBC to assess the degree of compensation for the decreased cell size, the hemoglobin and the smear; (2) a hemoglobin electrophoresis or HPLC to quantitate normal, and variant hemoglobins; (3) an inclusion body or Brilliant Cresyl Blue preparation to semi-quantitatively assess excess β-like chains and distinguish α- and β-thalassemia, and a (4) zinc-protoporphyrin or similar screen to exclude iron deficiency. α-Thalassemia results in excess β-like chains that form tetramers (β4: Hb H, γ4: Hb Barts) that precipitate in proportion to the number of missing α-genes, resulting in a positive inclusion body prep (Table 84-3). A negative study in the face of adequate iron is suggestive of β-thalassemia. The diagnosis of β-thalassemia is less direct. Excess α-chains are less stable and degrade, thus the inclusion body prep is normal and no α-tetramers are detectable on electrophoresis or HPLC. Frequently β-thalassemia results in up regulation of HbA_2 or HbF; thus the presence of either is suggestive of the diagnosis. Many mistakenly exclude the diagnosis if HbA_2 or HbF is not elevated, but this is not appropriate (e.g., deletion of the δ and β genes results in thalassemia but HbA2 is not elevated).

DNA testing is increasingly available and cost-effective though it remains problematic as no single assay or panel detects all abnormalities. PCR assays for the most common α-thalassemia deletions are available, and their utility is dependent on the frequency of the specific deletion in the patient's ethnic background. Due to the variety of mutations leading to β-thalassemia, β-locus sequencing is most efficacious, but misses most deletional forms. The use of CGH (comparative genome hybridization) arrays is being developed for assessment of the α-locus to allow a more comprehensive and less biased approach.

Pathophysiology

The pathophysiology of thalassemia is complex but in overview, unpaired globin chains lead to ineffective erythropoiesis and hemolysis, the degree of which depends on the specific form of thalassemia and patient's genetic background (Appendix Figure 84-L). Free globin chains increase reactive oxygen species while decreased glutathione and antioxidant stores result in oxidative damage to the fragile red cell membrane, as well as to apoptosis in a Fas-mediated process. The end result is a cadre of processes contributing to the heterogeneity of disease presentation. Phosphatidyl serine moves to the outer leaf of the red cell membrane, enhancing macrophage-mediated destruction in the spleen and marrow. Phosphatidylserine also acts as a substrate for factor V and VIII binding, enhancing generation of thrombin, which together with decreased protein C and S levels and increased platelet activation and adhesion leads to increased thrombosis. In an attempt to compensate for the hemolysis and ineffective erythropoiesis, medullary and extramedullary erythropoiesis is increased leading to skeletal abnormalities such as the thalassemic facies, and thinning of the cortex of long bones (Appendix Figure 84-M). The latter, along with endocrine abnormalities (see the following section) lead to increased fractures. High levels of non-transferrin bound iron from red cell destruction, increased intestinal absorption from inappropriately low levels of hepcidin, and transfusions lead to iron deposition, resulting in liver, cardiac, and endocrine dysfunction.

Forms and Variations

α-Thalassemia

Most mutations are deletions entirely eliminating a gene's activity. With deletion of each subsequent gene, hemoglobin synthesis, and thus MCV, is decreased, there are more unpaired β-like chains, which increases the precipitations on the inclusion body prep and worsens ineffective erythropoiesis, resulting in a lower hemoglobin. (See Appendix Table 84-F for typical laboratory findings). A one-gene deletion (silent carrier) is clinically benign; two-gene deletions (thalassemia trait) lead to a borderline low Hgb and decreased MCV, thus are easily confused with iron deficiency. A three-gene deletion (HbH disease) leads to anemia and significant microcytosis, which can be worsened by viral suppression or oxidizing drugs, such as those avoided in G6PD deficiency. Although individuals do not have increased morbidity or mortality, in rare instances they can display growth delays or acute drops in Hgb requiring PRN transfusions. A subset of HbH patients, those with HbH with a HbCS (Constant Spring) allele, are severely affected and more likely to require transfusion. A four-gene deletion (hydrops fetalis) typically results in fetal demise while presenting significant medical risk to the mother. With the aid of serial in utero transfusions, some fetuses survive and once born will require life-long transfusions as described for β-thalassemia major.

β-Thalassemia

In contrast to α-thalassemia, the plethora of β-gene mutations leads to a continuous spectrum of disease. β^0-thalassemia denotes non-expressing alleles, whereas β^+-thalassemia is used for genes that express a reduced amount of normal protein. Most mutations do not eliminate ε- or γ-gene expression, thus it is unusual for clinical complications to occur until several months of life, when infants become dependent on β-globin chains. Nomenclature is based on this continuum of phenotypic severity rather than genotype. β-thalassemia trait, also referred to as thalassemia minor, is due to a single silent allele and is benign and clinically similar to α-thalassemia trait. Although the term thalassemia major (aka Cooley anemia) is reserved for transfusion dependent phenotypes, those patients with clinical sequelae, but who are not dependent on transfusions for survival are referred to as having thalassemia intermedia. The latter require the most clinical decision-making as

Table 84–3 Distinguishing Laboratory Features of α- and β-Thalassemias

Diagnosis*	BCB Prep†	HbA_2‡	HbF	HbH	Hb Barts in Newborn§
Normal	–	nl	nl	nl	–
α-Thalassemia	+	nl	nl	nl or ↑	+
β-Thalassemia	–	nl or ↑	nl or ↑	nl	–

Can be negative for a one α-globin deletion (silent carrier), for compound heterozygotes with combined α- and β-thalassemia, and other hemoglobinopathies (e.g., HbE or HbS). Table shows typical results; exceptions occur.
*All forms of α -or β-thalassemia are pooled; specific results will vary.
†Brilliant cresyl blue (*BCB*) or inclusion body prep. Results vary by lab, but this can be done semiquantitatively. This can be negative when a one α-globin deletion (silent carrier) is present. This assay is unreliable in the presence of other hemoglobins (e.g., HbS or HbE). This can be negative when α- and β-thalassemia are simultaneously present.
‡HbA_2 results vary depending on laboratory method.
§Hb Barts increases with the degree of α-thalassemia.
Hb, Hemoglobin type; *nl,* normal; ↑, increased; –, negative; +, positive.

there is increasing awareness of the high morbidity in many of these patients.

HbE/β^0-Thalassemia

Of the numerous hemoglobin variants, this compound heterozygous state is worth special mention. The HbE mutation is common throughout Southeast Asia and results in a RNA splicing abnormality and a destabilizing amino acid substitution, leading to a thalassemic allele. When combined with another β-thalassemic allele the phenotype is extraordinarily variable, with some thriving, and a subset being transfusion dependent. Management is similar to other thalassemias.

Combined Mutations

Patients with combined α- and β-thalassemia are an elegant demonstration that a significant degree of the pathophysiology is due to unpaired globin chains and not solely decreased chain production. As an example, the clinical severity of β-thalassemia decreases as patients have additional deletions of α-globin genes. Having both decreased α- and β-chains leads to low MCV and MCH, but with fewer unpaired globin chains cells are more stable, thus patients have a higher RBC and improved Hgb than with either mutation alone.

Natural History

Natural history is highly variable depending on the genotype, modifying genetic factors, and critically, what interventions are available, and at what stage of illness. When a patient comes to medical attention depends on the severity of anemia, type of thalassemia, family history and awareness, and, critically, local medical expertise and resources. If not diagnosed by newborn screening or from a known familial risk, children can present with anemia, growth delays, boney abnormalities, and most important for the intensivist, congestive heart failure. With time, whether transfused or not, toxicity from iron overload and deposition develops.

Assessment of Iron Overload

Serum ferritin is a poor indicator of iron stores.[110] Though inexpensive and easily obtained, it is elevated with inflammation and does not correlate well with tissue iron content, especially in patients receiving chelation therapy. Serial observations may help track trends but this is not a substitute for direct tissue measurements. While previously liver biopsy was the gold standard for assessment of liver iron content (LIC) it is limited by (1) its invasiveness and risk, (2) it not correlating with accumulation in the heart and other target organs, and (3) sampling errors, as only a small region of liver is assessed while iron accumulation is heterogeneous throughout the liver. MRI-based assessment of iron overload is based upon relaxation times correlating with iron content. These techniques are evolving rapidly, making it essential to discuss options with local radiologists, as standards and practices vary greatly. Ferriscan was the first Food and Drug Administration-approved MRI assessment of iron, obviating biopsies, but it is limited to the assessment of hepatic iron.[111] In contrast, T2* imaging is increasingly available and allows simultaneous assessment of hepatic and cardiac iron, and potentially, other target organs.[112] A lower T2* correlates with higher degrees of iron overload (see "Cardiac Failure" below).

Spectrum of Disease

Although a summary of clinical problems and management are listed below and in Appendix Figure 84-N, please refer to the Northern California Comprehensive Thalassemia Center standard of care guidelines[113] for more details: http://thalassemia.com/documents/thalhandbook2008.final.pdf.

Anemia

Although there is much debate as to the optimal Hgb that should be targeted, in the ICU one must factor in the acuteness of the anemia, the degree of cardiovascular compromise, and the patient's baseline Hgb. A baseline level of under 7 g/dL is often the threshold for initiating chronic transfusions, though a higher threshold is used if growth, skeletal malformations or extramedullary erythropoiesis become problematic. The goal should be to maintain a Hgb of 9 to 10 g/dL pretransfusion (10 to 12 g/dL if cardiac disease is present), but no higher than 14 g/dL posttransfusion. As with SCD, profound anemia or cardiac compromise may require a slow transfusion, diuretics, or even exchange transfusion to avoid congestive heart failure. Blood products should be leuko-reduced to minimize alloimmunization, febrile nonhemolytic transfusion reactions, and CMV transmission. As with SCD, blood should be matched for ABO, Rh (Cc, D, Ee), and Kell. Family and related donor transfusion should be avoided if a hematopoietic stem cell transplant is to be considered as alloimmunization to donor antigens increases graft rejection.

Transfusion-Related Complications

Chronic or frequent transfusions increase infectious risk (described in Chapter 82) as well the risk of alloimmunization. Because of inappropriately low hepcidin levels, the ability of the body to absorb iron is unopposed, leaving blood loss and sloughing of endothelial and skin cells as the only mechanism to decrease iron in the face of iron overload. This is estimated to lead to a loss of 1 mg/day in an adult that pales in comparison to the approximately 200 mg of iron in each unit of blood. Although previous focus was on hepatic iron overload and cirrhosis, there is increasing awareness of iron overload in the heart, pituitary and endocrine organs leading to dysfunction (the the following section), and excessive melanin production leading to "bronze" pigmentation. Iron overload requires chelation, which can result in additional complications (Appendix Table 84-G).[113] Because of its short half-life, deferoxamine therapy is given continuously (subcutaneously or intravenously), and complications may include oto- or ophthalmologic toxicity, allergic reactions with life threatening hypotension (primarily when given intravenously), growth failure, metaphyseal cartilaginous dysplasia, bacterial infections (e.g., *Yersinia*), and inadvertent chelation of other cations including zinc, copper, selenium, and calcium. The need for continuous subcutaneous infusions often leads to problems with compliance, in part overcome by the use of oral deferasirox. Though quality of life may be improved, compliance issues remain, and more than 30% of patients on deferasirox have a reversible increase in creatinine; renal and hepatic failure has been reported.[110] Optimal dosing of either drug is determined over time, taking into account the degree of overload, transfusion regime, and whether a neutral, or negative iron balance is desired. Please see the cardiac failure section for emergent dosing and new approaches.

Cardiac Failure

Cardiac failure, defined as a low ejection fraction with a component of cardiomyopathy, is the major cause of death in thalassemic patients with iron overload. A thalassemic patient in failure should be assumed to have cardiac iron overload until proven otherwise. Risk factors include transfusion history and underchelation. Excess unbound iron from transfusion and inappropriate gastrointestinal absorption freely penetrates cardiac myocytes leading to progressive tissue damage. Iron accumulates predominantly in the epicardial portion of the ventricular septum and ventricular free walls, stimulating the production of free radicals, resulting in peroxidative tissue damage, decreased cardiac contractility and dysrhythmias. This, in combination with the high output state from chronic anemia, results in the early development of cardiac failure. Cardiac iron overload occurs years after the liver becomes overloaded. Initial cardiac iron deposition increases the influx of additional iron resulting in a rapid accumulation and the potential for rapid decline, a wide range of dysrhythmias and failure after years of normal function. The clinical presentation is that of congestive heart failure; however, some present solely with abdominal pain due to liver distension. Clinicians should always have a low threshold to evaluate for cardiac dysfunction. Before the introduction of iron chelation therapy in the 1960s, the majority of patients with thalassemia died from congestive heart failure by age 16 years. With advances in both transfusion and chelation therapy survival has increased, with 80% of patients living to age 40 years.[114] Lifespan is highly dependent on the underlying thalassemia as well as the transfusion and chelation history.

Assessments

Cardiac iron accumulation and function must both be assessed. Ferritin and assessments of LIC cannot be used, because kinetics of iron loading and unloading differ between the organs. Iron assessment by T2* is invaluable as one can assess cardiac iron, as well as LIC.[112] A T2* of over 20 ms is not associated with increased cardiac risk. In contrast, a value of 10 to 20 ms denotes overload and increased cardiac risk, and a T2* of under 10 ms portends a high risk of cardiac dysfunction and an emergent situation requiring aggressive chelation (Appendix Table 84-H).[110,113,115] Echocardiography is essential, and left ventricular dysfunction is highly suggestive of iron overload.[116] Given the high output state, some suggest the cutoff for a normal ejection fraction in thalassemics should be 60%.[117] Electrocardiogram often revels biventricular dysfunction with left ventricular hypertrophy, a prolonged PR interval, bradycardia, ST-T wave change, and T-wave inversions. Iron-related parathyroid, and thyroid and adrenal dysfunction, as well as vitamin D and thiamine status should be investigated for as these impact cardiac function.

Management

The key to management of iron-related cardiac dysfunction is chelation. High-risk cardiac patients (failure, arrhythmias, a cardiac T2* <10 ms, or an LIC >30 μg/g dry weight) demand emergent intervention. Conservative therapy consists of continuous deferoxamine. It should be given around the clock, seven days a week due to its short half-life and having higher efficacy than the same dose given intermittently. Dosing should be at least 50 mg/kg/day, intravenously through a central line, or subcutaneously and increased to 100 mg/kg/day (6 g/day maximum) as tolerated. Ascorbic acid (2 to 4 mg/day) releases iron, facilitating chelation while drug is present, but should not be used in the absence of a chelator as the increased release of iron may lead to cardiac damage. Total iron must be assessed to avoid toxicity from overchelation. Afterload reduction, diuresis and inotropic support should be considered, and serial echos to follow shortening and ejection fractions are indicated. Additional measures to optimize cardiac function include maintaining a Hgb of 10 to 12 g/dL, protecting oxidative damage with carnitine, correcting thyroid and parathyroid deficiencies and the administration of intravenous calcium with oral vitamin D to maintain cardiac contractility. Liver dysfunction predisposes to hypoalbuminemia, increasing the risk of acute renal failure due to the combination of poor cardiac output and aggressive diuresis. Therefore, administration of albumin may be indicated. Unless emergent, interventions such as pacemakers and cardiac transplant should not be considered until after cardiac iron has been reduced because dysfunction is often reversible with chelation.

Optimal chelation strategies in emergent situations are evolving rapidly, thus a hematologist or local expert on chelation should be consulted. While deferoxamine is proven to chelate cardiac as well as liver iron, increasing data suggests that deferasirox may be effective as well. Deferiprone (L1) is small molecular weight oral chelator awaiting Food and Drug Administration approval that has been used extensively in

Europe and studies suggest it may be superior for removal of cardiac iron, but its major limitation is the risk of agranulocytosis. The availability of additional agents is leading to new regimes for cardiac iron removal making use of dual therapy with agents with nonoverlapping toxicity profiles.

Hepatic Dysfunction

The liver is a target for damage from iron overload, transfusion-related viral hepatitis, medications, autoimmune disease, and genetic factors such as α_1-antitrypsin deficiency and Wilson disease. Routine screening for liver synthetic function, LFTs and hepatitis serologies is essential. Assessment of liver damage is often multi-modal, requiring a T2* for LIC, and CT or routine MRI to assess tissue damage and cirrhosis. Liver biopsy may be necessary to more fully assess the underlying damage.

Endocrine Abnormalities

Iron deposition can lead to hypopituitarism, hypothyroidism, hypoparathyroidism, diabetes, delayed puberty, and growth failure, as well as testicular or ovarian failure. Early detection of deficits and early supplementation is essential. Growth and sexual maturation is attenuated by chronic anemia. Growth hormone has had limited efficacy. Although hormone replacement is often effective in treating hypogonadotropic hypogonadism in males, this is far less successful in females.

Growth, Osteoporosis, Osteopenia, and Fractures

Chronic anemia, endocrine dysfunction, and chelation interact with extra-medullary hematopoiesis to limit growth, and lead to thinning of the cortex and decreased mineralization, resulting in extreme and potentially chronic pain and fractures. Dual-energy x-ray absorptiometry or quantitative computerized tomography is essential for assessment. Osteoclast inhibitors such as bisphosphonates and vitamin D and calcium therapy may be useful, as well as maximizing bone deposition and strength with exercise and by avoiding smoking.

Thrombosis and Pulmonary Emboli

The mechanisms described in the pathophysiology section lead to a thrombotic state resulting increased venous thrombosis and emboli. Embolic risk is likely elevated with splenectomy.

Pulmonary Hypertension

Pulmonary emboli and hemolysis (see "Sickle Cell Disease" section above) likely both contribute to pulmonary hypertension.

Therapies and Interventions

Interventions for specific complications are described previously and in Appendix Figure 84-N. Although transfusions are the mainstay of therapy for severe thalassemics, guidelines for when to initiate transfusions and what Hgb to target vary with each individual's presentation, and among centers. In the acute setting it is essential to remain aware of the patients' recent baseline Hgb, maintain a higher Hgb (10 to 12 g/dL) for cardiac failure, and consult with hematology. Although transfusion is noncurative, HSCT, gene therapy and inducers of non-adult globin genes are actively being optimized. While all are promising, none are currently useful in the acute setting.

Hematopoietic Stem Cell Transplantation

Currently HSCT remains the only proven cure for thalassemic patients. Long transfusion histories increase the chance of graft failure, necessitating an aggressive myeloablative conditioning regimen, which in turn can lead to a high treatment-related toxicity if significant end-organ damage is present. Success is dependent on having an adequate donor, and the degree of end-organ damage. The latter is assessed using the Lucarelli staging system that factors in the degree of hepatomegaly, the degree of portal fibrosis, and the quality of the chelation treatment given before the transplant.[118] With improved pre-transplant care and increased myeloablation and immunosuppression, even the highest risk group has done well with matched-sibling donors with a 90% event-free survival, 96% overall survival, and 7% rejection rate.[119]

Gene Therapy

Three major barriers to HSCT, graft failure from rejection, the difficulty of finding a suitable donor, and graft versus host disease are all addressed by gene therapy. Though many strategies are being evaluated, the open clinical trials use retroviral or lentiviral vectors containing β-like globin genes that are used to infect patient CD34+ hematopoietic progenitors, followed by autologous transplantation. Additional approaches include adding a small-interfering RNA (siRNA) cassette to decrease α-globin, thus improving chain balance, or transducing modified transacting factors to activate δ-gene expression.

Inducers of Other β-like Genes

As expression of other β-like globin genes will ameliorate disease severity, numerous agents have been tried. Results from clinical trials vary in part by genotype, but the discussion in this chapter will be limited to a generic approach. Histone deacetylases such as the short chain fatty acid butyrate initially showed promise in increasing expression from the δ-genes, but have showed variable efficacy.[120-122] Current efforts are focused on developing related compounds such as additional histone acetylases (e.g., suberoylanilide hydroxamic acid), and additional short chain fatty acids that may induce embryonic globin genes. Hydroxyurea is less efficacious than in sickle cell, but some success has been observed in combination with erythropoietin.[123] Previously, promising results with the demethylating agent 5-aza-cytidine led to the development of the DNA methyltransferase inhibitor decitabine that results in demethylation and activation of fetal globin genes.[123,124] Early studies, and the potential to develop an oral form make decitabine an exciting future prospect for the treatment of SCD and β-thalassemia.

Gastrointestinal Structure and Function

Lee M. Bass and David M. Steinhorn

PEARLS

- The gastrointestinal tract serves four vital roles essential to the maintenance of health: (1) digestion/absorption, (2) barrier between the external environment and internal environment, (3) synthesis and counterregulation of many substrates and hormones, and (4) excretion/elimination/detoxification of metabolic and digestive waste.
- Organization of hepatocytes into acinar/zonal structures leads to specialization of cellular function and varying susceptibility to ischemic injury depending on the distance from the vascular supply.
- Maintenance of intestinal mass and integrity is best achieved by the provision of nutrients directly into the lumen even at levels that do not support total nutritional needs for the patient.
- Common liver function tests (e.g., alanine aminotransferase/aspartate aminotransferase, γ-glutamyltransferase, alkaline phosphatase) reflect cellular injury, whereas actual functional state is reflected in maintenance of ammonia level, synthesis of clotting factors, and bilirubin elimination.

Abnormalities in gastrointestinal (GI) and hepatobiliary function occur frequently in the pediatric intensive care unit (PICU) from primary GI disease, following surgery, or from complications of systemic disease. The pediatric intensivist is called on for expertise in the preoperative and postoperative management of numerous GI tract and hepatobiliary diseases, as well as secondary dysfunction that may complicate diseases involving other organ systems. The GI tract subserves a wide range of functions beyond simple digestion that have an impact on systemic immunological, endocrinological, and microbiological functions.[1] Intact gut function beyond digestive function is of vital importance for the maintenance of health. Recent attention to alterations in GI function, interactions between liver and lung and between liver and kidneys have led to the view that the gut plays a role as an "engine" of multiple organ dysfunction.[2] Thus a practical working knowledge of the GI system and its integrated function is essential for the management of critically ill patients.

Intestinal Structure, Digestion, and Absorption of Nutrients, Water, and Electrolytes

The alimentary tract has several primary functions. These include mechanical and enzymatic degradation of nutrients, absorption of biochemical substrates, hormone regulation of substrate flow, separation of the external from internal environments, and excretion of waste. The alimentary tract essentially functions to alter nutrients to be compatible with the internal environment of the body.

The functional absorptive unit of the intestines consists of villi and crypts. The cells of the small intestine are separated from one another by specialized junctions that serve as gaskets to prevent back diffusion of material into the intestinal lumen. A mucus layer secreted by goblet cells in crypts separates enterocytes from direct contact with the luminal contents (Table 85-1).

Stem cells in crypts produce enterocytes and other specialized epithelial cells that migrate up the villous axis as they become differentiated. This migratory process takes 48 to 72 hours. Mature villous cells live 6 days. They have microvilli making up the brush border that contain digestive enzymes and membrane bound transport systems for nutrient and electrolytes. Small bowel enterocyte microvilli are estimated to increase the luminal surface area of the cell 14- to 40-fold.[3] The cells at the villous tip have a predominantly absorptive function, while crypt cells are primarily secretory. Rotavirus infections cause villous loss resulting in small intestinal mucosa composed largely of crypts and immature villi. This causes a net secretory state leading to malabsorption and osmotic diarrhea. Malabsorption of nutrients is another manifestation of villous injury.

Water and Solute Transport Across the Intestinal Epithelium

Surface area and integrity of intercellular junctions are the major determinants of water and solute flux across epithelium. The transport of solute and water across epithelium occurs either by active or passive transport or by facilitated diffusion (Table 85-2). The gut conserves large volumes of endogenously secreted material associated with digestion. The average luminal fluid input of the gut is about 9 L/day and

composed of oral intake and endogenous secretions. Approximately 8.8 L is absorbed, about 7 L in the small intestine and 1.8 L in the colon. Less than 0.2 L is excreted as a component of the normal stool output. When rapid changes in dietary intake or endogenous secretions occur, the intestinal mucosa can adapt transport functions in order to compensate for the changes. The loss of mucosal surface area through disease or surgical resection alters net flux of solute and water in GI tract. Furthermore, loss of specialized absorptive function may occur following loss of specific areas of gut. An example of this occurs in the setting of short bowel syndrome from resection of terminal ileum, with loss of ability to absorb bile acids and intrinsic factor.[3] Malfunction of absorptive mechanisms may lead to life threatening loss of fluid and electrolytes.

Nutrients absorbed include macronutrients such as carbohydrates, protein, and lipids; and micronutrients including minerals, electrolytes, trace elements, vitamins, and other metabolic cofactors such as biotin and carnitine. Critical illness leads to reduced intake of all nutrients and important alterations in substrate requirements and utilization.

There is a contrast between fasting in healthy persons and periods of increased physiological stress. In healthy individuals, prolonged fasting causes compensatory responses including: a decrease in overall metabolic rate, a decrease in gluconeogenesis from amino acids, increased reliance on ketone bodies for energy as the body attempts to conserve energy and protein stores, and depressed levels of insulin, cortisol, and catecholamines leading to chronic malnutrition.

In contrast, critical illness alters energy requirements. In general, the prolonged physiological stress during critical illness causes an increased metabolic rate as well as gluconeogenesis in excess of that needed to maintain serum glucose. Proteolysis and peripheral oxidation of amino acids with increased ureagenesis is also observed. This state leads rapidly to malnutrition as a result of so-called *autocannibalism,* characterized by levels of glucagon higher than insulin levels and by elevated catecholamines and cortisol that drive the relentless breakdown of peripheral tissues. These hormonal changes result in catabolism of endogenous stores of protein, carbohydrates and fat to provide metabolic substrate necessary to support the metabolic stress response.[4] Children with burn injury demonstrate extreme hypermetabolism in the initial phases of illness.[5] Children on dialysis have a negative nitrogen balance and loss of folate and selenium.[6] Use of catecholamines or neuromuscular blocking agents represent risk factors for undernutrition in critically ill children on dialysis.[7] During high physiologic stress, nutrition delivered to patients must be changed to allow for decreased reliance on fat and carbohydrate for energy production. Proteins are increasingly relied on and must be replaced with additional amino acids to support ongoing synthesis of protein including immunoglobulins by the liver and immune system. Protein requirements for various age groups are as follows: 0 to 2 years, 2 to 3 g/kg/day; 2 to 13 years, 1.5 to 2 g/kg/day; and 13 to 18 years, 1.5 g/kg/day.[8] Depressed levels of specific amino acids have been found in critically ill children.[9]

Enteral nutrition is the preferred method of feeding for critically ill children. Restriction of fluid intake seems to be the main barrier to the delivery of adequate nutrition, particularly in infants undergoing cardiac surgery.[10] Early transpyloric enteral nutrition is well tolerated in critically ill children and is not associated with an increase in incidence of complications.[11] Small-bowel feeds allow a greater amount of nutrition to be successfully delivered to critically ill children compared with gastric feeds. However, small-bowel feeds do not prevent aspiration of gastric contents.[12] The institution of a feeding protocol has been found to achieve goal feedings quickly and also improve tolerance of enteral feedings in patients admitted to the pediatric intensive care unit.[13] Enteral nutrition may also have some anti-inflammatory effects by lowering expression of specific cytokines.[14] The use of specialized formulas is not currently recommended in critically ill children. No effect from adequacy of feeding has been seen on hormone levels such as insulinlike growth factor-1 (IGF-1) and thyroid hormones.[15]

Digestion of Carbohydrates

Dietary carbohydrates may be classified in several ways (Box 85-1). Monosaccharides, such as glucose and fructose, are present in fruits, sweet corn, corn syrup, and honey. Disaccharides are simple sugars, such as sucrose (glucose + fructose), maltose (glucose + glucose), and lactose (glucose + galactose), the principal mammalian sugar. Polysaccharides, such as starch, are polymers of glucose and are abundantly present in wheat, grains, potatoes, peas, beans, and vegetables. Fiber consists of nondigestible complex polysaccharides of plant origin. This includes both water insoluble and water soluble fiber. The average American diet is 3:1 soluble to insoluble fiber. Some studies have shown that a water-soluble fiber, partially hydrolyzed guar gum can be used to decrease stool

Box 85–1 Conditions Impairing Dietary Carbohydrate Uptake

Disaccharidase deficiency (acquired or congenital)
Pancreatic insufficiency
Membrane-associated transporter defect

output in cholera.[16] Insoluble fibers affect fecal bulk, whereas soluble fibers have viscous effects in the upper GI tract including delayed gastric emptying, decreased postprandial glycemic response, and a constipating effect.

Carbohydrates are a major source of calories in healthy children. Carbohydrates are generally broken down by means of glycolysis and the Krebs cycle pathway (see Chapter 74). Carbohydrates may be stored as glycogen and lipids when ingested beyond momentary energy needs or converted to structural materials. A person's requirement for energy is highly dependent on activity level or, in hospitalized patients, the degree of hypermetabolism accompanying illness. The maximal ability to utilize carbohydrates may be limited during periods of high physiological stress as a result of the complex effects of hormonal mediators of the stress response.

Digestion of carbohydrates begins with the process of chewing that decreases the size of food particles, thereby increasing the total surface area for subsequent action by digestive juices. Salivary secretions are necessary for lubrication and also contain salivary amylase, an endoenzyme that cleaves oligosaccharides. Salivary amylase is rapidly inactivated by gastric acid, leaving the majority of starch digestion to occur in the duodenum under the action of pancreatic amylase and the intestinal brush border disaccharidase enzymes. Amylase contained in human milk facilitates starch digestion in breast-fed infants because of their low levels of endogenous salivary and pancreatic amylase.[17] Pancreatic amylase is the major enzyme of starch digestion resulting in short oligosaccharides, maltotriose, maltose, and α-limit dextrins. The amylase concentration becomes limiting in cases of pancreatic insufficiency when amylase levels become less than 10% of normal.[18]

The enterocyte is incapable of absorbing carbohydrates larger than monosaccharides. Therefore, further hydrolysis to monosaccharides is performed by intestinal *brush-border disaccharidases* of which the clinically important ones are lactase, which breaks down lactose, and sucrase, which breaks down sucrose. These enzymes are synthesized in the enterocyte and are subsequently inserted into the apical brush border membrane. With the exception of lactase and occasionally sucrase, the disaccharidases are rarely rate-limiting for complete carbohydrate digestion. Deficiencies of any of the disaccharidase enzymes, either acquired or hereditary, may result in carbohydrate malabsorption. This is characterized by osmotic diarrhea with elevated fecal reducing sugars, abdominal distension and flatulence secondary to fermentation of undigested oligosaccharides by colonic bacteria. An example of this is congenital sucrase isomaltase deficiency, an autosomal recessive disorder that is associated with absence of sucrase and maltase.[19,20]

Absorption of carbohydrates occurs in several ways. During periods of high luminal carbohydrate concentration, simple diffusion of monosaccharides may occur. Additionally, two transport mechanisms exist in the brush border for the absorption of monosaccharides.[21] First, glucose, galactose and xylitol are transported with sodium by the Na^+/glucose cotransporter. A low intracellular sodium concentration is created by the sodium-potassium-adenosine triphosphatase (Na^+-K^+ adenosine triphosphatase [ATPase]) pump located on the basolateral membrane. The resulting concentration gradient leads to movement of luminal sodium across the apical membrane, bringing with it glucose or galactose in a one-to-one molar ratio. Glucose-galactose malabsorption is a deficiency of this transport mechanism leading to neonatal onset of severe diarrhea.[22] The second mechanism is a non-energy-dependent facilitated transport system for fructose. The intestinal transport mechanisms are summarized in Table 85-2. The capacity to absorb fructose is limited, and excess ingestion has been found to cause symptoms of carbohydrate malabsorption.[23]

Clinical conditions that cause loss of the epithelium and brush border system may lead to symptoms of carbohydrate malabsorption. These conditions include: rotoviral gastroenteritis, inflammatory bowel disease, celiac disease, sprue, ischemia/hypoxia, bacterial overgrowth of the proximal gut as a result of either stasis or use of antacids, and malnutrition. Severe mucosal damage requires 7 to 10 days for recovery of brush border function. Several infant and enteral formulas rely on starch as a carbohydrate source to minimize reliance on lactase. Recent studies have observed that lactose digestive capability with lactase can be maintained despite small bowel mucosal damage.[24] Lactose absorption is primarily related to lactase activity as opposed to mucosal growth.[25]

The digestion of carbohydrates is generally very efficient, ranging from 80% to 100% of absorption from starch depending on the source of the starch. Bacterial fermentation of fiber and undigested carbohydrates produces short-chain fatty acids, used as fuel by the enterocytes, as well as gaseous hydrogen and methane, contributing to the flatulence associated with increased dietary fiber and malabsorption syndromes.

Digestion of Proteins

The GI tract has developed efficient mechanisms for processing exogenous peptides and complex proteins (Box 85-2). It is also very efficient at recycling endogenous proteins such as digestive enzymes, mucus, sloughed cells, and plasma proteins that leak into the alimentary tract.[26] The recommended dietary protein intakes in healthy children range from 2.5 to 3.5 g/kg/day in early infancy to 1.2 g/kg/day during childhood, and 0.8 to 0.9 g/kg/day in adolescence.[8] The enteral processing of proteins may be divided into digestive and transport phases.

In the digestive phase, gastric acid secretion initiates denaturation of complex proteins making them more susceptible to the actions of proteolytic enzymes. The chief cells of the stomach release pepsinogens that are converted to active pepsins under the influence of gastric acid. The pepsins are endopeptidases that release relatively large peptides and are inactivated when the pH rises above 4 as the food enters the duodenum. The completeness of gastric proteolysis depends in part on the rate of gastric emptying, the pH of intragastric contents, and the types of protein ingested.[26] It is noteworthy that patients with achlorhydria or those receiving antacids, H_2 blockers, or both agents have no evidence of impaired protein digestion ability. In addition to initiating protein digestion in the mature subject, pepsins act as milk clotting factors, which

Box 85–2 Conditions Impairing Dietary Protein Uptake

Ineffective pancreatic protease secretion
Abnormal epithelial transport (Hartnup, lysinuric protein intolerance)

are important in the neonate for curd formation and provide bulk to the infant's stools.

Luminal digestion proceeds in the small intestine mediated by five pancreatic peptidases that are secreted by the pancreatic acinar cells as proenzymes and activated by enterokinase and trypsin. Each peptidase possesses proteolytic activity at specific internal or external peptide bonds. Proteins are degraded typically into mixtures of one-third free amino acids and two-thirds peptides containing two to six amino acid residues,[27] which are suitable substrates for the brush border peptidases. The brush border peptidases convert the oligopeptides into monopeptides, dipeptides, and tripeptides suitable for transport into the enterocyte.

In the transport phase, specific membrane-associated transport mechanisms exist for the uptake of amino acids and dipeptides.[28] They involve *simple diffusion, facilitated transport,* and *carrier-mediated active transport* (Table 85-3). Na^+-coupled active transport is an energy-dependent process associated with the uptake of luminal Na^+ and an amino acid (or glucose) and exchange of the sodium and associated molecule for K^+ through the basolateral membrane on the serosal side.[29] Peptide transport may also occur using an H^+/peptide transport protein which moves according to an H^+ gradient in the acidic pH microclimate of the intestinal brush border. This microclimate is maintained by Na^+-H^+ exchange in the brush border and Na^+-K^+-ATPase in the basolateral membrane.[30] An important characteristic of these transporters is that many amino acids are absorbed more rapidly as dipeptides than as free amino acids. This fact has been capitalized on in the development of enteral nutritional formulas because oligopeptide mixtures have a lower osmolarity and are more efficiently absorbed than single amino acid solutions of equal nitrogen content. Because of the efficient gastrointestinal absorption of dipeptides, patients with specific amino acid transport defects (e.g. Hartnup disease [defective tryptophan transport] and lysinuric protein intolerance [defect in dibasic amino acid transport: lysine, arginine]) infrequently have GI symptoms related to dietary protein malabsorption and instead more commonly manifest with non-GI symptoms such as aminoaciduria.

Once inside the enterocyte, peptides are quickly degraded into their constituent amino acids by cytoplasmic peptidases that complement the activity of the brush border peptidases. Only minute quantities of intact peptide and protein gain access to the systemic circulation. The cytoplasmic amino acids derived from digested proteins are a major source of free amino acids used directly by the enterocyte. When absorbed beyond cellular needs, the free amino acids are released to the portal venous circulation for hepatic and systemic use. Only 23% of absorbed amino acid nitrogen passes to the periphery without modification.[31] Of the remaining nitrogen, 57% is converted to urea with the carbon skeleton salvaged for synthesizing other substances and 20% of the total ingested amino acids are used directly for hepatic protein synthesis.

Table 85–3 Pattern of Biochemical Tests Based on Category of Liver Disease

Biochemical Test	Hepatocellular Necrosis	Cholestasis	Infiltrative Process

0, Normal; *+ to +++,* degrees of elevation; *PT,* prothrombin time.

During periods of fasting, the enterocyte derives the majority of its nourishment from the mesenteric arterial vascular supply, whereas during digestion, the enterocyte derives a significant part of its nutrient requirements from the luminal contents. Experience with mucosal recovery and adaptation after injury reveals that an enteral route of nutrition permits optimal recovery. In the premature infant and neonate, the small intestine is capable of absorbing intact milk proteins by pinocytosis. These proteins may include secretory immunoglobulins from breast milk as well as food antigens.[32] Peptidase inhibitors have been demonstrated in colostrum and breast milk, partially explaining the failure of normal digestive mechanisms to degrade some of these complex dietary proteins. Both antibodies and antigens ingested with maternal milk create an important part of the immune repertory developed during early infancy.[33] Although the exact time of "closure" of the intestinal mucosa to the uptake of macromolecules has not been defined in human infants, other mammals demonstrate marked intestinal impermeability to foreign proteins by the time of weaning[34] from breastfeeding.

Digestion of Lipids

Dietary fat accounts for approximately 50% to 70% of the nonprotein calories consumed by infants and approximately 30% of nonprotein calories consumed after age 2 years (Box 85-3).[35] Dietary fat is ingested principally in the form of triglycerides containing the fatty acids palmitate and oleate (C16:0 and C18:1, respectively). Dietary triglycerides of animal origin predominantly contain long-chain (i.e., longer than C14 chain length) saturated fatty acids. Polyunsaturated fatty acids are mostly of vegetable origin and include linoleic and linolenic acid, also referred to as essential fatty acids because of absent de novo synthesis in humans. Other dietary lipids include fat-soluble vitamins, cholesterol, prostaglandins, waxes, and phospholipids.

In healthy adults, digestion and absorption of fat is complete with only 5% to 7% of ingested fat escaping absorption. Under normal physiological conditions healthy infants up to age 9 to 12 months fail to absorb 15% to 35% of dietary

Box 85–3 Conditions Impairing Dietary Lipid Uptake

- Decreased bile salt pool in gut (biliary obstruction, short bowel syndrome)
- Impaired pancreatic secretions (pancreatic insufficiency, pancreatitis)
- Suboptimal pH in gut (gastric hypersecretion)
- Rapid transit time (short gut syndrome, diarrheal states)
- Mucosal diseases (celiac disease, irritable bowel disease, bacterial overgrowth)
- Impaired enterocyte function (abetalipoproteinemia)

fat. Digestion and absorption of dietary fat is generally completed by the middle third of jejunum; however, the presence of dietary fiber may reduce the rate and extent of absorption. Loss of dietary fat places children at significant risk for calorie and fat-soluble vitamin malnutrition.

Digestion of Fat

Fat digestion begins with formation of emulsions, which increase the surface area for enzyme interaction. Emulsification begins with release of fat by mastication and gastric "milling" of chyme. Bile salts and coating by phospholipid derived from the diet results in a stable emulsion droplet with a hydrophobic center consisting of triglyceride, cholesterol esters and diglyceride in a hydrophilic envelope. Mammary, lingual, and gastric lipases play an important role in direct lipolysis of long- and medium-chain triglycerides that are present in maternal milk.[36] Lingual and gastric lipases are active at pH <5 and begin digestion of fat in the stomach; however, overall only play a limited role in the digestion of lipids. Intragastric lipolysis is consistent across all age groups.[37]

Most of the enzymatic degradation of dietary lipids to fatty acids and monoglyceride is by the action of pancreatic lipase and co-lipase, and requires an alkaline environment (pH 6 to 8). This underscores the importance of secretion of bicarbonate by the pancreas and biliary tree in order to neutralize gastric acid. Co-lipase is an essential cofactor for lipase action. Co-lipase's role is to displace the bile salt-triglyceride interaction in emulsion droplets and micelles to facilitate lipase hydrolysis of the triglyceride. Triglyceride hydrolysis occurs at the interface between the emulsion droplet and aqueous phase within the lumen. This is a two-step process. The first step is the enzymatic hydrolysis of long-chain triglycerides and liberation of fatty acids from the glycerol backbone. The second step is formation of fatty acid micelles, that is most efficiently accomplished with the aid of bile salts[38] to traffic the fatty acids across the unstirred water layer to the mucosa for absorption.

Transit through the unstirred water layer adjacent to the epithelial surface is considered the rate-limiting step in lipid absorption. Intrinsic gut brush border lipase enzymes are involved as well. The milieu of the unstirred water layer is acidic (pH 5 to 6) owing to the activity of the brush border membrane sodium-hydrogen (Na^+/H^+) exchanger. The acid environment facilitates dissociation of fatty acids from micelles resulting in a high concentration of fatty acids necessary for diffusion across the mucosal membrane.[39,40]

Once inside the enterocyte, long-chain fatty acids and monoglycerides are resynthesized into triglycerides and packaged as chylomicrons. Lipoproteins (e.g., apo-A, apo-B) and cholesterol are attached to the intestinal chylomicrons and confer important properties for the subsequent systemic uptake and metabolism of the chylomicrons. This process appears to be defective in cystic fibrosis and may account for some of the fat malabsorption seen in this disease.[41] Chylomicrons are exported into the intercellular space and transported through the intestinal lacteals to become part of the intestinal lymph. On entering the bloodstream through the thoracic duct, the chylomicrons are associated with other apolipoproteins that allow them to be recognized by specific peripheral tissues.[42]

Dietary lipids containing short- and medium-chain (C6 to C12) triglycerides are handled differently from those of long-chain triglycerides. As much as 30% of medium-chain triglycerides may be absorbed intact into enterocytes by passive diffusion and enter the portal venous blood directly. Medium-chain triglycerides are hydrolyzed by pancreatic and mammary lipases to fatty acids and monoglycerides and rapidly enter the enterocytes where they emerge into the portal venous system without re-esterification as occurs with long-chain fatty acids.

Intestinal Lymphatics

The intestinal lymph, known as *chyle,* is composed of chylomicrons and lipoproteins secreted by the intestinal epithelium in the postprandial state together with nonresorbed interstitial fluid. Chyle follows the intestinal lymphatic channels along the mesentery and enters regional lymph nodes from which it flows cephalad through the thoracic duct and ultimately enters the central circulation. In the fasting state, intestinal lymph production is relatively low. It increases 20-fold during the active absorption of a typical meal. Intestinal chyle is joined by lymphatic drainage from other tissues including liver and pancreas. Protein content of chyle is 2.2 to 5.9 g/dL with a triglyceride content of 0.4 to 6.0 g/dL and 400 to 6800 lymphocytes/dL. During digestion of a meal containing long-chain fats, chyle has a typical milky white appearance because of the presence of chylomicrons. Rate of formation of chyle depends on the state of nutrient absorption, portal venous pressure, and the rate of lymphatic uptake. Factors that increase portal pressure (e.g., cirrhosis, congestive heart failure) or impair the flow of lymph back to the central circulation (e.g., increased central venous pressure, superior vena cava syndrome) predispose to the collection of chylous ascites in the abdomen.

Regulation of Electrolyte and Water Movement

Movement of water is closely linked to the movement of solute in the form of electrolytes and nutrients. Water transport is a largely passive process that occurs through paracellular routes in the intestine coupled with solute movement. Expression of transporters involved in intestinal water and electrolyte transport is regionally specific. Electrolytes are taken up by enterocytes at the apical membrane and extruded through the basolateral membrane into the paracellular space. The relatively hypertonic paracellular fluid pulls water into this space, increasing the hydrostatic pressure locally. Because the tight junction between enterocytes is more impermeable

to fluid flux than the capillary membranes, fluid and electrolytes are preferentially driven in the direction of the vascular space.[1,43,44] Tight junctions are selective and dynamic in function and are regulated by a number of signaling pathways and cellular processes that can determine the size, selectivity, and flow of molecules across this barrier.[3]

The gut responds to both systemic and local stimuli to regulate motility, transport, and digestive functions. Secretion and motility are mediated through typical agonist membrane receptor mechanisms, by local autocrine and paracrine action, or through remote endocrine and neurocrine actions. Regulation of intestinal motility is crucial for keeping the chyme in contact with the epithelial surface long enough for efficient absorption of nutrients while permitting removal of unusable material and bacteria from the alimentary tract on a regular basis. GI smooth muscle demonstrates phasic and tonic patterns of contraction. Numerous factors affecting the frequency of contractions include changes in autonomic tone, stimulation of the gut by neurohormonal peptides or pharmacologic agents, and noxious stimuli associated with infectious or inflammatory processes. Hypoxia and ischemia decrease motility, frequently leading to paralytic ileus. Neural regulation of the GI tract integrates the processes of intestinal water and electrolyte transport, motility and blood flow. The augmentation of water and electrolyte absorption after a meal in the jejunum is neurally mediated.[45] The enteric nervous system is capable of functioning independently but also may be modified by autonomic nervous system.[3]

Many other factors alter the functions of the gut. The terminal ileum and colon are particularly important in this respect. The presence of an ileostomy increases the risk of excessive sodium losses, dehydration, and electrolyte abnormalities. Terminal ileal resection or other diseases of the terminal ileum such as Crohn disease or radiation enteritis may result in bile acid malabsorption. In patients with bile acid malabsorption, bile acids reach the colon, which stimulates electrolyte and chloride secretion. Patients with mild to moderate malabsorption present with watery diarrhea and may respond to a bile acid binder such as cholestyramine.[46] Impairment of water and ion absorption in inflammatory bowel disease may occur because of numerous mechanisms including alteration of epithelial integrity, augmented secretion, and reduced absorption. In addition, intestinal inflammation is associated with defects in epithelial barrier function. It is not known what effect inflammation may have on ionic function.[47] Hyperosmolality of the ileal and colonic contents leads to an osmotic diarrhea. This state is seen when unabsorbed nutrients enter the distal alimentary tract and are broken down by enteric bacteria, resulting in increased luminal osmotic activity and osmotic diarrhea.

Electrolyte Transport

Several basic mechanisms exist for the transport of electrolytes by the epithelia. Na^+ may be transported by numerous mechanisms. The regulation of Na^+ absorption is closely regulated such that anion secretion is closely aligned with Na^+ absorption.[48] A Na^+-H^+ exchange-mechanism present throughout the intestine results in a 1:1 exchange of luminal sodium for protons. Coupled Na-Cl absorption, Na-Cl co-transport, Na-K-Cl co-transport, and movement of Na^+ down its electrochemical gradient as in Na-Glucose co-transport are other mechanisms by which Na^+ moves across the intestinal epithelium. The Na^+-H^+ exchanger plays a role in regulation of intracellular pH, regulation of cell volume, initiation of cell growth in response to various trophic factors, and metabolic response to insulin. To maintain electrical neutrality, the epithelium simultaneously exchanges Na^+ for H^+ and Cl^- for HCO_3. The presence of glucose in the lumen of the small intestine stimulates increased sodium absorption through coupled transport. Uptake of glucose is carrier mediated although the coupled transport of glucose with sodium is electrogenically driven by the Na^+ gradient across the cell membrane.[49] Absorption of glucose by Na-Glucose transport results in activation of myosin light chain kinase to regulate tight junction-permeability.[50] Backflow of sodium into the lumen is a passive process since a major task for the GI tract is sodium conservation. Systemic acidosis increases Na^+ and Cl^- absorption in the ileum and colon, whereas alkalosis has the opposite effect. As seen in other epithelial tissues, aldosterone increases ileal and colonic absorption of Na^+ and can increase absorption of water in colon three- to fourfold.[51] Spironolactone blocks this effect. Glutamine has been shown to stimulate water and electrolyte absorption in the jejunum.[52] Glucocorticoids increase sodium and water absorption in the distal colon. Opiate receptor stimulation increases active sodium and chloride absorption in the ileum, and opiate antagonists decrease basal absorption of water and electrolytes. The primary antidiarrheal effect of opiates, however, is mediated through a slowing of transit time.[1]

In the colon, active absorption and secretion of K^+ occurs in a manner consistent with K^+-H^+ exchange, is electroneutral and independent of Na^+-Cl^- exchange. After the ions have entered the enterocyte at the luminal surface, extrusion occurs through the basolateral membrane into the paracellular spaces. The process of sodium extrusion depends on Na^+-K^+-ATPase pumping function located at the basolateral membranes. Oxidative stress inhibits water and electrolyte absorption in the jejunum through inhibition of Na-K ATPase on the basolateral membrane.[53]

Extrusion of Cl^- occurs along an electrochemical potential difference.[54] The intraluminal secretion of water and other electrolytes appears to follow active secretion of Cl^- from the crypt cells of the jejunum, ileum, and colon. This is a common physiological pattern in the liver, pancreas, and kidney. Numerous substances such as muscarinic receptor agonists, serotonin, and substance P likely work through second messengers and signaling cascades to induce active chloride secretion. Vasoactive intestinal peptide mediates increased secretion of electrolytes and water by increased cyclic adenosine monophosphate production that stimulates active chloride secretion and inhibits sodium-chloride absorption. Certain arachidonic acid metabolites, especially prostaglandins (e.g., prostaglandin E_1), have been shown to increase active chloride secretion leading to increased loss of electrolytes and fluid. Many laxatives and antacids may affect fluid and electrolyte balance by stimulating active electrolyte and fluid secretion in the terminal ileum. In addition, these agents may increase mucosal permeability and stimulate motility.[1]

Disruption of normal Na^+-K^+-ATPase activity results in the net secretion of fluid and electrolytes. This mechanism is the final common pathway in a number of secretory diarrheal states such as cholera, enterotoxigenic *Escherichia coli, Salmonella* spp., *Campylobacter jejuni,* and *Clostridium perfringens*

that appear to act via second messenger pathways via their toxins.[55] Rotavirus appears to have several mechanisms of causing diarrhea. The first appears to be a mechanism of increasing chloride secretion with a resulting secretory diarrhea mediated by Ca^{++}, a different mechanism than most bacterial mediated diarrheal diseases. The second is an osmotic diarrhea caused by villus destruction and resultant malabsorption.[56] In addition, the effects of various paracrine and endocrine mediators alter intestinal adenyl cyclase activity and lead to changes in electrolyte and water balance.[54]

Zinc

Normal zinc homeostasis is required for a functional immune system, adequate antioxidant capacity, glucose homeostasis, and wound healing. In addition, zinc is a required co-factor for many enzymes, transcription factors, and replication factors. In noncritically ill patients, zinc supplementation is associated with improvement in markers of immune function. Plasma zinc concentrations are low in critically ill children, correlate with measures of inflammation and are associated with the degree of organ failure.[57] Large intestinal losses of zinc with and without complexed proteins often occur in association with high intestinal fluid losses through gastrointestinal stomas and fistulae. Although some patients with sepsis have demonstrated significantly faster recovery with zinc supplementation among other anti-oxidants.[58] there is currently inadequate evidence to recommend the routine use of high-dose zinc supplementation in the critically ill.[59]

Hydrogen Ions

Hydrochloric acid secretion by the gastric parietal cell is necessary for pepsinogen activation (pH <5.0) and to reduce bacterial colonization. H^+ and bicarbonate are produced from water and carbon dioxide by the action of carbonic anhydrase within the parietal cell. The bicarbonate is secreted into the bloodstream in exchange for chloride at the basolateral membrane. Chloride and potassium are both secreted along with H^+ across the apical membrane against a large concentration gradient. This is an active process, mainly because of the action of the proton pump, H^+/K^+-ATPase, that represents the final step in gastric acid secretion.[60]

Histamine, gastrin, and acetylcholine are the main stimulants of gastric acid secretion.[61] Gastric distension, dietary amino acids, and amines stimulate gastrin hormone secretion by G cells located in the gastric antrum. Gastrin is the most potent endogenous stimulant of gastric acid secretion and stimulates release of histamine by the enterochromaffin-like cells. Histamine then binds to histamine-2 (H_2) receptors on parietal cells leading to acid secretion. Prostaglandins and somatostatin have an inhibitory effect on gastric acid secretion via specific receptors located on the parietal cell.[62]

H_2 receptor antagonists (e.g., ranitidine, famotidine, cimetidine) block histamine-mediated gastric acid secretion found in postprandial acid secretion, Zollinger-Ellison syndrome and other disorders associated with hypergastrinemia. Proton pump inhibitors (PPIs) (e.g., omeprazole, lansoprazole, pantoprazole) block gastric acid secretion by inhibiting the parietal cell H^+/K^+-ATPase. The PPIs bind irreversibly to the enzyme and subsequent secretion of acid can occur only with the synthesis of new proton pump enzyme, a process that takes 12 to 24 hours. For these reasons, PPIs have revolutionized gastric acid suppression therapy.[61,63] H_2 receptor antagonists and PPIs are similarly effective for preventing bleeding in the upper part of the GI tract in patients receiving mechanical ventilation.[64] Recent studies have shown that some oral PPIs suppress acid in intensive care unit (ICU) patients to a greater extent than IV.[65] Patients at risk of stress ulcer–related bleeding are most likely to benefit from prophylaxis.[66]

Pancreas

The pancreas exhibits both endocrine and exocrine functions and acts in concert with the liver to regulate blood glucose levels. Endocrine-secreting cells of the pancreas are aggregated in the islets of Langerhans. There are approximately 1 million islets in the human pancreas. Four distinct cell types in the islets which serve the pancreatic endocrine function include (1) B-cells that secrete insulin (50% to 80%), (2) A-cells that secrete glucagon (5% to 20%), (3) D-cells that secrete somatostatin (5%), and (4) PP cells that secrete pancreatic polypeptide.[21,67]

Branches of the celiac, superior mesenteric and splenic arteries provide the pancreas blood supply. Venous drainage occurs via pancreaticoduodenal veins, splenic veins, and ultimately the portal vein, providing direct hormonal influence over hepatic metabolism. Both parasympathetic and sympathetic innervation of the pancreas occurs by means of the vagi and abdominal plexuses, respectively. Vagal innervation of acini, islets, and ducts facilitates secretory function, whereas sympathetic innervation occurs primarily to vascular structures. Functional ectopic pancreatic tissue may be found commonly throughout the upper gastrointestinal tract.

Pancreatic Exocrine Secretory Function

The functional unit of the exocrine pancreas consists of an acinus composed of specialized cells containing secretory granules that drain into ductules, which coalesce to form the pancreatic duct. In contrast to the pancreatic endocrine cells that demonstrate specialized function, each acinar cell is capable of secreting all the pancreatic digestive enzymes. The basolateral membrane has receptors for hormones and neurotransmitters that stimulate pancreatic secretion of the digestive enzymes stored in zymogen granules near the apical membrane of each acinar cell.[68] Ultimately, the pancreatic duct joins with the common bile duct and drains into the duodenum through the ampulla of Vater. Anatomic variation exists. 74% of people have a common channel, whereas 19% have a separate opening and 7% have an interposed septum.[69]

Pancreatic juice is an isotonic fluid, containing primarily Na^+, K^+, Cl, and HCO_3^-. The total volume of secretion is approximately 2.5 L daily. Cystic fibrosis transmembrane conductance regulator is the main channel for chloride secretion in the pancreas and may be involved in other ion transport.[70] Secretion of bicarbonate and water is mediated through the actions of the gut hormones secretin, cholecystokinin, and vasoactive intestinal peptide. Stimulation of the vagus nerves or the administration of acetylcholine induces digestive enzyme secretion. These effects may be blocked with atropine.

There are four phases of pancreatic secretion: *Basal secretion* represents approximately 2% of the potential maximum

HCO_3. The *cephalic phase* is mediated by the vagal nerves in response to the sight and smell of food. The *gastric phase* consisting of secretion of a protein-rich pancreatic juice of low volume and HCO_3 occurs following either distention of the stomach[71] or after the ingestion of food. The *intestinal phase* is characterized by marked output of digestive enzymes, fluid, and HCO_3.

Presence of bicarbonate is essential to achieve an optimal pH (>5) for pancreatic digestive enzyme activity and to ensure solubility of bile salts. In addition to bicarbonate, the primary secretory products of the exocrine pancreas are amylase, lipase, and the proteases. The secondary digestive enzymes consist of nucleases, colipase, and lecithinase. The roles of the pancreatic digestive enzymes are discussed in the sections on carbohydrate digestion (amylase), lipid digestion (lipase), and protein digestion (proteases). Cholecystokinin is the major humoral mediator of meal-stimulated enzyme secretion. It is released from the small intestinal mucosa in response to presence of fat, protein and starch. The response is related to total load rather than concentration. Cholecystokinin activates afferent neurons in duodenal mucosa that leads to secretin release via a vasovagal reflex.[72] Inhibitors of exocrine pancreatic secretion include somatostatin, pancreatic polypeptide and peptide YY.[73] Octreotide, a somatostatin analogue has been used for its antisecretory effect in clinical management of pancreatic-pseudocysts and fistulae, but its use in acute or chronic pancreatitis remains controversial.[74] Inflammation of the pancreas both from infectious and non-infectious causes can produce a dramatic systemic inflammatory response resulting in generalized permeability changes and acute lung injury.[75]

Hepatobiliary System

Examination

A complete physical examination of all children admitted to an ICU should include inspection, palpation, and auscultation of the abdomen with particular attention to hepatic or splenic enlargement, distended superficial venous channels, abdominal masses, the characteristics of the bowel sounds, and finally visual inspection of the perianal region for signs of trauma, fistulae, and venous distension.

Palpation of the liver provides information about the hepatobiliary tract as well as function of the right side of the heart. Normally, the liver is palpable roughly 1 to 3 cm below the right costal margin in the mid-clavicular line; however, assessment of liver *span*, and not palpation alone, is the only reliable non-radiological method for determining liver size. Liver span is determined by percussion, palpation, and auscultation along the right mid-clavicular line with the patient supine and breathing quietly. Dullness of the upper border is determined by percussion. Either palpation or auscultation is used to establish the lower border. The liver span increases with body weight and age in both sexes, ranging from 4.5 to 5.0 cm at 1 week of age to 7 to 8 cm in boys and 6.0 to 6.5 cm in girls by age 12 years.[76]

Examination of the liver should note consistency, contour, tenderness, the presence of any masses or bruits, and assessment of spleen size. Documentation of the presence of ascites and stigmata of chronic liver disease is important. Tenderness over the liver suggests inflammation or stretching of the fibrous capsule through rapid enlargement. Conditions associated with downward displacement of a normal liver include hyperinflated lungs, pneumothorax, retroperitoneal masses, and subdiaphragmatic abscess. End-stage liver disease and cirrhosis are associated with a reduced liver span corresponding to decreased hepatic cell mass. The spleen tip may be palpable normally in children, especially during inspiration. Enlargement of the spleen generally represents elevated portal venous pressures or invasive processes such as sequestration, malignancy, extramedullary hematopoiesis, or hyperplasia of the reticuloendothelial system.[77]

Anatomy: Microanatomy, Structure, and Function

The liver is the largest organ in the body and is composed of 60% hepatocytes, approximately 17% to 20% endothelial cells and Kupffer cells (reticuloendothelial cells), 3% to 5% bile ducts, and 1% hepatic stellate cells and oval cells. The liver has a dual vascular supply derived from the hepatic artery branches of the celiac axis providing about 30% of the blood supply and the portal vein providing approximately 70%. Innervation of the liver is by the parasympathetic branches derived from both vagi and sympathetic branches, which also carry afferent fibers deriving from thoracic segments. Denervation of the liver, such as seen after liver transplantation, does not affect function.[78]

The "liver lobule," the functional unit of the liver is composed of interconnected hepatocytes (hepatic plates) one to two cells thick and 20 to 25 cells in length separated by a venous sinusoidal space and radiating around the central vein like spokes in wheel (see Figure 85-1). The narrow tissue space between the endothelial cells and hepatic plates is called the space of Disse, which in turn connects with lymphatic vessels in the interlobular septa. Hepatic sinusoidal endothelial cells are flat cells that do not form intracellular junctions and overlap one another. They are fenestrated, allowing plasma to enter into the space of Disse and come into direct contact with the surface of hepatocytes.[79] This facilitates bidirectional exchange between the hepatocytes and the sinusoidal space. Macrophage-derived Kupffer cells line the sinusoidal space, have a phagocytic function, and mediate the hepatic inflammatory response.

Hepatic stellate sells, also known as *ito cells*, lie within the space of Disse, serve as the hepatic storage site of vitamin A, are effectors of fibrogenesis, and play a role in extracellular matrix remodeling after recovery from injury. Chronic activation and proliferation of hepatic stellate cells may lead to noncirrhotic portal hypertension, fibrosis, and cirrhosis.[80] Bile canaliculi lie between adjacent hepatocytes and drain into small terminal bile ducts, that successively drain into larger bile ductules, intralobular bile ducts and eventually the extrahepatic bile ducts. Tight junctions between the hepatocytes at the canalicular space permit unidirectional transport of substances from the hepatocytes into the canalicular space. Several different carriers, receptors and transport proteins facilitate movement of compounds across the sinusoidal, hepatocyte and canalicular membranes. ATP-binding cassette proteins are expressed in the canalicular membrane and play an important role in transportation of organic ions. Alkaline phosphatase, leucine aminopeptidase and γ-glutamyl transpeptidase are transaminase enzymes selectively localized in the bile canaliculi.

The microcirculatory "path" within the lobules leads along a declining hydrostatic pressure gradient from the terminal

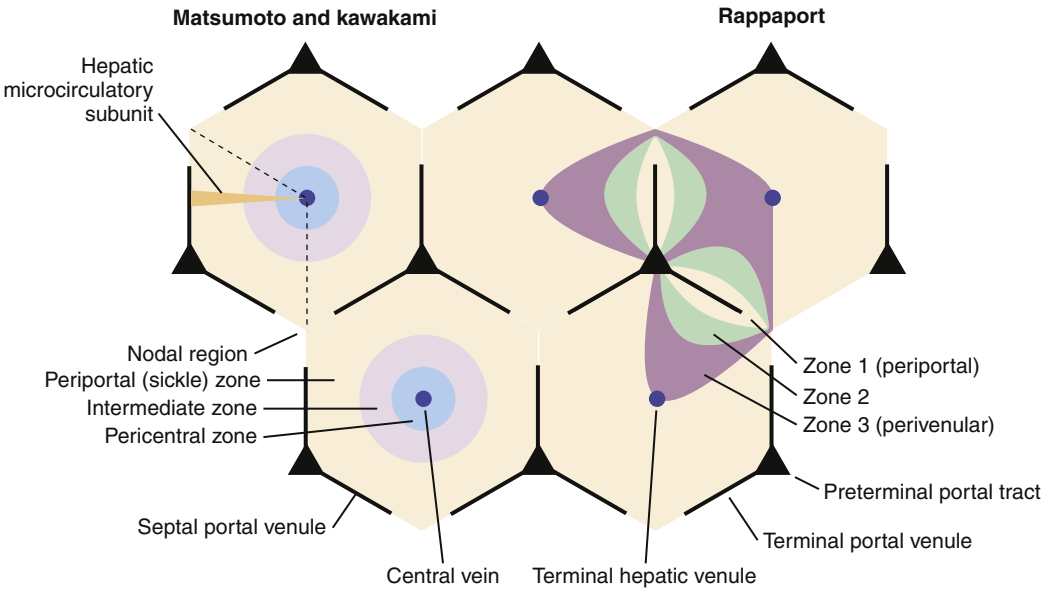

Figure 85–1. Microanatomy of the liver depicting the hepatic acinus and microcirculatory subunits. Arrangement of simple liver acinus forms zones centered about portal triads (preterminal portal tract contains terminal afferent vascular branches, bile ductules, lymph vessels, and nerves). Zone 3 forms the microcirculatory periphery because its cells are the farthest from afferent vessels. Cell damage in area surrounding the terminal hepatic venule, which extends into zone 3 produces a typical stellate pattern of fibrosis. Extensive fibrosis in zone 3 leads to bridging necrosis. *(Modified from Wanless IR: Anatomy, histology, embryology, and developmental anomalies of the liver. In Feldman M, Friedman LS, Slesinger MH, editors:* Slesinger and Fordtran's gastrointestinal and liver disease, *ed 7, Philadelphia, 2002, Saunders Elsevier.)*

hepatic arterioles and portal venules within the portal triad towards the central vein representing the terminal branch of the hepatic vein, resulting in three hepatocyte functional zones (see Figure 85-1). Zone 1 hepatocytes closest to the portal triad are exposed to sinusoidal blood containing the highest concentration of solutes and oxygen. In contrast, zones 2 and 3 represent hepatocytes more distant from the portal blood supply and are exposed to a declining oxygen and solute gradient. In addition, zone 3 hepatocytes actively participate in drug metabolism and disposition. Ischemic injury and drug hepatotoxicity impacts zone 3 hepatocytes to the greatest degree.[81]

Portal Circulation

The portal venous system drains the intestines, pancreas, and spleen with numerous collateral anastomoses to other venous beds of the abdomen. There is a mixing of portal and systemic blood circulation within the sinusoids, and all the blood eventually drains from the liver via the hepatic veins to the inferior vena cava. The liver has a high blood flow (~27% of the resting cardiac output) and low vascular resistance. The portal pressure gradient (PPG) is the pressure difference between the inferior vena cava and the portal vein and averages 0 to 5 mm Hg. Portal hypertension is defined as a PPG between 6 and 10 mm Hg. A PPG greater than 10 mm Hg carries risk for development of esophageal varices and a PPG greater than 12 mm Hg predisposes towards ascites formation.[82] Obstruction of the portal venous drainage at any level leads to portal hypertension. Portal hypertension may be classified as prehepatic, intrahepatic, or posthepatic, according to the level at which the obstruction to flow occurs. Determination of the location of obstruction is critical for instituting appropriate therapy.

Ascites formation is multifactorial. The central event in ascites formation in cirrhosis is splanchnic arterial vasodilatation secondary to portal hypertension. This creates an increase in capillary pressure because of increased blood inflow leading to leakage of fluids. Additionally, impairment of systemic hemodynamics and renal function leads to sodium and water retention with intravascular volume expansion.[83-85] Ascites may form in the absence of portal hypertension as the result of low plasma oncotic pressure associated with malnutrition, with renal or enteral protein losses, or through impaired thoracic duct lymph drainage. Rarely, arterial-portal venous malformations may lead to portal hypertension as a result of excess portal blood flow. One additional factor predisposing to ascites is an elevated central venous pressure that increases formation and impairs resorption of interstitial fluid often associated with generalized anasarca.

Hepatic Function

The function of the liver may be broadly characterized in terms of (1) production of substances uniquely made in the liver, (2) the degradation, elimination, and detoxification of biological materials, (3) the maintenance of biochemical homeostasis, and (4) storage of nutritional materials.

The liver occupies an ideal place in the scheme of digestion. Hepatocytes are exposed to large quantities of absorbed nutrients after ingestion of a meal with 20% of the total absorbed nitrogen used for hepatic protein synthesis. Of the large number of plasma proteins synthesized by the liver, several are of major significance in the ICU and deserve particular attention.

Albumin has a half-life of approximately 20 days, and is a significant contributor to colloid oncotic pressure. Decreased serum levels may predispose to edema formation and decreased binding of bilirubin, calcium, xenobiotics, and other highly protein-bound molecules. Low serum albumin levels can be secondary to impaired synthesis from protein-calorie malnutrition, chronic liver disease, cachexia,

or cytokines. Alternatively, increased losses from proteinuria, protein losing enteropathy, burns, or other iatrogenic losses including paracentesis may cause hypoalbuminemia.[86]

Prealbumin, also known as transthyretin, is a visceral protein with a short half-life of 1.9 days. Because hepatic synthesis is exquisitely sensitive to both the adequacy and levels of protein and energy intakes it may be used a nutritional marker and for monitoring short-term response to nutritional intervention.[87]

α_1-Antitrypsin is an important antiprotease with regulatory activity for elastase and other proteases. α_1-Antitrypsin can be important in regulating elastase-induced tissue injury in certain lung diseases and its absence leads to uncontrolled proteolytic activity in the lung.[88] Because α_1-Antitrypsin is an endogenous protein that is relatively resistant to hydrolysis by enteric bacteria, elevated levels detected in feces suggest protein losing enteropathy.[89]

Hepatic synthesis of transferrin facilitates iron transport in the plasma by binding two molecules of iron. Ferritin is the primary storage molecule of iron with each molecule storing up to 4500 atoms of iron. Many coagulation factors are synthesized in the liver. They include plasminogen, fibrinogen, and factors II, V, VII, IX, X, XI, XII, and XIII. Factors II, VII, IX, and X are the so-called *vitamin K–dependent* factors that require vitamin K for synthesis and secretion in active form.[90] In addition, the anticlotting proteins antithrombin III, protein C, and protein S are synthesized largely in the liver and may be vitamin K dependent. Several additional common plasma proteins are synthesized by the liver including haptoglobin, ceruloplasmin, lipoproteins, α-fetoprotein, and the C3 component of complement.

Alterations in plasma proteins frequently occur during acute and chronic liver disease. Although the levels of many of these proteins may rise as part of the systemic inflammatory response (acute phase reactants), plasma levels are generally reduced during liver disease, depending on the duration of hepatic insufficiency and the half-lives of the specific proteins. Thus a decrease in albumin with its half-life of 16 to 21 days generally represents a chronic disease state, whereas a prolonged prothrombin time may be seen within hours of acute hepatic failure because of the short half-life of factor VII (about 6 hours).[91]

Detoxification and catabolism of ammonia, bilirubin, and xenobiotics is essential to life. Ammonia arises through bacterial degradation of nitrogenous compounds in the intestine, as well as from other physiological sources including the kidneys and peripheral tissues such as skeletal muscle and the brain. Ammonia is transported to the liver via the portal vein in high concentrations and is quickly degraded in the liver to urea. High levels of ammonia are incompatible with life and during hepatic failure, hyperammonemia represents a life threatening aspect of liver disease.[92]

Bilirubin elimination is another critical excretory function of the liver. Bilirubin is mainly derived from the heme portion of hemoglobin. Smaller amounts are made through the breakdown of cytochromes and myoglobin. Heme is catabolized to bilirubin in the reticuloendothelial system and involves several steps, including transport to the hepatocyte and cellular uptake, cytosolic transport within the hepatocyte, conjugation, active cellular export, and elimination. Impairment at any juncture becomes manifest as hyperbilirubinemia and ultimately clinical jaundice.

Enterohepatic Circulation

Bile acids represent a family of steroid molecules derived from cholesterol. They act to eliminate cholesterol from the body and to solubilize dietary fats through a detergent-like action. Enterohepatic circulation acts to conserve bile acids since a minimum concentration of bile acids are required for micelle formation. Bile salts are secreted into the duodenum with 97% reuptake in the terminal ileum, undergoing recycling 4 to 12 times per day. The distal and terminal ileum have specialized transport mechanisms for absorption of bile salts and vitamin B_{12}, that are adversely affected by terminal ileal resection, jejunostomies, inflammatory bowel disease, or other acquired lesions in this anatomical region (e.g., necrotizing enterocolitis). Functional loss of the distal and terminal ileum results in malabsorption of vitamin B_{12}, bile salt deficiency, and impaired digestion and absorption of fat-soluble vitamins and long-chain fats. Furthermore, unresorbed bile acids have a detergent effect on the colonic epithelium resulting in secretory diarrhea.[1]

Hepatic insufficiency, either from immaturity or as a result of disease affects the elimination of many drugs (see Chapter 87). A large number of commonly used drugs of all classes including aminophylline preparations, narcotics, barbiturates, H_2-blockers, vasodilators, antidysrhythmics, and others demonstrate significant hepatic elimination. The hepatic P-450 system plays a central role in many of the mixed-function oxidative reactions responsible for converting lipophilic compounds into more water-soluble ones. In addition, the liver may conjugate drug metabolites to form products that can be eliminated easier in bile or through the kidney. The half-life of many drugs may be prolonged during hepatic insufficiency as a result of a decrease in the total number of functioning hepatocytes. In addition, the half-life of many drugs may be prolonged through competitive inhibition by the presence of other drugs, or may be shortened by induction of elimination reactions. For example, phenobarbital decreases the half-life of xanthines and may increase the toxicity of acetaminophen. Adjustment of medication dosage and schedule must be considered for those drugs with significant hepatic elimination when impaired liver function exists.[93]

Hepatic regulatory function involves (1) interconversion of amino acids to maintain physiological plasma levels, (2) gluconeogenesis to maintain adequate glucose serum levels for glucose-dependent tissues, and (3) regulation of numerous plasma hormones (Box 85-4).

The direct secretion of insulin and glucagon into the portal circulation exposes the liver to much higher concentrations of these hormones than peripheral tissues. This relationship amplifies the hepatic influence over carbohydrate metabolism. Approximately 50% of secreted insulin and a large portion of glucagon are degraded on a first-pass basis by the liver. Both of these hormones are known to have hepatotrophic effects and are thought to be important for differentiation and regeneration of hepatocytes. Intensive insulin therapy in the critical care setting has been shown to have a beneficial effect on liver function.[94]

The last category of hepatic function involves storage of glycogen, triglycerides, folic acid, vitamin B_{12}, and vitamins A and D. The liver uses glycogenolysis to mobilize hepatic glycogen stores and provide an almost immediate source of glucose to maintain serum levels. The liver glycogen stores contain up

to a 2-day supply of glucose.[95] Synthesis of vitamin D_3 (cholecalciferol) occurs in the skin with subsequent accumulation of D_3 in the liver. Hydroxylation at the 25-position that occurs in the liver results in a large pool of circulating 25-(OH)D_3, the precursor of the active 1,25-(di OH)D_3. Defective storage and absorption of dietary vitamin D and 25-hydroxylation may be present in chronic liver failure.[96]

Host-Defense Mechanisms of the Gut: Immunology and Microbiology

Both the intestine and the hepatic-based macrophages can serve as a major source of nitric oxide following injury or stimulation.[97] The recently recognized role of nitric oxide on immune function further emphasizes the role of the gastrointestinal tract in systemic responses. The frequent association of hepatic dysfunction with the acute respiratory distress syndrome has led to intensive investigation of the lung-liver axis during critical illness.[98-100] A major unifying theme in these organ interactions is the regional activation of macrophages and platelets and damage to the endothelium after injury leading to both localized and remote organ function disturbance. The gut has become one of the important focuses in our evolving understanding of the syndrome of multiple organ dysfunction.[101]

Numerous mechanisms exist to maintain homeostasis within the gut. These include exclusion by mucosal barrier, phagocytosis and clearing of translocating bacteria and macromolecules, immunologic tolerance to ubiquitous antigens, and coordinated self-limited inflammatory responses leading to clearance of antigens while limiting tissue injury.

Innate mechanisms exist to prevent infection by bacterial pathogens. In the upper GI tract, action of salivary enzymes, gastric acid, pancreatic enzymes, and the detergent effect of bile acids all act to limit the amount of viable bacteria in the small intestine. The secreted mucous layer preventing attachment and adherence of bacteria combined with intestinal peristalsis continually prevents establishment of infection. In the colon, with its heavy colonization of bacteria, competitive inhibition acts to prevent infection with pathogenic species. Other innate mechanisms include tight junctions between intestinal epithelial cells that act to exclude bacteria, antigens and other macromolecules.[102] *Clostridium difficile* toxin and enteropathogenic *E. coli* act by disrupting these tight junctions.[103,104] Antibiotics profoundly reduce the number of anaerobic and coliform bacteria in the alimentary tract with particular reduction of *Bifidobacterium* and *Lactobacillus* species.[105] Routine stress ulcer prophylaxis with acid suppressing medications such as H_2 blockers and PPIs create a risk of nosocomial pneumonia due to loss of protective gastric acid. However, a recent meta-analysis and systematic review failed to show a significant association between PPI use and respiratory infections.[106] Intestinal motility is a critical factor for clearing antigens and bacteria from the gut lumen and thus reducing bacterial overgrowth with its resultant malabsorption of nutrients. Decreased motility leading to bacterial overgrowth may be seen in premature infants and may be associated with many disorders seen in older children, including the use of narcotics and some neuromuscular blockers (e.g., pancuronium bromide).

A physical barrier composed of mucin and the glycocalyx is formed over the intestinal epithelium by secretions from the goblet cells. It forms a gel that can change from a semisolid to a semifluid state under varying intraluminal conditions and thus provides either a relatively impervious barrier protecting the epithelium from osmolar forces or a fluid medium helping to propel bacteria and antigens aborally.[1]

Mucosal blood flow appears to be an important mechanism for maintaining mucosal integrity in both the stomach and the small intestine. Inadequate microcirculation in the gastric mucosa, that provides cytoprotection, appears to be a major factor contributing to stress ulceration in critically ill patients. As submucosal and mucosal blood flow diminishes, the buffering ability for acid that back diffuses into the tissues is reduced and leads to tissue necrosis. Hypoxia, hypotension, and states of high circulating catecholamines are commonly associated with altered mucosal circulation and stress ulceration.[107] Finally, the small intestine, especially the terminal ileum, of newborns and infants is more sensitive to hypoxia and ischemia than that of adults, predisposing them to mucosal injury and necrotizing enterocolitis.[108]

Bacterial translocation is defined as the migration of bacteria or bacterial products from the intestinal lumen to mesenteric lymph nodes or other extraintestinal organs, representing a disruption of the normal host flora equilibrium that leads to a self-perpetuating inflammatory response and ultimately to infection. This process is increasingly being recognized as potential source of pathogens producing bacteremia and sepsis in a variety of premorbid disease conditions such as cirrhosis and prematurity.[109,110] Translocation may occur directly through the M cells that cover the Peyer's patches or it may occur by ingestion of viable pathogenic material by the mobile phagocytic system with transport into the host bypassing the previously outlined barrier mechanisms. The three main mechanisms predisposing a host to bacterial translocation are (1) disruption of the ecological equilibrium allowing intestinal bacterial overgrowth, (2) deficiencies in the host immune

defenses, and (3) damage to the intestinal mucosa vasculature that causes increased permeability.[111] Certain aerobic enteric bacteria including *E. coli, Proteus mirabilis*, and *Klebsiella pneumoniae* appear to be more commonly associated with translocation from the gastrointestinal tract, presumably because oxygen in the blood may exert an inhibitory effect on anaerobic organisms. Intra-abdominal inflammatory foci are susceptible to invasion by translocating bacteria, suggesting one mechanism for abdominal abscess formation.[112] Some studies have demonstrated that administration of glutamine improves the prognosis of critically ill patients by maintaining the physiologic intestinal barrier and by reducing frequency of infection.[113]

Of central importance to the immune function of the gut are the gut-associated lymphoid tissues consisting of Peyer patches and single lymphoid nodules of the intestinal mucosa and appendix. In addition to mounting protective responses to invading microbial pathogens and detecting and eliminating neoplastic cells, the mucosal immune response has two unique characteristics: secretion of antibodies that complex antigen in the lumen without activating complement and induction of tolerogenic T lymphocytes that maintain controlled local responses to commensal bacteria or dietary constituents with no systemic reactions (oral tolerance).[102]

Peyer patches consist of mononuclear cells, plasma cells, macrophages and other antigen-presenting cells. B cells are the predominant lymphocyte. Peyer patches are covered by a specialized epithelium containing M cells, that transport luminal antigen into the patches. Migration of lymphocytes from one compartment to another provides communication of immunological information. In addition, migration of lymphocytes to extraintestinal tissues including the mammary gland, female genital tract, and bronchus-associated lymphoid tissue may mediate immune responses in those tissues. Penetration of the mucosal barrier by antigenic material occurs because the epithelial barrier is not totally impermeable to macromolecules. It may be accelerated by inflammation or mucosal damage. Increased permeability and tissue damage occur with such diverse disease entities as infectious enterocolitides, idiopathic inflammatory bowel diseases, hypersensitivity diseases such as celiac sprue and food allergies, and gut ischemia or hypoxia. As barrier mechanisms fail in the injured gut, bacterial penetration is more likely to occur, producing portal and systemic bacteremia. Cell-mediated cytotoxic reactions and antibody-dependent, cell-mediated cytotoxicity represent two responses of the gut-associated lymphoid tissues to encounters with antigens. These processes involve the cooperative interaction of other lymphoid cells such as killer, lymphokine-activated killer, and natural killer cells. Infected or necrotic cells and noncellular antigenic material are targeted for ultimate lysis by phagocytic cells in the circulation and reticuloendothelial system.

Kupffer cells, which account for the largest pool of mononuclear phagocytes with direct access to the blood, play a major role in clearing portal bacteria. In addition, Kupffer cells are key participants in response to tissue injury or organ invasion through the elaboration of cytokine mediators, such as tumor necrosis factor and interleukin-1, and the release of nitric oxide, leading to many of the systemic responses seen in sepsis.[97] Through their intimate proximity to the hepatocyte, Kupffer cells interact directly with hepatocytes by means of cell-cell and paracrine interactions. In response to tumor necrosis factor and interleukin-1, well-documented alterations in hepatic function occur including the inhibition of albumin synthesis, gluconeogenesis, and P-450-mediated detoxification. Acute-phase reactant synthesis is also induced by tumor necrosis factor and interleukin-1.[114]

Gastrointestinal and Hepatobiliary Testing in the Intensive Care Unit

Diagnostic testing in the ICU permits the identification of organ system injury and dysfunction and assists in monitoring the course of a disease as well as response to therapies. Laboratory testing is helpful in detecting and monitoring hepatocellular injury and dysfunction. In the ICU setting, impaired synthetic function is the hallmark of liver failure. This is of more immediate concern than hepatocellular injury alone. Decreased synthesis of the liver dependent clotting factors I (fibrinogen), II (prothrombin), V, VII, IX and X, results in a prolonged prothrombin time. In the absence of vitamin K deficiency or related inhibitors, this represents liver failure. Because factor VII has the shortest half-life shortest half-life (2 to 6 hours) compared to the other factors, it acts as the rate-limiting step for conversion of prothrombin to thrombin. The use of recombinant activated factor VII in acute liver failure remains under debate.[91] Other less specific measures of liver dysfunction include increased bilirubin, decreased serum albumin and decreased prealbumin.

Liver failure may also be associated with life-threatening hypoglycemia from a variety of mechanisms including decreased hepatic glycogenolysis, gluconeogenesis and release of glucose, hyperinsulinemia from impaired hepatic degradation, and increased glucose utilization secondary to anaerobic metabolism. A frequent finding in advanced liver failure is elevated serum ammonia reflecting impaired ureagenesis and/or other ammonia clearance mechanisms. Ammonia elevation results from urea cycle defects, portal systemic shunting, and events such as large gastrointestinal bleeds that generate substrate for increased ammonia production by enteric bacteria. In the setting of impaired liver function, this leads to hyperammonemia.[115]

Liver disease can be broadly categorized into hepatocellular, cholestatic, and infiltrative processes. The biochemical tests commonly used to detect cholestasis, which is impaired bile flow, and hepatocellular injury are serum bilirubin and aminotransferase activities (alanine transaminase [ALT], aspartate transaminase [AST]). Cholestasis, reduced bile excretion or transport, and biliary obstruction in the bile canaliculi or large ducts are represented by elevations in serum conjugated bilirubin, bile acids, alkaline phosphatase (ALK), γ-glutamyltransferase (GGT), or 5′-nucleotidase.

The van den Bergh reaction assesses conjugated (direct fraction) bilirubin levels. The unconjugated (indirect) fraction represents the difference between the total bilirubin and the direct fraction. Elevated levels of predominantly indirect bilirubin result from (1) increased bilirubin load to the liver (e.g., hemolysis); (2) diminished uptake and intracellular transport; and (3) reduced conjugation (e.g., immaturity, fulminant necrosis).

In children, elevations in ALK may be seen with rickets or during periods of rapid skeletal growth. Isoenzymes may distinguish between liver or bony sources. ALT and AST are

hepatic cytosolic enzymes that catalyze the reversible transfer of the α-amino group of the amino acids alanine and glutamate producing pyruvic and oxaloacetic acids respectively. Elevations in serum activities of ALT and AST suggest hepatocellular injury (see Table 85-3). AST is also present in myocardial tissue, skeletal muscle, kidney, pancreas and erythrocytes. Therefore increased serum AST is not specific for hepatocellular injury. Alanine transaminase is present in only relatively low concentrations in tissues other than liver, thus providing greater specificity for hepatocellular injury than AST. Falling levels of AST and ALT in the setting of rising levels of conjugated bilirubin represent worsening destruction of hepatocytes suggesting liver dysfunction rather than recovery. Elevated serum lactate dehydrogenase activity lacks specificity and may be seen in association with hepatocellular injury, hemolysis and myopathy; however, when in association with elevated serum creatinine phosphokinase or aldolase indicates myopathy or a rhabdomyolysis injury.

Imaging of the hepatobiliary system has become easier, safer, and more reliable in the last decade. Ultrasonography is particularly useful in the ICU and allows rapid, safe, bedside evaluation of (1) hepatic vascular structures and patterns of blood flow; (2) structural abnormalities such as tumors, abscess, hematoma, or dilated intrahepatic bile ducts; (3) the gallbladder, extrahepatic, pancreatic and common biliary system; (4) the pancreas; (5) the genitourinary system; and (6) the abdomen and retroperitoneum. In addition, ultrasound can provide guidance for therapeutic interventions such as drainage of abscesses.

Computed tomographic scan with and without contrast and magnetic resonance imaging provide additional methods for evaluating the abdominal and retroperitoneal organs for masses, abscesses, and fluid collections. A downside to both modalities is that they usually require a prolonged period away from the ICU, which may lead to instability in a tenuous, critically ill patient.

Many of the radioisotope studies can be performed in the ICU and provide a wide range of diagnostic possibilities in critically ill patients. Technetium-99m (^{99m}Tc) iminodiacetic acid compounds are handled by the hepatobiliary system much like bilirubin and provide a qualitative and semiquantitative image of function and structure. These compounds may be used diagnostically to evaluate infants with persistent jaundice and also used in follow-up after Kasai procedure or liver transplantation.

Of the available biochemical markers of pancreatic disease, serum amylase and lipase determinations are the most widely available. Serum lipase is elevated in about 87% of patients with acute pancreatitis and demonstrates fewer false-positive results than amylase testing. Transient hypocalcemia

Table 85–4 Diagnosis of Selected Hepatobiliary Disorders

Form of Liver Injury	Supportive History/Laboratory Data
PREDOMINANTLY HEPATOCELLULAR	
Viral hepatitis	Viral serologies: hepatitis A, B, C, E; Epstein-Barr virus; cytomegalovirus, varicella zoster virus, herpes simplex virus
Drug-induced hepatitis	History of toxic/excess ingestion ± elevated eosinophil count
Ischemia	Shock, status post–cardiac surgery
Autoimmune hepatitis	Increased globulin ratio, antinuclear antibody, anti–smooth muscle antibody, anti-liver kidney microsomal antibody
Wilson disease	Serum ceruloplasmin, 24-hour urine copper
α-Antitrypsin deficiency	α_1 antitrypsin phenotyping
CHOLESTATIC	
Bacterial sepsis	*Proteus*, *E. coli* urinary tract infection
Galactosemia	Urine-reducing substances, *E. coli* sepsis, red blood cell galactose-1-phosphate uridyltransferase
Tyrosinemia	Urine succinylacetone
Biliary atresia	Intraoperative cholangiogram
Anatomic anomalies: choledochal cysts, biliary stricture, cholelithiasis, congenital hepatic fibrosis, Caroli disease	Ultrasonography, cholangiogram
Alagille syndrome	Butterfly vertebrae, posterior embryotoxon on eye exam, echocardiogram
Cystic fibrosis	Sweat test, genetic testing
Graft-versus-host disease, venoocclusive disease	History of bone marrow transplant, high-dose busulfan
Ischemia	Extracorporeal membrane oxygenation
INFILTRATIVE	
Hepatocellular carcinoma, hepatoblastoma	α-Feto protein
PREDOMINANTLY COAGULOPATHIC	
Neonatal hematochromatosis	Serum iron and ferritin

(<8.0 mg/dL) occurs in about 30% of patients with pancreatitis. Mild to moderate hyperglycemia as a result of islet cell damage is seen in up to 25% of cases, often necessitating the administration of exogenous insulin.

Evaluation of the alimentary tract consists of examining gastric aspirates and stool samples for gross bleeding or occult blood with the guaiac test (Hemoccult). A positive result mandates further evaluation and surveillance to determine the source and severity of gastrointestinal tract blood loss. Nasogastric lavage may be used to distinguish a source of bleeding as being proximal or distal to the pylorus. ^{99m}Tc sulfur colloid or red blood cells labeled with ^{99m}Tc may provide information regarding the site of active mucosal bleeding and are less invasive than arteriography.

Esophageal pH monitoring is useful for evaluating the efficacy of antisecretory therapy. It may be useful to correlate symptoms (e.g., cough, chest pain) with acid reflux episodes and to select those infants and children with wheezing or respiratory symptoms in whom gastroesophageal reflux is an aggravating factor. The sensitivity, specificity, and clinical utility of pH monitoring for diagnosis and management of possible extraesophageal complications of gastroesophageal reflux are not well established.[116]

Imaging studies are of primary importance in acutely ill patients in a number of circumstances. Plain radiographs can be reliably used to locate radiopaque objects, to diagnose intestinal ileus, mechanical obstruction and perforated viscus. Contrast studies are required to diagnose organ and soft-tissue inflammation including appendicitis, pancreatitis and its complications, mesenteric and retroperitoneal masses, abscesses/fluid collections, intussusceptions, and anatomical anomalies.

GI bleeding from sites distal to the ligament of Treitz and proximal to the terminal ileum that are inaccessible to video endoscopy (e.g., Meckel diverticulum, vascular malformations, altered anatomy post-GI surgery) are best assessed using radio nuclide scans and angiography. Because of the need to perform the more sophisticated imaging studies away from the controlled environment of the ICU, the studies must be tailored to the patient's diagnostic needs according to the priorities of the initial stabilization of life-threatening illness and subsequent treatment of the underlying pathologic condition.

Video and or fiberoptic endoscopy in the hands of operators skilled in managing small children has found a place in ICU management to (1) diagnose the source of upper gastrointestinal tract bleeding, (2) to control and sclerose bleeding varices, (3) to place percutaneous gastrostomy tubes for feeding, and (4) for the placement of stents to maintain patency of the distal biliary and pancreatic tract.

See Table 85-4 for suggested diagnosis tests for selected hepatobiliary disorders.

Disorders and Diseases of the Gastrointestinal Tract and Liver

Scottie B. Day and Samuel A. Kocoshis

PEARLS

- So much reliance is placed on electronic monitoring of patients that physicians are often tempted to perform only a cursory examination or go days without laying hands on the patient. Regrettably, adopting such an approach deprives the clinician of an adequate perspective on the patient's day-to-day condition and deprives the patient of optimal care.
- When compared with a scintiscan of the lungs after administration of a radiolabeled meal or with the discovery of lipid-laden macrophages after bronchoalveolar lavage, the use of colorants is notoriously inaccurate.
- Several antireflux barriers exist in the region of the lower esophageal sphincter. Beyond intrinsic myogenic tone, barriers such as the cardioesophageal angle, the abdominal esophagus (which acts as flutter valve), the mucosal rosette of the sphincter (which acts as a choke valve), and the diaphragmatic crura themselves act to prevent reflux of gastric contents.
- The association between *Helicobacter pylori* infection and both chronic gastritis and duodenal ulcer is well established, but the role of *H. pylori* in the pathogenesis of gastric ulceration remains somewhat speculative.
- Intravenous administration of somatostatin or its synthetic analogue, the active octreotide moiety, has been effective in stemming variceal hemorrhage and may work for other causes of bleeding. In addition to their hemodynamic effects, they inhibit gastric acid production.
- Crohn's disease and ulcerative colitis are chronic, relapsing disorders without known causes. The transmural inflammation of Crohn's disease may affect any portion of the alimentary tract in a patchy distribution, whereas the inflammation of ulcerative colitis is confined to the mucosa of the colon.
- The diagnosis of necrotizing enterocolitis may be confirmed by an abdominal plain film showing pneumatosis intestinalis, hepatic portal air, or both. A random breath hydrogen/carbon dioxide ratio greater than 8 ppm/mm Hg strongly suggests the diagnosis. Because the pathogenesis is unknown, treatment must be symptomatic. In most centers, feedings are discontinued for 48 hours to 2 weeks depending on the severity of symptoms. Fluid resuscitation and broad-spectrum parenteral antibiotics are the basis of medical therapy. Surgical resection is reserved for severe cases when medical management fails and gangrenous bowel develops.
- Abdominal compartment hypertension and sydrome are two distinct entities becoming increasingly recognized in the intensive care setting. Prompt recognition of clinical symptoms and signs may prevent vital organ compromise.

Gastrointestinal Evaluation of the Critically Ill Child

Dramatic advances in pediatric critical care have resulted in improved outcomes for children admitted to pediatric intensive care units (PICUs). Indeed, the improved technology available today has resulted in improved management strategies for a variety of conditions. So much reliance is placed on electronic monitoring of patients that physicians are often tempted to perform only a cursory examination or go days without laying hands on the patient. Regrettably, adopting such an approach deprives the clinician of an adequate perspective on the patient's day-to-day condition and deprives the patient of optimal care. Daily physical examination is of paramount importance in the assessment of children with either life-threatening gastrointestinal disease or gastrointestinal manifestations of multisystem disease. The current approach to gastroenterologic diagnosis and therapy as well as principles of gastroenterologic physical examination are therefore reviewed in this chapter.

Abdominal Examination

Astute clinicians recognize that the abdomen extends from "the neck to the knees." A thorough examination of the head, neck, and chest is essential when patients with abdominal symptoms are evaluated. For example, pneumonia may be discovered by chest auscultation in the child who has abdominal pain. All too often, a child whose abdominal symptoms are due to pneumonia undergoes exploratory laparotomy for a purportedly "surgical" abdomen.

The abdominal examination, which can be difficult to perform on young children without life-threatening illness, is made more difficult in the ICU setting. Pain and fear limit cooperation. Patients who are obtunded by narcotics, sedatives, or an underlying central nervous system (CNS) disorder display inconsistent responses to abdominal palpation. Neuromuscular blockade abolishes abdominal guarding. Children

with multisystem trauma may not localize pain. These impediments notwithstanding, the observant clinician can glean a great deal of information from a carefully performed examination. Simple inspection of the child's abdomen can reveal generalized distention; abnormally prominent abdominal wall veins (which signify portal hypertension); or anterior and lateral abdominal wall ecchymoses, such as Cullen's sign or Grey Turner's sign (which herald acute pancreatitis). In addition, because of the child's relatively undeveloped abdominal musculature, visceromegaly or abdominal masses may be apparent on inspection.

Auscultation will ascertain the frequency and quality of peristaltic sounds. They normally occur every 10 to 30 seconds and are low pitched. High-pitched, frequent bowel sounds suggest enteritis or obstruction. In obstruction, bowel sounds characteristically reverberate and seem to originate "from a deep well." Bowel sounds are absent in paralytic ileus or peritonitis. Ancillary findings include venous hums, which suggest portal obstruction, or bruits that may denote arteriovenous malformations.

In pediatric patients, palpation should generally precede percussion because it is less threatening. The child should be in the supine position, and when possible the hips and knees should be comfortably flexed to enhance abdominal wall relaxation. The abdomen should be palpated through all phases of respiration in all four quadrants. The examiner should lightly palpate to judge guarding and tenderness and should use gentle ballottement. Deeper palpation better localizes organomegaly or masses.

Percussion permits estimation of visceral size and helps to diagnose obstruction, peritonitis, or ascites. Excessive tympany implies that bowel loops are distended with air, whereas dullness suggests that excessive fluid or a solid mass is present. Shifting dullness is relatively easy to detect in cooperative children with percussion of the abdomen with the child in the supine, left lateral, and right lateral positions. When the child with ascites is in the supine position, dullness is found primarily over the flanks. The dullness moves to a new level nearer the midline when the child is moved to each lateral position. It is essential to perform a digital examination of the rectum in children with gastrointestinal dysfunction. Inspection of the perineum may reveal perianal or perirectal abscesses, which may be the first sign of acute leukemia, chronic granulomatous disease of childhood, or Crohn's disease. Similarly, deep fissures or sentinel piles suggest ulcerative colitis or Crohn's disease, and hemorrhoids can be found in portal hypertension. The digital examination should be performed in the alert, older child only after its purpose is explained. Any material that returns on the examining finger should be evaluated for occult blood. Absence of stool in the vault can corroborate Hirschsprung's disease in an infant with abdominal distention and a history of obstipation. Rectal masses related to pelvic abscesses or tumors may be digitally palpated. Rectal tenderness signifies mural or extramural inflammation or infection.

Gastrointestinal Endoscopy

The development of flexible fiberoptic endoscopes appropriately sized for use in infants and children has greatly expanded the value of endoscopy in diagnosing and treating a variety of gastroenterologic disorders in critically ill pediatric patients. For example, pediatric endoscopes with an outside diameter of 5 mm can now be used for diagnostic purposes in newborn infants. Electrocautery, injection therapy, or variceal banding of gastrointestinal bleeding sites can also be performed with devices that now fit within the biopsy channels of a standard 9.4-mm pediatric endoscope. Upper gastrointestinal endoscopy (esophagogastroduodenoscopy [EGD]) is performed most often with the child under deep sedation or general anesthesia, although some clinicians report successful unsedated upper endoscopy in very young infants. Many pediatric endoscopists in North America use a combination of narcotic sedative and benzodiazepine to achieve acceptable sedation analgesia.[1] Other agents commonly used for sedation are propofol and ketamine. General anesthesia with endotracheal intubation is appropriate when the side effects of sedation or the endoscopy pose an undue risk of respiratory compromise (e.g., when underlying pulmonary disease, upper airway disease, or disorders of respiratory control are present) or if the patient is at risk for aspiration of gastric contents (e.g., when massive upper gastrointestinal hemorrhage is present or when an emergency foreign body extraction is performed on a child with a full stomach). In an ICU setting, patients supported by ventilators should receive additional sedation and neuromuscular blockade if the endoscopist anticipates that the procedure will be lengthy or excessively difficult.

Advantages of elective endotracheal intubation for EGD also include control of both the airway and ventilation during the procedure. In very small patients, the relatively large endoscope may partially obstruct the glottis. Distention of the gut with air may interfere with diaphragmatic movement. The risk of inadvertent extubation during EGD, however, mandates careful fixation of the endotracheal tube and careful monitoring of ventilation during the procedure by a physician from the critical care team.

Because bacteremia may occur during both upper and lower gastrointestinal endoscopy, some endoscopists routinely use perioperative antibiotics for endoscopy in patients with a central venous line or ventriculoperitoneal shunt. In recent years, therapeutic endoscopy has complemented diagnostic endoscopy. Gastrointestinal tract hemorrhage from varices, peptic ulceration, and angiodysplasia may be controlled by injection therapy or photocoagulation, electrocoagulation, and thermocoagulation. Band ligation of esophageal varices is also a proven therapy for variceal hemorrhage. Percutaneous endoscopic gastrostomy has become a popular alternative to surgical gastrostomy for patients in the ICU who cannot take oral alimentation on a long-term basis.

The diagnosis and treatment of oropharyngeal dysphagia can be difficult but is improved with the use of fiberoptic endoscopic evaluation of swallowing (FEES). The endoscope can be passed transnasally to visualize both laryngeal and pharyngeal structures. Both the structure and functioning of the pharyngeal phase of swallowing can be evaluated by giving the patients food and liquid boluses. Sensory testing can also be conducted to elicit the laryngeal adductor reflex. Some studies have suggested a good correlation between FEES and videofluoroscopy.

Wireless video endoscopy or video capsule endoscopy (VCE) is a noninvasive technology used to provide imaging of the small intestine, an anatomic site often difficult to visualize. The images acquired are of excellent resolution and the procedure uses the principle of physiologic endoscopy via passive movement and does not inflate the bowel, so images of

the mucosa are captured in a collapsed state. Primary indications include the diagnosis of obscure gastrointestinal bleeding, small bowel tumors, or Crohn's disease. There is growing experience in the use of this technology for children older than 6 years. Advantages include its noninvasive nature and the ability to examine the small bowel mucosa, which is not possible with push enteroscopy. Disadvantages include the impossibility of any tissue sampling or therapeutic intervention. However, studies have suggested that the overall yield of VCE is superior to push enteroscopy and barium studies.[2-4]

Gastroesophageal Reflux Monitoring

Like gastrointestinal endoscopy, esophageal reflux monitoring has benefited from technical advances that permit insertion of miniature, flexible electrodes into the esophagus of the smallest children.

Esophageal pH monitoring has been in use since the late 1970s. Esophageal pH is continuously recorded for 24 hours, and the duration of esophageal acidification, defined as decreases in pH less than 4, is quantified. Additional variables including the quantity of reflux in the 2 hours after a feeding and during fasting are determined. Detection of alkaline reflux episodes, which commonly occur in the postprandial period when food buffers gastric acid, is not possible with this technique. The administration of apple juice (pH < 4) rather than formula for feedings during the monitored period has been proposed to circumvent this limitation; however, it is an imperfect strategy insofar as normative data are scarce for older children whose esophageal pH is measured during apple juice feedings. Furthermore, the technique is unreliable for children who have been maintained with histamine-2 (H_2) antagonists or proton pump inhibitors. For reliable pH monitoring of such children, proton pump inhibitors must have been discontinued for at least 72 hours and H_2 antagonists for at least 48 hours. Critical care physicians may not have the luxury of stopping these agents temporarily in critically ill patients who are at risk for stress ulceration of the gastrointestinal tract.

Esophageal impedance monitoring[5] is the preferred means of measuring gastroesophageal reflux among patients who are receiving acid suppression or in whom alkaline reflux is suspected. The intraesophageal impedance device measures total opposition to current flow between two electrodes and expresses the value in ohms. Because air and fluid have different conductivities, the contents of the esophagus can be differentiated at any point in time. Thus when the esophagus is devoid of fluid, a baseline impedance is measured. When a bolus of fluid enters the esophagus from refluxed material or from a swallowed bolus, the impedance changes. These changes in intraluminal impedance thus permit the continuous monitoring of pH neutral or alkaline reflux episodes.

In addition to detecting pathologic quantities of reflux in children who have symptoms suggestive of reflux disease, reflux monitoring is also useful in determining whether a temporal correlation exists between gastroesophageal reflux and pathologic events such as cough, bronchospasm, or apnea. Because it does not determine the cause of vomiting, reflux monitoring adds little to the evaluation of vomiting children.

For the ambulatory child capable of undergoing an endoscopy, a small pH transducer capsule can be deployed and attached to the esophagus, being left in place to monitor esophageal acidification for up to 48 hours with an external sensor before being naturally sloughed. The advantage of this device is that nasoesophageal intubation need not be performed, thereby creating a more "natural" environment. For the critically ill, intubated patient, this device is impractical to place and offers no advantage over traditional reflux monitoring.[6,7]

Use of Colorants to Identify Aspiration in the Intensive Care Unit

Patients who are obtunded or who have been ventilator dependent for an extended time are at significant risk of pulmonary aspiration. A deceptively simple way of documenting aspiration in patients receiving gavage or gastrostomy feedings in the past has been to add a coloring agent such as blue dye No. 1 or methylene blue to formula. The rationale for this strategy was that quantities sufficient to tint formula should be readily apparent when suctioned from the lungs. The fallacy of the technique is that when compared with scintiscanning of the lungs after administration of a radiolabeled meal or with the discovery of lipid-laden macrophages after bronchoalveolar lavage, the use of colorants is notoriously inaccurate. Furthermore, all colorants are dangerous when instilled into the gastrointestinal tract. They are customarily absorbed in minimal quantities, but among critically ill patients, the gastrointestinal tract becomes porous to all macromolecules and appreciable quantities of dye are absorbed. Once absorbed, even minimal quantities function as metabolic poisons, uncoupling oxidative metabolism, thereby resulting in life-threatening metabolic acidosis among susceptible patients.[8]

Radiologic Procedures

Plain Films

The abdominal x-ray film provides valuable assistance to the clinician evaluating children with abdominal distention, guarding, or tenderness. Dilated, gas-filled bowel loops, with or without air-fluid levels, can signify obstruction or ileus. Air-fluid levels in a "stepladder" configuration along the length of small bowel suggest obstruction, whereas levels that appear in a parallel configuration suggest ileus. Pneumatosis intestinalis and mucosal "thumbprinting" are signs of bowel wall ischemia and can often be appreciated on the plain film. Pneumoperitoneum can be evaluated with the inspection for air in the lesser sack, air between bowel loops, or a visible falciform ligament. Even though an upright film is optimal for visualizing peritoneal air, lateral decubitus or cross-table lateral films are acceptable substitutes in bedridden patients. Air in an abscess cavity or air in liver parenchyma, biliary tree, or portal venous system should be acknowledged as signs of serious intraabdominal infection.

Abnormal densities such as abdominal masses, ascites, or calcifications can often be identified on plain films. Calcifications in the region of the gallbladder, pancreas, or appendix suggest cholelithiasis, pancreatitis, or appendicitis, respectively. The abdominal contour and the contour of extraperitoneal structures such as lung bases, pelvic organs, and kidneys should always be assessed.

Contrast Radiography

Although endoscopy is more sensitive than single-contrast radiography for identifying mucosal ulceration, contrast radiography remains a valuable procedure in the critical care

setting. In general, the upper gastrointestinal tract series and small bowel series are indicated when partial small bowel obstruction is suspected. A contrast enema will document (and possibly treat) intussusception and document Hirschsprung's disease. The type of contrast agent for a particular examination depends on the clinical condition of the patient undergoing the examination. Although barium sulfate is superior to water-soluble contrast agents for outlining mucosa, its use in typical patients in the ICU is riskier because barium may form a concretion in a patient with ileus and because barium leaking into the peritoneum from a perforated hollow viscus can cause serious peritoneal injury. Hyperosmolar, water-soluble contrast agents are usually not favored because they pose the risk of dehydration. Currently, isosmolar agents are more commonly used for studies on the critically ill patient.

Ultrasonography, Computed Tomographic Scanning, and Magnetic Resonance Scanning

Ultrasonography, computed tomographic (CT) scanning, and magnetic resonance imaging (MRI) each have advantages and disadvantages. For example, in the slim child with little mesenteric fat, ultrasonography is sometimes better than CT scanning of abdominal viscera. Conversely, CT scanning is superior for abdominal imaging of obese individuals.[9] MRI is limited by its inability to distinguish bowel loops from adjacent structures and by blurring caused by motion. It is helpful, though, in identifying vascular tumors, which are seen as low-intensity masses on T1-weighted images and high-intensity masses on T2-weighted images. Ultrasonography or CT is used when an intraabdominal abscess, cystic lesion, hepatobiliary disease, tumor, ascites, or pancreatitis is suspected. In the identification of pancreatic lesions, dynamic CT scanning is a most imaging technique. CT also best identifies enlarged periaortic nodes. CT or MR enterography are other modalities used in the detection of small bowel inflammatory disease. Oral hyperhydration can achieve adequate luminal distension often not requiring nasoenteric intubation. Unlike routine CT or MRI, enterography can display mural changes along with perienteric inflammatory changes with much better resolution. These studies are more accurate than the standard small bowel follow-through or enteroclysis.[10-13]

Ultrasonography of the liver and biliary tract identifies hepatic parenchymal disease, biliary stones, or congenital abnormalities such as choledochal cyst. Intussusception, pyloric stenosis, and acute appendicitis are particularly amenable to ultrasonographic diagnosis. In addition, Doppler flow analysis has significantly aided the preoperative and postoperative evaluation of liver transplant recipients by identifying congenital vascular anomalies and postoperative vascular thromboses.

Radionuclide Scanning

Radionuclide scanning is helpful when patients in the ICU have pulmonary aspiration, gastrointestinal bleeding, intraabdominal abscesses, or cholestasis.

Gastroesophageal reflux and the rate of gastric emptying can be measured with liquid-phase gastroesophageal scintigraphy.[14] Technetium-99 sulfur colloid is mixed with formula or another enterally administered liquid. When there is a scan above and below the diaphragm in 30- to 60-second windows during the first postprandial hour after isotope administration, the number of reflux episodes, the height of the reflux column, and the rate of gastric emptying are quantitated. A 4- to 6-hour delayed scan of the lungs determines whether pulmonary aspiration of that meal has occurred.[15]

Three techniques are used to aid in the diagnosis of gastrointestinal bleeding. ^{99}Tc sulfur colloid and ^{99}Tc-labeled red cells are used in patients with continuous or intermittent bleeding. The advantage of sulfur colloid is that less than 0.1 mL of blood per minute will be shown. Bleeding in a spot near the liver or spleen, however, may be obscured by high levels of activity in those organs. Tagged red blood cell scans detect intermittent bleeding by means of delayed scans, but migration of blood down the gastrointestinal tract over time may preclude exact localization. ^{99}Tc pertechnetate scanning does not require active bleeding to localize a Meckel's diverticulum. Isotope is concentrated by gastric mucosa, and if a scan reveals an ectopic focus a Meckel's diverticulum can be suspected. Scan results are negative in the 15% of diverticula not containing gastric mucosa. A variety of non-Meckel's lesions (most of which require surgical correction) cause false-positive results on pertechnetate scans. The sensitivity of the scan can be increased when acid suppression is given prior to scanning.

Resolution of hepatobiliary scans has improved dramatically since the introduction of derivatives of ^{99}Tc iminodiacetic acid. Scanning can now document cholecystitis when there is no gallbladder uptake or biliary obstruction when there is no excretion into the bowel. Other entities such as biliary leaks or cystic lesions of the biliary tree can also be documented. Furthermore, delayed or reduced hepatocyte uptake can confirm impaired hepatocellular function.

Intraabdominal abscesses and inflammatory intestinal lesions can be localized with radioscintigraphy.[16] Leukocytes are extracted from the patient, tagged with a radioisotope in vitro, and are reinjected. Scanning of the area in question is then performed. Technetium hexamethyl propyleneamine oxime (HMPAO) has replaced indium because of improved resolution of HMPAO scans and because HMPAO scans can be completed within 4 hours rather than 72 hours.

Testing for Occult Blood Loss

Occult blood loss is generally determined with the Hemoccult or Gastroccult test; these are modifications of the guaiac test.[17,18] They work because hemoglobin oxidizes the reagent to a blue product. The recently marketed Hemoccult Sensa (Beckman Coulter, Inc., Brea, Calif.) slide detects as little as 2 to 3 mL of blood loss per day. This slide is virtually 100% sensitive when blood loss equals 10 mL/day.[8]

In the stomach, blood can be denatured, and this can lead to false-negative results. Gastroccult, which contains borate-buffered reagent, significantly improves the sensitivity for testing gastric contents. (Urine test tapes should never be used for gastrointestinal occult blood testing because they are too sensitive.) Therefore even physiologic quantities of enteric blood loss (<1 mL of blood per day) will yield positive results.

Stool pH and Reducing Substances

Excessive enteral carbohydrate loads may worsen preexisting diarrhea in critically ill children. Carbohydrate malabsorption can be assessed with the measurement of reducing sugars

and pH of stool. The two tests should always be used in conjunction because colonic transit time and quantity or type of colonic flora affect either of these tests. Malabsorbed sugars appear in feces when colonic transit is sufficiently rapid and are detected by Clinitest tablets or reagent strips; more than 0.5 mg of sugar per 100 mL of stool water suggests malabsorption. If the malabsorbed dietary sugar is primarily sucrose, a nonreducing sugar, the Clinitest result is negative unless the stool is first hydrolyzed with hydrochloric acid. Stools can be negative for reducing sugars despite carbohydrate malabsorption if colonic transit is slow enough to permit complete bacterial fermentation. In such an event, pH of fresh stool (measured by nitrazine paper) is consistently below 5.5. The pH of samples not tested for several hours, however, tends to rise over time as short-chain fatty acids generated from sugar fermentation are further metabolized.

The Intensive Care Unit as a Satellite Laboratory Facility

Regulations of the Joint Commission on Hospital Accreditation prohibit testing for occult blood loss or stool testing by anyone other than an individual certified in accordance with the Clinical Laboratory Improvement Act (CLIA). Thus for many pediatric critical care units, "bedside" testing has moved from the bedside to the clinical laboratory. Turnaround time for measuring occult blood in stool has risen from seconds to hours. Furthermore, when fecal samples are sent to the clinical laboratory for measurement of reducing sugars and pH, results are meaningless insofar as bacterial metabolism of sugars continues ex vivo in these samples between the times of collection to the time of testing. Critical care units wishing to perform reliable fecal testing on site must train a cohort of staff in common bedside tests and obtain CLIA certification for each staff member. Furthermore, just as many ICUs have chosen to comply with CLIA regulations and have established approved satellite laboratory facilities, to measure blood gases or serum electrolytes, they can extend the scope of their laboratory activities to include bedside gastroenterologic testing.

Breath Hydrogen Testing

Breath hydrogen testing confirms monosaccharide or disaccharide malabsorption and small bowel bacterial overgrowth. The technique documents intestinal bacterial fermentation of carbohydrates; their byproduct is hydrogen gas. Fasting alveolar hydrogen concentrations greater than 40 ppm suggest bacterial overgrowth. A rise in concentration of 20 ppm occurring beyond 90 minutes after an enteral carbohydrate challenge suggests carbohydrate malabsorption. A peak less than 60 minutes after the challenge is consistent with bacterial overgrowth.

Because of difficulties in consistent alveolar air sampling, some investigators internally standardize by measuring both H_2 and carbon dioxide (CO_2) and expressing their results as a ratio.

Perhaps breath hydrogen testing is most valuable in the ICU as a screening test for neonatal necrotizing enterocolitis. Cheu et al.[19] showed that randomly obtained breath H_2/CO_2 ratios greater than 8 ppm/mm Hg strongly suggest necrotizing enterocolitis.

Life-Threatening Complications of Gastrointestinal Disorders

Esophagus

Congenital Esophageal Anomalies

Esophageal atresia and tracheoesophageal fistula are true neonatal emergencies. With an incidence of 1 in 3000 live births, they are among the most common congenital anomalies of the esophagus. Five anatomic varieties exist in the following descending order of frequency: (1) blind proximal esophageal pouch with distal esophagus originating at the tracheobronchial junction (80%), (2) blind proximal esophageal pouch with blind distal esophageal pouch (8%), (3) uninterrupted esophagus with H-type tracheoesophageal fistula (4%), (4) proximal esophagus fistulizing into trachea with blind distal esophageal pouch (2%), and (5) interrupted esophagus with both proximal and distal esophagus communicating with trachea (1%).

The embryogenesis of this disorder is unknown, but other cardiovascular, gastrointestinal, skeletal, or urogenital anomalies are present in 50% of cases.

Infants with a blind proximal esophagus have excessive salivation, respiratory distress, and cyanosis. Diagnosis of blind proximal esophagus can be made by the failure to pass a nasogastric tube into the stomach. Complete atresia leads to a gasless lower gastrointestinal tract. An H-type fistula is sometimes seen on contrast radiography or esophagoscopy, but bronchoscopy is usually the most sensitive diagnostic tool.

Treatment is surgical. A simple fistula can be ligated, and a short atresia can be repaired primarily. Long atresia, however, may require staged treatment with initial esophagostomy and gastrostomy and subsequent definitive repair after internal or external traction is applied. Circular myotomy of the esophagus reduces anastomotic tension. Occasionally a "gastric tube" procedure or colonic interposition is required.

Caustic Injury to the Esophagus

Despite widespread efforts by poison control centers to publicize the dangers of household caustics, thousands of inadvertent ingestions occur annually; most occur in children younger than 5 years. Crystalline products produce greater damage to the hypopharynx and upper airway because of prolonged mouth contact and a smaller volume reaching the esophagus. In recent years most household cleaners have been reformulated to contain less lye, but pure liquid lye can be purchased if desired. Its resemblance to milk leads to numerous inadvertent ingestions by children (see Chapter 106).

Tissue damage can be caused by either strong alkali or acid. Deep esophageal burns are more common after alkali ingestion. Alkalis produce rapid liquefaction of esophageal tissue, and burns can range from first to third degree in depth.[20] An intense inflammatory infiltrate develops, and blood vessels thrombose to produce ischemic necrosis. Perforation may occur within hours or days. Strictures can occur weeks to years after ingestion.[21] Esophageal burns occur infrequently after acid ingestion, but gastric or duodenal erosions have been reported.

Symptoms that predominate are chest pain and the inability to swallow secretions. Children with upper airway damage often exhibit stridor. When mouth burns are present, the chances of esophageal injury are 75%.[10] Conversely, 25% of patients with significant esophageal burns have no pharyngeal or mouth involvement.[20]

Treatment of severe stridor should be directed toward establishing an airway, and emergency tracheostomy should be contemplated. Upper endoscopy within 24 hours is advisable. If burns are minor, no further therapy is necessary, and patients are at low risk of sequelae. Third-degree burns require ongoing intensive care, though. The role of antibiotics and steroids remains controversial.[12] Although steroids reduce tissue damage when given before experimental injury, recent double-blind clinical trials show no efficacy of steroids in preventing sequelae.[22] When third-degree burns are endoscopically evident, a nasogastric tube should be positioned with endoscopic guidance. This tube will enable early feeding and serve as a guide for future dilations if they become necessary. Some surgeons have advocated early placement of gastrostomies and esophageal stents in patients with third-degree burns.[23]

Esophageal Foreign Bodies

A variety of metallic, wooden, or plastic foreign bodies in a myriad of shapes and sizes can be swallowed by children. All that are lodged in the esophagus require urgent removal (within 24 hours). Even more urgent endoscopic retrieval is required for button batteries or pennies minted after 1983 that are lodged in the esophagus because both are caustic to esophageal mucosa and may cause damage within 1 to 4 hours. The preponderance of evidence suggests that once a battery has escaped the esophagus, complications from an unretrieved battery are rare.[24]

Similarly, pennies minted after 1983 are predominantly zinc based and can be nearly as caustic within the esophagus as button batteries. No published epidemiologic studies are available on which to base the approach to zinc-based pennies within the stomach or small intestine.

Gastroesophageal Reflux

Several antireflux barriers exist in the region of the lower esophageal sphincter. Beyond intrinsic myogenic tone, barriers such as the cardioesophageal angle, the abdominal esophagus (that acts as flutter valve), the mucosal rosette of the sphincter (that acts as a choke valve), and the diaphragmatic crura themselves act to prevent reflux of gastric contents. A complex set of factors, including hormonal changes, anatomic relationships, increased or decreased sensitivity to neurotransmitters, and CNS derangements, act to produce inappropriate sphincter relaxation (usually transient), which leads to most episodes of gastroesophageal reflux. With the advent of more sophisticated otolaryngolocal procedures such as the laryngotracheoplasty and slide tracheoplasty, prevention of gastroesophageal reflux is of utmost importance to facilitate surgical healing. Some surgeons advocate the use of aggressive acid suppression postoperatively because acid-induced damage can result in significant cicatrix formation at the site of laryngotracheal surgery.

Life-threatening events such as apnea and pulmonary aspiration are sometimes attributed to reflux. The relationship between infantile apnea and reflux remains in question,[25] but both human and animal data suggest that reflux can occasionally be associated with obstructive breathing patterns. Severe pulmonary aspiration of refluxed material can also take place. A number of protective mechanisms such as an active gag reflex, cough reflex, and laryngospasm protect against aspiration,[26] but these reflexes may be lost under special circumstances such as obtundation. Symptoms of obstructive apnea often include a brief episode of stridor accompanied by a struggle to breathe, a change in skin color to red or purple, and finally cyanosis and cessation of respiratory effort. Patients who have aspirated massive amounts of fluid become tachypneic and dyspneic shortly after the meal. Food or formula is often found in the nares or mouth. Cough may occur. The diagnostic modality most helpful in documenting a temporal relationship between apnea and acid reflux is 24-hour esophageal reflux monitoring combined with simultaneous electrocardiography, pneumography by chest wall impedance, pneumography by nasal thermistor, pulse oximetry, and endtidal CO_2 measurement. Aspiration is often difficult to document, but the presence of a new infiltrate on chest x-ray films and a consistent clinical history provide strong circumstantial evidence. If repeated aspiration is suspected, an upper gastrointestinal tract series may reveal gastroesophageal reflux and immediate aspiration of barium; however, aspiration of gastroesophageal refluxate that occurs minutes or hours after a feeding may be missed with contrast radiography. A milk scan may be more sensitive than radiography for documenting this type of aspiration. Children who are not fed orally may nevertheless aspirate oral secretions. The scintigraphic "salivagram" is performed with the placement of a drop of saline containing ^{99m}Tc sulfur colloid on the tongue.[27] Subsequent imaging permits observation of its handling. Appearance of isotope in the trachea and bronchi confirms aspiration.

When recurrent aspiration is suspected but not confirmed noninvasively, bronchoscopy with bronchoalveolar lavage may support the diagnosis by returning fluid-containing lipid-laden alveolar macrophages.[28] Aspiration during swallowing and aspiration of refluxed gastric contents cannot be distinguished by this method in patients who are fed orally.

Although some clinicians view one episode of reflux-induced aspiration or apnea as an absolute indication for fundoplication, the decision to perform fundoplication should be based on the severity of the initial episode, underlying conditions that predisposed the child to the episode, risk for recurrence, and the expected natural history of reflux for a particular patient. In other words, some patients may be successfully managed with pharmacotherapy (a proton pump inhibitor with or without a prokinetic agent such as metoclopramide or erythromycin).

Stomach and Duodenum

Gastric Volvulus

Acute gastric volvulus may be of two types. When the whole stomach revolves about its long axis, organoaxial volvulus has occurred. When the fundus and pylorus exchange positions, the volvulus is mesenteroaxial. Predisposing factors include paraesophageal hernias or eventration of the diaphragm.

Because a closed obstruction has occurred, the patient is unable to vomit despite severe pain, distention, and retching. Plain radiographs reveal a markedly distended stomach with air-fluid levels, and contrast radiography may reveal cardioesophageal junction obstruction. An immediate operation is indicated.

Gastric Ulcer

Whereas some authors suggest that duodenal ulcers outnumber gastric ulcers in childhood,[1] others have reported that young children are more likely to have gastric ulcers. Most

gastric ulcers lie at the junction of gastric fundus and body. Those high in the fundus are usually related to stress. Antral ulcers are often the result of use of nonsteroidal antiinflammatory drugs (NSAIDs).

A well-recognized complication of severe illness requiring admission to the ICU is stress ulceration of the stomach. Bleeding becomes an important source of morbidity and mortality in patients with burns and trauma, as well as in those who have undergone major operations or have systemic disease. Prophylaxis against bleeding is common in the ICU setting. Antacids, H_2-receptor antagonists (H_2RA), proton pump inhibitors such as lansoprazole and pantoprozole, and sucralfate are most often used. Unfortunately, elevation of gastric pH by antacids and H_2RA removes one barrier against bacterial colonization and may increase the risk of pneumonia with organisms colonizing the stomach.[29] Large controlled trials, however, have failed to confirm this concern. Sucralfate is equally effective as prophylaxis against bleeding but does not affect gastric pH. If sucralfate is given concurrently with antacids or acid-suppressing medications, its efficacy will be reduced because it requires an acidic environment for optimal effect. Furthermore, sucralfate administered in close temporal proximity to other enterally administered medications may reduce their bioavailability by binding with them within the intestinal lumen.

Most patients with gastric ulcers are hypochlorhydric rather than hyperchlorhydric because exposure to detergents or toxins such as NSAIDs, pepsin, bile salts, or ethanol erodes the gastric barrier to back-diffusion. A second consistent finding among patients with gastric ulcers is delayed gastric emptying, which may be an epiphenomenon or central to the pathogenesis of ulcers. The association between *Helicobacter pylori* infection and both chronic gastritis and duodenal ulcer is well established, but the role of *H. pylori* in the pathogenesis of gastric ulceration remains somewhat speculative.[30]

Clinical features of gastric ulcer resemble those of duodenal ulcer. Pain predominates and is epigastric in location but usually follows eating more closely. Nausea and vomiting may occur. Milk or antacids relieve the pain. The two complications of gastric or duodenal ulceration most commonly requiring intensive care are perforation and bleeding. Perforation, requiring immediate surgical intervention, produces exquisite pain and rapid development of peritoneal signs in patients without immunosuppression.

Hematemesis heralds gastric ulcer bleeding and may be as massive as that of duodenal ulcer. Careful, repeated assessment of vital signs and prompt restoration of circulating blood volume by large-bore venous catheters are essential. Saline solution or epinephrine gastric lavage through a large sump tube is mandatory. "Iced" saline lavage offers no advantage and excessively depresses core temperature.

Efforts should also focus on reducing gastric acid production with a parenteral proton pump inhibitor.[31] Continuous intravenous vasopressin infusion, commonly used for control of variceal hemorrhage, reduces arterial flow through the splanchnic bed. Selective intraarterial infusion appears to be unnecessary. Intravenous administration of somatostatin or its synthetic, active octreotide moiety, has been effective in stemming variceal hemorrhage and may work for other causes of bleeding. In addition to their hemodynamic effects, they inhibit gastric acid production.

When the patient's condition is stable, endoscopy may be performed to localize the ulcer. Endoscopic therapy may then be performed on actively bleeding ulcers or those with visible vessels (which tend to rebleed). Ulcer beds may be photocoagulated, electrocoagulated, or thermocoagulated. They may also be injected with hemostatic agents such as epinephrine. If nonsurgical techniques fail to stop the bleeding, one of several surgical options (that include ulcer oversewing or resection, variations of gastric drainage procedures, and vagotomy) must be performed. Fortunately, successful pharmacologic and endoscopic therapies have precluded the need for these surgical therapies in all but the rarest circumstances.

Duodenal Ulcers

The incidence of duodenal ulcer in childhood is unknown. A large series completed before the popularization of endoscopy suggested an incidence of 4.4 cases per 10,000 pediatric patients per year, which is, no doubt, an underestimation.[32] The male predominance seen among adults is present only among postpubertile children. The risk for patients with blood group O is 1.3 times that expected.

A number of factors have been implicated in the pathogenesis of duodenal ulcers. Unquestionably, excessive acid production plays a major role. Some factors leading to hypersecretion include excessive gastrin or histamine production and increased vagal tone. Approximately half of patients with ulcers are also hyperpepsinogenemic, and their mucosal integrity may therefore be suboptimal.[33] Infection with *H. pylori* reduces the ulcer healing rate and increases the recurrence rate.[34] Although approximately 90% of adult duodenal ulcers are associated with *H. pylori* infection, only about 50% of pediatric duodenal ulcers are related to *H. pylori*.[35] The effects of diet and stress have been minimized in the recent literature.

Symptoms are similar to those of adults. Epigastric pain occurs after meals and often awakens the child from sleep. Vomiting occurs in 40% of patients.

The major life-threatening complications are perforation and hemorrhage, which lead to a "surgical" abdomen and shock, respectively. Abdominal plain films reveal free air if perforation has occurred. Hemorrhage presents as hematemesis, hematochezia, or melena. Endoscopy is the most sensitive tool to localize the ulcer and to characterize the risk for rebleeding. Ulcers with visible vessels in the crater are at greatest risk of recurrent hemorrhage and may require endoscopic coagulation. Principles of management are identical to those for gastric ulcer. Obviously, antibiotics such as clarithromycin, amoxicillin, and metronidazole should be used for the first 14 days of a 1-month course of acid suppression when ulcers are associated with infections.

Small Intestine and Colon

Malrotation

In embryonic life the cecum and ascending colon are located on the left side of the abdomen and the small bowel is on the right. During gestation, the midgut transiently protrudes into the umbilicus and rotates 270 degrees, and the cecum is moved to the right lower quadrant and the duodenojejunal junction to the left upper quadrant. Incomplete rotation is of little consequence unless midgut volvulus, which can be a catastrophic event, occurs.

Some patients with malrotation experience partial duodenal obstruction because of extrinsic compression by mesenteric

bands. Chronic diarrhea and protein-losing enteropathy may be seen, among others, without complete obstruction.

Clinical features of obstructing volvulus include severe abdominal pain, bilious vomiting, and abdominal distention. Surgical treatment requires a Ladd procedure, in which mesenteric bands are divided and the bowel is returned to its fetal position. Failure to promptly relieve the volvulus leads to ischemic necrosis of all of the gut supplied by the superior mesenteric artery (proximal jejunum to midtransverse colon). Short gut syndrome results from resection of the affected intestine.

Necrotizing Enterocolitis

Necrotizing enterocolitis is primarily a disorder of premature infants, affecting 2.5% of neonatal patients in the ICU but only 0.2% of all infants. The most common areas involved are the ileum and proximal colon, but any part of the intestinal tract may be affected. Its pathogenesis is unknown, but bowel ischemia, feeding of hyperosmolar formula, rapid advancement of feeding,[36] reduced immune surveillance, and population of the bowel by excessive quantities of enterotoxin-producing bacteria[37] may all play a role.

The classic clinical features are abdominal distention, bilious vomiting, and bloody stools, but symptoms are more subtle in some infants. If left unrecognized, necrotizing enterocolitis may become fulminant, leading to shock, disseminated intravascular coagulation, and apnea.

The diagnosis of necrotizing enterocolitis may be confirmed by an abdominal plain film showing pneumatosis intestinalis, hepatic portal air, or both. A random breath H_2/CO_2 ratio greater than 8 ppm/mm Hg strongly suggests the diagnosis.[19] Because the pathogenesis is unknown, treatment must be symptomatic. In most centers, feedings are discontinued for 48 hours to 2 weeks depending on the severity of symptoms. Fluid resuscitation and broad-spectrum parenteral antibiotics are the basis of medical therapy. Surgical resection is reserved for severe cases when medical management fails and gangrenous bowel develops. Perforation may sometimes be managed successfully in infants with very low birth weight with simple peritoneal drainage performed with the infant under local anesthesia,[38] and a multicenter study is currently being conducted to compare the outcomes of simple drainage and resection in such high-risk infants.

Low Cardiac Output Syndrome

Over the past decades, advancements in surgical techniques have led to significant improvement in morbidity and mortality after pediatric heart surgery. However, patients remain at risk for decreased cardiac ouput and impaired systemic oxygen delivery, especially in the early postopertaive period. The drop in cardiac ouput after cardiac surgery is characterized as low cardiac ouput syndrome (LCOS). LCOS is defined as an inability of the heart to provide adequate oxygen delivery to meet the body's metabolic demand. It is primarily due to transient myocardial dysfunction compounded by acute changes in myocardial loading. Cardiopulmonary bypass, along with residual cardiac abnormalities, may further aggravate the underlying low cardiac output state.[39,40] Although there are several manifestations of this clinical constellation beyond the scope of this chapter, it is important to recognize its clinical signs and symptoms (see Chapter 31). Systemic venous congestion may be observed in the gastrointestinal tract. Manifestations include hepatomegaly, ascites, and peripheral edema. Hypoperfusion to the liver can result in hepatic insufficiency and may lead to coagulopathy if severe enough. Furthermore, intolerance to enteral feeding may be evident in these patients with LCOS and central venous hypertension. Feeding difficulties may be further compounded by high-dose inotropes and narcotic infusions. These patients often require parenteral nutrition. Complications such as mesenteric ischemia or necrotizing enterocolitis may be observed in rare cases and are often fatal.[41,42]

Food Allergy

Food allergy can be defined as a reproducible, immunologically mediated reaction to an ingested food protein. Pathogenic events can be classified according to the schema of Gell and Coombs as type I (reagenic, immediate hypersensitivity reaction), type II (cytotoxic reaction), type III (immune-complex reaction), or type IV (delayed hypersensitivity reaction).

Manifestations may be systemic[43] or confined to the gastrointestinal tract.[44] Life-threatening systemic manifestations include acute urticaria and anaphylaxis.[43] Gastrointestinal reactions, which are sometimes severe, include allergic enteritis, allergic colitis, and celiac crisis.[44]

Acute urticaria is usually easily recognized by the classic wheal and flare cutaneous lesions often accompanied by laryngeal edema and angioedema. Anaphylaxis is an antigen-triggered immune reaction that leads to vascular collapse and bronchospasm.[45]

Food protein–induced enteropathy is characteristically a disorder of the infant and toddler. The small bowel develops patchy villous atrophy. Symptoms and signs range from those of malabsorption and enteric protein loss to those of profound diarrhea and shock. Colitis caused by food protein sensitivity is seen most commonly among infants younger than 6 months.[44] Bloody, mucoid diarrhea develops several days or weeks after their first oral antigen challenge. Even though this colitis usually takes a benign course, it may be severe enough to mimic necrotizing enterocolitis.

Although some do not categorize gluten enteropathy as true food allergy, it shares enough features with allergy to justify inclusion with this category of disorders.[44] Celiac crisis is a rare, life-threatening complication that may occur among untreated patients with a large gluten load or in treated patients as a result of dietary indiscretion. Massive fluid and electrolyte loss leads to shock.

The cornerstone of long-term therapy is elimination of the offending food, but emergency measures are also required. Immediate administration of epinephrine and corticosteroids is essential in the treatment of anaphylaxis. Urticaria may require the administration of antihistamines, corticosteroids, and epinephrine.[45] Steroid use also seems to benefit patients in celiac crisis. Rapid administration of crystalloid or colloid is crucial in the management of any of these reactions.

Hemolytic-Uremic Syndrome

The hemolytic-uremic syndrome may occur in epidemic or sporadic forms (see Chapter 71) . It is frequently preceded by enteric infection with bacterial[46] or viral pathogens. Infection with *Escherichia coli* O157:H7 has preceded an inordinately high number of cases.[47,48] Some instigating factors, such as bacterial verotoxin, cause endothelial damage in the kidney, liver, heart, brain, adrenal glands, and gastrointestinal tract.

Clinical features include a prodrome of abdominal pain, vomiting, and diarrhea, which may be bloody. Patients may have endoscopic, radiographic, or histologic evidence of ischemic bowel disease. As gastrointestinal symptoms improve, anemia and thrombocytopenia rapidly appear and produce pallor, petechiae, and ecchymoses. Subsequently, patients become oliguric, hypertensive, and azotemic. The clinical course may be complicated further by pancreatitis. Seizures may occur.

The intensivist caring for children with acute, hemorrhagic colitis must pay exceptional attention to fluid balance, hemogram, and renal function tests. Any sudden change in hemoglobin, platelet count, blood urea nitrogen, or urine output should be considered a potential sign of the hemolytic-uremic syndrome. In the absence of hypovolemic shock, fluid intake should be curtailed if hemolytic-uremic syndrome is documented. In the event of severe renal insufficiency, dialysis is necessary. Plasma exchange and anticoagulants are probably not beneficial.[49] High-dose vitamin E has been suggested as a nonspecific adjunct to therapy.

Inflammatory Bowel Disease

Crohn disease and ulcerative colitis are chronic, relapsing disorders without known causes. The transmural inflammation of Crohn disease may affect any portion of the alimentary tract in a patchy distribution, whereas the inflammation of ulcerative colitis is confined to the mucosa of the colon. The latter always involves distal colon, and its contiguous inflammation extends for varying distances from the rectum. The two entities are different enough to usually permit accurate categorization, but there is sufficient overlap in symptoms and distribution that the diagnosis is indeterminate in 15% of cases. Table 86-1 summarizes the clinical, radiographic, endoscopic, and histologic differences between the two.

The cause of these disorders remains speculative. Clearly, genetic factors predispose patients to one or the other, but environmental factors also appear to play a role.[50] Etiologic factors considered important over the years have included psychogenic predisposition, food allergies, infectious processes, immunologic deficiency, and immunologic hyperreactivity.

Presenting signs and symptoms include abdominal pain; bloody or nonbloody diarrhea; anorexia; abdominal mass; and extraintestinal manifestations, such as weight loss, fever, arthritis, or erythema nodosum. Patients are often anemic and hypoproteinemic, and they may show hematologic or biochemical signs of acute-phase response. The radiographic and histologic features are typical (see Table 86-1).

The cornerstone of medical management has long been the use of corticosteroids, but 5-aminosalicylic acid (5-ASA) is effective for mild to moderate ulcerative colitis and Crohn's colitis. Evidence is less compelling that 5-ASA is effective in small intestinal Crohn disease. Immunosuppressants, such as 6-mercaptopurine (6-MP) and methotrexate, have been used for Crohn disease, and 6-mercaptopurine also seems effective in the treatment of ulcerative colitis. Biologic therapy has revolutionized the therapy of Crohn disease.[51] Infliximab, a monoclonal antibody against tumor necrosis factor, has shown dramatic efficacy against Crohn disease in up to 75% of patients. A second anti-TNF agent, adalimumab, can be given subcutaenously but appears to be less efficacious than infliximab. Other biologic agents such as antibodies against proinflammatory cytokines and antisense molecules blocking white cell adhesion molecules are currently in development.

Table 86–1 Differential Diagnosis Between Ulcerative Colitis and Crohn Disease

Feature	Ulcerative Colitis	Crohn Disease
RELATIVE INCIDENCE OF SYMPTOMS		
Rectal bleeding (gross)	Common	Rare
Diarrhea	Often severe	Moderate or even absent
Pain	Less frequent	Almost always
Anorexia	Mild or moderate	Can be severe
Weight loss	Moderate	Severe
Growth retardation	Usually mild	Often pronounced
Extraintestinal manifestations	Common	Common
INVOLVEMENT		
Small Bowel Involvement		
Extensive	—	10%
Lower ileum	5%–10%	90%
Colon	100%	75%
Rectum	95%	50%
Anus	5%	85%
DISTRIBUTION OF LESIONS	Continuous	Segmental
RADIOLOGIC FEATURES	Superficial ulcers, loss of haustration, no skip areas, shortening	Serpiginous ulcers, thumbprinting, skip areas, string sign
PATHOLOGIC CHANGES	Diffuse mucosal disease	Focal transmural disease, granulomas
RESPONSE TO TREATMENT		
Steroids and sulfasalazine	75%	25%–75%
Parenteral nutrition and elemental diets	Poor	Very good for small bowel
Azathioprine and 6-mercaptopurine	Good in selected cases	Good in selected cases
Surgery	Excellent	Fair or poor
COURSE		
Remissions	Common	Common
Relapse after surgery	Rare	5%–100%
Cancer risk	High in pancolitis	Slight

Modified from Silverman A, Roy CC, editors: *Pediatric clinical gastroenterology*, ed 3, St Louis, 1983, Mosby, p 354.

Probiotics, such as nonpathogenic helminths and anaerobic lactobacillus species, are also under study.

Severe complications may also be directly attributed to therapy. Pancreatitis has been associated with 5-ASA and 6-MP. In addition, bone marrow suppression as well as hepatitis has been observed with 6-MP. Infliximab has been associated with lymphoid malignancies and the concomitant use of 6-MP with infliximab may syngergistically heighten the risk

of lymphoma. Patients who take infliximab should also be observed for possible anaphylaxis.

Complications most likely to require an intensivist's attention are perforation, toxic dilation of the colon, and fulminant colitis. A patient whose bowel has perforated exhibits decreased bowel sounds and abdominal rigidity. Point and rebound tenderness may be present. Abdominal x-ray films may reveal free intraperitoneal air. Most perforations in Crohn disease produce intra-abdominal abscesses, but peritonitis does not. Some abscesses, however, can contaminate the peritoneum. Free colonic perforation tends to occur among patients with ulcerative colitis. Toxic dilation and fulminant colitis are also more common with ulcerative colitis but may occasionally occur in Crohn colitis. Because management of severe inflammatory bowel disease frequently includes immunosuppression with high-dose corticosteroids, cyclosporine, or azathioprine, some of the signs and symptoms of perforation may be masked in the population most likely to have such complications. Factors such as patient immobility, antiperistaltic drugs, rigorous cathartic use, and electrolyte imbalance are frequently associated with toxic dilation of the colon. Patients initially have massive abdominal distention and pain. X-ray films reveal an increased transverse colonic diameter. The patient's status is observed through careful monitoring of vital signs, physical examination, and repeated abdominal radiographs. Management includes giving nothing by mouth during nasogastric tube suction and inserting a rectal tube for decompression. Frequent position changes may aid in redistributing air distally. Fluid and electrolyte balance is aggressively maintained, and broad-spectrum parenteral antibiotics are given. Efforts at medical management should not exceed a few hours because of the extreme risk of perforation. Clinical decompensation or perforation is an indication for urgent surgical resection of the colon.

Fulminant colitis is characterized by fever, shock, severe abdominal pain, 10 or more bloody stools per day, and abdominal tenderness. Broad-spectrum antibiotics, intravenous steroids, immunosuppressants such as cyclosporine,[52] red blood cell transfusion, and fluid replacement are the mainstays of treatment for fulminant colitis. Small, uncontrolled series have also suggested that infliximab may be beneficial for fulminant colitis.[53] Failure to respond within a few days, however, warrants colectomy.

Hirschsprung Disease

Hirschsprung disease occurs in 1 in 5000 live births. It may be the result of incomplete craniocaudal migration of neural crest elements, but some investigators believe that ganglion cells degenerate after migration. Aganglionosis may involve as little as a few centimeters or the entire colon and small bowel (in rare cases). Total colonic Hirschsprung disease occurs in clusters in some families with the risk being 21% in those families.[54] The inheritance of familial Hirschsprung disease appears to be polygenic, with mutations in several loci of the RET proto-oncogene being associated with autosomal dominant Hirschsprung disease that is most commonly the short-segment type. Mutations of the endothelin receptor type B gene are more likely to be observed in long-segment, autosomal recessively transmitted Hirschsprung disease. Other gene mutations may also modify the expression of the disease.[54]

The most common feature of Hirschsprung disease is the failure to pass meconium in a timely fashion after birth; 94% of infants with Hirschsprung disease pass their first stool beyond 24 hours of life. Most patients with Hirschsprung disease are constipated but cannot pass flatus. If their condition is undiagnosed during the first months of life, they may fail to thrive.

Physical findings include abdominal distention and an empty rectum on digital examination. Barium enema often reveals a narrow-caliber aganglionic distal colon; a transition zone; and a dilated, ganglionic proximal colon. It is essential that the barium enema be performed without prior enema preparation to preserve the transition zone. Absence of the anal-inhibitory reflex on anorectal manometry is suggestive. The diagnosis is confirmed histologically by rectal biopsy of the distal rectal mucosa where hypertrophic nerve trunks but no ganglion cells are found. Acetylcholinesterase staining of the specimen improves the diagnostic yield by enhancement of the abnormal nerve trunks.

In some children the course of Hirschsprung disease is punctuated by episodic, severe enterocolitis, which leads to copious, bloody diarrhea, fever, and shock. The intensive care of patients with enterocolitis should emphasize reconstitution of circulating blood volume with crystalloid, colloid, and red blood cells. Broad-spectrum parenteral antibiotics are advisable. After the patient's condition is stabilized, urgent decompressive enterostomy is indicated. Pull-through operations are usually performed after several months. Enterocolitis in the remaining ganglionated intestine may occur even in some patients who have undergone a pull-through operation.[55]

Acute Colonic Pseudo-obstruction

First described by Oglivie,[56] acute colonic pseudo-obstruction is occasionally observed among critically ill adults and children who are immobilized in an ICU setting. It is characterized by massive cecal dilation of 5 to 10 cm on abdominal plain film. The mechanism is uncertain, but it appears to occur among patients given neuromuscular blockade and antimotility drugs such as narcotics. If left untreated, it may result in colonic perforation at the cecal level. Therapy should involve decompression of the gastrointestinal tract by nasogastric and rectal intubation and suction. Placing the patient in the prone position also seems to be effective initial therapy. None of these measures, though, seem to be as effective as is parenteral administration of neostigmine.[40] Adverse effects of neostigmine, such as excessive salivation or abdominal cramping are self-limiting, but bradycardia that occasionally occurs must be managed with atropine.

Abdominal Compartment Syndrome

Abdominal compartment sydrome (ACS) is defined as organ dysfunction caused by intraabdominal hypertension. The organ dysfunction observed with abdominal compartment syndrome may go under-recognized because it affects patients who are critically ill and their organ dysfunction may erroneously be ascribed to their underlying illness. If untreated, ACS can lead to crucial organ failure and death. The clinician must take great care in children to be familiar with this clinical entity as timely recognition and intervention can be life saving.

The standard method for measuring intraabdominal pressure is through the assessment of bladder pressure. A three-way stopcock is placed between the catheter and pressure tubing. The bladder is emptied and sterile isotonic sailne is

injected in the distal stopcock and into the bladder to allow for a continuous fluid column. There is some variability in the amount of fluid administered based on tubing and patient size. The pressure transducer is zeroed at the level of the mid-axillary line and the pressure is measured at end-expiration while supine.

Intra-abdominal hypertension (IAH) and ACS are distinct clinical entites. The intra-abdominal pressure is a steady pressure wtihin the abdominal cavity. The normal range is variable based upon individual patient differences. Much of the variability is due to the body habitus of the patient. IAH is defined as a sustained pressure of 12 mm Hg or greater.[57] ACS is defined as sustained pressure greater than 20 mm Hg associated with organ dysfunction. Although recording of pressure is important for research purposes, the clinical presentation is the most important component in defining ACS. ACS can be classified as primary or secondary. Primary ACS is due to injury or disease in the abdominal region, such as trauma or organ transplantation, and often requires early surgical decompression. Secondary ACS is due to conditions requiring extensive fluid resuscitation, such as sepsis, burns, or other capillary leak syndromes.

IAH can impair practically every organ system resulting in ACS. It can impaire cardiac function by reducing venous return as well as impairing cardiac function directly via diaphragmatic pressure. In mechanically ventillated patients, peak inspiratory and mean airway pressures will be significantly increased resulting in barotrauma. In addition, chest wall compliance is markedly reduced. Renal impairment may be attributed to several mechanisms in patients with ACS. Venous drainage can be impaired by renal vein compression. The subsequent cardiac output fall can lead to renal artery vasoconstriction via the renin-angiotensin systems. The urine sodium and chloride concentrations will typically be decreased while the renin, aldosterone and antidiuretic hormone may be markedly increased.[58,59] The most sensitive organ to changes in intra-abdominal pressure is the gut. Both human and animal studies have shown decreased intestinal mucosal perfusion at intra-abdominal pressures of 20 mm Hg. Impaired mesenteric venous drainage results in intestinal edema which can increase intra-abdominal pressure and result in worse hypoperfusion and possible bowel ischemia.[60] Finally, intracranial pressure (ICP) can be elevated leading to a decrease in cerebral perfusion.[61]

The management of IAH and ACS is requires both supportive care and, in some instances, surgical decompression. In general, surgical decompression is indicated for ACS. There is increasing evidence that surgical decompression prior to development of ACS may be beneficial.[62] Following decompression, the abdomen is left open and typically covered with a Dacron mesh or humanized regenerative tissue matrix. Early recognition and timing of decompression of ACS may be crucial in the preservation of organ function (see Chapter 89).

Acute Pancreatitis

Even though gallstone pancreatitis and ethanolic pancreatitis are uncommon in children, numerous structural, toxic metabolic, and infectious diseases are associated with acute childhood pancreatitis. Appropriate radiographic or biochemical evaluation for pancreatitis should be performed on all children admitted to the ICU with acute abdomen.

Acute pancreatitis is preceded by intrapancreatic activation of proteases. The triggering mechanism remains obscure, but once protease inhibitors are overcome and trypsinogen is converted to trypsin, a cascade of steps produces active proteases, lipase, and amylase. The enzymes induce local and distant organ damage, which includes edema, increased vascular permeability, cytolysis, and fat necrosis.

The clinical hallmark of acute pancreatitis is severe, boring epigastric or left upper quadrant pain that radiates through to the back. Serum amylase and lipase levels are greatly elevated, and radiographic imaging studies reveal pancreatic enlargement, sonolucency, or irregularity of the margin. Ultrasonography is a satisfactory screening technique, but CT scanning should be used when the course is severe. If CT scanning is performed with a dynamic, contrast-enhanced technique, interstitial pancreatitis can be differentiated from the more ominous necrotic pancreatitis, which often requires surgical debridement.

Because serum lipase is almost exclusively pancreatic in origin and amylase comes from a number of organs, the serum lipase concentration may be a better indicator of pancreatitis. Use of both measures to follow the course of pancreatitis is preferable to using either one alone.

Several nonspecific laboratory derangements such as anemia, hypoglycemia, hypocalcemia, and hypoproteinemia may occur. Intensive support may be required for severe, acute attacks. Severe, hemorrhagic necrosis of the pancreas carries a poor prognosis. Extraordinarily large third-space fluid and electrolyte losses must be replaced. If significant hyperglycemia occurs, insulin must be given. Calcium infusions may also be necessary. Physicians should be able to minimize pancreatic stimulation by giving the patient nothing by mouth and using nasogastric suction, although the efficacy of suction has been questioned for patients without ileus. Use of protease inhibitors, H_2 antagonists, somatostatin, 5-fluorouracil, and glucagon has not found much support in the literature. Antibiotics are not indicated unless an abscess is suspected. Some studies support the use of free-radical scavengers such as selenium, methionine, vitamin E, and vitamin C.[63]

Several complications may be catastrophic. Rupture of a pancreatic duct or leakage of a pseudocyst must be suspected if ascites develops. Gastrointestinal hemorrhage during pancreatitis may originate from a variety of sources. Discovery of gastric varices suggests splenic vein thrombosis. Gastritis may also appear. Pseudoaneurysms of the hepatic or splenic artery may bleed into the pancreas. Small bowel or colonic ischemia caused by fat necrosis may produce gastrointestinal hemorrhage. Infected pancreatic necrosis is uniformly fatal unless the patient undergoes an emergency operation to debride the necrotic tissue.

Time to recovery from pancreatitis is variable and may be prolonged (weeks to months). Nutritional management during that interval is affected by the desire to avoid stimulation of the pancreas by enteral administration of nutrients. Although total parenteral nutrition (TPN) is indicated during the initial phase of severe pancreatitis,[64] enteral administration of elemental formulas by nasojejunal tube phase has been successfully implemented[65] early in the course of the illness. If such a nutritional strategy does not exacerbate the pancreatitis, it is preferable to using TPN because of its relative safety when compared with TPN.

Acute and Chronic Liver Failure

The term *liver failure* refers to the constellation of symptoms, signs, and biochemical aberrations that appear when hepatic synthetic capacity is severely compromised. Liver failure is categorized as fulminant when encephalopathy appears within the first 2 months of the illness, as late onset when it appears within 6 months, and as chronic when it appears beyond the sixth month of liver dysfunction. Infectious, metabolic, and toxic liver diseases, as well as biliary obstruction, may lead to liver failure (Table 86-2). Obviously, it is advisable to establish a cause of liver disease before the onset of liver failure. It is beyond the scope of this chapter to outline a diagnostic approach to childhood liver disease, but several reviews are available (see Chapter 88).[66,67]

Elucidating the cause of fulminant hepatic failure is often made more difficult by the rapid development of coagulopathy and ascites, which preclude percutaneous liver biopsy. Laparotomy with surgical wedge biopsy may be necessary. More recently, techniques for transjugular liver biopsy have been developed.[68, 69] A core of liver tissue is obtained by passing the biopsy forceps retrograde through the superior vena cava and hepatic vein after introduction via the jugular vein. The biopsy site then bleeds directly into the liver parenchyma, minimizing extravasation.

Hepatic encephalopathy is a consistent finding in adult liver failure, although it occurs inconsistently and relatively late in pediatric cases.[70]

Progressive hepatic encephalopathy culminates in coma. When patients have entered coma, CNS resuscitation becomes necessary. Patients should undergo elective endotracheal intubation, and they should be hyperventilated. Administration of narcotics and benzodiazepines should be avoided. Benzodiazepine antagonists provide temporary improvement in consciousness among patients with hepatic encephalopathy.[71] Beyond CNS metabolic derangements, cytotoxic cerebral edema often complicates hepatic failure. Placement of an intracranial monitoring device should be contemplated; the risk of instrumentation in patients with coagulopathy should be weighed against the benefit of continuous CNS pressure monitoring (see Chapter 59).

Plasmapheresis or plasma exchange remove circulating mediators and toxins from patients with liver failure. This temporary effect may be due to removal of neuroinhibitory factors.

A variety of bioartificial liver support devices have been formulated as a bridge to liver transplant. Since most of these patients go onto liver transplantation, it will be difficult to ever demonstrate superiority of these devices over conventional plasmapheresis.[72,73]

The non-CNS manifestations of liver failure are protean. Hepatosplenomegaly is common in the early stages of fulminant failure, but the liver may shrink rapidly. In end-stage liver disease caused by cirrhosis, the liver is shrunken, firm, and nodular. Most patients with liver failure have jaundice. Spider angiomas, palmar erythema, ascites, and peripheral edema are common features of chronic liver disease. Fetor hepaticus (mercaptan breath) may be present.The biochemical features of liver failure are variable depending on its cause, duration, and severity. Hypoglycemia should be corrected when present. Serum bilirubin levels may be elevated or normal. Liver aminotransferase concentrations are increased in acute liver disease but decrease as hepatocytes are lost and therefore may be only mildly elevated or normal in cirrhosis and in the terminal stages of failure. Decreasing aminotransferase levels and albumin in the face of rising bilirubin, prothrombin time, and partial thromboplastin time denotes a failing liver. Serum globulin and ammonia levels are usually elevated. The serum aminogram reveals an elevated aromatic/branched-chain amino acid ratio.

Renal insufficiency may appear because of prerenal azotemia, acute tubular necrosis, or hepatorenal syndrome.[50] Patients with both acute and chronic liver failure frequently have renal failure. Hepatorenal syndrome (HRS) is the most common cause of acute renal failure in this population. From 40% to 80% of patients with hepatic failure develop HRS. The onset often occurs following an acute change in intravascular volume. The development of HRS is precipitated commonly by hemorrhage, excessive diuresis, or sepsis. HRS is a diagnosis of exclusion once other causes of renal failure and absent diuretic response are further explored. Although certain clinical characteristics may or may not exist in the description of HRS, almost all patients have hyponatremia prior to the development of renal insuffiency.[74] The treatment is nonspecific but includes volume administration and maintenance of adequate systemic perfusion. This is achieved by overcoming the sphlanchnic vasodilation and increasing renal perfusion and filtration (see Chapter 88).[75]

Patients with late-onset or chronic liver failure are likely to have portal hypertension. Ascites may develop as plasma oncotic pressure decreases or portal pressure increases. Patients who are hyponatremic usually have total-body sodium overload,[76] and they should be treated with moderate salt restriction but vigorous fluid restriction, colloid

Table 86–2 Diseases that Cause Liver Failure

Viral	Hepatitis (A, B, C, D, E), CMV, HSV, EBV, VZV, HHV-6, parvovirus B19, parainfluenza, yellow fever
Idiosyncratic	Halogenated hydrocarbons, coumadin, methyldopa, phenytoin, carbamazepin, valproic acid, rifampicin, penicillin, sulfonamides, quinolones
Toxic dose–dependent	Acetaminophen (Paracetamol), isoniazid, tetracycline, methotrexate, carbon tetrachloride, amphetamines, amanita phalloides toxin
Toxic synergistic	Ethanol + acetaminophen, barbiturate + acetaminophen, isoniazid + rifampicin
Metabolic	Wilson disease, alpha-1-AT-deficiency, galactosemia, tyrosinemia, Reye syndrome, NASH
Associated with pregnancy	Acute fatty liver of pregnancy, HELLP syndrome
Vascular	Budd-Chiari syndrome, veno-occlusive disease, shock, heart failure
Miscellaneous	Autoimmune hepatitis, malignant infiltration, hyperthermia, sepsis

CMV, Cytomegalovirus; *HSV,* herpes simplex virus; *EBV,* Epstein-Barr virus; *VZV,* varicella zoster virus; *HHV,* human herpesvirus; *NASH,* nonalcoholic steatohepatitis; *HELLP,* hemolysis, elevated liver enzymes, and low platelet count.

Data from Gotthardt D, et al: Fulminant hepatic failure: etiology and indications for liver transplantation, *Nephrol Dialysis Transplant* 22(suppl 8):viii5-viii8, 2007.

administration, and diuretic therapy are the cornerstones of therapy. High-volume abdominal paracentesis is proven to be safe in both adults and children who have ascites compromising ventilation.

Spontaneous engorgement of esophageal, gastric, and rectal veins leads to varices. Similar prominent veins in the abdominal wall and around the umbilicus (caput medusa) may develop. Splenic congestion from impaired venous flow into the portal system results in splenomegaly and hypersplenism so that patients are classically anemic or pancytopenic. Less commonly, unknown factors lead to intrapulmonary arteriovenous shunting, which characteristically causes hypoxemia.

Coagulopathy and bleeding are frequent in patients with liver failure. Thrombocytopenia, which may be profound, is a common component of hypersplenism. Fat-soluble vitamin malabsorption in patients with cholestasis leads to vitamin K deficiency, which prevents hepatic production of clotting factors II, VII, IX, and X. Ultimately, failed synthesis of all liver-dependent clotting factors results in prolonged prothrombin time (unresponsive to vitamin K administration) and partial thromboplastin time.

The sites of bleeding are predictable. Bleeding from incisions, needle puncture sites, nose, and gingiva are common but are usually not life threatening. Persistent bleeding may require packed red blood cell transfusion. In contrast, intracranial and variceal bleeding may be fatal and demand immediate attention. Esophageal varices bleed because of acute changes in variceal pressure or because of gastric hyperacidity. Platelets should be given to patients with thrombocytopenia. Patients with coagulopathy may receive fresh frozen plasma if their coagulopathy is mild; however, those whose prothrombin time is markedly deranged (international normalized ratio [INR] >2) may have pulmonary edema if attempts are made to correct the coagulopathy by administration of plasma alone. Acceptable alternatives include plasmapheresis[77] or the administration of recombinant factor VII concentrate[78] as bridges to transplantation.

Mechanical means of hemorrhage control include direct compression, creation of portosystemic shunts, and surgical transection/reanastomosis of the esophagus. Endoscopic control of bleeding from varices involves sclerotherapy in infants too small to tolerate a banding device or endoscopic banding in toddlers and older children.[79] Balloon tamponade by Sengstaken-Blakemore tube carries substantial risk and has largely been abandoned. It should not be used to manage persistent bleeding after sclerotherapy because of the risk of esophageal perforation.

Complications of portal hypertension can be managed with surgical shunting procedures that decompress the portal system by creating a venous anastomosis between the portal and systemic circulations. Several surgical varieties exist. Central vascular shunts, such as portocaval or mesocaval shunts, carry substantial risk. Transjugular intrahepatic portosystemic shunts are frequently used in children who weigh more than 10 kg as a bridge to transplantation.[80] In the past, shunt thrombosis was sometimes treated with surgical esophageal transaction, but urgent liver transplantation with either a cadaveric or living related donor is the preferred therapeutic strategy under such conditions (see Chapter 88).

Other extracorporeal liver assist devices, analogous to dialysis for renal failure, remain investigational a decade after their inception.[72,73,82] In any event, the basic principles of therapy must be directed toward CNS resuscitation, minimization of gastrointestinal bleeding, normalization of metabolic state, and correction of coagulation profile. Ultimately, orthotopic transplantation holds the greatest promise for saving patients with end-stage liver disease.[83,84]

Chapter 87

Gastrointestinal Pharmacology

Louis L. Bystrak, Ann Marie Heine, Kelly A. Michienzi, and Sasko D. Stojanovski

PEARLS

- Antiemetic management in both chemotherapy induced nausea and vomiting and postoperative nausea and vomiting is rooted in a multiple-drug approach with distinct targets of action.
- Risk of nausea and vomiting should be assessed for individual patients before optimal, guideline-driven, medical management is determined.
- H_2-receptor blockers and proton pump inhibitors remain the preferred agents over prokinetic agents in the treatment of gastroesophageal reflux disease.
- Risk factors for clinically significant gastrointestinal hemorrhage include mechanical ventilation, coagulopathy, and Pediatric Risk of Mortality score >10.
- Proton pump inhibitors are the preferred agent for treatment of gastrointestinal hemorrhage due to acid suppression; however, combination therapy may be necessary.
- Liver injury in children may result from autoimmune disease, metabolic disease, infectious causes, acute hepatitis, ischemia, irradiation damage, and exposure to toxins or medications.
- In a pediatric critical care environment, rectal administration of medication may be most beneficial when intravenous access issues are present, either because of an inability to maintain or achieve intravenous access or in situations when placement of an intravenous line is otherwise not necessary.
- Consideration of the activity of the CYP450 isoenzymes, with specific focus on age differences, may aid in accurate drug dosing.

Nausea and Vomiting

Introduction and Definitions

Uncontrolled nausea and vomiting in the pediatric intensive care unit may result in consequences that range from minor patient discomfort to life-threatening infection or electrolyte imbalance. To the patient this can mean wound dehiscence, gastrointestinal (GI) bleeding, malnutrition, dehydration, pulmonary aspiration, and increased anxiety with future medical interventions.[1] Indeed, nausea and vomiting has been referred to as the "big little problem" with the capacity to delay discharge, monopolize nursing care, and impact financial resources.[2] These costs can be limited with a focus on prophylactic treatment, employing recent drug developments and guideline-driven therapy when possible. The data that drive these guidelines are, particularly in pediatrics, largely based on studies that look at vomiting more specifically than nausea.[3] Because nausea is an unpleasant, largely subjective sensation in the epigastrium that may be associated with vomiting, it is more difficult to quantify objectively.[3,4] Vomiting, defined as the forceful expulsion of gastric contents from the mouth, can be more easily measured for medication assessment purposes. Although distinct, when vomiting is discussed here, it can be inferred to also pertain to managing nausea (unless otherwise noted).

The causes of nausea and vomiting in intensive care are as diverse as their consequences and include radiation, increased intracranial pressure, meningitis, diabetic ketoacidosis, hypercalcemia, hyponatremia, hepatitis, pancreatitis, bowel obstruction, GI bleeding, and surgery. Common medications that can trigger vomiting include antineoplastics, anesthetics, antibiotics, contrast media, and opiates. This section's focus, and on which the majority of research has focused, considers chemotherapy-induced nausea and vomiting (CINV) and postoperative nausea and vomiting (PONV). Before moving on to these topics specifically, the mechanism mediating nausea and vomiting will be explored.

Pathophysiology

The vomiting center or emetic center or "central pattern generator," located in the medulla oblongata, is a collection of neurons that may trigger vomiting after receiving input from the chemoreceptor trigger zone, abdominal vagal afferents or cerebral cortex.[1,5-7] The chemoreceptor trigger zone, located in the area postrema region near the fourth ventricle, is not fully protected by the blood-brain barrier; and is therefore vulnerable to antineoplastic agents, or other stimuli in the blood or cerebral spinal fluid.[5-7] The vagus nerve provides important stimuli to both the chemoreceptor trigger zone and vomiting center, and appears to have the largest role in CINV.[5,7] This occurs when cells within the GI tract are exposed to chemotherapy and release mediators, including 5-hydroxytryptamine (5-HT), substance P, and cholecystokinin, that stimulate the vagus nerve.[5,7] Finally, the role of the cerebral cortex is less well defined, but is thought to play a role in anticipatory nausea and vomiting.[1]

The mechanism described is most dependent upon the neurotransmitter receptors for dopamine, serotonin (5-hydroxytryptamine type 3), and substance P.[1,5-7] Additional receptors that are thought to play a supporting role

include corticosteroid, histamine, cannabinoid, acetylcholine, opiate, neurokinin-1, and gamma-aminobutyric acid.[1,6,8] The intricate cascade briefly described here and multiple neurotransmitter involvement, foreshadow treatment guidelines that will often be rooted in multiple agents that target various pathways.

Chemotherapy-Induced Nausea and Vomiting: Types of Emesis

Emesis that occurs from chemotherapy is divided into three distinct categories. Anticipatory CINV occurs before chemotherapy administration and occurs as a conditioned response in patients that have had significant past CINV. Acute CINV occurs within 24 hours of chemotherapy administration and is the most widely studied. Delayed nausea and vomiting occur after 24 hours and may persist for 7 days. Pediatric patients that have well-controlled acute nausea and vomiting are less likely to have delayed nausea and vomiting.[8] This highlights the importance of "staying ahead" of symptoms with prophylactic treatment.

Treatment Guidelines

The advent of 5-HT_3 receptor antagonists in the early 1990s provided a new cornerstone in how acute nausea and vomiting is managed in patients receiving highly or moderately emetogenic chemotherapy. The first-generation 5-HT_3 receptor antagonists of dolasetron, granisetron, and ondansetron have been established in pediatrics to be equally effective, and equally toxic, with the most common side effects including headache, constipation, and dizziness.[3,9-13] It should be noted that the approved pediatric dose of granisetron of 10 ug/kg once daily is likely ineffective, and a dose of 40 ug/kg once daily is more appropriate.[3,13,14,20] The 5-HT_3 receptor antagonists have been established, at the appropriate doses, to be as effective when given orally as when given intravenously, and that single daily dose schedules are as effective as multiple-dose schedules.[15-20] These agents are most useful for CINV occurring within the first 24 hours after administration of chemotherapy.[21]

In 2003, what may be considered a "second-generation" 5-HT_3 receptor antagonist, palonosetron, gained Food and Drug Administration approval for both acute and delayed CINV. It is unique from other 5-HT_3 antagonists because of its long half-life (21 to 37 hours in children and 40 hours in adults) and greater affinity for 5-HT_3 receptors.[14,22] Three phase III trials have established palonosetron as not inferior to older 5-HT_3 antagonists.[23-25] A trial comparing palonosetron with ondansetron in pediatric patients found a significant reduction in emesis on the first 3 days after treatment, and in nausea intensity the first 4 days after treatment favoring the palonosetron group.[26] Further prospective study is needed before palonosetron can be established as superior to other 5-HT_3 receptor antagonists. To date, CINV guidelines have not stated any one 5-HT_3 receptor antagonist to be superior to another.[20]

Corticosteroids, most commonly dexamethasone or methylprednisolone, are potent antiemetics and have a critical role in managing acute and delayed CINV in pediatrics. Their exact mechanism of action is unclear, but may involve decreasing 5-HT_3 release in the periphery.[27] However, corticosteroids also have the potential to decrease the effect of antineoplastic drugs on brain tumors, osteosarcomas and carcinomas.[27] Dexamethasone may augment the ability of a number of carcinomas to resist both radiation and chemotherapy.[3] Interferon or interleukin-2 may be less effective when used along with steroids.[1] Corticosteroids may also impact the quality of brain tumor images generated by computed tomography or magnetic resonance imaging by altering the distribution of contrast media.[3] In addition to these concerns, the usual side effects of steroids must be kept in mind, including: hyperglycemia, hypokalemia, anxiety, euphoria, and insomnia. It would be prudent to consult a patient's chemotherapy protocol or an oncologist before initiating corticosteroids in a pediatric patient with a malignancy to verify the appropriateness of this approach.

The neurokinin-1 receptor antagonist is the most recent antiemetic class. These are effective for both acute and delayed nausea and vomiting in moderately and highly emetogenic chemotherapy. Such agents are approved in CINV only when used in conjunction with a 5-HT_3 antagonist and a corticosteroid. Currently the only medications that represent this class on the market are oral aprepitant and intravenous fosaprepitant. They are generally well tolerated with diarrhea, fatigue, headache, and hiccups being common side effects.[28-30] Both aprepitant and fosaprepitant are substrates, inhibitors and inducers of the cytochrome P450 enzymes 3A4 and 2C9.[14] A thorough review of potential interactions for individual patients is merited. Most notable of these cytochrome interactions are: The effect of Coumadin (brand name form of the generic warfarin) on coagulation pathway (altered prothrombin time, International Normalized Ratio) may be reduced, the concentration of corticosteroids will be increased with a dose reduction needed when used for CINV with aprepitant, and a backup contraception method should be used for patients taking oral contraceptives.[30] This class of medication does not have approval for patients younger than 18 years, nor are suggested dose modifications available.[14] One study examined aprepitant dosed for young adults in patients ages 11 to 19 years weighing 43 to 105 kg.[31] Aprepitant containing regimens performed comparably to non-aprepitant-containing regimens, but an increase in the number of cases of febrile neutropenia was noted in the aprepitant patients.[31] Further prospective study is necessary before neurokinin-1 receptor antagonists are prescribed in pediatric patients.

Other agents commonly seen in pediatrics for CINV include benzodiazepines, most often lorazepam, which is routinely employed for anticipatory nausea and vomiting at a dose of 0.04 to 0.08 mg/kg/dose (maximum dose, 4 mg).[14] Diphenhydramine is anecdotally used in pediatric patients despite its absence from guidelines and reviews of CINV.[3,20] Dopamine receptor antagonists, including phenothiazines (e.g., prochlorperazine), butyrophenones (e.g., droperidol), and benzamides (e.g., metoclopramide), cause a high incidence of dystonic reactions when used at high doses for several days and potentially oculogyric crisis.[20,32] Cannabinoids (i.e., dronabinol) are limited by their lack of pediatric data, and their side effects, which include euphoria, sedation, depression, and hallucinations.[14] A scopolamine patch may have some utility in patients older than 12 years that are able to wait up to 12 hours for relief.[3] Generally speaking, these agents should only be considered for pediatric patients who do not tolerate first-line therapy alone.

Determining appropriate antiemetic therapy requires one to first evaluate the likelihood that a particular chemotherapy

Table 87–1 Antiemetic Selection for Chemotherapy Based on Emetogenicity of Frequently Encountered Single-Day Pediatric Chemotherapy

Emetic Risk (Incidence of Emesis with no Prophylaxis)	Antineoplastic Agent*	Recommended Antiemetic
High (>90%)	Cisplatin Cyclophosphamide >1.5 g/m^2 Dactinomycin Methotrexate >5 g/m^2	Children: day 1: 5-HT$_3$ antagonist + dexamethasone Adults: Day 1: 5-HT$_3$ antagonist + dexamethasone + NK-1 antagonist Day 2, 3: dexamethasone + NK-1 antagonist Day 4: dexamethasone
Moderate (30%-90%)	Carboplatin Cyclophosphamide <1.5 g/m^2 or oral Cytarabine >1 g/m^2 Daunorubicin Doxorubicin Etoposide (oral) Ifosfamide Irinotecan Methotrexate >1 g/m^2	Children: day 1: 5-HT$_3$ antagonist + dexamethasone Adults: For anthracycline and cyclophosphamide combination: Day 1: 5-HT$_3$ antagonist + dexamethasone + NK-1 antagonist Day 2, 3: NK-1 antagonist (dexamethasone if NK-1 antagonist contraindicated) All other regimens: Day 1: 5-HT$_3$ antagonist + dexamethasone Day 2, 3: dexamethasone or 5-HT$_3$ antagonist
Low (10%-30%)	5-Fluorouracil Asparaginase Cytarabine <1 g/m^2 Etoposide Methotrexate >100 to <1000 mg/m^2 Topotecan	Children: day 1: 5-HT$_3$ antagonist or dexamethasone Adults: day 1: dexamethasone
Minimal (<10%)	6-Thioguanine (oral) Hydroxyurea (oral) Methotrexate <100 mg/m^2 or oral Rituximab Vinblastine Vincristine	Children and adults: 5-HT$_3$ antagonist or dexamethasone only if needed

5-HT$_3$, 5-Hydroxytryptamine-3; *NK-1,* neurokinin-1.
*Table focuses on more common pediatric chemotherapy (see references 20 and 33 through 38 for complete list). Medication is parental unless otherwise stated.

regimen will produce nausea or vomiting.[20,33-35] This has been accomplished with literature and expert opinion and is summarized in Table 87-1, with subsequent dosing information provided in Table 87-2.[14,20,33-40] This categorization is largely based on adult data, so it is vital to take individual patient parameters and CINV history into account. If a chemotherapy regimen is close to the next highest emetic risk category, it is better to be aggressive with antiemetic management.

Table 87-1 includes aprepitant and dexamethasone that may be contraindicated for multiple reasons in children as discussed previously. In such patients, medications that are less-well supported for delayed CINV, such as diphenhydramine or 5HT$_3$ receptor antagonists, may be employed based on individual practitioner preference. Other areas of future research include breakthrough emesis that occurs despite adequate prophylaxis in a single cycle, and refractory emesis that occurs despite adequate prophylaxis over multiple cycles.[8] Additional areas that require further investigation in pediatric CINV include multiple-day chemotherapy, high-dose chemotherapy with stem cell rescue, and intractable symptoms in terminal patients.[41-43] Finally, each institution would be well advised to conduct a pharmacoeconomic review to aid in antiemetic selection of pharmacologically equivalent products.

Postoperative Nausea and Vomiting

Assessing the risk of the pediatric surgical candidate is the first step in determining PONV prophylaxis. Strabismus repair, tonsillectomy, hernia repair, orchiopexy, penile surgery, or any procedure where anesthesia time is 30 minutes or longer have an increased likelihood of PONV.[4,40,44] Children aged 3 years and older continue to increase their risk of PONV until they become pubescent.[40,44] Patients who have a history of PONV, motion sickness, or patients with first-degree relatives with such histories are more prone to have PONV.[40,44] Prophylaxis is recommended only for children thought to be at moderate or high risk of PONV.[4] Regional anesthesia is optimal in such patients.[4] However, if general anesthesia is necessary, the following may reduce the risk of PONV: using intraoperative supplemental oxygen, adequate hydration, minimizing opioid or neostigmine exposure, and avoiding nitrous oxide or volatile anesthetics when possible.[40]

Individual institutions should determine which patients are at moderate or high risk. These patients should receive a combination of two or three agents with distinct mechanisms of action for PONV prophylaxis.[4,40] A 5HT$_3$ receptor antagonist and dexamethasone combination is a reasonable first choice.[4] Other options include dimenhydrinate, perphenazine, or droperidol.[4,40,44] Because of potential for QT prolongation and *torsades des pointes*, droperidol should be reserved for patients who have failed first-line therapy and are hospital inpatients.[4] Droperidol should be dosed once for prophylaxis at 0.05 mg/kg (maximum, 1.25 mg), or at 0.01 to 0.03 mg/kg/dose for PONV treatment.[14,40] Finally, NK-1 receptor antagonists have been established as potent agents for PONV in adult patients, but even if approved in pediatrics it seems likely a multiple agent approach to PONV as described above will remain the standard of care.[45-48]

Table 87–2 Antiemetic Dosing in Chemotherapy-Induced and Postoperative Nausea and Vomiting[14,36,39,40]

Medication	CINV (IV)	CINV (PO)	PONV (IV)	PONV (PO)
Dolasetron	First dose 30 min before chemo: ≥2 y: 1.8 mg/kg (max*: 100 mg)	First dose 1 h before chemo: ≥2 y: 1.8 mg/kg (max, 100 mg)	15 min before anesthesia cessation: ≥2 y: 0.35 mg/kg (max, 12.5 mg)	2 h before surgery: ≥2 y: 1.2 mg/kg (max, 100 mg)
Granisetron	First dose 30 min before chemo: ≥2 y: 10 μg/kg/day per manufacturer *or* 20–40 μg/kg/day divided in 1–2 doses (max, 3 mg/dose)	First dose 1 hr before chemo: Adults: 2 mg q24h or 1 mg q12h	Before anesthesia induction or after reversal: ≥4 y: 20–40 μg/kg (max, 1 mg)	N/A
Ondansetron	First dose 30 min before chemo: ≥6 months: 0.15 mg/kg (max, 12 mg), then at 4 and 8 h Adults: may consider once-daily dose of 32 mg	First dose 30 min before chemo: 4–11 y: 4 mg q8h >11 y: 8 mg q8h or 24 mg q24h	Before anesthesia induction: ≥2 y and <40 kg: 0.1 mg/kg >40 kg: 4 mg	1 h before anesthesia: adults: 16 mg
Palonosetron	First dose 30 min before chemo: ≥2 y: 0.25 mg	First dose 1 hr before chemo: Adults: 0.5 mg	Immediately before anesthesia: adults: 0.075 mg	N/A
Dexamethasone	First dose before chemo: Children†: 10 mg/m^2 (max, 20 mg), then 5 mg/m^2 q6h or 10 mg/m^2 q12h	First dose before chemo: Children†: 10 mg/m^2 (max, 20 mg), then 5 mg/m^2 q6h or 10 mg/m^2 q12h	Before induction of anesthesia: children: 0.15 mg/kg (max, 8 mg)	N/A
Fosaprepitant (IV)/Aprepitant (PO)	30 min before chemo: adults: 115 mg (follow with PO aprepitant next 2 days)	1 hr before chemo: adults: 125 mg, then 80 mg q24h for the next 2 days	N/A	Within 3 h before anesthesia: adults: 40 mg

CINV, Chemotherapy-induced nausea and vomiting; *PONV,* postoperative nausea and vomiting; *IV,* intravenous; *PO,* oral; *max,* maximum dose; *N/A,* not applicable.
*Maximum dose is recommended adult dose unless otherwise stated; see appropriate adult reference for complete dosing.
†Dosing is only intended for pediatric patients not receiving aprepitant; see appropriate adult reference because dosing varies based on emetogenicity of therapy, type of CINV (e.g., acute, delayed), and aprepitant interaction.

Diarrhea

Introduction and Definition

It is estimated that in the United States, diarrhea-based illnesses result in approximately 200,000 hospital admissions and 400 deaths per year.[49] The majority of acute diarrhea episodes stem from infections to the GI tract and it is estimated that 20% to 40% of children treated with broad-spectrum antibiotics will develop diarrhea.[50,51] Infectious causes include viruses (e.g., Rotavirus), bacteria (e.g., *Escherichia coli*, *Shigella*, *Clostridium difficile*), and parasites (e.g., *Cryptosporidium parvum*, *Giardia lamblia*). Noninfectious causes include appendicitis, intussusception, food allergies, irritable bowel syndrome, and ulcerative colitis. Diarrhea may be defined for practical purposes as a decrease in stool consistency, along with an increase in frequency to more than three bowel movements in 24 hours.[49] After diarrhea is identified, rehydration is paramount. Identifying the underlying cause will guide specific treatment.

Treatment

If *C. difficile* is identified, any potentially contributing broad-spectrum antibiotics should be discontinued, or streamlined to more a specific agent if possible. Oral metronidazole for 10 days is first line therapy in mild to moderate disease.[51,52] Cases that require protracted courses of metronidazole should include monitoring for peripheral neuropathy. Oral vancomycin should be considered for patients with severe symptoms, intolerance to metronidazole, or metronidazole failure.[51-53] Indeed, there is growing evidence in the adult population of superior outcomes when vancomycin is used first line for severe disease.[52,53] Probiotics, bile-acid sequestrants, intravenous immunoglobulin, or tapering doses of vancomycin may be considered for recurrent cases. The impact of *C. difficile* can be minimized with prevention that includes good hand hygiene, infection control, and appropriate antibiotic usage. It would be prudent to limit acid suppressing agents (e.g., proton pump inhibitors, histamine H_2 antagonists) to legitimate indications, as a positive association has been identified in adult populations between acid suppression and *C. difficile* disease.[54,55]

Probiotics are widely defined as live microorganisms that offer health benefits. These agents have been studied in pediatric patients in terms of potential reduction in antibiotic-associated diarrhea. One meta-analysis found that for every seven pediatric patients administered probiotics, one fewer would develop antibiotic-associated diarrhea. Positive risk reduction was identified, in decreasing strength, for those treated with *Lactobacillus* GG, *Saccharomyces boulardii*, and the combination of *Bifidobacterium lactis* and *Streptococcus thermophilus*.[56] Significant reductions were not found with *L. acidophilus/Bifidobacterium infantis* or *L. acidophilus/L. bulgaricus*.[56] A second meta-analysis reviewing *Lactobacillus* GG, *L. sporogenes*, and *Saccharomyces boulardii* found a significant decrease in antibiotic-associated diarrhea but nonsignificant overall results in intent-to-treat analysis.[57] Such agents require further study from an efficacy and pharmacoeconomic standpoint before

they become the standard of care. If these agents are used, sufficient live organism content should be verified. These agents should be used cautiously, if at all, in premature infants and in patients with any of the following: short bowel syndrome, central catheters, cardiac valve disease, and immune compromise.[58,59]

Other important treatments for diarrhea include the antimotility agents loperamide and diphenoxylate. Both inhibit excessive GI peristalsis and increase GI transit time.[14] Neither medication should be used in diarrhea resulting from pseudomembranous enterocolitis or any infectious cause, because it is critical that toxins produced are cleared from the GI tract.[14,49] Underlying electrolyte imbalances and dehydration should be addressed before these antimotility agents are initiated, because the potential exists that intestinal fluid retention may exacerbate such underlying conditions. Side effects to be mindful of include: sedation, confusion, ileus, and respiratory depression (with younger children at increased risk).[14]

Constipation

Introduction and Definition

Constipation is defined as a reduction in the number of bowel movements. This number varies significantly based on the infant or child's age and breastfeeding status with exclusively breast-fed infants having an increased frequency of bowel movements.[60,61] The differential diagnosis underlying constipation in a pediatric intensive care unit is extensive and includes: anatomical (e.g., anal stricture, rectal abscess), metabolic (e.g., hypothyroidism, cystic fibrosis), neurologic (e.g., Hirschsprung disease, cerebral palsy), and connective tissue disorder (e.g., systemic lupus erythematosus).[61] Medications such as opiates, phenobarbital, antacids, antihypertensives, anticholinergics, and antidepressants, and lead may all contribute to a child's constipation.[61]

Treatment

Any underlying disease state or anatomical anomaly should be managed individually. If medication related, the offending agent should be discontinued if possible; or the minimal effective dose should be targeted. Constipation itself is addressed as a two-step process of disimpaction lasting 3 to 5 days, followed by maintenance. The duration of the latter stage is determined by symptom recurrence when treatment is withdrawn.[60,62]

Disimpaction may be accomplished with oral or rectal medication administration. The oral route is less invasive and may give a sense of empowerment to the child, but the rectal route is quicker and may be necessary if the child has abdominal pain. Oral options include mineral oil, oral electrolyte solutions, lactulose, sorbitol, magnesium hydroxide, magnesium citrate, senna, and bisacodyl. Mineral oil may result in lipoid pneumonia if aspirated and is not recommended in children younger than 1 year or any patient on aspiration precautions. Options for rectal disimpaction include phosphate soda, saline, or mineral oil enemas followed by a phosphate enema. Also effective are glycerin suppositories in infants, and bisacodyl suppositories in older children. Soapsuds, tap water, and magnesium enemas are discouraged because of their potential toxicity.[60] Enemas are to be avoided in children younger than 3 years and in young children with severe neurologic deficiencies as they are more likely to be retained with subsequent resulting toxicities.[62]

Maintenance therapy with polyethylene glycol 3350 without electrolytes (MiraLax) has demonstrated superior palatability in children, and although not yet recommended by guidelines in infants, there is growing evidence of its safe use in this population.[60,62] Other maintenance therapies include mineral oil, magnesium hydroxide, lactulose, and sorbitol. Bisacodyl or senna may be necessary as a stimulant laxative as rescue therapy, but should be avoided for extended use.[60]

Gastroesophageal Reflux Disease

Treatment of gastroesophageal reflux disease (GERD) should alleviate symptoms and prevent or heal esophageal damage. Although researchers conducting multiple pediatric studies have used varying doses, multiple drug therapies, and nonpharmacologic therapies, guidelines do exist for the treatment of GERD in infants and children.[63] Many patients who may be admitted to the intensive care unit for other conditions are likely to have preexisting gastroesophageal reflux conditions and corresponding surgical and pharmacologic therapies. These populations include patients with reactive airway disease, recurrent pneumonia, neurologic impairment, premature infants, and genetic syndromes including Down syndrome.

Histamine-2 Receptor Antagonists

Histamine-2 (H_2) receptor antagonists inhibit gastric acid secretion by means of competitive inhibition of H_2 receptors of the gastric parietal cells. H_2 receptor antagonists are generally well tolerated. Common adverse effects include nausea and headache. Although thrombocytopenia may occur, it is often difficult to determine the sole cause in critically ill patients. Ranitidine should be avoided in patients with acute porphyria. Tachyphylaxis is well documented for intravenous and oral H_2 receptor blockers in adult and pediatric populations. Infants may suffer from irritability, headache, and somnolence, which when mistaken for GERD symptoms, may lead to an unwarranted increase in dose.[63] All of the currently available H_2 receptor blockers require dosage adjustment for renal impairment. Although fewer pediatric studies exist for ranitidine and famotidine, these agents are frequently used and may be preferred over cimetidine because of fewer drug interactions and central nervous system adverse effects. Availability of both oral and intravenous formulations allow for easy continuation of therapy when patients are admitted to the intensive care unit.

Proton Pump Inhibitors

By covalently bonding to the hydrogen-potassium-adenosine triphosphatase (ATP) of parietal cells, proton pump inhibitors (PPIs) suppress gastric acid secretion for the life of the parietal cell. Ideally, therapy should be given 30 minutes before feeding so that peak plasma concentrations coincide with parietal cell stimulation. Administration with food reduces bioavailability by fifty percent. Although their serum half-lives are relatively short; the pharmacological effect persists until new parietal cells are generated.[64] Omeprazole, esomeprazole, and lansoprazole have been approved for use in pediatrics. Extemporaneously compounded suspensions of omeprazole and lansoprazole are frequently used, even in patients with various

types of feeding tubes. Intravenous lansoprazole is no longer available. Neither intravenous pantoprazole nor esomeprazole is Food and Drug Administration (FDA)–approved for use in pediatric patients. Until sufficient pediatric dosing information becomes available, intravenous PPIs are likely to be reserved for patients with active GI bleeding or contraindication to alternative therapies. Although PPIs are generally thought of as well tolerated, both long- and short-term adverse effects are gaining more attention. Reactions include idiosyncratic reactions, drug-drug interactions, drug-induced hypergastrinemia, and drug-induced hypochlorhydria.[63] The most common side effects are headache, diarrhea, constipation, and nausea.[14] Case reports of biopsy proven interstitial nephritis associated with PPI use have emerged. Thus far no pediatric cases have been reported.[63] The FDA and Health Canada are currently investigating potential links between PPIs and decreased effectiveness of clopidogrel. Although the data are primarily from adult reports, the potential interaction may be relevant in pediatrics as well. PPIs should not be discontinued abruptly because a hypersecretory phase results.[63,65] Acid suppression, whether from H_2 receptor antagonists or PPIs, may increase the rates of community-acquired pneumonia, gastroenteritis, candidemia, and necrotizing enterocolitis.[63,66-68]

Antacids

Both aluminum hydroxide and magnesium hydroxide are effective treatments of GERD. In infants, however, aluminum hydroxide formulations can increase plasma levels of aluminum to those reported to cause osteopenia, microcytic anemia, and neurotoxicity. Aluminum-based antacids should be avoided in patients with renal impairment. Efficacy of calcium carbonate antacids has not been demonstrated in pediatric patients. Depending on the antacid formulation chosen, adverse effects may include electrolyte disturbances, nausea, flatulence, diarrhea, or constipation. Because alternative therapies are available and generally well tolerated, antacids should be reserved for intermittent symptom management rather than chronic treatment of GERD.[63]

Surface Agents

Sucralfate, an aluminum salt of sulfated sucrose, forms a protective barrier by binding to damaged mucosa in an acidic environment. Although it has demonstrated effectiveness in the treatment of esophagitis, it is not recommended for long-term treatment of GERD in children because of a lack of efficacy data and safety concerns associated with aluminum toxicity.[63]

Prokinetic Therapy

Prokinetic agents are of interest in GERD because of their ability to enhance esophageal peristalsis and accelerate gastric emptying. Cisapride is a prokinetic agent that at one time was widely used not only for GERD, but also for a variety of adult and pediatric motility disorders, including constipation and gastroparesis. It was prescribed more frequently than metoclopramide in children most likely because of its broader range of action and decreased risk of neurological side effects. Prolongation of the QTc interval with potential life-threatening ventricular arrhythmias was reported when cisapride was used concomitantly with drugs that inhibit the hepatic cytochrome P450-3A4 system. This uncommon, yet potentially fatal, adverse effect led the manufacturer to place it under a limited access protocol requiring close supervision by a pediatric gastroenterologist.

Erythromycin is a macrolide antibiotic and motilin agonist. It increases motility in the proximal GI tract. The most frequent adverse effects include abdominal cramping, nausea, vomiting, diarrhea, cardiac dysrhythmias with interacting medications, and risk of bacterial overgrowth. Metoclopramide promotes gastric emptying by acting as an antagonist to the inhibitory actions of dopamine in the gut. It also sensitizes the gut to acetylcholine and increases lower esophageal sphincter tone.[69] Metoclopramide blocks dopamine receptors in the chemoreceptor trigger zone and accelerates gastric emptying and intestinal transit time without stimulating gastric, biliary, or pancreatic secretions.[14] Adverse effects are common; are dose dependent; and can include extrapyramidal effects, seizures, and Parkinsonian reactions, which may be irreversible.[14,63] The FDA required the addition of a boxed warning to metoclopramide drug labels regarding the risks of long-term or high-dose use. Chronic use of metoclopramide has been linked to tardive dyskinesia, which may include involuntary and repetitive movements of the body, even after drug discontinuation. It is noted that these adverse effects are more prevalent in elderly populations.[70] Extrapyramidal reactions in children and younger adults are more likely after intravenous administration of high doses, particularly within 24 to 48 hours after starting therapy.[14] Prescribers are urged to carefully consider legitimate indications for initiating drug therapy. Current GERD guidelines recommend against use of prokinetic agents.

Gastroesophageal Reflux Disease and Acute Life-Threatening Event

An acute life-threatening event (ALTE) is an episode of combined apnea, color change (cyanosis, pallor, plethora), abnormal muscle tone (limpness and stiffness), choking, and gagging that requires intervention. Some patients have succumbed to sudden infant death syndrome who have had a history of ALTE with documented GER. This combination is rare and assigning the timing and causality of the event is extremely difficult. Neither pharmacotherapy nor surgical intervention has been adequately studied in secondary prevention of ALTE. Those patients who may benefit from pharmacologic intervention may include those whose ALTEs were obviously associated with vomiting, regurgitation, or obstructive apnea.[63]

Stress-Induced Mucosal Damage: Ulcer Prophylaxis

Prospective studies reveal similar incidence of GI hemorrhage between adult and pediatric intensive care units. Of 1006 patients admitted to a pediatric intensive care unit, 10.2% had upper GI hemorrhage; however, only 1.6% of the admissions were viewed as clinically significant. Respiratory failure, coagulopathy, and a Pediatric Risk of Mortality score greater than or equal to 10 were identified as independent risk factors for GI hemorrhage.[71,72] Other studies also identified pneumonia, multitrauma, a surgical operation longer than 3 hours,

and circulatory shock in patients as high-risk factors.[73,74] One subsequent pediatric study demonstrated mechanical ventilation as the only statistically significant risk factor for clinically significant bleeds after multivariate analysis.[75] Children ventilated for greater than 48 hours were at additional risk of hemorrhage if thrombocytopenia, coagulopathy, organ failure, high pressure ventilator settings (>25 cm H_2O), or Pediatric Risk of Mortality score greater than 10 were present.[76] Mechanical ventilation and coagulopathy are recognized as independent risk factors in adult patients.[72] Because of the low incidence of clinically significant hemorrhage, prophylaxis may only be warranted in those patients with risk factors.[77]

Sucralfate, H_2 receptor antagonists, antacids, and PPIs have been used for prophylaxis of stress-induced mucosal damage in pediatric critical care patients. Individual trials including comparative studies and case series have shown each agent to be effective. With the low incidence of clinically significant bleeds, studies intending to demonstrate superiority of one drug class or agent over another would require an extremely large sample size. Therefore pediatric studies use a surrogate endpoint of gastric pH 4 or greater to evaluate efficacy of various dosing regimens.[78-80]

One study included 165 patients treated with ranitidine, antacid, sucralfate, or placebo. There were no differences among the treatment groups and all treatment groups had a lower incidence of bleeding than the placebo group.[81] Another study compared ranitidine, omeprazole, sucralfate, or placebo for stress ulcer prophylaxis and also compared adverse events. No differences were found among groups with regard to macroscopic stress ulcer bleeding, mortality, or ventilator-associated pneumonia.[82] Because multiple agents appear to be effective for stress ulcer prophylaxis, selecting an appropriate agent may be patient specific. However, when prescribing prophylaxis to adult patients, the inadequacy of sucralfate it is widely recognized after the landmark trial by Cook et al.[83] published in 1998 that demonstrated significantly lower rates of clinically relevant bleeding in the ranitidine treatment group. In addition there was no significant difference in pneumonia rates in this 1200-patient trial. Critical care patients do present challenges with regard to drug administration for antacids and sucralfate. Both agents require multiple doses per day, lack intravenous formulations, and may chelate or inhibit absorption of other drugs. In addition, aluminum toxicity may be of greater concern in critical care patients because of the potential for renal impairment. H_2 receptor antagonists are commonly used because of the availability of intravenous formulations. Adverse effects of the central nervous system, particularly in patients with renal impairment who have not been dose adjusted; thrombocytopenia; and drug interactions remain a concern. Most of these adverse events, however, can be prevented or at least monitored for early detection. PPIs may also be used orally, intravenously, or off-label through feeding tubes.

Stress ulcer prophylaxis is recommended, along with other supportive therapies, for acute lung injury and acute respiratory distress syndrome in children.[84] Stress ulcer prophylaxis is also recommended as supportive care for patients with sepsis in the 2008 Surviving Sepsis Campaign. H_2 receptor antagonists use was recommended with a stronger level of evidence than PPIs.[85] Some experts believe that although greater acid suppression is achieved with PPIs over H_2 receptor antagonists, PPIs should be used as second-line agents for stress ulcer prophylaxis because of the greater association with adverse effects such as community-acquired pneumonia, ventilator acquired pneumonia, and *C. difficile* infection.[86]

Gastrointestinal Hemorrhage

Clinical guidelines for treatment of nonvariceal upper GI bleeding in adults include recommendations for pharmacotherapy.[87] Unfortunately, this body of evidence does not exist in the pediatric population. H_2 receptor antagonist use is discouraged as primary treatment for patients with acute bleeding. Although octreotide and somatostatin are more effective than H_2 receptor antagonists, these agents are also not recommended for routine management. PPIs are cited as the drugs of choice for treatment of acute nonvariceal upper GI bleeding.[87] High-dose intravenous proton pump inhibitor therapy (80 mg pantoprazole bolus followed by 8 mg/hr for 72 hours after endoscopic therapy[39]) is preferred over H_2 receptor antagonists alone, or in combination with octreotide, to prevent rebleeding in adult patients. As more data become available regarding the use of intravenous proton pump inhibitors in pediatric patients, parallels may be seen between the treatments of adult and pediatric nonvariceal upper GI bleeding.

Proton Pump Inhibitors

Multiple oral proton pump inhibitors are approved for pediatric use. Pantoprazole and esomeprazole are available intravenously in the United States; however, neither product's intravenous formulation has been well studied in children. Doses have been extrapolated from the adult high-dose intravenous pantoprazole recommendations for use in clinical practice in pediatric patients with nonvariceal upper GI bleeding. Although it is not yet specified in the literature, many pediatric sites reportedly use a pantoprazole loading dose of 2 mg/kg IV, followed by 0.2 mg/kg/hr for 72 hours (neither the loading dose nor continuous infusion should exceed the adult dose).

Octreotide and Somatostatin

Octreotide is a somatostatin analogue. Its pharmacologic actions include inhibition of gastric acid secretion and decreased splanchnic blood flow. Although its 1.7-hour half-life is approximately 30 times longer than that of somatostatin, octreotide is usually administered through continuous infusion for GI hemorrhage. Adverse effects include abdominal pain, sinus bradycardia, nausea, pain at the site of injection, elevation of liver enzymes, chest pain, emesis, headache, dizziness, fatigue, flushing, and diarrhea. Long-term use (longer than 1 month) has been associated with changes in thyroid function, gallstone formation, and cholecystitis.[88]

In adults, octreotide has been shown to decrease the duration of hemorrhage and prevent recurrence of peptic disease more so than cimetidine or ranitidine. A Cochrane Review cited improved initial hemostasis and decreased transfusion requirements; however, no change was evident in rebleeding or secondary outcomes when octreotide was used to treat variceal bleeding.[88] Few researchers have evaluated octreotide for GI hemorrhage in children. In one study, continuous infusion of octreotide in seven patients was evaluated. Bleeding ceased in six of the seven patients. The duration of infusion ranged

from 24 to 234 hours. Although bleeding stopped within 24 hours in nearly half of the patients, on average, bleeding stopped after 40 hours. The most notable adverse effect was hyperglycemia.[89] Subcutaneous octreotide has also been used for severe chronic GI hemorrhage for periods of 24 to 50 months.[90]

Vasopressin

Generally vasopressin has been used for treatment of variceal bleeding more frequently than for nonvariceal upper GI bleeding. In fact, adult guidelines do not address the use of vasopressin for non-variceal bleeding.[87] Vasopressin acts by mechanisms similar to octreotide; however, its effects on blood pressure make it a less desirable option in many patients.[91] From a medication safety perspective, vasopressin prescribing can be confusing given the wide range of accepted dosing conventions and variety of indications in pediatric patients (e.g., diabetes insipidus, GI hemorrhage, shock). Dosing recommendations that require units per kg per unit time require careful decimal place checks. Intensive care units should decide on the accepted dosing convention and dose range for vasopressin for each indication and use infusion pumps with safety software that can accommodate the predetermined limits to prevent 10-fold dosing errors.

Helicobacter Pylori Infection

Patients who have GI bleeding of unknown etiology should be tested for *Helicobacter pylori*. At minimum, therapy requires three different medications administered twice daily for 1 to 2 weeks. Three different regimens are recommended for first-line treatment in pediatrics. Each consists of a proton pump inhibitor in combination with amoxicillin and clarithromycin, amoxicillin and metronidazole, or metronidazole and clarithromycin. Second-line options incorporate bismuth subsalicylate or ranitidine, and tetracycline as one of the antibiotic choices.[92] Tetracycline is contraindicated in patients younger than 8 years because of permanent discoloration of teeth, enamel hypoplasia, and retardation of skeletal development and bone growth.[14] Noncompliance with *H. pylori* regimens is the most commonly cited reason for treatment failure.[92] Pediatric *H. pylori* treatment guidelines are currently under revision.[93]

Drug-Induced Liver Injury

Cause

Liver injury in children may result from autoimmune disease, metabolic disease, infectious causes, acute hepatitis, ischemia, irradiation damage, and exposure to toxins or medications.[94,95] Drug-induced liver injury (DILI) has been noted to account for more than 50% of cases of acute liver failure in adults and approximately 20% in children, with acetaminophen as the agent most cited in the United States.[96,97] Most cases of DILI in children are mild, and many correct after the offending medication is discontinued.[97] However, some still progress to chronic liver injury.[98,99] Diagnosis of DILI is largely a diagnosis of exclusion. DILI patients typically present within 12 months of starting the suspected medication.[98] The Pediatric Acute Liver Failure (PALF) Study Group, a multinational, multisite consortium, was formed to prospectively study acute liver failure in children from birth through 18 years of age.[94,97] The 24 sites in the PALF study group hope to improve understanding of the pathogenesis, treatment, and outcomes of acute liver failure in children.[95] The PALF study group found that of the first 348 children enrolled through 2005, 14% had acute liver failure caused by acetaminophen, 5% caused by a drug or toxin other than acetaminophen, 10% caused by metabolic disease, 6% caused by autoimmune liver disease, 5% was idiosyncratic DILI, and 49% of unknown cause.[95,97,98] Younger children were more likely to develop ascites, require ventilator support, and require red blood cell and plasma infusions than older children.[95]

Various clinical scoring systems, including the Roussel Uclaf Causality Assessment Method (RUCAM) and the Naranjo Probability Scale, have been developed as a means to increase the specificity of diagnosis of drug hepatotoxicity. These scales consider the postexposure interval, biochemical pattern, exclusion of alternative causes, extrahepatic manifestations, rechallenge attempts, and previously reported cases. Their routine use has been limited in pediatrics and is not routinely recommended.[97] Table 87-3 summarizes the pharmacologic agents most cited as causing DILI in adult and pediatric patients. The corresponding references provide a more thorough discussion of the individual agents and/or case reports.

Treatment

Various pharmacological agents may be started to manage the wide-ranging adverse effects that arise from liver failure.

Cerebral Edema and Hepatic Encephalopathy

Protein restriction to 2 to 3 g/kg/day may help lessen excessive ammonia production,[100] whereas fluid restriction to 75% of maintenance may prevent cerebral edema and reduce encephalopathy.[101] Intravenous mannitol, continuous furosemide infusions, and tight glucose control have also been used for treatment of cerebral edema.[101] Oral antibiotics, in particular neomycin, have been effective in reducing ammonia production in adults with hepatic encephalopathy by suppressing ammonia-forming bacteria in the gut.[94,100] However, neomycin should be used cautiously in children because of potential renal toxicity and deafness. Synthetic disaccharides such as lactulose are metabolized by bacteria in the colon to form organic acids that lower the colonic stool pH and trap diffusible ammonia, thus decreasing serum ammonia levels. Lactulose forms the basis of therapy in children with hepatic encephalopathy and elevated serum ammonia levels, although the bulk of research surrounding its use is in adults.[100] Levocarnitine may offer another option for reduction of ammonia levels in the brain, whereas albumin infusions have been used to reduce plasma ammonia levels.[101] Sodium benzoate has been used in adults with cirrhosis, and may provide an alternative option in children.[94,101,103]

Ascites

Ascites is the accumulation of fluid in the peritoneal cavity. Although liver transplantation is the only definitive treatment for refractory ascites, many pharmacologic and nonpharmacologic options exist for acute management of ascites. Diagnostic abdominal paracentesis can help in directing therapy. Traditionally, bed rest has been recommended, however a lack of scientific evidence and difficulty enforcing in children may limit its

Table 87–3 Common Agents Cited in Drug-Induced Liver Injury[94,96-99,103,117,145-147]

Drug Class or Group	Specific Agents and Reaction	Comments
Analgesics	Acetaminophen: necrosis	
	Aspirin: Reye syndrome, necrosis	
	Bromfenac*: acute liver failure	
	Celecoxib: hepatocellular	
	Diclofenac: hepatitis, cholestasis	
	Etodolac: fulminant hepatic failure	
	Ibuprofen (rare): hepatitis, vanishing bile duct syndrome	
	Indomethacin: cholestasis, necrosis	
	Meloxicam: hepatitis	
	Naproxen: cholestasis	
	Oxaprozin: hepatocellular, hepatitis	
	Piroxicam: hepatocellular, cholestasis, necrosis	
	Sulindac: hepatitis, cholestasis	
Cardiovascular agents	Amiodarone: steatohepatitis, acute liver failure	
	Angiotensin-converting enzyme inhibitors (captopril, enalapril, fosinopril): hepatitis, cholestasis	
	Angiotensin II receptor inhibitors (irbesartan, candesartan, losartan): cholestasis, hepatocellular	
	β-Adrenergic receptor blockers (propranolol, metoprolol, acebutolol, atenolol, labetalol): hepatocellular, cholestasis	
	Calcium channel antagonists (diltiazem, nifedipine, verapamil): hepatitis, cholestasis	
	Hydralazine: hepatitis, necrosis, granulomas, cholestasis	
	Labetalol: necrosis, hepatitis	Labetalol: most hepatotoxic β-blocker
	Methyldopa: hepatitis, cholestasis, steatosis, cirrhosis, granulomas	
	Thiazide diuretics (hydrochlorothiazide, chlorothiazide, chlorthalidone): cholestasis	
Drugs used to treat diabetes mellitus	Glucosidase inhibitors (acarbose): hepatitis, cholestasis	Thiazolidinediones: monitor baseline liver tests and every 2 months after during first year of therapy
	Human insulin: hepatitis	
	Metformin: hepatitis, cholestasis	
	Sulfonylureas (chlorpropamide, gliclazide, glipizide, glimepiride, tolazamide, tolbutamide): hepatitis, cholestasis, vanishing bile duct syndrome	
	Thiazolidinediones (troglitazone,* rosiglitazone, pioglitazone): liver failure, hepatotoxicity, fibrosis	
Lipid-lowering agents	Ezetimibe: elevated serum transaminases	
	Fibrates (fenofibrate, gemfibrozil, nicotinic acid): hepatitis, acute liver failure, cholestasis, necrosis	
	HMG-CoA reductase inhibitors (statins) (atorvastatin, cerivastatin,* fluvastatin, lovastatin, pravastatin, simvastatin): cholestasis, hepatitis, acute liver failure	Statins: monitor liver function at baseline, within 12 weeks, and then every 6 months
Anticonvulsants	Carbamazepine, oxcarbazepine: cholestasis, hepatitis, vanishing bile duct syndrome, acute liver failure	
	Felbamate: hepatitis, acute liver failure (reserve use to drug-refractory epilepsy and Lennox-Gastaut syndrome)	Felbamate: discontinue immediately if aminotransferase is elevated

Drug Class or Group	Specific Agents and Reaction	Comments
	Lamotrigine: hepatitis	
	Phenobarbital: acute hepatitis, cholestasis	
	Phenytoin: hepatitis (rare), cholestasis, granulomas, focal necrosis	
	Topiramate: acute liver failure, hepatocellular	
	Valproic acid: steatosis, necrosis, increase in aminotransferases; greatest risk in first 2 years of life; progression to liver failure most common in patients with underlying mitochondrial disorders	
Psychotropic and antidepressant medications	Atomoxetine: hepatobiliary	
	Chlorpromazine: cholestasis	
	Clozapine: hepatocellular, fulminant hepatic failure	
	Haloperidol: cholestasis	
	Nefazodone: liver failure	
	Olanzapine: hepatitis	
	Paroxetine: hepatitis	
	Pemoline: hepatitis, acute liver failure	
	Prochlorperazine: cholestasis	
	Risperidone: hepatocellular	
	Thiazide diuretics (hydrochlorothiazide, chlorothiazide, chlorthalidone): cholestasis	
	Trazodone: hepatocellular, cholestasis	
	Tricyclic antidepressants (amitriptyline, imipramine): cholestasis	
Chemotherapy and immunosuppressants	Azathioprine: hepatitis, hepatic veno-occlusive disease	
	Busulfan: hepatic veno-occlusive disease	
	Chlorambucil: cirrhosis, fibrosis, (rare)	
	Cyclosporine: cholestasis	
	Dacarbazine: acute hepatic failure	
	Dactinomycin (in combination with radiotherapy): hepatitis	
	Erlotinib: hepatitis, hepatorenal syndrome	
	Fluorouracil (when given intra-arterially): hepatitis, sclerosing cholangitis	
	Flutamide: cholestasis	
	Gemcitabine: hepatitis	
	Interleukin-2: hepatitis	
	L-asparaginase, pegaspargase: liver steatosis, hepatitis, necrosis, fibrosis	
	Megestrol acetate: cholestasis	
	Mercaptopurine, azathioprine: hepatitis, cholangitis	
	Methotrexate: cirrhosis, fibrosis, steatosis	
	Natalizumab: hyperbili	
	Nitrosoureas (carmustine, lomustine, streptozotocin): hepatitis, hepatic veno-occlusive disease	
	Paclitaxel, docetaxel: hepatitis	
	Plicamycin: hepatitis, necrosis	Plicamycin: most hepatotoxic chemotherapy agent commercially available
	Recombinant α-interferon: hepatitis	
	Tamoxifen: cholestasis	
	Thioguanine: hepatic veno-occlusive disease

Drug Class or Group	Specific Agents and Reaction	Comments
Anesthetics	Halothane: hepatitis, necrosis	
Anti-infectives	**ANTIBIOTICS**	
	Amoxicillin and amoxicillin/clavulanic acid: cholestasis, hepatitis	
	Oxacillin, cloxacillin, dicloxacillin, flucloxacillin: cholestasis	
	Erythromycin: cholestasis, necrosis, hepatitis	
	Tetracycline, minocycline: microvesicular steatosis, hepatitis	
	FLUOROQUINOLONES	
	Ciprofloxacin, ofloxacin, levofloxacin, norfloxacin: hepatitis	
	Rifampin: hepatitis	
	SULFONAMIDES	
	Sulfamethoxazole and trimethoprim, sulfamethoxazole: hepatitis, cholestasis, granulomas	
	Nitrofurantoin: cholestasis, granulomas, chronic hepatitis	
	ANTIFUNGALS	
	Fluconazole, itraconazole, ketoconazole, flucytosine, terbinafine: cholestasis, hepatitis, necrosis	
	ANTIRETROVIRALS	
	Nucleoside analogue reverse transcriptase inhibitors (didanosine, stavudine): hepatic steatosis and lactic acidosis	
	Nevirapine: hepatitis	Nevirapine: monitor liver enzymes for first 18 weeks of therapy
	PROTEASE INHIBITORS	
	Ritonavir, tipranavir: acute liver failure, hepatitis, cholestasis	
	ANTITUBERCULOUS AGENTS	
	Isoniazid: hepatocellular necrosis	
	Pyrazinamide + rifampin or isoniazid	Rifampin + pyrazinamide combination use is discouraged by the CDC and ISDA because of severe liver injury
Miscellaneous	Allopurinol: hepatitis, fulminant hepatic failure	
	Amatoxin, found in wild mushrooms: acute liver failure	
	Cocaine: ischemic liver necrosis	
	Designer drugs of amphetamine (ecstasy): resemble acute viral hepatitis, acute liver failure requiring transplant	
	Estrogens: cholestasis	
	Marijuana and hashish: alterations in liver enzymes	
	Ondansetron: hepatitis	
	Propylthiouracil: hepatitis	
	Tolcapone: acute liver failure	
	Vitamin A (dose dependent): fibrosis, portal hypertension	
	Zafirlukast: hepatitis, necrosis	
Herbals	Camphor: necrolytic hepatitis	
	Cascara sagrada: cholestasis	
	Chaparral leaf, germander: acute and chronic hepatitis, cholestasis, cirrhosis, fulminant liver failure	
	Greater celandine: chronic hepatitis, cholestasis, fibrosis

role.[104] Dietary restriction of sodium, such as restriction to 1 to 2 mEq/kg/day for infants and children and 1 to 2 g/day in adolescents, may help increase diuresis.[104,105] Diuretics are used to increase urinary sodium excretion, leading to a negative fluid balance and weight loss. The target negative fluid balance in children of approximately 10 ml/kg/day is often used.[104] Conflicting approaches to initiation of diuretics exist. Spironolactone typically is added first, with thiazide and loop diuretics (mainly furosemide in children) added if maximal doses of spironolactone are insufficient. Spironolactone acts to inhibit aldosterone at the distal renal tubule, thus inhibiting reabsorption of sodium, whereas furosemide inhibits sodium reabsorption in the ascending limb of the loop of Henle. Initial doses can be given once or twice daily, and titrated upwards as necessary.[94,101,104] Another approach is to initiate both spironolactone and furosemide upfront in a ratio of 5:2, with subsequent change to spironolactone monotherapy once a desired diuresis occurs.[105] Monitoring of serum electrolytes, acid base status, urine output and serum creatinine is necessary with all diuretic use, especially when using spironolactone and furosemide in combination. Potassium supplementation may be necessary. In patients with hypoalbuminemia, albumin infusion followed by furosemide may offer a brief, brisk diuresis.[101, 104] Fluid restriction is typically not necessary in children. In refractory ascites, other options may include large volume paracentesis, transjugular intrahepatic shunts, although unlike with adults have limited use in children, peritoneovenous shunts, and ultimately liver transplantation.[104] The most significant complication of ascites is spontaneous bacterial peritonitis.[105] *E. coli* and *Klebsiella pneumoniae* are the most common causes, hence an intravenous, third-generation cephalosporin such as cefotaxime is often used for empiric therapy as it covers 95% of the associated flora.[100,105] A β-lactam and β-lactamase combination agent, such as ampicillin/sulbactam, may offer an alternative,[104] as well as once-daily norfloxacin in cirrhotic patients with ascites for prevention of spontaneous bacterial peritonitis.[105] Trimethoprim-sulfamethoxazole has been considered a therapeutic alternative to fluoroquinolones given safety concerns in pediatrics.[100]

Coagulopathy and Hemorrhagic Complications

As both procoagulant and anticoagulant proteins are reduced in acute liver failure, clinically relevant bleeding rarely occurs. Intravenous vitamin K can be used to control coagulopathy, whereas severe cases may be treated with fresh frozen plasma and cryoprecipitate.[101] Recombinant factor VII offers another alternative for correction of prothrombin time/INR abnormalities when active bleeding is present, although its high cost may preclude its use.[94] Prophylaxis with H_2 receptor blockers, PPIs, or sucralfate is started to prevent any GI bleeding.[94,101] Infection may precipitate bleeding in this population; thus initiation of antibiotics should be considered if bleeding develops.[94] The use of nonselective β-blockers in children, while successfully used in both primary and secondary prevention of variceal hemorrhage in adults with portal hypertension, is controversial. Insufficient data exist to demonstrate its use in this population; however, use may be considered as related to a risk reduction in bleeding. Both endoscopic injection sclerotherapy and endoscopic variceal ligation for variceal bleeding have been shown to be effective in treating varices in children and preventing future bleeding, thus these options are considered first-line, with beta blocker use adjunctive therapy.[100] For emergent treatment of variceal bleeding in children, intravenous octreotide or continuous vasopressin is often initiated in an attempt to lower splanchnic vascular tone, thus decreasing portal venous pressure.[100,101] However, approximately 30% of children treated with octreotide will still have a persistent hemorrhage despite conservative management and octreotide.[100]

Pruritus

Pruritus may be a result of prolonged cholestasis or noncholestatic liver disease. Treatment of underlying cholestatic disease should improve pruritus. Cholestyramine, an anion exchange resin, is widely used.[106] Other agents that have been used and may offer benefit include ursodiol, opioid antagonists such as naloxone and naltrexone, rifampin, antihistamines, dexamethasone, and ondansetron.[98,106] Trials have also evaluated prednisolone, cyclosporine, methotrexate, exposure to ultraviolet light, s-adenosyl methionine, antioxidants, macrolide antibiotics, and plasmapheresis with varying results.[106]

Cholangitis

Primary care consists of fasting, adequate intravenous hydration and broad spectrum antibiotics such as a third-generation cephalosporin and/or aminoglycoside to cover gram-negative bacilli, mainly *Enterobacter* spp.[107]

Miscellaneous

Acetaminophen is a widely used over the counter medication and the most common cause of DILI in children in the United States. DILI can occur after ingestion of therapeutic doses of acetaminophen over several days to treat clinical symptoms or a single overdose. Interventions for toxic acetaminophen ingestion include inhibiting drug absorption (i.e., gastric lavage), dialysis,[108] prevention of the conversion to the toxic intermediate metabolite *N*-acetyl-p-benoquin imine (i.e., through use of cimetidine), replenishment of glutathione stores to prevent hepatotoxicity, and liver transplant. Methionine, cysteamine and *N*-acetylcysteine (NAC) are available agents to detoxify *N*-acetyl-p-benoquin imine.[109] NAC is available either oral or intravenously in the United States and is the antidote of choice with fewer GI and central nervous system adverse effects compared with these other agents.[109,110]

It has been proposed that NAC may be useful therapy in other types of liver failure because of its ability to enhance hepatosplanchnic perfusion, to improve oxygen supply and demand, and its presumed cytoprotective and antioxidant effects. NAC may offer benefit in this patient population; however, many unanswered questions regarding dose, duration, and timing still remain.[111,112]

Dose Adjustments for Hepatic Dysfunction

Drugs absorbed via the GI tract undergo hepatic metabolism via a Phase I reaction (i.e., oxidation, reduction or hydrolysis) mediated be the CYP450 family of enzymes. These enzymes are found primarily in the liver.[96,105] These reactions cause the biotransformation of the parent compound to a more polar compound, that is more readily excreted.[99,113] Many adverse drug reactions and therapeutic failures can be attributed to genetically based differences in drug metabolism and elimination. Individuals can be divided into three groups: poor metabolizers, intermediate metabolizers, and extensive metabolizers. Average doses of medications given to poor metabolizers leads to higher drug exposure and greater risks of adverse drug reactions and drug toxicity.[99] The CYP3A subfamily makes up the largest group of CYP enzymes in the liver, with CYP3A4 the most important for post natal metabolism.[103,114-116] Consideration of the activity of the CYP450 isoenzymes, with specific focus on age differences, may aide in accurate drug dosing. For example, children require doses 50% to 100% higher than adults of drugs metabolized primarily by CYP2C9, whereas CYP3A4 activity is low at birth and reaches 72% of adult values at 1 year of age.[115] However, age-related changes in the pharmacokinetics of various drugs may be difficult to separate from altered enzyme activity due to altered liver mass, liver blood flow, and changes in plasma drug binding.[113]

There are no specific diagnostic tests or pathological findings to diagnose liver dysfunction. Routine laboratory tests to assess liver function are helpful in identifying a hepatic insult; however, these findings are not specific to viral, autoimmune, metabolic disorders or drug-related causes, nor do they identify the extent that hepatic metabolism may be impaired.[117] When hepatotoxicity is attributed to a dose-dependent hepatotoxin such as acetaminophen, blood levels of the suspected agent should be drawn.

Table 87–4 The Child-Pugh Score

Points	1	2	3
Encephalopathy	None	Minimal (stage I–II)	Advanced (coma) (stage III–IV)
Ascites	Absent	Controlled	Refractory
Bilirubin (mg/dL)	<2	2–3	>3
Albumin (g/dL)	>3.5	2.8–3.5	<2.8
Prothrombin time	<4	4–6	>6
Child-Pugh class A: 5–6 points	Child-Pugh class B: 7–9 points		Child-Pugh class C: 10–15 points

Modified from Pugh RN, Murray-Lyon IM, Dawson JL, et al: Transection of the oesophagus for bleeding oesophageal varices, *Br J Surg* 60:646-649, 1973.

The Child-Pugh score, adapted from the original Child score proposed in 1964, has been extensively used in adults as a user-friendly classification system for liver disease. This score is used as a prognosis of liver disease and as an indicator of a patient's ability to metabolize drugs eliminated by the liver.[118] However, this tool does not have the ability to predict the liver's ability to metabolize individual drugs.[116] Although various recent tools exist to classify liver disease, such as the Model for End-Stage Liver Disease (i.e., MELD) score widely used in adult liver transplantation ranking, the Child-Pugh score is the classic standard.[116,119] Patients are divided into three risk groups, based on their degree of liver dysfunction. Class A is low risk/mild disease, class B is intermediate risk/moderate disease, and class C is high risk hepatic dysfunction/severe disease (Table 87-4). Even with the wide acceptance and use of the Child-Pugh score, there are a limited number of medications containing specific recommendations for dosage adjustment based on hepatic function as categorized by the Child-Pugh score.[116] In 2005, a review of all Food and Drug Administration-approved medications found that only 23 included guidance for dosage adjustment based on Child-Pugh. Dose adjustments were typically recommended starting with Class B liver dysfunction, with many agents suggesting nonuse in patients with Class C rankings.[120]

Rectal Administration of Medication

Many drugs otherwise approved for oral and/or intravenous use have been administered rectally, in both adults and children. Rationale for using the rectal route varies. Rectal administration allows for avoidance of the orogastric route when necessary or avoidance of the intravenous route when access is an issue or when parenteral dosage forms are not available. The rectal route allows for a higher local concentration of drug in situations where limited systemic absorption is desired. Administration via this route may afford a less-costly alternative to a considerably more expensive parenteral product, and may offer an alternative when a parenteral product is unavailable. Although generally well accepted amongst patients and their families[121,122] clinicians may need to overcome resistance to rectal administration from patients and families because of personal perceptions.

Interpatient variability surrounding rectal administration is a key factor for clinicians to consider. Drug absorption may be accelerated or delayed. The rate of rectal transmucosal

absorption is affected by various factors. First, the formulation of the product itself varies, causing differences in the time to liquefaction with suppositories, the volume of liquid administered and the concentration of the drug. The length of the rectal catheter helps determine the site of absorption. Drugs administered high in the rectum, which is drained by the superior rectal veins, typically are carried to the liver via the portal vein, thus subject to first-pass hepatic metabolism. Drugs administered low in the rectum are delivered into the venous circulation by the inferior and middle rectal veins before passing through the liver. Presence of stool in the rectum and rectal pH can alter drug absorption. Rectal pH affects absorption by ionizing varying amounts of drug. The rectal mucosa in children typically has a more alkaline pH.[123] Nonionized drugs have greater lipid solubility, causing enhanced absorption across biological membranes. The rectal retention of the drug administered also affects absorption.[124]

The rectal route has been commonly studied with the use of rectal diazepam gel (Diastat). This commercially available product is used for prolonged or repetitive seizures in children and has approval by the FDA for at-home administration by a trained nonprofessional caregiver. Clinical trials and postmarketing data have reported a low rate of serious respiratory adverse events,[125] a major concern of many clinicians surrounding at-home use; however, cases have been reported in chronic, high-dose users of fluctuating effects of rectal diazepam, including reappearance of seizure activity.[126] This product may offer an alternative to other oral and intravenous benzodiazepine options available in a critical care setting, especially in emergent situations if access cannot be readily achieved. The controlled environment of a critical care unit can easily recognize adverse effects as opposed to home administration.

Clinically, successful rectal administration of medication in children has dealt mainly with anticonvulsants such as diazepam, lorazepam, and oxcarbazepine for status epilepticus[127]; sedatives such as diazepam, midazolam, and ketamine in varying uses[124,128]; localized treatment for irritable bowel disease using mesalamine[129-131]; vancomycin for pseudomembranous colitis[132]; antibacterial agents such as erythromycin[133]; antiemetics[134]; cardiovascular agents such as nifedipine and metoprolol[135-138]; and analgesics, specifically acetaminophen, nonsteroidal antiinflammatory drugs, and tramadol, for temperature reduction and postoperative pain control.[121,122,139,140] Although the American Academy of Pediatrics dissuades the rectal use of acetaminophen without consultation with a health care provider,[141] it has been widely used and studied.[139,140,142,143] In addition, rectally administered nonsteroidal anti-inflammatory medications, opioid analgesics, antiseizure medications, antiemetics, anticholinergic medications, antidepressants, psychostimulants, and antibiotics have been used with success in the hospice and palliative care settings.[144]

In a pediatric critical care environment, rectal administration of medication may be most beneficial when intravenous access issues are present, either because of an inability to maintain or achieve intravenous access or in situations when placement of an intravenous line is otherwise not necessary. Rectal administration in children is relatively painless, and comparable to rectal temperature monitoring, a common practice. Practical considerations for prescribers include knowledge of available dosage forms for rectal use, either commercial or those approved for orogastric use, interpatient variability of absorption, varying amounts of immeasurable drug expelled by the patient, thus altering dosage, and social considerations including patient and/or family perceptions of rectal medications, especially in older children and adolescents.

Chapter 88

Acute Liver Failure, Liver Transplantation, and Extracorporeal Liver Support

David M. Steinhorn, Estella M. Alonso, and Timothy E. Bunchman

PEARLS

- Pediatric liver failure represents a large number of heterogenous etiologies, although the management of acute failure is similar in most situations.
- Although orthotopic transplantation is definitive for irreversible hepatic failure, many cases of acquired acute failure may experience complete, recovery making the *timing* of transplantation a critical decision best undertaken in a transplant center.
- Extracorporeal support provided as continual renal replacement therapy can contribute to stabilization by optimizing (1) fluid balance, (2) electrolyte status, (3) nutritional support, and (4) coagulation status.
- The best outcomes following transplantation are seen in patients who are managed by a knowledgeable team pre- and postoperatively including hepatologists, transplant surgeons, and a meticulous intensive care unit team.

Acute liver failure (ALF) is a relatively rare and potentially fatal disease. It represents a heterogeneous condition with numerous etiologies in which the pathophysiology is diverse and frequently unclear, preventing substantial advances in specific therapy. Recognized etiologies include infections, toxins, metabolic disorders, infiltrative diseases, autoimmune hepatitis, ischemic, or irradiation damage, although a proportion of cases are unable to be diagnosed and fall into the cryptogenic group.[1-4] For the pediatric intensivist, the mainstay of therapy consists of *meticulous* supportive measures, with a focus on anticipation and prevention or treatment of complications and early consideration for liver transplantation.[5-10] With the onset of cerebral edema in children with acute liver failure, the risk for permanent disability increases dramatically.[11-13] Thus the timely intervention to prevent the metabolic derangements associated with acute liver failure is pivotal in preventing progression and the morbidity associated with this condition.[14-16] The rewards of bridging children with end-stage liver failure are reflected in the recent publication of the Pediatric Acute Liver Failure (PALF) Study Group, in which 53% of patients survived with medical therapy alone and an additional 30% survived with the aid of liver transplantation.[3]

Definition

Liver failure is defined as the loss of vital functions of the normal liver that entails synthesis of serum proteins including clotting factors and albumin, bile production and excretion, detoxification of organic anions, metabolism and storage of glucose and fatty acids and elimination of ammonia and other byproducts of energy utilization and protein metabolism. The significant compromise of these functions implies loss of a critical mass of hepatocytes, and the clinical manifestations of liver failure are dependent on the extent and time course of liver cell death.

The clinical syndrome of acute or "fulminant" liver failure is defined as the onset of hepatic encephalopathy and coagulopathy within 8 weeks of the onset of liver disease in the absence of preexisting liver disease in any form.[1,17] This narrow definition does not adequately address children with new-onset liver disease who develop encephalopathy more than 8 weeks after presentation or children with subclinical chronic liver disease such as autoimmune hepatitis or Wilson disease who present initially with liver failure. Although the management principles of children are similar for most etiologies of liver failure,[15,16] it is important for the intensivist to recognize that the prognosis can be remarkably different for the different underlying causes.

Epidemiology

The cause of ALF in children continues to be age dependent[2,3,18] with viral hepatitis probably the most common cause of ALF in all age groups overall. Severe hepatitis from echovirus and adenovirus is seen almost exclusively in the neonatal population. Liver failure can be one of the manifestations of overwhelming herpes infection in the newborn or immunocompromised patient. Metabolic liver disease and familial erythrophagocytosis are most commonly found in infants. Acute hepatitis A and B infections are rare causes of ALF in North America, but are a common cause of ALF in school-aged

Box 88–1 Investigations in Fulminant Hepatic Failure

Baseline essential investigations
Biochemistry
- Bilirubin, transaminases
- Alkaline phosphatase
- Albumin
- Urea and electrolytes
- Creatinine
- Calcium, phosphate
- Ammonia
- Acid-base, lactate
- Glucose

Hematology
- Full blood count, platelets
- PT, PTT
- Factors V or VII
- Blood group cross-match

Septic screen
Omitting lumbar puncture
- Radiology
- Chest radiograph
- Abdominal ultrasound
- Head CT scan or MRI

Neurophysiology
- EEG

Diagnostic investigations
Serum
- Acetaminophen levels
- Cu, ceruloplasmin (>3 years)
- Autoantibodies
- Immunoglobulins
- Amino acids
- Lactate
- Pyruvate
- Hepatitis A, B, C, E
- EBV, CMV, HSV
- Other viruses

Urine
- Toxic metabolites
- Amino acids, succinylacetone
- Organic acids
- Reducing sugars

CMV, Cytomegalovirus; *EBV,* Epstein-Barr virus; *HSV,* herpes simplex virus; *PT,* prothrombin time; *PTT,* partial thromboplastin time.

children in developing countries.[19] Drug-induced liver disease is more common in older children especially that secondary to intentional acetaminophen overdose.[20] Acute liver failure of indeterminant cause is common in all age groups, accounting for 40% of ALF among patients younger than age 3 years and 60% in those age 3 years and older.[20]

The incidence of ALF in childhood is not well described but has been estimated to be 2000 cases per year in adults in the United States. A recently established multicenter database (PALF) including 24 pediatric liver centers in the United States, Canada, and England, has collected demographics and outcome data from 348 pediatric cases of acute liver failure over a 6-year period.[20] A specific etiology could not be determined in 49% of the cases. Overall survival in this group was 84% at 3 weeks after presentation with 36% of the survivors receiving liver transplantation.[3,20] Considering the infrequency of this diagnosis and the frequent associated morbidity and mortality it is not unexpected that few pediatric subspecialists are comfortable managing patients with this diagnosis.

Clinical Presentation by Etiology

The clinical presentation varies with etiology but, in most cases admitted to the pediatric intensive care unit (PICU), there is hepatic dysfunction with hypoglycemia, coagulopathy and encephalopathy. Jaundice may be a late feature, particularly in metabolic disease. The clinical onset may be within hours or weeks. Most pediatric patients who develop ALF are previously healthy, with no history of major medical problems and no clear exposure to hepatitis or toxins.

Beyond the acute stabilization and attempts at detoxification of children with ALF, subsequent diagnosis and management of these patients must occur at a center familiar with the needs of this subset of critically ill children and with the resources (e.g., blood banking, continuous renal replacement therapy) necessary to provide optimal care until either recovery or transplantation occurs. The decision to transfer a patient with evolving signs of progressive liver failure must be made in a timely manner, because the risks of transporting patients in a deteriorating condition with advanced hepatic encephalopathy or uncontrolled bleeding can be monumental. When liver transplantation is not possible due to geography or other considerations, such transfer to a distant center may be a futile effort and a very disruptive experience for the terminal patient (and family) with advanced liver failure.

Family Support

Families of children with acute liver failure are naturally devastated by the development of potentially fatal, acute organ failure in their child. Such families require a considerable amount of psychological support and counseling, particularly as many families will not be able to grasp the seriousness of their child's condition and the implications of liver transplantation. Living donor transplantation is a reasonable option for families who are able to quickly assimilate the broad implications of ALF. The family's ability to comply with long-term care and medication regimens, should liver transplantation be necessary, is critical to the ultimate success of the process. The particular problems of suicide attempts and gestures in adolescents may require additional psychiatric help.

Management

Initial Assessment and Care

There is no specific therapy for acute and end-stage liver failure except hepatic replacement. Management therefore is directed toward early consideration for liver transplantation, hepatic support, treatment of acquired infections, and prevention and treatment of complications while awaiting recovery or a suitable donor for liver transplantation.[15,16,22-36] The key elements in managing patients before transplantation are meticulous medical support in the setting of an intensive care unit and rapid referral to a transplant center. It is essential to take a full history from the parents; this would include establishing appropriate risk factors such as information on intravenous injections, infusions of blood products, foreign travel or contact with individual exhibiting jaundice. It is important

Table 88–1 Clinical Stages of Hepatic Encephalopathy[3]

Stage	Asterixis	EEG Changes	Clinical Manifestations
I (prodrome)	Slight	Minimal	Mild intellectual impairment, disturbed sleep-wake cycle
II (impending)	Easily elicited	Usually generalized	Drowsiness, confusion, coma/inappropriate behavior, disorientation, mood swings
III (stupor)	Present if patient cooperative	Grossly abnormal slowing of rhythm	Drowsy, unresponsive to verbal commands, markedly confused, delirious, hyperreflexia, positive Babinski sign
IV (coma)	Usually absent	Appearance of delta waves, decreased amplitudes	Unconscious, decerebrate or decorticate response to pain present (stage IVA) or absent (stage IVB)

to establish what medications the child has taken, including over-the-counter preparations, folk remedies and herbal supplements, what medications might be in the household, and in adolescents to inquire about the use of illicit drugs and sexual contact. Folk remedies, some Chinese herbs, and herbal supplements (e.g., pennyroyal) in particular are often overlooked by parents giving a medical history but may be vital information in establishing an etiology.[27] Until a diagnosis is made (Box 88-1), it is assumed that all children are infectious and that all blood, excretions and secretions are potentially capable of transmitting viral hepatitis. Enteric isolation procedures must be enforced (http://www.cdc.gov/ncidod/dhqp/pdf/isolation2007.pdf) until an infectious etiology has been ruled out.

The initial physical examination should determine the status of major organ systems including hepatic, cerebral, cardiovascular, respiratory, renal, and acid–base balance. The patient's level of consciousness and degree of hepatic encephalopathy (Table 88-1) should be established using a reliable scale[3,28,29] and a complete central nervous system examination performed including examination of reflexes and mental status. Progression of coma may be assessed by serial examinations. Evidence of chronic liver disease or other signs which may suggest an etiology, such as Kayser-Fleischer rings, caput succedaneum, cataracts, and needle marks, should be established. Liver size and consistency should be determined and documented. The presence of impaired central nervous system function with acute liver disease is an indication for immediate hospitalization independent of any other clinical or biochemical findings. Observation in a suitable facility to intervene immediately with mechanical ventilation, intracranial pressure monitoring, if deemed beneficial, rapid availability of blood products and the ability to maintain acid-balance/fluid and electrolyte balance is critical. Typically, this level of support warrants referral to a transplant center where greater experience and availability of emergency transplantation may prove lifesaving.

A central venous catheter is useful for assessment of right heart function and volume status, but must be placed with care in patients with significant coagulopathy or thrombocytopenia. Use of a multilumen catheter, which enables simultaneous administration of blood products, dextrose solutions to maintain normal serum glucose levels, intravenous fluids and drugs, is helpful and may be replaced if needed to facilitate exchange blood transfusions or renal replacement therapy when required. An indwelling arterial line for continuous measurement of blood pressure and for biochemical and acid-base monitoring is frequently helpful especially in patients with evolving cardiopulmonary instability or in whom intracranial pressure monitoring is planned.[30] A nasogastric tube is passed and placed to gravity, with regular gentle saline lavage to detect upper gastrointestinal hemorrhage. The urinary bladder is catheterized and strict output measured to help in the evaluation of fluid status and renal function. Ideally, the patient is placed on a bed that permits the body weight to be recorded frequently.

Baseline biochemical and other investigations should be performed and management initiated as in Box 88-2. Frequency of biochemical monitoring will depend on the severity of illness, ranging from daily in mild cases to every 4 to 6 hours in patients in stage III and IV coma, and should include complete blood count, blood gases, electrolytes, aminotransferases, and prothrombin time, plus daily monitoring of plasma creatinine, bilirubin, and ammonia. A baseline chest radiograph is useful to diagnose cardiac dysfunction or aspiration.

Box 88–2 Management of Fulminant Hepatic Failure

No sedation except for procedures
Minimal handling
Enteric precautions until infection ruled out
Monitor:
- Heart and respiratory rate
- Arterial BP, CVP
- Core/toe temperature
- Neurological observations
- Gastric pH (>5.0)
- Blood glucose (>4 mmol/L)
- Acid-base
- Electrolytes
- PT, PTT

Fluid balance
- 75% maintenance
- Dextrose 10%–50% (provide 6–10 mg/kg/min)
- Sodium (0.5–1 mmol/L)
- Potassium (2–4 mmol/L)

Maintain circulating volume with colloid/FFP
Coagulation support only if required
Drugs
- Vitamin K
- H_2 antagonist
- Antacids
- Lactulose
- *N*-acetylcysteine for acetaminophen toxicity
- Broad-spectrum antibiotics
- Antifungals

Nutrition
- Enteral feeding (1–2 g protein/kg/day)
- PN if ventilated

BP, Blood pressure; *CVP,* central venous pressure; *FFP,* fresh frozen plasma; *PN,* parenteral nutrition; *PT,* prothrombin time; *PTT,* partial thromboplastin time.

An abdominal ultrasound may indicate liver size and patency of hepatic and portal veins, particularly if liver transplantation is being considered.

Fluid Balance

The aim of fluid balance is to maintain hydration and renal function while not provoking cerebral edema. Maintenance fluids consist of 10% dextrose in 0.25 normal saline, and intake should be 75% of normal maintenance requirements unless cerebral edema develops. A total sodium intake of 0.5 to 1.0 mmol/kg/day is usually adequate. Potassium requirements may be large, 3 to 6 mmol/kg/day, as guided by the serum concentration. As patients may become hypophosphatemic, intravenous phosphate may be given as potassium phosphate. Maintenance of euglycemia is critical and may require 3 to 6 mg/kg/min of dextrose infusion or greater.

Attempts should be made to maintain urinary output using loop diuretics in large doses (furosemide at 1 to 3 mg/kg dosed intravenously every 6 hours), vasoactive-inotropic agents and colloid/fresh frozen plasma (FFP) to maintain adequate preload and renal perfusion. Should profound oliguria occur, early consideration should be given to hemofiltration or dialysis prior to the development of hemodynamic instability (see section below on hemofiltration).

Anemia should be corrected, maintaining the hemoglobin concentration above 10 g/dL to provide acceptable oxygen delivery to tissues. Coagulopathy should be managed conservatively; the massive requirements for fresh frozen plasma may result in fluid overload requiring the institution of renal replacement therapy. In addition, the use of frequent FFP when not essential to control bleeding may confuse the signs of clinical recovery, which is often best reflected in an improving prothrombin time.

Nonspecific Adjunctive Therapy

It is usual to administer a single dose of vitamin K (2 to 10 mg intravenously) although it is frequently not effective. Proton pump inhibitors and antacids (see below) should be administered prophylactically to minimize the risk of gastrointestinal hemorrhage from stress erosions. The role of *N*-acetylcysteine in the management of ALF other than acetaminophen poisoning has been investigated with promising results. A multicenter, randomized trial of a continuous infusion of *N*-acetylcysteine over the first 72 hours after presentation in adult patients with ALF suggests that *N*-acetylcysteine may improve spontaneous survival in patients with early stages of encephalopathy.[31,32]

Antibiotic Therapy

The results of surveillance cultures can be used to guide antibiotic therapy in the event of suspected infection, but broad-spectrum antibiotics (amoxicillin, cefuroxime, metronidazole, and prophylactic fluconazole) are only prescribed if sepsis is suspected or liver transplantation is anticipated.

Nutritional Support

The role of parenteral nutrition in the management of patients with acute liver failure is controversial. The main aims of therapy are the following:

1. To maintain blood glucose (>40 mg/dL) and ensure sufficient carbohydrates for energy metabolism
2. To reduce protein intake to 1 to 2 g/kg/day, either enterally or parenterally
3. To provide sufficient energy intake to reverse catabolism, either enterally or parenterally

Children who are mechanically ventilated should receive parenteral nutrition to minimize negative nitrogen balance because it may be 7 to 10 days before full normal diet is resumed after transplantation.

Central Nervous System Monitoring

A baseline electroencephalogram may be helpful to stage coma; however, the findings are typically nonspecific. Computed tomography scans may be useful early in encephalopathy as a baseline examination to be compared with subsequent imaging to evaluate for signs of progressive, cerebral edema later in the disease. Frequent evaluation of neurological function with serial examinations and blood ammonia is essential to follow the progress of hepatic encephalopathy. Continuous or frequent electroencephalography may demonstrate abnormal electrical activity as a heralding sign of progressive hepatic encephalopathy or subclinical seizure activity. The role of intracranial pressure monitoring remains controversial (see Cerebral Encephalopathy and Edema sections in the following sections). The choice of intracranial pressure monitoring system is dependent on the standards of the individual institution and neurosurgeon consulting on the case (see also Chapter 59). All forms of intracranial monitoring are potentially hazardous in patients with severe coagulopathy, but they may provide helpful information on changes in intracranial pressure and improve selection for liver transplantation.[30]

Prevention and Management of Complications

The clinical course before transplantation of patients with advanced hepatic failure is dominated by the myriad complications affecting a wide range of organ systems. Monitoring for evidence of those complications and their skillful and timely management should be the focus of the intensivist in the preoperative period. The following discussion covers the most common organ system dysfunctions seen in this critically ill patient population.

Hypoglycemia

Hypoglycemia (blood glucose <40 mg/L) develops in the majority of children. It may contribute to central nervous system impairment and other organ dysfunction. Factors contributing to hypoglycemia include (1) failure of hepatic glucose synthesis and release, (2) hyperinsulinemia (due to diminished of hepatic degradation), (3) increased glucose utilization (due to anaerobic metabolism), and (4) secondary bacterial infection.[33-36]

Frequent bedside monitoring of blood glucose concentrations (every 2 to 4 hours) and the intravenous administration of glucose (10% to 50% dextrose) are required to prevent this complication. Patients may typically require 5 to 8 mg/kg/min of dextrose infused to meet these goals; however, clinicians should avoid excessively high rates of glucose infusion and the resulting hyperglycemia. Increased insulin production, secondary to excess glucose infusion, leads to increased glucose need and net lipogenesis that can be avoided by permitting the blood glucose to remain between 40 and 60 mg/L. Profound *refractory* hypoglycemia carries a grave prognostic implication and often heralds the imminent death of the patient.

Coagulopathy and Hemorrhage

The management of coagulopathy and hemorrhage is a major challenge in the overall care of the child with acute liver failure. Profound disturbances in hemostasis develop secondary to failure of hepatic synthesis of clotting factors and fibrinolytic factors, reduction in platelet numbers and function, and/or intravascular coagulation.[37,38] The coagulation factors synthesized by hepatocytes include factors I (fibrinogen), II (prothrombin), V, VII, IX, and X, and a reduction in synthesis leads to the prolongation of prothrombin and partial thromboplastin time

The prothrombin time is the most clinically useful measure of hepatic synthesis of clotting factors. Prolongation of the prothrombin time often precedes other clinical evidence of hepatic failure, such as encephalopathy, and may alert the clinician to the severity of acute hepatitis; it is a guide to the urgency of liver transplantation. Administering vitamin K parenterally (2 to 10 mg intravenously) assures the sufficiency of this essential cofactor, but rarely improves coagulation in ALF.

The prothrombin time depends on the availability of factor VII, which has the shortest half-life (approximately 4 to 7 hours) of the clotting factors and decreases more rapidly than other liver-derived clotting factors when production does not keep up with its utilization. As a result, measurement of factor VII is be a more sensitive indicator than the prothrombin time but is typically not as readily available. Fibrinogen concentrations are usually normal unless there is increased consumption such as in disseminated intravascular coagulation (DIC). The level of factor VIII may help differentiate between DIC and ALF because factor VIII is synthesized by vascular endothelium and therefore is normal or increased in ALF as an acute-phase response or from decreased utilization. Decreased levels of factor XIII may contribute to poor clot stabilization.

A reduction in platelet numbers ($80 \times 10^3/\mu L$) occurs in up to half of adult patients, although thrombocytopenia is less of a problem in pediatric experience. Severe thrombocytopenia, requiring platelet transfusion, suggests hypersplenism, intravascular coagulation, or aplastic anaemia. Use of extracorporeal support devices may also contribute to abnormally low platelet numbers.

Intravascular coagulation as detected by abnormal concentrations of fibrin degradation products is present in almost all ALF patients, indicating ongoing clot deposition and dissolution, most probably as a consequence of tissue necrosis in the liver. Rarely significant in ALF, DIC can contribute to organ damage. Sepsis may also be present as an additional cause of DIC. With the ready availability of activated Factor VIIa concentrate, the intensivist should recognize that the administration of commercial concentrates containing activated clotting factors may itself precipitate DIC.

Oozing from needle puncture sites and line insertion is common, whereas pulmonary or intracranial hemorrhage may be terminal events. Petechiae reflect decreased platelet function, disturbed vascular integrity, or DIC.

Although in the early stages of assessment prolongation of prothrombin time is a sensitive guide to prognosis and the need for liver transplantation, coagulopathy resulting in significant bleeding should be treated with FFP infusion at a rate of 15 to 20 mL/kg FFP every 6 hours, or by continuous infusion at a rate of 3 to 5 mL/kg/h, with the addition of cryoprecipitate and platelets as needed. Treatment to improve coagulation status should also be attempted prior to invasive procedures. In the very small infant, recombinant Factor VIIa may provide significant hemostasis with less volume loading.

Administration of recombinant factor VIIa (40 μg/kg) reliably corrects the coagulation defect in patients with acute liver failure for a period of 6 to 12 hours and may be useful in preparation for invasive procedures.[39] Double-volume exchange transfusion may also temporarily improve coagulation to control life-threatening hemorrhage, especially in patients with DIC. Hemofiltration may be necessary to control fluid balance and provide fluid "space" if large amounts of coagulation support are required. Platelet counts should be maintained above $50 \times 10^3/\mu L$ by infusion of platelets. DIC is rarely severe enough to warrant the risks of heparin infusion to break the vicious cycle.

Prevention of Gastrointestinal Hemorrhage

Gastrointestinal tract hemorrhage may be life-threatening and secondary to gastritis or stress ulceration. PPIs (pantoprazole 0.5 to 1.0 mg/kg/day up to 20 mg for children <40 kg) or high-dose H_2 antagonists (ranitidine 1 to 3 mg/kg dosed every 8 hours) should be administered intravenously to reduce the risk of upper gastrointestinal tract bleeding. Prevention of gastrointestinal hemorrhage may also prevent further hyperammonemia by eliminating the large protein load to the intestines.

Encephalopathy

Clinically, acute hepatic encephalopathy is defined as any brain dysfunction that occurs as a result of acute hepatic dysfunction[40] and may be exacerbated by sepsis, gastrointestinal bleeding, electrolyte disturbances, or sedation, particularly benzodiazepine administration. Clinical manifestations and progression are highly variable, but acute hepatic encephalopathy usually evolves over days through definable stages. In rare cases, it may progress rapidly with coma and fatal cerebral edema developing within hours of the earliest detectable signs.

A scale for grading clinical encephalopathy is presented in Table 88-1. This scale is useful for assessing encephalopathy in older patients and the table includes guidelines for assessing infants, particularly in the early stages of encephalopathy.

The earliest abnormalities may not be detectable by clinical assessment, but are apparent to family members. Personality changes, reflective of forebrain dysfunction, include regression, irritability, apathy and occasionally euphoria. Younger children are more likely to be irritable and apathetic. Sleep disturbances, such as insomnia or sleep inversion, are often observed.

Intellectual deterioration, observed in stage I of chronic hepatic encephalopathy, is usually not evident in acute encephalopathy. Constructional apraxia related to disturbed spatial recognition may be present. Simple age-related tasks may be clinically useful tools for the day-to-day assessment of inattentiveness and apraxia. Subtraction of serial 7s (in older children and adults), recall of events (such as recently viewed videos), handwriting, and figure-drawing are appropriate tasks that older children can be asked to repeat daily in order to assess early encephalopathy. Younger children when asked to color a figure in a simple coloring book may not complete the task (inattentiveness), or scribble far outside the lines (constructional apraxia).

As the patient progresses into stage II hepatic encephalopathy, drowsiness and lethargy are readily apparent. Mental deterioration is clearly eviden—the personality changes and

behavior becomes inappropriate, with outbursts of anger or crying. Infants exhibit increasing irritability and often produce high-pitched screams. They may refuse to take feedings. Asterixis develops and is a useful sign, but it cannot be elicited with regularity in children less than 8 to 10 years of age. Motor impairment becomes evident, including ataxia, dysarthria and apraxia. Other neuromotor disturbances that can be detected at this stage include hyperreflexia, sustained clonus, rigidity, extensor posturing, and bizarre facial expressions. Electroencephalogram abnormalities are detectable at this stage.

Stage III hepatic encephalopathy is characterized by deepening somnolence and stupor. The patient is arousable by vigorous physical stimuli, but does not respond to commands. Patients are disoriented and often do not recognize family members. School-aged children and teenagers in deepening stage II and stage III coma often exhibit extreme agitation and rage. Biting and aggressive behavior may be a problem, and individuals caring for such children must be aware of the potential health risks involved. Seizures may develop. Neurological findings are more profound (see Table 88-1).[3]

Progression into stage IV hepatic encephalopathy is heralded by the onset of coma. The patient responds only to painful stimuli. At first, the patient is flaccid, but in deeper stage IV the patient will assume decerebrate posturing, and brainstem reflexes are lost. Respirations may become ineffective requiring mechanical support to prevent death.

Acute hepatic encephalopathy is completely reversible after resolution of the hepatic dysfunction as long as neuronal death has not developed due to the consequences of cerebral edema.

Management of Hepatic Encephalopathy

Although the role played by ammonia in the development of encephalopathy is controversial, traditional therapy to reduce ammonia production or accumulation is indicated. The essential components of therapy are (1) restriction of dietary protein, (2) enteral antibiotics, (3) enteral lactulose, (4) continuous hemofiltration in patients with renal insufficiency, and (5) controlling the complications of acute liver failure that contribute to ammonia accumulation.

In the early stages of hepatic encephalopathy, conventional measures are taken to minimize the formation of nitrogenous substances by the intestine. A cathartic, such as sodium-free magnesium sulphate and/or a nonabsorbable disaccharide (lactulose 1 to 2 mL/kg every 4 to 6 hours) may be administered orally or via the nasogastric tube. Enteral neomycin (50 to 100 mg/kg/day) may also be used to reduce ammonia production by colonic bacteria if diarrhea secondary to lactulose is a problem. Protein intake should be limited to 0.5 to 1.0 g/kg/day in this phase and may be administered enterally or parenterally to limit the production of ammonia. Caloric intake is maintained in the early stages with glucose polymers and supplemented by infusion of 10% dextrose solution or greater as needed while frequently monitoring blood glucose.

The older patient with aggressive delirium is a particular risk to care providers. Sedation is not usually needed, except in violent patients to prevent self-injury. Elective ventilation should be considered if the encephalopathy progresses compromising the airway or if respiratory distress occurs. If sedation is required, either for restraint or during procedures, short-acting barbiturates or opiates can be safely used, but benzodiazepines should be avoided. There are potential therapeutic implications related to the γ-aminobutyric acid (GABA) receptor, which has been implicated in encephalopathy. Flumazenil (a benzodiazepine antagonist) may produce temporary reversal of hepatic encephalopathy.[41,42] Administration is followed within minutes by a clinical response, which may last for several hours, and it has been suggested that a lack of response to flumazenil may indicate a poor prognosis.

Cerebral Edema

Cerebral edema may develop between stage III and stage IV encephalopathy and present within hours of the onset of coma. Brain death associated with cerebral edema is the most frequent cause of death in acute liver failure and contributes to reduced survival after liver transplantation.[13,43-46] Every effort should be made to prevent this complication since the prognosis is poor once it has become manifest.

The diagnosis and management of cerebral edema associated with hepatic failure is analogous to that utilized for other forms of cytotoxic cerebral edema.[13,30,45]

Renal Dysfunction

Renal insufficiency complicates the course in 75% of children with ALF[47,48] and may be due to prerenal azotemia, acute tubular necrosis and functional renal failure.

Prerenal azotemia may be due to dehydration or gastrointestinal bleeding because of absorption of nitrogenous substances from the gut. A marked increase in blood creatinine concentration may develop from decreased glomerular filtration and/or increased muscle breakdown.

Acute tubular necrosis is seen in the minority of patients and may occur because of hypovolemia or dehydration and may be induced after mannitol infusion or diuretic therapy. Features include: abnormal urinary sediment; urinary sodium concentration greater than 20 mmol/L, reduction in creatinine clearance (urine/plasma creatinine ratio <10), and oliguria (urine output <0.5 mL/kg/h).

Functional renal failure (hepatorenal syndrome) is the most common cause of renal insufficiency. Features include sodium retention (urinary sodium concentration <20 mmol/L), normal urinary sediment, and reduced urinary output (<1 mL/kg/h). The etiology is multifactorial, and electrolyte imbalance, sepsis, and hypovolemia all play a part. Endotoxemia may contribute to renal injury.[49]

The aim of management is to maintain circulating volume to prevent hypovolemia and ensure that urine output is greater than 0.5 mL/kg/h. A fluid challenge with isotonic volume expander (10 mL/kg) may be successful unless central venous pressure indicates fluid overload (>8 to 10 cm H_2O), in which case the use of furosemide (1 to 2 mg/kg intravenously) or (0.25 mg/kg/h by infusion) may be effective. Established renal failure requires hemodialysis or continuous renal replacement therapy as detailed in the following section (see Chapter 72).

Although functional renal failure recovers quickly after liver transplantation, acute tubular necrosis may severely complicate the postoperative management.[49,50] Although 50% of patients require hemodialysis or continuous renal replacement therapy, renal function returns to normal after successful liver transplantation.

Ascites

Use of ultrasound in the pretransplant assessment has demonstrated excessive peritoneal fluid in most ALF patients, probably from acute portal hypertension, from lobular collapse,

vasodilatation, poor vascular integrity, and reduced oncotic pressure. Clinically evident ascites occurs in less than half the patients but may be a site for secondary bacterial or fungal infection, indicating the necessity for paracentesis in septic patients without an obvious focus of infection. Therapy for ascites is not indicated, other than the correction of oncotic pressure with albumin infusion and general fluid management. Paracentesis may be indicated if peritonitis is suspected or if the intra-abdominal pressure leads to impaired renal perfusion or intractable embarrassment of diaphragmatic movement.

Secondary Bacterial and Fungal Infections

The majority of adults and 50% of children will develop significant infection[51,52] that may be related to impairment of cellular and humoral immune systems.[53] The organisms most often implicated are gram positive (*Staphylococcus aureus, S. epidermidis*, and streptococci), presumably of skin origin. Gram-negative bacteria or a fungal infection is occasionally observed. Urinary tract infections from indwelling catheter, and pulmonary infection, particularly in ventilated children, are common.

Management includes surveillance cultures from the endotracheal tube, indwelling catheters, and urine. Broad-spectrum antibiotics should be started at the first suspicion of sepsis, as the signs may be subtle and fever may be absent as part of the immune paralysis seen with advanced liver failure. Cefuroxime (75 to 150 mg/kg/day divided every 8 hours), piperacillin/tazobactam (240 mg/kg/day; piperacillin component divided every 8 hours), and/or metronidazole (30 mg/kg/day divided every 6 hours), if there is a suspicion of anaerobic infection, are reasonable first-line medications. When fungal infection is suspected, antifungals such as amphotericin (1.5 mg/kg/day) or fluconazole (3 to 6 mg/kg/day) should be included, although are potentially nephrotoxic. Positive cultures in the absence of clinical infection should result in removal or replacement of the infected catheter and administration of the appropriate antimicrobials, with close attention to the possibility of additional, perhaps opportunistic infection. Aminoglycoside antibiotics should be avoided, if possible, because they can contribute to renal failure.

Hemofiltration for Hepatic Support

Although the definitive therapy for *irreversible* hepatic failure is organ transplantation, because of limited organ availability, transplantation may not be available in short enough time to prevent irreversible complications (e.g., cerebral edema, fatal hemorrhage). Therefore therapies have been developed over the last decade intended to temporize and support adult patients suffering from acute fulminant hepatic failure or so-called *acute-on-chronic hepatic failure* have been used in the adult population. They use a single vascular access with a clearance of toxins resulting from hepatic failure using a charcoal filter.[54] Such techniques have been used less frequently in pediatrics and to date there is very limited pediatric literature to support this therapy.[55,56] Attempts to create extracorporeal artificial liver systems using living hepatocytes in various configurations have shown promise[57-59]; however, as yet unsolved technical problems have limited the utility and widespread availability of this approach to research centers only.[58,60]

As an alternative to extracorporeal hepatic systems, many programs have used continuous hemofiltration as a way to support electrolyte status and ammonia clearance as well as to permit the administration of large quantities of FFP in patients with hepatic failure (see Chapter 72). This has been used in primarily in patients with concurrent renal insufficiency. Such therapy is continued until either the patient recovers or progresses on to irreversible loss of hepatic function with subsequent hepatic transplant or death. The specific techniques of continuous hemofiltration will depend upon the capability of the PICU, but all such approaches depend on optimizing clearance of medium and small molecular weight compounds as well as maximizing nutritional and anticoagulation support.

Data have shown that small molecular weight solutes (e.g., urea) can be cleared equally effectively with convective (continuous venovenous hemofiltration [CVVH]) or diffusive (continual venovenous hemodiafiltration [CVVHD]) approaches.[61] Personal experience has also demonstrated that ammonia, which is not effectively cleared during acute hepatic failure, can be equally cleared by CVVH and CVVHD. In addition, exogenous amino acids delivered via total parenteral nutrition can be equally cleared with both the modalities with a slightly greater clearance in convective methods.

Therefore the choice of CVVH versus CVVHD is based on the preferences, capabilities, and experience of each center. Using this therapy requires controlled anticoagulation in spite of the prolonged clotting times associated with liver failure. Because of the underlying coagulopathy, such patients may require little to no anticoagulation.[62] It should be remembered that the prolonged clotting times resulting from liver failure are due to decreased factor levels rather than to direct antagonism of clotting mechanisms (i.e., anticoagulation). Thus, some patients may have a paradoxical coagulation status in which they appear "anticoagulated" based on clotting times but yet have a tendency to be hypercoagulable partially due to depressed levels of anticlotting factors and intravascular coagulation as well. Most programs have used citrate or no therapy for this population for anticoagulation.[63-65] Citrate is intended to bind calcium within the hemofiltration circuit decreasing its availability as a cofactor in the clotting cascade. Calcium then is infused back to the patient distal to the hemofiltration circuit to rescue the patient from potential risk of hypocalcemia. Citrate is cleared both via the dialysis membrane as well as the residual hepatic function. Hepatic citrate metabolism results in bicarbonate production, which typically results in metabolic alkalosis. However, in patients with hepatic failure, citrate may be poorly metabolized and may accumulate over time. This condition may result in so-called *citrate lock* that represents residual citrate in the patient as the delivery of citrate exceeds its hepatic clearance. This can be accentuated if the patient receives banked blood products containing citrate such as FFP, although this is becoming less common in contemporary blood bank practice. Citrate can be used nonetheless in this population by minimizing citrate infusion and watching closely for the signs and symptoms of citrate lock (i.e., clinical hypocalcemia). Laboratory evidence for citrate lock is a rising total of calcium with a falling ionized calcium level when measured in the patient's blood rather than a sample drawn from the hemofiltration circuit. The decision to use no anticoagulation, heparin anticoagulation, or citrate anticoagulation is based on local experience and preference. In the hands of an experienced hemofiltration program, any of these approaches can be successfully used.

In undertaking either CVVH or CVVHD, one must use an appropriate solution to provide for either convective or diffusive clearance. Since the mid 2000s, the Food and Drug Administration–approved the use of dialysis solutions as drugs, paving the way for commercially produced solutions to be used for convective clearance in the mode of CVVH. This has allowed programs to replace "custom" mixed solutions in the hospital's own pharmacy that have been associated with significant complications due to errors in mixing.[66]

For diffusive methods (CVVHD), multiple solutions are available that commonly are bicarbonate based, some with calcium and some without. The calcium free solutions are more commonly used in a citrate anticoagulation protocol. Use of Normocarb HF as a replacement solution creates options of bicarbonate-based solutions for either convective or diffusive clearance.[67] Lactate is normally hepatically metabolized but in this population lactate from the dialysis solution may rise due to the diminished hepatic clearance. Whereas lactate is not thought to be directly toxic except at exceedingly high levels, rising lactate levels may prompt the clinician to undertake unwarranted investigation for sepsis, bowel necrosis, etc. It is well recognized that patients with lactate-based solutions will exhibit lactate concentrations that are detectable[68] using conventional clinical lactate assays. One can discriminate between patient and dialysis solution derived lactate by measuring the dextro- and levo- portion of lactate. Unfortunately, this test is not widely available and often will take an average of 4 to 6 weeks for an answer. Data by Barenbrock et al.[69] have demonstrated that bicarbonate-based convective solutions result in improved hemodynamics when compared to lactate-based solutions. Therefore many programs prefer bicarbonate-based solution. Clinicians can choose solutions compounded by the hospital pharmacy or the Food and Drug Administration-approved solution Normocarb that is now available for dialysis and continuous therapy. The latter eliminates the risk for pharmacy error and is less expensive.[70]

Once continuous hemofiltration has been initiated, the goals for hepatic support are several: The first goal is fluid management of the patient. An edematous patient at the time of liver transplant will have difficulty with closure of the abdomen as well as subsequent wound healing. Therefore preoperative maintenance of euvolemia and minimizing tissue edema is desirable. The second goal is the correction of electrolyte disturbances. Often patients with fulminant hepatic failure develop sodium perturbations, metabolic acidemia as well as other electrolyte disturbances. CVVHD with bicarbonate-based solutions can maintain normal electrolytes and minimize the adverse effects of electrolyte changes on the central nervous system. The third goal is to optimize nutrition and minimize the loss of visceral and somatic protein pools. Because liver failure often represents a catabolic state, the provision of nutrition in these patients benefits not only their postoperative care, but also helps support them during the period of organ failure before transplantation. Providing excess protein ammonia and may worsen hepatic encephalopathy, but modest amounts (0.75 to 1.50 g/kg/day) of high bioavailable protein or amino acids with suitable nonprotein calorie source will enhance wound healing, antibody synthesis and support body protein pools until transplantation can be performed. By balancing nutrition with the clearance of amino acids and ammonia through continuous hemofiltration, one optimizes the nutritional status that will benefit both the pretransplant and posttransplant status of the patient. The fourth goal is to maintain a balanced state of anticoagulation while noting the predisposition of the patient to bleeding. Many programs use frequent or continuous FFP therapy to reduce the risk of spontaneous bleeding from the underlying coagulopathy as well as to improve the response to anticoagulation therapy. The last benefit of continuous therapy is for control of ammonia levels and removal of potentially toxic substances not eliminated by the failed liver. Although hyperammonemia is not the sole cause of hepatic encephalopathy, the use of continuous hemofiltration is an effective adjunct in controlling the ammonia level in patients with hepatic failure.

If the condition of the patient necessitates ongoing continuous hemofiltration preoperatively, one may need to consider its intraoperative use as well. Intraoperative fluid flux with blood products, as well as other fluid management may need to be addressed during the operation. Blood transfusion can expose the patient to large potassium loads that may not be tolerated well by oliguric patients. Experience has shown that the use of intraoperative hemofiltration during liver transplantation can be safely and effectively undertaken.[71] The use of hemofiltration without anticoagulation provides optimal intraoperative support, whereas continuing to infuse calcium to offset the risk of hypocalcemia associated with intraoperative FFP and blood administration.

Continuous hemofiltration represents an important adjunctive support modality for patients with advanced hepatic failure and multiorgan dysfunction. By virtue of its ability to provide both a modicum detoxification as well as create a more desirable fluid balance, continuous hemofiltration may be a life-sustaining bridge to transplant for patients.

Extracorporeal Hepatic Support

Extracorporeal hepatic support has been under development for over two decades.[55,59] In general such systems are composed of immobilized living hepatocytes or multiphase dialytic and plasma exchange/absorber systems. There have been obstacles with each of these approaches and both systems have been used in clinical trials in adults and children with mixed results. Given the complexity of each system neither approach has gained widespread adoption although in Europe, there appears to be greater acceptance in particular for supporting adults with hepatic failure.[72] Because of the limitations in availability, expertise, and adaptation to smaller pediatric patients, extracorporeal support cannot be considered a standard of care at this time, although in centers where it is available for use, it may be a valuable bridge to either recovery or transplant. In lieu of specific extracorporeal liver support systems, the use of continuous renal replacement therapy as described above in conjunction with continuous FFP infusion can achieve many of the goals of support in the patient with advanced liver failure.

Liver Transplantation

Liver transplantation should be considered in all children who develop a stage III or IV hepatic coma, as spontaneous survival in this group is only 40%.[20,73,74] Transplantation is indicated for all forms of ALF, namely viral hepatitis (including of hepatitis B), drug-induced live injury including acetaminophen overdose and halothane hepatitis and liver injury of indeterminant

cause. It is also appropriate for certain forms of inborn errors of metabolism, for example Wilson disease and tyrosinemia type I, although contraindicated for some children with multisystem disease or mitochondrial DNA deletions.[75] Because the certainty of a successful outcome after liver transplantation is less likely than with other forms of liver disease[76,77] selection is critical[78] and is based on previous experience of mortality in the pretransplant era.[73] Transplantation using a living donor can accelerate the process and is associated with better outcome in the setting of acute liver failure.[19,79,80]

Etiology of ALF is an important factor in determining whether transplantation is appropriate. The highest mortality is seen in children with indeterminate hepatitis, particularly those with a rapid onset of coma and progression to stage III or IV hepatic coma, a shrinking liver, falling transaminases associated with an increase in bilirubin, and coagulopathy. Such children should be immediately considered for transplantation. Children with fulminant Wilson disease are unlikely to recover with medical treatment and require transplantation.

In contrast, children with hepatitis A and children with drug-induced liver disease, particularly acetaminophen poisoning, may make a complete recovery with intensive medical therapy. Thus, careful monitoring for poor prognostic factors is required before selection.

In practical terms, it is appropriate to list for emergency liver transplantation all children who have reached stage III hepatic coma as the shortage of donor organs may mean a considerable wait for transplantation, or death on the waiting list.

As the development of irreversible brain damage is a major contraindication to transplantation, it is essential to be certain that brain damage has not occurred before the operation. Current techniques are inadequate, but include intracranial pressure monitoring, the identification of cerebral infarction or intracranial hemorrhage by cerebral computed tomography or magnetic resonance imaging scans and establishing evidence of mid-brain herniation, such as fixed, dilated pupils.[30]

Auxiliary transplantation, in which the recipient liver is left in situ to regenerate, is controversial treatment for acute liver failure, but may have the benefit that the graft may be removed if the original liver regenerates.[81] It is not suitable for transplantation for acute liver failure secondary to metabolic liver disease because there is no potential for these livers to recover and there may be a risk of hepatoma in the cirrhotic liver.

Relative contraindications for transplantation include untreated sepsis, HIV infection, and the presence of vascular thrombosis.[82] Absolute contraindications for isolated hepatic transplantation include progressive terminal extrahepatic disease, irreversible or rapidly degenerative central nervous system disease, intestinal failure, or untreatable metastatic diseases.

Technical Aspects of Liver Transplantation

A detailed discussion of the techniques of liver transplantation is beyond the scope of this chapter. Several aspects of intraoperative management, however, are pertinent to the intensivist in managing the patient postoperatively.

First and foremost in reducing intraoperative and postoperative morbidity is to send the patient for transplantation in the best condition possible. This means that (1) infections have been treated, (2) excess edema has been avoided, (3) cardiopulmonary and renal systems are functioning well, and (4) the brain has been spared irreversible damage.

Limited availability of donor organs has led to the development of techniques for using "technical variant grafts" (reduced size, living donors, and split liver) to expand the donor pool and reduce waiting time.[83] The ability to provide a reduced segment allows smaller children to receive grafts from larger donors, increasing the availability of organs for younger patients. Although technical variant grafts may reduce waiting list mortality in the setting of acute liver failure, they are associated with a higher rate of postoperative complications. However, patient survival for recipients of technical variant grafts is similar to that seen with whole liver transplants, thus leading to a favorable risk/benefit ratio for selection of these types of grafts. Intraoperative issues affecting the postoperative course are listed in Table 88-2. In general, these issues can be managed with conventional approaches while adhering to two critical, postoperative principles: (1) maintain patency of vascular anastomoses, and (2) maintain normal to slightly supraphysiologic arterial pressure to provide adequate perfusion of the graft. Avoidance of excessive hemoconcentration and rapidly correcting all clotting parameters is key to successful care.

Immune Suppression

Currently, calcineurin inhibitors (e.g., cyclosporine [Neoral], tacrolimus [Prograf]), comprise the initial approach to immunosuppression. Tacrolimus is usually combined with low-dose steroids. Cyclosporine-based protocols may incorporate steroids and a third agent (e.g., azathioprine or mycophenolate [CellCept]).[74]

Most centers have tended to reduce the use of corticosteroids because of the poor growth and infectious risks associated with their use. The practice of steroid withdrawal varies between centers with weaning often started at 3 to 12 months posttransplant. The exception to this rule pertains to children who were transplanted for autoimmune hepatitis who have a high incidence of recurrence.

Postoperative Management Issues of Concern to the Intensivist

The postoperative period is critical due to the need to anticipate predictable complications and to detect unexpected issues as early as possible. The intensivist must be aware of the

Table 88–2 Common Postoperative Issues After Liver Transplantation

Postoperative Condition	Intraoperative Cause
Fluid overload	Intraoperative crystalloid, fluid shifts
Capillary leak syndrome	Altered perfusion state, multiple blood products, venous congestion
Hypoxemia	Atelectasis, edema, mucus plugging
	Distended abdomen impairing ventilation
Renal dysfunction	Altered perfusion, impaired venous return, renal vasoconstriction secondary to calcineurin inhibitor exposure
Coagulopathy	Inadequate fresh frozen plasma/platelets transfusion
	Small for size graft
	Primary poor graft function

risk for early complications including primary nonfunction, bleeding, hepatic artery or portal vein thrombosis, and bile leak. Later complications include infections, rejection, hypertension, renal dysfunction and lymphoproliferative disease.

As in all other organs, prolonged ischemia because of vascular compromise will potentially lead to the loss of graft function. It is impossible to overly stress the need for close and rapid communication between the PICU team caring for the postoperative transplant patient and the surgical and hepatology teams responsible for the operative interventions and managing the immunosuppression following transplantation. Joint rounding in the immediate postoperative period of *at least* once a day with all teams caring for the patient will facilitate the best communication during the critical postoperative period.

Primary Nonfunction

Primary nonfunction of the graft is a disastrous complication necessitating immediate retransplantation. Of children with graft failure within 30 days, primary graft dysfunction accounted for 25.6%.[74] Evidence of primary nonfunction includes worsening coagulopathy, acidemia, rising liver enzymes, and cholestasis. All measures used to support a patient with minimal liver function must be considered and instituted since the condition will become rapidly fatal in the absence of retransplantation.[82]

Bleeding

Postoperative bleeding occurs due to the profound coagulopathy and thrombocytopenia that many patients have going into liver transplantation as well as the dilutional coagulopathy and thrombocytopenia that can occur intraoperatively. Bleeding should abate as the function of the graft returns postoperatively. In addition, patients may return to the pediatric intensive care unit on heparin infusions in an attempt to maintain patency of the hepatic artery and portal vein anastomoses. Monitoring drainage devices for trends in the amount and the characteristics of the drainage is critical to detect postoperative bleeding at the surgical site. Additionally, monitoring of the hemoglobin is important as an indirect sign of bleeding and to assure adequate oxygen carrying capacity, optimally 8 to 10 g/dL. Platelet count should be followed and maintained in a suitable postoperative range as agreed on by both surgical and medical teams. Attempts to achieve perfect clotting function are generally avoided due to the high potential to promote thrombosis of the vascular anastomoses. Worsening coagulopathy suggests hepatic dysfunction, sepsis with DIC, or unrecognized internal bleeding and requires rapid, aggressive diagnosis with treatment of the underlying cause.

Monitoring Vascular Anastomotic Patency

Progress in microsurgical techniques has led to improvements in maintaining vascular patency. During the first 30 days after transplant, vascular complications are a major cause of graft failure. Forty-three percent of liver graft loss in children is directly attributable to either hepatic arterial or portal vein thrombosis.[74] Of the vascular complications, hepatic artery thrombosis occurs most commonly, 10% overall and is probably the most important, because it can lead to biliary leaks, strictures, and intra-abdominal infection.[84] Routine assessment of hepatic artery patency using color Doppler ultrasonography at the bedside is critical during this period. Magnetic resonance angiography or computed tomography angiography can be helpful in defining the status of vascular structures but can be technically difficult to perform in critically patients. Attempts at revascularization may be successful, if performed early. The intensivist should work closely with the surgical and radiology team to detect early signs of vascular occlusion. Avoidance of excess hemoglobin (hyperviscosity) and overzealous transfusion of platelets and clotting factor replacement in the immediate postoperative period is essential. Once again, detailed discussion with the other members of the transplant team will achieve consensus and minimize risks.

Infection

Sepsis continues to be the most frequent final pathway leading to death in liver transplant recipients.[85] The presence of arterial thrombosis or biliary leak significantly increases the risk of infection as well as abscess formation. Patients having undergone previous abdominal surgery and those who have received pretransplant steroid therapy are at increased risk for postoperative infection. Percutaneously drainage of intra-abdominal abscesses can be an effective method to treat these infections provided there is no evidence of an enteric leak. A high index of suspicion for postoperative infection in the immunosuppressed patient must be maintained with early culture and institution of antibiotic treatment including antifungal and anti-cytomegalovirus as indicated by the patient and donor status. Children are at particular risk for cytomegalovirus and Epstein-Barr virus infections because many are naive to these viruses at the time of transplantation. Passenger donor lymphocytes in the graft are a frequent source of primary infection. Prophylactic therapy with antiviral medication can delay infection and monitoring active viral replication by polymerase chain reaction can be a useful tool to assist in adjustment of immunosuppressive medications in patients with early, acute infection.[85]

Biliary Complications

Biliary complications include biliary anastomosis dehiscence and bile leaks from the cut surface of the liver. Approximately 15% of patients experience biliary complications within the first 30 days and 25% or more will experience this complication in long-term follow-up.[74] Early bile leaks may be diagnosed by the appearance of bile in the abdominal cavity drains, by nuclear scan or transhepatic contrast studies. Cut surface leaks from minor biliary radicals may resolve spontaneously, but leaks from the biliary anastomosis or from larger cut surface ducts require operative management. Bile duct ischemia secondary to hepatic artery thrombosis that results in a stricture or leak will likely require retransplantation. Bile leaks increase the risk of postoperative infections that require aggressive attempts to diagnose and treat with targeted antibiotic therapy when possible.

Rejection

The median time to first rejection after transplant in one series was 16 days with 40% to 70% of children experiencing a first episode of rejection 7 to 10 days after successful transplantation.[85] Laboratory findings including elevation in AST and γ-GTP followed by elevations in bilirubin. Liver biopsy is important to confirm the diagnosis of acute rejection and distinguish patients with viral infection, biliary obstruction, or graft ischemia who may have a similar clinical presentation. Early detection of rejection is critical to allow the initiation

of intensified immunosuppression to reverse the process and minimize graft loss.

Complications of Immune Suppressive Medications

Each of the immune suppressant agents in common use has potential undesirable side effects.[86] The most common issues are listed in Table 88-3. The majority of patients will receive a calcineurin inhibitor and corticosteroids setting the stage for postoperative hypertension with or without deterioration in biochemical renal function. Hypertension is treated with conventional pharmacologic agents and may remain a persistent problem. Diabetes is also relatively common in patients receiving tacrolimus with a prevalence of 25% at 3 months posttransplant. Hyperglycemia in the immediate postoperative period can be controlled by insulin drip and should not limit the clinician's ability to deliver adequate caloric intake.[87] Cyclosporin and tacrolimus-related encephalopathy and seizures occur in 11% and 8% of patients, respectively, with the most common onset in the first 2 weeks after transplantation. Both can be managed by reduction or elimination of the calcineurin inhibitor exposure. Seizure control will frequently require short-term treatment with antiepileptic medications.[88]

Table 88–3 Adverse Effects of Immunosuppressants

Agent	Adverse Effect
Tacrolimus	Hypertension, headache, infection, seizures, hyperglycemia, insulin resistance/diabetes, renal failure, PTLD, cardiomyopathy
Cyclosporine	Hypertension, infection, seizures, hyperglycemia, renal failure, hirsutism, gingival hyperplasia, PTLD
Sirolimus	Hypercholesterolemia, infection, edema, poor wound healing, PTLD
Corticosteroids	Hypertension, increased appetite, Cushing syndrome, acne, gastritis, poor wound healing, osteoporosis, poor linear growth
Mycophenolate	Intestinal hypermotility, cramping, diarrhea, infection, leucopenia, depressed WBC/plt counts

PTLD, Posttransplant lymphoproliferative disorder; *WBC,* white blood cell; *plt,* platelet.

Acute Abdomen

Robert Sawin

PEARLS

- Observation of a child's vital signs, position, and demeanor can be as valuable as palpation in assessing the abdomen.
- Decisions about imaging tests to assess the abdomen must consider the differential diagnosis, risks, and whether the results of the study will change therapy.
- Abdominal compartment syndrome cannot be defined by absolute intra-abdominal pressure alone.

The abdomen is both the primary source of disease conditions that require care in the intensive care unit (ICU), and frequently, is a secondary source of additional pathophysiology for children in the ICU being treated for other conditions. In either case, the early recognition of these conditions and the judicious use of surgical intervention can be key to the successful outcome in the ICU population.

Anatomic and Physiologic Considerations

The Peritoneum

The peritoneum provides a protective environment for the intra-abdominal organs, and, because of its marked sensitivity, a valuable "window" for the examining health care provider. It is composed of a single layer of mesothelial cells lining the abdominal cavity along the abdominal wall (the parietal peritoneum) and the intra-abdominal viscera (the visceral peritoneum). The space between these is the peritoneal cavity. Beneath the mesothelium is a submesothelial layer of extracellular matrix, capillaries, and lymphatics.[1] The peritoneum's sensitivity to inflammation, ischemia, and necrosis is mediated by the fluid in the peritoneum that contains macrophages and other leukocytes.[2] Thus, with a focus of inflammation anywhere in the peritoneal cavity, inflammatory mediators are released by these leukocytes, often resulting initially in poorly localized, generalized pain. With irritation of the peritoneum associated with early appendicitis, for example, the patient interprets the inflammation as periumbilical pain. This is related to the embryologic development along dermatomes. As more inflammatory cytokines are secreted throughout the peritoneal cavity, the pain becomes more generalized and will eventually result in spasm of the overlying muscles of the abdominal wall, interpreted by the examiner as guarding.

Pain in the gastrointestinal tract is mainly limited to conditions that result in distention of the organ. Inflammation or irritation of the mucosa is generally not the cause of pain, except in the stomach. Disease states that result in full-thickness inflammation of the bowel wall, however, can stimulate the visceral peritoneum, inciting the release of leukocytic and tissue macrophage derived inflammatory mediators that results in pain. Patients who are receiving drugs such as steroids, which blunt the immune response, have reduced production of these peritoneal inflammatory mediators, and consequently can have deceptively little pain despite a significant intra-abdominal disease. Just as in other parts of the body, ischemia associated with any abdominal condition results in severe pain, often out of proportion to what is detected on physical examination.

Visceral Blood Flow

The regulation of visceral blood flow is a tightly controlled balance of neural, humoral, paracrine, and metabolic factors.[3] In the gut, enteral feeding increases the blood flow and the metabolic demands on the intestinal mucosa. Some of these effects are directly related to the nutrients in the intestinal lumen, whereas others are dependent on the enteric nervous system and the associated refexes, on gastrointestinal hormones, and on gastrointestinal vasoactive mediators such as adenosine, endothelin-1, and nitric oxide.[4] In pathologic states such as sepsis alone or shock, whether from sepsis, hemorrhage, or cardiac failure, visceral blood flow is reduced, which can lead to ischemia of the intestinal mucosa and submuscosa. Even with restoration of blood pressure and cardiac output after treatment of shock, microvascular perfusion of the intestine may remain impaired resulting in mucosal ischemia and persistent lactate production.

Such ischemia can lead to altered integrity of the mucosal barriers to bacteria and other pathogens, thus increasing the entry of endotoxins into the splanchnic venous and lymphatic systems. These pathogens can fuel the inflammatory response. This finding has fostered the theory of "the gut as a central organ of sepsis or multisystem organ failure."[5] Whether the translocation of bacteria or endotoxin from gut lumen to splanchnic drainage is the chicken or egg can be debated; regardless, this perturbation of intestinal blood flow contributes to the pathophysiology of shock and sepsis.

Other conditions in the ICU can affect splanchnic blood flow, especially mechanical ventilation with high inspiratory

pressures, high positive end-expiratory pressure, or high tidal volumes.[6,7]

Physical Exam of the Abdomen

The examination of the child's abdomen requires keen observation, patience, and sensitivity to the patient's fears and their parents' anxiety. One should first notice the child's position and demeanor. Children with peritonitis do not move or writhe about the bed because this only worsens their pain, whereas a child with visceral ischemia that has not progressed to peritonitis may be actively seeking a more comfortable position. As mentioned earlier, pain out of proportion to the findings on physical exam in an ICU patient is suggestive of ischemia, independent of the location in the body. Tachycardia is a very sensitive marker for significant intra-abdominal disease and therefore its absence should prompt the examiner to look for other explanations of the reported pain. Observation of the patient's facial expressions is important throughout the physical exam, especially in nonverbal children.

The exam of a child with abdominal pain should begin by avoiding palpation of the abdomen. Testing for rebound tenderness is only valuable in older children and should be avoided in children younger than adolescence as it is too startling, and thus has a high false-positive rate. Shaking the bed, asking the child to cough, or gently grabbing the hips and moving them from side to side will cause a painful response in conditions with peritonitis and is much less threatening to younger children. Once the manual examination is to begin, the examiners should make certain that their hands and stethoscopes are warm. For the verbal child who has localized the pain to a specific portion of the abdomen, the examiners should start the palpation in the opposite quadrant. In generalized peritonitis, spasm of the rectus abdominis can be detected regardless of where the source of the inflammation is located. When rectus spasm is detected on one side of the abdomen, a comparison to the rectus on the other side is helpful; when both are in spasm, it could be a manifestation of guarding by an anxious child, and therefore distraction should be employed. Distraction can often be created by engaging in conversation with the verbal child, or by using the warmed stethoscope to listen with light pressure over the area of the abdomen in question, followed by gradually increasing the pressure to elicit a response. Asking the child to take a deep breath and "blow it all the way out" while feeling the rectus can overcome the spasm if it is due to voluntary guarding, whereas a child with peritonitis will fail to relax the rectus spasm. Bowel sounds are highly variable and their assessment is not usually useful in the ICU patient.

If palpation in one area causes referred pain in a different location (Rosvig sign), that is suggestive of localized peritonitis in the area of pain, classically seen in appendicitis, but also can be seen in other localized abdominal conditions.

In addition to steroids, other medications can interfere with the reliability of the physical exam of the abdomen. Although patients receiving opiates may have a blunted response to painful stimuli, significant intraperitoneal pathology can still be ascertained by careful observation. Those patients who are receiving paralytic drugs are particularly challenging because the rectus abdominis spasm that is associated with peritonitis may be substantially blunted. Observation of the face, heart rate, or blood pressure can still be valuable, especially by comparing these findings during examination to other areas of the body. Just as in the nonsedated, non-ICU patient, beginning the exam on another portion of the body gives the examiner a baseline for comparison.

Laboratory Tests

Assessment of possible intra-abdominal conditions should include blood and serum tests that measure inflammation, acid-base abnormalities, possible coagulopathy, and those focused on suspected involved organs. The leukocyte count and differential, hematocrit, and platelet count should always be checked for patients with suspected abdominal disease. Leukocytosis, especially with an increased percentage of neutrophils or immature forms should raise one's concern about an infectious process. Neutropenia suggests a more severe infection or a suppression of the patient's bone marrow from medications or from the infection; such a situation might make clearance of a bacterial infection more difficult. Similarly, both an increased and decreased platelet count can indicate an intra-abdominal infection. Serial declines in the platelet count are particularly suggestive of a continuing inflammatory consumption seen in conditions such a necrotizing enterocolitis. Hematocrit levels must be followed in any child in the ICU because they can demonstrate intra-abdominal bleeding or hemolysis related to disseminated intravascular coagulopathy. Other coagulation tests should be considered, especially in children with severe infections or those with liver dysfunction. In such situations the prothrombin time, partial thromboplastin time, d-dimers, and fibrin split products are helpful to characterize and monitor the coagulopathy.

Abnormalities of acid-base balance should be monitored regularly in a child hospitalized in the ICU with an abdominal disease process. The source of increased acid can either be an overproduction, such as ongoing lactate generation by ischemic bowel, or decreased acid clearance by the liver or kidneys in conditions associated with shock and decreased visceral blood flow. Lactate is a very sensitive measure of intestinal ischemia, especially when monitored serially for trends. Arterial blood samples are more reliable than venous samples in that measurement. Hyperlactemia is not specific to intestinal ischemia and can be associated with any tissue necrosis or underperfusion of organs.

Liver function test, more accurately termed liver injury tests, include transaminases (ALT and AST), bilirubin, and gamma glutamine transferase. These can be elevated with trauma to the liver, active hepatic inflammation, hepatic ischemia, or obstruction of the hepatic venous outflow, known as Budd Chiari syndrome. The latter can result in extremely elevated transaminase levels. Elevation of the gamma glutamine transferase without a significant rise in the transaminase suggests a biliary condition such as common bile duct obstruction or cholecystitis.

Amylase is a valuable diagnostic test for children with abdominal pain or unexplained intra-abdominal sepsis as hyperamylasemia can indicate pancreatitis. Elevated amylase is not specific to pancreatic insults and can be elevated with head trauma, decreased renal clearance, and intestinal obstruction. Serum lipase can be an additive test to the

assessment of the pancreas. It tends to be more specific to the pancreas, but can be mildly elevated in intestinal obstruction as well. When both amylase and lipase are markedly elevated, pancreatitis is most likely. Children with a history of severe or chronic pancreatitis might not have marked elevations, so the level of the enzyme does not always correlate with the severity of the disease.

Imaging Options

The reliability of abdominal exam is subjective and highly variable, and may be dependent on the experience of the observer, the fluctuating status of the patient and his or her medications, the patient's level of anxiety, and many other factors. Consequently, most ICU providers have developed a dependency on imaging studies to ascertain whether intra-abdominal pathology warrants intervention. For reasons of resource efficiency as well as considerations about the potential risks of ionizing radiation, prudence needs to be exercised before ordering expensive, potentially obfuscating data from imaging studies. The following factors should always be evaluated before performing each study:

1. Specifically, what is one looking for (i.e. what is the differential diagnosis)?
2. How reliably will this study rule-in or rule-out those diagnoses (i.e. what is the specificity and sensitivity of the study)?
3. Will the results of this study change the management (i.e. will a negative result prompt the termination of a drug regimen or life-supporting technology, and will a positive study necessitate surgical intervention or initiation of a new therapy)?
4. Are the risks, such as ionizing radiation, transportation of a heavily medicated or unstable patient from the ICU to the radiology suite, the administration of intravenous contrast, or other factors offset by the value of the study?

Ultrasonography

Ultrasonography has several advantages over other imaging studies, most notably its portability, which obviates the need for moving the patient and its lack of ionizing radiation exposure. In addition, the use of Doppler modality permits assessment of visceral blood flow to kidneys, pelvic organs, and the gastrointestinal tract. When the relative positions of the mesenteric vein and artery can be accurately determined, an abnormal orientation suggests an increased risk of malrotation, even without midgut volvulus.[9] The presence of a "whirlpool sign" can be diagnostic of malrotation with midgut volvulus.[10] Neither finding is sensitive enough to exclude the diagnosis of malrotation. Thus, if suspected, malrotation requires an upper gastrointestinal contrast study to assess the position of the duodenal-jejunal junction.[11] Assessment of gall bladder wall thickening suggestive of acalculous cholecystitis or biliary tree dilation are particularly accurate. Intra-abdominal and pelvic fluid collections can be identified and characterized well with ultrasonography, suggesting collections that would be suitable for drainage, either surgical or percutaneous, via ultrasound guidance. In the patient with bowel obstruction or severe paralytic ileus, the resultant intestinal distention creates ultrasonic distortion, minimizing the value of this imaging modality.

Abdominal Plain Radiographs

Plain radiographs of the abdomen can be revealing and also are portable, relatively inexpensive, involve small amounts of radiation, and require minimal patient movement. To be of greatest value, however, the abdominal radiograph should be done with the patient in at least two different positions, such as supine and upright, and ideally as lateral decubitus as well. Cross-table laterals can also add value. These different views facilitate the identification of air-fluid levels suggestive of small bowel obstruction, and the presence of pneumoperitoneum indicating likely visceral perforation. Pneumoperitoneum in a patient with high inspiratory pressures on a mechanical ventilator can sometimes be unrelated to abdominal pathology, but rather a consequence of air dissecting through mediastinal and diaphragmatic tissue planes. Other plain radiograph findings suggestive of intestinal disease include "thumb printing," pneumatosis intestinalis, and portal venous gas.

Computed Tomography

Abdominal computed tomography (CT) scans are accurate, fairly rapid, and can be used to guide interventional procedures such as percutaneous biopsies or drainage of intra-abdominal fluid collections. Except in institutions where CT scans are located in the ICU or those that have mobile CT units, patients must be transported to access imaging with this modality. That requirement can be a significant challenge with children who are ventilated or hemodynamically unstable. In addition to the transport challenges, the radiation exposure of a CT scan may pose a risk for developing malignancies later in life, especially for those children who receive serial radiographs.[12] That risk can be reduced by using directed scans (i.e., limiting the scan to the portion of the abdomen in question). Other risks include the administration of intravenous contrast material that can cause anaphylaxis in those who are allergic, or renal injury, especially in those who might already be hypovolemic or receiving nephrotoxic drugs.[13] That risk can be minimized as well, by using non-ionic contrast materials, or with the administration of sodium bicarbonate and N-acetylcysteine before the administration of the intravenous contrast. Administration of enteral contrast can result in aspiration if there is intestinal obstruction or delayed gastric emptying with vomiting or gastroesophageal reflux.

The abdominal CT scan can be very effective at identifying the condition of all the intra-abdominal organs, and the retroperitoneal spaces. It is being used with increasing success to assess for bowel obstruction. Identification of fluid collections and their characteristics can help ascertain whether blood, bile, or pus is present and whether it can be drained percutaneously. To make certain that nonopacification of fluid-filled loops of bowel is not misconstrued for pathologic collections of fluid, enteral contrast should be given as long as no contraindications exist. With intravenous contrast and carefully timed image capture, conclusions about organ perfusion can be assessed as well. Colonic and intestinal ischemia, necrotizing pancreatitis, and decreased renal perfusion can all be seen reliably.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) of the abdomen can be valuable, especially because the risks of radiation can be obviated, but the logistical challenges of moving an ICU patient

to the MRI suite are similar to those mentioned previously for CT scans. The added challenges posed by MRI include the slower speed of the image capture that interferes with accessing the unstable patient for interventions, as well as the restrictions for certain MRI-incompatible ICU equipment to be in the MRI scanning room. Despite this, MRI enterography and cholangiography are now capable of generating very revealing images of the gastrointestinal and hepatobiliary tracts.[14] Thus, if the value of the images can offset the risks of transporting a sick child to the MRI suite, it should be considered.

Abdominal Conditions Requiring Intensive Care Unit Care

Perforated Viscera

Children with perforation of the gastrointestinal tract will frequently require either preoperative resuscitation or postoperative stabilization in the ICU. The most common condition resulting in perforation is appendicitis. Although perforated appendicitis is common, occurring in 30% to 50% of children who present to children's hospitals with appendicitis,[15] it is unusual for it to result in serious intra-abdominal sepsis. Nevertheless, deaths do still occur in such children, related most often to septic shock with cardiovascular collapse or severe acute respiratory distress syndrome.

Other sites of perforation in the gastrointestinal tract include gastric perforation from either severe gastritis, gastric ischemia, or after manipulations such as insertion of gastric tubes or transpyloric feeding tubes. In children with chronic gastrostomies, accidental dislodgements or manipulations of the gastrostomy site can result in separation of the stomach from the abdominal wall, leading to spillage of gastric contents into the peritoneal cavity. Because the acidic gastric pH results in lower bacterial counts, such perforations do not usually result in serious intra-abdominal sepsis. However, chronically hospitalized children, or children with gastroesophageal reflux on chronic acid suppression therapies may be colonized with resistant bacterial or fungal organisms such as Candida species that can lead to serious septic consequences.

Ingested foreign bodies can lead to perforation anywhere in the gastrointestinal tract, with common items being sharp materials such as pins or nails, fish bones, disc batteries, and magnets.[16] Trauma can also result in perforation, notably in lap seat belt injuries from motor vehicle accidents, or in cases of nonaccidental trauma where a punch or kick can compress the small bowel against the vertebral column causing a jejunal perforation. Therefore, characteristic in this mechanism is that the intraoperative finding of a jejunal perforation in the absence of a known trauma history should prompt an evaluation by the hospital's child abuse team.[17]

Ischemia

Volvulus of a loop of small intestine can occur when a segment of bowel, typically distal ileum, becomes entrapped beneath an omphalomesenteric remnant. This particular lesion can be very difficult to diagnose as neither contrast enema radiographs nor antegrade upper gastrointestinal contrast studies are likely to reach the involved area of volvulus. In addition, such children will often not have impressive physical exam findings until the bowel has become ischemic. At that point, systemic sepsis can occur rapidly. Similar pathophysiology can develop from a twist of bowel within an internal hernia.

In children with intestinal malrotation, the entire intestine supplied by the superior mesenteric artery (i.e., from jejunum to right transverse colon) can twist, resulting in midgut volvulus. In a somewhat similar manner, the colon alone can twist when there is sufficient redundancy in the mesocolon, typically in the cecum or the sigmoid colon. In any of these situations with intestinal and mesenteric twisting, the resultant venous congestion can compromise the capillary inflow to the bowel wall, ultimately leading to irreversible ischemia if the bowel is not untwisted promptly.

In the pediatric ICU, another cause of intestinal ischemia is low cardiac output or hypoxemia. Children with congenital heart disease, particularly those with single ventricle physiology or severe cyanotic heart disease, can develop mucosal ischemia after cardiac surgery, manifested as pneumatosis intestinalis on radiographs, bloody stool, metabolic acidosis with elevated serum lactate, and sepsis. Children on potent vasoactive pressors such as epinephrine or norepinephrine, and those receiving extracorporeal support, can develop ischemia as well. This is a variant of necrotizing enterocolitis and can involve the entire small intestine, and less commonly the colon. If the diminished cardiac output or hypoxemia is corrected and the ischemia is limited to the mucosa, surgical treatment may be avoided. Resection is necessary if the acidosis or systemic perturbations are refractory or if perforation results. Unfortunately, because this disease can involve the entire gut, the utility of resection may be limited.

Other causes of intestinal ischemia include small bowel obstruction, usually from adhesions after previous laparotomies, or, less commonly, related to incarcerated inguinal hernias. If the bowel becomes sufficiently distended, the intraluminal pressure can exceed the intramural perfusion pressure of the microcirculation, resulting in ischemia. Other, less common causes of intestinal ischemia include conditions that alter the microcirculation of the bowel wall such as vasculitis or hemolytic uremic syndrome.

The systemic physiologic insult of intestinal ischemia is usually proportional to the degree of ischemic tissue. Thus, midgut volvulus or total intestinal involvement with necrotizing enterocolitis can be the most catastrophic of these disease states acutely, and can have the most devastating long-term consequences, with short bowel syndrome and intestinal failure a common consequence if the ischemia is irreversible.

Neutropenic Enterocolitis

Children who have significant neutropenia, whether drug-induced from chemotherapy for malignant diseases or as a primary disease, may develop inflammation of the intestinal tract. The most common location is the right colon. Historically, this has been termed typhlitis, but more accurately is labeled neutropenic enterocolitis, because it can affect other portions of the intestinal tract as well. It may be preceded by mucositis that permits the intestinal bacteria to invade the bowel wall. Affected children exhibit fever, abdominal pain and tenderness, abdominal distention, ileus or diarrhea, radiographic signs of inflammation, and sometimes hemodynamic instability. The diagnosis is made best by CT scan or ultrasound.[18] Surgical treatment is reserved for those patients

with peritonitis or hemodynamic instability after appropriate resuscitation.

Pancreatitis

Severe pancreatitis can require intensive care in children. Etiologies for the pancreatitis are most often idiopathic in children, but anatomic causes such as gallstones, pancreatic trauma, or pancreas divisum can also be responsible. Drugs and hemolytic uremic syndrome can be unusual causes of severe pancreatitis. In severe cases, pancreatitis can lead to significant third-space fluid losses, pleural effusions, retroperitoneal hemorrhage, abscess formation, and hypocalcemia. Necrotizing pancreatitis, although rare in children, can require repeated surgical debridement to eradicate the ongoing source of sepsis.

Hemorrhage

Intra-abdominal hemorrhage can result from trauma or surgical procedures or manipulations. In blunt trauma, the spleen is the most commonly injured abdominal organ. To avoid the risk of overwhelming postsplenectomy infection, nonoperative management is attempted as long as hemodynamic stability can be maintained. Hospitalization in the pediatric ICU with strict bed rest is indicated when the splenic injury is Grade IV or V, or if there are other significant injuries. The risk of delayed splenic rupture after nonoperative management is extremely low. If surgery is necessary, attempts to salvage the spleen with splenorrhaphy are important. Before surgery, if time permits, the child should be immunized for encapsulated bacterial organisms including *Hemophalus influenza*, *Streptococcus pneumoniae*, and meningococcus.

The liver is also a commonly injured organ in blunt abdominal trauma, and it too can usually be managed nonoperatively. The development of hemobilia several weeks after nonoperative management of hepatic laceration is uncommon, but when it occurs it can result in significant gastrointestinal bleeding. This can usually be managed with arteriographic embolization or endoscopic biliary stent placement,[19] but sometimes requires resection of the involved hepatic segment or lobe.

Other Specific Conditions

Cholecystitis

Gall stones are increasingly common in children, perhaps because of the increased use of parenteral nutrition with its associated risk of cholestasis. Gall stones can result in cholecystitis, biliary obstruction, or pancreatitis that can complicate an ICU course for a child. Acalculous cholecystitis can be seen in children who are hospitalized in the ICU, particularly those who are receiving large does of opiates that leads to biliary dyskinesia, or those who have decreased perfusion of the abdominal organs because of hypotension. Acalculous cholecystitis can be associated with a significant systemic inflammatory response, and should be considered as a source of unexplained sepsis in a child. Ultrasonographic and CT scan findings of a dilated gall bladder with a thickened gall bladder wall and pericholecystic fluid are diagnostic, although a radionuclide study such as a hepatobiliary iminodiacetic acid scan is the most accurate functional imaging study.

Empiric antibiotic coverage for common biliary pathogens such as Gram negative organisms like klebsiella, pseudomonas, or *Escherichia coli* should be started immediately. Cholecystectomy would be definitive therapy. In critically ill children who might not tolerate a trip to the operating room, percutaneous drainage of the gall bladder done by ultrasound guidance in the ICU can be an effective temporizing procedure.

Abdominal Compartment Syndrome

Intra-abdominal hypertension (IAH) is defined as intra-abdominal pressure (IAP) that is >12 mm Hg. Although this is relatively uncommon in pediatric ICU patients, it can be associated with a high morbidity and mortality. If the IAP reaches a point where perfusion to intra-abdominal organs is compromised, a constellation of organ dysfunctions may occur including renal insufficiency, intestinal ischemia, hepatic dysfunction, elevated diaphragms, and respiratory insufficiency.[20-22] This constellation is termed abdominal compartment syndrome (ACS). Risk factors for ACS include massive fluid resuscitation for any illness, intra-abdominal hemorrhage, intra-abdominal inflammation or infection from any cause, obesity, and tight abdominal wall closures following laparotomy. As with compartment syndrome in extremities, there is no absolute pressure to define the presence of ACS; the intravascular volume status, blood pressure, and systemic vascular resistance are all factors that can impact the perfusion pressure of the abdominal organs and minimize the effect of the IAP. An abdominal perfusion pressure can be calculated as the mean arterial pressure minus the IAP. If abdominal perfusion pressure is > 60 mm Hg, a higher survival rate has been reported. The diagnosis of ACS is made when there is a sustained increased IAP in combination with signs of organ dysfunction such as decreased cardiac output, oliguria, and respiratory insufficiency. Other organ systems that can be affected by IAH include the reduction of portal and mesenteric venous flow, potentially leading to hepatic dysfunction and intestinal edema and ischemia. In addition, the increased intrathoracic pressure that can result from the elevated diaphragms can raise intracranial pressure.

When signs of IAH are evident in the setting of abdominal distention, pressure measurements can be made using nasogastric tubes, rectal catheters, bladder catheters, and peritoneal drainage tubes such as peritoneal dialysis catheters. The most reliable and easily practical measurement can be obtained using a closed system of a Foley bladder catheter connected to a fluid column and a pressure measuring device such as a tube manometer or a pressure transducer. Ultrasound evaluation, including Doppler imaging of renal, portal, and mesenteric blood flow can be helpful in the assessment of end-organ perfusion, as well as estimating the intra-abdominal venous pressure by assessing the caliber of the inferior vena cava. CT scan can also reveal poor perfusion of these organs and a flattened inferior vena cava, as well as increased abdominal girth, especially in the anterior to posterior dimension.

If the diagnosis of ACS is suspected, efforts to augment perfusion must be initiated. Avoid the reverse Trendelenburg or prone positions because these can increase IAP. Effective decompression of the gastrointestinal tract is important and can be optimized by effective nasogastric tube drainage, administration of prokinetic medications, and colonic decompression by either enemas or colonoscopy. Supporting

renal function is also important and includes liberal use of diuretics along with volume resuscitation. If these maneuvers have not improved the organ function, temporary decompression by insertion of an abdominal drain to decrease the amount of fluid in the abdomen may be necessary. If this does not adequately decompress the IAH, laparotomy is necessary with placement of a sterile patch or silo that may provide sufficient compliance to reverse the ACS.

The morbidity of ACS is significant, with mortality rates of >50% reported, especially if treatment is delayed until multisystem organ failure develops. After decompression, and after resolution of any end-organ dysfunction occurs, and after the underlying causes of the IAH have abated, delayed closure of the abdomen can be considered. Sometimes that closure will require abdominal wall reconstruction techniques such as skin flap closure without fascial repair or skin grafts. Primary or delayed primary fascial repair may be feasible, sometimes requiring separation and release of the muscle groups, or insertion of prosthetic patches such as synthetic mesh, Goretex, or biologic sheet materials made from human dermal grafts or porcine intestinal submucosa.

The Intestine as a Source of Sepsis

The intestine is an organ endowed with large quantities of both lymphatic tissue and bacteria. Consequently, it can be a central organ in the systemic inflammatory response in children hospitalized in the ICU. The role of the gut's immune system is not fully understood, but may play a key role in some intestinal inflammatory diseases such as Crohn disease. In addition, the interplay between the gut-associated lymphoid tissue and the bacteria present in the bowel lumen is important in critical illness. The sick child with decreased visceral blood flow and under severe stress likely has alterations in the mucosal integrity of the intestine. That loss of integrity can lead to bacterial invasion of the bowel wall with subsequent entry of the bacteria/toxins into the lymphatic or portal venous circulation. Once in the circulation, such bacteria/toxins can trigger a severe systemic inflammatory response, even if the bacteria are not detectable as a blood stream infection. Use of enteral antibiotics to decrease potentially pathologic gut bacteria has proven effective in reducing intestinal sources of sepsis in some settings, while replacement of gut flora using probiotics or synbiotics has been employed with some success in others.

Surgical Intervention

The decision to perform a laparotomy or laparoscopy in a pediatric ICU patient can be very challenging. There are indeed times when a patient can be "too sick" to go to the operating room and other times when the patient is so sick that only an immediate operation will provide a chance for successful treatment.

With the possible exception of patients with continued intra-abdominal hemorrhage or abdominal compartment syndrome, delaying operative treatment with time spent on preoperative resuscitation is usually valuable. Induction of general anesthesia in a hypovolemic, or acidotic patient with cardiogenic or septic shock can be dangerous. An understanding of the differential diagnosis can be most helpful in planning the appropriate antibiotic coverage and the timing of the surgical treatment. Most of the conditions that require laparotomy in ICU patients have an infectious component and thus empiric broad spectrum antibiotics should be administered early in the resuscitation. Depending on the disease, resuscitation and antibiotics alone may obviate the need for emergent laparotomy. Effective communication between the surgical team and ICU team is therefore essential. To optimize the timing of the operation, the surgical team should be ready to go immediately, once the preoperative resuscitation is sufficient. In situations where physical exam or radiographs do not provide localization, bedside imaging can help localize the disease.

The Innate Immune System

Rachel S. Agbeko and Mark J. Peters

PEARLS

- Innate immunity provides the front-line "ready-made" response to pathogen invasion.
- These same pathways are activated in response to other critical insults including trauma, hypoxic/ischemic injury, and bypass.
- Pattern recognition molecules recognize exogenous as well as endogenous molecular patterns.
- Genetic changes may have functional sequelae in the immune response.

The immune response aims to ward off pathogens and mitigate injury. Traditionally a distinction is made between adaptive and innate immune responses. The adaptive immune system has been studied in the greater detail and is essentially a *specific* response to individual pathogens. Adaptive immunity is a highly sophisticated process with many safety mechanisms to target responses at pathogens (or pathogen-infected cells) while leaving normal tissues alone. This sophistication and specificity takes time to develop (days to weeks) and has many effector cells and molecules to deliver a coordinated response (T and B lymphocytes, immunoglobulins). Although the adaptive response is essential for health and in particular for the phenomenon of immunological memory, it is not sufficient to address a sudden major bacteremia or widespread tissue injury—or even the thousands of minor bacterial inoculums all individuals experience during their lifetimes—for example, during teeth brushing. Bacterial growth is exponential under optimal conditions—*Neisseria meningitides* counts can double in 20 minutes. Given these threats, there is a need for a "ready-made" system that can act swiftly to neutralize external threats. This is called the *innate immune system*.

In humans, the innate immune system is largely present at birth (in contrast to the years it takes to build an adaptive immune repertoire). Innate immunity is phylogenetically conserved and found in nearly all multicellular organisms; again, this contrasts with the adaptive immune system that is found in vertebrates only. Its hallmarks are immediacy, promiscuousness, redundancy, and generality. Given that the adaptive immune system evolved in the presence of innate immunity, these systems do not operate in isolation from each other; rather the innate immune system presents to and instructs the adaptive part of immunity.

Innate immunity encompasses immune cells, such as tissue macrophages, neutrophils, and monocytes, but also cells that are primarily known for other functions: platelets and endothelial cells. Complex networks of circulating mediators including the complement cascade, collectins, defensins, and the coagulation cascade are integral parts of innate immunity. Recent work has highlighted apparent contributions from neurohumoral and autonomic nervous systems.

No critically ill child is admitted to intensive care without activation of its innate immune system. No intensivist can function adequately without a good working knowledge of innate immunity, because it is central to many of the clinical entities he or she faces on a day-to-day basis. Infection, trauma, ischemia-reperfusion, acute respiratory distress syndrome, and cardiopulmonary bypass sequelae are all largely mediated by the innate immune system.

The immune system can be considered as a complex tool to distinguish tissues that are "infectious non-self" from "non-infectious self."[1] More recently a distinction between "dangerous" and "nondangerous" matter has been proposed as a better description for innate immunity.[2]

This chapter provides a framework and outline of concepts in innate immunity that will help understand some of the pathophysiological processes central to pediatric critical care.

Components of the Innate Immune System

An ideal first-line response to invading microbes would readily recognize and promptly neutralize infectious agents without widespread collateral tissue injury. The innate immune system achieves these objectives to some degree by a combination of circulating molecules that either cause direct pathogen lysis or prime pathogens for phagocytosis and by phagocytic cells themselves.

Complement, lectins, and defensins are important humoral defenses. The main cellular components are neutrophils, monocytes, macrophages, and dendritic cells. Platelets and endothelial cells are now understood to have innate immune functions also. There are complex interactions between these components as well as with the coagulation, endocrine, and the autonomic nervous systems.

The afferent, or "sensing," limb of the innate immune system consists of pattern recognition molecules that recognize typical molecular structures on pathogenic micro-organisms. Gram-negative lipopolysaccharide and Gram-positive lipoteichoic acid are obvious targets, but pattern recognition

molecules are also directed against characteristic non-human patterns of sugars involving mannose, glucose, fructose, *N*-acetyl-D-glucosamine, and *N*-acetyl-mannosamine. Mannose-binding lectin (MBL) binds to all of these and thus recognizes a wide variety of bacteria, viruses, yeasts, fungi and protozoa, but also endogenous ligands.[3]

The importance of these danger signals is illustrated by the number of names competing in the literature to describe them: pathogen-associated molecular patterns, danger associated molecular patterns, and most recently *alarmins*.[4] Whatever name used, the importance is that when such patterns encounter pattern recognition molecules of the innate immune system, they initiate and/or potentiate a cascade of events that is aimed at rapid killing of invading pathogens or reestablishing immune homeostasis.

Circulating Pattern Recognition Receptors: Complement, Lectins, and Defensins

Pattern recognition molecules also circulate in the bloodstream. The lectin-complement pathway facilitates pathogen removal via carbohydrate recognition mediated phagocytosis. The alternative complement pathway is a continuously activated bactericidal humoral mechanism.

Sugar-recognizing *collectins*, molecules that contain collagenous structures and C-type carbohydrate recognizing domains (CRD) include MBLs and surfactant proteins A and D (SP-A and SP-D). Mannose binding lectin is a liver derived acute phase reactant whereas SP-A and SP-D are synthesized in the lung. The main determinant of MBL levels is genotype, whereas SP-A and SP-D do increase significantly with inflammatory stress. Collectins bind to many microbes: viruses, bacteria, fungi, and protozoa and prepare organisms for phagocytosis (opsonization) and activate complement pathways. The ficolins, L-ficolin, M-ficolin, H-ficolin, are similar but they have different structures with a fibrinogen-like domain. Both MBL and the ficolins initiate the lectin pathway of complement activation via associated serine proteases.[5]

Similarly, antimicrobial proteins such as bactericidal/permeability increasing protein and lactoferrin have pathogen killing properties. Notably, these factors do not induce a downstream cytokine response.

Alarmins, such as α and β defensins, and cathelicidins are expressed in neutrophils, intestinal Paneth cells, and epithelial cells in the respiratory tract. Defensin synthesis and release occurs constitutively but increases with cellular activation. Defensins exert a dose-dependent direct bactericidal activity and function as chemo-attractants for phagocytes. They also act generally to increase phagocytic function by increasing production of reactive oxygen species, binding to C1q to activate the classical complement pathway and inhibiting the production of immunosuppressive adrenal glucocorticoids.[6]

Neutrophils

Neutrophils are a key element in the rapid clearance of bacterial and fungal invasion. They are equipped to sense pathogens, to migrate toward them, and subsequently to ingest and kill them. Neutrophils typically circulate for only of 6 to 8 hours after release from the bone marrow. They "scan" the vascular endothelium for signs of local inflammation by rolling on weak adhesion molecules (selectins). When the endothelium displays signs of local inflammation or injury—such as a high local concentration of interleukin-8 (IL-8), neutrophils alter the structure of their main adhesion molecules (β_2-integrins) and firmly adhere to the site of trouble. They then pass through the endothelium and hunt pathogens (or injured tissue) in need of removal. They may digest pathogens or tissue with a combination of enzymes such as elastase and they eat their fill through phagocytosis. Organisms that are phagocytosed into neutrophil vacuoles are then subjected to protease activity and changes in charge conditions—that disrupt the bacterial membranes by ion shifts. Ideally, once spent, the full neutrophil quietly undergoes apoptosis—the debris of which is phagocytosed in due course.

The degree of local (and subsequently systemic) inflammation is determined to some degree by the balance between the numbers of infective organisms and the extent of neutrophil recruitment and activation. An inadequate neutrophil response means the infection is unlikely to be controlled as a minor local problem—hence, the very high frequency of bacterial blood stream infections that occur in patients who are neutropenic after chemotherapy or bone marrow transplantation. Patients who are unable to localize neutrophils to the endothelium and hence the tissue (via congenital failures of firm adhesion: "leukocyte adhesion deficiencies") typically fail to heal normally minor wounds—but bacteremias are less common. Finally, in the most severe forms of *purpura fulminans* associated with overwhelming bacterial infection, typically circulating neutrophil counts are low, reflecting the very widespread endothelial activation and injury. This means the whole circulating neutrophil pool is depleted by adhesion to multiple sites of infection and damage. Neutropenia in this scenario is a very powerful predictor of poor outcome and reflects a severe infection that has outstripped the host's early control mechanisms.

Cellular Pattern Recognition Receptors

The archetypal pathogen-associated molecular pattern is the gram-negative cell wall component lipopolysaccharide (LPS), to which humans are exquisitely sensitive. Endotoxin or LPS is recognized by the humoral factor LPS binding protein and the cell membrane receptor toll-like receptor 4 (TLR4). LPS binding protein, a liver-derived glycoprotein, binds to LPS and shuttles it to an immune cell surface (e.g., a monocyte). The monocyte receives the LPS binding protein/LPS compound on a complex consisting of TLR4, CD14, and MD2. On binding, the transmembrane receptor TLR4 signals to intracellular components, that in turn, activate nuclear factor κB (NFκB)-mediated downstream gene expression cytokine activation (Figure 90-1). Thus a gram-negative infection such as meningococcemia gives rise to a rapid nonspecific response that aims to kill the inoculum and contain the infection.

TLR4 is only one of a family of related molecules. There are at least 10 related receptors in humans (Table 90-1). These TLRs are evolutionary preserved from the worm *Caenorhabditis elegans* and strikingly homologous to Toll, a gene product essential to *Drosophila* immunity. These TLRs are transmembrane glycoproteins that are characterized by an extracellular binding domain with varying numbers of leucine-rich-repeat motifs

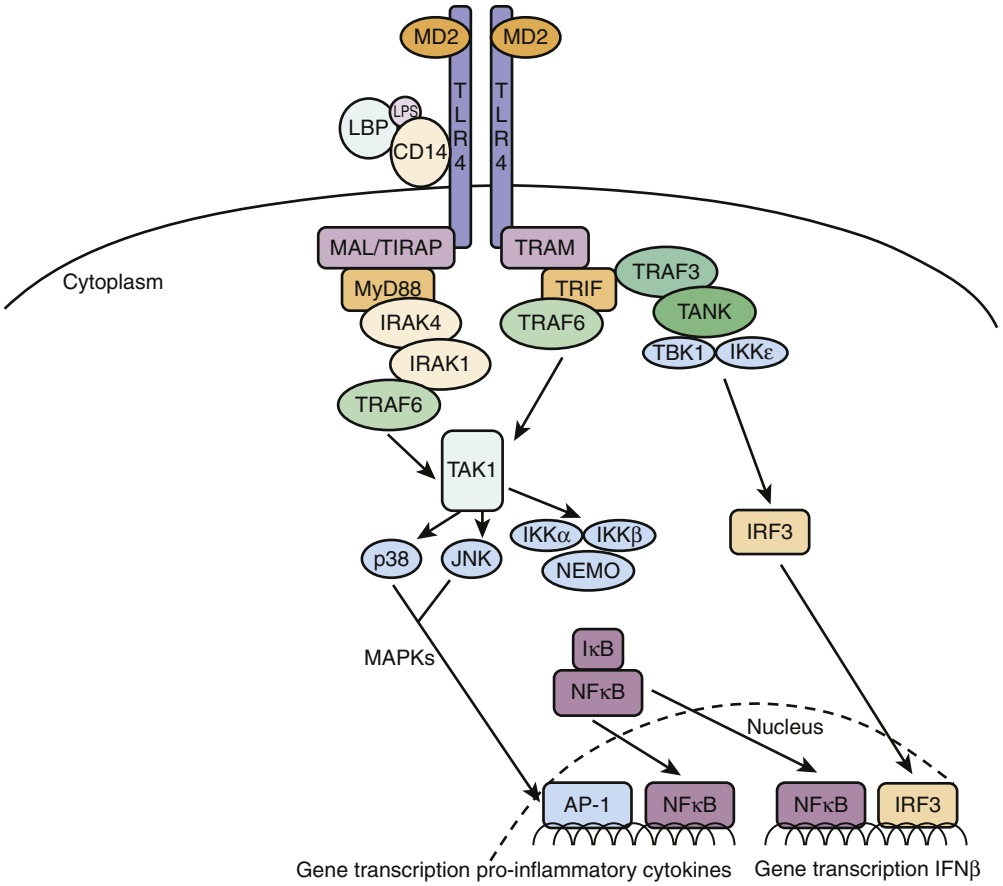

Figure 90–1. LBP shepherds LPS to the TLR4 complex. On ligation, TLR4 dimerizes and activates the two distinct MyD88- and MyD88-independent TRIF-dependent pathways. The early inflammatory phase is characterized by the MyD88-dependent pathway. This pathway activates MAPKinase and NFκB mediated pro-inflammatory gene induction. The TRIF-dependent pathway will activate late-phase NFκB and IRF3 mediated gene expression resulting in a more endotoxin tolerant response.[38-40] LBP, Lipopolysaccharide binding protein; LPS, lipopolysaccharide (endotoxin); CD14, cluster of differentiation 14; MD2, myeloid differentiation protein 2; TLR4, Toll-like receptor 4; MyD88, myeloid differentiation primary-response protein 88; MAL/TIRAP, MyD88 adaptor like/Toll-interleukin 1 receptor (TIR) domain containing adaptor protein; IRAK4, interleukin 1 receptor associated kinase 4; IRAK1, Interleukin 1 receptor associated kinase 1; TAK1, transforming growth factor β-associated kinase 1; TRIF, TIR domain-containing adaptor protein inducing interferon β; TRAM, TRIF-related adaptor molecule; TRAF6, tumor necrosis factor receptor–associated factor 6; TRAF3, tumor necrosis factor receptor–associated factor 3; TANK, TRAF family member–associated NFκB activator; TBK1, TANK binding kinase 1; IKKε, inhibitor of nuclear factor κB kinase ε; IKKα, inhibitor of nuclear factor κB kinase α; IKKβ, inhibitor of nuclear factor κB kinase β; p38, p38 kinase; JNK, c-Jun N-terminal kinase; MAPKs, mitogen activated protein kinases; NEMO, nuclear factor κB essential modulator; IRF3, interferon regulatory factor 3; IκB, inhibitor κB; NFκB, nuclear factor κB; AP-1, activator protein 1.

and an intracellular cytoplasmic signaling domain homologous to that of the interleukin-1 receptor (IL-1R). This Toll/IL-1R homology (TIR) domain sits beneath the plasma membrane and interfaces primarily with the key signaling adaptor myeloid differentiation primary response gene 88 (MyD88).[7]

TLR2 recognizes cell wall component lipoteichoic acid and peptidoglycan of Gram-positive bacteria, whereas TLR5 recognizes flagellin on *Salmonella enterica*. Viral matter is recognized by TLR3, TLR7, and TLR8. TLRs also combine in heterodimers and thus generate wider ligand specificity, for instance TLR6/TLR2 recognizes the fungal cell wall component zymosan. TLR9 recognizes bacterial DNA, which is distinct from mammal DNA by way of the presence of unmethylated CpG dinucleotides.

One TLR may also recognize different pathogen components; TLR4 not only binds LPS, but also the structurally unrelated fusion protein of respiratory syncytial virus and *Plasmodium falciparum* glycosylphosphatidylinositol. Recently, TLR4 has been observed to ligate endogenous molecules such as heat shock proteins and fibrinogen. These interesting observations suggest that these pathways contribute to the ongoing immune response from other insults such as trauma rather than being specific to individual pathogens. This fits with a danger model of immunity, rather than a strict pathogen non-self and non–pathogen self model.

TLRs are expressed on many immune and nonimmune cells, including macrophages, platelets, and cardiac myocytes. This expression is modulated rapidly in response to pathogens and cytokines. Many of these TLRs (e.g., TLR1, -2, -4, -5), are expressed on the cell wall, others are found intracellularly (e.g., TLR3, -7, -9).

A different type of pattern recognition receptors recognize pathogens after invasion in the cytosol. RIG-I-like receptors (RLRs) respond to viral RNA. Activation induces NFκB-mediated gene transcription and production of type I interferon (INF). Of particular relevance to the intensivist are the nucleotide binding oligomerization domain and leucine rich repeat containing molecules (NLRs). The best studied of these

Table 90–1 Human Toll-like Receptors

PRR	PAMP	Organism	Endogenous Ligand	Location
TLR1-TLR2	Triacyl lipopolypeptide	Gram-positive bacteria		Cell surface
TLR2-TLR6	Diacyl lipopeptide LTA Zymosan	Mycoplasma Gram-positive bacteria Fungus		Cell surface
TLR2	Porins Peptidoglycan Hemagglutinin protein	*Neisseria* Gram-positive bacteria Measles	Hyaluronic acid HSP HMGB1	Cell surface
TLR3	dsDNA	Virus		Intracellular vesicles
TLR4	LPS Envelope proteins	Gram-negative bacteria RSV	Fibrinogen HSP ROS Hyaluronic acid Heme HMGB1	Cell surface
TLR5	Flagellin	*Salmonella*		Cell surface
TLR6				Cell surface
TLR7	ssRNA	RNA virus		Intracellular vesicles
TLR8	ssRNA	RNA virus		Intracellular vesicles
TLR9	CpG DNA DNA Malaria hemozoin	Bacteria DNA virus Parasites		Lysosomes
TLR10	Unknown	Unknown		B lymphocytes

PRP, Pattern recognition receptor; *PAMP,* pathogen-associated molecular pattern; *LPS,* lipopolysaccharide; *HSP,* heat shock protein; *ROS,* reactive oxygen species; *HMGB1,* high mobility group protein B1; *RSV,* respiratory syncytial virus; *dsDNA,* double-stranded deoxyribonucleic acid; *ssRNA,* single-stranded ribonucleic acid; *CpG DNA,* cytosine phosphodiester bond guanine deoxyribonucleic acid.

proteins, NOD1 and NOD2, both contain N-terminal CARD domains and are specialized in detection of bacterial peptidoglycan components. Two types of activation occur: NOD1 and NOD2 ligation causes their oligomerization, that in turn induces downstream gene expression via NFκB activation. Alternatively, NLRs activate caspase-1 activating complexes, also known as inflammasomes, that in turn mature cytokines IL1-β and IL-18.[8] Inflammasomes may be seen as sensors for danger. For instance, loss of cell integrity activates the inflammasome and hence the potent pro-inflammatory cytokine IL-1β. The significance of this pathway is increasingly recognized. Recent data show the inflammasome to be integral to the pathogenesis of severe *Staphylococcus aureus* infections.[9]

Signaling

Ligation of a cell surface TLR will activate a cascade of events, ultimately leading to gene transcription of proteins. These proteins, in turn, activate and dampen processes to allow for an appropriate host defense. Figure 90-1 provides an example of downstream signaling in response to LPS binding to the TLR4 complex. Toll-like receptors dimerize and change in conformation; this allows for recruitment of adaptor molecules to the TIR domain of the receptor. Four adapter molecules exist: MyD88, Mal (TIRAP), TICAM1, and TRAM. Different TLR ligands induce selected recruitment of these adaptor molecules explaining some of the distinct responses after TLR ligation.

Myeloid differentiation primary response gene 88 is essential for all downstream signaling via TLRs (except for TLR3). In addition, Mal is essential for TLR2 and TLR4 signaling, arguably the most important TLRs in critical care.

After activation of these adaptor molecules, IL-1 receptor–associated kinase 4 (IRAK4) and IRAK1 are recruited. These, in turn catalyze a cytoplasmic cascade that ultimately leads to mitogen-activated protein kinases (MAP kinases) p38, ERK1, ERK2, and consequently NFκB-mediated gene transcription in the cell nucleus. A MyD88 independent pathway exists, that has a role in dendritic cell maturation and INF-α/β production.[10]

Crosstalk

The innate and adaptive immune systems interact continuously. Considering them as separate systems reflects an enormous simplification. Even more so, now newer data indicate the complexity of the interactions between immunity and other complex body systems. Coagulation, neuroendocrine, cardiovascular, and autonomic nervous systems all influence, and are influenced by, immune responses. At the simplest level, this is shown by many molecules having important properties in multiple systems (e.g., acetylcholine is a neurotransmitter as well as a paracrine regulator of lymphocytes, or epinephrine stimulates the bone marrow to release neutrophils into the circulation). High plasma glucose levels arising from the stress response and insulin resistance during critical illness may inhibit complement binding to and killing of microorganisms.

Two examples of well-characterized "crosstalk" between these systems are discussed in the following section. Plasminogen activator inhibitor 1 (PAI-1) is a potent inhibitor of fibrinolysis. It achieves this response by inhibiting both tissue and urinary type plasminogen activator. Levels are increased after

trauma and sepsis, especially so in severe meningococcal sepsis. Inflammatory mediators tumor necrosis factor (TNF)-α, IL-1, and IL-6, complement 5a, and LPS all act to increase PAI-1 production. In turn, PAI-1 contributes to a procoagulant state and inhibits neutrophil apoptosis. Although this may help to contain inflammation at the site of infection, genotypes associated with high levels of PAI-1 production are associated with worse outcome in septic shock. The PAI-1 4G/5G insertion deletion promoter polymorphism influences PAI-1 plasma concentration (4G is associated with higher concentration). So there is a direct link between how readily the immune system triggers an increased clotting tendency in critical illness and poor outcome.

Similarly, the inflammatory mediator IL-6 stimulates release of the potent coagulation activator tissue factor from activated endothelial cells, monocytes, and macrophages. This promotes thrombin formation that, in turn, converts fibrinogen to fibrin. Thrombin and fibrin generation are increased in inflammation, in part, because fibrinolysis is impaired from increased activity of PAI-1, but also secondary to diminished activated protein C and tissue factor pathway inhibitor.[11] These processes have been the targets for numerous clinical trials of drugs with anticoagulant/pro-fibrinolytic actions—all aiming to achieve anti-inflammatory effects by targeting coagulation systems.

A recent example of a novel interaction between the coagulation and immune systems is that TLR4-activated platelets interact with neutrophils to trap and kill bacteria in so-called neutrophil extracellular traps. In vitro studies showed that LPS as well as plasma from septic adults could induce this phenomenon.[12]

The nervous system is an integral part of inflammation. At a local level inflammatory responses induce pain—one of the defining elements of inflammation. Regionally, sympathetic and parasympathetic activation will, in general, inhibit inflammation. Centrally, the hypothalamic-pituitary-adrenal axis has an overarching immunomodulatory role by activating many neuroendocrine responses.

Importantly, immune cells carry the receptors for neurotransmitters, neuropeptides, and neurohormones, including adrenergic and cholinergic receptors. These receptors may respond in an autocrine or paracrine manner. Alternatively, the autonomic nervous system and innate immunity may be directly linked by the "cholinergic anti-inflammatory reflex." In vivo sepsis models suggest that vagal stimulation may directly dampen TNF-α production via NACHR7 receptors on macrophages.[13]

The sympathetic-immune interface is another area of growing interest. At a local level sympathetic activation may have pro- as well as antiinflammatory effects. Based on current understanding, the most prominent general effect is inhibition of inflammation.[14]

Because this is a new field and many questions remain unanswered, it should be little surprise that there exists debate about the clinical significance of neural modulation of the immune response.[15]

Similarly, the hypothalamic-pituitary-adrenal axis will release stress hormones CRF, cortisol, epinephrine, and α-melanocyte-stimulating hormone that regulate gene transcription and translation of cytokines.[16] The neuroendocrine fine tuning of inflammation warrants a discussion that is beyond the scope of this chapter.

Hypoxic-ischemic injury

The primary function of intensive care is to maintain tissue oxygenation. When this is inadequate, tissue injury occurs. Mechanisms of hypoxic injury are reviewed elsewhere in this text, but an intensivist should appreciate that failed perfusion also initiates an inflammatory cascade[17] and that hypoxia is itself is a regulator of the immune response.

Acute inflammation commonly occurs under local hypoxic circumstances—neutrophils and macrophages function well in these conditions, indeed they are activated by them. In part this effect is mediated by cytosolic hypoxia–inducible factors (HIFs). Constitutive and inducible HIF subunits bind to DNA and induce upregulation of genes for neutrophil adhesion, activation of phagocytosis, and inhibition of apoptosis. Pro-inflammatory cytokine production is also enhanced.

This cascade sounds very similar to that described after bacterial invasion. This is exactly the point—acute inflammation has many common responses to a variety of insults. Indeed, the overlap is greater still because these same HIF proteins can be robustly stabilized in an active configuration by some bacteria, and some TLR genes also upregulate HIFs. So infection causes tissue hypoxia with inflammatory consequences, but pure hypoxia activates many similar pathways.[18]

Complex System

The complexity of the early response to infection or insult is difficult to overestimate. A single injection of LPS to human volunteers has been shown to induce differential expression of nearly 4000 genes in leukocytes. These gene products join hundreds of inter- and intracellular protein and lipid mediators of inflammation—many with multiple effects. The immune response evolves rapid with time and differs between different organs or body compartments.

Complex systems such as this have a number of typical characteristics. They can appear to be unpredictable because they can produce vastly different end results with only apparently small differences in starting conditions. They also exhibit "robustness" wherein major changes (such as therapeutic inhibition of a proinflammatory mediator such as TNF) have surprisingly little measurable effects because other mediators carry the same information at times of crisis. Failure to appreciate these characteristics of the immune response has in part contributed to the very limited success of therapies for severe sepsis.[19]

Predisposition to an (in)Appropriate Response

Premature death from infectious disease is attributable to genetic influences to a higher extent than cardiovascular disease or cancer.[20] With the advent of methods to identify subtle changes in genes coding for components in the innate immune system it became possible to search for specific genetic predisposition to an inappropriate innate immune response.

Gene variations occur as single nucleotide polymorphisms, insertion or deletion or copy number variation. Early work on genetic polymorphisms showed that a high TNF-α and low IL-10 pattern, suggesting a vigorous pro-inflammatory potential, was associated with better outcome in meningococcal

disease.[21] Conversely, recent work suggested that a polymorphism associated with high TLR1-mediated inflammatory cytokine production was strongly associated with increased mortality and organ dysfunction in sepsis.[22]

There are many studies of genetic variability in critical illness, but very few provide compelling evidence of genetic variation influencing outcome. One reason may be the complexity of the clinical phenotype: i.e. heterogeneity in patients, grouped as "SIRS," "sepsis," or "acute respiratory distress syndrome." These definitions may be insufficiently precise in clinical critical illness where patient differ widely in, for example, the contribution of chronic disease to the acute state.[19]

Genetic association studies in areas with more uniformity in disease definition and better understanding of the pathophysiology of disease have isolated some effects of polymorphisms. For instance, a TNF-α receptor mutation in a standardized mouse model of sepsis improves survival but worsens localized control of infection.[23,24]

The innate immune system is complex with many redundancies. It may be unrealistic to identify those parts that have a discernible effect on outcome in the complex outcome called critical illness by analyzing variance in individual mediators. This is effectively the same issue that has confound randomized clinical trials in severe sepsis as recently highlighted.[25] Design and execution of genetic association studies need to be held against robust and reproducible end-points and rigorous quality markers.[26,27]

Despite all these difficulties, there are some observations that contribute to our understanding of innate immune variability in critical illness. The following is a sample of studies that illustrate some of these issues.

A recent systematic review and meta-analysis showed susceptibility to pneumococcal disease with MBL deficiency (odds ratio, 2.57 [95% confidence interval, 1.38 to 4.8]) but not for the single TLR2 polymorphism Arg753Gln. It may be that complement activation is a more important part of innate immunity than TLR2 or that this specific TLR2 polymorphism does not exert a strong enough difference in response.

Similarly, no evidence was found for a susceptibility to meningococcal disease for TLR4 Arg299Gly or the PAI-1 4G/5G insertion deletion promoter polymorphism.[27] However, the PAI-1 4G/5G polymorphism was shown to influence the *severity* of disease in meningococcal septic shock: children who were homozygous for the high-producing 4G were more likely to have vascular complications or to die.[28] Interestingly, a recent study shows that critically ill children with a genotype associated with high complement activation were less likely to develop systemic inflammation.[29] It may be more interesting to study the influence of genetic differences on specific patterns of disease severity rather than overall outcome that reflects the sum of so many pathophysiology processes.

Another example is variability in the adaptor molecule Mal (TIRAP). This molecule is an essential part of TLR2 and TLR4 downstream signaling. In a large multiethnic cohort (n = 6106) the effect of Mal polymorphism S180L was studied with respect to invasive pneumococcal disease, malaria, and tuberculosis.[30] Heterozygosity was associated with reduced disease severity. The authors postulated that this was due to reduced NFκB medicated cytokine response. Homozygous variant allele carriers would thus mount an inadequate antimicrobial response and wild-type carriers would mount an excessive response.

A better-known heterozygote protection against infectious disease is sickle cell trait that protects against malaria. Homozygous sickle cell anemia however predisposes to increased susceptibility to infectious disease. Children with sickle cell anemia were 25 times more likely to present with bacteremia than controls in a recent study from sub-Saharan Africa.[31]

Cytokines

Cytokines are polypeptide intercellular messengers. Because they were first described as agents that contribute to the severity of the immune response in sepsis with direct or indirect cytotoxic properties, they have often been considered to be harmful mediators and potential targets for therapeutic blockade. The reality is much more complex. Cytokines have actions stimulating or inhibiting the immune response. Pro-inflammatory cytokines include TNF-α, INFγ, IL-1β, IL-6, and IL-8, whereas IL-10 and IL-4 are thought to have predominantly anti-inflammatory properties. However, the distinction of pro- and anti-inflammatory cytokines also does not do justice to the pleiotropic functions of these proteins. For instance, dependent on timing and location, the prototypical pro-inflammatory cytokine TNF-α may have a function in pro-inflammation or in resolution of inflammation. One key issue is the appropriateness of the TNF-α action—an injection of TNF-α to a healthy volunteer causes temperature and signs of systemic inflammatory (and perhaps shock if the dose is high). This is the *cost* of TNF-α without the potential *benefit* of immune activation to kill an invading microorganism. The cost-benefit of a cytokine such as TNF-α is dependent on the scale of the infective insult it is facing. Meta-analysis of animal models and human trials with agents that block TNF-α or its receptor suggest that TNF-α is useful when the insult is mild; but harmful when the insult is very severe.[32] This dose-dependent complexity is typical of cytokine responses.

A good but extreme example of the potential harm that an acute pro-inflammatory cytokine excess can cause, in the absence of a pathogen needing killing, occurred in North West London in 2006. A phase I trial of the anti-CD28 monoclonal antibody TGN1412 in healthy adults was stopped because of a massive rapid onset of a systemic inflammatory response with multiple organ dysfunction syndrome and concomitant lymphopenia, monocytopenia, thrombocytopenia, and peripheral gangrene. This antibody caused direct T-cell activation independently of T-cell receptor ligation (in a similar manner to toxic shock toxins). Serum cytokine levels rose very rapidly with high levels of TNF-α, INFγ, and IL-6, followed by IL-8, IL-2, IL-1β, IL-10, IL-4, and IL12p70.[33]

Another, perhaps more familiar, example is secondary hemophagocytic lymphohistiocytosis. This multisystem disease results from a persistence of the inflammatory response to a systemic viral infection beyond its useful phase. The bone marrow and liver fail as they are infiltrated by activated cells derived from monocytes/macrophages. This typically occurs in patients with a congenital predisposition in which lymphocyte apoptosis is abnormal. The resultant abnormal persistence of the inflammatory response induces excessive monocyte/macrophage activation. The disease is treated by steroid immunosuppression—even though the original trigger was viral infection.[34]

Therapeutic Interventions

Numerous attempts have been made to intervene in the acute response to infection either with agents that block elements of the acute response or which top-up infusions of endogenous or innate immune or anticoagulant molecules (e.g., recombinant bactericidal/permeability increasing protein,[35] activated protein C).[36] None has shown convincing evidence of benefit in children (or adults). There are powerful arguments that even very effective agents would have failed in the methodology of inclusive randomized clinical trials because of wide variability in inclusion severity criteria and control group mortality between centers.[32,37] It may be that it is just not feasible to intervene with a single agent in the complex system with the redundancy we have discussed above. Or it may be that anti-inflammatory drugs cause harm to many patients who were already at very low risk of bad outcomes. One way forward would be to characterize the inflammatory and coagulation responses in individual patients and target intervention to the specific needs of that patient. The other approach is to recognize that the majority of poor outcome from sepsis worldwide could be averted with attention to excellent early recognition and prompt resuscitation. This should be the priority, at least in the short term.

Chapter 91

Infection and Host Response

Mary Michele Mariscalco

PEARLS

- Innate and acquired immunity are closely interrelated, defects in one path will likely affect others.
- Pathogen-associated molecular patterns (PAMPs) and damage-associated molecular patterns use "same" pattern recognition receptors, and may result in similar immune response.
- Local immunity against an invading pathogen is robust and complex. Uncontrolled infection locally results in a systemic immune response.
- Cellular and soluble elements on the hemostatic system are intricately related to the immune response.
- Acquired immunity depends both on pathogen and host's response to PAMP.

Historical Perspectives

"*Rubror et tumor cum calore et dolore*," or redness and swelling with heat and pain, were recognized as the four cardinal signs of inflammation by Cornelius Celsus (30 BCE to 38 CE). It was not established until the late 1800s to early 1900s that the body used both cellular and humoral components to identify and destroy microbes. Through the work of such pioneers as Elie Metchnikoff, Paul Ehrlich, and Almoth Roth, it was demonstrated that certain humoral factors called *opsonins,* later identified as antibodies and complement products, rendered bacteria more susceptible to ingestion and killing by phagocytic cells. Antibodies together with complement could also kill bacteria directly.

Traditionally, the immune system has been divided into innate and adaptive components. Clonal expansion of lymphocytes in response to infection is absolutely critical to the development of the immune response. However, it takes 3 to 5 days for clonal expansion to produce sufficient numbers of "effector" cells. Clearly, this is more than enough time for a pathogen to damage the host. The innate immune system is fundamental in eliminating the infection, and if not, then controlling it, until the adaptive immune responses eliminate it. If the innate and adaptive immune responses are "adequate," the infection remains localized. If not, then the systemic response to infection, or "sepsis" results (see Chapters 90 and 103). What has become increasingly clear is that the adaptive and innate immune systems can each affect the functioning of the other.[1]

In the past 25 years, new concepts that are fundamental to the care of critically ill patient have arisen directly from our understanding of the host's response to infection. (1) Inflammatory reactions first characterized as a response to infection are the foundation of a number of other pathogenic mechanisms, such as ischemia/reperfusion injury, direct trauma, drug-induced injury, inhalational injury, and multiple-system organ dysfunction. (2) The response to infection may lead to further injury of the host. Alternatively, an exuberant antiinflammatory response may likewise be deleterious, resulting in immune suppression and fibrosis (see Chapter 104). (3) There is a direct interaction between the neuroendocrine axis and inflammation (see Chapter 102). (4) There is a fundamental interrelationship among endothelium, inflammation, and coagulation, and efforts to intervene in one will likely have effects in others (see Chapter 101).

Innate Immune Versus Adaptive Immune Response

The innate immune system is phylogenetically ancient. Innate immune recognition is genetically predetermined (i.e., by germline-encoded receptors). Thus these receptors have evolved by natural selection, and have defined specificities for infectious organisms. In contrast, in the adaptive immune system, the T-cell and B-cell receptors are somatically generated in a way that gives each lymphocyte a unique structural receptor. Because the T- and B-cell receptors are not encoded in a germline, they are not predetermined to recognize any particular antigen. No matter how useful these "receptors" become, they cannot be passed down to the next generation. Although there are potentially a large number of variants of germline-encoded receptors (perhaps in the hundreds), there are 10^{14} and 10^{18} different somatically generated immunoglobulin receptors and T-cell receptors, respectively.[1] Microbes are heterogenous and can mutate at very high rates. This can be handled appropriately by the adaptive immune system. This heterogeneity, however, represents more of a challenge for the innate immune system. As such, a different strategy, phylogenetically older than the adaptive system, evolved. The innate immune system has developed receptors that recognize "pathogen-associated molecular patterns" (PAMPs). PAMPs are highly conserved structures present in a large group of microorganisms. The common features of PAMPs are (1) PAMPs are only produced by microbial pathogens, not hosts; (2) structures recognized by the innate immune system are usually essential for survival or pathogenicity of the

microorganism; and (3) PAMPs are usually invariant structures shared by an entire class of pathogen. The best known examples of PAMPs are bacterial lipopolysaccharide (LPS), peptidoglycan, lipoteichoic acid (LTA), mannans, bacterial DNA, double-stranded RNA, and glucans.[2]

Pattern Recognition Receptors

In the innate immune system, pathogen recognition molecules are called *pattern recognition receptors* (PRRs) and belong structurally to several families of proteins: leucine-rich repeat domains, calcium-dependent lectin domains, and scavenger receptor domains. Functionally, PRRs can be divided into three classes: secreted, endocytic, and signaling. Secreted PRRs function as "opsonins." They bind to microbial cell walls, flagging them for recognition by the complement system and by phagocytes. Members of the secreted PRRS include C-reactive protein (CRP), mannose binding lectin, and the ficolins.[3-5] These molecules recognize sugar residues that are rich on microbial surfaces and can function directly as opsonins, promoting phagocytosis. Alternatively, they can also function indirectly by activating the classical complement pathway (CRP) or the lectin-dependent pathway (ficolin and mannose-binding lectin).[4]

Endocytic pattern-recognition receptors occur on phagocytes and can mediate the uptake and delivery of pathogens into lysosomes. Once in the lysosomes, the microbe can be destroyed. The macrophage mannose receptor recognizes carbohydrates with large numbers of mannoses (characteristic of microorganisms) and mediates their phagocytosis by macrophages. The macrophage scavenger receptor binds to bacterial cell walls and effectively clears them from the circulation. Complement receptor 3 (also known as Mac-1 and CD11b/CD18), in addition to recognizing microbes opsonized with complement, can function by binding mannose molecules directly, thus also functioning as an endocytic pattern-recognition receptor.[2] Dectin-1 present on macrophages is the endogenous receptor for β-glucan, a major cell wall component of budding yeast. Mutations in dectin 1 lead to mucocutaneous fungal disease, though fungal phagocytosis and killing is normal in affected individuals.[6]

Toll-Like Receptors

Work done by Janeway and Medzhitov revolutionized understanding of the critical role of the innate immune system as the first step in adaptive immunity.[7] They identified the human counterpart of a protein found in fruit flies (*Drosophila melanogaster*) known as Toll. The Toll protein in fruit flies is responsible for infectious susceptibility to fungi. This protein in humans, human Toll-like receptor 4 (TLR4), recognizes LPS, and is located on antigen-presenting cells (APC) such as dendritic cells, macrophages, and monocytes. Through a complex signaling cascade TLR-4 results in activation of cytoplasmic nuclear factor-κB (NF-κB). NF-κB can then translocate into the nucleus and induce the transcriptional activation of a wide variety of inflammatory and immune responses.[2] These responses include the induction of cytokines, such as tumor necrosis factor-α (TNF-α), interleukin-1 (IL-1), IL-6, IL-12, and the induction of costimulatory molecules such as CD80 and CD86. The presentation of antigen by the major histocompatibility complex (MHC) II molecule on the APC is insufficient to induce the activation of the T-cell receptor, and thus the T cell. There must also be expression of CD80 or CD86 by the APC that is required for full T-cell receptor activation. Thus normally pathogen-specific T cells should only be activated and not self-antigen.

At present there are nine human TLR receptors.[8] The TLRs recognize molecules common to pathogens ranging from protozoa to bacteria to fungi and to viruses. The TLRs that recognize bacterial cell wall components (TLR1, -2, -4, and -6) are located on the cell surface, forming homodimers and heterodimers. Once ligated, they then translocate to the endosome for signaling (see Chapter 103).[9] TLR3, TLR7, and TLR9 reside in the endosome, recognize nucleic acids produced by viruses and bacteria, and thus are available for activity against intracellular viruses.[10]

Endogenous proteins such as heat shock proteins, surfactant protein A, high mobility group 1 (HMGB1), uric acid, and fibrinogen among many others may also function as ligands for TLRs and other PRRs. These endogenous proteins are termed *damage-associated molecular patters* (DAMPs).[11,12] The immune system has critical roles in normal physiologic processes, such as tissue remodeling after injury and development and scavenging of apoptotic cells; it is thought that the DAMPs participate in "alerting" the immune system. Mitochondria have evolved from an endosymbiont alphaproteobacterium. They have their own DNA, enriched in hypomethylated CpG-containing sequences. Zhang et al.[13] detected mitochondrial DNA in the blood of patients with systemic inflammatory response after major trauma at levels that would active TLR9 and phosphorylate signaling molecules downstream of TLR9. Accordingly, TLR9 could be signaled by mitochondrial DNA. Mitochondrial proteins from human tissues injected into animals activated formyl-peptide receptors on neutrophils, resulting in neutrophil activation and acute organ injury. As mitochondria are released from injured and dying cells (necrosis, not apoptosis), this may be the "signal" for systemic inflammation in these disease states.

There are several other classes of PRRs in addition to TLRs: RIG-I–like receptors (RLRs), Nod-like receptors (NLRs), and C-type lectin receptors (CLRs) (previously described). RLRs, an intracellular receptor, recognize single- and double-stranded viral RNA and transmit their signal through a common adaptor protein, interferon promoter stimulator-1 (IPS-1) and NF-κB, to induce type I interferon production and antiviral responses.[10] Double-stranded RNA-dependent protein kinase (PKR) is a unique PRR in that it can turn off protein translation directly; its effect does not seem to be modulated by downstream effectors.[14] Nod1 and Nod2 are NLRs that recognize PAMPs derived from the bacterial cell wall. Nod1 and Nod2 are localized to the cytoplasm and can elicit TLR-independent antibacterial responses. Other NLRs, such as NALP1, NALP3, IPAF, and NAIP5, are components of a molecular complex called the *inflammasome*. The inflammasome complex comprises one or some of the NLR proteins and caspase-1. Caspase is activated in this complex and cleaves critical inflammatory molecules such as pro-IL-1β and pro-IL-18 to produce mature proteins.[10] The NALP3 inflammasome is activated by stimuli such as uric acid crystal, silica, and asbestos; thus NALP3 appears to be a receptor for danger-associated molecular patterns. Infections with the malaria parasite or the fungus *Candida albicans* were also reported to activate the NALP3 inflammasome.

What follows is a focus on the pathogen ligands of the PRRs, in particular TLR4. It had been recognized for a number of years that CD14, present on monocytes and blood-derived macrophages, and lipopolysaccharide binding protein (LBP), found in plasma, were critical for an LPS response. However, CD14 is a glycosylphosphatidylinositol-anchored protein lacking transmembrane and intracellular domains and would be unable to signal intracellular processes. CD14 is also present to a limited extent on neutrophils.[15] In addition, a soluble form of CD14 could substitute for membrane-bound form of CD14 in LPS-mediated signaling. Thus it was clear that at least one other molecule present on the cell surface would be needed to elicit an LPS-dependent response. TLR4 knockout mice and human TLR4 mutations conferred such a role for this receptor for LPS-induced responses in humans and mice. TLR4 requires an additional molecule, MD-2, that is part of the complex on the cell surface. LPB is an acute phase reactant.[2,16] It catalyzes the transfer of LPS to CD14, which is then able to interact with TLR-4 and MD-2, resulting in intracellular signaling through the Toll/IL-1 receptor homologous region (TIR) adaptor molecules.[9] Downstream signaling events result in release of transcriptional activating factors including NF-κB, that guide gene transcription of many genes, including TNF and interferon-β (IFN-β), a type I interferon. TNF is discussed at greater length later in this chapter; however, it is a central mediator in innate immune response pathway. IFN-β is critical in adaptive and antiviral immunity (see Chapter 103 for a description of other TLRs).

Endogenous Antimicrobials

The epithelial surface of the skin, gastrointestinal tract, and bronchial tree produce a number of antibacterial peptides.[17] Leukocytes are also a rich source of these or similar proteins that can be secreted into the phagolysosome or alternatively secreted into biofilms protecting the mouth and gastrointestinal tract.[18,19] These antimicrobial proteins include the defensins, cathelicidin, lactoferrin, and bacterial permeability increasing factor (BPI).[20] Because the antimicrobial peptides are heavily positively charged (due to cationic amino acids), they specifically target bacterial cell membranes whose outermost leaflet of lipid bilayer is heavily populated with negatively charged phospholipid head groups.[17] Thus they also act as pattern recognition receptors. It is still unclear exactly how these antimicrobial peptides actually kill microbes. Possibilities include the creation of physical holes that cause cell contents to "leak out," disturbances of cell membrane function by "scrambling" the lipid bilayer, or fatal depolarization of the normally energized bacterial membrane.[21]

The α defensins are stored in the granules of neutrophils, monocytes, and macrophages, and are released extracellularly. The β defensins are produced by Paneth cells, reproductive tissues, epithelial cells, and keratinocytes; some are produced constitutively, some in response to LPS and proinflammatory products such as TNF and IL-1. Cathelicidin/LL37 is stored in neutrophil granules but is also produced by keratinocytes and epithelial cells in response to inflammatory stimuli. In addition to the antimicrobial effects of the defensins and cathelicidin, both are chemotactic for CD4 and CD8 T cells, phagocytes, and immature dendritic cells. They also enhance antigen-specific immunity and regulate complement activation.[20]

Lactoferrin and BPI are found in secondary and primary granules of the neutrophils, respectively, but they are also secreted or presented on epithelial surfaces. Lactoferrin is found in milk, tears, saliva, and other secretions such as bile, pancreatic juice, and small intestinal secretions. Lactoferrin is structurally similar to transferrin, though its affinity for iron is about 300 times higher, allowing it to retain iron at low pH.[22] Both lactoferrin and BPI have cationic-rich regions that are critical to binding and neutralizing LPS. Lactoferrin also has direct antimicrobial actions. Lactoferrin can potentiate the cytotoxic effects of monocytes and T cells.[22] BPI was initially identified in neutrophil primary granules. Because of its high affinity for the lipid A region of LPS, it is particularly cytotoxic for gram-negative bacteria, and its antibacterial activities are synergistically enhanced by defensins and cathelicidin.[23] In addition, BPI can function as an opsonin, enhancing phagocytosis.

Antimicrobial peptides have been used in a number of conditions and, though initially promising, their potential has not been completely realized. In the largest study to date, recombinant fragment of BPI, $rBPI_{21}$, was trialed in 400 children with severe meningococcal sepsis.[24] Although $rBPI_{21}$ had no effect on survival, fewer patients had multiple severe amputations, and by day 60 had a more functional outcome compared with those who did not receive $rBPI_{21}$.[24] A mammalian cathelicidin, protegrin, had no effect on the development or reduction of mucositis among patients who received stomatotoxic chemotherapy.[25]

Soluble Components of Immunity

C-Reactive Protein

CRP is phylogenetically ancient and is highly conserved in evolution. It is a member of the pentraxin family of calcium-dependent ligand-binding plasma proteins, the only other member of which is serum amyloid P (SAP). Although CRP is an acute-phase reactant in humans, SAP is not. In mice the major acute-phase reactant is SAP, with a minor fraction being CRP. In humans, plasma CRP is produced only by hepatocytes and is predominantly under the transcriptional control of IL-6. It is greatly elevated in infections, allergic complications of infection, inflammatory diseases, necrosis, trauma, and malignancy. It is modestly elevated or absent in systemic lupus erythematosus, scleroderma, dermatomyositis, ulcerative colitis, leukemia, and graft-versus-host disease. CRP binds to glycan and phospholipids of bacteria, fungi, and parasites. When aggregated or bound to macromolecular ligands, CRP is recognized by C1q and activates the classic complement pathway; thus it initiates direct microbial toxicity. Because it also recognizes phospholipids, in particular phosphocholine, it may be involved in handling apoptotic and necrotic cells.[3]

Complement System

The complement system is critically positioned to participate in both the innate and adaptive immune response.[26] However, it is also critical for the disposal of immune complexes from tissues and clearance of apoptotic cells.[4] The three pathways in which complement may become activated are the classic, alternative, and mannose-binding lectin pathway. Although complement activation initiates differently in each, all three

converge at the cleavage of C3 (Figure 91-1). The classic pathway is initiated by the binding of the C1 complex (consisting of C1q, C1r, and C1s) to antibodies bound to antigen on the cell wall. The mannose-binding lectin pathway is initiated by binding of the complex of mannose-binding lectin and the mannose-binding lectin-associate proteases 1 and 2 (MASP1 and MASP2) to arrays of mannose groups on the surface of the bacterial cell wall. Both MASP2 and C1q then function similarly in forming the C4bC2a complex, representing the convertase for C3. Bacterial products, LPS, yeast cell wall particles, and aggregated antibody, including immunoglobulin (Ig)A and IgE, are all capable of activating the alternative pathway. The alternative pathway is initiated via low-grade cleavage of C3 in plasma to C3b. C3b binds to the hydroxyl groups on cell surface carbohydrates. C3b binds factor B to form a C3bB complex, which is activated by factor D, forming C3bBb and stabilized with properdin. C3bBb then functions as an alternative convertase for C3, that cleaves many molecules of C3 to C3b. C3b binds to hydroxyl groups on the microorganism around the area of complement activation. C3a, an anaphylatoxin, is released by the C3 convertase. C3b can also bind to the C3 convertase to form C5 convertase. The C5 convertase releases the anaphylatoxin C5a and initiates the formation of the membrane attack complex (MAC), C5b6789.[4] The membrane attack complex created inserts into the cell membrane, creates large pores, and leads to osmotic lysis of the target.

Thus the complement system amplifies the initial response to the organism. In addition to lysing the target organism, opsonization with complement fragments C3b/C4b and C3bi (fragment C3b) occurs, resulting in phagocytosis by neutrophils, monocytes, and macrophages. Binding occurs through specific complement receptors, CR1 for C3b/C4b (CD35) and CR3 for C3bi (CD11b/CD18, also known as *Mac-1* and $\alpha_M\beta 2$). The anaphylatoxins C3a, C4a, and C5a produced are low molecular weight, biologically active peptides defined by their actions on small blood vessels, smooth muscle, mast cells, and peripheral blood leukocytes. Blood vessels, smooth muscle cells, basophils, and mast cells respond to all three anaphylatoxins. Neutrophils, monocytes, and macrophages respond to C5a. The anaphylatoxins promote edema and increase vascular permeability through the release of histamine from mast cells and through the local production of vasodilatory prostaglandins such as prostaglandin E_2 (PGE_2) and edemogenic leukotrienes (LT) C_4, D_4, and E_4. C5a is a powerful activator of granulocyte function including chemotaxis, degranulation, and increased oxidative metabolism. C5a actions occur through its seven-transmembrane–spanning, G protein–coupled receptor, C5aR.[27] In animal models, C5a/C5aR is critical to the development of sepsis and multiple organ failure, and potentiates many early response cytokines and coagulation. C5aR is present not only on leukocytes, but also other tissue, including the brain, kidney, gastrointestinal tract.[27,28]

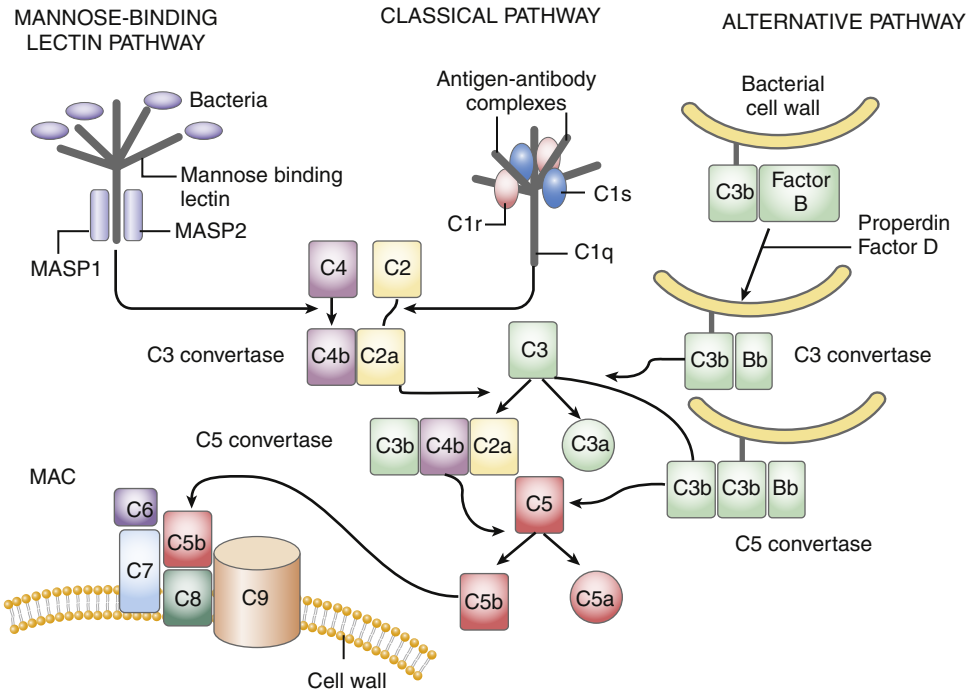

Figure 91–1. The three activation pathways of complement: the mannose-binding lectin, the classic, and alternative pathways. The three pathways converge at the point of cleavage of C3. The mannose-binding lectin (MBL) pathway is initiated by binding of the complex of the MBL and MBL-associated proteases 1 and 2 *(MASP1, MASP2)* to arrays of mannose on the bacterial cell wall. MASP2 then activates first C4, then C2 to form the C3 convertase, C4b2a. The classic pathway is initiated by the binding of the C1 complex (which consists of C1q, two molecules of C1r, and two molecules of C1s) to antibodies bound to antigen on the surface of the bacterial cell wall. C1s, similar to MASP2, then activates C4 followed by C2 to form C4b2a (the C3 convertase). The alternative pathway is initiated by covalent binding of a small amount of C3b to hydroxyl groups on the cell surface carbohydrates and is activated by low-grade C3 in plasma. This C3b binds factor B to form C3bB, which is then activated by factor D to then form C3bBb, the alternative pathways C3 convertase. Properdin stabilizes this activation step. The C3 convertase then cleaves many molecules of C3 to C3b and C3a (an anaphylatoxin). C3b binds covalently around the site of complement activation, some of which binds to the C4b and C3b of the classic and alternative pathway C3 convertase, respectively, to form the C5 convertase. The C5 convertase cleaves C5 to C5a (an anaphylatoxin) and C5b, which initiates the formation of the membrane attack complex (MAC). *(Modified from Walport MJ: Complement. First of two parts,* N Engl J Med *344:1058, 2001.)*

Complement activation also occurs after oxidative stress such as occurs with ischemia/reperfusion. Complement activation is an early event after injury and the inhibition of complement activation or its components offer tissue protection after reperfusion.[29] Finally, complement proteins transduce various cell signals. Complement can activate B and T cells. It can regulate apoptosis of various cell types (see Chapter 100).[20,26]

Immunoglobulin

The different immunoglobulins (Igs) secreted by B cells (IgG, IgA, IgM, IgD, and IgE) are known as *isotopes*. IgD plays little role, if any, in containment of microorganisms. Ig isotypes can be divided into subclasses, variants that show slight structural differences but are sufficiently alike structurally to be essentially identical to other members of the isotype class. There are four IgG subclasses: IgG1, IgG2, IgG3, and IgG4. As seen in Table 91-1, isotype subclasses have specialized roles in the immune response. For example, IgG2 has a major role in the formation of carbohydrate antibodies, but has poor complement fixation characteristics. The antibody system consists of Ig present in serum, protecting the blood and tissue spaces, and that present in the secretory system, lining the gastrointestinal and respiratory tracts and present in tears. The serum component is mostly IgG (85%), with lesser amounts of IgA and IgM. The secretory system consists mostly of secretory IgA (85%), which is structurally different than serum IgA, and lesser amounts of IgG and IgM. All Igs have a basic four-chain structure composed of an identical pair of heavy (H) and light (L) chains. The H-L pairs are held together by interchain disulfide bonds and noncovalent forces. The binding site for antigen is formed by one H and one L chain. IgM is a polymer of five four-chain units, and secretory IgA is a dimer. Polymeric forms (Figure 91-2) possess a J chain that is synthesized with the H and L chains and serves to stabilize the sulfhydryl groups during polymerization. At regular intervals along the peptide chain a disulfide bond forms an intrachain loop, known as the *Ig domain*. This motif is repeated among immunoglobulins, T-cell receptors, adhesion proteins, and histocompatibility antigens. Proteins with these Ig domains share close homology structurally and functionally and suggest a common evolutionary origin. They are termed *members of the Ig superfamily* (IgSF), and all are involved in cell interaction processes associated with recognition.

The Ig molecule is divided into regions, the amino acid sequence of which is similar, such as regions needed for complement fixation or attachment to receptors on leukocytes. However, other regions are highly variable; those that bind

Table 91–1 Biologic Properties of Ig Classes and IgG Subclasses

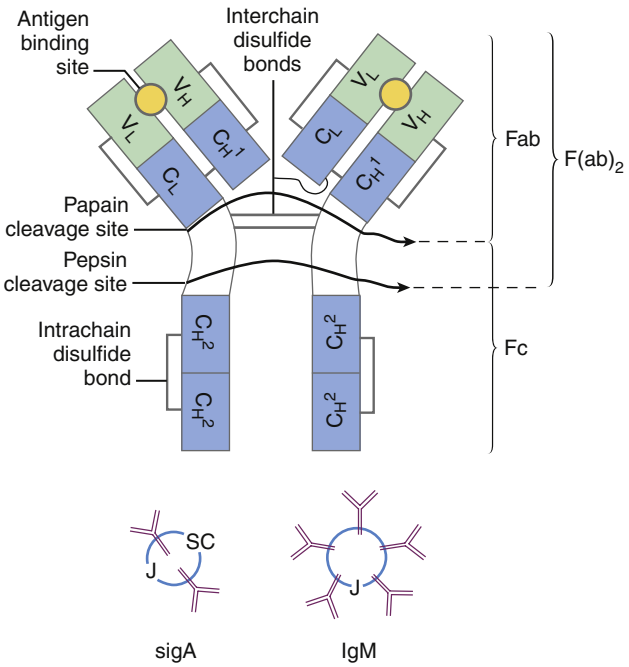

Figure 91–2. Basic immunoglobulin (Ig) structure. Sites of cleavage for papain or pepsin are shown with resulting fragments. The intrachain disulfide bond forms the region of the Ig domain. *Insets* show polymeric immunoglobulins, secretory IgA (*left*) and IgM (*right*). J chain is common to all polymeric forms; SC is the secretory component. V_L, Variable domain of light chain; C_L, constant domain of light chain; V_H, variable domain of heavy chain; C_H, constant domains of heavy chain.

to antigen have the highest divergency and are collectively known as the *hypervariable region*. Thus each Ig chain can be divided into constant and variable regions. The H chain has three constant regions and one variable region; the L chain has one variable region and one constant region. The hypervariable region of the L and H chain is tightly apposed and forms the combining site for antigen (see Figure 91-2). The digestion of Ig with papain and pepsin generates fragments with varying biologic capability. The Fc region of the Ig molecule accounts for its isotypic biologic capability. This is the region critical for complement fixation and recognition by Fc receptors on the leukocytes. The Fab region provides for specific unique antigen-antibody interactions. The F(ab′)2 fragment is formed with pepsin cleavage; the affinity for antigen is twice as great as Fab alone.

Contact Activation System

There are four major plasma protein systems that contribute to the host's defense and participate in the development of inflammatory tissue injury: the complement system (previously discussed), the contact activation system (also known as *Hageman factor* or *intrinsic coagulation system*), the extrinsic coagulation cascade, and the fibrinolytic system (see Chapter 80). The contact activation system is critical to host defense and control of local blood flow at sites of injury. Hageman factor (Factor XII) is activated spontaneously (XIIa) on contact with negatively charged surfaces, such as lipid A of LPS and vascular basement membranes (Figure 91-3). High-molecular-weight kininogen (HMWK), prekallikrein, and factor XI circulate in the plasma as complexes. Factor XIIa will activate factor XI and cleave prekallikrein to kallikrein. Kallikrein will then cleave HMWK to bradykinin. The kallikrein-kinin system also encompasses the tissue (or glandular) kallikrein-kinin system (see Figure 91-3). Tissue kallikrein is immunologically distinct from plasma kallikrein and present throughout the body as an inactive "pro-" substance. In the presence of intracellular enzymes, plasmin, or plasma kallikrein, tissue kallikrein is produced, secreted, and active in the tissue where it is made. Tissue kallikrein can then cleave HMWK to bradykinin directly, or it can cleave low-molecular-weight kininogen (LMWK) or tissue kininogen (T-kininogen) to kallidin that is then directly converted to bradykinin. In the plasma, 80% of kininogen is low molecular weight.

Bradykinin is an exceedingly potent vasoactive peptide.[31] It can cause venous dilation, increased vascular permeability, hypotension, bronchoconstriction, and activation of phospholipase A_2. Phospholipase A_2 releases arachidonic acid from cell membrane and initiates the production of both proinflammatory and antiinflammatory phospholipids-derived products (see subsequent section and Figure 91-3). Bradykinin is metabolized by angiotensin-converting enzyme (ACE) to inactive peptides. Bradykinin, along with prostanoids, stimulates the pain response through polymodal receptors and C-fibers (capsaicin sensitive).[32] Bradykinin has been shown to be responsible for the four signs of inflammation: heat, redness, swelling, and pain. The bradykinin effect is enhanced by simultaneous production of prostanoids. Prostanoids, particularly along with the low pH of exudates, inhibit the activity of kininases such as ACE.

Lipid-Derived Mediators of Inflammation

Although these products per se are not "soluble" components of immunity, their production nonetheless has both proinflammatory and antiinflammatory effects. They are discussed here because of their production as a result of the contact activation syndrome. These mediators are not stored preformed, but are rapidly generated after cell stimulation. Arachidonic acid (AA, or eicosatetranoic acid) is a 20-carbon fatty acid. Its metabolites are termed *eicosanoids*. The eicosanoids are produced by a variety of cell type–, tissue-, and species-specific biosynthetic pathways. Prostanoids are a specific class of mediators generated via initial actions of cyclooxygenase. The eicosanoid family includes the thromboxanes, prostacyclins, leukotrienes, hydroeicosotetranoic acids (HETES), epoxyeicosatrienoic acids (EETs), lipoxins, and isoprostanes. Release of AA and the 1-alkyl-2-acetyl analogs of phosphatidyl choline (platelet activating factor [PAF]) occurs through the action of phospholipase A_2 and phospholipase C on cell membrane phospholipids. Phospholipases can be stored in lysozymes or exist in the cytoplasm. Through cell activation, they translocate to the inner cell membrane, where they can hydrolyze cell membrane phospholipids. The major routes of AA metabolism for proinflammatory effects are the 5-lipoxygenase pathway (production of the leukotrienes, LT) and the cyclooxygenase pathway (production of prostaglandins and thromboxane, i.e., prostanoids). Of particular interest are newly recognized classes of prostanoids derived from polyunsaturated fatty acids (omega-3 fatty acids) that mediate antiinflammatory effects, the resolvins and protectin.[14]

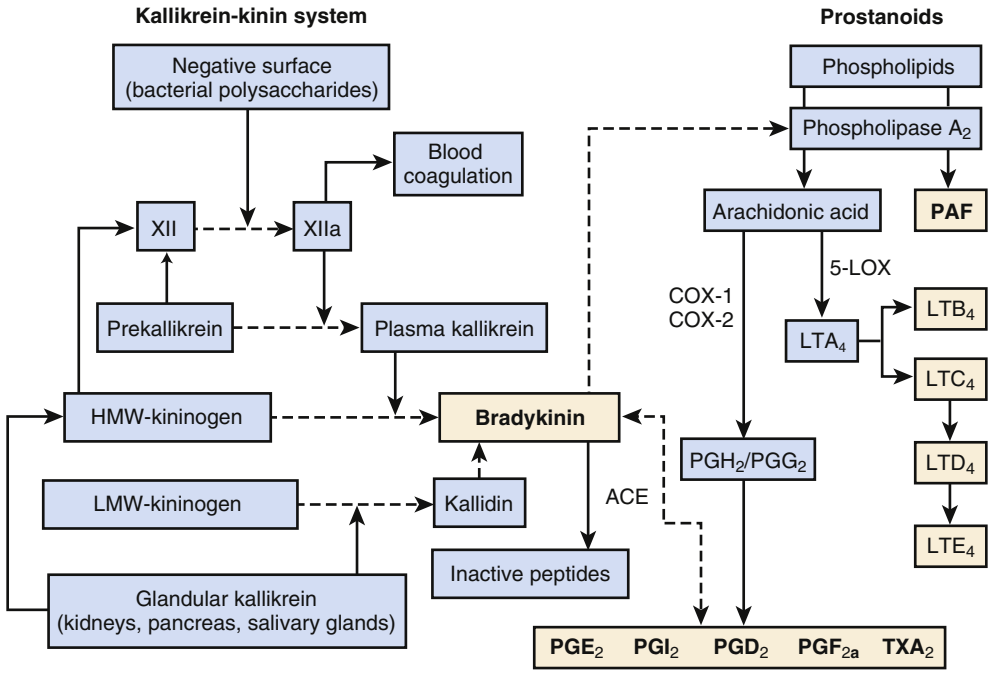

Figure 91–3. Contact activation system and prostanoid production. Bradykinin can be produced by either the plasma kallikrein (*top left*) or tissue (glandular) kallikrein system (*bottom left*). Once formed, bradykinin can activate phospholipase A_2, and thus drive prostanoid production. In addition, it can potentiate the affects of the prostaglandins and vice versa. Bradykinin is metabolized into inactive peptides via several steps, the last of which is enzymatically driven by angiotensin-converting enzyme *(ACE). HMW,* High molecular weight; *LMW,* low molecular weight; *PAF,* platelet activating factor; *COX-1,* cyclooxgenase-1; *COX-2,* cyclooxygenase-2; *5LOX,* 5-lipoxygenase; *LT,* leukotriene; *TXA_2,* thromboxane A_2; *PG,* prostaglandin. *(Modified from Ueno A, Oh-ishi S: Roles for the kallikrein-kinin system in inflammatory exudation and pain: lessons from studies on kininogen-deficient rats,* J Pharmacol Sci *93:1, 2003.)*

The 5-lipoxygenase pathway is prominent in leukocytes and mast cells. Leukotrienes C_4, D_4, and E_4 are potent vasoconstrictors and bronchoconstrictors with specific effects on the peripheral airways. LTB_4 is produced by neutrophils, monocytes, and macrophages within minutes of cell activation. LTB_4 is a powerful chemoattractant and activator of other leukocytes, resulting in enhanced leukocyte-endothelial cell interactions, sequestration of leukocytes in the pulmonary vasculature, and induction of permeability at the endothelial interface.

Thromboxane A_2 is principally produced by platelets but also by neutrophils and macrophages. Thromboxane induces platelet aggregation and is also a potent vasoconstrictor of vascular beds, especially pulmonary, coronary, splanchnic, and renal. It induces bronchoconstriction and increases microvascular permeability. The major prostaglandin produced by the endothelium is prostaglandin I_2 (PGI_2). PGI_2 is important in the control of hemostasis and is a potent inhibitor of platelet aggregation. It is four to eight times more potent that PGE_2 in its vasodilatory action. Unlike PGE_2, however, it is not metabolized by the pulmonary endothelium. PGE_2 is produced by neutrophils, platelets, macrophages, and endothelium. Both PGE_2 and PGI_2 inhibit adhesion of neutrophils to endothelium. The production of PGE_2 by hypothalamic microvessels in response to pyrogens such as LPS initiates fever.

Platelet activating factors (PAFs) are implicated in a diverse range of human pathophysiologic conditions, including shock, ischemia/reperfusion injury, asthma, anaphylaxis, necrotizing enterocolitis, and a number of other inflammatory states. Though historically PAF was first described as a potent platelet activating substance, it has diverse biologic effects, many of which are platelet independent. PAF, through its G protein–linked receptor, induces microvascular permeability, transformation of the endothelium from an anticoagulant to a procoagulant state, and vasoconstriction. Produced in very small amounts, it can be presented at the endothelial surface and serve as an activating agent for neutrophils as they are tethered and roll on the endothelium (see further description of leukocyte localization). Increased levels of PAF have been demonstrated in animal models and clinical studies of septic shock, acute lung injury, and necrotizing enterocolitis. Although isolated effects of PAF can be demonstrated, there is a complex interaction among PAF, prostaglandins, and cytokines in the pathophysiologic changes associated with sepsis, shock, trauma, and ischemia/reperfusion injury.[33,34]

Cytokines

Cytokines are signaling proteins secreted by cells that affect the functional properties of other cells of the same organism. The cytokine family includes lymphokines, chemokines, interleukins, and interferons. Unlike circulating hormones, cytokines travel short extracellular distances before interacting with target cell surface receptors in a paracrine or autocrine manner. Cytokines can be detected in serum samples, particularly during times of maximal production, as occurs in sepsis. Cytokines as a group are low-molecular-weight (<80 kDa) proteins. They interact with high-affinity cell surface receptors specific for each cytokine. Their cell surface binding ultimately leads to changes in the pattern of protein synthesis and/or altered cell behavior. They often have multiple-overlapping cell regulatory functions. Many cytokines are

produced early in infection, whereas others are produced at later stages.

Interleukin-1 and Tumor Necrosis Factor

IL-1 is a phylogenetically old molecule that predates the evolution of lymphocytes and immunoglobulin. Its activity extends beyond immune function. IL-1 is produced by a wide variety of cells, including macrophages, endothelial cells, epithelial cells, and vascular smooth muscle cells. There are two separate forms of IL-1, IL-1α, and IL-1β. In contrast, TNF-α is produced by cells primarily of the innate immune system, including monocytes/macrophages, NK cells, mast cells, and neutrophils under specific conditions. TNF is also produced by other cell types under conditions of stress. For example, TNF is produced by cardiac myocytes and is implicated in both acute and chronic congestive heart failure as well as in the cardiomyopathy associated with sepsis. TNF-β (also known as *lymphokine*) is produced by T lymphocytes, but occasionally antigen-activated T cells may also produce TNF-α. Both TNF and IL-1 are produced as small precursor molecules or "pro" molecules that are cleaved by IL-1β converting enzyme in the inflammasome (by caspase 1) and TNF-α converting enzyme, ADAM17 (***a d***isintegrin ***a***nd ***m***etalloproteinase), respectively. Once cleaved, these proteins are then excreted. It should be noted that caspase-1 (in the inflammasome) and ADAM17 are multifunctional proteinases and have activity on other interleukins and inflammatory molecules. IL-1 is the only cytokine with a natural inhibitor, IL-1 receptor antagonist (IL-1RA) produced by the same cells that produce IL-1. IL-1RA functions to downregulate the proinflammatory effects of IL-1. IL-1 and TNF-α are the early major mediators of gram-negative endotoxin shock (see Chapter 103). As outlined earlier in this chapter, signaling of cells by TNF and IL-1 occurs at least in part through NF-κB, and consequently share a similarity in receptor function and signaling molecules.

For routine infection and injury, IL-1β and TNF-α are transiently expressed and secreted. Their activities are modulated by coproduction of naturally occurring antiinflammatory cytokines, such as IL-10 and IL-1RA. The levels of these cytokines fall off rapidly; thus production is tightly regulated. Dysregulated cytokine production, such as occurs in chronic diseases such as rheumatoid arthritis and inflammatory bowel disease, has lead to the development of anticytokine therapy such as human recombinant IL-1RA (Anakinra), human/murine chimeric monoclonal antibody against TNF-α (Infliximab), and recombinant fusion protein composed of the extracellular binding domain of TNF receptor II and human IgG1 (Etanercept). With the development of these products, there is increasing evidence that neutralization of TNF-α is associated with increased risk of opportunistic infections, including mycobacterial diseases. Blockade of IL-1 using IL-1RA appears at present to be safe.[35] Using such blocking agents in animal models it appears that neutralization or gene deletion of TNF-α is associated with reduction of host defense in models of live gram-positive or gram-negative infections as well as infection by intracellular microbes such as *Salmonella* and *Listeria.* Absence of IL-1RA can also result in decreased resistance to *Listeria* or gram-positive bacteria. TNF and IFN-γ (discussed in the following paragraphs) are required for defense against infection caused by *Mycobacterium tuberculosis.*[35]

Il-17 is produced by an effector helper T cell, Th17, as well as natural killer (NK) cells and NK-T cells (combined properties of both NK and T cells). Th17-driven inflammation is typified by neutrophils predominating the inflammatory response. A number of pathogens induce Th17 response, including *Citrobacter, Klebsiella pneumonia, Mycobacterial tuberculosis,* and fungi such as *Candida albicans.*[36] To eliminate the body of fungi and certain extracellular pathogens requires inflammation driven by Th17. Most cell types have IL-17 receptors, and signaling through this receptor produces IL-6, TNF, IL-8, antimicrobial peptides, and matrix metalloproteinases. IL-17 is also implicated in several inflammatory conditions, including rheumatoid arthritis, psoriasis, multiple sclerosis, and inflammatory bowel disease.[36]

IL-18 is a member of the IL-1 family of ligands. It has unique characteristics in that only in conjunction with IL-12 is IFN-γ produced by activated T cells and by LPS-stimulated macrophages. IL-18 is implicated in the development of endotoxic shock and in the myocardial depression that occurs in these models.[37] As a key mediator of IFN-γ production, IL-18 serves an important role in controlling infections from *Salmonella, Cryptococcus,* toxoplasma, *Candida*, and *Mycobacterium* organisms, often through its modulation of the production of nitric oxide.[37,38]

IL-12 is produced by monocytes, macrophages, dendritic cells, neutrophils, and to a lesser extent B cells. IL-12 effects are primarily on T and NK cells. The responses by T cells and NK cells include increased proliferation, increased IFN-γ production, increased cytotoxic activity (cytotoxic T lymphocytes and NK cells), and for T cells, polarization toward a Th1 phenotype (see following discussion). Patients with defects in IL-12 or IL-12 receptor have increased susceptibility to mycobacterial and salmonella infections. Neonates have diminished IL-18 and IL-12 production contributing to inadequate IFN-γ production and increased susceptibility to infections.[39,40]

IL-6 is one member of the IL-6 family of cytokines. It is produced by many cell types including the cardiac and skeletal myocytes, but mainly by macrophages and monocytes, adipose cells, endothelial cells, T lymphocytes, mast cells, and osteoclasts. Many cell types respond to IL-6, including hepatocytes. IL-6 is the factor most directly responsible for the production of acute phase reactants. Its production is somewhat delayed compared to IL-1 and TNF, IL-6 levels remain elevated longer than the other two. IL-6 deficient animals have an increased susceptibility to *Listeria monocytogenes, Streptococcus pneumoniae, Escherichia coli, Candida albicans,* and mycobacterial infections.[35,41]

IL-10, like IL-6, is a pleiotropic cytokine that exerts both immunosuppressive and immunostimulatory effects. It is produced primarily by $CD4^+$ T cells, B cells, and other cell types. Its predominant suppressive effect is to inhibit Th1 (IFN-γ and IL-2) cytokine production. It downregulates MHC II expression, thus limiting its interaction with T cells and NK cells. It also inhibits cytokines involved in inflammatory responses, including prostaglandin E_2, TNF-α, IL-1, IL-6, and IL-8. IL-10 induces the production of IL-1RA. IL-10 can upregulate FCRγI on monocytes, macrophages, and NK cells, enhancing antibody-mediated cellular cytotoxicity.

IL-2 is produced by CD4 T cells when they encounter foreign peptide-MHC complex on antigen-presenting cells. This cytokine is critical for adaptive immune response in that it has both an autocrine and paracrine function, triggering T cells to undergo multiple rounds of proliferation and differentiate into effector T cells.

Interferons and Other Soluble Products

IFN-α and IFN-β are known as type I interferons. IFN-α is produced by monocytes and macrophages, whereas IFN-β is produced by fibroblasts and other cell types. The major stimuli for type I interferon are viral infections; they also respond to T-cell–derived factors in adaptive immune responses. Type I IFNs inhibit viral replication, and patients with insufficient production suffer from severe progressive or fulminant viral disease. These IFNs inhibit cell proliferation, enhance the lytic potential of NK cells, and increase class I HLA while decreasing class II HLA. IFN-γ is a type II IFN and is produced primarily by $CD4^+$, $CD8^+$, and NK cells (Figure 91-4). IFN-γ has antiviral and antiproliferative activity. It upregulates class I and II HLA expression, thus enhancing cellular toxicity and antigen presentation, respectively. IFN-γ activates monocytes and macrophages as well as neutrophils, resulting in enhanced killing of intracellular organisms, including mycobacteria and listeria. In addition, IFN-γ induces inducible nitric oxide synthase in macrophages, resulting in the generation of nitric oxide, a critical component for bactericidal function. Animals with a deficiency of IFN-γ have decreased survival in response to salmonella and mycobacterial infections. Patients with complete loss of IFNγ receptors have severe, early life infections with salmonella and viral infections (including respiratory syncytial virus, parainfluenza, herpes simplex virus, and cytomegalovirus) with a high mortality rate.[35,40,42] IFN-γ is a critical cytokine at the interface of the adaptive and innate immune system because of its function on NK cells and ultimately monocytes/macrophages.

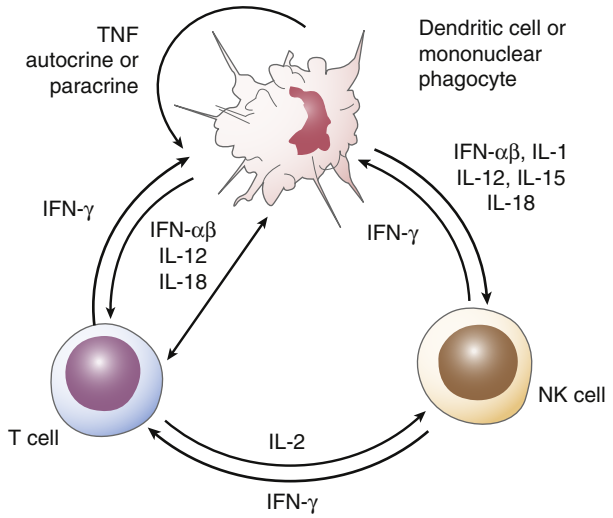

Figure 91–4. Secreted cytokines and effects on adaptive (T cell) and innate (dendritic cell/mononuclear phagocyte) and NK cells. NK cells activate mononuclear phagocytes and dendritic cells via IFN-γ secretion. With activation, mononuclear phagocytes demonstrate increased phagocytic and antimicrobial actions against intracellular pathogens. The phagocytes secrete cytokines which activate the NK cells, inducing IFN-γ production. IFN-γ from NK cells, and IFN αβ, IL-12, IL-18 from the mononuclear phagocytes/dendritic cells in turn activate the T cell along the TH-1 pathway. Activation of the T cell produces IL-2 and IFN-γ, which affects the mononuclear phagocyte/dendritic cell, NK cell, other T cells. Activation of the mononuclear phagocyte/dendritic cell results in production of TNF that has both autocrine and paracrine effects. (*Modified from Douglas S, Kapur R, Merrill JD, et al: In Stiehm ER, Ochs HD, Winkelstein JA, editors:* Immunologic disorders of infants and children, Philadelphia, *2004, Saunders Elsevier.*

Macrophage migration inhibitory factor (MIF) has been identified for more than 40 years, though its function has only been well defined in the past 15 years with the cloning of human MIF cDNA. Although T cells were initially believed to be the main source, monocytes, eosinophils, basophils, dendritic cells, B cells, mast cells, and neutrophils all express MIF. In contrast to other cytokines, MIF is secreted and stored in intracellular pools and therefore does not require de novo protein synthesis before secretion. MIF has a very broad tissue distribution and is expressed by cells and tissues that are in direct contact with the host's natural environment as well as organs involved in the stress response (hypothalamus, pituitary, and adrenal glands). MIF is implicated in both gram-negative and gram-positive infections. MIF-deficient animals have increased susceptibility to low-dose inoculum of salmonella and *Escherichia coli.* In contrast, blockade of MIF results in improved survival in animals treated with high doses of *E. coli*, after cecal ligation and puncture, or after bacterial superantigen challenge. Recent work supports that MIF also has isomerase activity and contributes to chronic inflammation seen in inflammatory bowel disease and cancer.[43,44]

High mobility group box 1 (HMGB1) has been identified as a late mediator of sepsis. Like MIF, antibodies to HMGB1 can be given many hours after the induction of sepsis and improve survival in animal models.[43,45] Also similar to MIF, HMGB1 is released from the cytoplasmic pool. Intracellular HMGB1 has diverse functions, including nucleosomal structure and function, as well as binding of transcription factors to their cognate DNA sequences. However, in systemic concentrations it has diverse proinflammatory responses mirroring the "late" effects of systemic inflammation and as such is often grouped with DAMPS (reviewed elsewhere[45]). Macrophages and neutrophils, when stimulated with LPS and C5a, respectively, release large amounts of HMGB1 into the culture medium. Systemic HMGB1 accumulation occurs in mice 8 hours after LPS administration, long after TNF and IL-1β levels have decreased. Humans with sepsis have elevated levels of HMGB1, and those whose levels were most elevated were at highest risk of dying.[46] In a mouse model of cecal ligation and puncture in which mortality rate was 75%, treatment with anti-HMGB1 monoclonal antibody 24 hours after injury decreased the mortality rate to 25%. It had no effect on recovery of bacterial counts from the spleens of these animals and thus did not appear to affect bacterial clearance.[47] A derivative of a Chinese herb, tanshinone IIA TSN IIA-SS, at concentrations (100 μmol/L) completely abrogated LPS-induced HMGB1 release.[48] This needs validation in other animal studies.

Chemokines are structurally and functionally related inflammatory cytokines with the ability to stimulate the chemotactic migration of distinct sets of cells, including neutrophils, monocytes, lymphocytes, dendritic cells, macrophages, fibroblasts, stem cells, and smooth muscle cells. The chemokine family is the largest family of cytokines, and although their main function is characterized as "chemotaxis," or directing migration through a concentration gradient, they also have a number of other functions, including cell activation, signaling, effects on angiogenesis and tumorigenesis, as well as immune cell polarization. To date there are 40+ identified chemokines.[49] They are small (~8 to 14 kDa), mostly basic molecules. They function through unique receptors that are G protein coupled and are seven membrane spanning

(i.e., have seven transmembrane domains).[50] The cytoplasmic domains of the receptors are critical for cell signaling and function. Chemokines may use more than one receptor for function. Chemokines are central to the process of extravasation of leukocytes that includes multiple steps involving interactions of adhesion molecules and the chemoattractant function of these proteins.[51] Chemokines are defined by structure, not function, and can be divided into two large and two small subgroups depending on the number and arrangement of conserved cysteines. The subgroups are CC, CXC, C, and CX3C. It should be appreciated that in the past 10 years, chemokines have been designated by their subgroup followed by ligand number; for example, IL-8 is CXCL8. Most chemokines are classified into two main groups according to function: (1) those concerned with hemostasis that are constitutively expressed and coordinate leukocyte trafficking during hematopoiesis and those with lymphocyte recirculation, and (2) those concerned with inflammation and tissue injury. Chemokines are produced by hematopoietic cells themselves as well as by endothelial cells, epithelial cells, and cells arising from the mesoderm, including fibroblasts, myocytes, hepatocytes, and lymphatic cells. Table 91-2 lists a select group of cytokines involved in infection and inflammation.

Granulocyte colony stimulating factor (G-CSF) and *granulocyte-macrophage stimulating factor* (GM-CSF) were initially identified by their ability to induce granulocytopoiesis and monocytopoiesis; however, they have marked effects on neutrophil and monocyte function. Although both G-CSF and GM-CSF are produced by bone marrow stromal cells, they are also produced by activated monocytes/macrophages and fibroblasts. G-CSF is also produced by epithelial cells of the gut and lung in response to inflammation. GM-CSF is produced by T lymphocytes and NK cells. G-CSF enhances the physiologic activation of mature neutrophils, whereas GM-CSF stimulates the functional activity of neutrophils, eosinophils, and monocytes/macrophages.[52,53] GM-CSF is critically involved in the normal surfactant turnover, and alveolar proteinosis is an autoimmune disease targeting GM-CSF.[54] Critical to the immune response is that production of G-CSF and GM-CSF results in increased neutrophil survival. Neutrophils usually have a half-life of less than 12 hours before removal from the circulation and undergo apoptosis. However, exposure to G-CSF or GM-CSF decreases apoptosis, leading to prolonged survival of circulating neutrophils and those that have moved to a site of infection. Removal of these cytokines, such as occurs in the resolution phase of inflammation, leads to induction of apoptosis and increased clearance of neutrophils. G-CSF and GM-CSF are approved for use in a variety of hematologic pathologies.[53] G-CSF and GM-CSF have been proposed for use in the nonneutropenic critically ill adult and neonatal population. However, studies to date do not support their routine use as either a treatment of established systemic infection or as prophylaxis to prevent systemic infection in high-risk individuals.[55-57]

Nitric oxide (NO) is a stable, free radical gas. Extensive work over the past 20 years has converged to establish NO as a major messenger molecule regulating immune function and blood vessel dilation as well as a neurotransmitter. NO is formed from arginine by the enzyme nitric oxide synthase (NOS). NOS-2 or inducible NOS (iNOS) is present in many tissues, whereas NOS-1 and NOS-3 are primarily present in neuronal and endothelial cells, respectively. NOS-1 and NOS-3 are present in low amounts and generate NO for neurotransmission and vasodilation. In contrast, NOS-2 is induced by microbial peptides and inflammatory cytokines and serves as a major bactericidal and tumoricidal agent. NO is critical in adaptive immunity to intracellular pathogens such as *Mycobacterium tuberculosis* and *Listeria monocytogenes*. NO enhances the activity of NK cells, γδ T cells, and macrophages. The condensation of NO and the reactive oxygen metabolite superoxide, O_2^-, results in the production of peroxynitrite ($OHNOO^-$), which decays to the highly reactive hydroxyl radical (OH) and nitrogen dioxide. These agents contribute in part to the killing of the microorganisms in tightly regulated structurally "isolated" areas of phagocytes, the phagolysosomes, discussed below.

Cellular Components of Immunity

The cellular components of immunity have traditionally been divided into innate and adaptive immunity, but such distinctions have become increasingly blurred and critical overlap occurs. For example, the dendritic cells and other antigen presenting cells, such as macrophages and monocytes, are part of the innate immune system; nonetheless, they directly drive adaptive immunity.

The cells of the immune system can be defined by the surface antigens they display. These surface antigens are denoted by the CD nomenclature and refer to cluster designation. These antigens denote the lineage and often the functional capacity of a cell. Surface antigens are revealed by using monoclonal antibodies, commonly with flow cytometry.

Lymphocyte types include the T cells, B cells, NK cells, and the NK T cell (NKT), which exhibits features of both NK and T cells. T cells got their name because the vast majority arise from the thymus. They mediate antigen-specific cellular immunity and play a critical role in facilitating antigen-specific B cell–dependent humoral immunity. B cells are the subset of lymphocytes that synthesize, express Ig on their surface, and differentiate to plasma cells that produce Ig. B cells arise from the bone marrow in humans and other mammals or bursa in birds.[58]

The major T-cell subsets are the $CD4^+$ helper/inducer and the $CD8^+$ suppressor/killer cells. Nearly all T cells bear a T-cell receptor composed of an α- and β-chain; they also express CD4 or CD8 coreceptors. Nearly all the αβ T cells recognize protein antigen in the form of peptide fragments bound to classic MHC molecules (MHC class I or MHC class II). The CD4 molecule augments binding to antigens presented in association with MHC II antigens, whereas CD 8 molecules are necessary for antigen binding to MHC I. The immunologic synapse is the highly ordered junction that forms between the APC, such as the dendritic cells or tissue macrophages, and the T cell during antigenic stimulation. The structure resembles a doughnut in which the T-cell receptor-peptide-MHC, CD3, CD4, or CD8 is in the center of the synapse. The costimulatory molecules CD2, CD28, CD54 (intercellular adhesion molecule-1 [ICAM-1]) on the T cell bind to their respective ligands LFA-3 (CD 58), CD80-CD86, LFA-1 (CD11a/CD18) on the APC on the perimeter of synapse (Figure 91-5).[59]

The $CD4^+$ naive cells, which are those never exposed to antigen, can differentiate into effector cells expressing specific patterns of cytokines. Originally designated as Th1 and Th2

Table 91–2 Chemokine/Chemokine Receptor Families (Partial List)

Name	Original Ligand Name*	Chemokine Receptor
CXCL1	GRO-α/MGSA-α	CXCR2>CXCR1

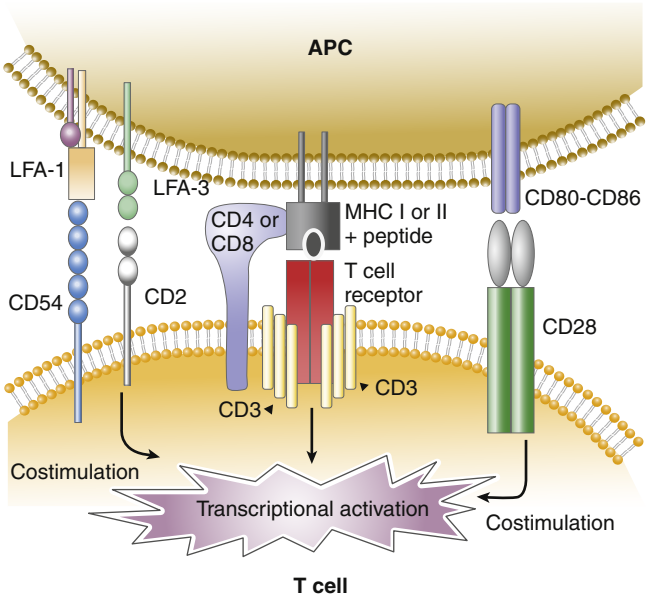

Figure 91–5. Immunologic synapse. Protein antigen bound to the major histocompatibility complex I or II (MCH I or II) is presented by the antigen presenting cell *(APC)* to the T-cell receptor. The T-cell receptor/CD3 complex is composed of the two chains of the T cell receptor (α and β) and the 6 subunits of the CD3(a γ and a δ subunit and two each of the ε and ζ subunits). CD8 or CD4 interacts with the MHC I or MHC II/antigen complex, respectively. Engagement of the T-cell receptor can then signal the T cell to activate a number of activities, including transcription. However, for activation to occur, there must be additional signals through costimulatory molecules on the T cell and APC. The T-cell receptor/CD3/CD4 (or CD8) complex is centered in the middle of the immunologic synapse, while the costimulatory molecules are in the periphery.

based on the cytokines they produce, there has been an explosion in the past 15 years delineating additional subtypes. Most of these cytokines produced by T cells are secreted, but some can be expressed on the cell surface. IL-12 and IFN-γ drive T cells into the Th1 pathway. IFN-γ is the signature cytokine produced by Th1 cells, but the Th1 cells also produce substantial amounts of IL-2, TNF-α, and TNF-β. The Th1 response is considered proinflammatory. IL-4 drives T cells into the Th2 pathway. Th2 cells also produce large amounts of IL-4 along with IL-5, IL-9, and IL-13. IL-4 and IL-13 (along with IL-10 produced by monocytes/macrophages) are considered anti-inflammatory or immunosuppressive. The Th2 response is critical for eosinophil function and is important in the development of IgE responses and the killing of parasites.

Th17 cells, which produce IL-17, result from activation of naive T cells by TGF-β plus an inflammatory cytokine (IL-21 alone, IL-6 + IL-23, or IL6 + IL-21).[36] IL-23 is produced by monocytes and dendritic cells. IL-21 is produced by Th17 cells and thus serves an amplification loop for Th17 differentiation. Important to highlight is that TGF-β is considered a prototypic antiinflammatory cytokine critical for the healing. It also serves as a warning of categorizing a particular molecule as either "pro" or "anti" inflammatory solely, which is often proven to be too simplistic as our understanding of immunity progresses. Th17 is critical for the control of extracellular cytokines, induces the destruction of matrix, and often synergizes with TNF and IL-1.[36]

TGF-β is produced by many cells. In the absence of IL-6, it will induce $CD4^+$ cells into a regulatory T cell, known as

a *T-reg*. T-reg cells are identified by a transcription factor, Foxp3+ (Forkhead box P3 transcription factor) and carry the IL-2 receptor CD25. Presence of Foxp3+ is implicated in the development of autoimmunity, allergy, and rejection in transplant medicine and suppression of immune responses to cancer.[60] There are several different types of T-regs. All require cell-to-cell contact for immune suppression.

Naive $CD8^+$ cells are not effective killer cells. However, after activation with antigen in the context of MHC class I by APCs in the presence of IL-2 and IL-12, they differentiate quickly into $CD8^+$ cytotoxic cells. These cells express perforin, granzymes, and Fas ligand and produce effector cytokines including TNF-α and IFN-γ. Perforins introduce pores into the target cell through which granzymes can enter, leading to the triggering of apoptosis and cell death. Alternatively, the cytotoxic T cell upregulates the Fas ligand (CD95L) that engages Fas (CD95) on the target cell, resulting in delivery of death signal culminating in apoptosis (Figure 91-6).

A small proportion of T cells in the circulation have γδ T-cell receptors that are not restricted to antigen recognition bound to either MHC I or MHC II. Thus γδ T cells do not have either CD4 or CD8 molecules on their surface. The γδ T cell recognizes either stress-induced or nonclassic MHC molecules directly or nonpeptide antigens, such as host or pathogen-derived lipids bound to these nonclassic MHC molecules. The γδ T cell is primarily located in epithelial tissues in certain species and performs effector functions that protect the host from infections and malignancy and maintains tissue integrity. These cells also play a critical role in regulating the immune response, leading to resolution of infection and inflammation.[61]

NK cells are large granular lymphocytes with innate immune function. They play a critical role in the early host defense against viral, bacterial, and other infections as well as cancer. NK cells recognize their targets through unique NK receptors and are able to recognize self-MHC class I or class I–like molecules that inhibit or enhance NK function. Their phenotype is characterized by the expression of the CD56 surface antigen and the lack of CD3. NK cells produce IFN-γ, TNF-α, IL-10, and GM-CSF. They exhibit spontaneous cytotoxic activity against virus-infected cells and mediate antibody-dependent cell cytotoxicity through FCRγIII (CD16). Cytotoxicity is the major effector function of NK cells. They bridge the innate and adaptive immune response (Figure 91-6).[62,63] The NKT cells express both CD56 and CD3 T-cell receptor and thus share receptor structures of both conventional NK and T cells. NKT cells are potentially capable of very rapid secretion of large amounts of Th1 or Th2 cytokines but also contain perforin. Both NK and NKT cells use the same mechanisms as the cytotoxic $CD8^+$ T cell for killing (i.e., perforin/granzyme cytotoxicity and Fas-ligand/fas cytotoxicity) (see Figure 91-6). The control and resolution of viral infections require the eliminate of the source of the virus, hence the destruction of the virus-infected cell before progeny virus is produced. This is mediated during the innate phase of the immune response by NK cells. In most cases, resolution of active viral infection ultimately requires the development of antigen-specific T lymphocytes, the majority of which are MHC class I–restricted $CD8^+$ T cells, although MHC class II $CD4^+$ cells and γδ T cells may also mediate cytotoxicity.

Phagocytic cells include neutrophils, eosinophils, monocytes/macrophages, and dendritic cells. They have in common

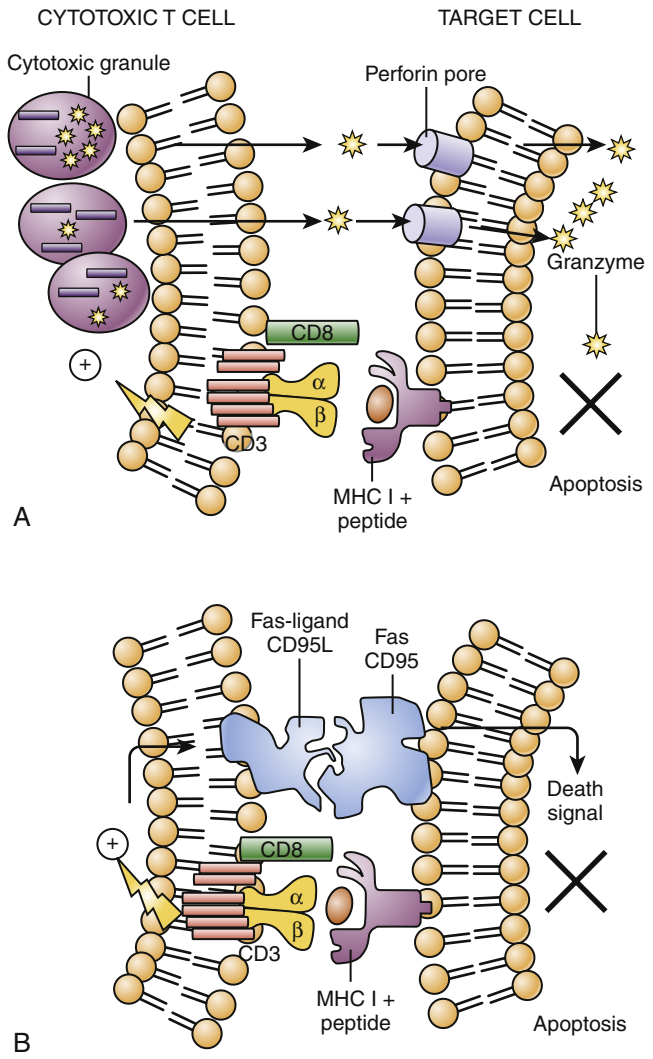

Figure 91–6. Mechanisms of antigen-specific MHC I–restricted T cell–mediated cytotoxicity. The engagement of the αβ T-cell receptor *(TCR)* in the CD3/CD8 complex of the T cell by antigenic peptide bound to MHC I on the target cell leads to T-cell activation and target cell death. **A,** Cytotoxicity occurs via the release of the contents of the cytotoxic granules from the T cell, including perforin and granzyme. A perforin pore is introduced into the target cell membrane by which granzymes can enter the target cell, leading to the triggering of apoptosis and cell death. **B,** Activation of the T cells leads to upregulation of the Fas-ligand *(CD95L),* which engages Fas *(CD95)* on the target cell, resulting in the delivery of a death signal culminating in apoptosis. Both of these mechanisms are also used by NK (natural killer) T cells and NK cells. *(Modified from Lewis DB, Wenwei T: The physiologic immunodeficiency of immaturity. Stiehm ER, Ochs HD, Winkelstein JA, editors:* Immunologic disorders of infants and children, *Philadelphia, 2004, Saunders Elsevier.)*

a number of different properties that are of prime importance to the host inflammatory response. Neutrophils, eosinophils, and monocytes/macrophages share the ability to phagocytose foreign material, release granule constituents, secrete inflammatory mediators and regulators, and synthesize reactive oxygen products through a unique reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase enzyme system present on the cell membrane. Neutrophils, eosinophils and basophils are all polymorphonuclear leukocytes (PMNLs). Neutrophils and eosinophils share similar mechanisms of cell migration, phagocytosis, and pathogen killing. All three cell types have segmented nuclei and contain granules, although

their granule content varies. Neutrophils are the host's main defense against bacterial and fungal infections. Eosinophils are important to the control of parasitic infections. Neutrophils may remain in the storage pool of the bone marrow for up to 5 days. Released from the bone marrow into the blood, about half the neutrophils circulate for about 10 hours; the other half remains in a marginated pool, so they are not accessible to phlebotomy. This marginated pool is thought to be in the spleen, along vessel walls, and in the lung microcirculation. Cells can be mobilized from this marginated pool by infection/inflammation and stress. Once circulating neutrophils migrate into the tissue they survive for 1 to 2 days, likely longer in the presence of G-CSF and GM-CSF.

Monocytes, macrophages, and dendritic cells are part of the mononuclear phagocyte system. Although these cells share characteristics with neutrophils and eosinophils, they also have unique properties, including antigen processing and interaction with lymphocytes in the generation of the immune response and extracellular killing of tumor cells. Monocytes are released from the bone marrow, circulate for 1 to 4 days, then migrate into the tissues. Three fourths of the circulating monocytes are localized to blood vessel walls in a marginated pool. Monocytes emigrate into tissue to replace resident macrophages and are either "free" or "fixed." Free macrophages are found in pleural, synovial, peritoneal, alveolar spaces and in inflammatory sites. Fixed macrophages are generally less motile and include those in the splenic sinusoids, Kupffer cells (liver), bone marrow reticulum, lamina propria of the gastrointestinal tract, lymph node reticulum, osteoclasts in the bone, and as microglia (in the central nervous system).[63] These macrophages are heterogenous in their phenotype and function. It has been hypothesized that macrophages have functional patterns such as seen with T cells (i.e., Th1- or Th2-driven phenotypes). However, work supports that monocytes and tissue macrophages develop their phenotypic function in response to changes in the microenvironment in which they are located rather than representing particular populations of monocytes that have been recruited there.[15]

The localization of phagocytes to a site of infection is reviewed in a subsequent section. However, after localization occurs, recognition of the pathogen by the phagocyte occurs through fragment receptors (FcRs; see previous section) and complement receptor or other pattern recognition receptors present on the phagocyte. On encountering a particle/pathogen, the appropriate receptors are activated and the phagocyte membrane ruffles. The phagocyte then assumes a bipolar configuration, with the formation of a "head," or pseudopod, and "tail," or uropod. The pseudopod surrounds a particle and fuses at its distal end to form a phagolysosome, thus internalizing the particle and a portion of the plasma membrane. The pseudopodia only advance over the portion of the particle or pathogen that is "opsonized" or where there are molecular patterns that fit the appropriate receptor on the phagocyte. Granules present in phagocytes then join this newly formed vacuole and discharge their contents within seconds. Neutrophils have at least three types of granules containing microbial enzymes, myeloperoxidase and lysozyme, proteases, cationic proteins, BPI, and defensins and acid hydrolases. They also contain molecules critical for adhesion and locomotion, such as Mac-1 (CD11b/CD18). Release of myeloperoxidase from primary granules is important in oxygen-dependent microbial killing. Release of other granule constituents, such as lysozyme, lactoferrin, defensins, and BPI, is of critical importance in decreasing the pH of the phagolysosome and in oxygen-independent microbial killing. Phagocytes are responsive to environmental cytokines such as TNF-α, IFN-γ, and chemokines that can prime the phagocyte for increased killing. Phagocytes also produce a large number of products in response to bacterial challenge. Monocytes/macrophages are a rich source of TNF-α and IL-1; even neutrophils produce TNF-α and IL-1, though in lesser amounts. Each cell produces chemokines that attract other leukocytes to the inflammatory focus. Phagocytes can also produce a number of lipid mediators that further stimulate the innate immune response.

The respiratory burst refers to the coordinated consumption of oxygen and production of metabolites that occur when phagocytes are exposed to appropriate stimuli. These events underlie all oxygen-dependent killing by phagocytes. Defects in the respiratory burst mechanisms result in the disorder chronic granulomatous disease. The NADPH oxidase system is a transmembrane electron transport system in which NADPH, the primary electron donor on the cytoplasmic side of the membrane, reduces oxygen in the extracellular fluid or within the phagolysosome to form O_2^- (superoxide). In turn two molecules of O_2^- spontaneously or enzymatically (through superoxide dismutase) generate hydrogen peroxide (H_2O_2). Although both O_2^- and H_2O_2 can directly injure bacteria, the oxidants that are formed from them are primarily responsible for microbicidal action. Myeloperoxidase released into the phagolysosome will enzymatically form hypohalous acids from halide anion. Hypohalous acids such as hypochlorous acid (HOCL) are extremely potent antimicrobials. These agents can then alternatively react with ambient amines (RNH_2) to form N-chloramines (RNHCL). RNHCL are lipophilic oxidizing and chlorinating agents that readily penetrate cellular membranes. The toxic effects of HOCL and RNHCL include sulfhydryl oxidation; hemoprotein inactivation; protein, amino acid, and DNA degradation; and inactivation of essential metabolic cofactors. Oxyradicals, in particular hydroxyl radical (HO), are some of the most powerful oxidizing substances known. In the presence of Fe^{3-}, O_2^-, and H_2O_2 combine to form HO. Presence of NOS-2 in phagocytes, in particular the macrophages, provides a source of NO that can react with O_2^-, producing peroxynitrite ($ONOO^-$), another toxic and powerful oxidant.[64]

Neutrophils from patients with chronic granulomatous disease retain some of the antimicrobial activity of normal neutrophils despite the inability to produce oxygen species. This is due to the many endogenous antimicrobials present in the granules that are critical to the killing of microbes. These antimicrobials, discussed earlier in the chapter, include defensins, bacterial permeability increasing protein, lactoferrin, and lysozyme. A number of other proteases, hydrolases, and nucleases in the granules of phagocytes, although not directly microbicidal, act synergistically with the antimicrobial agents to contribute to killing. These products can also result in host injury if released from the neutrophil. Neutrophil elastase, collagenase, and gelatinase (also known as matrix metalloproteinase-8, -9, respectively) can hydrolyze key components of the extracellular matrix. Neutrophil elastase not only can degrade almost all components of the extracellular matrix, but can also cleave a variety of key plasma proteins such as immunoglobulins, complement proteins, and clotting factors. The activity of the elastase outside the cells is regulated

primarily by α_1-proteinase inhibitor. Neutrophil elastase can mediate injury outside the neutrophil when α_1-proteinase inhibitor is inactivated by oxidants.[65]

Dendritic cells (DCs) are a distinct lineage of migratory leukocytes. They initiate the primary immune response yet are part of the innate immune system. DCs exist in most tissues of the reticuloendothelial system. They are prominent in tissues exposed to the external environment with frequent exposure to foreign antigen. DCs from different tissues have varying cell membrane markers and functions and include thymic DCs, interstitial DCs (heart, lung, kidney, intestine), interdigitating DCs (lymph nodes), and Langerhans cells (epidermis). The features these DCs have in common are that they originate from bone marrow $CD34^+$ stem cells and migrate through the bloodstream to tissues to become immature DCs. Immature DCs take up antigen or respond to environmental cues through pattern recognition receptors and other receptor and nonreceptor mechanisms. This then results in maturation of the DCs and production of unique sets of cytokines and receptors. Depending on the specific environmental signal, DCs will mature into different clones.[66,67]

Immature DCs migrate to and remain in the periphery, where they express low levels of MCH I and II. These immature DCs will then mature either after phagocytosis of foreign antigen or by activation of one of its receptors (e.g., TLR). The mature DC will then migrate to the local lymphoid organ; as they do, they increase cell surface expression of MHC as well as T costimulatory molecules (i.e., CD80-CD86) and begin to secrete specific cytokines. Mature DCs lose the ability to phagocytose. In the lymphoid organ, the DC will present antigen to the $CD4^+$ or $CD8^+$ T-cell receptor via MHC II or I, respectively. The DC costimulatory molecules CD80 or CD86 must engage their ligand, CD28, on the T cell for full activation (Figure 91-6). It should be noted that for the initial immune response, the DC (or APC) must be in geographic proximity of the $CD8^+$ and CD4+ cell. Alternatively, the DC or APC may be preconditioned by an activated $CD4^+$ cell that is then able to activate naive $CD8^+$ cells to become cytotoxic T cells.[66,67] Not all macrophages function well as antigen presenting cells; elicited peritoneal macrophages do, but alveolar macrophages and Kupffer cells do not.[15]

Platelets

As previously described, hemostasis and inflammation overlap. The endothelial surface that is usually *anticoagulant* becomes *procoagulant* in infection and inflammation. Platelets themselves have inflammatory, antimicrobial, and immune-modulating factors. In a platelet thrombus, neutrophils, and to a lesser extent monocytes, are recruited to the developing thrombus via adhesion receptors (discussed in the following section). In addition, leukocytes and platelets adherent to endothelial surface can attract the other cell type. Platelets secrete a number of stored chemokines that activate neutrophils and monocytes, T cells, and NK cells. These include the neutrophil-activating chemokines: NAP2 (CXCL7), PR4 (CXCL4), GRO-α, (CXCL1), ENA-78 (CXCL5), as well as the monocyte-activating chemokines: RANTES (CCL5), MIP-1α (CCL3), and MCP-3 (CCL7). Platelets also contain antimicrobial peptides such as thrombocytins as well as HMGB1. They can synthesize IL-1β. Platelet interactions with neutrophils alter the production of LTB_4 that may be important for T-cell homing. Platelets can also convert arachidonate metabolites supplied by neutrophils to leukotriene C_4 and lipoxins, providing additional modulatory signals in cell-to-cell interactions.[68] Platelets express TLR4, and complex interactions between platelets and neutrophils may lead to trapping of bacteria within the vasculature, which is discussed in following sections.[56]

Leukocyte Localization

In response to infection and in normal immune surveillance all leukocytes must travel from their sites of production to the point at which their function is required. There is a multiple-step process for localization to occur. Permutations in this process exist in specialized vascular beds such as the lung, liver, and kidney.[69,70]

In general, the multistep process begins by activation of the postcapillary venular endothelial surface by inflammatory cytokines such as IL-1, TNF, IL-4, and IFNγ. The surface transforms from a nonadhesive surface to one that is proadhesive through the expression of specific ligands. These ligands will recognize their cognate receptors on the circulating effector leukocytes (and platelets) (i.e., neutrophils, eosinophils, monocytes, NK cells, activated T cells). Endothelial ligands that are upregulated include members of the selectin family and IgSF (Table 91-3). Selectins are responsible for the initial capture of the leukocyte from the free-flowing stream as well as rolling on the endothelial surface of the IgSF that is critical for leukocyte slowing, arrest, and migration on the cell surface (Figure 91-7). The leukocyte ligand for E- and P-selectin is PSGL-1 (CD162, P-selectin glycoprotein ligand 1). The leukocyte receptors for the IgSF are the β2 integrins, in particular Mac-1 (CD11b/CD18), LFA-1 (CD11a/CD18), and the β1 integrin VLA-4 (CD49d/CD29). The leukocyte integrins are heterodimers composed of an α and β subunit. The β subunit may be shared by multiple members of a subfamily, whereas the α subunit confers specificity. Mac-1 functions not only in leukocyte recruitment, but also as a receptor for complement fragment C3bi; hence its alternative name of complement receptor 3. LFA-1 also functions as coinducer of the immune response in the immunologic synapse as discussed above (Table 91-3). The endothelial surface also secretes a number of chemokines and other activating substances, such as PAF, that activate the leukocyte and mediate the transition from rolling to arrest. After the leukocyte has arrested, it polarizes, then "crawls" and emigrates through the endothelial lining of the vessel. This emigration, known as *diapedesis*, is in response to activating agents (chemokines, LTB_4) released by cells present in the subendothelial matrix, released bacterial products (N-formyl peptides), or through complement activation (C5a). This process is also dependent on leukocyte integrins that recognize IgSF on the endothelial cells necessary for transendothelial migration (see Figure 91-7). Locomotion through the subendothelial matrix requires additional leukocyte integrins (VLA-1, -2, -3, 5, -6) that recognize matrix proteins, including fibronectin, collagen, vitronectin, and vimentin. What effector cell is recruited and the tissue to which it is recruited depend on the adhesion molecules present on the endothelial surface and the effector cells as well as the "signals" released or presented at the endothelial surface and in the subendothelial region.[71-73]

Table 91–3 Adhesion Molecules in Inflammation and Hemostasis

Name	CD Classification	Primary Cell Expression	Ligand
INTEGRIN FAMILY			
β1 Integrins			
α1β1 (VLA-1)	CD49a/CD29	T and B-cell subsets, mono	COL I, COL IV, LN
α2β1 (VLA-2)	CD49b/CD29	T-cell subsets, mono, PLT, PMN	COL I, COL IV, LN
α3β1 (VLA-3)	CD49c/CD29	T-cell subsets, mono	FN, COL I, LN
α4β1 (VLA-4)	CD49d/CD29	T-cell, B-cell, Eos, mono, PMN, baso	FN, VCAM, Tsp, JAM2
α5β1 (VLA-5)	CD49e/CD29	T-cells, PMN, PLT	FN, Tsp
α6β1 (VLA-6)	CD49f/CD29	T-cells, PMN, PLT, EC	LN
α9β1		PMN, mono	VCAM-1, OSP, tenascin
β2 Integrins			
αLβ2 (LFA-1)	CD11a/CD18	PMNS, T- and B-cell, Eos, mono, NK, macro	ICAM-1, ICAM-2, ICAM-3, JAM-1
αMβ2 (Mac-1)	CD11b/CD18	PMNS, mono, Eos, NK, macro, lymph subset	ICAM-1, iC_3b, Fg, FN, Factor X,
αXβ2 (p150,95)	CD11c/CD18	PMN, mono, Eos, lymph subset	JAM-3, GPIb- IX-V
β3 Integrins			
αIIbβ3 (GPIIbIIIa)	CD41/CD61	PLTS	VWf, FN, Fg, VN, Tsp, COL
αVβ3 (vitronectin receptor)	CD51/CD61	Macro, mono, T-cell, PLT, EC, PMN	VWf, VN, FN, Fg, PECAM-1, Tsp, LN, OSP, tenascin, COL
β7 Integrins			
α4β7	CD49d/β7	Gut-associated lymphocyte	VCAM, MAdCAM-1, FN
αEβ7	CD103/β7	Gut-associated lymphocytes	E-CAD
IMMUNOGLOBULIN SUPERFAMILY (IGSF)			
ICAM-1	CD54	T+B-cell, mono, EC, pneumocyte, hepatocytes, epithelial cells, fibroblasts	LFA-1, Mac-1
ICAM-2	CD102	EC	LFA-1
ICAM-3	CD50	Lymph, PMN, mono	LFA-1, αDβ2
VCAM-1	CD106	EC	α4β1, α4β7
JAM-1		EC, epithelial cells, PMNs, mono, lymph, RBC	LFA-1, JAM-1
JAM-2		HEV, EC	JAM-2, JAM-3, α4β1
JAM-3		Lymph	Mac-1, JAM3
MAdCAM-1		Peyers patch HEV, mesenteric LN	α4β7, L-selectin
PECAM-1*			
SELECTINS			
L-selectin	CD62-L	Lymph, mono, Eos, baso, PMN	CD34, GlyCAM-1, MAdCAM-1, Unknown EC ligand, PSGL-1, PNAD, sLe^x-bearing ligands
P-selectin	CD62-P	EC, PLTS	PSGL-1, E-selectin, GPIb-IX-V
E-selectin	D62-E	EC	PSGL-1, sLe^X-bearing ligand(s), CLA
SELECTIN LIGANDS			
PSGL-1	CD162	PMN, Eos, mono, lymph	P-selectin, L-selection, E-selectin
GlyCAM-1		Lymph node + Lung EC	L-selectin
CD34	CD34	Peripheral LN HEV, leukocyte precursors	L-selectin
OTHER			
CD99	CD99	T cells, endothelial cells, monocytes	CD99, ?
PECAM-1*	CD31	EC, PMN, PLT, mono, lymphocyte subsets	PECAM-1, αVβ3

*PECAM-1 (platelet endothelial adhesion molecule-1) is now considered a member of the ITIM family, but by convention it is still listed in the IGSF and Other.
VLA, Very late antigen; *mono,* monocytes; *PLT,* platelet; *Eos,* eosinophils; *PMN,* polymorphonuclear leukocyte; *baso,* basophil; *EC,* endothelial cell; *COL I,* collagen type I; *COL IV,* collagen type IV; *LN,* laminin; *FN,* fibronectin; *VCAM,* vascular cell adhesion molecule; *Tsp,* thrombospondin; *NK,* natural killer cell; *macro,* macrophages; *ICAM,* intercellular adhesion molecule; *JAM,* junctional adhesion molecule; *lymph,* lymphocytes; *iC3b,* inactivated form of complement component C3b; *Fg,* fibrinogen; *OSP,* osteopontin; *MAdCAM-1,* mucosal addressin cell adhesion molecule-1; *E-CAD,* E-cadherin; *GlyCAM-1,* glycosylation-dependent cell adhesion molecule-1; *PSGL-1,* P-selectin glycoprotein ligand-1; *sLe^x,* sialylated Lewis X antigen; *CLA,* cutaneous lymphocyte-associated antigen; *vWf,* von Willebrand factor, *Vn,* vitronectin; *PNAD,* peripheral node addressin; *GP1b-IX-V,* glycoprotein complex present on the surface of platelets.

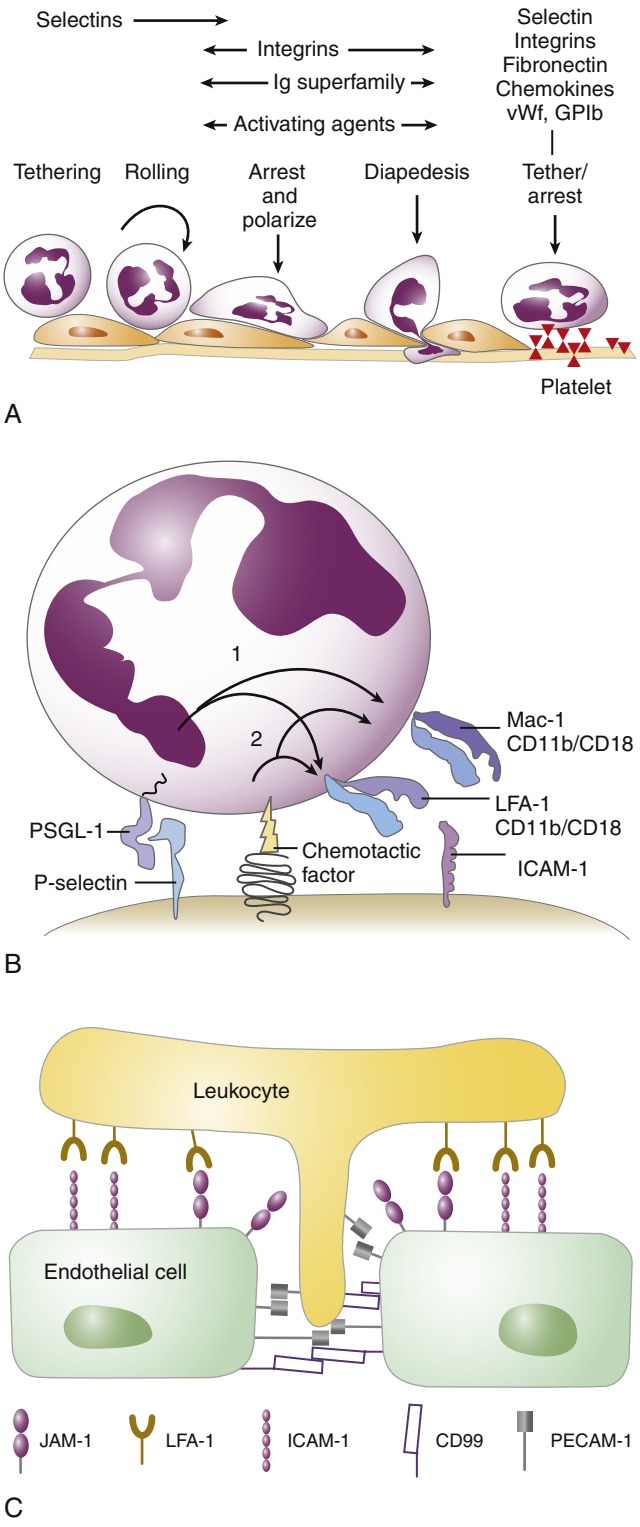

Figure 91–7. Leukocyte localization. **A,** Leukocytes are captured from the free-flowing stream (tether) and roll on the endothelial lining of the blood vessel. This interaction is mediated by all three members of the selectin family. The leukocyte slows, arrests, and changes shape (polarizes). Integrins and their ligands, the immunoglobulin superfamily (IgSF), mediate these steps. The cells then crawl, or diapedese, over the surface of the endothelium until they migrate through the endothelium. The integrins, members of the IgSF, and CD99 all have a role in this response. A leukocyte also may be tethered by adherent platelets or adherent leukocytes. Platelets through β3 integrins and GPIb-IX-V can bind directly to collagen or fibronectin on exposed basement membrane, or alternatively to von Willebrand factor bound to the endothelium or basement membrane. Platelets can release cytokines that activate leukocytes directly once tethered. Leukocytes can bind to platelets directly through integrins or to fibrinogen that is bound to platelets. **B,** Model of leukocyte activation leading to arrest. Leukocytes tether to the endothelium expressing P-selectin via P-selectin-glycoprotein-ligand 1 *(PSGL1).* In the presence of shear, PSGL-1 can activate the leukocyte integrins LFA-1 and Mac-1 (*arrow 1*). Chemotactic factors expressed on the endothelial surface can also directly activate LFA-1 and Mac-1. LFA-1 and Mac-1 both can bind to endothelial ICAM-1 at domains 1 and 3, respectively. **C,** Proposed mechanisms for transendothelial migration. With stimulation of the endothelial cell, ICAM-1 is upregulated. JAM-1, which is localized at the interendothelial cleft, is mobilized away from the cleft. With activation of the leukocytes, migration across the vascular endothelial can then occur via LFA-1, PECAM-1, JAM-1, and CD99. Leukocyte LFA-1 can bind to JAM-1 and ICAM-1 on the endothelial surface. Leukocytes can then traverse the interendothelial cleft through sequential transhomophilic interactions of PECAM-1 and CD99. *Ig,* Immunoglobulin; *vWF,* von Willebrand factor; *JAM,* junctional adhesion molecule; *PECAM,* platelet endothelial adhesion molecule. *(From Mariscalco M: Integrins and cell adhesion molecules. Polin RA, Fox WW, Abman SH, editors:* Fetal and neonatal physiology, *Philadelphia, 2004, Saunders Elsevier.)*

This multistep paradigm is also critical for the homing of lymphocytes to the high endothelial venules, a specialized endothelium of the secondary lymphoid organs. Here naive lymphocytes (rather than activated cells) tether, roll, arrest, and emigrate through the endothelial surface. The naive lymphocytes migrate toward DC or APC that secrete cytokines and chemokines necessary for activation of the T cell through the T-cell receptor.[74] One critical chemokine is SDF-1 (CXCL12). Its receptor, CXCR4, is present on almost all lymphocytes and many monocytes. The multistep paradigm is not operative in all vascular beds. In lungs the inflammatory cells do not "roll," but instead are physically trapped in the pulmonary capillary bed and emigrate from this area rather than in the postcapillary venules.[75] In the liver, leukocytes are physically trapped in the sinusoids. Because the sinusoidal endothelia has large pores, the leukocytes can easily interact with the underlying hepatocytes[76] The platelet can also function as a surface to which a leukocyte can bind by the activated release from the Weibel-Palade body of P-selectin at sites of injury or inflammation to the endothelium (see Figure 91-7).

An increasing number of genetic defects in leukocyte localization have been identified. Those that involved adhesion receptors critical for neutrophil recruitment result in neutrophilia and severe, recurrent skin abscesses. In patients with leukocyte adhesion deficiency type-1 (LAD-1), there is a selective defect in the expression and/or functional activation of β2 (CD18) integrins. In patients with the rarer defect, LAD-2, there is defective rolling of leukocytes on inflamed endothelium due to lack of fucosylated glycoconjugates on the selectins. Finally, patients with LAD-3 have a functional defect in the activation of β1 and β2-integrin avidity, leading to defective leukocyte arrest on vascular endothelium.[71,77,78]

Host Response to Infection: A Summary

There is a coordinated and highly regulated response by the body to microbial infection. As outlined in Figure 91-8, the first defense is local immunity. The epithelial surface functions

as a physical barrier. Through the release of antimicrobial peptides from the epithelium and secretory IgA from submucosal plasma cells, microbial burden is decreased. The epithelial cells at the site of infection will produce cytokines and chemokines that regulate the invasion of the area by leukocytes. However, these cytokines will also modulate the submucosal macrophages and plasma cells that are constitutively present. The presence of soluble agents critical for opsonization (including Ig and complement components) permit the efficient phagocytosis of organisms by recruited neutrophils and monocytes as well as resident macrophages. The presence of T cells and plasma cells early in the infection depends on a previous encounter with the organism. If the host has immunologic memory for the microbe, then there will be fairly rapid (i.e., within 1 day) expansion of the memory T cells to effector cells (i.e., cytotoxic T cells) and expansion of memory B cells and differentiation to plasma cells to produce IgG. It should be noted that at each step of the process, the number of bacteria decrease.[76,79]

If the host must mount a primary immune response to control and eliminate the infection, it may take 3 to 5 days for microbial or viral elimination to occur if local mechanisms or innate immune systems response are inadequate. As outlined in Figure 91-9, the initiation of adaptive immunity for a typical viral infection occurs within 2 days. Between 3 and 4 days, there is the establishment of the adaptive immune response with

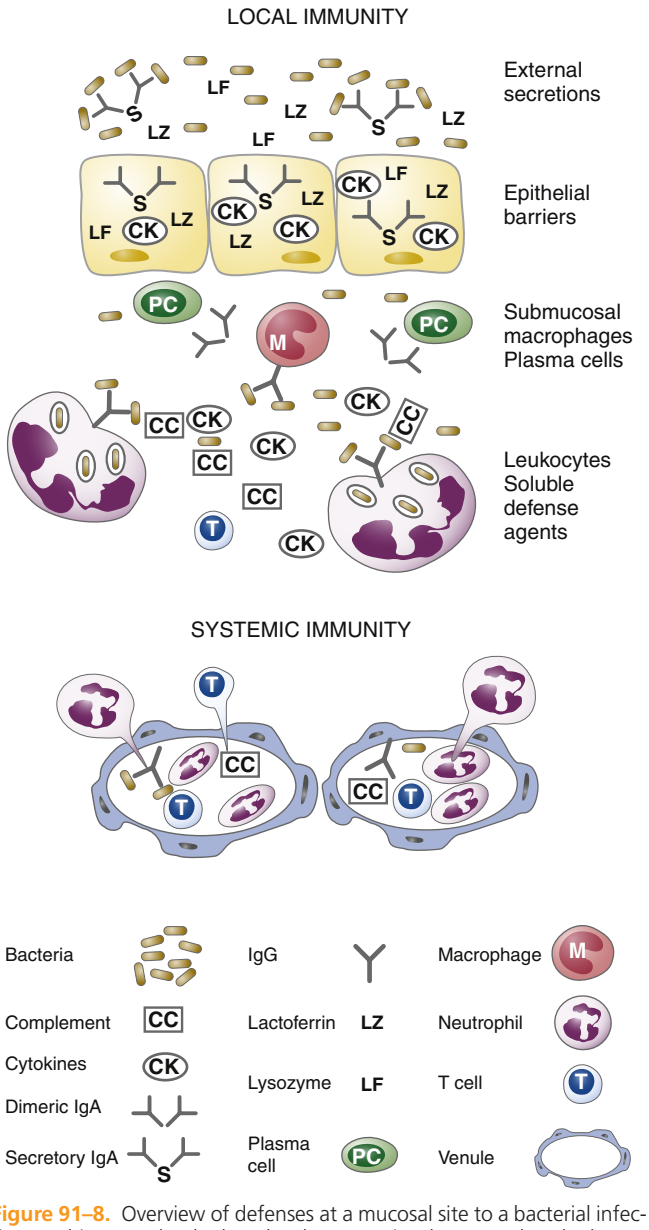

Figure 91–8. Overview of defenses at a mucosal site to a bacterial infection. In this example, the host has been previously exposed to the bacterial pathogen. Thus there is a rapid innate immune response, specific antibody, and T-cell response. The number of bacteria decreases as each level of defense is encountered. *(Modified from Goldman AS: Back to basics: host responses to infection,* Pediatr Rev *21:342, 2000.)*

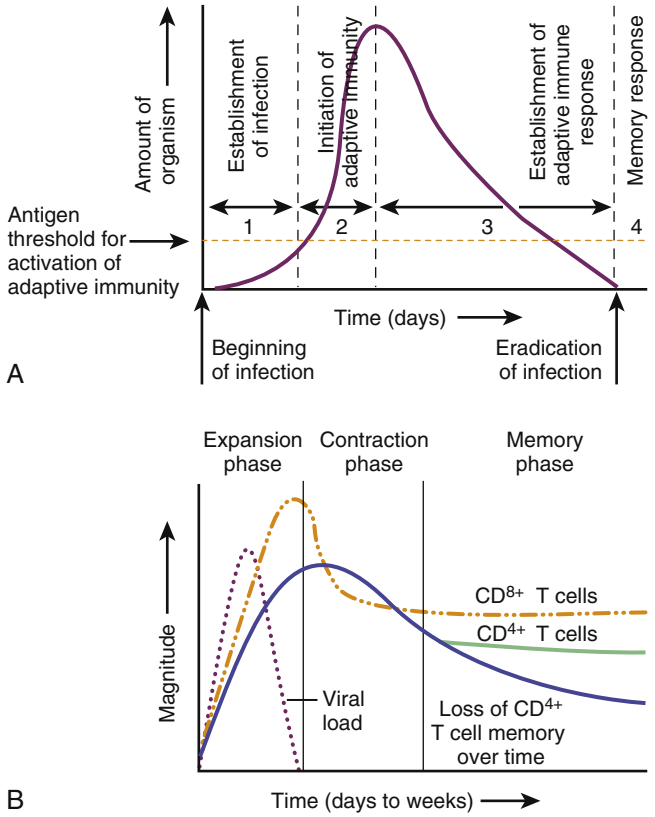

Figure 91–9. Time course of a typical acute infection. **A,** During period 1, the infectious agent (bacterial or viral) replicates. In period 2, an immune response is initiated when the numbers of pathogen exceed the threshold dose of antigen required for an adaptive immune response. Simultaneously, the pathogen continues to replicate, retarded only by the innate and nonadaptive responses. Immunologic memory is believed to be initiated during this stage. During period 3, after 4 to 5 days, effector arms of the immune response begin to clear the infection. In period 4, the clearance of the infectious agent and the decrease in the antigen dose below the response threshold results in the cessation of the response. The presence of antibody, residual effector cells, and immunologic memory provide lasting protection against reinfection. **B,** During a viral infection, antigen-specific T cells clonally expand during the first phase in the presence of antigen. Soon after the virus is cleared, the contraction phase follows and the number of antigen-specific T cells decreases due to apoptosis. After the contraction phase, the number of virus-specific T cells stabilizes and can be maintained for great lengths of time (memory phase). Magnitude of the CD4+ T-cell response is less than that of the CD8+ cells, and the contraction phase can be less pronounced. The number of memory CD4+ T cells may decline slowly over time. *(Modified from Huang AYC, Rigby MR: The immune response: generation, regulation and maintenance. Stiehm ER, Ochs HD, Winkelstein JA, editors:* Immunologic disorders of infants and children, *Philadelphia, 2004, Saunders Elsevier.)*

clonal expansion of $CD8^+$ and $CD4^+$ effector cells, and eradication of the infection occurs. After eradication of the infection there is contraction of the clonal response, but the continued presence of antibody, residual effector cells, and immunologic memory provide lasting protection against reinfection.

Apoptosis is the process of programmed cell death necessary for the resolution of the inflammatory response (see Chapter 100). As cells begin to die, they express ligands on their surfaces that signal resident tissue macrophages for removal via phagocytosis. During apoptosis the cell's nucleus and cytoplasm condense, nuclear DNA is degraded into small dense pieces, and marked cytoplasmic vesiculation and blebbing of the plasma membrane occur. In the final stages the cell collapses into multiple fragments (apoptotic bodies). Apoptosis can be triggered by external forces such as interaction of CD95 ligand (Fas ligand) on cytotoxic T lymphocytes or NK cells with CFD95 on a target cell such as a virally infected cell (see Figure 91-6). Apoptosis can also be initiated by signals arising from DNA or mitochondrial damage.[80,81] The signals converge on activation of a family of proteases called *caspases* that cleave multiple substrates to induce destruction of the cell from within. This process is central to peripheral deletion of excess T and B lymphocytes as the immune response wanes, to clearances of infected cells, and to resolution of inflammation with the removal of emigrated leukocytes.[82] The final step of apoptosis is the removal via the tissue macrophage.[83] In the process of eliminating apoptotic cells, the macrophage produces "immunosuppressive" cytokines such as TGF-β and other cytokines that downregulate the inflammatory response (e.g., IL-10).

It is clear that phagocytic members of the reticuloendothelium system, in particular the Kupffer cells and the NKT cells of the liver, work to trap and kill bacteria in the bloodstream. However, it is also clear that neutrophils are also critical to this process; patients with neutropenia have bacteremia despite having adequate macrophage function. Only recently has there been some understanding as to the mechanism. Neutrophils under select conditions can be activated to cause the release of "neutrophil extracellular traps" (NETS), which are weblike structures of DNA. These NETS contain proteolytic activity that can trap and kill bacteria.[70] Using intravital microscopy, Clark et al.[84] demonstrated that platelet TLR4 detects TLR4 ligands in the blood and induces platelet binding to adherent neutrophils. The NETS were present and functional under flow conditions and ensnared bacteria within the vasculature. The formation of the NETS occurred primarily in the liver sinusoids and pulmonary capillaries.[84]

Chapter 92

Congenital Immunodeficiencies

M. Teresa de la Morena

PEARLS

- A congenital immunodeficiency should be considered in patients with a family history of immunodeficiency, recurrent or persistent infections, infections with unusual organisms, or severe infections with pathogens of low virulence.
- The absolute lymphocyte count is highest during the first year of life. Persistent lymphopenia (<2000 cells/μL) in a child younger than1 year warrants evaluation for combined immunodeficiency.
- Immunoglobulin (Ig) levels of IgG, IgA, and IgM in peripheral blood are influenced by age. Transplacentally acquired IgG antibodies reach a nadir at approximately 3 to 4 months of age.
- Collection and banking of 1 to 3 mL of serum prior to any gamma-globulin delivery is a useful and practical recommendation; subsequent serology studies will be influenced by the IgG content in any gamma-globulin preparation given to the patient and not a reflection of the patient's own gamma-globulin G.
- IgG serology testing for infectious diseases in the presence of agammaglobulinemia is not helpful and gives a false sense of security.

The discovery of antimicrobials in the middle of the last century allowed for the description of patients with defects of immune function. These classic descriptions recognized the primary immunodeficiency diseases (PIDs) in association with recurrent or persistent infection, infections with unusual organisms (opportunistic pathogens), or unusually severe presentations of infectious diseases with pathogens of low virulence. These patients became the experiments of nature that established the immune system as essential for host defense.[1] The subsequent observation that many of these patients succumb to malignancy or autoimmune diseases further underscores the role that the immune system plays in the pathogenesis of these disease states.

Taken together, PIDs are a group of more than 150 different heterogeneous disorders of immune function in which more than 100 different defective genes have been recognized (Figure 92-1).[2] The estimated overall prevalence varies, but is generally accepted to be close to 1:10,000. This suggests that there may be approximately 400 new cases of primary immunodeficiency in infants born in the United States each year (4.0 million live births).[3] Early and prompt diagnosis is essential because curable and life-saving therapies are available. If a molecular diagnosis is established, prenatal diagnosis can be offered to parents and family members.

Classically, PIDs are congenital and hereditary; most newly diagnosed patients are infants and children, and a family history is occasionally recognized. However, because we live in an antibiotic era, some of these children may survive into young adolescence and adulthood before a diagnosis is made. The specialist in critical care may be the first physician to think about the diagnosis in a child who presents with a life-threatening infection to the intensive care unit (ICU).

Although there may not be a particular physical phenotype to encompass all these disorders because most children with PID appear normal, some physical findings that should make the clinician think about a congenital immunodeficiency include failure to gain weight, absent tonsils, persistent thrush, difficulties with healing, rashes and eczema that do not resolve with conventional therapies, severe warts, gum disease, cutaneous granulomas, unexplained hepatosplenomegaly, telangiectasias in eyes and ears, ataxia, dwarfism, cartilage abnormalities, and oculocutaneous albinism (Box 92-1).

There are particular syndromes associated with defects in immune function. These include, among others, DiGeorge syndrome, defects of DNA repair (ataxia/telangiectasia, Nijmegen breakage syndrome, Bloom syndrome), immuno-osseous dysplasias (cartilage/hair hypoplasia and Schimke syndrome), Hoyeraal-Hreidarsson syndrome, immunodeficiencies with associated defects in pigmentation (Chediak-Higashi syndrome, Griscelli syndrome, Hermansky-Pudlak syndrome), and those with associated phagocytic defects (Kostmann syndrome, Papillon-Lefevre syndrome, and Shwachman-Diamond syndrome).[3]

Despite 6 decades of advances in the field of immunology, the clinical and immunologic phenotypes that define patients with classic PIDs remain the same. This chapter provides a practical, general overview of those PIDs that may be encountered by the critical care specialist, discusses recommendations for laboratory evaluations and the value of screening tests, and provides recommendations for consultation with immunology specialists and initial therapies.

The Immune System and the Classification of the Primary Immunodeficiency Diseases

The human immune system has evolved to protect the individual from infectious microbes. It does this by using a complex interactive network of cells, proteins, and organs. This response is both innate and adaptive based on unique characteristics.

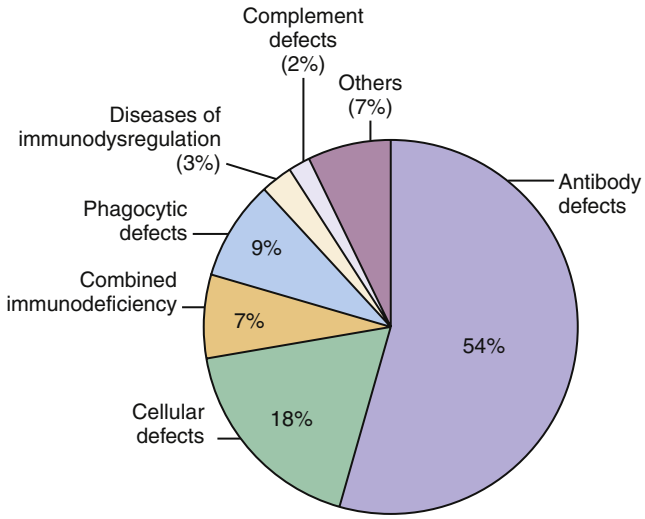

Figure 92–1. Distribution of the major primary immunodeficiency disorders. *(Data from The Jeffrey Modell Foundation Survey, 2009.)*

Box 92–1 Physical Exam Findings that may Suggest a PID

- Dysmorphic facial features
- Heart murmur
- Persistent oral thrush
- Failure to thrive and gain weight
- Atypical dermatitis and erythroderma that does not resolve with standard therapies
- Absent or small tonsils for age
- Gingival disease
- Persistent lymphadenopathy and/or hepatosplenomegaly
- Telangiectasias

The innate response to a pathogen occurs immediately (within hours), lacks clonal specificity for a particular pathogen, and does not confer long-lasting protection—that is, immunologic memory. Both cellular and humoral factors constitute its major components. These include (1) antimicrobial products and physical barriers such as the skin and mucosal surfaces; (2) receptors for pathogen molecules, including the family of Toll-like receptors (TLRs); (3) the phagocytic cells (neutrophils and macrophages); (4) dendritic cells; (5) the complement system; and (6) natural killer (NK) cells.[4]

The adaptive immune response, while triggered by components of innate immunity, takes days to evolve, requires processing and presentation of antigens derived from the pathogen, is specific to the particular pathogen and, more importantly, confers immunologic memory; that is, the individual "remembers" the signature of a pathogen on subsequent encounters. Specificity is determined by the vast range of molecular diversity of the antigen receptor (the T-cell receptor [TCR] complex and the immunoglobulin molecule). Immunologic memory is the ability to respond rapidly and effectively to pathogens previously encountered. This mechanism implies the preexistence of antigen-specific lymphocytes.

The effector cells of the adaptive immune response are T and B lymphocytes. These cells derive from a hematopoietic stem cell (HSC) precursor. It is generally accepted that HSCs differentiate into a common lymphoid progenitor (CLP) that gives rise to T, B, and NK cells. Lymphopoiesis is tightly regulated and leads to the expression of a functional antigen receptor on the surface of the lymphocyte. For the B cell, it is the immunoglobulin molecule; for the T cell, it is the TCR complex. Cellular microenvironment, growth factors, cytokines, and chemokines, along with silencing or activating certain genes at different stages of lineage commitment, are some of the multiple factors contributing to a successful and mature lymphocyte. Although mouse lymphoid development has been well elucidated, human lymphoid development has been fragmented; our knowledge is patched together from in vitro analysis of bone marrow–derived cells, patients, and comparisons to the mouse models.[4]

Patients with PID have taught us that despite the apparent redundancy of the system, quantitative and qualitative defects in individual components and/or pathways result in abnormal function and susceptibility to particular infections.[1]

Historically, defects of cellular, humoral, phagocytic function, and complement defects constituted the classic classification of PID (see Figure 92-1). As understanding of the immune system has evolved, PIDs can also be considered as defects that involve either innate or adaptive immune responses. In the 1970s, the World Health Organization sponsored a committee of experts in the field of PID to classify and define these disorders. Since then, the International Union of Immunological Societies Expert Committee on Primary Immunodeficiencies has met regularly to update the classification of PID. The most recent publication was published in the *Journal of Allergy and Clinical Immunology* in December 2009.[2] In this review, PIDs are classified as being (1) combined T- and B-cell immunodeficiency, (2) predominately antibody deficiencies, (3) well-defined immunodeficiency syndromes, (4) diseases of immune dysregulation, (5) predominately phagocytic defects, (6) defects of innate immunity, (7) autoinflammatory disorders, and (8) complement deficiencies. As new clinical phenotypes are identified and the genetics of these disorders are unraveled, future classifications will reflect advances in the understanding of disease pathogenesis.[5]

Laboratory Diagnosis of Congenital Immunodeficiencies

Most patients admitted to the ICU have many laboratory tests performed. It is important to recognize laboratory results that should not be arbitrarily dismissed as attributable to the severity of the patient's illness. Initial tests and radiologic studies performed on presentation can provide clues that, together with the clinical course and identification of pathogens (Table 92-1), suggest further evaluation or consultation with an immunologist.

The most common of the complement defects are defects of the classic complement cascade. The standard approach that screens for the integrity of this pathway measures the hemolytic capacity of a patient's serum to lyse 50% of antibody-coated sheep erythrocytes. This test is called the total hemolytic complement 50 (TCH50).

Initial screening laboratory studies for PIDs are outlined in Table 92-2. These include (1) complete blood cell count (CBC), (2) quantitative immunoglobulins, (3) specific responses to vaccinations in immunized individuals, (4) lymphocyte subpopulations, and (5) total hemolytic complement.

CBCs can be very informative. Presence or absence of leukocytosis may suggest a normal or abnormal response of the

marrow to infection. Cytopenia such as neutropenia (as indicated by the absolute neutrophil count) is a common feature of a series of PIDs and may allow their recognition in context of other findings.[6] Total lymphocyte count should be calculated and matched to appropriate aged-matched controls.[3] It is important to recognize that the absolute lymphocyte count (ALC) is highest during the first year of life.[7] An ALC of less than 2000 cells/μL is not a common consistent finding in consecutive CBCs in infants younger than 1 year. This finding warrants further investigation because it may be the first objective data to suggest a diagnosis of combined immunodeficiency.[8] Anemia may indicate autoimmunity and in this context is characteristic of several defects of immune function.[2] Thrombocytopenia in a child with severe eczema should prompt the clinician to review the peripheral smear carefully with a pathologist to determine the platelet size; this would allow the diagnosis of Wiskott-Aldrich syndrome. The careful examination of the peripheral smear can identify presence of Howell-Jolly bodies, which are seen in asplenia. Unique morphologic abnormalities of neutrophils are pathognomonic of diseases such as Chediak-Higashi syndrome (Figure 92-2).

Quantification of immunoglobulin (Ig) G, IgA, IgM, and IgE should be performed. As is the case with ALCs, the levels of immunoglobulins in circulation is influenced by the age of the child.[3] At birth, term infants have serum IgG levels that are equal to the maternal level or exceed it by 5% to 10%.[9] Transplacentally acquired antibodies disappear rapidly after birth, reaching a nadir at 3 months. Average concentrations at this time are 60 mg/dL for infants born at 25 to 28 weeks of gestation, 104 mg/dL for infants born at 29 to 32 weeks, and 430 mg/dL for infants born at term.[3,10,11] However, these low levels of maternal IgG antibody appear to be associated with less risk of infection than might be expected. A longitudinal study of the ability of preterm infants to form specific antibodies provides a partial explanation for this low risk.[12] By about 9 months of age, infants have formed specific IgG antibodies in response to immunization with diphtheria, tetanus toxoids, and pertussis vaccine. Also by about this age, their antibodies have functional opsonic activity against *Escherichia coli* and coagulase-negative staphylococci. The ability of newborn infants to produce an active antibody response to antigenic stimulation develops in an orderly fashion. An adult pattern of antibody responses is not acquired until 4 to 5 years of age. Analysis of the factors responsible for this developmental pattern is complex because production of antibody depends not only on B lymphocyte maturity, but also on interactions with other cells that may mature at different rates.

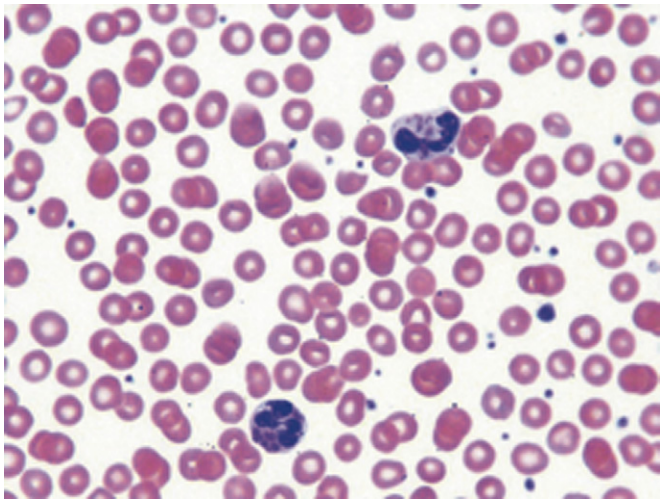

Figure 92–2. Peripheral smear showing mature and band neutrophils (*top*) with basophilic cytoplasmic inclusion consistent with Chediak-Higashi syndrome.

Fetuses can produce serum antibodies and IgM, predominantly in response to intrauterine infection.[13] Preterm infants respond nearly as well as term infants to immunization beginning at 2 months with DTP, poliovirus, and hepatitis B vaccines.[14-16] Term infants immunized or infected during the first few days of life usually produce protective antibody responses, although at somewhat lower levels than do adults.[17-19] The presence of fetal bone marrow B lymphocyte pools similar in size to those of adults and with comparable isotype diversity suggests that their functional deficits may reflect a developing memory repertoire with increased specificity to antigen or the need to generate T lymphocytes capable of producing strong B lymphocyte signals, rather than inherent B lymphocyte immaturity as a sole factor.

Responses to childhood immunizations are very helpful for evaluation of the functional antibody responses. Appropriate responses speak to cognate T- and B-cell interaction necessary for T-dependent antigen responses, and polysaccharide responses speak to antigen responses that do not require T cell help, such as those of the blood group antigens. The collection of 1 to 3 mL of serum that is saved before any gamma-globulin administration is a useful practical recommendation because subsequent serology studies will be

influenced by the specific gamma-globulin content of the unit delivered to the patient.

Analysis of lymphocyte subpopulations by flow cytometry is essential when defects of adaptive immunity are entertained. Circulating lymphocytes are distinguished by unique surface molecules that permit their identification. Cluster of differentiation (CD) is a surface marker that identifies a particular differentiation lineage recognized by a group of monoclonal antibodies. Classification of lymphocytes by CD antigen expression is widely used in clinical medicine. Thus T cells are identified as carrying CD3 helper T cells; CD3 and CD4 cytotoxic T cells; CD3 and CD8 NK cells by CD16/56. CD19 identifies circulating B cells. As with ALC, the percent and absolute numbers of different circulating lymphocytes is age dependent.[7] In general terms, two thirds of circulating lymphocytes are T cells and one third are B cells; two thirds of T cells are $CD4^+$ and one third are $CD8^+$.

These initial screening laboratory tests will rule out the following PIDs (see Table 92-2): (1) antibody defects such as X-linked agammaglobulinemia (XLA), IgA deficiency, common variable immunodeficiency (CVID), or transient hypogammaglobulinemia of infancy (THI); (2) cellular defects such as severe combined immunodeficiency (SCID), DiGeorge syndrome, and Wiskott-Aldrich syndrome; (3) phagocytic defects defined by neutropenia; and (4) defects in the classic complement pathway.

The screening tests of immune function described are not be able to identify other immunodeficiencies that require more advance testing and consultation with an immunologist. Examples include chronic granulomatous disease, defects of Toll signaling, diseases of immune dysregulation, and defects of the alternative complement pathway.

1. Defects of innate immunity:
   - Phagocyte defects: chronic granulomatous disease, leukocyte adhesions defects, and defects in the interferon (IFN)-γ and interleukin (IL)-12 axes
   - Defects of Toll signaling pathways: IL-1-associated kinase-4 (IRAK-4), the adaptor protein myeloid differentiation primary response gene (MyD88), and defects in NEMO
2. Unique syndromes associated with immunodeficiency: hyper IgE syndrome
3. Diseases of immune dysregulation:
   - Familial hemophagocytic lymphohistiocytosis (HLH)
   - Autoimmune and nonautoimmune lymphoproliferative syndromes
   - Autoinflammatory disorders associated with periodic fevers
4. Complement deficiencies: alterations of the lectin or the alternative complement pathways

Advanced testing generally require functional assays that are not commonly accessible to small laboratories and many times require referral to outside centers with unique expertise. Included among these studies are proliferative assays to mitogens and antigens, enzyme analysis, assays that result in expression of molecules of cellular activation (e.g., CD40 ligand on activated T cells for the diagnosis of hyper IgM), neutrophil oxidative activity (dihydrorhodamine analysis by flow cytometry or nitroblue tetrazolium testing), or analysis of the alternative complement pathway, among others. In general, these studies would require the discussion with a specialist in clinical immunology to guide the evaluation and help with the interpretation of the results.

Clinical Presentations of Congenital Immunodeficiency Syndromes

This review is not intended to discuss all known immunodeficiency syndromes characterized thus far. Instead, it focuses on those PIDs that can be encountered by the intensive care specialists and, if left unrecognized, contribute to delayed diagnosis and are life threatening.

Combined T- and B-Lymphocyte Defects

Severe Combined Immunodeficiency

Severe combined immunodeficiency (SCID) was first recognized in the late 1950s and was subsequently divided into Swiss-type agammaglobulinemia (i.e., autosomal recessive) and sex-linked lymphopenic immunologic deficiency.[20] X-linked SCID (XLSCID), today known as *common gamma-chain deficient SCID* or *γc-SCID,* is the most common of all forms of SCID. This combined immunodeficiency is due to mutations in the common γ-chain, an essential signaling molecule. XLSCID comprises 40% to 50% of all SCID phenotypes. Five different cytokine receptors (for IL-2, -7, -9, -15, and -21) require signaling through this molecule. Fourteen different autosomal recessive forms of SCID have been identified.[2] The common characteristic of all forms of SCID is the occurrence of a block in the differentiation of T cells, whereas B cells may or may not be present, but are unable to function, and normal or abnormal development of NK cells occurs. Cytokine-dependent signaling, premature lymphocyte cell death, defective recombination or assembly of the antigen receptor, and inability of the T cells to egress effectively from the thymus explain some of the molecular mechanisms that result in the different SCID phenotypes (Table 92-3).[2] The incidence ranges from 0.89 to 1.40 per 100,000 live births/year[21-23]; these disorders are fatal if not promptly recognized and treated.

Clinical Presentations and Laboratory Findings in SCID. Common clinical presentations among most forms of SCID that should alert the clinician to consider this condition in the differential diagnosis[8,24] include (1) normal birth and delivery; (2) age of presentation to medical attention and/or admission to an ICU usually before 1 year of life (frequently after 3 months of life because of the protection

Table 92–3 Lymphocyte Phenotype Pattern and Genotype in SCID

Lymphocyte Phenotype	*Main Mechanism*	Molecular Defect
$T^-B^+NK^-$	Signaling pathway	γC, JAK3
$T^-B^-NK^-$	Cell death	ADA, PNP
$T^-B^-NK^+$	Ag receptor assembly	RAG1/2, artemis, DNA ligase IV, DNAPKcs, cernunos
$T^-B^+NK^+$	Other signaling molecules	CD45,IL7R, CD3ζ,ε,δ, coronin-1 A

γC, Common gamma chain; *JAK3,* Jannus-associated kinase 3; *ADA,* adenosine deaminase; *PNP,* purine nucleoside phosphorylase; *RAG,* recombinase activating gene; *DNAPKcs,* DNA-activated protein kinase catalytic subunit; *IL,* interleukin.

provided by transplacental transfer of maternal IgG antibodies); (3) overwhelming infections with common pathogens such as rotavirus, respiratory syncytial virus (RSV), cytomegalovirus (CMV), parainfluenza virus and adenovirus; (4) opportunistic infections such as *Pneumocystis jiroveci;* (5) persistent oral candidiasis and failure to thrive; (6) chronic hepatitis or sclerosing cholangitis; (7) persistent diarrhea; (8) skin rash that does not resolve with standard therapies; (9) enteroviral encephalitis; and (10) disseminated varicella zoster postvaccination. It is important to recognize that children with SCID, if transfused with nonirradiated packed red blood cells, may develop overwhelming and life-threatening graft-versus-host disease within 1 to 2 weeks because of clonal expansion of donor-derived leukocytes present in the blood product.

Absent thymic shadow on the initial admission chest radiograph and persistent lymphopenia (<2000 cells/μL^3) since admission can be easily overlooked. Many cases of SCID could be predicted by reviewing the absolute lymphocyte count at birth.[25]

When SCID is suspected, urgency in the confirmation of the diagnosis is necessary because these children can survive if prompt therapies are instituted. Rapid laboratory evaluation and consultation with an immunologist are recommended. HIV must be quickly ruled out and the following studies performed:

1. Lymphocyte subpopulations by flow analysis to identify both the percentage and absolute numbers of circulating T cells (CD3, CD4, CD8), B cells (CD19), and NK cells (CD16/56); this allows for the phenotypic characterization of the type of SCID.
2. Quantitative immunoglobulins (IgG, IgA, and IgM). It is important to recognize that if the child is younger than 3 months, maternal IgG antibodies may still be present. In young infants with hyper IgM, the level of IgM may not be elevated.
3. Lymphocyte proliferative responses to mitogens (phytohemagglutinin A, concanavalin-A, pokeweed mitogen) and antigens (*Candida* and tetanus toxoid, if the child has been previously immunized). These latter tests evaluate the integrity of signal transduction essential for cell proliferation when encountering an antigen.

Therapy for Patients with Clinical Suspicion or Diagnosis of SCID. While managing a child with suspected SCID, medical therapies should be targeted at both identifying pathogens (often more than one pathogen may be identified in the same individual) and instituting both targeted and prophylactic antimicrobials. Fungal and prophylaxis against *Pneumocystis jiroveci* should be started. Trimethoprim-sulfamethoxazole (TMP/SMX) may be initiated as early as 1 to 4 weeks of age with close monitoring of liver function and transaminases.[26] Storage of 1 to 3 mL of serum before gamma-globulin infusions is helpful, as previously mentioned. Gamma-globulin should be give at doses of 400 to 500 mg/kg every 3 to 4 weeks intravenously (IV). If IV access is difficult, subcutaneous administration of IgG is possible. Blood products should be irradiated and CMV negative. No live vaccines such as rotavirus or varicella should be given to the patient or family members in contact with the child. Rotavirus vaccine strains have been reported as causing diarrhea and being the first manifestation in several children with SCID.[27]

After the diagnosis is made, the patient should be transferred to a center with experience in the management and treatment of these disorders. Human leukocyte antigen (HLA) typing of patient and family and consultation with the stem cell transplant team should be pursued. Without a hematopoietic stem cell transplantation (HSCT), children with SCID die.[24] Now considered standard of care, this procedure has achieved the most successful survival record, ranging from 63% to 100% when an HLA-matched sibling donor has been available and 50% to 77% when haploidentical or HLA-mismatched donor is used.[28-35] The lack of donor availability, variable evidence of long-term immunologic reconstitution, and other limitations have led to the extensive use of unrelated but matched donors as a source of stem cells for SCID. The outcomes have improved over the recent years, with survivals ranging from 63% to 80%.[31-33,36]

Other Combined Immunodeficiency Disorders

Many other forms of combined immunodeficiency have been described. In general, these are rare conditions, and similar general concepts of diagnosis and management strategies as for SCID should apply. Family histories are helpful because consanguinity is not uncommon. Microcephaly, deafness, ectodermal dysplasia features, cartilage abnormalities, and hematologic abnormalities such as eosinophilia and cytopenia may be clues that can further guide the molecular analysis.[2]

Hyper Immunoglobulin M Syndrome

Hyper IgM comprises a group of disorders of Ig isotype class switch recombination.[37] First described by Rosen et al.,[38] it was initially classified as a defect in antibody production. Patients had very low levels of circulating IgG and IgA antibodies and elevated levels of IgM. By 1985, Mayer,[39] in critical co-culture experiments, demonstrated that B cells, isolated from hyper IgM patients, could produce IgG and IgA in vitro when incubated with T cells derived from a Sezary T-cell lymphoma and suggested a role for T lymphocytes in Ig isotype switching.[39] It was not until 1993 that three independent groups identified CD40 ligand (also known as CD154) as the molecule responsible for the X-linked, and most common form, of hyper IgM (XHIGM).[40-42] As molecular mechanisms of class switch recombination have been elucidated, so have the identification of autosomal recessive forms of hyper IgM.[43]

IgM molecules are not opsonins because there are no receptors on phagocytes for the Fc portion of this immunoglobulin molecule. Phagocytosis is promoted by complement activation, C3 deposition on the bacterial surface, and subsequent phagocytosis. XLHM patients are deficient in antibody responses that require T-cell help. Examples include protein antigens such as bacterial toxins or bacterial capsules wall proteins as seen in *Staphylococcus pyogenes*. The "combined" nature of this immunodeficiency is due to the role that CD40 ligand plays in the effector function of both macrophages and T cells. For example, activation of macrophages against opportunistic infections such as *Pneumocystis jiroveci* requires binding of CD40 found on the macrophage surface to its ligand, which is expressed on an activated T cell. This T cell/macrophage interaction allows for activation of the macrophage and subsequent microbial killing by intracellular production of oxygen radicals, nitric

oxide, and lysosomal enzymes. Therefore these patients are susceptible to infections similar to those seen in other hypogammaglobulinemic states and pathogens that require intact T-cell function such as viruses, fungi, and parasites.[44-46]

Clinical and Laboratory Presentation of X-Linked Hyper Immunoglobulin M. This is a rare immunodeficiency that becomes manifest in most cases before the age of 4 years. In a cohort of 79 patients studied, *Pneumocystis pneumonia* was the initial presentation in more than 50% of patients.[46] Neutropenias (seen in >50% of cases), other cytopenias, sclerosing cholangitis–associated cryptosporidium infection, hepatitis, progressive neurodegeneration,[47] and gastrointestinal malignancies[48] contribute to morbidity and mortality.[45,46] When a patient presents to the ICU in respiratory failure and *P. jiroveci* is isolated from bronchoalveolar lavage, after HIV is ruled out three PIDs should come to mind: SCID, hyper IgM, and X-linked agammaglobulinemia (XLA).

Laboratory studies in patients with XHIGM demonstrate an inability to muster a leukocytosis in the face of severe infections. This is due to a lack of GM-CSF production by macrophages. Circulating numbers of T and B cells are normal with the exception of decreased memory T cells (CD45RO). Poor antibody responses to protein antigens and lack of CD154 (CD40 ligand) expression on the T cells when these are stimulated in vitro are features of hyper IgM. Similar to XLA patients, germinal centers within the lymph nodes are not developed in XHIGM.

In contrast, patients with a rare autosomal recessive form of hyper IgM due to mutations in activation-induced cytidine deaminase (AID), an enzyme involved in isotype switching, come to medical attention in early childhood with recurrent bacterial sinopulmonary and gastrointestinal infections. Opportunistic infections and neutropenia are uncommon. Cellular immunity is normal, and yet massive lymphadenopathy and lymphoid hyperplasia are characteristic.[49]

Treatment of hyper IgM is directed at replacing antibodies and preventing opportunistic infection. Gamma-globulin infusions at dose of 400 to 500 mg/kg every 3 to 4 weeks, TMP/SMX prophylaxis, and G-CSF as needed for neutropenias are standard therapies. HSCT has also been successfully performed in XHIGM.[50]

Antibody Deficiency Syndromes

Antibody deficiency syndromes represent the most common type of PID (see Figure 92-1). Colonel Ogden Bruton was first to publish and describe a patient with absent gamma-globulins who had been admitted multiple times (19 admissions) for infections with *Streptococcus pneumoniae*.[51] The understanding of the function of gamma-globulins at that time provided the human experiment that linked infections with encapsulated organisms and the absence of gamma-globulin proteins. As happens many times in science, luck participated in this discovery; a novel Tiselius electrophoresis apparatus had recently been incorporated for clinical use at the Walter Reed Hospital, and this child's serum happened to find its way into the machine.[52] Years later, interestingly, the first child described appeared to best resemble a patient with common variable immunodeficiency (CVID) rather than XLA or Bruton agammaglobulinemia. The description of this patient, coupled with the successful isolation of gamma-globulin from human sera, allowed or life-saving therapy with gamma-globulin infusions. Today, gamma-globulin use is not limited to patients with XLA.[53] This initial case report along with others at the time provided the stage for successful decades of discoveries of PID and their therapies. The careful analysis of children with PID by pioneers such as Robert Good, Fred Rosen, Charlie Janeway, and Jerry Winkelstein initiated the field of clinical immunology as it is understood today.

It took almost 4 decades for the discovery of the molecular defect responsible for XLA.[54,55] Called *Bruton's tyrosine kinase* (BTK), this molecule is essential for B-cell development. Children with XLA have absent or extremely low circulating B cells and therefore absent circulating antibody levels. Autosomal recessive agammaglobulinemia from other defects of B-cell development has similar clinical and laboratory findings as XLA. Mutations in the μ heavy chain locus, surrogate light chain (λ5), signaling, and adaptor components of the B-cell receptor (Igα, Igβ, and *BLNK* gene) are among more than 15 intrinsic B-cell immunodeficiencies.[56-58]

Other clinical defects of antibody production include (1) CVID, (2) IgA deficiency, (3) transient hypogammaglobulinemia of infancy, (4) specific antibody deficiency with normal Ig concentrations, and (5) isotype or light chain deficiencies with normal numbers of B cells.[2] The pattern of circulating immunoglobulins, presence or absence of B cells, response to childhood vaccination, and need for lifelong IgG replacement are key laboratory and therapeutic characteristics that help the clinician distinguish the clinical phenotypes of antibody deficiency production. Good syndrome, thymoma associated with agammaglobinemia or hypogammaglobinemia, is a rare entity of unknown etiology that usually presents in adults.[59]

Clinical Presentations and Laboratory Findings in Antibody Defects. Antibodies are essential for host defense. These molecules participate in neutralization of bacterial toxins and viruses, opsonization of bacteria for successful phagocytosis, and complement activation of encapsulated bacteria. Recurrent and persistent otitis media, sinusitis, pneumonias, and gastrointestinal infections are the classic manifestations of antibody deficiency syndromes.[56,60,61] In general, most children with XLA/ARA will present to medical attention within the first 2 years of life[56] as maternal transplacentally acquired antibodies disappear. Yet when treated promptly, antibiotic therapies can be very effective; therefore it is not uncommon for these children to be diagnosed later in life.

By consensus, CVID is defined as occurring in a patient older than than 2 years with (1) low IgG and low IgA and/or IgM below two standard deviations of the mean; (2) B cells present; (3) failure to make specific antibodies in response to infection or routine vaccinations; and (4) variable T-cell abnormalities.[62] Several molecular defects have been described that speak to the heterogenous nature of the condition.[63-66] Bronchiectasis, granulomas, diffuse lymphadenopathy, autoimmunity, and malignancy are common clinical associations.[67] In a recent retrospective analysis of 32 pediatric patients who met the criteria for CVID, meningitis was found in 25% and sepsis in 16% of those older than 4 years.[68]

IgA deficiency, the most common of the antibody deficiency syndromes (1:400 to 1:700 live births), rarely will appear in a patient presenting to the ICU in septic shock, but recurrent sinopulmonary infections and gastrointestinal infections with *Giardia* are not uncommon.

Transient hypogammaglobulinemia of infancy represents a state in which the physiologic nadir of circulating IgG levels is prolonged. Most of these children do well, but case reports of severe overwhelming infections have been described.

Streptococcus pneumoniae and *Haemophilus influenzae* are infectious agents frequently isolated from patients with antibody defects.[64,67,69-71] It is important to recognize that asplenia should also be considered in the differential diagnosis of the immunized patient with overwhelming sepsis due to *S. pneumonia* and *H. influenzae.* Careful review of the peripheral smear will identify the presence of Howell-Jolly bodies.

Staphylococcus aureus and *Pseudomonas aeruginosa* can cause sepsis in XLA or ARA patients.[60,69,71,72] This suggests that antibodies probably play an important role in the clearance of these pathogens. However, the role of neutrophils cannot be underestimated because many patients with XLA/ARA have associated neutropenias at time of presentation. Encephalomyelitis from enteroviruses and hepatitis viruses can cause significant morbidity in children with XLA/ARA and CVID despite receiving IgG replacement.[60,73] Enteroviruses, mycoplasma, and *Ureaplasma urealyticum* have been isolated from joints of patients with XLA.[61,74,75] Although rare, patients with XLA have been described as presenting with *Pneumocystis jirovecii*.[72] *Giardia lamblia* is a common pathogen isolated in patients with both cellular and antibody deficiency.[60,67]

Treatment of antibody deficiency syndromes requires gamma-globulin infusions for life. These are given at doses of 400 to 500 mg/kg every 3 to 4 weeks, and levels are maintained at greater than 600 to 800 mg/dL.

Congenital Defects of Phagocytes

Chronic Granulomatous Disease

Chronic granulomatous disease (CGD) was initially described by two groups. In 1954, Janeway and colleagues[76] reported a group of males with hypergammaglobulinemia and recurrent infections and proposed that the former was the cause for the latter. Five years later, Robert A. Good's group at the University of Minnesota corrected the misinterpretation and demonstrated that the hypergammaglobulinemia was the consequence of infections and that the cause was ineffective microbial killing by neutrophils.[77] Both X-linked and autosomal recessive forms are described. The fundamental defect in CGD is the inability of phagocytes to generate superoxide anion (O^-) caused by the absence or dysfunction of one of the components of the NADPH oxidase system.[78] Many pathogens normally produce hydrogen peroxide (H_2O_2) when ingested by phagocytes. Aerobic pathogens produce catalase, which breaks down the H_2O_2 produced by microbes. CGD neutrophils cannot produce their own reactive oxygen species. They are uniquely susceptible to infection with catalase-positive organisms such as *S. aureus, Burkholderia cepacia, Serratia marcenses, Aspergillus,* and *Nocardia* spp. Pulmonary disease, deep-seated abscesses, and suppurative lymphadenitis are common sites of infectious presentations.[79] Interestingly, these patients are rarely bacteremic. Perianal abscesses, colitis, and gastric outlet obstruction may be the initial presenting signs for patients with common gastrointestinal manifestations.[80] Laboratory findings include mild to moderate leukocytosis and hypergammaglobulinemia. Different laboratory methods have been used to assay superoxide production. The nitroblue tetrazolium test, one of the first tests developed, relies on the reduction of nitroblue tetrazolium by reactive oxygen intermediates from a yellow color to an insoluble blue. In CGD phagocytes, dye is not reduced to blue, so no color appears within the neutrophils. This assay is currently rarely used and is mainly of historic value. Currently the most commonly used method of analysis is the dihydrorhodamine test (DHR) by flow cytometry. Nonfluorescent DHR is taken up by normal phagocytes. DHR is then oxidized to rhodamine, which produces a green fluorescence providing quantitative fluorescence that can help differentiate between X-linked forms (*no* increase in fluorescence with stimulation) and the autosomal recessive form (*small* amount of increased fluorescence). Carriers of X-linked mutations will show a *mosaic* pattern of fluorescence (some with normal fluorescence and some without). Therapy for CGD includes antimicrobial prophylaxis (e.g., TMP/SMX and itraconazole)[81] and immunomodulators such as IFN-γ.[82] Aggressive management of infections and need for invasive diagnostic tests to obtain culture-driven targeted therapies are often necessary.

Long-term follow-up data suggest significant morbidity caused by infections and only 50% to 55% survival through the third and forth decades of life.[83,84] Hematopoietic SCT has been a therapeutic option for the past 2 decades.[85,86] In 2002, the European Group for Blood and Marrow Transplantation (EBMT) reported results of 27 transplants from 1985 to 2000. Almost all (22 of 23) patients survived. These patients had received a myeloablative busulfan-containing conditioning regimen from HLA-identical donors, achieving full and stable donor chimerism.[87] More recently, excellent survival (90%) after HSCT has been reported by the Newcastle group, with a median 61 months of follow-up.[88]

Complement Deficiencies

Recognized as "complementing" the antimicrobial activity of antibodies, the complement system encompasses a series of serum proteins that bind the surface of pathogens or circulating complexes of antibody bound to antigen. On activation, a cascade of sequential biochemical events results in opsonization and killing of bacteria, recruitment of inflammatory cells, clearance of immune complexes, and disposal of apoptotic cells. The first report of absence of a complement protein was identified by chance.[89] Since then, defects in individual complement proteins or those regulatory proteins that prevent the progressive activation of the inflammatory cascade have been described.[90] Most defects in complement proteins are autosomal recessive. However, deficiency of the inhibitor of C1 (C1INH) is autosomal dominant, whereas the deficiency of properdin is X-linked recessive.

The clinical presentation of patients with complement deficiencies can be varied. Blood-borne or systemic pyogenic infections with encapsulated organisms, especially *Neisseria meningitidis* but also *Streptococcus pneumoniae* and *H. influenzae,* are common. Bacteremia, sepsis, and meningitis represent frequent initial clinical presentations that often require ICU admission.[91] The association of complement defects and rheumatologic disorders is well established. In general, defects in early complement components such as C2 or C4 are frequently linked with systemic lupus erythematosus, discoid lupus, dermatomyositis, and scleroderma. Hemolytic uremic syndrome and glomerulonephritis are common manifestations of factor H deficiency.[92]

Hereditary angioedema (HAE) is caused by deficiency in the inhibitor of C1 (C1INH). As a consequence of this lack of inhibition, factor XII becomes activated and leads to the activation of kallikrein and plasmin; kallikrein then catalyzes the formation of bradykinin and plasmin activates C1, which cleaves C2 and generates C2a, which is further cleaved by plasmin to generate C2 kinin. Both bradykinin and C2 increase vascular permeability leading to the edema. Clinical manifestations include localized swelling of the skin, respiratory tract, and gastrointestinal tract. The ICU specialist may be the first to recognize this disorder because attacks involving the upper airway may be life threatening. Epinephrine, corticosteroids, and antihistamines are not effective, and fresh frozen plasma in an acute attack may contribute to worsening edema due to availability of substrate. In 1972, two reports demonstrated the benefit of antifibrinolytic therapy for patients with HAE.[93,94] Four years later, androgens were demonstrated to be effective in preventing HAE.[95] Unfortunately, androgens do not have effect until 24 to 48 hours, so careful monitoring is necessary to ensure that the edema does not progress. By 1980, C1INH concentrate had been isolated and demonstrated as an effective therapy in randomized controlled trials.[96,96a] Attacks usually begin to subside 30 to 60 minutes after 200 to 500 units of the C1 inhibitor. Recent clinical trials using bradykinin-directed therapies (plasma kallikrein inhibitor or a β_2 bradykinin receptor antagonist) also suggest possible benefit in treating patients with HAE.[97]

Other Well-Defined Immunodeficiency Syndromes

Wiskott-Aldrich Syndrome

Described first by Wiskott[98] and then by Aldrich et al,[99] this X-linked disorder is classically defined by the clinical triad of severe eczema, microthrombocytopenia, and immunodeficiency and affects 1 in 10^5 to 1 in 10^6 live male births/year.[100,101] The gene responsible for Wiskott-Aldrich syndrome (WAS) was identified by positional cloning by Derry et al.[102] in 1994. The gene encodes a protein (WASp) that is constitutively expressed in all hematopoietic stem cell–derived lineages. The structure of WASp is complex, and its role in actin cytoskeletal rearrangements explains many of the clinical consequences of impaired immune function. Lack of inflammatory cell recruitment and defects in signaling pathways, immunologic synapse formation, and phagocytosis are some explanations of how lack of WASp expression affects immune function.[103] Furthermore, failure of adequate immune surveillance can lead to the development of autoimmunity and malignancy seen in these patients.[104,105] Mutations in WASp can also be identified in patients with X-linked thrombocytopenia.[106,107] In contrast to WAS, these patient with X-linked thrombocytopenia do not have associated immunodeficiency or malignancy and overall prognosis is better, although the incidence of infection is increased in splenectomized patients.[108] When WASp mutations result in constitutive activation of WASp, a different clinical phenotype characterized by congenital neutropenia and severe bacterial infections has been described.[109,110] Together, these highlight the important role that WASp has in hematopoietic development and function.

Clinical and Laboratory Presentation of Wiskott-Aldrich Syndrome. Petechiae in the newborn period, bloody diarrhea, and bleeding with circumcision are key historic clues. Eczema is a major clinical feature. Although usual therapies for severe atopic dermatitis are used, many times the disease is difficult to control and bacterial and viral superinfections occur. The most consistent laboratory finding is thrombocytopenia (usually between 3000 and 70,000/μL) with low platelet volume (usually <5 fL).

Immunodeficiency is a consistent feature in WAS. Clinical manifestations commonly take the form of skin abscesses, recurrent sinopulmonary infections, and life-threatening meningitis and sepsis. *Staphylococcus* spp., *S. pneumoniae, Pseudomonas* spp., *Pneumocystis* spp., and systemic fungal infections are common pathogens. Viral infections with CMV, herpes simplex, and disseminated varicella have also been described.[105,111]

Immunologic studies may demonstrate variable function that can change with time and the age of the child. Typical manifestations include generalized progressive lymphopenia; variable immunoglobulins levels, but a general pattern of elevated IgA, low IgM, normal IgG, and elevated IgE[112]; poor specific antibody responses to both protein and more particularly to polysaccharide antigens, including reduced isohemagglutinin levels[113]; and abnormal T-cell proliferation to both mitogens and antigens are commonly seen.

Intensive care specialists must recognize that up to 30% of these patients may present with a life-threatening intracranial, gastrointestinal, or pulmonary bleeding episode.[105] Random donor platelet concentrates are effective for prophylaxis and after hemorrhagic complications. All blood products must be CMV negative and irradiated. It is important to not administer drugs that interfere with platelet function. Treatment with monthly gamma-globulin infusions and prophylactic antibiotics has changed long-term outcomes for these patients.[114] Nonetheless, the only definitive therapy for WAS is HSCT. A collaborative study of the International Bone Marrow Transplant registry analyzed 170 transplantations performed for WAS between 1968 and 1996. The overall 5-year probability of survival was 70% (95% confidence interval [CI], 63% to 77%). Best outcomes were noted for patients receiving donation from an HLA-identical sibling: 87% (74% to 93%) compared with 52% (37% to 65%) for those receiving an other related donor's cells. Matched unrelated donor transplantation demonstrated a 5-year probability of survival of 71% (58% to 80%). Of interest, if children receiving matched unrelated donor cells were transplanted before the age of 5 years, the outcome was similar to HLA-matched sibling transplants.[115]

A more recent long-term outcome analysis for patients transplanted for WAS was performed by the European Society for Immunodeficiencies (ESID) and EBMT.[116] Included in the study were patients who had survived at least 2 years after HSCT. Survival was similar: 7-year event-free survival of 75%. Yet a 20% incidence of autoimmunity was associated with mixed chimerism independent of chronic graft-versus-host disease. Furthermore, infection related to splenectomy was identified as an iatrogenic complication.[116]

DiGeorge Syndrome

The original descriptions of congenital absence of the thymus gland are attributable to Henry Harington in 1928[117] and subsequently by David Lobdell in 1959.[118] In 1965, an abstract was presented by Max Cooper to the Society of Pediatric Research, "A New Concept of the Cellular Basis Of

Immunity."[119] In it, Angelo DiGeorge introduced for the first time autopsy findings of children with congenital hypoparathyroidism who died of overwhelming infections. The finding of thymic aplasia strongly argued for the role of the thymus in the control of infections in humans and supported the theory that Cooper and Good were proposing from experimental studies. A dual immune system was hypothesized: cellular or thymic origin and humoral (i.e., antibody driven). Today DiGeorge syndrome (DGS) is recognized as a heterogenous disorder characterized by a triad of clinical features: congenital heart disease, immunodeficiency, and hypocalcemia. Cytogenetic and molecular studies have demonstrated that in greater than 90% of patients with DGS, a deletion of chromosomal region 22q11 occurs. Other genetic disorders such as velocardial facial syndrome and the conotruncal anomaly facial syndrome represent genetic syndromes with overlapping characteristics with DGS. Facial characteristics; midline defects, including palatal abnormalities, cleft lip and palate; swallowing difficulties; umbilical hernia; skeletal, renal, urogenital anomalies; learning disabilities; and neuropsychiatric disorders are common features of children with the 22q11 syndrome.[120,121]

Clinical and Laboratory Presentation of DiGeorge Syndrome. The spectrum of immunodeficiency is broad. Complete and partial DGS defined the clinical spectrum of immunodeficiency, in which those with complete DGS have absent or very low T-cell numbers, have severely impaired immunologic function, and will present within the first year of life with the same types of infections as children with SCID. Viral and opportunistic infections may be life threatening. Complete diGeorge syndrome is fatal within the first 2 years of life. In contrast, children with partial DGS may demonstrate improvement of T-cell defects over time. Autoimmune cytopenias, malignancies (particularly B-cell lymphomas), and juvenile idiopathic arthritis are other clinical features seen in patients with DGS.

Intensivists caring for children with congenital heart disease must have an understanding of the degree of T-cell defects in these patients because it will guide management and institution of prophylactic therapies if indicated. Attention should be directed toward simple studies available before any surgical procedures; chest radiograph looking for the presence of a thymic shadow and a CBC are generally readily available and provide invaluable information. Profound lymphopenia should alert the clinician to the potential diagnosis of complete DGS and therefore SCID phenotype. Lymphocyte subpopulations and consultation with a clinical immunologist are indicated. Irradiated blood products and live vaccines should not be administrated until immunologic function is understood. Depending on the degree of immunologic function, prophylaxis against *Pneumocystis* and/or fungal infections may be indicated.

DNA Repair Defects with Immunodeficiency

DNA repair defects comprise a group of disorders that include ataxia telangiectasia (AT), Nijmegen breakage syndrome, and Bloom syndrome. All are characterized by defects in DNA repair and genome instability. The immunodeficiency is variable but can progress over time. AT is a rare autosomal recessive disorder characterized by cerebellar cortical degeneration, ocular and cutaneous telangiectasias, immunodeficiency, and predisposition for development of malignancies. Sinopulmonary infections can lead to pulmonary fibrosis and death.[122] AT cells are sensitive to ionizing radiation and radiomimetic chemicals because the cells fail to activate cell cycle checkpoints after treatment with these agents. When an infant is diagnosed with lymphoma or leukemia, attention to a potential diagnosis of AT is important because radiation therapy should be avoided or changed from conventional dosing.[123] The AT gene encodes a protein involved in cell cycle control and DNA repair pathways. Progressive decrease in circulating T cells and a decrease in IgA with elevated IgM are common laboratory findings.

Hyper Immunoglobulin E Syndrome

Hyper IgE syndrome, previously called *Job syndrome,* has been recently understood in molecular terms. An autosomal dominant or sporadic form is caused by mutations in signal transducer and activator of the transcription 3 gene (*STAT3*). A rare condition, this form of hyper IgE is characterized by elevated levels of IgE, recurrent skin boils (mainly due to *S. aureus)*, pneumonia with pneumatocele formation, eczema, coarse facial features, delayed shedding of primary teeth, and hyperextensible joints.[124,125] A recent report on the cause of death in patients with hyper IgE underscored the role that *Pseudomonas* and *Aspergillus* species play in these patients and suggested intensified antifungal and gram-negative bacterial prophylaxis as possible strategies to prevent these infectious complications in those patients who have cystic lung disease.[126]

A second form of hyper IgE is due to mutations in tyrosine kinase 2 (TYK2), which is an inherited autosomal recessive disorder. These patients have unique susceptibility to intracellular bacteria (*Mycobacterium* and *Salmonella* species), fungi, and viruses. Skeletal and connective tissue abnormalities are not seen. Central nervous system hemorrhage associated with infections has been described.[2,127]

Diseases of Immune Dysregulation

Diseases of immune dysregulation comprise a group of diseases that include familial hemophagocytic lymphohistiocytosis (FHLH), immunodeficiency with hypopigmentation (Chediak-Higashi and Griscelli syndromes), lymphoproliferative syndromes, and syndromes with associated autoimmunity.[2]

Familial Hemophagocytic Lymphohistiocytosis. Degranulation of cytotoxic T lymphocytes (CD8 cells) and NK cells are an essential component of both viral and intracellular bacterial clearance. Molecular defects that interrupt this granule-dependent cytotoxic activity of lymphocytes are responsible for the familial forms of HLH. Defects in perforin, hMunc 13-4, and syntaxin-11 describe FHLH types 2, 3, and 4.[128] Patients with Chediak-Higashi syndrome (see Figure 92-2), a rare autosomal recessive disorder characterized by partial albinism and giant intracytoplasmic granules within all granulated cells, have mutations in the *CHS/LYST* gene that presumably is responsible for the lack of secretion of lytic granules,[129] thereby impairing NK and cytotoxic T-cell function. In patients with Griscelli syndrome type 2, the immune dysregulation is the result of mutations in RAB27A, a member of the GTPase family of proteins, which also results in NK and cytotoxic T-cell dysfunction due to an inability of these cells to release their

cytolytic granules.[130] Patients with X-linked lymphoproliferative syndrome (XLP) succumb to infections with Epstein-Barr virus (EBV) infections. The defect lies in an SH2-associated protein (SAP) that associates with the SLAM (surface receptors of the signaling lymphocytic activating molecules) family of receptors. In the absence of SAP, NK-mediated cytotoxicity is impaired and is thought to be responsible for compromising the clearance of EBV-infected B cells.[131]

As a consequence of ineffective cytotoxicity, uncontrolled activation and proliferation of T lymphocytes occurs, macrophages are activated, and cytokines are released, resulting in a life-threatening clinical syndrome. The clinical presentation of persistent fevers, hepatosplenomegaly, and cytopenia associated with a systemic uncontrolled inflammatory response should alert the clinician to these disorders.

Classification and terminology of HLH can be confusing, but it is generally accepted that both genetic and acquired forms exist (Box 92-2). The estimated incidence of FHLH is 1 in 50,000 births.[132] Secondary HLH is considered an acquired form and is associated with infection, autoimmunity, and malignancy. It is important to recognize that the identification of a pathogen associated with this clinical syndrome does not distinguish between familial or secondary forms; many times a prodromal infectious process is described in patients in whom a diagnosis of FHLH is made.[133] The histologic findings include the infiltration of lymphocytes and histiocytes with hemophagocytic activity.

Laboratory findings include hypofibrinogenemia, hypertriglyceridemia, liver dysfunction, and progressive pancytopenia. A recent retrospective chart review by Allen et al.[134] suggest that ferritin levels higher than 10,000 μg/L may be specific and sensitive for the diagnosis of HLH.[134]

Because of the mortality associated with HLH, in 1991 the HLH Study Group of the Histiocytic Society published the first diagnostic guidelines for HLH (since revised by Henter et al.[135] in 2007). A diagnosis of HLH can be established by molecular testing or by demonstrating five of the eight following criteria: (1) fever; (2) splenomegaly; (3) cytopenias involving two or more cell lines (hemoglobin <9.0 g/dL or, for children <4 weeks of age, <12.0 g/dL; platelets <100,000/μL; neutrophils <1000/μL); (4) hypertriglyceridemia and/or hypofibrinogenemia (fasting triglycerides ≥3 mmol/L, fibrinogen <1.5 g/L); (5) ferritin greater than 500 μg/L; (6) soluble CD25 (interleukin-2 receptor) 2400 U/mL or higher; (7) decreased or absent NK cell activity; and (8) hemophagocytosis in bone marrow, cerebrospinal fluid, or lymph nodes.[135]

Despite the usefulness of guidelines, these diagnostic criteria lack specificity. Thus a diagnostic clinical algorithm has been proposed based on perforin expression.[136] In 19 patients diagnosed according to the 1991 criteria,[137] mutations in perforin were identified in all subjects who demonstrated absent perforin expression by flow cytometry.[136]

Box 92–2 Classification of Hemophagocytic Lymphohistiocytosis

Primary (Genetic Forms)

Familial forms (usually <1 year of age in 70%–80%)
- FHLH 1: Gene unknown, AR, infancy
- FHLH2: Perforin (20%–40%)
- FHLH 3: hMunc 13-4
- FHLH 4: Syntaxin 11 (STX)

Immunodeficiency syndromes
- Chediak-Higashi syndrome: Lyst
- Griscelli syndrome: RAB27A
- XLP: SAP
- WASp
- SCID: AR and X-linked

Secondary (Acquired)

Infection-associated HLH
Autoimmunity
Malignancy

FHLH, Familial hemophagocytic lymphohistiocytosis; *HLH,* hemophagocytic lymphohistiocytosis.

Effective treatment of HLH consists of combinations of proapoptotic chemotherapy, immunosuppression, and HSCT for patients with FHLH and those with persistent disease despite immunosuppression.[138] Results with HLH-94 treatment protocol showed a 55% disease-free survival at 3 years.[139] However, nearly a quarter of these patients demonstrated persistence or recurrence of disease.

The similarities in the clinical presentations of HLH, systemic inflammatory response syndrome, multiorgan dysfunction, and macrophage activation syndrome warrant further prospective studies that test the specificity and sensitivity of current HLH diagnostic guidelines (see Chapter 98).

Summary

PIDs represent a heterogenous group of disorders, many of which are life threatening. For many PIDs, prompt diagnosis can be easily established with simple laboratory studies available to the practicing clinician. Recognizing clinical phenotypes of antibody, cellular, phagocytic, and complement defects is essential because life-saving therapies are available. With the institution of newborn screening for SCID, the next decades will provide insight into the true incidence of this fatal disease and allow for the healthy survival of many such infants.

VI Chapter 93

Acquired Immune Dysfunction

Gwenn E. McLaughlin and Andrew C. Argent

PEARLS

- Most patients admitted to the pediatric intensive care unit are immunosuppressed to varying degrees.
- Critical illness induces immunoparalysis, a phenomenon marked by downregulation of major histocompatibility complex class II molecule expression on the surface of monocytes, but not B cells. Suppressed monocyte/macrophage function reduces clearance of immune complexes, impairs antigen-presenting capabilities, and decreases natural killer cell function.
- The long-term effects of transfusions on the immune system and subsequent disease susceptibility are unknown, but even 19 years after a blood transfusion, recipients have fewer peripheral T cells, particularly helper T cells, than nonrecipients.
- Pneumocystosis is still the most common AIDS-defining illness in children and can present with variable pulmonary infiltrates; but hypoxemia is often out of proportion to clinical and radiographic examination.
- Malignancies account for 2% of AIDS-defining illnesses in pediatric patients. The increase compared to non-HIV-infected children is attributed to lymphoma. Lymphomas in immunodeficiencies are generally of B-cell type and often arise in the central nervous system.
- Postexposure prophylaxis for occupational HIV exposure should begin as soon as possible and continue for 4 weeks.

Acquired immune dysfunction is by definition a secondary phenomenon following another disease process, such as infection or trauma, or an intended or unintended effect of therapy. Protein calorie malnutrition probably accounts for the greatest number of immunodeficient patients in intensive care units (ICUs) worldwide, whereas human immunodeficiency virus (HIV) infection is the most widely recognized cause of acquired immune deficiency. Impairments in humoral and cellular immunity occur as a consequence of immaturity, malignancy, transfusion, sepsis, shock, viral infections, tuberculosis (TB), and malaria.[1] Iatrogenic immunosuppression occurs most frequently with medications given to either inactivate or kill lymphocyte populations, particularly those used in cancer chemotherapy and autoimmune disease, and to control transplant rejection.[1] When all these precipitants of immunodeficiency are taken into account, it becomes apparent that most patients admitted to the pediatric ICU are immunosuppressed although to varying degrees. Patients with acquired immunodeficiency are at risk for opportunistic infections and unusual presentations of common infections. If immunosuppression is known or suspected, the physical exam should focus on the mucosal surfaces, catheter entry sites, the skin (including wounds), and the central nervous system. Understanding patterns of disease that are specific to each type of immune dysfunction can lead to both earlier appropriate empiric therapy and diagnostic tests (Table 93-1).[1,2] Unlike congenital immunodeficiency, many cases of acquired immunodeficiency are reversible.

Immune Function and Critical Illness

Critical illness often involves the activation of the inflammatory cascade that must be turned off for the patient to survive.[3] In response to stress, proinflammatory cytokines such as tumor necrosis factor-alpha (TNF-α); interferon; and interleukin-1 (IL-1), IL-6, and IL-12 are produced along with antiinflammatory agents such as IL-10 and TNF receptor.[3-6] The production of IL-10 is associated with downregulation of major histocompatibility complex class II (human leukocyte antigen [HLA]-DR) molecule expression on the surface of monocytes, but not B cells. If the resulting downregulation of the immune system is prolonged a condition occurs known as immunoparalysis. Suppressed monocyte/macrophage function reduces clearance of immune complexes, impairs antigen-presenting capabilities, and decreases natural killer cell function. Activated T cells are important sources of interferons, which in turn control infection by stimulating nicotinamide adenine dinucleotide phosphate oxidase (NADPH oxidase) and nitric oxide production and by increasing adhesion molecule expression. Immunoparalysis is confirmed in the laboratory by reduced expression of HLA-DR antigens on peripheral blood monocytes and decreased TNF-α production in response to lipopolysaccharide (LPS) exposure.[5] Immunoparalysis and has been shown in patients after trauma, neurosurgical procedures, and cardiopulmonary bypass operations.[7-11] This phenomenon may in part explain the increased incidence of life-threatening nosocomial infections including those considered opportunistic in these patients.[12, 13]

Absolute lymphocytopenia has often been reported in previously healthy patients in response to critical illness, including burns, neurotrauma, cardiopulmonary bypass, and viral inefections.[14-17] Total lymphocyte counts measured in 22 children fell to a nadir at 6 hours after anesthesia for major surgery with minimal recovery out to 48 hours.[14] Helper

Table 93–1 Infections Seen with Various Types of Immune Deficiency

	Common	Less Common
GRANULOCYTOPENIA		
Bacteria	*Staphylococcus aureus, Staphylococcus pneumonia, Klebsiella, Pseudomonas*	*Enterobacter, Acinetobacter, Stenotrophomonas*
Fungi/molds	*Candida, Aspergillosis, Zygomycosis*	
Parasites		
Viruses		HSV1 or 2, VZV
CELLULAR DEFECTS		
Bacteria	*Legionella, Nocardia*	*Mycobacterium tuberculosis*
Fungi/molds	*Pneumocystis, Cryptococcus, Mucormycosis*	
Parasites	*Toxoplasma*	
Viruses	CMV, EBV, adenovirus, VZV	
HUMORAL DEFECTS		
Bacteria	*S. pneumonia, Haemophilus influenzae*	
Fungi/molds		Pneumocystis
Parasites		*Giardia lamblia*
Viruses		VZV
COMBINED DEFECTS		
Bacteria	*S. aureus, S. pneumonia, Klebsiella, Pseudomonas*	*M. tuberculosis, Listeria monocytogenes, Legionella*
Fungi/molds	Pneumocystis, aspergillosis, *Cryptococcus*	Zygomycosis, murcomycosis
Parasites	*Toxoplasma*	
Viruses	CMV, VZV, influenza, parainfluenza, RSV, adenovirus	HSV 1 or 2

CMV, Cytomegalovirus, *EBV,* Epstein-Barr virus; *HSV,* herpes simplex virus; *VZV,* varicella-zoster virus.
Modified from Safdar A, Armstrong D: Infectious morbidity in critically ill patients with cancer, *Crit Care Clin* 17:531, 2001.

cells were most affected. Cardiopulmonary bypass further induced lymphocyte apoptosis compared to surgery alone.[15] Exogenous corticosteroids have long been known to induce lymphocute apoptosis. Because critical illness also evokes a hormonal stress response, elevated endogenous corticosteroids are hypothesized to induce lymphopenia; however, there is no direct correlation between cortisol levels and lymphocyte counts.[16,17] In contrast, prolactin levels have been shown to correlate with lymphopenia in several studies and prolonged suppression of prolactin was associated with lymphocyte depletion, nosocomial infection and death.[17,18] Prolactin is required for lymphocyte proliferation and protects lymphocytes from steroid induced apoptosis. Other drugs used in critically ill patients may contribute to lymphopenia. Dopamine inhibits prolactin release even at very low doses, whereas metoclopramide increases prolactin release.[18,19] Dopamine and dobutamine also affect lymphocyte function directly.[20] Growth hormone deficiency is associated with decreased natural killer cell activity.[21]

Critically ill patients frequently receive blood transfusions that are known to modify the immune response see also Chapter 82, Transfusion Medicine. Patients with cancer who receive transfusion at the time of resection have greater risk of dying than those who do not.[22] In contrast, certain patients who receive blood transfusion before transplant have a lower incidence of rejection[22]; however, transplant recipients who receive an HLA-DR mismatched transfusion have accelerated graft rejection.[23] The long-term effects of transfusions on the immune system and disease susceptibility are unknown, but even 19 years after transfusion, blood recipients have fewer peripheral T cells, particularly helper T cells, than patients who did not undergo transfusion.[24] Blood transfusions after trauma or cardiopulmonary bypass are associated with increased infection; however, in major surgery or trauma it is difficult to sort out the effect of transfusion compared with the effect of critical illness.[25,26] The use of autologous transfusion in elective surgery may reduce the risk of immunosuppression.[27]

In addition to HIV, viruses such as measles, influenza, and human T-cell lymphotrophic virus-1 can suppress the immune response.[28-31] The neutrophils of patients infected with measles are not activated and therefore are unable to phagocytize and kill bacteria.[28] Lymphopenia has been associated with measles and respiratory syncyctial virus (RSV) and two paramyxoma viruses that can infect monocytes.[29-32] In both infections, mortality is often related to secondary infections. Okada et al. documented that the measles virus infected only small number of lymphocytes but apoptosis occurred in noninfected lymphocytes.[29] The duration of lymphopenia was age dependent and was most prolonged in infants. The same response was not observed in response to a live measles vaccine.[30] Absolute lymphocyte counts were lower in hospitalized RSV-infected patients than controls and were lowest in patients admitted to the intensive care unit.[31] No mortality was observed and lymphocyte counts recovered. In children with a known immunodeficiency such as following cancer therapy and RSV, the development of lower respiratory tract infection was associated with profound lymphopenia (<100 cells/μL) and mortality was 31%.[32]

Although for many previously healthy children immune dysfunction recovers with time, treatment of the underlying condition and/or withdrawal of immuosuppression, for others it does not. This phenomenon is associated with multiple organ failure and death.[12,13,18] For example, an absolute lymphocyte count less than 1000 cells/μL lasting longer than 7 days was associated with a more than sixfold increase risk of death in one pediatric study.[18] For this reason, several investigators have attempted to proactively reverse this process.[33-41] In neutropenic patients with sepsis, granulocyte stimulating factor (G-CSF) reduces the likelihood of death; however, in non-neutropenic patients only one clinical trial has yet shown benefit.[36] Adults with severe community-acquired pneumonia treated with G-CSF plus antibiotics had less sepsis-related organ failure than those treated with antibiotics alone.[37] During immunoparalysis, interferons, which are major activators of monocytes, are reduced. Exogenous interferon gamma-1b therapy administered to 10 consecutively admitted patients

with less than 30% HLA-DR expression restored both HLA-DR expression and production of IL-6 and TNF-α.[39] Aerosolized interferon-γ administered to trauma patients with immunoparalysis (defined as suppressed HLA-DR expression on alveolar macrophages) was associated with a lower incidence of ventilator-associated pneumonia.[40] Monocytes can also be stimulated by granulocyte macrophage colony stimulating factor (GM-CSF). In nine consecutive patients with immunoparalysis documented by reduced mean HLA-DR expression in peripheral blood monocytes, 5 μg/kg of GM-CSF produced a fourfold increase in mean HLA-DR expression and a ninefold increase in TNF-α response to LPS in as little as 24 hours.[41] When given to septic patients with acute respiratory distress syndrome (ARDS), GM-CSF was associated with improved gas exchange and increased neutrophil respiratory burst.[38] Clinical investigations aimed at reversing the downregulated immune system are ongoing and not without risk.

Malnutrition and Immune Deficiency

A significant proportion of children admitted to ICUs (even in affluent countries) have been noted to be malnourished, whereas many others will receive inadequate nutritional intake during their stay in intensive care, implying that many critically ill children will have abnormal immune function secondary to nutritional problems.[42-45] Immune system dysfunction occurs so early in the course of malnutrition that measures of immune competence such as anergy and total T-cell numbers are sensitive indicators of a patient's nutritional status.[46] Nutrition influences the course of HIV and tuberculosis, susceptibility to infection in older patients, the body's ability to respond to vaccines, and many other aspects of immune function.[45-48]

Protein or protein-calorie malnutrition is generally only studied in humans in its most severe form. Because of interspecies variability in immunoglobulin synthesis and cytokine regulation, extrapolation of animal data to humans may be inappropriate.[48] Protein malnutrition alters production of epithelial cell membrane glycoprotein receptors, immunoglobulin A, and mucus, increasing the risk of bacterial colonization.[48] Mobilization of neutrophils is delayed, natural killer cell lytic activity is reduced, and imbalances in critical T-cell subsets occur. All contribute to increased susceptibility to infection. Severe malnutrition attenuates the acute phase response and interferon production, but other proinflammatory compounds and T-cell subsets are upregulated. The common tautology that protein deficiency reduces all protein synthesis is not supported by available data.[48] In the human condition, selective protein deficiency without concomitant essential fatty acid and micronutrient deficiency is unlikely.

By definition, essential fatty, linoleic, and alpha-linoleic acids, cannot be synthesized by mammalian cells and must be obtained through the diet.[49] Linoleic acid is found in plant oils and animal fats, alpha-linolenic acid in plant oils.[49,50] For children in many parts of the world access to fat other than cow's milk is severely limited. The n-3 polyunsaturated fatty acids (PUFAs), eicosopentaenoic acid and docosahexaenoic acid (DHA), synthesized from alpha-linolenic acid or obtained from a diet of fish, suppress lymphocyte responses to mitogen stimulation.[48] Accumulating evidence suggests that dietary supplementation with n-3 PUFAs is a "natural" immunosuppressant that may be useful in autoimmune diseases such as lupus erythematosus, rheumatoid arthritis, and diabetes mellitus.[49] Moderate n-3 PUFA intake can enhance the immune response. For example, supplementation of infant formula with a small amount of DHA accelerates development of T-cell responsiveness in preterm infants (see also Chapter 75).[50]

There are many specific nutrients now identified as vital to immune function. Vitamin A has essential functions in immune cells and indirectly contributes to protection from infection through maintenance of vital epithelial cell differentiation and barrier function of the lung and intestine.[51] Vitamin A deficiency occurs in an estimated 100 million children worldwide[52] and is a risk factor for increased death from pneumonia and diarrhea.[45] A survey of hospitalized children in Malawi showed that one third had severe vitamin A deficiency and one third had moderate deficiency.[52] Paradoxically, these children exhibited monocytes with preferential synthesis of TNF-α as compared with IL-10. This shift was perhaps triggered by the underlying disease that prompted hospitalization. Results of several randomized, double-blinded, placebo-controlled trials conducted in malnourished children have shown improved antibody response to vaccines and fewer diseases of the gastrointestinal and respiratory systems after vitamin A supplementation.[45,51,52] Vitamin A supplementation in individuals who are not deficient has no benefit, whereas high retinal levels are associated with an increased diarrhea and pneumonia.[53] Vitamin C (ascorbic acid) is highly concentrated in leukocytes, and low leukocyte vitamin C concentrations are associated with reduced immune function.[50] Epidemiological data suggest that higher vitamin C consumption lowers the risk of cancer and cardiovascular disease, but despite numerous clinical trials with participants of both sexes and varying ages, no definitive evidence that vitamin C supplementation reduces the frequency or symptoms of upper respiratory infections exists. High-dose vitamin C does improve several measures of immune function and does not appear to have any side effects.[45] Vitamin D receptors are found on numerous immune cell types.[54] Vitamin D deficiency is associated with depressed macrophage function and impaired delayed hypersensitivity.[53] Vitamin E (-tocopherol) is a potent lipid-soluble antioxidant. Study results of vitamin E supplementation ranging from 200 to 800 mg/day in healthy adults showed increasing CD4/CD8 ratios, mitogen responsiveness, antibody production, and decreasing free radical production; however, a dosage of 300 mg/day for 3 weeks resulted in suppressed bactericidal activity in humans.[46] Optimal daily requirements of these nutrients in health and disease remain to be determined.

Of the trace elements that may affect the immune system, selenium, zinc, and iron have been the most widely studied. Selenium balances redox states and suppresses inflammation through its vital role in several antioxidant enzymes and intranuclear factors, including the glucocorticoid receptor, activator protein-1, and nuclear factor-κB.[47] In HIV infection, selenium supplementation modifies cytokine release, decreasing TNF and IL-8 while increasing IL-2. Selenium improves T-cell proliferation and differentiation. Selenium deficiency in the host enhances the mutation rate

of Coxsackie and influenza viruses, but excessive selenium intake is toxic to the immune system and other organs.[47] Zinc, as with selenium, is required for the activity of more than 100 enzymes.[52] Zinc supplementation increases the number of CD4+ T cells; thus, the CD4/CD8 T-cell ratio is improved. Zinc deficiency has been documented in alcoholics and in patients with burns and gastrointestinal disorders.[53] Zinc supplementation reduces bacteremia, hospitalization rates, and vaso-occlusive crises in patients with sickle cell anemia.[47] In young children, zinc supplementation reduced the duration of diarrhea and frequency of respiratory infections.[47] Worldwide, 20% to 25% of the population has iron deficiency, that results in impaired cell mediated immunity, particularly in neutrophil and natural killer cell function.[56] Although an association between iron availability and susceptibility to certain bacterial infections exists, there is little evidence that iron supplementation in deficient individuals inhibits immune responses or increases susceptibility to infections.[47]

Human Immunodeficiency Virus Infection and Acquired Immune Deficiency Syndrome

Acquired immune deficiency syndrome (AIDS) is a clinical syndrome resulting from infection by HIV-1 (and very rarely HIV-2), an RNA retrovirus dependent on a reverse transcriptase for replication.[57] Surrounding the RNA and its reverse transcriptase are core proteins p24 and p18. A viral envelope is composed of the host cell membrane studded with glycoproteins gp120 and gp40. Entry of HIV into cells is mediated by the binding of gp120 to the CD4 membrane protein of the host's T-helper cells in the presence of a host coreceptor of the chemokine family, either CCR5 on macrophages or CXCR4 on other cell lines. After HIV replication, the host's T-helper cells undergo apoptosis resulting in severe deficiency of both cell-mediated and humoral immunity. Because pediatric HIV infection is most commonly transmitted from mother to infant, the acquired immunodeficiency is occurring in a host whose immune system, unlike the adult's immune system, is relatively naive and has developed little natural immunity.[57,58] This may in part explain the shorter time required for progression of HIV infection to AIDS in perinatally infected children when compared with children infected after the age of 2 years.[59] Antiretroviral therapy can effectively reverse this immune dysfunction.[60]

The diagnosis of HIV-1 infection in adults and children older than 18 months is accomplished by identification of antibodies specific to viral proteins: first through a rapid enzyme-linked immunosorbent assay and then confirmed by the more time-consuming Western blot analysis.[60] Because infants carry transplacentally acquired maternal antibodies, HIV infection in infants younger than 18 months must be documented by HIV DNA polymerase chain reaction (PCR) or HIV RNA assay.[60] Generally DNA PCR is repeated three times (between 14 and 21 days, at 1 to 2 months, and at 4 to 6 months of age) with sensitivity increasing over time. [57] Some centers also perform testing at birth. Subtypes of HIV have been identified with subtype B predominating in the United States.[57] The DNA PCR assays are less sensitive for non-B subtypes than are RNA assays. If either test is positive, the child's HIV enzyme-linked immunosorbent assay can be repeated at 1 year to document seroconversion.[57]

The diagnosis of AIDS requires confirmation of both HIV infection and an AIDS-defining illness.[61] AIDS-defining illnesses include nonspecific findings such as fever; weight loss; lymphadenopathy or diarrhea for more than 2 months; and specific findings such as encephalopathy, lymphoid interstitial pneumonitis (LIP), opportunistic infections, recurrent infections, and associated malignancies. In 1994 the United States Centers for Disease Control and Prevention modified an earlier classification system for HIV infection ranging from indeterminate to asymptomatic to severely symptomatic (i.e., AIDS) in an effort to stratify the severity or progression of the disease, by adding age specific CD4+ T cell counts and percentages.[61] These categories aside, there appear to be at least two patterns of response to HIV infection in untreated children.[59,62] Children younger than 4 years, especially those aged 1 year or younger, are more likely to have *Pneumocystis carinii* pneumonia (PCP); have severe progressive encephalopathy, wasting, or both; and die earlier. Older children tend to have a less serious course, characterized by recurrent bacterial infections, LIP, nephropathy, and thrombocytopenia. The time course for vertically transmitted HIV infection to progress to AIDS in children is variable and may be more than 10 years; however, in children, AIDS is most commonly seen between 5 and 8 months.[63] The density of CCR5 receptor on nonactivated T cells correlates with the decline of CD4+ T cells and prognosis.[64]

Epidemiology

In North America at the end of 2007, the adult prevalence of HIV was 0.6% compared with 5% in sub-Saharan Africa.[65] Ninety-six percent of individuals living with HIV reside in low and middle income countries. Sub-Saharan Africa had the highest incidence of HIV infection accounting for 67% of the world's cases with young women three times more likely than men to be infected. East Africa and Central Africa have reduced the prevalence of HIV infection through educational programs. In Western Europe many new cases of HIV/AIDS are reported from persons who emigrated from or traveled to countries with a high HIV prevalence.

As of December 2007, 2 million children lived with HIV/AIDS worldwide, of which 370,000 were newly infected and 270,000 died annually.[65] Vertical transmission of HIV infection from untreated mother to fetus occurs at a rate of 20% to 35% but is reduced by 66% when antiretroviral therapy monotherapy (zidovudine [ZDV]) is taken during pregnancy, delivery, and the neonatal period.[65,66] Even though simple inexpensive monotherapy can reduce vertical transmission by 40% to 50%, only 33% of infected pregnant women receive treatment.[65,66] When used in combination with elective cesarean delivery and formula feeding, perinatal antiretroviral therapy has reduced the vertical transmission of HIV to less than 2% in the United States. Currently trials suggest that highly active antiretroviral therapy (HAART) in pregnancy may be more effective in preventing transmission than monotherapy.[67,68] It may also be important to extend antiretroviral therapy for the mother during the period of breastfeeding.[67,69,70] Although there has been extensive development of appropriate therapies, a major challenge has been actual delivery of programmes to prevent mother to child transmission.[71-73]

Antiretroviral Therapy

In the United States, antiretroviral therapy for HIV-infected children was initiated in 1985 with zidofovir, a reverse transcriptase inhibitor, as monotherapy.[74] As of February 2009, 22 antiretroviral agents were approved and available for use in the United States, 17 have a pediatric indication.[60] Because resistance develops with monotherapy, multiple drug regimens known as HAART are used in children and adults.[75] There are five classes of agents available and three drugs are typically selected from at least two classes. Measurement of both HIV-1 viral load (by RNA PCR) and the number of CD4+ T cells is performed to monitor the effectiveness of HAART.[60] Baseline viral loads are higher in children than in adults and have a slower decay rate after the introduction of HAART.[66] Pediatric studies in which dosage adjustments were directed by pharmacokinetics resulted in superior decreases in viral loads compared with fixed dosages based on weight.[60] Each antiretroviral therapy has its own toxicity and potential for drug interactions (Table 93-2). Antiretroviral therapy is rapidly evolving and should be directed by a specialized practitioner.[60]

Initiation of antiretroviral therapy can result in rapid immune recovery. A subset of patients experience an inflammatory response as the immune system is reconstituted.[76] Most cases have another occult infection in addition to HIV. In one study, nearly 50% were associated with mycobacterial infections such as *Mycobacterium avium intracellulare* and herpes viruses such as *Varicella zoster*. Clinical presentation is related to the focus of infection. Enhanced screening and subsequent treatment of opportunistic infections such as tuberculosis program before beginning HAART may prevent the reconstitution inflammatory syndrome. The World Health Organization has recommended prednisone for patients with tuberculosis who experience severe paradoxical reactions. However, there are no randomized controlled trials to support this practice.[76]

The number of people receiving HAART surpassed 2 million in 2007, but two thirds of those who need it still have no access to drug.[65] Ninety percent of HIV-infected children live in sub-Saharan Africa and underdeveloped countries of Asia.[65] Because of cultural, economic, and political factors, HIV prevention and treatment have been only slowly introduced in these regions. In Malawi, without antiretroviral therapy, the mortality rate at 3 years of age for HIV-infected children reached 89%.[78] This high mortality rate may be related to the burdens of infectious diseases and malnutrition, and is seen in other parts of the world. The care of these children is complicated by overcrowding, limited access to clean water, and malnutrition, that contributes to the high frequency of TB, cytomegalovirus (CMV), hepatitis, and gastroenteritis seen in this population. Still there is growing evidence that antiretroviral can be provided successfully to children in resource limited settings.[79,80] Even in this environment, the efficacy of early initiation of anti-retroviral therapy in children has been confirmed.[81] In the United States 75% of HIV-infected children in the United States are alive at age 5 years.[80] Most data regarding outcome and survival of HIV-infected children presented in this chapter are drawn from patients who did not receive antiretroviral therapy from the time of birth and may have never received it. Such data are likely still applicable to underdeveloped countries.

Table 93–2 Adverse Effects of Antiretroviral Agents

Agent	Effect
NUCLEOSIDE ANALOGUE REVERSE TRANSCRIPTASE INHIBITORS	Almost all produce headache, gastrointestinal distress, fever; less frequently peripheral neuropathy, pancreatitis, and lactic acidosis with hepatomegaly
Abacavir	5% have severe hypersensitivity reaction (HLA-B 85701 allele)
Didanosine (ddI)	
Emtricitabine	Hyperpigmenation
Lamivudine	
Stavudine	
Tenofovir	
Zalcitabine	
Zidovudine	Bone marrow suppression, myopathy, mitochondrial dysfunction, liver toxicity
NONNUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS	Almost all produce headache, fatigue, gastrointestinal distress, and rash, sometimes progressing to Stevens-Johnson syndrome
Efavirenz	Central nervous system alterations: somnolence, delirium
Nevirapine	Hepatitis, hypersensitivity reaction
PROTEINASE INHIBITORS	Almost all produce headache, gastrointestinal distress, paresthesias, rash; less frequently pancreatitis, hyperglycemia
Atazanavir	Jaundice
Darunavir	
Fosonprenavir	
Indinavir	Asymptomatic hyperbilirubinemia, nephrolithiasis, elevated lipid levels
Lopinavir/ritonavir	
Nelfinavir	
Ritonavir	Increased liver transaminases
Saquinavir	Exacerbation of chronic liver disease
Tipranavir	
INTEGRASE INHIBITORS	
Raltegravir	Headache, gastrointestinal distress, fatigue, pruritus, myopathy
ENTRY INHIBITORS	
Maraviroc	Rash
FUSION INHIBITORS	
Enfuvirtide	Inflammation at infection site

Modified from Van Rossum AM, Fraaij PL, de Groot R: Efficacy of highly active anti-retroviral therapy in HIV-1 infected children, Lancet Infect Dis 2:93, 2002.

Pulmonary Complications and Respiratory Failure

Pulmonary complications remain the most frequent indication for admission of children with AIDS to an ICU.[82,83] Bacterial pneumonia is common in this population.[84,85] Along

with the usual pathogens frequently seen in childhood, such as *Streptococcus pneumoniae* and mycoplasma, immunodeficient children are also susceptible to pseudomonal and staphylococcal infections.[66,67] The incidence of *Haemophilus influenzae* infection is declining where vaccination is available, whereas immunization against pneumococcal infections has been associated with a significant drop in pneumococcal disease in HIV infected children.[86] Empiric therapy for pneumonia in such children should cover the most common pathogens and be based on hospital-specific susceptibility profiles, but it is important to note that children with HIV infections may not respond to standard antibiotic therapies for lower respiratory tract infections.[87]

Pneumocystis Jirovecii Pneumonia

Although increased emphasis on early prophylaxis has reduced its incidence, PCP is still the most common AIDS-defining illness in pediatrics.[88,89] Children not previously recognized to be infected with HIV may present as early as 3 to 4 weeks of age, whereas the median age or presentation to intensive care units is between 3 and 6 months of age, and coincides with the timing of a natural decline in maternal antibodies.[83] In children known to be at risk of HIV infection, PCP prophylaxis is indicated starting at 4 to 6 weeks of age as CD4+ T cell counts obtained before the development of infection are not predictive of infection and can drop precipitously.[90] *Pneumocystis jiroveci* is unique to humans and has a predilection for the lung.[91] PCP generally presents with cough, fever, tachypnea, and dyspnea of several days' duration.[91] Physical examination typically reveals retractions and grunting. Auscultation of the chest may reveal normal examination findings or rales, rhonchi, and wheezing. The chest radiograph generally shows diffuse interstitial infiltrates, but pulmonary infiltrates can be variable in children, in part because infants have a greater propensity for atelectasis.[91,92] Hypoxemia is often out of proportion to clinical and radiographic examinations. A selectively elevated serum lactate dehydrogenase level is suggestive, although not diagnostic of PCP.[91] For a confirmation of a PCP diagnosis, bronchoalveolar lavage should be performed. Flexible fiberoptic bronchoscopy has a diagnostic yield of 90% to 97% and allows one to look for other pathogens as well.[91,93] Nonbronchoscopic bronchoalveolar lavage and sputum induction can also be used.[93] Patients in whom no diagnosis is obtained from bronchoalveolar lavage should undergo an open lung biopsy. This procedure has a diagnostic yield for PCP of 97% in the study of patients with underlying malignancy or immune suppression.[91]

The preferred antiprotozoal therapy for PCP is the combination of trimethoprim and sulfamethoxazole (TMP-SMX) (20 mg/kg/day trimethoprim).[91] Patients in whom this combination agent fails have not been shown to respond to a change in antiprotozoal therapy. In fact, higher doses of both components may be required to achieve therapeutic levels in critically ill patients.[91] Sulfa allergy as manifested by severe drug eruptions including Stevens-Johnson syndrome is less frequent in children than in adults; however, this complication may prompt a change to therapy with pentamidine isethionate (4 mg/kg/day). When adverse events such as pancreatitis and renal failure occur as a result of pentamidine, atovaquone (40 mg/kg/day) is an alternative treatment.[91] Twenty-one days of therapy are followed by prophylactic therapy, for which TMP-SMX is also the agent of choice. For patients allergic to sulfa, PCP prophylaxis can be achieved with pentamidine, dapsone, or atovaquone, although these agents have not been rigorously studied in children.

Several adult randomized controlled trials showed efficacy of high-dose steroids in HIV positive adults with moderate PCP.[91] Although no controlled studies have been performed in children, improved outcomes in children who received corticosteroids have been described in several case series.[94-97] Even in the face of respiratory failure, the survival rates reported with adjunctive corticosteroids therapy are 91% to 100% in a limited number of children.[96,97] Because PCP mimics other diseases such as miliary TB and CMV pneumonitis, PCP should be confirmed and other coinfections excluded before corticosteroid administration. Adults who have respiratory failure despite adjunctive corticosteroids have a high risk of death. Failure to improve after 5 days of mechanical ventilation and the development of pneumothorax were strongly predictive of death in adults.[98]

Pneumocystis pneumonia has also been reported in patients receiving high dose steroids, transplant related immunosuppression and the new monoclonal antibodies that modulate the immune system.[91] Pneumocystis pneumonia behaves differently in non-HIV-infected patients. The onset of the disease may be more abrupt. The mortality is greater in cancer patients than AIDS patients and corticosteroids are not as clearly beneficial.

Because the alveoli of patients infected with pneumocystis are filled with protozoal and inflammatory cells, PCP is associated with a reduced functional residual capacity. Many of these patients are small infants in whom the second inflection point of the lung's pressure-volume curve is reached at relatively low peak and mean airway pressures; thus, early institution of high frequency oscillatory ventilation may be warranted.

Cytomegalovirus Pneumonitis

Children at risk for vertical transmission of HIV are also at risk for CMV infection. Pneumonitis from CMV is also a common complication of solid organ and hematopoietic stem cell recipients. The presentation of CMV pneumonitis can closely mimic that of PCP with diffuse interstitial infiltrates and hypoxemia, but there is generally a more insidious onset; however, some reports of a more fulminant course exist.[99] Failure of PCP to respond to conventional therapy may be evidence of concomitant CMV infection. Signs of retinitis, hepatitis, or colitis should be evaluated in patients with pneumonia because they may indicate widespread CMV disease.

The definitive diagnosis of CMV pneumonitis must be made by identification of characteristic intracellular viral inclusion bodies in pulmonary macrophages or biopsy specimen because recovery of CMV from bronchoalveolar lavage by culture may represent viral shedding rather than invasive disease.[99] Detection of viral antigen by immunofluorescence is a second confirmatory test.[99] Serological markers of CMV are not useful in HIV-infected adults.[99] The treatment for CMV disease, in addition to HAART, is ganciclovir 5 mg/kg given twice daily followed by long-term suppressive therapy.[99,100] Foscarnet and cidofovir have been used in other immunosuppressed patients, but these drugs have significant nephrotoxicity.[99,100] Although solid organ transplant recipients receive prophylaxis against CMV disease with ganciclovir, this

approach has not been applied to patients with AIDS. The use of leukoreduced blood products may reduce the risk of primary infection.

Other Viral Pathogens

Children with AIDS are more likely to experience lower tract disease and pneumonia when contracting RSV and influenza.[101,102] For RSV, the estimated incidence of lower tract disease was twofold greater in HIV-infected children. It is not clear that HIV infection increases the likelihood of death.[102,103] The incidence of lower respiratory tract disease requiring hospitalization in influenza was eightfold higher in children with HIV infection.[102] HIV-infected children with influenza pneumonia were older and more likely to have another underlying disease or concurrent infection. Despite these comorbidities there was no difference in clinical outcome. Other pathogenic viruses recovered from pediatric patients with AIDS include adenovirus, parainfluenza, herpes simplex, and measles. In vitro data suggest ribavirin and cidofovir may be effective against some of these viral pathogens; however, evidence of in vivo efficacy is limited to anecdotal reports in immunosuppressed patients.[103,104] Immunosuppressed children have been noted to shed viral pathogens such as RSV and influenza for a prolonged period time, and therefore nosocomial viral infections may be a significant problem if infection control practices are not maintained.[105,106]

Mycobacterial Pathogens

Worldwide, approximately one third of the human population is infected with the Mycobacterium bacillus.[107] Most of these individuals live in developing countries where the prevalence of HIV infection is high. The incidence of *M. tuberculosis* appeared to level off in the United States by 1985 but began rising steadily in 1988—an increase attributed to the AIDS epidemic.[109] The increased incidence of pediatric TB is likely due to increased exposure to adults with active infection. HIV-infected children with TB have higher CD4+ T-cell counts than those observed with other classic opportunistic infections.[63] Although adults generally acquire HIV infection after acquiring TB, the opposite is true in children. Thus the HIV-infected child never has a chance to mount an immunological response to *M. tuberculosis*. In contrast to adults who have apical, cavitary lesions, children have more peripheral disease.[107] Most pediatric patients with AIDS have diffuse infiltrates consistent with LIP or PCP.[109] These children also have a high incidence of extrapulmonary manifestations such as hepatosplenomegaly and meningitis.

Aggressive efforts to confirm mycobacterium infection by culture are required because anergy obscures Mantoux testing, as well as the development of pleural effusions and localized lymphadenopathy. Use of PCR to identify *M. tuberculosis* nucleic acids in bronchoalveolar lavage and cerebrospinal fluid (CSF) specimens can accelerate the ability to diagnose this infection.[112] Recovery of mycobacterium by sputum induction has been reported in infants and very young children.[88] In some regions, organism recovery is necessary for antimicrobial susceptibility determination; 25% of isolates are resistant.[107,111,112] In countries where the diagnostic approaches are not readily available, it is useful to obtain radiographs of family members.[112]

Pending sensitivity reports, treatment of TB is initiated with a five-drug regimen.[113] The presence of multidrug resistance increases the likelihood of death. These patients should simultaneously be treated with antiretroviral therapy; however, rifampin is contraindicated with protease inhibitors and nonnucleoside reverse transcriptase inhibitors.[113] During HAART, reconstitution of the immune system may increase the inflammatory response to pulmonary TB. Children with TB and HIV infection who are not treated with HAART have a higher mortality rate than children not infected with HIV.[113] They must be treated for a longer time, perhaps because of poor drug absorption and a weakened immune system.[113] Before the introduction of HAART, isoniazid prophylaxis prevented both tuberculosis and death in HIV-infected children[114]; however, this has not been shown in the era of antiretroviral therapy.[11]

Mycobacterium avium-intracellulare complex (MAC) can also be recovered from the lungs of children with pneumonia.[82] Colonization is difficult to differentiate from invasive disease. Treatment options include coverage with clarithromycin in combination with ethambutol, rifabutin, or amikacin. Primary prophylaxis once a week with azithromycin is recommended in children older than 2 years and younger than 1 year with CD4 counts persistently below 75. Children between 1 and 2 years of age should receive prophylaxis for CD4 counts less than 50.[90]

Fungal Infections

Candida is frequently recovered from sputum and bronchoalveolar lavage samples in children with AIDS, but whether it is a true pathogen is questionable. In adults in whom a biopsy specimen can be obtained by bronchoscopy, *Candida* is thought to be a rare cause of pulmonary disease but a more frequent cause of bronchitis.[116] Aspergillosis has also been reported in older children with multiple opportunistic infections, prolonged hospitalization, neutropenia, and corticosteroid use.[117] Unlike *Candida*, recovery of aspergillosis from the respiratory tract is indicative of invasive disease. Cryptococcosis occurs in 5% to 15% of adults but in only 0.6% to 1% of children.[117] This ubiquitous organism enters the body through the respiratory tract. Therefore initial symptoms are generally both pulmonary and nonspecific. Bronchoalveolar lavage fluid should be examined by India ink stain and culture. Blood culture and latex agglutination are also necessary. Recommended therapy is amphotericin B in combination with 5-flucytosine (100 mg/kg/day) for 2 weeks followed by fluconazole (12 mg/kg/day divided in two doses) for 8 additional weeks.[118] Cryptococcal antigen titers are useful in the evaluation of possible relapse. Prophylaxis for the prevention of cryptococcal disease is not recommended in children. Fusariosis has been reported in neutropenic patients with AIDS. Other fungal infections such as histoplasmosis, cryptococcosis, coccidiomycosis, and disseminated *Penicillium marneffei* are reported in patients with AIDS who are living in or traveling through endemic areas. [82,119]

Lymphoid Interstitial Pneumonitis

LIP is a lymphoproliferative disorder associated with viral infections. In children LIP is almost exclusively seen with Epstein-Barr virus (EBV) and HIV.[120] LIP occurs in

30% to 50% of pediatric patients with AIDS, presenting in the second year of life in that patient population with high antibody titers and recurrent bacterial infections. Generally the children also have diffuse lymphadenopathy and hepatosplenomegaly. Children with LIP may have mild pulmonary symptoms such as dry cough but generally are admitted to the pediatric ICU only when an acute infection is superimposed on their chronic condition. When such is the case, maximal therapy of the acute exacerbation is indicated, including mechanical ventilation. On chest radiograph hilar adenopathy and reticulonodular infiltrates are seen. Pulmonary function tests reveal reduced lung volumes and diffusing capacity. Histologically, peribronchial lymphoid nodules containing plasma cells and lymphocytes are observed. Most specimens show predominantly CD8-positive T cells.

Spontaneous radiographic resolution was reported in 65% of children with LIP.[121] Patients with hypoxemia are treated with steroids, and resolution is seen in most patients in 2 to 4 weeks. If the patient is persistently febrile, MAC infection should be ruled out before steroid administration.[82]

Upper Airway Obstruction

Young children and infants exhibit upper airway obstruction with greater frequency than adults. Whereas classic viral laryngotracheitis is the most common cause in the immunocompetent patient, immunocompromised patients are susceptible to a greater variety of infectious entities, including bacterial tracheitis, CMV-related ulceration of the trachea, and *Candida* infections of the airway oropharynx.[122,123] The clinical course in HIV-infected children is different with many requiring tracheostomy.[123] Although in the general population *Staphylococcus aureus* is the most commonly reported cause of bacterial tracheitis, *Pseudomonas* species are a frequent cause of tracheitis in patients with AIDS. Given the complexity of the differential diagnosis of stridor in this population, early laryngoscopy and bronchoscopy are indicated.[97] Recurrent tracheitis may be an indication for tracheostomy. Length of stay and outcome are not affected by the presence of HIV infection.[97]

Cardiovascular Complications

Septic Shock

After the introduction of PCP prophylaxis, severe sepsis became the most common reason for ICU admission in patients with AIDS.[124] Of bacteremia episodes with an identified organism identified in the Pediatric AIDS Clinical Trials Group, 69% were pneumococcal.[63] In this study there was a low incidence of *H. influenzae* probably because of vaccination. HIV-infected patients do appear to be more susceptible to *S. aureus* and pseudomonas infections. In one series of pediatric patients with AIDS, 10% of patients had gram-negative bacillary bacteremia with a risk of death that was greater than 40%.[125] *Pseudomonas* sepsis accounted for 26% of these episodes.[126] *Pseudomonas* infection is frequently associated with neutropenia, that may be a cause or effect phenomenon.[125,126]

Vasculitis

Vasculitis has been reported in patients with HIV infection, but it is not clear if HIV causes the condition or is merely an association although there are a variety of suggested mechanisms.[127-131] Many infections reported in HIV-infected patients, including herpes viruses and mycobacterium, can cause inflammation by direct infection or an immune-mediated response. The most frequently involved organs are skin, peripheral nerve or muscle, and the central nervous system (CNS).[129] Several cases of polyarteritis nodosa have been reported.[129] When vasculitis is noted, an infectious agent should be sought. The authors have observed an increased incidence of arterial catheter complications among HIV-infected children and it is probably wise to exercise caution in the use of central venous and arterial catheters in HIV-infected children.

Myocardial Dysfunction

Cardiac dysfunction develops in 19% to 25% of HIV-infected children and is the presenting sign in a minority of children.[132,133] About 10% of a survey population had chronic congestive heart failure, whereas another 10% had transiently decreased ventricular function.[106] Cardiac complications appear to occur more frequently in rapidly progressing patients with encephalitis and other AIDS-defining illnesses. Because tachycardia and hepatomegaly are so common in pediatric AIDS patients with fever, pulmonary infection, and anemia, a clinical diagnosis of cardiac involvement is difficult to make. Enlargement of the cardiac silhouette may not be appreciable even in patients with significant muscle hypertrophy or pericardial effusion. Given these inherent difficulties in the detection of cardiac disease, assessment of a critically ill child with AIDS should include echocardiography. When assessment is prospectively followed by echocardiography, the earliest sign of cardiac involvement is diastolic dysfunction.[133] At autopsy, aside from biventricular dilation, macroscopic evidence of cardiac dysfunction has been difficult to find in adults or children. Microscopically, in a limited number of cases, lymphocytic infiltrates are observed, but actual myocyte necrosis is rare.[134] Mild foci of lacy interstitial fibrosis may also occur.[134,135] True myocyte inflammation or myocarditis is rare in children.

HIV cardiomyopathy likely has several causes. Direct evidence of myocardial infection by HIV-1 has been documented by culture, Southern blot test, and in situ hybridization,[134,135] but it is unclear if the myocytes, that express no CD4 receptors, actually harbor HIV. Coxsackie B3 virus, CMV, adenovirus, EBV, and *Toxoplasmosis gondii* have also been identified as pathogens.[136,140] Of 32 HIV-infected children who died, 7 had evidence of CMV infection and 10 had evidence of adenovirus infection by PCR performed on myocardial tissue.[136] Selenium deficiency has been documented in severely malnourished children with AIDS whose cardiac function improved after selenium supplementation.[139] In additional case reports, ZDV is indicated as a cause of cardiac failure.[137]

In the ICU, patients with severe cardiac dysfunction respond to management of preload, increasing contractility, and afterload reduction. Endocarditis, myocardial ischemia, and other potentially treatable causes of cardiac dysfunction should be ruled out with electrocardiography and echocardiography. Pharmacological afterload reduction should be considered as first-line therapy, with digitalization and diuretic therapy as appropriate. Other than selenium supplementation there is no direct therapy available for HIV-related cardiomyopathy.[139] Agents that are associated with myocardial dysfunction, such as pentamidine, foscarnet, and dideoxyinosine (ddI), should

be avoided.[137,140] A small population of patients has been noted to have transient cardiac dysfunction manifested by tachycardia and poor peripheral perfusion despite adequate filling pressures. This has been noted during PCP infection and may be related to cytokine release. Survival data following clinically evident congestive heart failure in children undergoing HAART have not been reported.

Dysrhythmias

In a survey of 81 HIV-infected children, dysrhythmias occurred in 35%, including atrial and ventricular ectopy, ventricular tachycardia, and ventricular fibrillation.[132] A syndrome of autonomic dysfunction has been reported in adult patients with AIDS, and similar lability in blood pressure and heart rate has been noted in a number of HIV-infected children. Catecholamine surges have been described in adults. Additionally peripheral neuropathy may contribute to altered vascular regulation and a propensity for cardiac arrhythmias.

Pericardial Disease

Pericardial disease is reported in approximately 30% of HIV-infected children undergoing echocardiography or autopsy.[132,135] In five pediatric patients in whom fluid was cultured, no pathogens were identified. In 14 adult patients in whom fluid was obtained, atypical mesothelial cells were identified. One patient had lymphoma, one had histoplasmosis, and a third had CMV identified by a pericardial biopsy specimen. A pericardial effusion greater than 5 mm in diameter was detected in 5.4% of prospectively evaluated HIV-infected children, but no episodes of tamponade were reported.[134,141] Cardiac arrest due to tamponade has been reported in five adult patients with AIDS.[142]

Renal Failure

HIV nephropathy was first reported in 1983 and may often be the first manifestation of AIDS.[143-146] This complication generally arises between ages 2.5 and 4.9 years. It appears to be more prevalent in children of African or Afro-Caribbean descent. The usual presentation of renal dysfunction is severe proteinuria (>3.5 g/day) with hypoalbuminemia and anasarca. This may be associated with renal tubular acidosis. Creatinine clearance is usually normal. Proteinuria may be accompanied by hematuria. Immunoglobulins are usually elevated while complement is normal. On ultrasound, the kidneys are enlarged. Biopsy specimens show focal and segmental glomerulosclerosis.[144] The course of the disease before HAART was usually fulminant, with end-stage renal disease developing in 8 to 9 months. Effective antiretroviral therapy slows or reverses the course of HIV nephropathy.[145,146] Atypical hemolytic uremic syndrome or thrombotic microangiopathy is also described in pediatric patients with AIDS.[146,147]

Potentially nephrotoxic drugs to which the HIV-infected patient may be exposed are legion. Indinavir and tenofovir are associated with increased risk of chronic renal failure.[118,121] Pentamidine-induced renal toxicity usually occurs in the second week of therapy. Proteinuria and particularly hematuria, that may be falsely attributed to HIV nephropathy or catheter-induced trauma, are hallmarks of pentamidine toxicity. Early recognition of this complication and cessation of pentamidine are key to recovery; rechallenge with the drug will prompt early return of proteinuria and hematuria. Toxicity from sulfadiazine during the treatment of toxoplasmosis is also reported and can be reduced by hydration.[147] Amphotericin-induced nephrotoxicity is particularly problematic when the drug is used in combination with aminoglycosides. Liposomal-encapsulated amphotericin B allows for higher doses with less toxicity.

In critically ill patients with AIDS, acute tubular necrosis may be precipitated by sepsis, hypovolemia, or hypoperfusion, and as in non–HIV-infected patients, it is reversible.[146] Thus the same principles for management and support of a patient with reversible acute renal failure apply to the HIV-infected population. For patients who are seen in the ICU with end-stage renal disease due to HIV nephropathy, the indications for dialysis are the same as in other patient populations, but the decision to undertake dialysis must be made on an individual basis (see also Chapter 72). Peritonitis during ambulatory peritoneal dialysis in pediatric patients with AIDS does not occur with any apparent greater frequency than in immunocompetent patients.[149] Kidney transplant has been successful in carefully selected HIV infected patients.[146]

Abdominal Complications

Patients with AIDS have multiple gastrointestinal complaints including dysphagia, abdominal pain, and chronic diarrhea, but these are generally not important in the ICU except that they affect nutritional status.[150] Other more life-threatening complications include severe dehydration, intra-abdominal sepsis, pancreatitis, and hepatic failure (Box 93-3).

Diarrhea occurs in 40% to 60% of children with AIDS and may produce severe dehydration.[151] Worldwide, acute diarrhea is the most common cause of death in children with AIDS.[151] In underdeveloped countries where poor sanitation increases the risk of diarrheal diseases, HIV-related hypovolemic shock is a common indication for pediatric ICU admission. Copious diarrhea is suggestive of small intestine involvement, whereas tenesmus suggests infection involving the distal colon and rectum. Diffuse enterocolitis produces a secretory diarrhea with profound volume losses. Patients with AIDS may have typical infectious enteritis and enterocolitis caused by *Salmonella, Shigella, Giardia*, *Campylobacter,* and rotavirus, but may also have an atypical, more prolonged course.[150,151] The frequent use of systemic antibiotics in HIV-infected children results in *Clostridium difficile* colitis. *Mycobacterium avium intracellulare*, cryptosporidium, *Giardia*, *Isospora belli*, CMV, and adenovirus may all induce opportunistic small bowel enteropathy.[150-152] Patients with MAC, CMV, and *Candida* infection typically also have extragastrointestinal infection.[153] A nonspecific enteropathy may arise as a result of the overgrowth of normal gut flora due to the effects of local immunodeficiency and antibiotic use. It is not uncommon to find heavy growth of *C. albicans* or *Pseudomonas aeruginosa* in stool cultures.

If findings from stool culture and analysis are negative, a flexible sigmoidoscopy with a rectal biopsy should be considered in the child with rectal bleeding, tenesmus, or both. Aspiration of duodenal secretions is particularly helpful in evaluation of patients from underdeveloped countries in that the aspirate may reveal infection with *I. belli*, *Cryptosporidium parvum*, or helminthic species. Additional evaluation may be desirable, including small bowel radiography or abdominal computed tomography (CT) scanning. If results of all diagnostic studies are negative,

Box 93–1 Gastrointestinal Complications in Immunodeficient Patients

Diarrhea

Bacteria
- *Salmonella*
- *Shigella*
- *Clostridium difficile*

Fungi
- *Candida*
- *Pneumocystis*

Viruses
- Cytomegalovirus
- Herpesvirus
- Varicella-zoster
- Adenovirus
- Rotavirus

Parasites
- Cryptosporidium
- Microsporidium
- *Entamoeba histolytica*
- *Giardia intestinalis*
- *Blastocystis hominis*

Medications
- Atovaquone
- Antiretrovirals

Pancreatitis

Infections
- Cytomegalovirus
- Adenovirus

Medications
- Protease inhibitors
- Pentamidine
- Foscarnet

diarrhea may be due to HIV therapy because most antiretroviral agents are associated with diarrhea (see Box 93-1).[154]

Recovery of MAC from the blood generally indicates invasive disease, but percutaneous needle aspiration with CT guidance of enlarged intraabdominal nodes may be confirmatory.[152] Antimicrobial therapy of disseminated MAC infection before HAART was unrewarding, and disseminated MAC was rapidly fatal. Current antimicrobial therapy is a double drug regimen of clarithromycin and ethambutol with the possible addition of a third agent, including rifabutin, ciprofloxacin, or azithromycin. Prophylaxis against MAC with azithromycin is indicated in children with CD4 counts less than 75 cells/uL and in infants with counts less than 100 cells/uL.[90] In patients treated with HAART diarrhea often persists despite improvements in immunologic function. [154]

The Acute Abdomen

The evaluation and management of acute abdominal pain in HIV-infected children is complicated by their immunosuppressed state. Localized signs of infection can be masked by immunosuppression, debilitation, and previous or current use of antibiotics. In fact, a significant intra-abdominal abscess may result in minor symptoms, with unremarkable elevations in white blood cell count or temperature. Thus diagnostic imaging with abdominal CT scan is invaluable for evaluation in this population. Although morbidity after surgical intervention is somewhat higher in patients with AIDS, there is still a significant survival when such intervention is undertaken promptly.[155-158] Gastric and proximal small bowel symptoms such as pain or bleeding may arise from stress gastritis and infiltrative processes caused by viruses, particularly CMV and adenovirus, *Giardia lamblia*, tuberculosis, and lymphoma. Supportive management of these conditions is the same as that for immunocompetent patients, although the appropriate antimicrobial therapy may be different.

Pancreatitis

Pancreatitis in the AIDS population results from both the disease and its treatment.[60,159,160] Pancreatitis presents as acute or persistent midepigastric pain and/or back pain and elevation of serum amylase, lipase, and triglyceride levels. Infectious causative entities include CMV, adenovirus, mycobacterium, fungal infections, cryptococcus, herpes simplex virus (HSV), and protozoal infections such as toxoplasmosis, *Pneumocystis*, and cryptosporidium. The list of drugs known to cause pancreatitis is extensive and includes the antiretroviral agent zalcitabine and the antiprotozoal agent pentamidine. The mechanism by which drugs induce pancreatitis is unknown.

Pancreatitis often goes undiagnosed. Autopsy findings reveal significant pancreatic lesions in approximately 10% of patients with AIDS, yet pancreatic lesions are rarely recognized during life.[159] Nine (17%) of 53 children seen at one institution demonstrated pancreatitis.[160] Four of five of these carried CMV. In one of these patients CMV was cultured from pancreatic duct fluid. Six of nine had serological evidence of EBV. Five children were receiving pentamidine at the time of presentation. Maintaining a high index of suspicion for pancreatitis is important because vomiting, abdominal distension, and malabsorption are common complaints in the HIV-infected child. Evaluation of these patients should include both serum lipase and amylase determinations because parotid inflammation seen in HIV infection can cause isolated elevations of serum amylase concentrations. Abdominal ultrasound is only useful in the detection of a large edematous pancreas and in follow-up assessment for pancreatic pseudocyst.

Treatment includes bowel rest and hyperalimentation along with removal of the offending agent as in the case of drug-induced pancreatitis. In infectious pancreatitis, treatment of the underlying cause, while indicated, may not change the course of the disease.[160] Despite intervention, seven of eight reported children with pancreatitis had active or recurrent disease at the time of death. The mean survival time from onset to death was 8 months (range, 0.5 to 13 months).[160] In this patient population anatomical abnormality is rarely the cause of pancreatitis, and there is little role for surgical intervention.

Hepatobiliary Failure

The cause of hepatic failure in HIV-infected patients differs from that of other adults and is affected by the patient's degree of immunosuppression.[161] In early stages, hepatic disease is usually a result of drug toxicity or hepatotropic virus infection. Drug-induced hepatotoxicity has been reported with sulfa drugs, isoniazid, rifampin, and rifabutin.[161,162] Several

antiretroval agents can cause heptatis.[60] If HIV progresses to AIDS the liver manifests systemic involvement of opportunistic infections.[161,163] Reviews of hepatic tissue disease in HIV-infected children document that CMV and mycobacterial disease are common in children, whereas classic viral hepatitis is relatively rare.[161,164,165] As the immune system is reconstituted in response to HAART, hepatitis B can flare up.[154] Chronic hepatitis becomes clinically significant as survival increases in patients receiving HAART.[154] Cholangitis and cholecystitis are well described in adult patients with AIDS. Biliary tract infections have been attributed to CMV, adenovirus, cryptosporidium, and microsporidia.[164-166]

Liver biopsy is only indicated when mycobacterial disease is expected or jaundice is present, as most diseases can be diagnosed by serological testing or PCR.[161] Drug toxicity has no specific biopsy finding. The HIV virus itself can cause a giant cell hepatitis. Dense lymphoid infiltrates, similar to those in the lung in LIP, are also described. Adenovirus, CMV, and HSV and other oppurtunistic infections can cause acute jaundice and hepatitis with fever.[163,165-169] Hepatitis B and C can occur in patients with AIDS.[154,170] In certain established diagnoses, biopsy may be indicated to assess disease progression and response to therapy.[161]

Because drug-induced hepatotoxicity may be reversible upon drug withdrawal, aggressive support for this cause of hepatic failure is indicated. Hepatitis B can be treated with the antiretroviral agents lamivudine in combination with the antiretrovirals tenofovir or entecovir.[154] Hepatitis C can be treated with ribavirin and interferon.[154] In most cases HAART is suspended during hepatitis C therapy.[154,170] Liver transplantation can be successful with proper patient selection.[171]

Hematologic Complications

Hematologic abnormalities are common in patients with HIV/AIDS. Isolated thrombocytopenia is likely mediated by antiplatelet antibodies and should prompt HIV testing.[172-174] As with other forms of antibody-mediated thrombocytopenia, this may respond to immunoglobulin, steroids or subtotal splenectomy.[173,175] Neutropenia may be antibody mediated, drug related, or secondary to sepsis. Granulocyte colony growth factors have reduced the incidence of sepsis in this setting.[176]

Anemia occurs in 20% to 73% of HIV-infected children and is an independent predictor of death from AIDS.[177,178] Most HIV-infected patients have normal erythrocyte size and shape but inadequate reticulocytosis. Iron deficiency, possibly related to malabsorption, accounts for 10% to 45% of anemia in HIV-infected children. Nutritional deficiencies of folate and vitamin B_{12} may also contribute to anemia. Many medications that are given to patients with AIDS cause anemia, including ZDV, acyclovir, TMP-SMX, and pentamidine. Anemia of chronic disease, mediated by inflammatory cytokines, likely accounts for additional cases. Rarely, antierythrocyte and antierythropoietin antibodies have been reported in patients with AIDS.[179] Pediatric patients with AIDS who have renal failure may lack erythropoietin.

Malignancies

Malignancies account for 2% of AIDS-defining illnesses in pediatric patients.[180] Of 162 pediatric AIDS patients with malignancy reported to the Centers for Disease Control and Prevention, 134 had non-Hodgkin lymphoma and 28 had Kaposi sarcoma.[180] Lymphomas are generally of the B-cell type and often arise in the CNS. Other reported conditions include B-cell leukemia, hepatoblastoma, leiomyomas or leiomyosarcomas, and cervical carcinoma.[180] In a cohort study of perinatally HIV-infected children, the cancer rate was nearly four times higher in children treated with HAART for less than 2 years when compared to those treated for more than 2 years.[181] The rates of childhood malignancy were compared between this cohort and the Surveillance, Epidemiology and End Result (SEER) Cancer Statistics Review. The higher rate in perinatally HIV-infected children was related to lymphomas. The development of cancer was 3 times more likely in those with low CD4+ T cell counts.

Several of these malignancies are associated with chronic viral infection. EBV DNA has been identified in most CNS tumors and in soft tissue tumors such as leiomyosarcomas or rhabdomyosarcomas reported in patients with AIDS. Infection with EBV is also associated with a polyclonal, polymorphic B-cell lymphoproliferative disorder similar to that seen in transplant patients receiving immunosuppression. In addition, in body cavity–based lymphoma, infection with human herpes virus type 8 (HHV-8) has been implicated. Human papilloma virus is associated with invasive cervical cancer. Hepatitis B infection is associated with the development of hepatocellular carcinoma.[154] Kaposi sarcoma is a malignancy associated with chronic infection with HHV-8 and unique to acquired immunodeficiencies seen in transplant and AIDS patients.[181] Its true incidence in the pediatric AIDS population is unknown because many tumors are intraabdominal and intrathoracic; thus, they are only noted on autopsy. Cutaneous manifestations are uncommon in the pediatric age group.

Neurologic Complications

CNS involvement occurs in 20% to 60% of HIV-infected children.[182] The clinical manifestations of CNS involvement are many, but generally it is the comatose patient with AIDS in the ICU who is a diagnostic dilemma. In this situation, treatable conditions must be ruled out before the diagnosis of AIDS encephalopathy can be made. Acute neurological manifestations include seizure disorders, cerebral vascular accidents, CNS lymphoma, and aseptic meningitis. Evaluation of these patients generally requires a series of biochemical and radiological tests. Biochemical tests can reveal hyponatremia, hypoglycemia, and hyperammonemia, which can arise from severe malnutrition, hepatic dysfunction, and pancreatitis. A toxicology screen can rule out ingestion. Imaging studies such as CT and magnetic resonance imaging (MRI) can reveal mass-occupying lesions such as intracranial hemorrhage, malignancies, or calcifications consistent with infection.[183] Lumbar puncture is necessary to rule out infection and cerebral spinal fluid should be routinely cultured and investigated for specific pathogens.

Human Immunodeficiency Virus Encephalopathy

Primary HIV infection of the CNS probably occurs in 4% of HIV-infected children by the age of 12 months.[183] This entity is termed HIV encephalopathy and can generally

be divided into two types: static with developmental delay or progressive similar to AIDS dementia in adults with progressive decline in neurologic functioning.[185] Direct HIV infection of the macrophages and microglia of the CNS is thought to cause release of inflammatory neurotoxins such as TNF or platelet-activating factor. Pathologically gliosis, microglial nodules, demyelination, and multinucleate giant cells are seen. Spinal cord examination similarly shows degeneration of corticospinal tracts, which clinically present as spastic diplegia. Vacuolar myelopathy involving the lateral and posterior columns, that presents as progressive muscle wasting and sensory loss, has also been observed in children.[182,184]

Diffuse atrophy is noted on CT.[186] Bifrontal white matter abnormalities are commonly seen on MRI.[183-186] In more severe cases periventricular and centrum semiovale hypodense areas may occur. One third of infected children may show calcifications of the basal ganglia. Calcifications observed before age 10 months are more likely due to an infection other than HIV, such as toxoplasmosis or CMV.[186]

AIDS encephalopathy is a diagnosis of exclusion. Other pathogens must be ruled out. Therefore evaluation includes imaging of the brain by CT or MRI and blood and CSF studies in search of specific pathogens such as cryptococcus, mycobacterium, CMV, HSV, varicella-zoster virus, and *Treponema pallidum*. If no alternative pathogen is identified, then therapy is directed at reducing the HIV RNA viral load.[187]

Cerebrovascular Disease

Vascular complications involving the CNS in HIV-infected patients are many.[188] A cerebral vasculopathy was reported to occur in 25% of patients who underwent an autopsy. Although infarctions were first thought to be a consequence of direct HIV injury to the vascular endothelium, others now argue that the vascular injury results from other infections.[189,190] Cerebral vasculitis has been reported in CMV, HSV, neurosyphilis, and other infections of the CNS, even when they occur in non–HIV-infected patients. A hypercoagulable state associated with elevated levels of anticardiolipin antibody and antiphospholipid antibody, decreased levels of protein S, and a clinical condition similar to thrombotic thrombocytopenic purpura has also been described in association with HIV infection.[191] Although stroke is common in patients with AIDS, intracranial hemorrhage is relatively rare. Autoimmune-mediated thrombocytopenia, diffuse intravascular coagulation, and CMV infection have been reported to lead to intracranial hemorrhage in patients with AIDS.[182,188,192,193]

Central Nervous System Malignancy

High-grade B-cell lymphoma is found in 4% of HIV-infected children and is the most common mass lesion found in the CNS of children with AIDS.[181,182] It generally presents between ages 5 and 10 years. Lymphoma can be distinguished from toxoplasmosis by increased uptake of tracer on single photon emission computed tomography (SPECT) or positron emission tomography (PET) imaging. It most frequently arises in periventricular white matter and is associated with EBV infection. Metastatic lymphoma can also occur.

Infections of the Central Nervous System

CNS infection by usual and opportunistic organisms in childhood AIDS accounts for only 13% of neurologic complications.[194-196] Primary CNS infections in HIV-infected children are caused by the usual etiologic bacterial organisms and *M. tuberculosis*. The usual presenting signs and symptoms are seen. Opportunistic infections such as CMV and aspergillosis are frequently observed at autopsy and generally result from disseminated disease.[194] Reactivated infections such as toxoplasmosis, herpes zoster, and progressive multifocal leukoencephalopathy caused by Jacob-Creutzfeldt virus infection also occur but are rare when compared with those in the adult population.[182,196]

The protozoal infection toxoplasmic encephalitis occurs in 30% of adult patients with AIDS but is generally seen in only older children. The incidence of maternal-fetal transmission does not appear to be affected by maternal HIV infection. Combination therapy with sulfadiazine and pyrimethamine is generally effective if initiated early. Clindamycin is an appropriate alternative in patients with sulfa allergy.[197] Corticosteroids are sometimes used in addition to first-line therapy to reduce edema. Relapse is common after treatment is stopped and maintenance therapy is necessary. Primary prophylaxis is offered to adults with serological findings that are positive for toxoplasma and a CD4 count of less than 200.

Progressive multifocal leukoencephalopathy presents with ataxia, aphasia, weakness, and lethargy.[194,198] CT may be relatively unremarkable with one or two nonenhancing hypodense areas of demyelination generally in subcortical white matter. MRI is more sensitive than CT for detection of these lesions. Presumptive diagnosis can be confirmed by stereotactic biopsy and identification of virus by DNA probes. There is no treatment for this condition, and death usually results from apnea.

Although not considered a reactivated infection, cryptococcal meningitis is typically seen in older children.[182,196] Cryptococcus spreads via the bloodstream to the CNS. Classic presentation includes fever, headache, and preceding alterations in mental status. Focal signs and meningeal signs are minimal. CSF counts may be normal, although intracranial pressure (ICP) is typically elevated. CT findings are nonspecific.

Treatment of coma in the HIV-positive patient is directed at the underlying cause. Supportive care follows the principles of therapy for all comatose patients, including airway protection, control of ICP where appropriate, and nutritional support. Specific therapy for the underlying condition must be applied. In situations in which no explanation for an acute neurologic deterioration is readily available, we have initiated antiviral therapy with ganciclovir, acyclovir, or both and awaited clinical improvement. This decision was based on evidence that CMV coinfection may be responsible for neurologic deterioration.[190,196] Some improvement has been reported in patients with HIV encephalopathy who were treated with ZDV or ganciclovir therapy, but the waxing and waning nature of the condition even without therapy makes any intervention difficult to evaluate.

Ethical Issues

The ethical issues surrounding the care of children with HIV infection are complex. The history of respiratory failure due to PCP pneumonia in HIV-infected patients provides a vignette that shows many of the dilemmas surrounding the care of

patients with AIDS. When the death rate was first reported as greater than 90% for these patients, many physicians refused to institute mechanical ventilation for this condition. Meanwhile, other physicians who would not concede that mechanical ventilation was hopeless eventually reported that the death rate for PCP-related respiratory failure was possibly only 50%, thereby stressing that such therapy was not futile. Physicians who were willing to try new therapies for PCP subsequently reported that the death rate could be reduced to 10% if corticosteroids were given. This story confirms that it is impossible to determine a therapy's efficacy at the outset of an individual patient's illness and a refusal to intervene only perpetuates the myth of futility. Only by continuing to care for these patients did physicians increase their clinical skills and obtain an opportunity to ultimately improve the survival of these patients.

In wealthy countries there is little doubt that children with HIV infections can be offered intensive care unless the admission diagnosis carries a grim prognosis. In developing countries the situation is much more complex. Many countries with high incidence of pediatric HIV infection simply don't have intensive care facilities for children or even adults.[199,200] Those countries with intensive for care for children may deny PICU care on the basis of ethical resource allocation.[201] The provision of invasive ventilation to HIV-infected children with severe pneumonia may not be successful without access to antiretroviral therapy.[202] Even if short-term patient outcomes improve, HIV infected children may be denied care based on long-term prognosis or resource utilization.[83]

Occupational Human Immunodeficiency Virus Exposure

Serious exposure to HIV in the health care setting is most likely to occur in the emergency department or ICU. The risk of exposure is 0.3% after a percutaneous exposure, and 0.09% after blood or body fluid contact with non-intact skin or mucous membrane. Risk assessment is based on the viral load, the volume of exposure, the type of exposure and the possibility of drug resistance.[171] Treatment recommendations of two versus three medications are based on the degree of risk. Most facilities have a contact person and procedure to begin prophylaxis within 2 hours.

Summary

A critically ill child with a life-threatening infection or trauma should be presumed to be immunodeficient. The approach to such patients requires selective surveillance and a low threshold for empiric therapy. Through experience, patterns of infections characteristic of specific immunodeficient states can be recognized, but the unusual presentation is always possible. In the future, immune stimulants may also be part of the physician's armamentarium, in addition to antimicrobial therapy.

Bacterial Infection, Antimicrobial Use, and Antibiotic-Resistant Organisms in the Pediatric Intensive Care Unit

John S. Bradley, Christopher R. Cannavino, Deborah E. Franzon, and Susan Duthie

PEARLS

- Delays in initiation of treatment are associated with worse outcomes. Early aggressive empiric therapy with broad-spectrum antibiotics will obtain the best clinical and microbiologic outcomes.
- The basic mechanisms of resistance include (1) alteration of the antibiotic structure by bacterial enzymes, (2) alteration of the antibiotic's target site within the pathogen, (3) extrusion of the antibiotic from the organism by efflux pumps, and (4) changes in the cell wall that prevent movement of the antibiotic into the organism.
- The prevalence of community-acquired methicillin-resistant *Staphylococcus aureus* has increased over the past decade.
- Antimicrobial stewardship programs that include implementing strategies that reduce unnecessary antimicrobial use, optimizing dose and duration, and minimizing adverse affects of antimicrobials can be cost-effective programs that address resistance in the intensive care unit setting.

Because of the severity of illness of children in the pediatric intensive care unit (PICU), there is little room for error in selecting the appropriate agent or combination of agents to treat bacterial infections. Antibiotic resistance has been increasing for both community-acquired pathogens and nosocomial pathogens, which has madethe task of antibiotic selection increasingly difficult. Each PICU has access to the susceptibility patterns of both community-acquired and nosocomial pathogens from the institution's microbiology laboratory, which tracks antibiotic resistance of isolated pathogens and distributes these data within the hospital as the antibiogram. These data can provide the clinician with the percentage of each pathogen that is susceptible to each antibiotic.

It is important to treat infections aggressively to obtain the best clinical and microbiologic outcomes. Judicious use of antibiotics is also important to reduce antibiotic pressure on pathogens and reduce the creation of antibiotic resistance. This chapter reviews the most clinically important classes of antibiotics, including those currently under investigation and not approved by the U.S. Food and Drug Administration (FDA) for use in children. Many textbooks about infectious diseases have excellent in-depth reviews of antibiotic characteristics,[1-3] and an annually updated review of all available, the FDA-approved document published by the American Society of Health-System Pharmacists.[4] Mechanisms of antibiotic resistance are reviewed, as is antibiotic therapy designed to meet the challenge of currently isolated antibiotic-resistant organisms. Tissue penetration characteristics and dosing of the antibiotic are critical; pharmacodynamic characteristics of different classes of antibiotics against different types of pathogens often help determine the dosing regimen required for microbiologic and clinical cure.[5,6] Inadequate dosing of antibiotics may actually facilitate the development of antibiotic resistance.[7] Timing of the first dose of antibiotics is also critical, and delay may increase morbidity and mortality.[8-10]

Antibiotic Classes

β-Lactam Antibiotics

β-Lactam antibiotics are a diverse group of antibiotics. The β-lactam ring that characterizes these compounds is usually attached to a ring structure that defines the class of antibiotic agents as penicillins, cephalosporins, carbapenems, or monobactams (Figure 94-1). The β-lactam structure is thought to interfere with bacterial cell wall synthesis and repair by preventing transpeptidation and transglycosylation of the pentapeptide precursors in the formation of peptidoglycan in the creation of the cell wall.[11] The target transpeptidase enzymes, also known as *penicillin-binding proteins* (PBPs), are vital for creating cell wall integrity to maintain the osmotic gradient between the organism and the external environment. The PBPs carried by different bacterial species have different

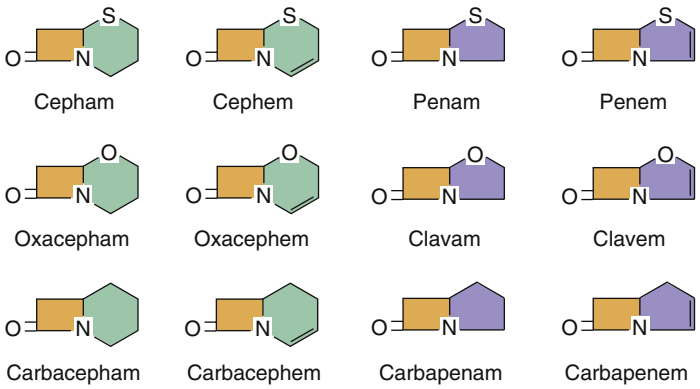

Figure 94–1. Structures of β-lactam antibiotics.

structures, leading to differences in the binding affinity for various β-lactam agents. Each organism may actually produce several PBPs. As a class of antibiotics, β-lactam are bactericidal at concentrations up to 2 to 4 times the minimum inhibitory concentration (MIC) of the agent.

Penicillins

Penicillins were the first agents of the β-lactam class to be developed and can be divided into groups that are based largely on spectrum of activity and chemistry: the natural penicillins (penicillin G, penicillin V), the aminopenicillins (ampicillin and amoxicillin), the penicillinase-resistant penicillins (methicillin, oxacillin, nafcillin), and the extended-spectrum penicillins (carbenicillin, mezlocillin, ticarcillin, piperacillin). Penicillin G was discovered by Alexander Fleming more than a half century ago and is primarily active against gram-positive organisms, both aerobic and anaerobic. The aminopenicillins are more active against gram-negative organisms such as *Escherichia coli* and *Haemophilus influenzae*. Penicillinase-resistant penicillins were developed to meet the challenge of the rapid development of penicillinase-mediated resistance in *Staphylococcus aureus*. These penicillinase-resistant penicillins are all active against *S. aureus*, except methicillin-resistant *S. aureus* (MRSA). They are also active against streptococci (except *Enterococcus* spp.). Nafcillin differs pharmacologically from the others in being excreted primarily by the liver rather than by the kidneys. Nafcillin displays a relative lack of nephrotoxicity compared with methicillin. Oxacillin also has a better renal safety profile than methicillin. Long-term, high-dose use of all β-lactam agents may be associated with reversible neutropenia.

The extended-spectrum penicillins all display enhanced gram-negative activity compared with the aminopenicillins. There are some variations in the activity demonstrated against *Klebsiella, Enterobacter, Serratia, Citrobacter,* and *Pseudomonas*. All the agents in this class are susceptible to the type I, chromosomal β-lactamases that are inducible or constitutively produced in strains of *Enterobacter, Serratia, Citrobacter,* and *Pseudomonas.* Exposure to the extended-spectrum β-lactams will select out strains that constitutively produce these β-lactamases. These strains are considered antibiotic resistant. Some experts think that the addition of an aminoglycoside to the β-lactam agent will prevent or retard the emergence of β-lactam resistance. In addition, the extended-spectrum penicillins are susceptible to the newly evolving plasmid-mediated extended-spectrum β-lactamases (ESBLs), which are constitutively produced by organisms that harbor them. Piperacillin and ticarcillin are currently the only available extended-spectrum penicillins in the United States and only in fixed combinations with β-lactamase inhibitors.

β-Lactam Antimicrobial plus β-Lactamase Inhibitor Combination

Timentin, (ticarcillin/clavulanate), Zosyn (piperacillin/tazobactam), and Unasyn (ampicillin/sulbactam) are all combinations of two β-lactam drugs. The first β-lactam drug, the true antibiotic, effectively binds to the target site in the bacteria and results in the death of the organism, assuming that the second β-lactam drug neutralizes the organism's β-lactamase. The second β-lactam drug has poor intrinsic activity as an antibiotic but still displays high affinity to and may bind irreversibly to and neutralize the β-lactamase enzyme the organism has produced. This agent is also known as a β-*lactamase inhibitor*. The combination adds to the spectrum of the original antibiotic when the mechanism of resistance is a β-lactamase enzyme. Not all β-lactamase inhibitors have an equal ability to inhibit all β-lactamases. Timentin and Zosyn have no significant activity against *Pseudomonas* beyond that of ticarcillin or piperacillin because their β-lactamase inhibitors do not effectively inhibit the β-lactamases of *Pseudomonas*. In general, the β-lactamase inhibitors present in the antibiotics Timentin, Zosyn, and Unasyn do not inhibit the adenosine monophosphate 3′5′ (AmpC), type 1 chromosomal β-lactamases present in *Enterobacter, Serratia*, and *Citrobacter*. They do, however, inhibit enzymes present in a number of other pathogens, including the β-lactamases often present in strains of *H. influenzae*, *Bacteroides fragilis*, and *S. aureus*.

Cephalosporins

Cephalosporins can be distinguished on the basis of activity against gram-negative pathogens and stability of the antibiotic to a number of the gram-negative β-lactamases. The cephalosporins fall roughly into five categories ("generations") on the basis of these characteristics. First-generation cephalosporins (cephalothin, cefazolin) are active against most strains of *E. coli* but are not entirely stable to the β-lactamases produced by some strains of *E. coli* and *H. influenzae*. The activity of these antibiotics against gram-positive pathogens such as *S. aureus* is close to that of oxacillin and nafcillin; however, none of the current cephalosporin antibiotics of any generation displays reasonable activity against the enterococci. Clinically relevant activity against *B. fragilis* does not exist for the first-generation

cephalosporins. The second-generation cephalosporins (cefamandole, cefuroxime) have chemically increased intrinsic activity against gram-negative organisms, including *E. coli* and *Klebsiella*. They are also more stable against the principal β-lactamases of *E. coli* and *H. influenzae*. Activity against *S. aureus* is significantly decreased compared with the first-generation cephalosporins but is sufficient to achieve clinical success in many situations and to warrant FDA approval for treatment of these organisms. A slightly different group of antibiotics, the cephamycins (cefoxitin, cefotetan), have activity against the gram-negative enteric bacilli similar to the second-generation cephalosporins but display enhanced anaerobic activity against *B. fragilis* and may play a role in the treatment of intra-abdominal infections. Their activity against *B. fragilis*, however, is inferior to metronidazole, clindamycin, or the carbapenems.The third-generation cephalosporins, cefotaxime and ceftriaxone, have enhanced stability against the most prevalent β-lactamases of *H. influenzae*, *E. coli*, and *Klebsiella* and enhanced activity against many of the enterobacteriaceae but are, unfortunately, not stable to the inducible chromosomal β-lactamases (AmpC, type I) of *Enterobacter*, *Serratia*, or *Citrobacter*. Ceftazidime, another third-generation cephalosporin, has far greater intrinsic activity against *Pseudomonas aeruginosa* than previous cephalosporins, but it too is degraded by the inducible chromosomal β-lactamases of *Enterobacter, Serratia,* and *Citrobacter*, as well as the chromosomal β-lactamases of *Pseudomonas*. None of the third-generation cephalosporins are as active against *S. aureus*. Cefepime, a fourth-generation cephalosporin, has the best overall activity against both gram-negative and gram-positive pathogens, with activity against *P. aeruginosa* equivalent to ceftazidime and activity against *S. aureus* equivalent to second-generation cephalosporins. It is also the most stable to β-lactamase degradation by all but some of the ESBL class of β-lactamases. The novel fifth-generation cephalosporins, ceftobiprole and ceftaroline, are the first β-lactam antibiotics with activity against MRSA. Ceftobiprole was recently approved by the FDA for the treatment of complicated skin and skin structure infections in adults. Ceftaroline is currently in phase III clinical development. In addition to activity against MRSA, the fifth-generation cephalosporins have a spectrum of activity similar to that of third- and fourth-generation cephalosporins. Ceftobiprole also exhibits in vitro activity against enterococci and *Pseudomonas*. Ceftaroline is not reliably active against ESBLs, whereas ceftobiprole has activity against *P. aeruginosa* similar to that of cefipime. Although still in phase III trials, ceftobiprole has potential for use as empiric monotherapy for serious infections in the ICU because it has activity against both MRSA and *P. aeurignosa*.[12]

Carbapenems

Three carbapenems, imipenem (combined with cilastin, an inhibitor of a renal tubular dehydropeptidase enzyme, to avoid nephrotoxicity), meropenem, and ertapenem are currently FDA approved in pediatric patients older than 3 for treatment of complicated skin and skin structure infections (SSI), complicated intra-abdominal infections, and meningitis. Pediatric clinical investigation of doripenem, a fourth-generation carbapenem recently FDA approved for adults, is ongoing. The carbapenems have a β-lactam ring structure that differs slightly from the penicillins and cephalosporins (see Figure 94-1), with chemical modifications to enhance activity and stability similar to those of cephalosporins. The broad antimicrobial spectrum of activity of the carbapenems is similar and includes gram-negative, gram-positive, and anaerobic organisms. Relevant gram-negative pathogens include enteric bacilli such as *E. coli*, *Klebsiella*, *Enterobacter*, and *Citrobacter* in addition to *P. aeruginosa*. They are active against gram-positive organisms including *S. aureus* and streptococci, although activity against the enterococci is substantially less than penicillin G or ampicillin. Meropenem is slightly more active against gram-negative pathogens and imipenem is slightly more active against gram-positive pathogens, although there is probably no clinical significance in these differences for most infections being treated. Although not FDA approved for the treatment of nosocomial pneumonia, meropenem has been shown to be effective in numerous clinical trials. Both agents are active against anaerobes, including β-lactamase–positive strains of *B. fragilis*. Ertapenem has a similar spectrum of activity to the other carbapenems, although intrinsic activity against *P. aeruginosa* is less than that of the other carbapenems. Nevertheless, it has a prolonged serum elimination half-life compared with the other agents, allowing for once- or twice-daily therapy compared with three or four times daily. Doripenem was recently approved for the treatment of complicated intra-abdominal and complicated urinary tract infections in adults. Its spectrum of activity is similar to the other carbapenems; however, it appears to have more potent in vitro activity against *P. aeruginosa*.

With respect to toxicity, the carbapenems are well tolerated, although imipenem displays interference with central nervous system (CNS) γ-aminobutyric acid inhibition of neuron activity and was shown to be associated with an increase in seizure activity in children treated for bacterial meningitis compared with historic controls.[14] On the basis of these observations, meropenem is the preferred carbapenem for children at risk for seizures or with CNS infections and inflammation. Meropenem is well tolerated in children. In pediatric trials, diarrhea and rash occur in less then 5%, and drug-related seizures were not observed in children with meningitis treated with meropenem.

Monobactams

Aztreonam, the only monobactam currently available, has a unique chemical structure in which the β-lactam ring is not attached to an adjacent 5- or 6-membered ring but does have chemical additions to the β-lactam ring that enhance activity and stability to β-lactamases. It displays aerobic, gram-negative activity, including activity against many strains of *P. aeruginosa*.

Aminoglycosides

Aminoglycoside antibiotics are bactericidal in a concentration-dependent fashion against a wide range of aerobic pathogens. The first antibiotic in this class, streptomycin, was isolated from *Streptomyces griseus* and was first available in 1944. Subsequently, other aminoglycosides have been isolated from fungi, and chemical modifications to enhance activity and decrease toxicity have been made to older agents. These agents inhibit protein synthesis by irreversible binding to the 30S ribosomal subunit. The gram-negative spectrum of activity is extensive, including enteric bacilli (*E. coli*, *Klebsiella, Enterobacter, Serratia*), *P. aeruginosa*, and many free-living gram-negative bacilli that may only be pathogenic for

immunocompromised children or those with trauma in which environmental contamination of deep tissues has occurred. These antibiotics have no clinically relevant anaerobic activity.

Although the first aminoglycosides exhibited substantial renal toxicity and ototoxicity, subsequent agents are significantly safer. With serum concentrations present within the therapeutic range, renal toxicity and ototoxicity are unusual. The most widely available parenteral agents are gentamicin, tobramycin, and amikacin. Because of the relatively low serum concentrations necessary to prevent toxicity and poor penetration into the spinal fluid, these agents are not used as primary therapy of CNS infections. Direct intrathecal instillation should also not be considered routinely for CNS infections because data collected during a prospective study of aminoglycosides as adjunctive therapy in neonatal gram-negative meningitis revealed higher rates of morbidity.[15] Streptomycin, the most toxic of the aminoglycosides, continues to be used infrequently in the treatment of tuberculosis, plague, and tularemia in children.

Caution should be exercised in the use of these agents in undrained abscess infections, including intraabdominal infections. The acidic and anaerobic conditions present in abscesses produce MICs against aerobic gram-negative organisms that are 10 times higher than those documented under ideal laboratory conditions.[16]

Aminoglycosides have demonstrated excellent clinical efficacy against susceptible organisms. Nevertheless, the toxicity of the antibiotics may preclude the attainment of serum and tissue concentrations that are severalfold higher than the MICs of the pathogens. Synergy between a β-lactam agent and an aminoglycoside in bacterial killing can be demonstrated against many gram-negative pathogens. For the critically ill or immunocompromised child, a combination of agents is often used to obtain the maximal antibiotic killing. In addition, some experts believe that the combination will retard the emergence of antibiotic resistance in gram-negative organisms containing inducible AmpC, chromosomal β-lactamases.

Glycopeptides

Vancomycin is currently the only available glycopeptide in the United States, although teichoplanin is available in other areas of the world and a new generation of glycopeptides is presently in clinical trials in adults. The glycopeptides are primarily active against gram-positive organisms, both aerobic and anaerobic. This class of antibiotic is cell wall active, as are the penicillins, but has a different mechanism of action in prevention of pentapeptide cross-linking in the formation of cell wall peptidoglycan.

Vancomycin is bactericidal against virtually all strains of staphylococci and against most strains of streptococci, although it is bacteriostatic against the enterococci. Resistance to vancomycin is noted to occur in strains of *Enterococcus faecium* (vancomycin-resistant enterococcus [VRE])[17] and has now been described in *S. aureus*.[18]

The tissue distribution of vancomycin is extensive, with elimination of unchanged antibiotic by the kidney. Dosage adjustment is required in renal insufficiency. Penetration into the cerebrospinal fluid (CSF) is not well studied and is erratic. Serum concentrations of approximately 40 μg/mL are thought to be necessary to achieve CSF concentrations sufficiently high enough to achieve a reliable microbiologic cure in meningitis or ventriculitis. The toxicities of vancomycin are primarily nephrotoxicity and ototoxicity. As with the aminoglycosides, close attention to serum antibiotic concentrations will avoid clinically significant toxicity.

The new generation glycopeptides, dalbavancin, telavancin, and oritavancin, are undergoing clinical trials. Telavancin, a lipoglycopeptide, was recently FDA approved in adults for the treatment of complicated skin or skin structure infections caused by gram-positive organisms.

Macrolides

Although erythromycin and related macrolides have been primarily used in the outpatient arena, they may be required in the PICU for children with severe pertussis or atypical pneumonia, or in children with extensive drug allergy precluding the use of standard anti-infective agents. The macrolides bind to the 50S ribosomal subunit of susceptible bacteria to prevent the formation of peptide chains, thereby inhibiting protein synthesis. Macrolides are primarily bacteriostatic at achievable tissue concentrations. Erythromycin is available for parenteral use as a lactobionate salt, whereas clarithromycin is only available as an oral agent. Azithromycin is composed of a 15-member ring structure and is considered an azalide. It is available in both oral and parenteral forms. In general, both clarithromycin and azithromycin are better tolerated than erythromycin because of the lack of degradation products seen with erythromycin that stimulate motilin receptors and lead to nausea, vomiting, and abdominal cramps. The macrolides have traditionally been used in the treatment of nonserious infections caused by group A streptococci, *S. aureus*, and *Streptococcus pneumoniae*. Both clarithromycin and azithromycin exhibit enhanced activity against respiratory gram-negative pathogens (e.g., *H. influenzae*). In addition, azithromycin has potential efficacy as a modulator of airway hyperresponsiveness,[19] even in the absence of overt infection,[20] that may have a role for children in the ICU with community-aquired pneumonia and exacerbation of underlying chronic lung disease or asthma.

Ketolides are a new class of antibiotics structurally similar to macrolides with enhanced bacterial ribosomal binding. Telithromycin is the first FDA-approved ketolide for treatment of community-acquired pneumonia in adults, including some multidrug-resistant strains of *S. pneumoniae* and group A streptococcus.[21] Reports of significant hepatotoxicity with telithromycin[22] use may limit further investigation in children. In addition, there is a "black box" warning for patients with myasthenia gravis.

All the macrolides demonstrate activity against *Mycoplasma pneumoniae*, *Chlamydia, Legionella,* and *Bordetella pertussis*. Macrolides are metabolized by cytochrome P450 enzymes, which cause potential drug-drug interactions (see Chapter 118). These interactions have been well documented with erythromycin and clarithromycin but appear to be absent with azithromycin. Clarithromycin and azithromycin achieve high intracellular concentrations, with demonstrated efficacy against intracellular pathogens. Clarithromycin and azithromycin also demonstrate activity against a number of nontuberculous mycobacteria.

Fluoroquinolones

This class of broad-spectrum agents has been extremely successful in adults over the past 20 years. Because of concerns regarding cartilage toxicity in weight-bearing joints of

experimental animals, however, pediatric studies were not undertaken. With the emergence of resistance to β-lactam agents in *S. pneumoniae,* increasing resistance in gram-negative pathogens, and the need for an oral agent in the treatment of *P. aeruginosa* and other resistant gram-negative pathogens, pediatric studies began in earnest in 1998. Ciprofloxacin, the first of the agents approved for use in adults, shows outstanding activity against *P. aeruginosa*, as well as many enteric bacilli causing both nosocomial infections (*E. coli*, *Klebsiella, Enterobacter, Serratia, Citrobacter*) and gastrointestinal infections (*Salmonella, Shigella, Campylobacter, Yersinia,* and *Aeromonas*). Although resistance to ciprofloxacin in *P. aeruginosa* and other bacilli has been increasing, susceptibility in pediatric inpatient units has remained reasonable. Ciprofloxacin is FDA approved in children older than 1 year for the treatment of complicated urinary tract infections, pyelonephritis, and postexposure treatment of inhalational anthrax. Subsequent chemical modifications of fluoroquinolones have resulted in a set of agents with good to excellent activity against gram-positive cocci, including group A streptococcus, *S. pneumoniae*, and *S. aureus*. These agents—levofloxacin, gatifloxacin, trovafloxacin, and moxifloxacin—are effective in both gram-positive and gram-negative infections. Successful pediatric investigations have been performed in pediatric bacterial meningitis (trovafloxacin), community-acquired pneumonia (levofloxacin), and otitis media (gatifloxacin and levofloxacin). Because of concerns for possible hepatotoxicity, trovafloxacin is used for serious infections only. After reports of an association with dysglycemia in adults, gatifloxacin is no longer being manufactured. Although case reports of possible cartilage toxicity exist, no documented case unequivocally caused by fluoroquinolones in children has been published in any prospective study.[23] A policy statement by the American Academy of Pediatrics Committee on Infectious Diseases states that "fluoroquinolone use should be restricted to situations in which there is no safe and effective alternative to treat an infection caused by multidrug-resistant bacteria or to provide oral therapy when parenteral therapy is not feasible and no other effective oral agent is available."

The mechanism of action of quinolones involves inhibition of DNA synthesis by interference with two bacterial enzymes. The activity of each specific quinolone and the rapidity of the development of resistance to the specific quinolone depend on the relative activity of the quinolone against these enzymes.[24]

Miscellaneous

Clindamycin

A member of the lincosamide family, clindamycin, as with erythromycin, inhibits the growth of bacteria by binding to the 50S subunit of the ribosome. Clindamycin is active against gram-positive organisms and many anaerobes, including most strains of *B. fragilis*. Activity against β-lactam–resistant strains of *S. pneumoniae* and *S. aureus* (MRSA) has led to increased use of clindamycin in children.[25]

In children with infection caused by strains of *S. aureus* or group A streptococcus that are suspected to produce toxin-mediated disease (e.g., toxic-shock syndrome, necrotizing fasciitis), clindamycin is often used (in conjunction with a β-lactam agent) to stop toxin production as quickly as possible. Retrospectively collected data suggest improved outcomes in patients treated with the combination.[26] Clindamycin may be used for treatment of MRSA skin infections and pneumonia; however, it is not recommended as the sole agent for critically ill patients with MRSA infections. In necrotizing infections, the addition of clindamycin to the treatment regimen may decrease the production of the Panton-Valentine leukocidin and other exotoxins.[27,28] Although diarrhea is relatively common with clindamycin (10% to 20%), *Clostridium difficile*–mediated pseudomembranous colitis occurs infrequently (approximately 0.1%) in children.

Linezolid

Linezolid is the first in a class of new antibiotics, the oxazolidinones. These antibiotics are protein synthesis inhibitors that interfere with mRNA binding at the 30S ribosome subunit. Linezolid is a bacteriostatic agent useful in the treatment of infections caused by gram-positive organisms, including MRSA and coagulase-negative staphylococci, VRE, as well as β-lactam and macrolide-resistant strains of *S. pneumoniae*. Linezolid has been studied and has received FDA approval for use in pediatric patients, including the neonatal age group. Linezolid is approved for the treatment of comminity- and hospital-acquired pneumonia, complicated and uncomplicated skin and soft tissue infections, and bacteremia caused by vancomycin-resistant organisms.

Linezolid is excreted by nonrenal mechanisms, although the oxidative metabolites are eliminated by the kidney. No dosage adjustment is recommended in renal insufficiency or in mild to moderate hepatic insufficiency. A concern that appears to have little clinical relevance in healthy children treated under controlled conditions is the drug's nonselective, reversible inhibition of monamine oxidase. Nevertheless, this drug interaction profile has potential impact on the patient in the PICU who is receiving adrenergic or serotonergic drugs. Linezolid has been reported to be associated with hematologic side effects and rarely with optic neuritis and peripheral neuropathy.

Metronidazole

A nitroimidazole derivative first available in 1957, metronidazole has remained a safe and effective antibiotic for parasitic and anaerobic bacterial infections. The primary use of metronidazole in the PICU includes infections caused by β-lactamase–positive strains of *B. fragilis* (intra-abdominal infections) and those caused by *C. difficile* (pseudomembranous colitis). Resistance to metronidazole has not been a clinical problem despite significant clinical use. Little is known about the mechanism of action. The distribution of drug in tissues is extensive, including CNS penetration. It has been a standard component of therapy for anaerobic deep tissue space infections and has been used in the treatment of anaerobic brain abscesses. It is the agent of choice (by the oral route, if possible) for the therapy of *C. difficile* colitis. It is metabolized by hepatic mechanisms and eliminated by renal pathways; therefore some dosing adjustments are required in patients with hepatic insufficiency. Less is known about dosing adjustments required in renal insufficiency.

Colistin

With antibiotic resistance increasing dramatically in gram-negative pathogens, colistin has returned to clinical use and now represents therapy of last resort for organisms resistant to all other available antibiotic therapy.[29]

Colistin (colistimethate), or polymixin E, has broad-spectrum bactericidal activity against gram-negative organisms by acting as a cationic detergent, destroying the bacterial cytoplasmic membrane. This agent may have a role in treatment of infections caused by gram-negative pathogens (e.g., *P. aeruginosa*, *Acinetobacter, Enterobacter, Klebsiella*) that are resistant to all other agents. Colistin has no activity against gram-positive organisms or against *B. fragilis*. The renal toxicity may manifest as decreased urine output, increasing blood urea nitrogen and creatinine, proteinuria, hematuria, and acute tubular necrosis. Peripheral neuropathy, confusion, coma, and seizures may occur. The drug is renally eliminated, and dosage adjustment is required with renal insufficiency. Current adult data suggests less toxicity than originally reported. Limited data in pediatric burn and critical care patients also suggest colistin is effective and safe for multidrug-resistant gram-negative infections.[30,31] In addition, aoerosolized colistin has been used as an adjunctive or monotherapy for gram-negative pulmonary infections. Clinically significant bronchospasm may occur.

Tigecycline

Tigecycline is the first in a new class of antibiotics, the glycylcyclines. Tigecycline inhibits protein synthesis and is generally considered a bacteriostatic agent. It is a derivative of minocycline, although not classified as a tetracycline. It has broad-spectrum antibacterial activity against gram-positive and gram-negative aerobes and anaerobes, including MRSA and multidrug-resistant gram-negative bacteria. It is not effective against *Pseudomonas, Provedentia,* and *Proteus* species. Tigecycline is approved for use in adult patients with complicated skin and SSIs, complicated intraabdominal infections, and community-acquired pneumonia. It is not approved for the treatment on hospital-acquired pneumonia, having demonstrating inferior efficacy in a study of ventilator-associated pneumonia. Tigecycline is mainly excreted unchanged into bile, with only 10% to 15% excreted unchanged in the urine. No dosage adjustment is necessary with renal insufficiency. Dose adjustment is necessary for patients with severe hepatic impairment.

Anaphylaxis and anaphylactoid reactions in patients allergic to tetracyclines have been reported. Similar to tetracyclines, permanent discoloration of teeth when used in patients younger than 8 years can occur. The role of tigecycline in the pediatric population has yet to be defined.

Daptomycin

Daptomycin belongs to a new class of antibiotics, the lipopeptides. Daptomycin disrupts the cell membrane and is rapidly bacteriocidal. It has a broad range of activity against all gram-positive bacteria including methicillin, vancomycin, and linezolid resistant organisms. It should not be used to treat pulmonary infections because surfactant inhibits its activity. Daptomycin is currently approved for use in adults with complicated skin and skin structure infections as well as right-sided endocarditis and staphylococcal bacteremia. A recent review of daptomycin therapy in invasive gram-positive infections in children showed its addition to the treatment regimen resulted in bacteriologic cure in six of seven patients with persistent bacteremia and was well tolerated.[32]

Daptomycin is excreted by the kidney and dosage adjustment must be made with renal insufficiency. The primary toxicity seen is a dose-dependent, reversible myopathy that can be monitored by elevation in serum creatinine phosphokinase.

Antibiotic Resistance

In the PICU, the clinician will encounter both community-acquired and hospital-acquired infections. Community-acquired infections caused by *S. aureus* and *S. pneumoniae* are increasingly problematic because of antibiotic resistance. Nosocomial infections may be caused by antibiotic-resistant gram-positive cocci (*Staphylococcus* spp., *Enterococcus* spp.) or gram-negative bacilli (enteric bacilli, *P. aeruginosa*, *Acinetobacter* spp., and other nonfermenting gram-negative rods). Antibiotic resistance may lead to increased morbidity and mortality as well as increased health care costs.[33]

Antibiotic Resistance Mechanisms

In the ICU, antibiotic use is extensive, resulting in selective pressure for antibiotic-resistant pathogens. Antibiotic resistance is not a new phenomenon. Bacteria are capable of surviving in an environment containing antibiotics by the expression of one or more of many different potential antibiotic resistance mechanisms. The basic mechanisms of resistance can be divided into two broad categories.[34] The first is by accumulation of multiple genes, each coding for resistance, that occur typically on resistance (R) plasmids and include (1) alteration of the antibiotic structure by bacterial enzymes, (2) alteration of the antibiotic's target site within the pathogen (by mutation at the binding site or enzymatic alterations of the binding site), or (3) changes in the cell wall that prevent movement of the antibiotic into the organism. The second basic mechanism may occur by extrusion of the antibiotic from within the organism by efflux pumps. Although community-acquired pathogens most often express only one mechanism of resistance, nosocomial pathogens may express many of these mechanisms simultaneously, and the result is a high degree of antibiotic resistance. In addition, the regulation of resistance gene expression may be altered to allow increased production of the gene product that leads to resistance.

Genes encoding antibiotic resistance may be shared between organisms within a species or between species. The transfer of antibiotic resistance genes by plasmids is a common method by which resistance is shared between bacteria. The description of mobile genetic elements helps explain the rapid development and spread of antibiotic resistance within the pathogens responsible for nosocomial infections.[35] Antibiotic resistance gene cassettes have the ability to assemble on integrons, that in turn may be associated with transposons, that are capable of "jumping" from plasmids to chromosomes, or vice versa, and from one segment of nucleic acid to another.[36] Antibiotic resistant mutants normally exist at low frequencies in any given population of bacteria. Antibiotic exposure is often the selection pressure allowing these otherwise silent mutants to achieve significant numbers, leading to treatment failure.

The clinical expression of antibiotic resistance may involve several different mechanisms operating simultaneously within a pathogen, with each mechanism expressed to a different degree on the basis of the regulation of resistance at a molecular level. For example, an organism with a weak β-lactamase that appears susceptible to an antibiotic in vitro may acquire an efflux pump, may develop porin deficiency, or both.

Either of these additional mechanisms will lead to a much lower concentration of antibiotic intracellularly, allowing the weak β-lactamase the opportunity to degrade the antibiotic before significant cell injury can occur. Most often, when a laboratory tests for susceptibility of a pathogen to an antibiotic, the sum of all resistance mechanisms (except those that may require induction) leads to an in vitro determination of susceptibility that the clinician must use to determine the best agent(s) for treatment.

Antibiotic Resistance and Infections in the Pediatric Intensive Care Unit

Current clinical challenges relate to pathogens that display newer resistance patterns. The ESBL-producing gram-negative pathogens are resistant to extended-spectrum penicillins, third-generation and some fourth-generation cephalosporins, with a proportion of these organisms also demonstrating decreased susceptibility to aminoglycosides, carbapenems, and fluoroquinolones. Some of these organisms are susceptible to β-lactam/β-lactamase inhibitor combinations. Outbreaks caused by ESBL-producing *Klebsiella* and *E. coli* have been widely reported.[51] Outbreaks by enteric gram-negative bacilli that carry chromosomal AmpC β-lactamases (present in *Enterobacter, Serratia,* and *Citrobacter*) have been occurring for several years and continue to present challenges.[52] *Acinetobacter baumannii* has caused recent reported outbreaks, primarily from Asia and Europe. The most critical aspect of *Acinetobacter* for the clinician is the ability of the organism to acquire resistance to all classes of antibiotics. *P. aeruginosa* has always been a nosocomial problem in neonatal ICUs and PICUs.[53] The nonfermenting gram-negative bacteria, including *Stenotrophomonas, Comamonas, Chryseobacteria* spp. (previously known as *strains of Flavobacteria*), and *Acinetobacter* spp. may also cause antibiotic-resistant organism infections, particularly in the immunocompromised child.

Community-acquired MRSA is increasingly a significant pathogen in children.[54] VRE strains have been reported in pediatric hospitals, particularly in neonatal ICUs, in oncology wards, and in patients with gastrointestinal disease.[17,55]

An Approach to Therapy in the Pediatric Intensive Care Unit

General Considerations for Antibiotic Therapy

After an infection is suspected on the basis of the clinical, laboratory, and imaging characteristics of the child, appropriate cultures should be obtained. Broad-spectrum antibiotics should be administered empirically, according to the local susceptibility patterns. Data suggest that using active antibiotics in the appropriate dose without delay decreases morbidity and mortality, the overall costs of treating the infection, and the emergence of resistance. The relative activity of antimicrobial agents against gram-negative (Table 94-1) and gram-positive pathogens (Table 94-2) is provided, although clinicians should consult the local antibiogram. Published data on resistance patterns come from a variety of sources. Each collection of isolates on which resistance is reported may include information for different geographic regions, different population groups (mostly adult based), different patient comorbidities, different tissue sites of infection, and different previous antibiotic exposures.[56-58] Because few published data collections have specific information on children, it is critical that the conclusions reached in these reports be taken with caution when they are applied to pediatric patients.

On the basis of the overall clinical assessment, supported by laboratory and imaging data and the response to empiric therapy, the physician needs to decide whether to continue therapy for a complete treatment course or to stop the antibiotics if data do not support an infection as the cause of the child's clinical state. Optimal duration of antibiotic therapy for infections in the PICU is poorly defined. Monitoring serum inflammatory markers such as procalcitonin may allow optimization of both the antibiotic regimen and duration of treatment.[59]

When culture results are available, antibiotic choice can be tailored to a more narrow spectrum for completion of therapy. If a child has a multidrug-resistant infection, the risk-benefit analysis may well favor the use of an antibiotic that does not have a favorable safety profile if no other alternative exists.

Antibiotic Therapy for Specific Pathogens

MRSA is a frequently isolated nosocomial and community-acquired pathogen in PICUs. Concern about the rate of hospital-acquired MRSA infection has prompted implementation of mandatory screening and reporting in many areas.[60] Almost 60% of catheter-related blood stream infections in the PICU are caused by gram-positive bacteria.[61] Vancomycin has been considered to be a mainstay of treatment for serious staphylococcal infections. Because of a growing concern for treatment failures, and increasing MICs to vancomycin, this tenet is being questioned. Some data in the adult population suggest that the use of high-dose vancomycin (target serum concentration/minimum inhibitory concentration of ≥400 μg/hr/mL) is associated with favorable clinical outcomes. Few pediatric clinical trials have looked at the question of whether alternative antibiotics are superior to vancomycin for MRSA. A pediatric study compared vancomycin to linezolid for the treatment of nosocomial pneumonia, bacteremia, or skin and soft tissue infections; the cure rates were similar.[62] Other newer agents, including daptomycin, tigecycline, and ceftobiprole, are available. Further study is needed to evaluate the effects of combination therapy for MRSA. Nonetheless, the addition of gentamicin or rifampin should be considered for severe infections, such as endocarditis. As previously noted, the addition of clindamycin to the treatment regimen may decrease the production of the Panton-Valentine leukocidin and other exotoxins.

Vancomycin-intermediately susceptible *S. aureus* and vancomycin-resistant *S. aureus* infections are rare in children. Treatment options include linezolid or alternative agents not approved in children (e.g., daptomycin, tigecycline, ceftobiprole, telavancin). In vitro susceptibility testing should guide definitive therapy.

The incidence of vancomycin resistant enterococcal infections is increasing and has been reported to be as high as 75% for *Enterococcus faecium* in adult ICUs. Linezolid is a mainstay of treatment; however, resistance to linezolid has been reported. Daptomycin and tigecycline both have excellent activity against VRE, although there is limited pediatric experience to date. A review of pediatric patients with multidrug–resistant gram-positive infection showed that the addition

*For vancomycin-susceptible strains.

of daptomycin to the treatment regimen resulted in clinical improvement in the majority of patients, and in six of seven patients with persistent bacteremia it resulted in bacteriologic cure.[63]

Antibiotic resistance is increasing in gram-negative organisms. These organisms include extended-spectrum β-lactamase producing enteric gram-negative bacteria (*Enterobacter, Serratia*, and *Citrobacter*) and multidrug–resistant *Pseudomonas, Stenotrophomonas*, and *Acinetobacter*. Treatment for patients potentially infected with these organisms should be guided by local resistance patterns and antibiograms. For nonresistant *P. aeruginosa*, ceftazidime (or an extended-spectrum penicillin) and an aminoglycoside (tobramycin or amikacin) represent effective therapy to achieve synergy and to retard the development of β-lactam resistance. Alternatives for resistant organisms include piperacillin/tazobactam, meropenem or imipenem (with or without an added aminoglycoside), or a fluoroquinolone such as ciprofloxacin if resistance is present for β-lactams and aminoglycosides. Extended- or continuous-infusion dosing strategies with β-lactams such as Zosyn, cefepime, or meropenem for treatment of susceptible *Pseudomonas* strains in critically ill patients optimizes bactericidal exposure[64] and have been associated with improved outcomes.[65] Colistin is also an option for multidrug–resistant gram-negative infections.

S. pneumoniae has developed increasing resistance to β-lactam antibiotics, macrolides, and trimethoprim-sulfamethoxazole. For children with suspected pneumococcal meningitis or other life-threatening pneumococcal infections, the addition of vancomycin to either ceftriaxone or cefotaxime has been the standard of care until susceptibility data are available and therapy can be narrowed if appropriate. Other options for therapy of non-CNS infections caused by resistant strains include a newer generation fluoroquinolone or linezolid.

Antimicrobial Stewardship

Antibiotic resistance is a challenge in the ICU setting, where there is a constant struggle to maintain balance between appropriate treatment of known life-threatening infection and broad empiric coverage of possible life-threatening infection. Principles have been established and stewardship guidelines for optimizing antimicrobial therapy have been published by a number of organizations, including the Infectious Diseases Society of America, the Centers for Disease Control and Prevention, and the World Health Organization. It is essential for hospitals to implement oversight and accountability over antimicrobial use as a matter of patient safety. Two broad interventional strategies for antimicrobial stewardship programs (ASPs) exist. One is the prospective audit and feedback program whereby ongoing review of antibiotic utilization and recommendations for adjustments are made to providers. A second strategy uses preauthorization in which antimicrobials are restricted by the intstitution and must be justified and approved at the time of use. Many ASPs are a blend of both strategies with an integration of supplemental programs such as formulary interventions, dose optimization, educational efforts, computer-assisted decision suppport, and adaptation of local published guidelines.[66]

With the move toward computerized provider order entry as the standard of care, there are ways to leverage computerized decision support for appropriate antimicrobial selection based on diagnosis and local susceptibility profiles and dose optimization integrating patient characteristics such as renal function, allergies, and potential drug interactions while preserving clinical judgment and physician autonomy.

Ideally, outcomes should be measured such as antimicrobial consumption (defined daily dose) or antimicrobial days of therapy to assess safety and cost effectiveness of ASPs. The ICU is an ideal environment for implementation of antimicrobial stewardship because of the intense use of antimicrobials and the existence of significant drug resistance.

Summary

As medical care becomes more sophisticated and children are hospitalized for longer periods, the risk of development of complicated infections caused by multi-drug–resistant pathogens increases. The physician is constantly being challenged to deliver effective antibiotic therapy, while at the same time preventing the selection of antibiotic resistance. Knowledge of the pathogens most likely to be present and the potential resistance mechanisms in these organisms is important in selecting empiric antibiotic therapy. An appropriate collection of cultures to obtain susceptibility information on the pathogens is crucial to optimize subsequent therapy and minimize antibiotic resistance.

VI Chapter 95

Life-Threatening Viral Diseases and Their Treatment

Nicole H. Tobin, Angela J.P. Campbell, Danielle M. Zerr, and Ann J. Melvin

PEARLS

- Obtain serum to store for future serologic testing when viral pathogens are considered as the potential cause of a critical illness.
- Diagnostic sensitivity is generally enhanced when samples for viral culture and staining are sent as early as possible in the course of illness.
- Samples that are obtained for fluorescent antibody, whether for a herpesvirus or a respiratory pathogen, should contain adequate cells.
- Initiate empiric treatment with acyclovir rapidly when herpes simplex virus encephalitis or neonatal disease is suspected.
- Rapid antigen and fluorescent antibody tests are potentially unreliable for new pandemic viruses such as novel influenza A (H1N1); molecular testing and empiric treatment for patients at elevated risk of influenza complications may be warranted.
- Initiate appropriate infection control precautions early to prevent spread of infection to staff and other patients when viral pathogens are suspected.

Viral infections are a frequent cause of disease in individuals of all ages. In general, the spectrum of illness is varied; however, young children and those with suppressed or deficient immune systems are at higher risk of having severe disease. This chapter covers viral causes of entities commonly seen in the intensive care unit: myocarditis, hepatitis, pneumonitis, and meningitis/encephalitis. The content is focused on cause, diagnosis, and treatment, in an attempt to provide the reader with guidance for the initial management of patients with serious viral diseases in terms of diagnosis and specific antiviral therapy.

Myocarditis

Background

Although many infectious and noninfectious causes have been identified, viruses account for most cases of myocarditis.[1] The spectrum of disease ranges from asymptomatic, with only minimal changes on the electrocardiogram, to fulminant, with rapid onset of severe disease. Likewise, myocardial involvement may be focal or diffuse.[2] Most patients have an indolent illness that may progress to dilated cardiomyopathy. Because of the varied presentations and the difficulty in the establishment of a definitive diagnosis, the true incidence of myocarditis is unknown. In a large series from Sweden, 1% of myocardial biopsies from autopsies conducted over a 10-year period fulfilled the Dallas criteria[3] for myocarditis.[4]

Pathogenesis

Although the pathogenesis of viral myocarditis is not well understood, viruses appear to enter cardiac myocytes or macrophages through specific receptors and coreceptors.[5] Viral virulence is likely modified by differential coreceptor binding[6] and variations in the viral genome.[7] Myocardial damage is thought to occur at least in part as a direct result of viral infection, with active viral replication leading to myocardial necrosis.[8] Coxsackie virus protease 2A cleaves dystrophin in cultured myocytes and in infected mouse hearts. The results are impaired dystrophin function and poor myocyte contractility.[9] In addition, both humoral and cellular immune responses contribute to the pathogenesis of myocarditis,[10,11] through postinfectious autoimmune processes,[11] cytotoxic T lymphocytes, and antibody-dependent cell-mediated cytotoxicity.[12] Cytokines[13] may also cause direct myocardial injury and affect cardiac function.

Cause

The viruses most frequently associated with myocarditis are enteroviruses, particularly Coxsackie virus B, and adenoviruses (serotypes 2 and 5).[14] Many other viruses have caused myocarditis in children, including influenza A, herpes simplex virus (HSV); human immunodeficiency virus (HIV); cytomegalovirus (CMV); respiratory syncytial virus (RSV); and the mumps and measles viruses, before the widespread use of the measles-mumps-rubella (MMR) vaccine (Table 95-1). Polymerase chain reaction (PCR) of cardiac tissue from endomyocardial biopsy specimens in 34 children with a clinical diagnosis of myocarditis identified adenovirus in 44%, enterovirus in 24%, and HSV in 6%.[15] In addition to enteroviruses, adenovirus,[14] CMV, human herpesvirus 6 (HHV-6) and parvovirus B19[16] are increasingly recognized as important causes of myocarditis in adolescents and adults. Adenoviruses and enteroviruses are the viruses most frequently identified in patients with dilated cardiomyopathy.

XXX, Most frequent; XX, frequent; X, less common or rare.
*Primarily in immunocompromised hosts.
†Primarily neonates and young infants.
‡Viruses detected in endomyocardial biopsies appear to have shifted over the past few decades.[2]

Clinical Presentation

Infants with myocarditis usually have symptoms that include poor feeding, fever, irritability, and listlessness. Physical findings are consistent with congestive heart failure. Enteroviral myocarditis in infancy frequently occurs in conjunction with severe hepatitis, pneumonitis, or both and can be difficult to distinguish from bacterial sepsis.[17] The death rate may be as high as 75%. Severe dysrhythmias have been described in infants with myocardial involvement from RSV,[18] and viral myocarditis has been implicated in some cases of sudden death.[19,20] Older children and adolescents are more likely to appear for examination after a prodromal viral illness. Early symptoms include lethargy, low-grade temperature, and decreased appetite. They may have diaphoresis, dyspnea on exertion, malaise, chest pain, and palpitations. Resting tachycardia disproportionate to the amount of fever is common, and an apical systolic murmur may be heard. A subset of children and adults have fulminant myocarditis, characterized by rapid onset of symptoms, severe hemodynamic compromise, and fever.[21]

Laboratory abnormalities may include elevated white blood cell count and erythrocyte sedimentation rate.[22] Serum aspartate aminotransferase (AST) levels are often elevated,[23] as are creatinine kinase-MB levels. Cardiac troponin I may be a more sensitive measure of cardiac muscle injury in myocarditis.[24]

Electrocardiographic abnormalities are almost always present in acute myocarditis, with findings of low-voltage QRS complexes and nonspecific ST and T wave changes. Both atrial and ventricular arrhythmias may be present, including supraventricular and ventricular tachycardia, as well as conduction abnormalities. Echocardiography reveals left ventricular dysfunction, in most cases with either segmental wall motion abnormalities or global hypokinesis. Pericardial effusions are common. In one series, nondilated, thickened, and hypocontractile left ventricles (LVs) were seen in subjects with fulminant myocarditis compared with significant LV dilation and normal LV thickness in subjects with a more insidious onset. Subjects with fulminant myocarditis had more evidence of inflammation on endomyocardial biopsy and were more likely to recover ventricular function.[25] Pulmonary edema, enlarged cardiac silhouette, and prominent pulmonary vasculature may be seen on a chest radiograph. Contrast-enhanced cardiac magnetic resonance imaging (MRI) can document the location and extent of inflammation and can be used to assist in diagnosis or to guide endomyocardial biopsy [26,27]

Acute Liver Failure

Background

Acute liver failure (ALF) is a rare condition, which prior to the availability of orthotopic liver transplantation, carried a mortality of 70% to 80% (see Chapter 88). Early studies of ALF in children used the adult definition that required rapid development of severe hepatic dysfunction with the development of hepatic encephalopathy within 8 weeks of clinical jaundice in a person without a prior history of liver disease. However, due to the difficulty in assessing encephalopathy in young children and the recognition that terminal liver failure can occur in the absence of clinical encephalopathy, the Pediatric Acute Liver Failure Study (PALF) group has accepted the diagnosis of ALF in children with no history of chronic liver disease who present with biochemical evidence of acute liver injury and severe hepatic-based coagulopathy regardless of the presence or absence of hepatic encephalopathy.[28] The causes of ALF in children can be metabolic, toxic, drug-related, immune-mediated or infectious. The percentage of ALF caused by viral infections varies significantly by age group and geographic location, with infections causing only 6% of ALF in a large pediatric series from North America and Great Britain[28,29] but 50% in a series from South America.[30]

Cause

While less than 1% of infections with these viruses result in ALF, the hepatotropic viruses, hepatitis A and B, comprise the majority of cases with a definitive viral diagnosis, particularly in endemic areas.[30-34] Infection with hepatitis C rarely causes ALF; however, there are case reports of ALF with both postnatally and perinatally acquired hepatitis C in children.[28,35,36] In 2006, PALF published a report of the first 348 children presenting with ALF to the study sites throughout North America and Great Britain. Only 6% of the cases in this series had definitive viral causes, with the viruses identified being adenovirus, CMV, hepatitis A, enterovirus, HSV, Epstein-Barr virus (EBV), and hepatitis C. However, both in this series and in a later series of 703 children published by the same group, almost 50% of all the cases were indeterminate, due at least in part to lack of a complete diagnostic workup.[29] It is likely that some of these indeterminate cases were also due to undiagnosed infectious causes. Additional viruses that have been implicated in ALF include hepatitis D and E, parvovirus,[37,38] varicella-zoster virus (VZV),[39] and HHV-6.[40,41] ALF in infants is most likely to be associated with systemic illness due to enterovirus, echovirus, HSV, HHV-6, or CMV.[28,42-44] While most perinatally acquired infections with hepatitis B are asymptomatic, infants born to women with both HBsAg and anti-HBeAb appear to be at greater risk for ALF due to perinatally acquired hepatitis B.[45]

Risk factors for HSV hepatitis outside of the neonatal period include pregnancy and immune suppression.[46,47] Immune suppression is also a risk factor for CMV-, adenovirus-, and VZV-associated ALF. Hepatitis E virus (HEV) is an enterically transmitted virus that causes epidemic hepatitis in many areas of the world, particularly the Indian subcontinent and Southeast Asia.[34] ALF can also occur in severe dengue[48,49] and yellow fever infection.[48-50] HEV, dengue, and yellow fever are not endemic in Western countries.

Clinical Presentation

Symptoms of acute hepatitis include jaundice, anorexia, fatigue, nausea, and vomiting.[32,51,52] In fulminant disease, there is rapid progression to hepatic failure and encephalopathy. Physical examination may demonstrate fever, hepatosplenomegaly with liver tenderness, scleral or cutaneous icterus, and mucosal bleeding. Patients with severe vomiting may have significant dehydration. Laboratory studies include elevated hepatic enzymes (10- to 100-fold increases in AST and alanine aminotransferase), hyperbilirubinemia, prolonged prothrombin time, and elevated ammonia levels. As hepatocyte necrosis progresses, hepatic enzyme levels and

liver size may decrease. Cerebral edema is common in patients with severe encephalopathy[32,52] and renal failure is a common complication.[51,52]

Viral Pneumonia/Pneumonitis

Background

Influenza and pneumonia combined are a leading cause of death of children in developing countries and the eighth leading cause of death in the United States for patients of all ages. A greater burden of disease is present in infants, young children, and older individuals.[53] Although only 20% to 50% of community-acquired pneumonias in adults are associated with viral pathogens,[54-58] viruses account for the majority of the causes of lower respiratory infection in children. It is estimated that more than 500,000 hospitalizations occur each year in the United States for lower respiratory tract infections among children younger than 18 years old,[59,60] and an estimated 80% of these hospitalizations are attributable to viral etiologies, with the majority in children aged less than 5 years.[59,61] The peak season is from midwinter to early spring.

Cause

The etiologic agents of viral pneumonia are varied (see Table 95-1), and recent studies using PCR for diagnosis have considerably improved the ability to detect viruses. RSV is the primary cause of hospitalization for respiratory tract illness in young children, with average annual hospitalization rates in the United States of 17 per 1000 children under 6 months of age and 3 per 1000 children younger than 5 years.[62] In a recent national surveillance study, most children with RSV infection had no coexisting medical conditions or characteristics that significantly identified them as being at greater risk for severe RSV disease, except for being younger than 2 years.[62] Among children, RSV infection is the cause of 50% to 90% of hospitalizations for bronchiolitis, 5% to 40% of those for pneumonia, and 10% to 30% of those for tracheobronchitis.[63] Repeat infections are common; in the healthy host, they are localized to the upper respiratory tract. Among immunocompromised patients, RSV upper respiratory infections can progress to fatal pneumonia, with the greatest mortality risk in patients with severe lower tract disease and in those in whom treatment is significantly delayed.[64,65]

Influenza epidemics occur annually with significant morbidity and death in young children and older individuals. In a national surveillance study, an average of 0.9 per 1000 children aged 0 to 59 months were hospitalized with laboratory-confirmed influenza, with the highest rate of 4.5 per 1000 children in the 0 to 5-month age group.[66] During the four influenza seasons from 2003 to 2007, the total number of reported pediatric influenza deaths ranged from 46 to 153, with an average of 82 deaths each year.[67] Infected infants younger than 2 months may have symptoms mimicking bacterial sepsis, commonly including apnea. In children younger than 5 years, influenza can cause symptoms of laryngotracheobronchitis, whereas pneumonia occurs in 10% to 15% of those younger than 3 years. Finally, older children generally exhibit the classic flulike symptoms of fever, headache, myalgia, and malaise with upper respiratory tract symptoms. Bacterial superinfection is a common and potentially severe complication of influenza. Among immunocompromised patients, risk factors for more severe disease and progression to the lower respiratory tract include lymphopenia and infection early after hematopoietic stem cell transplant.[65, 68] With earlier antiviral treatment, progression to the lower tract and mortality have been markedly reduced.

In 2009, the emergence of a pandemic strain of influenza A, termed *novel H1N1,* led to a greatly increased burden of influenza disease worldwide. Children and young adults were at a disproportionate risk for infection and hospitalization, with 60% of infections occurring among those 18 years of age or younger, and 95% in those younger than 50 years.[69-71] The overall attack rate was highest among children aged 5 to 14 years (147 per 100,000 population),[69] but infants had the highest hospitalization rates and persons aged 50 years or older had the highest mortality rates once hospitalized.[69,71] This differs from seasonal influenza, where about 60 percent of influenza-related hospitalizations and 90 percent of influenza-related deaths occur in people 65 years and older. From April to October of 2009, the Centers for Disease Control and Prevention (CDC) received reports of 145 pediatric deaths associated with influenza infection.[67] Correcting for underascertainment, the CDC estimates the actual count may be three to four times greater than reported (http://www.cdc.gov/h1n1flu/estimates_2009_h1n1.htm). The majority of hospitalized cases had underlying medical conditions associated with severe seasonal influenza; secondary bacterial infections were observed in 15% to 30% of fatal cases.[71,72]

In a typical influenza season, parainfluenza viruses (PIVs) are generally second only to RSV as important viral causes of lower respiratory infection in children and immunocompromised patients.[73-77] The average annual PIV hospitalization rate is 1.02 per 1000 children 0 to 59 months of age, with the highest rate of 3.01 per 1000 in children 0 to 5 months of age.[77] PIVs account for 50% of hospitalizations for acute laryngotracheitis (croup) and at least 15% of cases of bronchiolitis and pneumonia. PIVs types 1 and 2 cause more cases of croup whereas PIV type 3 is more likely to infect the small air passages and cause pneumonia or bronchiolitis. However, any PIV can cause lower respiratory tract disease, particularly during primary infection or in immunosuppressed patients. In immunocompromised hosts, virologically confirmed PIV pneumonia has a 30-day attributable mortality rate of at least 30% to 35%.[75,78,79] Unlike RSV lower tract disease, in which RSV is usually the single pathogen, copathogens may be identified with PIV pneumonia more than 50% of the time,[75] and management of PIV pneumonia should include workup and treatment for copathogens.

Other respiratory viruses that can cause pneumonia, particularly in young children and immunocompromised hosts, include human metapneumovirus, adenovirus, human rhinoviruses (HRVs), and human coronaviruses (HCoVs). Since it was first described in 2001,[80] human metapneumovirus has been shown to be a common cause of croup, bronchiolitis, and pneumonia in children, the elderly, and immunocompromised patients.[81-89] The clinical manifestations of human metapneumovirus are indistinguishable from RSV. Adenovirus pneumonia can occur as an isolated event or as part of disseminated disease. Risk factors for adenovirus pneumonia include a compromised immune function, chronic underlying respiratory or cardiac disease, and age younger than 7 years.[90] Adenovirus pneumonia due to specific serotypes has been associated with outbreaks among young children (types 3 and 7),[91] high school students (type 11),[92]and a recent community-based outbreak that included children (type 14).[93] HRVs

occasionally cause lower respiratory tract disease requiring admission to intensive care among pediatric and immunosuppressed patients, although a causative role is sometimes difficult to define because HRVs frequently occur in association with copathogens.[94-98] Among pediatric patients, a new species of rhinovirus (HRV-C) has been discovered that may cause more severe disease than HRV-A or HRV-B, although this association is not yet clearly elucidated.[99-104]

The HCoV family currently includes five viruses that are known to infect humans: HCoV-229E, HCoV-OC43, the severe acute respiratory syndrome-associated CoV (SARS-CoV), and the recently described HCoV-NL63 and HCoV-HKU1. The SARS outbreak originated in Guangdong Province in China in the fall of 2002 and was characterized by a life-threatening, atypical pneumonia caused by a novel coronavirus most likely derived from masked palm civets.[105] SARS-CoV was spread by close contact with infected humans, mostly to household contacts and health care workers. Death from progressive respiratory failure occurred in approximately 10% to 15% of adult patients[106-110]; in children, morbidity was less and no deaths occurred.[111-113] SARS-CoV is not currently circulating in the world. The most recent human cases of SARS-CoV infection were reported in China in April 2004 in an outbreak resulting from laboratory-acquired infections.[114] Should SARS-CoV re-emerge, updates to the case definition, including clinical criteria for moderate or severe respiratory illness of unknown cause and epidemiologic criteria for exposure, can be found at www.cdc.gov/SARS. Other HCoVs have been reported to cause pneumonia in children and immunocompromised patients treated for hematologic malignancies.[115-119]

Additional information about respiratory viruses including RSV, influenza, PIV, and adenovirus is available in Chapter 47.

Although CMV usually causes relatively benign disease in immunocompetent hosts, it is frequently severe and often fatal in immunocompromised hosts, including patients with acquired immunodeficiency syndrome (AIDS), malignancy, congenital immune deficiencies, and transplant recipients. CMV is a herpesvirus and, like other herpesviruses, it can cause latent infection in vascular endothelial cells, monocytes and macrophages, polymorphonuclear neutrophils, and renal and pulmonary epithelial cells. Cellular damage is caused directly by the viral lytic infection or indirectly by the immune response of the host. Among allogeneic stem cell transplant recipients, the risk of CMV pneumonia is high; historically, treatment of CMV pneumonia with ganciclovir and intravenous immunoglobulin (IVIG) in the late 1980s dramatically reduced mortality from 80% to 100% without therapy to approximately 50%.[120] The spectrum of CMV pneumonia has changed with the introduction of routine antiviral prophylaxis and preemptive therapy strategies.[121] As a result, CMV disease during the first 3 months after hematopoietic cell transplantation has been reduced from 20% to 30% to less than 5% in most studies.[122] CMV disease now primarily occurs late after transplant. Risk factors for late CMV disease include reactivation of (or primary infection with) CMV during the early period after transplant, and therapy for acute or chronic graft-versus-host disease.[120] Among solid organ transplant recipients, the risk of CMV disease is greatest for lung transplant recipients, followed by liver, heart, and renal transplant recipients.[120,123]

Hantaviruses are known for causing hemorrhagic fevers and acute severe respiratory infection in young adults. Hantaviruses can spread from mammal to mammal, including humans, by exposure to aerosolized feces, infected urine, or other secretions. In the United States, the Sin Nombre virus, which causes the pulmonary syndrome, is found in 10% to 80% of deer mice in rural areas of North America, although the overall seroprevalence rates in the western United States are less than 0.1%.[124] In the United States, hantaviral infections are rare in children under the age of 10 years; however, severe cases resulting in death have been described in children as young as 5 years old in South America.[124,125] Hantaviruses cause disease by creating leakage of plasma and erythrocytes through the vascular endothelium in the lung (hantavirus pulmonary syndrome [HPS]) or the kidneys (hemorrhagic fever with renal syndrome). The differential diagnosis includes influenza A, rickettsial disease, borreliosis, tularemia, *Legionella pneumophila, Chlamydia pneumoniae*, *Mycoplasma pneumoniae* and *Pneumocystis jiroveci*. HPS is fatal in 35% to 40% of cases across the Americas.[124,126] Supportive care, including early consideration of extracorporeal membrane oxygenation, is key to treatment of patients with HPS.

Clinical Presentation

The clinical presentation of viral pneumonia/pneumonitis usually consists of fever, increased respiratory rate, cough, and increased work of breathing, with grunting, flaring, retracting, and use of accessory muscles in infants and young children. Decreased oral intake with increased insensible loss due to the increased respiratory rate is often present and may lead to dehydration. Some patients have centrally mediated apnea, and other patients have an overwhelming sepsislike syndrome with increased peripheral pulses, decreased central blood pressure, and lethargy. A history or examination findings of certain symptoms, including rhinorrhea, conjunctivitis, otitis media, and previous exposure to an ill child or adult, should immediately raise suspicion of a viral cause. However, many patients with influenza, and most adults and adolescents with SARS-CoV, have no preceding upper respiratory illness. Radiographic findings generally include evidence of hyperinflation and peribronchial cuffing, and a focal or diffuse infiltrate may or may not be present. Bacterial coinfection may appear after, or concomitantly with, the viral infection.

Clinical features of HPS include a noncardiogenic pulmonary edema and a prodrome of fever, headache, and myalgia, usually with nausea and diarrhea, for 4 to 5 days before the onset of cough and dyspnea. There is a lack of upper respiratory symptoms. Tachycardia and tachypnea with hypotension then develop and rapidly progress to acute respiratory distress syndrome. Laboratory findings include leukocytosis, elevated hematocrit, and thrombocytopenia in the early cardiopulmonary phase; prolonged partial thromboplastin time may occur in severe cases. Rapidly evolving diffuse bilateral interstitial infiltrates are seen on chest radiograph.

Central Nervous System Infections

Background

Aseptic meningitis, encephalitis, and myelitis are inflammatory conditions of the central nervous system (CNS), involving meninges, brain, and spinal cord, respectively. Disease is caused by a variety of infectious pathogens, but viruses cause

most disease. Viruses gain entry to the CNS via the bloodstream (enteroviruses and arboviruses) or by direct neuronal spread (HSV and rabies). Pathogenesis may involve direct viral invasion or a vigorous virus-specific immune response resulting in damage to the neurons and supporting cells. Alternatively, infection may trigger activation of an immune response specific for the oligodendroglia or the myelin components themselves. In the latter case, disease may follow an upper respiratory tract or other infection and primarily take the form of a demyelinating process. This disease is commonly termed postinfectious encephalomyelitis or acute disseminated encephalomyelitis.

Individuals of all ages are at risk for CNS viral infections. However, neonates, older individuals, and those with immune deficiencies are prone to more frequent and more serious CNS viral infections.

Cause

The potential viral causes are multiple; however, enteroviruses, herpesviruses, and arboviruses are responsible for most disease (see Table 95-1). Enteroviruses account for up to 99% of cases of aseptic meningitis when a cause is identified.[127] Enterovirus meningitis in older children and adults is typically self-limited and associated with few complications. In contrast, enteroviral infections in neonates may mimic bacterial sepsis, and CNS involvement is often manifested as encephalitis. Parechovirus, another cause of meningoencephalitis in neonates, is a close relative of enteroviruses and clinically very similar.[128]

HSV is a common cause of CNS infection in individuals of all ages. During the neonatal period, HSV type 2, and to a lesser extent type 1, cause encephalitis because of the vertical transmission of the virus.[129] In contrast, in older children and adults, most HSV encephalitis is caused by type 1. HSV-2, however, can cause benign aseptic meningitis in association with primary and recurrent genital infections.[130] Other members of the herpesvirus family (CMV, EBV, VZV, and HHV-6) can also cause aseptic meningitis and encephalitis, albeit less commonly. CMV encephalitis occurs mostly in immunosuppressed individuals but may occasionally appear in otherwise healthy individuals.[131,132] EBV aseptic meningitis and encephalitis present with or without the classic findings of infectious mononucleosis.[133] Acute cerebellar ataxia is a common and usually benign complication of chickenpox. VZV encephalitis can sometimes occur in immunocompetent individuals,[134,135] but more frequently occurs in immunocompromised individuals following days, weeks, or months after a case of varicella or zoster. Zoster encephalitis can be complicated by small- or large-vessel vasculitis (granulomatous arteritis), which carries the potentially serious consequences of infarction.[134,136] HHV-6 has only rarely been reported to cause encephalitis in healthy children during primary infection,[137] whereas it appears to be a more common problem for immunosuppressed patients, such as those receiving stem cell transplants.[138,139]

Arboviruses (arthropod-spread viruses) are important causes of aseptic meningitis and encephalitis. The specific arbovirus determines the epidemiology, morbidity, and risk of death of associated disease. The La Crosse and St. Louis encephalitis viruses account for most arboviral CNS infections in the United States. The La Crosse virus is found mainly in the Midwest, typically occurs in the summer and early fall, and is associated with a relatively low death rate. The St. Louis encephalitis virus occurs in every state but is more common in the Midwest, Florida, and Texas and has been responsible for large urban outbreaks.[140,141] Eastern equine virus occurs less frequently, and mainly in the Northeast and Southeast, but carries a high rate of morbidity (70% to 80%) and death (20% to 80%).[142,143] West Nile virus encephalitis first appeared in the United States in the summer of 1999 in New York state.[144] Over the following summers, the West Nile virus moved southward and westward across the United States, infecting both animals and humans. Most individuals infected with the West Nile virus are symptom free or experience flulike illness; however, older individuals and those with underlying immune deficiency can experience encephalitis that may result in death. In addition to the more typical presentation of encephalitis, an acute flaccid paralysis has also been associated with West Nile virus infection.[145]

A number of viruses are infrequent causes of encephalitis, including mumps, influenza, and lymphocytic choriomeningitis viruses (LCMVs). Historically, mumps virus accounted for a large proportion of aseptic meningitis and encephalitis cases in the United States.[146] Currently, because of the widespread use of the trivalent MMR vaccine, meningitis and encephalitis due to mumps are extremely rare.[147] Influenza has been associated with encephalitis/encephalopathy, especially in Japan. In a national survey representing the 1998-1999 season, 142 cases, most occurring in children younger than 5 years, are reported.[148] LCMV is an infrequently recognized cause of meningoencephalitis. This virus is found in the urine, droppings, and saliva of infected mice, guinea pigs, and hamsters, and disease in humans arises after exposure to these substances.

Postinfectious encephalomyelitis refers to an acute self-limited demyelinating process most commonly following viral respiratory infections and varicella. In contrast, subacute sclerosing panencephalitis (SSPE) and progressive multifocal leukoencephalopathy (PML) are two chronic, usually fatal, demyelinating diseases due to measles and JC virus, respectively. SSPE most commonly follows 5 to 10 years after natural measles infection. SSPE is extremely rare in the United States; however, it may occur as often as one case per a population of 10,000 in areas of the world where the MMR vaccine is not widely used.[149] PML is also rare, usually affecting those with AIDS or, rarely, those with other serious immunodeficiencies. Transverse myelitis has been most frequently associated with enteroviruses; however, VZV,[150,151] CMV, influenza A,[152] and hepatitis A[153] have been reported causes, even in immunologically normal individuals.

Clinical Presentation

Historic clues and physical findings can be helpful in focusing the search for an etiologic agent. Travel or residence in areas where arboviruses are endemic during the appropriate season for arthropod transmission (typically summer months) and a history or evidence of insect bites should raise suspicion for arboviruses. Seasonality also plays a role in enteroviral diseases, because in temperate climates enteroviruses are more prevalent during summer and fall months. History of a mother with recent symptoms consistent with viral illness (fever, sore throat, gastroenteritis, rash) should raise suspicion of enterovirus in a neonate with encephalitis or sepsis-like illness. VZV encephalitis and myelitis typically follow chickenpox or zoster by weeks to months and commonly

occur in older individuals or those with immunosuppression, such as transplant recipients.[154] VZV encephalitis may be complicated by CNS vasculopathy and resulting infarctions. Chronic encephalitis/meningitis due to enteroviruses occurs in individuals with agammaglobulinemia. Chronic or relapsing encephalitis may also be due to VZV, measles (SSPE), or rubella (progressive rubella panencephalitis), though the latter two are extremely rare with the current widespread use of the MMR vaccine. HIV itself may cause encephalopathy/encephalitis or may also be associated with certain opportunistic infections such as PML. Significant exposure to rodent droppings should raise concern for LCMV. Finally, history of exposure to a bat should raise the concern for rabies.

The classic clinical presentation of viral meningitis is characterized by acute onset of fever, headache, photophobia, vomiting, and nuchal rigidity. A more chronic presentation might indicate enteroviral disease in an immunosuppressed host, whereas recurrent aseptic meningitis can be associated with HSV-2. Encephalitis is characterized by acute onset of fever, signs of encephalopathy such as depressed consciousness, focal neurologic findings, and seizures. A chronic progressive presentation might indicate more unusual causes, such as PML and SSPE. Transverse myelitis is characterized by an abrupt onset of weakness of the limbs progressing to flaccid paralysis. Diminished deep tendon reflexes progress to nonexistent, and there is associated sensory deficit. VZV myelitis usually follows varicella or zoster by 1 to 2 weeks.

Cerebrospinal fluid (CSF) findings in aseptic meningitis typically include a normal glucose level, a normal to slightly elevated protein level, and a pleocytosis of up to 1000 cells/μL. The pleocytosis is classically monocytic (>80%); however, there can be an initial predominance of polymorphonuclear cells in the first 48 hours of illness.[155] CSF findings in encephalitis can be normal, or there may be pleocytosis and elevated protein levels. The results of brain computed tomography (CT) and MRI studies are usually normal in viral meningitis, whereas disease is often seen in the setting of viral encephalitides. In general, CT scan is relatively insensitive for detecting acute encephalitis. MRI is the more sensitive study for detecting disease because of its ability to detect altered water content (see Chapter 56).[156] In acute viral encephalitis, early findings include edema with minimal contrast enhancement. As disease progresses, edema and enhancement become more obvious and may be accompanied by mass effect, hemorrhagic changes, and necrosis. As the inflammation resolves, atrophy may become prominent. In HSV, imaging studies may reveal edema and enhancement, often first involving the temporal lobes with subsequent spread to other areas of the brain. Changes can ultimately progress to atrophy, multicystic encephalomalacia, and gyriform high attenuation, especially in children.[157,158] In postinfectious encephalomyelitis, the lesions may be seen throughout the CNS. The lesions are more readily elucidated by MRI and primarily involve the white matter, although gray matter may also be involved.

Exotic Viral Diseases

With both the increase in foreign travel and the threat of bioterrorism, the potential to treat a child with an exotic viral disease exists. Although discussion of these infections, which include Andes virus, B virus, monkeypox, and the hemorrhagic fever viruses (Ebola virus, Marburg virus, Lassa virus, Crimean-Congo hemorrhagic fever virus, Argentine hemorrhagic fever virus, Bolivian hemorrhagic fever virus) is beyond the scope of this chapter, these infections should be kept in mind. If one of these agents is suspected, then the patient and patient garments should be contained in a single room, and infection control, infectious disease specialists, or the public health department should be called immediately.[159-161]

Diagnosing Viral Disease

The key to diagnosis of viral pathogens is high-quality specimens obtained early in the course of disease. There are five main ways to diagnose a viral infection: (1) identification of the virus in cell culture through observation of characteristic cytopathic effect; (2) identification of the virus by assays that link specific antibodies to the viral antigens (complement fixation, neutralization, immunofluorescence assays, enzyme-linked immunosorbent assay); (3) microscopic identification of characteristic viral inclusion bodies; (4) serologic procedures that show either an early antibody (immunoglobulin M [IgM]) or a fourfold or higher rise in IgG antibody titers between an acute phase and (at least 10 to 14 days later) convalescent phase serum; and (5) molecular techniques that amplify target viral DNA or RNA.

If a viral cause is suspected, a few diagnostic studies can be performed immediately. Acute-phase serum should be held for later interpretation. It is critical that this specimen is drawn before administration of IVIG or blood products. Samples for viral cultures and PCR testing should be collected from the appropriate sites with Dacron or rayon swabs with plastic shafts (or other specific swabs appropriate for testing by PCR). Both cotton and wood inhibit viral growth and may contain substances that inhibit the enzymes used in PCR. The virology laboratory should be informed of the diagnosis or suspected pathogens because the cell lines chosen for inoculation vary by what virus is suspected. Nasal washes/swabs and swabs of the base of a vesicle or ulcer (for VZV, HSV) should include good cellular content, because fluorescent antibody assays stain cells and the more cells available, the more sensitive the assay. Table 95-2 outlines appropriate samples and testing for a number of specific viral pathogens.

Myocarditis

Isolation of virus from the myocardium provides a definite viral diagnosis of myocarditis; however, recovery of viruses from the myocardium by culture is rarely possible, even in cases of histologically proven myocarditis. Controversy now exists as to whether endomyocardial biopsy and histologic confirmation will continue to be recommended in myocarditis given the availability of cardiac MRI and the risks associated with biopsy.[162] Viral culture of peripheral specimens such as stool and nasopharyngeal secretions or the demonstration of a fourfold rise in specific viral antibody titers provides an indirect determination of causality; however, the sensitivity is also low, 16% to 26%[15,163] and 30% to 40%, respectively. Molecular biologic techniques such as PCR and in situ hybridization have expanded the number of viruses implicated in the etiology of myocarditis. In addition, because of the increased sensitivity of PCR, the application of PCR for viral nucleic acid in myocardial tissue provides a virologic diagnosis in up to 60% of cases.[15]

Table 95–2 Potential Diagnostic Tests and Corresponding Specimens for Diagnosis of Viral Pathogens

Viral Agent	Specimen	Recommended Diagnostic Tests*
Adenovirus	NP, pharynx, BAL fluid Tissue Serum/plasma†	FA, culture, shell vial or rapid culture, PCR FA, culture, PCR, histology PCR
Arboviruses (California encephalitis, Colorado tick fever, EEE, SLE, WEE, West Nile)‡	Serum (acute and convalescent)/plasma CSF	IgM and IgG antibody,§ PCR and immunohistochemistry for some IgM‖ and IgG antibody,§ PCR
Coronaviruses (OC43, 229E, HKU1, NL63, and SARS)¶‡	NP aspirate (preferred for SARS) or swab, OP swab, BAL, serum/plasma (SARS), stool (SARS), tissues (SARS) Serum	PCR IgM and IgG antibody§
Enteroviruses (echoviruses, coxsackie viruses, enteroviruses)‡	CSF, pharynx Stool** Serum (acute and convalescent)	PCR, culture Culture IgM and IgG antibody available for some
Hantavirus‡	Serum Tissue (lung, kidney, spleen preferred; ante-mortem: lung or bone marrow)	PCR, IgM and IgG antibody§ PCR, culture and immunohistochemistry
Hepatitis viruses	Serum	Serology for all
• **HAV**	Serum	Anti-HAV IgM
• **HBV**	Serum/plasma Liver	HBsAg, anti-HBcAb IgM, PCR PCR
• **HCV**	Serum/plasma Liver	Anti-HCV, PCR PCR
• **HDV**	Serum Liver	Anti-HDV PCR
• **HEV**	Serum Liver	Anti-HEV IgM PCR
HERPES VIRUSES		
• **CMV**	NP or BAL Blood Serum Plasma Tissue Urine	FA, culture, shell vial or rapid culture PCR§§ Buffy coat antigen, PCR IgM and IgG antibody§ PCR FA, culture, histology, PCR Culture, shell vial or rapid culture
• **EBV**	Serum Plasma, CSF Tissue	IgM antibody or slide agglutination test (monospot) PCR PCR, Immunohistochemistry
• **HHV-6**	Serum/plasma, CSF Tissue	PCR PCR, immunohistochemistry
• **HSV I and II**	CSF, plasma Base of lesion, NP, conjunctiva, tissue Serum Stool (neonates)	PCR, culture FA, culture, PCR IgG antibody (differentiation between type 1 and type 2 requires special lab)§ Culture
• **VZV**	Base of lesion, tissue Serum Plasma, CSF	FA and culture, PCR IgM and IgG antibody§ PCR
Influenza A and B	NP, pharynx, BAL fluid Tissue	FA, culture, IA (rapid), PCR‡‡ FA, culture, PCR
JCV‡	Brain CSF	Brain biopsy,†† PCR PCR
LCM‡	Serum CSF	IgM and IgG antibody§ IgM
Measles (Rubeola)‡	Serum Urine, blood, NP	IgM and IgG antibody§ culture
• SSPE	CSF	Oligoclonal bands, IgG, measles titer

Continued

Table 95–2 Potential Diagnostic Tests and Corresponding Specimens for Diagnosis of Viral Pathogens—cont'd

Viral Agent	Specimen	Recommended Diagnostic Tests*
Metapneumovirus	NP, BAL fluid	FA, PCR
Mumps‡	Buccal swab Serum, CSF Pharynx, urine	PCR, culture IgM and IgG antibody§ Culture (rarely grows)
Parechoviruses	CSF, serum/plasma, NP, pharynx, stool	PCR (not widely available), culture (not diagnostic because CPE same as enteroviruses)
Parainfluenza viruses	NP, BAL fluid, tissue	FA, culture, PCR
Parvovirus	Plasma Serum	PCR IgM and IgG antibody§
Rabies virus‡	Serum, CSF Saliva, brain, tissues, urine Punch biopsy (nape of neck), brain	Rabies-specific antibody by neutralization assay Virus isolation/culture (rarely helpful), Fluorescent microscopy (consult ID)
RETROVIRIDAE		
• **HIV**	Serum/plasma, CSF	Screening HIV EIA, DNA PCR RNA PCR (viral load)
• **HTLV**	Serum Tissue	PCR, HTLV EIA PCR
Rotavirus	Stool	EIA or latex particle agglutination assays (commercially available); electron microscopy, culture, polyacrylamide gel electrophoresis, PCR (research labs)
RSV	NP, BAL fluid, tissue	FA, culture, shell vial culture, IA (rapid), PCR
Rubella‡	Serum, NP, pharynx, CSF, blood, urine	IgM and IgG antibody§ Culture

Choice of test depends on clinical setting, including organ system involved and immune status of host.
NP, Nasopharyngeal secretions; *OP,* oropharyngeal; *CSF,* cerebrospinal fluid; *BAL,* bronchoalveolar lavage; *FA,* fluorescence assay; *EIA,* enzyme immunoassay; *IA,* immunoassay; *ID,* infectious disease; *CPE,* cytopathic effect; *EEE,* Eastern equine encephalitis; *SLE,* St. Louis encephalitis; *WEE,* Western equine encephalitis.
*Multiple diagnostic tests are available for each pathogen. Commonly recommended diagnostic tests are listed; however, if results are negative or specimens are not available, infectious disease consultation may be helpful for additional or special testing.
†PCR is usually run on plasma, though some laboratories may run serum samples.
‡Pathogen may have significant public health implications and testing should be performed in consultation with infectious disease and/or local public health department (for enteroviruses, if enterovirus 71 suspected). Testing is often not available without assistance of the Public Health Department, and recommended specimens and tests are frequently evolving; see www.cdc.gov/ for updates.
§IgM and IgG antibody may also be referred to as "serology" on laboratory request forms. For all viral pathogens, when testing for IgG it is optimal to collect acute and convalescent sera approximately 4 weeks apart.
‖IgM antibody does not cross the blood-brain barrier. If found in CSF, IgM antibody denotes central nervous system infection.
¶For suspected SARS, patients should also be evaluated with respiratory FA for influenza A, B, and RSV, sputum Gram stain and culture, blood culture, and urine for *Legionella* and pneumococcal antigen. Blood, serum, and respiratory specimens should be saved. See www.cdc.gov/ncidod/sars/diagnosis.htm for updated diagnostic information.
**Enteroviruses are shed in the stool for weeks and may not be diagnostic.
††Gold standard.
‡‡FA and rapid testing have low sensitivity for 2009 novel influenza A (H1N1); PCR testing is the most sensitive and is necessary for subtyping.
§§Because shedding of CMV occurs in the lungs of seropositive stem cell transplant recipients without overt CMV disease, the recovery of CMV DNA by PCR from BAL fluid (which is considerably more sensitive than culture) without shell vial or culture positivity is of uncertain significance. PCR for CMV DNA in BAL or biopsy fluid should thus not be ordered routinely.

Acute Liver Failure

Viral diagnosis relies on serology, detection of viral nucleic acid in serum, and detection of viral antigens or nucleic acids in tissue obtained from liver biopsy. Hepatitis A infection is confirmed by demonstrating anti-HAV IgM antibodies. In patients with acute hepatitis A, anti-HAV IgM antibodies are detectable in the serum at the onset of symptoms, peak 1 week after onset of symptoms, and become undetectable by 3 to 6 months postinfection. The presence of HBsAg (hepatitis B surface antigen) in serum indicates active HBV replication and is present in acute and chronic HBV infection. Due to the destruction of actively infected hepatocytes, HBsAg may be absent in ALF and the only marker of acute HBV infection may be anti-HBcAb (anti-HBV core) IgM antibodies. Hepatitis B DNA can also be demonstrated in serum and liver tissue by PCR. Absence of HBsAg or HBV-DNA in the serum does not rule out HBV as the cause of ALF, as HBV DNA has been demonstrated in liver tissue of patients with non-A and non-B ALF in whom serologic markers did not suggest HBV infection.[164] Hepatitis D, a hepatotropic virus that causes infection only in the presence of active hepatitis B infection, should be looked for in patients with acute HBV hepatitis, as coinfection or superinfection with HDV may result in more severe disease.[165] Hepatitis D coinfection can be determined by demonstrating anti-HDV antibodies or HDV-RNA in serum.[166]

Although the newer generation antibody assays for hepatitis C are more sensitive than past assays, anti-HCV antibodies may not be detectable early in disease. Therefore, when the epidemiology suggests possible infection with HCV, serum and liver tissue should be analyzed for HCV-RNA by PCR.

HSV hepatitis is frequently a result of newly acquired infection, thus serology may not be helpful. Skin or mucosal lesions, if present, should be cultured for HSV. Liver tissue should be sent for viral culture and PCR for HSV. HSV may also be demonstrated in blood by PCR. Both serology and tissue or blood PCR can be used to diagnose infection with EBV, CMV, HHV-6, HEV, and parvovirus. Diagnosis of adenovirus and enterovirus generally requires PCR of blood and tissue or culture of infected secretions.

Pneumonia/Pneumonitis

If available, fluorescence assays or PCR testing on nasal wash specimens are the initial diagnostic tests of choice for respiratory viruses, because most of these pathogens are concentrated in the nasopharynx. However, by the time the patient has developed lower respiratory tract disease, a lower respiratory sample by bronchoscopy may provide the best yield and may be positive even with a negative nasopharyngeal sample. The sensitivity of indirect immunofluorescence assays is generally as high as 90% to 95% for RSV, influenza A and B, and PIV 1, 2, and 3; if a rapid result is needed, this may be the best approach. However, PCR may be used if the results can be provided in an expedited fashion, as this is a more sensitive assay albeit more expensive. A rapid antigen test for RSV and influenza is also available. However, for the pandemic 2009 influenza A (H1N1) virus, in particular, FA and rapid testing have shown low sensitivity and a negative test result is not reliable.[167-170] PCR testing is most sensitive and necessary for correct virus subtype identification. Adenovirus immunofluorescence assays are available in some laboratories, but sensitivity is generally lower (around 50% to 70%). Shell vial assays can increase sensitivity, and although they are usually performed for CMV, they can also be performed for RSV and adenovirus. The same samples can be sent for culture in addition to immunofluorescence studies; this should be considered for immunocompromised and severely ill children with respiratory distress/failure of unclear etiology if PCR testing is not available. The diagnosis of hantavirus can be made by culture of the virus (which is difficult), PCR for viral RNA from serum, plasma, or tissues, or serologic testing. Antibodies to hantaviruses are usually detectable in serum on the first day of symptoms.[124] A review of diagnostic testing options for etiologies of viral pneumonia is provided in Table 95-2.

Meningitis/Encephalitis

CSF, blood, and throat swabs should be collected for evaluation. One can make a diagnosis of enterovirus by culturing the virus from CSF or by detecting virus in CSF using reverse transcriptase PCR. Because of the greater sensitivity of PCR, compared with culture,[171,172] it should be used whenever possible. Viral culture of a throat swab may also reveal enterovirus and is indicative of a current or recent infection. Rectal or stool viral cultures are less helpful because enteroviruses may be shed in the stool for weeks after infection. DNA PCR of CSF offers relatively sensitive and specific diagnosis of herpesviruses.[132] Detection of viral-specific antibodies in the CSF can add supporting evidence. Additionally, the detection of HHV-6 DNA in plasma or serum by PCR confirms active systemic viral replication. Arboviruses are typically diagnosed through detection of antibodies in acute and convalescent serum specimens. CSF may also be tested for antibodies. PCR and immunohistochemistry have also been used to diagnose arboviral infections and are available in some settings. Diagnosis of LCMV is made through serologic testing. The JC virus can be detected in CSF with PCR, and this appears to be a relatively sensitive and specific method for diagnosing PML.[173,174] Definitive diagnosis, however, is usually made with brain biopsy. Diagnosis of SSPE is made with the evaluation of CSF for oligoclonal bands, IgG level, and specific measles antibody titer.

Treatment for Viral Infections

In general, for most life-threatening viral infections the primary treatment is supportive. Because of improvements in intensive medical care, death from these illnesses has decreased even without the availability of specific antiviral therapy. Despite recent advances, there are no effective antiviral medications for many viral infections. There are, however, antivirals for most of the herpes group viruses and many of the respiratory viruses. For most infections, the efficacy of antiviral therapy is decreased if therapy is delayed, so early diagnosis and rapid initiation of therapy are essential. Consultation with an infectious disease specialist is recommended because some antiviral agents are not commercially available and new treatment modalities continue to be identified. A listing of antiviral agents, indications, and dosages is provided in Table 95-3.

Myocarditis

Mechanical circulatory support should be considered for children with fulminant myocarditis unresponsive to standard management (see Chapter 27). Aggressive therapy is warranted because both adults and children who survive their illness have a good prognosis for return to normal ventricular function.[175-177] Cardiac transplantation may be necessary for those children refractory to other management. Current recommendations do not support the use of immunosuppressive therapy[22,178] or nonsteroidal antiinflammatory agents,[179,180] particularly early in the course of myocarditis. Treatment with high-dose IVIG has been associated with improved left ventricular function in several small studies in children[181,182] and warrants investigation in larger, controlled studies. In adults, a controlled study found IVIG to be no better than placebo for acute dilated cardiomyopathy[182] and a Cochrane Review found no role for the routine use of IVIG in presumed viral myocarditis.[183] Several immune modulators are being investigated for use in treatment of myocarditis.[179,184] Specific antiviral therapy is indicated when the inciting viral agent has been identified.

Acute Liver Failure

The role of antiviral therapy in ALF is limited. Acyclovir should be initiated if HSV is suspected or confirmed, and there are reports of the successful use of lamivudine for treatment of severe acute hepatitis B.[185,186]

Trials using plasma exchange and plasmapheresis have demonstrated improved hemodynamic parameters, decreased intracranial pressure, and improved survival.[187,188]

Table 95–3 Antiviral Agents and Indications for Use

Virus	Drug of Choice/Dose†	Alternate Agents/Dose
Adenovirus	There is no currently approved therapy for the treatment of adenoviral infections.	Both ribavirin and cidofovir have in vitro activity against adenovirus, and cidofovir appears to be more clinically active.[201] Antiviral therapy may be considered for immunocompromised patients with severe adenoviral pneumonia. Small case series in immunocompromised children have suggested potential efficacy with intravenous ribavirin (25 mg/kg loading dose then 10 mg/kg/day; available on compassionate use basis)[202] or cidofovir (5 mg/kg once weekly[203,204] or 1 mg/kg three times a week).[205]
Coronavirus	There is no currently approved therapy for the treatment of coronaviral infections.	The sudden and severe nature of the SARS outbreak in 2002–2003 necessitated the use of empiric treatment strategies. A number of agents have been used to treat SARS-CoV, including ribavirin, lopinavir-ritonavir, oseltamivir, and corticosteroids; however, none was given in a controlled fashion, and the efficacy of these drugs has not been established.[201,206]
Enterovirus	There is no currently approved therapy for the treatment of enteroviral infections.	
Hantavirus	There is no currently approved therapy for the treatment of hantaviral infections.	Intravenous ribavirin has shown benefit in hantavirus renal syndrome,[207,208] but not in hantavirus pulmonary syndrome at the cardiopulmonary stage.[209,210] There is an ongoing NIH/NIAID-sponsored controlled trial of intravenous methylprednisolone for hantavirus pulmonary syndrome in Chile.[126]
HERPES VIRUSES		
• **CMV**	Ganciclovir (5 mg/kg q12h × 2–3 weeks, then 5 mg/kg q24h) is primary therapy for CMV disease. IVIG (500 mg/kg qod × 2 wk then once weekly) or CMV-IG (150 mg/kg, same schedule) should be given concurrently for CMV pneumonia in immunocompromised patients.	Foscarnet (90 mg/kg q12h × 2–3 weeks, then 90 mg/kg q24h), cidofovir (5 mg/kg/wk; high risk of renal toxicity, use with probenecid and saline hydration). Increased efficacy of cidofovir as second-line therapy suggested in allogeneic stem cell transplant recipients with CMV pneumonia in one small study.[211]
• **HSV**	Acyclovir (20 mg/kg/dose IV q8h) for encephalitis in neonates and children <12 years and for neonates with disseminated disease; 10 mg/kg/dose IV q8h for children >12 years.	No specific dosing recommendations are available for HSV-associated hepatitis and pneumonitis. At least 10 mg/kg/dose should be considered outside the neonatal period.
• **HHV-6**	There is no currently approved therapy for the treatment of HHV-6 infections.	Foscarnet and ganciclovir have in vitro activity. Case reports and series show variable clinical response with one or both drugs in combination.
• **VZV**	Acyclovir (10-12 mg/kg/dose IV q8h); high-dose acyclovir (20 mg/kg/dose) should be used for VZV encephalitis or for disease in immunocompromised children.	
Influenza A/B	Oseltamivir (2 mg/kg q12h × 5 days; max 75 mg bid)* or zanamivir (≥7 years) 10 mg (2 oral inhalations) q12h × 5 days. There may be benefit of using higher than approved doses of oseltamivir in immunosuppressed patients as licensing studies showed a trend to more rapid clearance of virus with the higher dose; this is under investigation.[65,212]	Rimantidine or amantidine (5 mg/kg/day div bid; max 75 mg bid), influenza A only. Local circulating influenza viruses must be considered. Combination therapy as empiric treatment may be indicated during periods of concomitant circulating viruses or for severely ill immunosuppressed patients.[65,194] The use of investigational agents such as IV zanamivir or IV peramivir may also be considered.[195-198]
JCV	No effective therapy.	In HIV infection, treatment with combination antiretroviral therapy may improve survival. Potential role for cidofovir.[213]
Metapneumovirus	There is no currently approved therapy for the treatment of metapneumoviral infections.	Ribavirin has in vitro activity against human metapneumovirus and has been shown to decrease viral load and lung inflammation in mouse models.[214,215] Case reports suggest ribavirin and IVIG may be used successfully in immunosuppressed patients.[216-218]

Continued

Table 95–3 Antiviral Agents and Indications for Use—cont'd

Virus	Drug of Choice/Dose†	Alternate Agents/Dose
Parechoviruses	There is no currently approved therapy for the treatment of parechoviral infections.	
Parainfluenza virus	There is no currently approved therapy for the treatment of parainfluenza viral infections.	Treatment for parainfluenza pneumonia should include coverage for copathogens.[75] Ribavirin is active in vitro and in animal models and has thus been used for treatment of parainfluenza pneumonia in immunocompromised hosts. Anecdotal reports of the benefit of aerosolized or systemic ribavirin have shown responses to be highly variable, and a retrospective series of stem cell transplant recipients showed no benefit.[75,201]
RSV	Aerosolized ribavirin (6 g reconstituted in 100 mL tid or 6 g in 300 mL administered over 12–18 hours daily) × 5 days has been used with modest efficacy in patients with severe RSV pneumonia and in immunocompromised patients[201,219]; not recommended for uncomplicated disease.	Combination therapy with aerosolized ribavirin and palivizumab (RSV monoclonal antibody, 15 mg/kg given once) may improve outcome of RSV pneumonia in immunocompromised and high-risk patients and may be used in combination for treatment of documented RSV pneumonia in these populations.[65,219,220]

IVIG, Intravenous immunoglobulin.
*Care should be taken when dosing children <1 year, with doses of 3 to 3.5 mg/kg recommended. In an influenza pandemic or some outbreak situations, treatment should not wait for laboratory confirmation of influenza because laboratory testing can delay treatment and because a negative rapid test for influenza does not rule out influenza. The sensitivity of rapid tests in detecting 2009 H1N1 ranged from 10% to 70%.
†These agents are generally recommended with infectious disease consultation for the infection listed. However, please note that not all these agents are FDA approved for the indicated use.

Experimental therapies such as *N*-acetylcysteine for non–acetaminophen-induced ALF, hepatocyte transplantation, and artificial hepatic support systems have shown promise in early studies.[188-190] For a detailed discussion of the management of ALF,[52] see Chapter 88.

Pneumonitis

The cornerstone of treatment remains supportive with supplemental oxygen, fluids, bronchodilators, and mechanical ventilation. Corticosteroids are generally of no proven benefit in viral-mediated pneumonia, and the data regarding systemic glucocorticoids among infants and young children with bronchiolitis show no benefit compared with placebo.[191,192] The use of empiric broad-spectrum antibiotics may be important until a diagnosis can be established, and because some viral infections such as PIVs, HRVs, and coronaviruses may occur in the context of a bacterial coinfection. For certain immunocompromised patients, fungal copathogens must also be considered. Early isolation and infection control measures for suspected viral infections should be implemented.

A number of antiviral strategies have been investigated or employed on an anecdotal basis to treat viral pneumonia, but the only FDA-approved agents include ribavirin for RSV and antivirals for influenza (oseltamivir, zanamavir, amantadine, and rimantadine). For influenza, the strain of local circulating viruses must be considered when planning a treatment regimen. Seasonal H3N2 viruses have shown almost universal resistance to adamantanes since the 2005–2006 season, and seasonal H1N1 viruses have shown rising oseltamivir resistance since 2008–2009.[193] Seasonal H1N1 viruses typically remain sensitive to adamantanes and zanamavir. The reader is encouraged to consult http://www.cdc.gov/flu/ for national surveillance data on influenza viruses circulating in the United States. Combination therapy as empiric treatment may be indicated during periods of concomitant circulating viruses or for severely ill immunosuppressed patients.[65,194] The use of investigational agents such as IV zanamivir or IV peramivir may also be considered.[195-198] Table 95-3 provides a detailed summary of antiviral agents for various causes of viral pneumonia.

Encephalitis

Untreated, HSV encephalitis carries a death rate in excess of 70%[199] and, even treated, death and complications for those who survive remain on the order of 15% and 20%, respectively.[200] Similarly, despite treatment, neonatal HSV CNS disease carries significant risk of death and morbidity, ranging from 0% to 15% and 43% to 68%, respectively.[129] Early identification of patients and rapid initiation of acyclovir have been associated with better outcome.[199,200] Unless an alternative cause is clear, high-dose acyclovir should be initiated in all children with encephalitis until HSV can be ruled out. Other specific antiviral therapy may be directed as outlined in Table 95-3.

Chapter 96

Infectious Syndromes in the Pediatric Intensive Care Unit

Sonny Dhanani and Peter N. Cox

PEARLS

- Because of the rapid progression of septicemia from meningococcus and variability of markers of infection such as white blood cell count and C-reactive protein, clinical diagnosis is imperative.
- Negative blood cultures do not rule out *Staphylococcus*; accordingly, clinical suspicion must often be relied on.
- Invasive group A β-hemolytic *Streptococcus* is commonly associated with toxic shock syndrome and necrotizing fasciitis.
- *Streptococcus pneumoniae* is the most common cause of otitis media and is a frequent cause of sinusitis. With regard to invasive disease in the critical care setting, pneumococcus most commonly presents as bacteremia, pneumonia, arthritis, and meningitis.
- Relying on serologic tests alone rather that clinical suspicion of Lyme disease can lead to missed diagnoses and overtreatment; markers should be ordered only to confirm objective clinical signs.
- Empiric therapy for Rocky Mountain spotted fever is essential early in the course of illness because fatal outcomes have been linked to missed or delayed diagnosis and treatment.
- Infectious syndromes with multiorgan involvement are often caused by nonbacterial etiologies, including viruses; a broad differential diagnosis should be considered.

The pediatric critical care unit is the epicenter of severe infection in most children's hospitals. Many of these infectious processes are nosocomial and are associated with either patient (e.g., immunocompromised) or procedural issues. Other infectious processes affect specific organs (bronchiolitis and meningitis). These specific infections and the general principles of sepsis management are described in Chapters 29, 47, 65, and 103. In this chapter, the authors describe some of the bacterial, viral, and other infections that may precipitate a systemic response and multiorgan involvement requiring intensive care unit admission. Salient and identifying features are highlighted and, where appropriate, specific comments are provided regarding therapeutic strategies.

Meningococcus

Etiology and Epidemiology

Neisseria meningitidis is a gram-negative diplococcus that is a common cause of bacterial meningitis. It also is responsible for 500,000 cases of a severe sepsis syndrome reported worldwide annually. It is estimated that 1.5 cases per 100,000 persons occur, with 1077 cases reported in 2007 in the United States. The case fatality rate is 10% to 14%.[1,2] Of the 13 serogroups, strains A, B, C, Y, and W-135 are implicated most often.[3] Most cases are isolated or sporadic, with less than 5% associated with outbreaks.[4,5] In the United States, serogroup B accounts for 30% to 70% of sporadic cases, whereas serogroup C is much less common but is often associated with small outbreaks.[6-8] Serogroup A is a common cause of cyclic epidemics in Sub-Saharan Africa ("meningitis belt") and Asia, with increasing outbreaks of W-135 notably in Saudi Arabia in 2001 and in Burkina Faso in 2002.[3,9] There were an estimated 700,000 cases in Africa over the past 10 years with an estimated 10% mortality rate.[10]

The disease most often occurs in children younger than 5 years, with the peak attack rate between the ages of 3 and 5 months. Children with complement C5-9 deficiency and asplenia are at increased risk.[3-5,11] Asymptomatic carriage state has been recognized, and pathogenesis is thought to begin on the nasopharyngeal surface.[12] Patients are considered capable of transmitting the organism for up to 24 hours after initiation of treatment.[2,5,12]

Clinical Presentation

Most invasive meningococcal infections present as meningitis, approximately 10% present as sepsis alone and about 40% present as both systemic and central nervous system (CNS) disease.[3,11,13] Since the introduction of the *H. influenzae* vaccine, *N. meningitidis* has become the second most common cause of bacterial meningitis in North America after pneumococcus.[14] With meningitis alone, the classic signs of headache and meningismus are present but their severity can be variable. Onset of septicemia often is abrupt with fever, chills, malaise, and rash. Rash is the hallmark sign presenting in up to 80% of cases.[6,15] Although petechial rash appearing in clusters at pressure sites is classic, urticarial or maculopapular

Figure 96–1. Ecchymosis of a sole with meningococcal sepsis. *(From Apicella MA: Neisseria meningitides. In Mandell GL, Bennett JE, Dolin R, editors:* Mandell: principles and practice of infectious diseases, *ed 5, New York, 2000, Churchill Livingstone.)*

rashes may also be present (Figure 96-1).[5] The shock state is mediated by endotoxin (lipopolysaccharide) release with subsequent complement activation and release of numerous inflammatory mediators.[12,16,17] Subsequently, rapid endothelial cell injury occurs, leading to capillary leakage, microvascular thrombosis, refractory peripheral vasoconstriction, and acute myocardial failure.[16] Septicemia can rapidly progress within hours to disseminated intravascular coagulopathy (DIC), shock, and death. Invasive disease can be complicated by an immune-mediated arthritis, pancarditis, endophthalmitis, pneumonia, and adrenal insufficiency from Waterhouse-Friderichsen syndrome.[12,18]

Diagnosis

Because of the rapid progression of septicemia and the variability of markers of infection such as white blood cell count and C-reactive protein, clinical diagnosis is imperative.[15] Clinical suspicion should be based on the characteristic rash and symptoms and signs of hypoperfusion, such as tachycardia, cool peripheral extremities, decreased urine output, and altered mental state. Aggressive treatment should be instituted prior to the onset of overt hypotension, that usually occurs before culture results are available.[19,20]

Confirmation may be difficult, particularly when patients have received early antibiotics. Positive cerebrospinal fluid (CSF) and blood cultures range from 50% to 80% in various series.[21] Nevertheless, cultures from blood and CSF are indicated. Lumbar puncture should be delayed if evidence of increased intracranial pressure, coagulopathy, or cardiovascular instability is present. Cultures from petechial scrapings and other body fluids such as synovial fluid can be helpful. Because *N. meningitidis* may be a part of normal flora, nasopharyngeal cultures are not helpful.[12] Latex agglutination is helpful for CSF but unreliable for urine and blood specimens. Polymerase chain reaction (PCR) for bacterial protein is being used in various centers, with sensitivity and specificity near 90%.[22,23]

Management

Conventional Therapy

Experience and epidemiologic data support rapid early intervention in the peripheral center and aggressive treatment in a tertiary care pediatric intensive care unit.[19,20,24] Rapid administration of antibiotics prior to transfer has been shown to improve prognosis.[25-27] Ceftriaxone 100 mg/kg/day divided once or twice daily is recommended as initial empiric therapy. After *N. meningitidis* is confirmed, then penicillin G 500,000 U/kg/day divided in six doses can be used based on sensitivities. Chloramphenicol is an alternative if the patient is allergic to penicillin.[5,12]

Significant capillary leakage is the hallmark feature in meningococcal sepsis. Thus the prominent problem faced in the early stages is maintenance of adequate circulating volume. Early and aggressive volume resuscitation is vital and has been shown to improve outcome.[28,29] Normal saline or 5% albumin solutions have been the standard fluids; no evidence indicates that other colloids, such as blood, change outcome. Ongoing need for continued volume resuscitation should be based on clinical signs of shock and may be as high as twice the child's circulating volume (e.g., 120 mL/kg).[11,19,30] Myocardial depression should be assumed and inotropes such as dopamine should be used early concomitantly with fluid to ensure adequate cardiac output. Epinephrine, norepinephrine, or vasopressin may be necessary. However, the need for high-dose α-adrenergic agents and vasopressin to maintain blood pressure may need to be balanced against the risk for distal extremity ischemia and necrosis. To ensure appropriate and rapid volume resuscitation and inotropic delivery, central venous access should be established as soon as meningococcal sepsis is suspected; however, volume resuscitation should not be delayed and should be started with peripheral or intraosseous access if central access is not yet available.[30,31]

Respiratory support often is necessary when fluid requirements greater than 40 mL/kg are required. Even if the patient is alert and oriented, early intubation and ventilation is beneficial for resuscitation and transport when meningococcus is suspected in order to ensure adequate oxygenation, reduce the patient's work of breathing, decrease metabolic demands, and maintain stability for transport. More importantly, there is a significant risk of pulmonary edema after aggressive fluid resuscitation in the face of myocardial depression.[31]

Numerous metabolic derangements often present because of cellular fluid shifts. Abnormal potassium, calcium, and magnesium concentrations can affect myocardial function and should be monitored and managed aggressively. Hypoglycemia is a common finding, and accordingly serum glucose concentration should be monitored closely. Metabolic acidosis is common and usually corrects with adequate perfusion and lactate clearance. Replacement of bicarbonate is reserved for pH less than 7.2 assuming adequate ventilation is present. [28,30,31]

DIC is common because of factor loss from capillary leak and clotting factor consumption. Derangements are treated with fresh-frozen plasma and cryoprecipitate as needed to prevent life-threatening hemorrhage. This process is associated with anemia and thrombocytopenia, for which packed red blood cells and platelet transfusions may be necessary, especially if spontaneous bleeding from mucous membranes and venipuncture sites occurs.[31]

Plastic surgical interventions may be necessary for amputations and skin grafting. Consultation with other services may be necessary for renal failure, secondary infections, and neurologic complications.[20,31]

Novel Therapy

In addition to standard cardiovascular and respiratory support, multiple specific treatment strategies for meningococcus have been proposed. They have been aimed at altering the inflammatory cascade, treating hemostatic abnormalities, and inducing vasodilation and perfusion.

The role of steroid therapy remains unclear. Exogenous steroids in the septic setting have been thought to enhance upregulation of adrenergic receptors and improve the response to catecholamines, such as exogenous inotropes. No evidence supports the routine use of steroids in meningococcal sepsis specifically but it is indicated in undiagnosed bacterial meningitis.[31] Adrenal replacement doses of hydrocortisone 1 to 2 mg/kg have been suggested for fluid and vasopressor recalcitrant septic shock.[28,30,32]

Immunotherapy, such as antiserum to *Escherichia coli*, that was thought to halt the immune cascade if given early enough, has not been shown to be beneficial in several trials.[33] Likewise, antiendotoxin HA-1A, a human monoclonal immunoglobulin (Ig)M antibody, had no significant benefit.[34] The overall limitation of antiendotoxin therapy is that it must be given very early in the disease process in order to halt the inflammatory response. An alternative to antiendotoxins may be bacteriocidal/permeability increasing proteins (BPIs). BPIs are found in neutrophils and neutralize endotoxins after their release. The results of a large multicenter trial were promising but underpowered.[35] Anticytokine therapy such as interleukin-1 receptor antagonists and anti–tumor necrosis factor antibodies have been studied for sepsis but not specifically for meningococcus. Plasmapheresis to remove cytokines and other mediators are being studied, but no difference in plasma concentrations or overall outcomes has been reported. Hemofiltration and plasma exchange to remove inflammatory mediators have been performed safely. However, the results are mixed, so they are not currently standard therapy.[36]

As mentioned, several hemostatic abnormalities are related to meningococcal disease, and it is postulated they are key to pathogenesis and severity of disease. Potential therapies to combat DIC include antithrombin-III (AT-III), tissue plasminogen activator (tPA), activated protein C, and heparin, as reviewed by Leclerc et al.[32] Case reports are encouraging, but adequate trials are pending. AT-III infusion may promote return of peripheral perfusion and salvage of limbs.[37] Tissue plasminogen activator was associated with an improvement in shock and a decrease in amputations.[38] In the largest pediatric sepsis interventional trial (RESOLVE) conducted to date, activated protein C was not superior to placebo in terms of shortening duration of organ dysfunction or decreasing mortality. Similarly, adjunctive treatment with activated protein C does not prevent other morbidity, such as significant loss of limbs and was associated with neonatal bleeding.[39,40] Many case reports have supported heparin infusions, but the benefits have not been reproduced in controlled studies.[41] Because of the significant risk of intracerebral bleeding, cost of therapy, and lack of prospective randomized studies, the impact of these adjunct therapies on morbidity and mortality are still being debated and investigated.[39]

Vasodilators to improve peripheral and end-organ perfusion have been studied in small populations, and results are variable. Prostacyclin has been reported to improve distal perfusion, whereas nitroprusside infusions and topical nitroglycerin also have been attempted, with some anecdotal success.[42]

Prevention and Vaccines

Prophylaxis of meningococcal disease is detailed in the American Academy of Pediatrics' Red Book and includes the use of rifampin or ceftriaxone for high-risk contacts. These include household contacts especially less than 2 years old, preschool exposures, and those with direct exposure to body fluids. Routine prophylaxis to health care professionals is not recommended.[5,31] Quadrivalent polysaccharide vaccine to serogroups A, C, Y, and W-135 have been available since the early 1980s but are largely ineffective. More recently, protein conjugate vaccines have been developed and have shown a strong primary response and has lead to a reduction in nasal carriage.[11] Following the introduction of protein conjugate serogroup C vaccine in the United Kingdom, the attack rate decreased by 94% in the immunized population.[43] A quadrivalent conjugate vaccine is now available in North America and further interest in the development of a vaccine to serogroup B, that causes approximately 50% of invasive disease worldwide, is ongoing.[44]

Prognosis

Morbidity and mortality with meningococcus has been difficult to estimate because of multiple serotypes, regional differences, and seasonal variations.[45] Fatalities have been reported as high as 75% in epidemic regions in Africa.[10] The case fatality ratio in the United States is 10% to 14%, with 11% to 19% morbidity in survivors including complications such as need for skin grafting, loss of limbs/digits, and neurologic disability.[44] Several prognostic scores have been developed using multiple clinical and laboratory values. A widely used and validated system is the Glasgow Meningococcal Septicemia Prognostic Score developed by Sinclair and validated by Thomson et al.[15,46] Data suggest that early recognition, early antibiotic administration, aggressive resuscitation, and transfer to a pediatric intensive care unit have reduced mortality of severely ill children from the previously reported rate of 35% down to 2% to 13%.[14,47,48]

Staphylococcus Toxic Shock Syndrome

Etiology and Epidemiology

Staphylococcus aureus is a gram-positive coccus grouped typically in clusters. It is responsible for a wide spectrum of clinical manifestations, including sepsis, pneumonia, cellulitis, arthritis, meningitis, and endocarditis. Staphylococcal

toxic shock syndrome (TSS) came into prominence in the early 1980s with the use of super-absorbent tampons and was named *menstrual-associated toxic shock*.[49,50] Thus this form of TSS had a particular predilection for adolescent and young women.[51] Now, approximately, half of cases in children are hospital acquired.[52,53] Most nonmenstrual cases have been associated with localized musculoskeletal infections, surgery, or insect bites.[54-56]

Staphylococci produce various toxins. These exotoxins are superantigens causing the activation of large number of T cells. In particular, TSS is linked to an enterotoxin named toxic shock syndrome toxin-1 (TSST-1). TSST-1 accounts for approximately 90% of cases of menstrual toxic shock. Other enterotoxins are responsible for up to 50% of nonmenstrual cases.[49,57] TSST-1 acts as a stimulating factor for the release of inflammatory mediators such as interleukin-1β, tumor necrosis factor-α, interleukin-2, and γ-interferon from macrophages and lymphocytes. This massive inflammatory mediator release causes generalized lymphocytic perivasculitis and interstitial edema. This capillary leak syndrome is characteristic of TSS and results in multiorgan dysfunction, including heart, lung, kidney, and brain involvement.[58]

Clinical Presentation

The Centers for Disease Control and Prevention (CDC) has defined TSS as fever, rash, hypotension, multiorgan involvement, and desquamation with specific criteria (Box 96-1).

Box 96–1 Staphylococcus TSS Case Definition

Fever: temperature ≥38.9° C
Rash: diffuse macular erythroderma
Desquamation: 1–2 weeks after onset of illness; involvement of palms, soles, fingers, and toes
Hypotension: systolic blood pressure ≤90 mm Hg for adults, ≤5th percentile for age in children, or orthostatic syncope
and
Involvement of ≥3 of the following organ systems:

- Central nervous system: disorientation or alteration in consciousness, without focal neurologic signs, when fever and hypotension are absent
- Gastrointestinal: vomiting or diarrhea at onset of illness
- Hematological: platelets ≤100,000
- Hepatic: total bilirubin or transaminase concentrations greater than twice the upper limit of normal
- Muscular: severe myalgia or CPK level greater than twice the upper limit of normal
- Mucus membrane: vaginal, oropharyngeal, or conjunctival hyperemia
- Renal: blood urea nitrogen or creatinine concentration greater than twice the upper limit of normal or at least five white blood cells per high-power field in the absence of urinary tract infection

and
Negative results on the following test:

- Blood, throat, or cerebrospinal fluid cultures for other organisms
- Serologic tests for Rocky Mountain spotted fever, leptospirosis, or measles

Modified from Centers for Disease Control and Prevention. Toxic-shock syndrome—United States, *MMWR* 32:201, 1982.

Onset usually is abrupt, with fever, chills, malaise, and diffuse macular erythroderma. Fever often is remarkably high and resistant, occurring with intense myalgias, vomiting, and diarrhea. The rash is described as a generalized erythematous, deep-red "sunburn" and can be accompanied by conjunctival erythema.[59-61] Within 24 hours, cardiovascular depression becomes prominent, with hypotension and decreasing systemic perfusion leading to severe shock and multiorgan dysfunction. Most cases do not cause infective endocarditis unless associated with congenital heart disease. Progressive liver and renal failure are common. The patient may manifest symptoms of diffuse toxic encephalopathy, usually without meningeal signs. Renal failure can be oliguric or nonoliguric. Scaling and desquamation, that are included in the diagnostic criteria, occur with resolution of fever and usually are prominent on the palms and soles.[62-63]

Diagnosis

Differential diagnosis for syndromes that include fever, rash, and multiorgan involvement are numerous and are summarized in Box 96-2. Diagnosis is mainly clinical, but can be supported with inflammatory markers associated with sepsis. The degree of leukocytosis often is not impressive but the percentage of immature cells usually is markedly high.[50] Metabolic derangements can support the diagnosis; for example, hypocalcemia and hypophosphatemia are not unique to TSS but can be profound.[64] Liver function abnormalities are common. Elevated urea and creatinine concentrations result from prerenal causes initially but also may involve acute tubular necrosis. Persistent lactic acidosis even with restoration of hemodynamics may reflect decreased tissue perfusion and end-organ ischemia.[61]

Negative blood cultures do not rule out staphylococcus; accordingly, clinical suspicion often must be relied on.

Box 96–2 Differential Diagnosis of Staphylococcus TSS

Bacterial
Meningococcemia
Invasive group A β-hemolytic *Streptococcus* toxic shock
Group A β-hemolytic streptococcus scarlet fever
Staphylococcus scalded skin syndrome
Salmonella infection

Viral
Measles
Enterovirus syndrome with myocarditis

Tick-Borne
Rocky Mountain spotted fever
Leptospirosis
Ehrlichiosis

Other
Stevens-Johnson syndrome and toxic epidermal necrolysis (drug reaction)
Kawasaki disease
Systemic lupus erythematosus

Modified from Chesney PJ: Pediatric infectious disease-associated syndromes. In Fuhrman BP, Zimmerman JJ, editors: *Pediatric critical care,* St Louis, 1992, Mosby.

Lumbar puncture is not warranted because CSF usually is benign in TSS. Swabs of the primary infection site, such as the postsurgical or vaginal sites can be helpful. TSST-1 antibody assays have been developed but are not recommended, especially because many of the nonmenstrual cases may have other causative endotoxins.[63,65]

Management

Because the course can be variable and unpredictable, close monitoring and observation are essential when TSS is suspected. Rapid and aggressive fluid administration is required because the severity of end-organ involvement is related to the degree of hypotension and duration of decreased perfusion. Volume requirements may be exceptionally high because of the massive capillary leak characteristic of TSS.[66] As a result, acute respiratory distress syndrome (ARDS), myocardial failure, and generalized edema are common. Fluid administration should be guided by close monitoring of blood pressure, central venous pressure, perfusion, and urine output. Other management issues include correction of acid-base abnormalities, electrolyte disorders including hypocalcemia, coagulopathies, renal failure, and fluid overload.[67] Mechanical ventilation, renal replacement therapy, and administration of blood products are often necessary.

Two premises to antibiotic therapy for TSS exist. The first is to kill the organism with a bacteriocidal antistaphylococcal β-lactamase–resistant agent such as cloxacillin or vancomycin. The second is to stop enzyme, toxin, and cytokine production with a protein synthesis inhibitor such as clindamycin. Of note, vancomycin is less effective against staphylococcus and should be limited to resistant organisms or allergic patients.[49,51,67]

Vaginal examination should be performed as soon as possible and foreign bodies removed and sent for cultures. Other possible foci for infection should be drained and irrigated, especially postsurgical sites.

Intravenous gammaglobulin (IVIG) has been shown to prevent T-cell stimulation by enterotoxin and may have a role in modulating the inflammatory response.[68] No systematically studied trials in humans have described benefits of IVIG, but numerous animal models exist. There are anecdotal examples of its effectiveness, especially in refractory cases.[58,69-71] Doses of 150 to 600 mg/kg/day for 5 days or a single dose of 1 to 2 g/kg have been used. In theory, the IVIG must be given early in the course of illness because its role is to prevent rather than treat the systemic inflammatory response.[51]

Corticosteroids have been used after retrospective studies reported beneficial effects on severity and duration of illness.[67,72] However, no further prospective studies have shown specific benefits against the TSST-1 enterotoxin. Therefore steroids usually are reserved for refractory cases where hypotension does not respond to fluids and inotropes. The development of specific antibodies to superantigens is a rapidly developing field.

Prognosis

With aggressive therapy, prognosis is good, with a mortality rate of less than 5%.[53,73] Death usually is related to ARDS or refractory arrhythmias. Mortality is higher in nonmenstrual cases.[74] Other specific risk factors for higher mortality have not been identified, although increasing age has been linked to poorer outcome.[75] Recurrent cases have been noted for both menstrual and nonmenstrual causation.[58,61]

Invasive Group A β-Hemolytic Streptococcus

Etiology and Epidemiology

Invasive group A β-hemolytic streptococcus (GABHS) is a gram-positive coccus often grouped as chains. GABHS accounts for 3.3% of bacteremia in children.[76] Infections resulting from GABHS have become more common, presenting with the two overlapping syndromes of TSS and necrotizing fasciitis.[77-79] The CDC has defined TSS caused by GABHS as having prominent features of shock and multiorgan failure (Box 96-3). TSS caused by GABHS is similar to the clinical entity described for *Staphylococcus* TSS. However, GABHS TSS is more commonly associated with bacteremia and underlying soft-tissue infection compared with staphylococcal TSS.[80-82] Necrotizing fasciitis is characterized by extensive local necrosis of soft tissue and skin. GABHS TSS is associated with necrotizing fasciitis in 50% of cases.[80,83] Apart from these two entities, invasive GABHS can present with more localized infections such as meningitis, pneumonia, osteomyelitis, septic arthritis, and surgical wound infections. It is important to note that severe invasive GABHS rarely occurs following isolated pharyngitis or scarlet fever; rather, most infections reflect the skin or soft tissue as the portal of entry.[84]

The CDC estimates the incidence is 4 to 5 cases per 100,000, with approximately 10,000 cases occurring yearly.[81,85] Overall mortality in the pediatric population is approximately 5% to 10% but is much higher in adults.[86,87] Approximately 10% of cases are hospital-acquired infections. Infections in clusters or outbreaks, even with close contacts, are uncommon.[77]

Box 96–3 Case Definition for Streptococcal TSS

1. Isolation of group A β-hemolytic streptococci:
   - From a normally sterile site: blood, cerebrospinal fluid, peritoneal fluid, tissue biopsy, etc.

   and
2. Clinical signs of severity:
   a. Hypotension:
      - Systolic blood pressure <90 mm Hg for adults; <5th percentile for age in children

      and

   b. Multiorgan involvement with ≥2 of the following:
      - Acute respiratory distress syndrome
      - Coagulopathy: platelets <100,000 or disseminated intravascular coagulopathy
      - Hepatic: total bilirubin or transaminases greater than twice the upper limit of normal
      - Rash: generalized macular erythroderma that may desquamate
      - Renal: creatinine twice the upper limit for age
      - Soft tissue necrosis: necrotizing fasciitis, myositis, or gangrene

If group A β-hemolytic streptococcus is isolated from a *nonsterile* site but other criteria are still fulfilled, then the case is defined as *probable*.

Modified from The Working Group on Severe Streptococcal Infections: Defining the group A streptococcal toxic shock syndrome. Rationale and consensus definition, *JAMA* 209:390-391, 1993.

Streptococcal necrotizing fasciitis can occur in otherwise healthy people at any age, but the incidence is higher in young children and the elderly. Risk factors include age younger than 2 years, diabetes mellitus, chronic cardiac or pulmonary disease, immunodeficiency syndromes, intravenous drug use, and malignancy.[88] In children, varicella seems to be an increasing risk factor in recent years. GABHS should be suspected as a secondary infection in children with recurrence of fever especially after day 3 of varicella illness or when lesions are more painful.[89] Several reports have implicated nonsteroidal antiinflammatory drugs as a risk factor for GABHS infection; however, a causal relationship has not been established.[78,90]

The pathogenic mechanism is unknown but is thought to be associated with a streptococcal pyrogenic exotoxin, which may act as a superantigen. This stimulates intense activation and proliferation of T lymphocytes and macrophages, resulting in a massive production of cytokines that, in turn, mediate tissue injury, and shock.[91]

Clinical Presentation

With TSS, most cases present initially with nonspecific flulike symptoms that include fever, chills, and myalgias. Half of the patients develop hypotension within the first 4 hours.[92] Multiorgan failure including ARDS and acute renal failure occurs in up to 55% of patients. Mechanical ventilation is necessary in 90% of patients who develop TSS.[93] Otherwise, presentation includes myositis, perihepatitis, peritonitis, myocarditis, DIC, and generalized septic shock.[86,94]

With fasciitis, severe localized pain is the most common initial symptom, usually without correlating physical signs.[92] It usually is an acute process with rapid progression. The legs are the most common site of infection, but the abdominal wall, groin, and perianal areas also are frequently affected. In newborns, the site most commonly affected is the umbilicus.[85]

Approximately 80% of infants eventually develop obvious signs of soft tissue infection, and of these 70% progress to deeper infections requiring surgical debridement. Over the first 24 to 48 hours, the area becomes erythematous and swollen without sharp margins. Skin vesicles and bullae may be bluish and may appear by days 4 to 5, heralding fasciitis. By this time, the area often becomes anesthetic and gangrenous secondary to thrombosis of small blood vessels. Marked swelling and edema may lead to compartment syndrome requiring urgent fasciotomies.[85,95]

Diagnosis

Signs and symptoms may not be specific for group A streptococcus; thus empiric treatment is initiated before diagnosis is confirmed. Invasive GABHS should be suspected especially when a risk factor such as varicella coinfection or diabetes mellitus is present. Swabbed gram stain and cultures taken from focal lesions probably are the most useful diagnostic tool. Bacteremia is present in 60%, but pending blood culture results should not delay treatment. Often only mild leukocytosis is present, but a left shift is striking.[96] Rising serum creatinine kinase concentration has correlated well with deeper soft tissue infections. When necrotizing fasciitis is suspected, magnetic resonance imaging can be helpful in confirming the diagnosis by identifying muscle and underlying fascia inflammation and necrosis.[97,98] GABHS was identified in 71% of necrotizing fasciitis cases.[99] However, one study in children found GABHS as a single organism in only 25% of the cases; the rest were polymicrobial.[61] Other organisms implicated in necrotizing fasciitis are listed in Table 96-1. Approximately half of necrotizing fasciitis cases involve mixed aerobic and anaerobic flora.[100]

Management

When invasive GABHS (TSS or necrotizing fasciitis) is suspected, aggressive hemodynamic support and prompt antibiotic therapy are essential. A high index of suspicion should encourage initiation of antibiotics specific to GABHS. Frequently, massive amounts of intravenous fluids are required because of the extensive capillary leak.[92] Inotropic agents such as dopamine are needed early in order to support adequate cardiac output. Vasoconstrictors such as epinephrine, norepinephrine, and vasopressin should be used with caution because impaired perfusion to necrotic areas may lead to loss of limbs. Milrinone may be a useful adjunct when vasodilation is necessary.[95]

With TSS, both GABHS and *S. aureus* should be covered with broad-spectrum antibiotics. With a microbiologic diagnosis, the antibiotics can be tailored later. Group A streptococci in general are extremely sensitive to β-lactam antibiotics, but invasive GABHS infections seem to respond less well to the penicillins alone.[101,102] With GABHS identified, penicillin G 200,000 to 400,000 U/kg/day in four to six divided doses can be administered. Clindamycin as an adjunct has proved effective at doses of 25 to 40 mg/kg/day in three to four divided doses.[95,103] Clindamycin works by inhibiting protein synthesis, thus suppressing bacterial toxin production and decreasing penicillin-binding protein synthesis. Clindamycin also has been shown to modulate the immune response.[101] Though no controlled clinical trials have demonstrated improved outcome with the addition of clindamycin, it is recommended in combination with a third generation cephalosporin as initial therapy.[90]

With necrotizing fasciitis, prompt surgical exploration and aggressive debridement are critical, with involvement of general, orthopedic, and plastic surgeons. By the time clinical signs are present, saving viable tissue may not be possible, but debridement is necessary to prevent the progression of inflammation and necrosis.[98] The patient often is returned to the operating room daily for inspection until the infection is adequately

Table 96–1 List of Common Organisms Causing Necrotizing Fasciitis

Gram-Positive Organisms (Percent)	Gram-Negative Organisms (Percent)
Group A streptococci (18–46)	*Escherichia coli* (8–28)
Enterococci (16–34)	*Enterobacter* (2–12)
Coagulase-negative *Staphylococcus* (15–37)	*Pseudomonas* (9–20)
Staphylococcus aureus (9–37)	*Proteus* (6–12)
Staphylococcus epidermidis (18)	Serratia (2–6)
Clostridia (5–21)	*Bacteroides* (18–48)
Mixed gram positives (10)	Mixed gram negatives (16)

Modified from Cunningham JD, Silver L, Rudikoff D: Necrotizing fasciitis: a plea for early diagnosis and treatment, *Mt Sinai J Med* 68:258, 2001.

controlled. Fasciotomies often are needed in the presence of compartment syndrome in order to facilitate adequate perfusion.[102] Amputation may be necessary and should be undertaken early if necessary. Then, daily dressing changes can continue with close monitoring of surgical margins. Often daily magnetic resonance imaging is warranted.[98,100]

Antibodies specific for the toxin do not exist, but use of IVIG 1 to 2 g/kg in a single dose has been effective in case reports in both TSS and necrotizing fasciitis.[69-71,104,105] The possible mechanism may involve prevention of T-cell proliferation and reduction of cytokine release. Some anecdotal reports of the benefits of hyperbaric oxygen also exist but are inconclusive.[106] No controlled trials have demonstrated the efficacy of either of these therapies.

Prognosis

Though incidence of fasciitis may be declining with the use of varicella vaccination, mortality rates for TSS still vary from 30% to 70%.[85,86,107,108] For necrotizing fasciitis, mortality rates range from 6% to 36%.[100] Morbidity is high, including surgical intervention in greater than 50% of suspected fasciitis cases.[84] Irreversible renal impairment is seen in up to 10%. The CDC estimated 1350 deaths related to GABHS in 2007.[81] Unfavorable outcome has been shown to be affected by delayed diagnosis and by the presence of organ failure at the time of admission.[109]

Invasive Pneumococcus

Etiology and Epidemiology

Streptococcus pneumoniae is the most common cause of otitis media and a frequent cause of sinusitis. With regard to invasive disease in the critical care setting, pneumococcus most commonly presents as bacteremia, pneumonia, arthritis, and meningitis. Meningitis is discussed in Chapter 65. This chapter focuses on bacteremia and pneumonia. Other less common pneumococcal infections include endocarditis, soft tissue cellulitis, pericarditis, peritonitis, and salpingitis.

S. pneumoniae is an encapsulated gram-positive diplococcus organized in chains. It is a nasopharyngeal colonizer and is found in up to 40% of healthy children.[110] Transmission via secretions and respiratory droplets increase in environments of close contacts, such as day care centers. Infection from *S. pneumoniae* may be secondary to mucosal barrier changes from other viral infections. In the Northern Hemisphere, invasive disease in children is more prevalent between September and May and can be associated with other viral illnesses such as influenza.[111,112] There are more than 90 serotypes of *S. pneumoniae,* with only a few identified as causing invasive disease. After host cells are invaded, the organism is resistant to phagocytosis because of its capsule and subsequently causes tissue damage.[113] The incidence is higher and the severity of invasive illness greater in children with congenital or acquired humoral immunodeficiencies, including HIV. Patients with deficient splenic function are susceptible (Box 96-4).[112,114]

The overall rate of invasive disease has dropped from 23 to 13 cases per 100,000 persons per year in 2002 in the United States.[115-117] It is relatively more common in newborns and infants up to age 2 years and much less in older children and teenagers.[116,118] Most younger cases result from bacteremia alone.[115] Older children are more likely to develop pneumonia. Per annum, an estimated 500,000 cases of pneumonia, 60,000 cases of bacteremia, and 3000 cases of meningitis related to streptococcus occur in the United States.[81,117] Meningitis occurs most commonly between the ages of 6 and 18 months, bacteremia occurs between 6 and 36 months, and pneumonia presents between 3 and 60 months.[119-121] Of the many children in the Third World who die of lower respiratory tract infection, *Streptococcus* is the primary agent.[122] Globally, *S. pneumoniae* is the most common cause of bacterial pneumonia, accounting for up to 70% of cases.[123] In a Canadian study, the overall incidence of bacterial pneumococcal pneumonia was 9.7 cases per 100,000.[124]

Clinical Presentation

Invasive pneumococcal disease is defined as the isolation of *S. pneumoniae* from normally sterile sites such as blood, pleural fluid, joint fluid, and CSF. Approximately 3% to 5% of febrile children between 3 and 36 months old are at risk for occult or asymptomatic bacteremia, of which 90% are caused by *S. pneumoniae*.[125] In most cases, occult bacteremia resolves without sequelae. However, persistent bacteremia may lead to septic shock with hypotension and end-organ involvement, spreading to the meninges, pleura, bones, and joints.

Pneumococcal pneumonia is associated with bacteremia in 40% of cases.[113,126] Presentation can be quite nonspecific,

Box 96–4 Risk Factors for Invasive Pneumococcal Disease

Organism Factors

Invasive properties of the pneumococcal serotype

Host Factors

Serotype-specific humoral immunity
Age <2 years
Specific ethnic background:
- African American
- Native American
- Alaskan Eskimo
- Micronesian
- Aboriginal (Australia and New Zealand)

Presence of viral respiratory infection
Not breast-fed
Underlying illness:
- Congenital or acquired antibody deficiency
- HIV infection
- Complement deficiency
- Congenital or acquired splenic dysfunction:
  - + Sickle cell disease
  - + Other hemoglobinopathies
  - + Surgical splenectomy
- Malignancy
- Nephrotic syndrome

Environmental Factors

Daycare attendance
Recent antibiotic use
Season of year
Smoke exposure
Overcrowding

Modified from Tan TQ: Pneumococcal infections in children, *Pediatr Ann* 31:242, 2002.

especially in infants. Symptoms range from those managed as an outpatient to those requiring mechanical ventilatory support. Most commonly, symptoms include fever, cough, tachypnea, malaise, and emesis.[126] On physical examination, hypoxia is associated with localized crepitations and decreased breath sounds that correlate with lobar infiltration on chest radiographs. Almost 50% of cases present with multilobar involvement and 40% with pleural effusions.[127] Although rare, necrotizing pneumonia, pneumatoceles, and lung abscesses can be seen. Pleural empyema occurs in up to 14% of pneumococcal pneumonia. Interestingly, lower lobe pneumonia may present with abdominal symptoms and signs, whereas upper lobe pneumonia may be associated with nuchal rigidity.[113]

Diagnosis

Diagnosis depends mostly on clinical suspicion. Initially, *S. pneumoniae* bacteremia should be suspected when the white blood cell count (WBC) is greater than 15,000 and absolute neutrophil count is greater than 10,000. Isolation from blood or sterile fluid confirms the diagnosis but should not delay treatment if pneumococcus is suspected.[128] Pneumococcal rapid antigen testing and PCR can aid in making the diagnosis, especially if antibiotics have already been started.[114,121] Sputum samples are rarely helpful in children; nasopharyngeal cultures may reflect only colonization rather than infection. However, if intubated, samples obtained via bronchioalveolar lavage are beneficial. Ultrasound or computed tomography (CT) can help identify effusions or empyema, which subsequently can be aspirated.[129]

Management

For critically ill patients potentially infected with invasive *S. pneumoniae*, a third-generation cephalosporin such as ceftriaxone or cefotaxime (25 to 100 mg/kg/dose every 8 hours) is recommended. Cefuroxime, a second-generation agent, is also an appropriate choice for non-meningitic cases.[112,130] If the patient is toxic, immunodeficient, or antibiotic resistance is suspected, then vancomycin 10 mg/kg/dose every 6 hours should be added. However, even when nonsusceptible strains were identified, complications, recovery, and mortality were no different than when penicillin alone was used.[114,131,132] Thus vancomycin should not be used routinely but is suggested when meningitis, severe multilobar pneumonia, carditis, meningitis, or hypoxia and hypotension are present. When pneumococcus is confirmed and sensitivities are determined, then antibiotics should be reevaluated and penicillin G 400,000 U every 4 to 6 hours started if susceptible. Clindamycin can be used for patients with penicillin hypersensitivity.[112,130]

During the past 2 decades, antibiotic resistance among pneumococcal strains has continued to increase and has complicated the management of invasive infections. Resistance stems from the alteration of penicillin-binding proteins, which are enzymes that are important in the production of bacterial cell walls. As a result of these alterations, there is a decreased affinity for β-lactam antibiotics and thus decreased susceptibility.[130] In the United States, 34% of strains were nonsusceptible to β-lactams, with 21% showing full resistance and 13% showing intermediate resistance. Similarly, full resistance to ceftriaxone also increased to 14%.[122] Resistance to other classes of antibiotics occurs by other mechanisms and is summarized by Kaplan.[130] Although resistance to vancomycin is not yet described, tolerance such that *S. pneumoniae* is inhibited but not killed has been reported.[133,134]

Treatment should continue for 7 days for bacteremia alone and 10 to 14 days for pneumonia. Symptoms such as fever and tachypnea may persist for 3 to 4 days after initiation of treatment. If fever persists, then further investigations for infectious collections or resistance are necessary.[114,134] If empyema is suspected, then the etiology should be established definitively with immediate thoracocentesis and empyema drainage. These procedures have been shown to decrease the severity and duration of illness. If only effusions are present, then draining is not imperative unless loculations develop or symptoms persist.[129] Dexamethasone as an adjunctive therapy is only warranted for meningitis cases in children 6 weeks of age and older.[112]

Prevention and Vaccination

Pneumococcal conjugate vaccine was licensed in the United States in 2000 for use in children younger than 2 years of age and older children at increased risk for pneumococcal disease. As a result, by 2006 the incidence of invasive pneumococcal infections had decreased by 77% in children less than 5 years old.[112,121] This vaccine targets the seven strains of pneumococcus that, in 2000, were the most common among children. Disease caused by pneumococcal strains not covered by the vaccine formulation has increased, and this increase was primarily driven by serotype 19A; however, new conjugate vaccines should provide protection against serotype 19A disease in the future.[121]

Prognosis

In most children, occult pneumococcal bacteremia resolves spontaneously without apparent sequelae. Overall mortality from documented bacteremia was reported to be 0.4% in one review.[135] The possibility of persistent bacteremia and spread to sterile site results in significant morbidity. Ten percent of patients with bacteremia develop focal complications. The case/fatality rate for pneumococcal pneumonia is 1% in children but up to 20% in adults.[135,136] Pleural empyema and chronic lung changes may occur in up to 14%.[113] The impact of penicillin resistance on the clinical presentation and outcome of invasive pneumococcus is still unclear[137,138] The role of new heptavalent conjugate vaccines on morbidity and mortality is evolving.[121]

Lyme Disease

Etiology and Epidemiology

Lyme disease is a multiorgan system disease caused by the spirochete *Borrelia burgdorferi*. Endemic to many parts of the United States, Lyme disease is transmitted by deer tick bites.[139] It has become the most common reported tick-borne disease in the United States, with almost 20,000 cases reported by the CDC in 2006.[140] The number of cases has been increasing yearly since 1992 (Figure 96-2).[141] Incidence is greatest in the northeastern, mid-Atlantic, and north-central

regions of the United States, although the incidence is rising in the northwest and California (Figure 96-3).[1,142,143] *B. burgdorferi* has also been reported in Asian countries including China.[144] Cases are highest in children between 5 to 14 years old. Two-thirds of cases have onset of symptoms in June and July. Numerous reports have commented on the overdiagnosis of Lyme disease as a result of misinterpretation of serologic tests, that may account for the inflated numbers.[145]

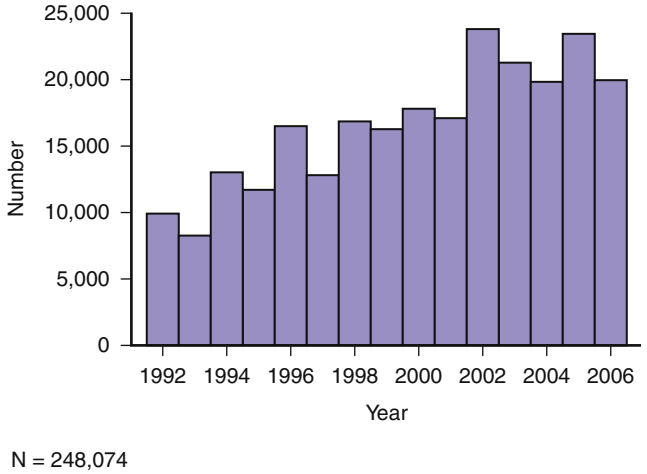

Figure 96–2. Number of reported cases of Lyme disease by year—United States, 1992–2006. *(From Centers for Disease Control and Prevention: Surveillance for Lyme disease—United States 1992-2006,* MMWR *57: 1–9, 2008.)*

Clinical Presentation

The classic infection was well described by Steere[146] and outlined by the CDC in 1995.[139] The clinical manifestations are divided into three stages: early localized (7 to 14 days after tick bite), early disseminated (3 to 10 weeks), and late disease (months). In 80% of patients, Lyme disease in so-called stage 1 starts as a slowly expanding erythema migrans rash with central clearing. The lesion begins as a red macule or papule at the site of the bite, which usually is in the head and neck region. The rash expands over days to a diameter greater than 5 cm. Only one third of cases presents with the classic central clearing lesion. This characteristic "bull's eye" or "target" lesion often is accompanied by nonspecific, intermittent flu-like symptoms such as fever, malaise, fatigue, headache, myalgias, and arthralgias. The incubation period from infection to onset of erythema migrans typically is 7 to 14 days but may be as short as 3 days and as long as 30 days.[142,147-149] Gerber et al.[143] described initial presentations in children with a single migrans lesion in 66%, multiple lesions in 23%, arthritis in 7%, meningitis in 1%, and carditis in 0.5%.[150] Symptoms in children included seventh nerve palsy in 14%, fever in 24%, fatigue in 58%, arthralgias in 33%, and headache in 42%.[143,149,151,152] Some infected individuals have no recognized illness and have only serologic evidence of infection. The initial rash usually fades within 3 weeks.[142]

After a few weeks the disease enters stage 2 and becomes disseminated. The first sign often is multiple smaller erythema migrans lesions and frank arthritis in up to 80% of cases. Approximately 15% of untreated patients develop neurologic symptoms such as a lymphocytic meningitis, encephalitis,

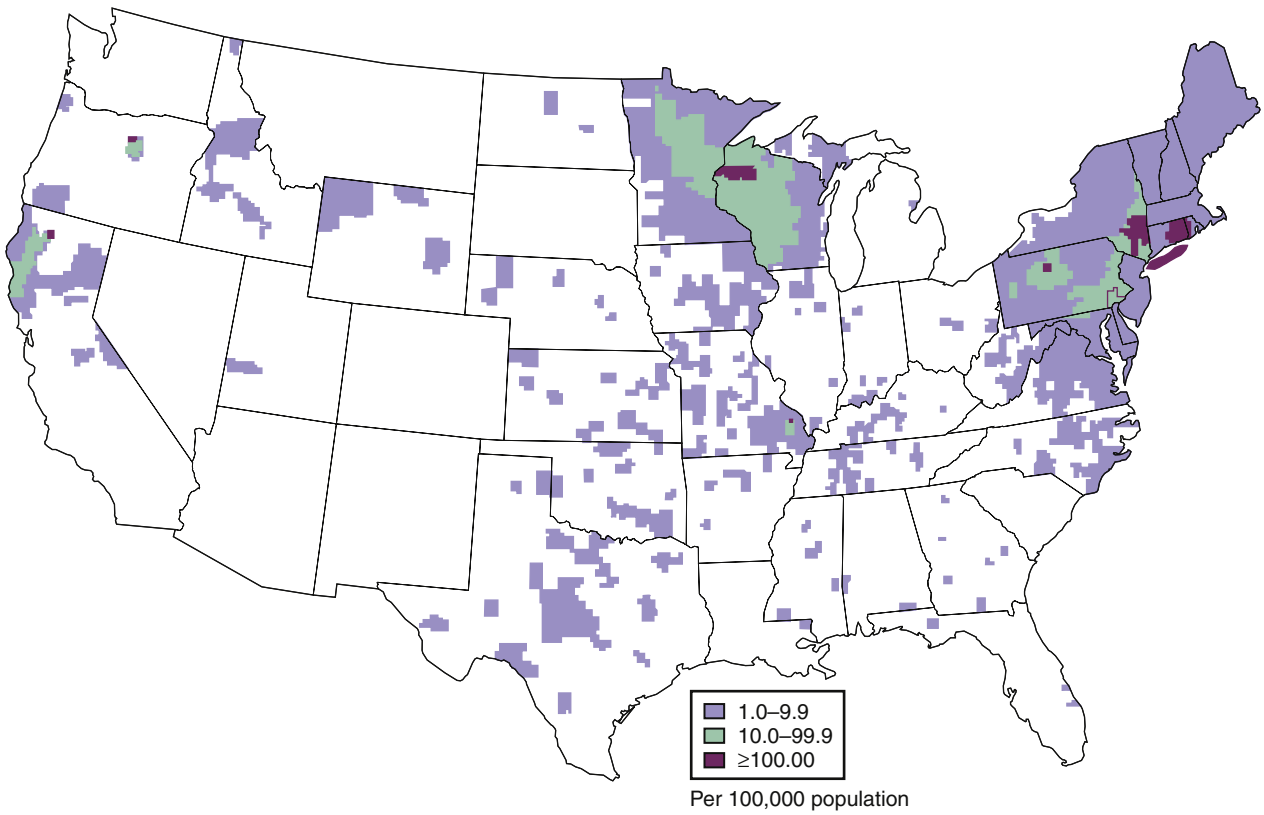

Figure 96–3. Number of reported cases of Lyme disease by county—United States, 1992–2006. *(From Centers for Disease Control and Prevention: Surveillance for Lyme disease—United States 1992-2006,* MMWR *57:1–9, 2008.)*

pseudotumor cerebri, cerebellar ataxia, radiculoneuritis, and focal neuropathies, particularly seventh nerve facial palsies and optic nerve deficits.[153,154] The neurologic abnormalities typically improve even without treatment. Approximately 5% of patients develop acute cardiac manifestations, most commonly atrioventricular block of varying degrees but also myocarditis and dilated cardiomyopathy. Carditis from Lyme disease is rare in children and is usually transient.[149,155] Arthritis of the knee and hip is the most common late presentation of Lyme disease, especially in children.[155] However, the diagnosis is often missed because of assumption of septic arthritis from other bacterial etiologies.[156]

In stage 3, late manifestations of damage to major organ systems may persist, particularly to joints and the neurologic system. In 5%, chronic symptoms of encephalitis, polyneuropathy, and cognitive impairment may persist. However, late neurologic disease is rare in children.[157-159] In 90% of patients, the arthritis is single joint and involves the knee; it can last up to 2 years.[160] Typically, the arthritis involves swelling rather than pain and redness; thus it presents as a less "septic" picture. Chronic arthritis now is rare with antibiotic treatment, but arthralgia symptoms persist in up to 33%.[142,148,161]

Diagnosis

Laboratory testing is neither required nor recommended.[155] Although the diagnosis usually is based on clinical suspicion, serologic assays can help confirm the diagnosis. Patients are frequently seronegative on early presentation, so clinical suspicion remains imperative. Because of the many false-positive results, especially in areas of low prevalence, the diagnosis should not be made solely on the basis of serologic tests.[162] Relying on serologic tests alone rather than clinical suspicion has led to missed diagnoses and overtreatment.[145] Thus markers should be ordered only to confirm objective clinical signs.

Borrelia is often found on culture from skin aspirates from migrans lesions or from blood culture in early, disseminated disease. Blood cultures usually are negative in the early, localized stage.[149,163] Serologic confirmation has improved with use of enzyme immunoassays, but again false-positive results are obtained for other spirochetal infections, viral infections (varicella), and autoimmune diseases. Because of difficulties with serologic assays, ELISA and Western blot testing are used to confirm the diagnosis.[1,151] Serology was positive in 80% of cases with neurologic or joint involvement and in 50% of cases with rash alone.[155] IgM-specific antibodies arise between 3 to 6 weeks, and IgG rises slowly and peaks months after the onset. Antibodies persist for years and should not be used to follow treatment success. PCR is more widely used but has low sensitivity and is prone to false-positive results, so is not recommended as the sole method for diagnosis.[162]

Overall, laboratory findings are nonspecific, with mild elevation in white cell count. Hepatic and renal functions are usually not affected. With arthritis, neutrophil predominant pleocytosis in synovial fluid can be associated with an elevated erythrocyte sedimentation rate. Lumbar puncture is recommended if neurologic symptoms are present and is especially useful for the confirmation of pseudotumor cerebri. Imaging is recommended before lumbar puncture in these cases.[151] However, the need for lumbar puncture is controversial when facial palsies present in isolation.

Management

The drug of choice for early, localized disease in children older than 8 years is doxycycline 100 mg twice daily. The American Academy of Pediatrics also recommends amoxicillin 50 mg/kg/day for younger children. Treatment with antibiotics is recommended for 14 to 21 days.[151] For early disseminated disease with mild migrans, isolated facial palsies, or mild arthritis, the same oral regimens are warranted. Some evidence shows that only 10 to 14 days treatment may be sufficient.[164] Treatment at the erythema migrans stage almost always prevents the development of later stages of the disease. Although the rash subsides within days, other symptoms may take several weeks before resolving. Treatment does not affect the resolution of nerve palsies but prevents the late disease.[154] Lyme arthritis alone can be treated with oral doxycycline or amoxicillin. Nonsteroidal antiinflammatory agents may be helpful. If severe or persistent arthritis, neurologic, or cardiac manifestations occur, then ceftriaxone 100 mg/kg/day intravenously for 21 days is recommended.[142,148,151,161] Children with prolonged PR intervals or heart block should be hospitalized with cardiac telemetry and treated with parental antibiotics.[155] Corticosteroids have not shown to be effective therapy for neurologic or arthritic symptoms.[165] Repeat courses of antibiotics have not shown benefit for chronic or severe cases.[166]

Prognosis

Although Lyme disease is rarely fatal, the morbidity, especially related to neurocognitive effects, can be severe if untreated.[149,155] Behavioral and sleep changes and auditory and visual deficits have been identified.[159] However, children treated appropriately have shown no cognitive deficits on long-term neuropsychological testing in prospective studies.[167] Almost half of children report recurrence of symptoms, usually arthralgias, but almost none have residual true arthritis.[168] Lyme disease may be linked to chronic fatigue and fibromyalgia.[169] Approximately 10% have recurrence of erythema migrans. Overall the success rate of treatment is approximately 95% with equivalent neurologic, cardiac, and daily functioning compared with matched controls.[149,170-172]

Rocky Mountain Spotted Fever

Etiology and Epidemiology

Rocky Mountain spotted fever (RMSF) is a tick-borne bacterial infection resulting in a diffuse small-vessel vasculitis with the potential for causing multisystem disease. It is among the most virulent and potentially fatal pathogens because it often presents as a diagnostic dilemma for clinicians.[173] RMSF is caused by *Rickettsia rickettsii*, small gram-negative coccobacilli carried by dog or wood ticks. Other rickettsial groups may also be responsible for spotted fever illnesses.[174] RMSF is transmitted while the tick feeds on blood during bites.[175] RMSF is endemic to the United States, Canada, Mexico, and Central and South America. The disease occurs mostly in the spring and early summer months, with almost half of cases occurring during May and June.[176,177] The incidence is particularly high in the southeastern, south central, and south Atlantic regions. Different rickettsial strains have higher prevalence in these different regions.[178,179]

In the United States, approximately 2.2 cases per 1 million per year are reported, with the highest incidence in children between 5 and 9 years old.[180,181] In 2007, 2221 cases were identified in the United States. The number of cases continues to rise each year (Figure 96-4).[141] Approximately 20% of these cases and almost 15% of the deaths were in children younger than 10 years.[1,182] Serologic infection with rickettsii is much more common than indicated by disease incidence reports, suggesting the existence of subclinical disease.[183] Rickettsiae invade and multiply in the endothelial cells of the vasculature, resulting in cytopathic vascular injury and leading to morbidity and mortality.[184]

Clinical Presentation

The incubation period after a tick bite is 2 to 14 days (mean, 7 days).[175] The classic triad consists of fever, rash, and headache with a history of a tick bite. The classic triad is present in only 60% and in less than 20% during the first 3 days.[185,186] Approximately 30% to 40% of patients do not recall receiving a tick bite.[187] Initial symptoms often are nonspecific, with malaise and myalgias.[188] The fever is observed in two thirds of patients by day 3. Other common presenting symptoms are nausea, vomiting, and abdominal pain, especially in younger children.[189,190] The rash often begins by day 4, with blanching maculopapules classically starting at the wrists and ankles and then appearing on the palms, soles, and trunk (Figure 96-5).[189] Later, in up to 50% of patients the rash may become petechial, purpuric, or even gangrenous.[182,191] Younger patients tend to develop the rash earlier.[192] Importantly, the absence of the pathognomonic rash does not exclude RMSF; an estimated 10% of cases are "spotless."[193] Headache is present in almost all adults and in most older children.[177] Encephalitis, focal neurologic deficits, and meningismus have been described in some patients.[189,194,195]

Rickettsiae invade and multiply in the endothelial cells of the vasculature, resulting in cytopathic vascular injury that is responsible for morbidity and mortality. Endothelial damage results in the activation of the clotting cascade, extravasation of fluid, and reduced perfusion. The increased vascular permeability leads to the major complications of edema, hypovolemia, and hypotension, with end-organ failure such as shock, coma, myocarditis, liver dysfunction, and renal failure.[182,190,195,196] Renal insufficiency on presentation is secondary to glomerular and tubular damage and has been shown to have prognostic implications with increased fatal outcomes.[197] On autopsy, rickettsial vasculitis has been found in the brain, spinal cord, cardiac tissue, and lungs.[195,196] Other complications include cardiac arrhythmias, gastrointestinal bleeding, and skin necrosis.[182]

Diagnosis

The WBC count often is quite variable and usually is not helpful. Most patients, however, develop thrombocytopenia as the disease progresses. Approximately 30% of patients also are anemic. Liver and renal function abnormalities are common.[175,177,198,199] Approximately 20% of patients have hyponatremia and hypoalbuminemia from massive capillary leak and fluid shift.[195] CSF shows mononuclear pleocytosis in one third of samples, with an elevated protein concentration in 20%.[185]

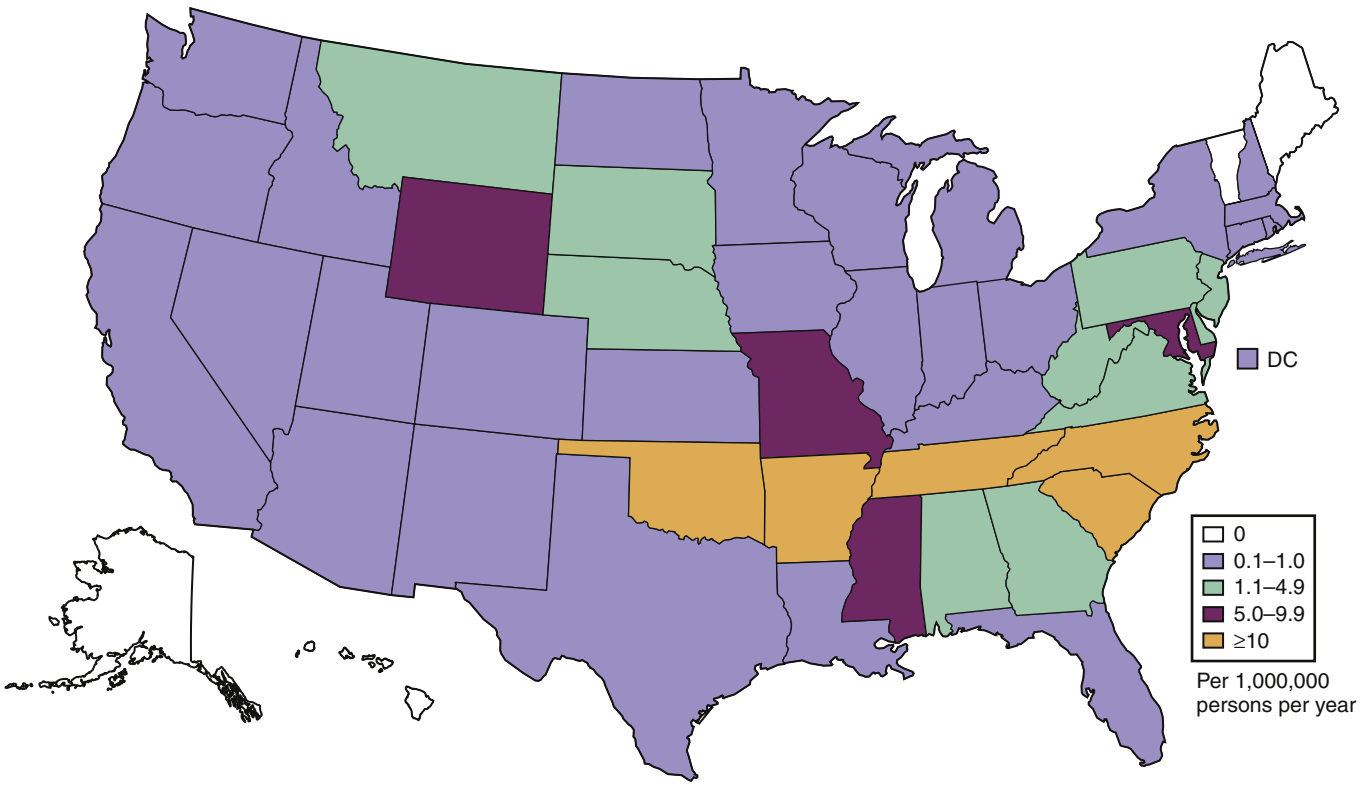

Figure 96–4. Distribution of average reported cases of Rocky Mountain Spotted Fever—United States 1997–2002. *(From Chapman AS, Bakken JS, Folk SM, et al: Diagnosis and management of tickborne rickettsial diseases: Rocky Mountain spotted fever, ehrlichiosis, and anaplasmosis—United States: a practical guide for physicians and other health care and public health professionals,* MMWR Recomm Rep *55:1-27, 2006.)*

Figure 96–5. Palmar rash associated with Rocky Mountain spotted fever. *(From Walker DH, Raoult D:* Rickettsia rickettsii *and other spotted fever group rickettsiae (Rocky Mountain spotted fever and other spotted fevers). In Mandell GL, Bennett JE, Dolin R, editors:* Mandell: principles and practice of infectious diseases, *ed 5, New York, 2000, Churchill Livingstone.)*

Because *R. rickettsii* often is not cultured, the diagnosis usually is clinical. For confirming the diagnosis, serotyping by direct immunofluorescence and immunoperoxidase staining are up to 90% sensitive and 100% specific on skin biopsies if a rash is present.[183,200] If available, PCR can reliably confirm the diagnosis early in blood or biopsy.[190,199] Serum antibodies using indirect immunofluorescence, complement fixation, and latex agglutination can be obtained but do not become positive until 7 to 10 days into the illness.[177,180] Thus these tests are impractical in the acute setting, and pending results should not delay treatment.

A differential diagnosis of enterovirus, measles, Epstein-Barr virus, cytomegalovirus, mycoplasma, scarlet fever, TSS, meningococcus, ehrlichiosis, and Kawasaki disease should be considered.[189]

Management

Empiric therapy is essential early in the course of illness because fatal outcomes have been linked to missed or delayed diagnosis and treatment.[178,201] The drug of choice for treatment of RMSF is doxycycline. Until recently, chloramphenicol was recommended by the American Academy of Pediatrics and CDC for children younger than 9 years because of the risk of teeth staining with tetracycline usage.[199] However, because of the risk of aplastic anemia and retrospective evidence of higher case/fatality rates with chloramphenicol, doxycycline now is first-choice therapy even in young patients.[202] In fact, the risk of staining is limited with a short course of therapy.[192,203] The fluoroquinolones also have activity against rickettsiae but have not been well studied in humans.

Doxycycline can be administered orally but should be used intravenously in the critical care setting when the patients are vomiting, obtunded, or have multiorgan involvement. Doses of 2 to 4 mg/kg/day divided every 12 hours are given for a minimum of 5 to 7 days and until the patient has been afebrile for at least 2 days.[177,199] Because initial therapy is empiric, other broad-spectrum antibiotics such as third-generation cephalosporins also should be started to cover other infections in the differential diagnosis.

Along with antibiotic therapy, aggressive supportive measures must be instituted. Restoration of massive fluid imbalances and cardiovascular support may be necessary. Correction of electrolyte abnormalities and coagulopathy are essential, and close monitoring of liver and renal dysfunction is indicated.[176,189]

Prognosis

Prior to antirickettsial therapy and aggressive supportive care, case fatality rates were higher than 30%, and approximately 13% of children with RMSF died. Even with treatment and the supportive care now available, the case/fatality ratio is 2% to 3%.[181,182,196] Geographic variations in case fatality have been recognized.[179] Some cases are not diagnosed until postmortem.[178] Delayed diagnosis and late initiation of specific therapy, especially after day 5 of illness, have the most significant association with higher mortality, emphasizing the need for empiric doxycycline as soon as RMSF is suspected.[177] Other risk factors for fatal outcomes include nonwhite race, male, age older than 40 years, absence of headache, no history of tick bite, gastrointestinal symptoms, and renal dysfunction.[186,192,194,195]

Hantavirus

Etiology and Epidemiology

Invasive infections for sepsis syndromes can be caused by non-bacterial causes including enterovirus and influenza virus species. These are discussed in other chapters. This chapter will focus on rarer viruses with specific cardiopulmonary syndromes; a classic example is Hantavirus. Hantavirus was first recognized in 1993 in the southwest United States and subsequently was named Hantavirus pulmonary syndrome (HPS).[204-206] In Europe and Asia, hantavirus species have been linked to a group of diseases with varying severity of hemorrhagic fever with renal syndrome (HFRS).[207,208] Since then, HPS has been recorded throughout North and South America and the clinical picture has been broadened to a cardiopulmonary syndrome.[209,210] Between initial cases in 1993 and 2006, a total of 438 cases with 20 to 50 new cases annually have been identified in 31 states.[1] There were 32 cases reported in North America in 2007.[141] The average age was 35 years old, with the youngest 11 years old (eight patients younger than 16 years old).[207] Ten cases in adolescents and five cases younger than 12 years old (youngest 5 years old) were reported in Argentina.[211]

Hantavirus has been linked to mice and rat species endemic to many areas in both urban and rural environments. The deer mouse is the main vector in rural areas throughout the United States and Canada. Infection occurs most commonly via inhalation of aerosolized saliva or excreta of infected rodents. The virus subsequently invades the pulmonary mucosa after inhalation with typically a 2-week incubation period, causing direct cellular damage that leads to increased vascular permeability.[212]

Clinical Presentation

HPS initially presents with a nonspecific illness manifested as fever, myalgia, headache, and gastrointestinal symptoms. When reviewed by Duchin et al.[204] in 1994, myalgia seemed to be the most frequently observed initial symptom. Shortness

of breath and cough occurred in 76%. Gastrointestinal symptoms varied from abdominal pain, nausea, vomiting, and diarrhea in up to 76%. The hallmark feature is rapidly progressive, noncardiogenic, pulmonary edema, and ARDS. The most common physical findings were tachypnea, tachycardia, and significant hypoxemia but otherwise were nonspecific (i.e., fever, malaise, anorexia).[204,210] In the cardiopulmonary syndrome, a dry cough then signals the onset of the cardiogenic phase with progression to shock and DIC.[213] Myocardial depression may be related to direct infiltration of cardiac endothelium resulting in atypical myocarditis. [214,215]

Hallmarks of the HFRS are prominent vascular permeability with subsequent petechiae and frank hemorrhages as well as severe renal involvement. Usually five stages are present, including febrile, hypotensive, oliguric, diuretic, and convalescent phases.[216] Up to 30% present with moderate-to-severe disease. Most often patients have severe abdominal and back pain. Pulmonary involvement does not seem to be a feature in Europe and Asia.[217,218] Although this serotype has been found, the HFRS clinical picture is rare in the United States, for reasons that are still unclear.

Diagnosis

Almost all patients had an elevated WBC count, with significant left shift, neutrophilia, myeloid precursors, and sometimes atypical lymphocytes.[204] Leukopenia and thrombocytopenia are also common features.[219] PTT was elevated in two thirds of patients with elevated D-dimers and abnormal fibrinogen levels. Hematocrit levels are elevated due to ultrafiltration of fluid in the lungs. On urinalysis, 40% had proteinuria and almost 60% had hematuria, although renal function abnormalities were uncommon in cases occurring in the United States.[214] The diagnosis is confirmed by PCR or by serology using enzyme-linked immunosorbent assay techniques. Chest radiographs show mostly rapidly progressive bilateral, diffuse infiltrates and developing pleural effusions.[214]

Differential diagnosis includes other sepsis syndromes such as meningococcus and other infectious causes of acute respiratory failure, such as pneumonic plague, leptospirosis, rickettsial infections, legionellosis, and atypical viral or bacterial pneumonias.

Management

Treatment is mainly supportive, especially of the respiratory system. Early intensive care management with prompt correction of pulmonary, cardiovascular, and electrolyte abnormalities is critical.[220,221] Cardiovascular support for hypotension and subsequent arrhythmias may be necessary.[215] However, fluid administration for hypotension must be balanced in the face of massive vascular leakage and significant pulmonary edema. Thus early use of vasopressors is recommended.[214] Extracorporeal membrane oxygenation support has improved survival.[222] Intravenous ribavirin has been used but has not shown a benefit in reducing mortality in HPS.[223,224]

Prognosis

Mortality rate is 35% with Hantavirus infection and usually is secondary to severe hypotension and arrhythmias secondary to vascular leakage and progressive hypoxemia.[225] The CDC reports the case fatality rate is 37% but was as high as 76% in some reviews of HPS.[204,226] Case/fatality rates in adolescents were up to 60% in patients younger than 12 years in an Argentinian review.[211]

Health Care–Associated Infection in the Pediatric Intensive Care Unit: Epidemiology and Control—Keeping Patients Safe

Tracie Northway, Joanne M Langley, and Peter Skippen

PEARLS

- Handwashing is the most important means of preventing nosocomial infection. Each pediatric intensive care unit should develop programs to increase compliance with hand hygiene.
- Nonessential invasive devices should be removed. Establish routines that require individual patient evaluation of device use daily.
- Antimicrobial stewardship aims to minimize overexposure and unnecessary use of broad-spectrum antibiotics. Antibiotic-resistant bacteria are an increasing concern as a cause of hospital-acquired infection, requiring a multipronged approach to control that includes adherence to isolation procedures, appropriate use of antibiotics, educational interventions, prescribing guidelines, and restriction of the use of some antibiotics.
- A comprehensive infection prevention and control program allied with organizational quality and patient safety programs is an essential strategy for minimizing hospital-acquired infections. Critical care teams should establish strong collaborative partnerships with the infection prevention and control service.
- Parents and visitors should be made partners of the infection control team to help prevent infection in their children.

Burden of Illness and Scope of the Problem

Children ill enough to require admission to a critical care unit are among the most vulnerable to infection in the hospital. Normal physical defenses such as skin integrity, the cough reflex, and gastric motility are interrupted in the critically ill child. Innate and adaptive immunity are compromised during high-acuity acute illness. Broad-spectrum antibiotics used as empiric therapy for suspected sepsis may disrupt normal protective flora and permit overgrowth by pathogenic bacteria and fungi. Younger children are more likely to require intensive care unit (ICU) admission than older children; this age group has a maturing immune system and may not have completed the full series of all routine childhood vaccines.

The most common health care–associated infections (HAIs) in the pediatric ICU (PICU) are primary bloodstream infections (BSIs) (28%), ventilator-associated pneumonia (21%), and catheter-associated urinary tract infections (15%). HAIs increase length of stay and morbidity and mortality rates for both adult and pediatric critically ill patients. This translates to an economic burden on the system as a whole.[1]

There has been renewed emphasis in the last decade on systematic strategies for preventing HAIs, both from a patient safety perspective and in an effort to reduce the cost of health care. In a public health care system, it is often argued that money is not saved by improving efficiency because each patient discharged is replaced by a new patient with comparable overall costs. In this context, the incentive to reduce HAIs is perhaps more on the ability to help decrease ICU and hospital length of stay and therefore improve access to the system. Infection prevention and control, patient safety, patient advocates, and health care providers alike see the value of improved health outcomes associated with reduction in nosocomial infections.

This chapter reviews the epidemiologic principles underlying infection prevention and control measures and recommends interventions to prevent the most common HAIs in the PICU.

Epidemiologic Principles of Infection Prevention and Control

Chain of Infection

The transmissibility of microorganisms between infected or colonized persons and susceptible hosts was perhaps most convincingly demonstrated in the 1847 observations of Ignaz Semmelweis, who introduced handwashing to the obstetric

wards of an Austrian maternity hospital and subsequently observed a reduction in the rates of puerperal fever.[2] In this instance, the initiation of hand hygiene after patient contact (cadavers) interrupted the spread of the infectious agent (group A *Streptococcus*) via the route of transmission (hands). Over time the epidemiologic roles of the susceptible host, the infected person, and the route of infection were more clearly elucidated and came to be known as the *chain of infection.* The interaction among these three components is dynamic, and infection may be favored when the host is more susceptible, the infectious agent is more virulent, and the route of transmission is more facilitating.

Children, long recognized as not just "little adults," are unique hosts because of their continuing physical, neurodevelopmental, and immunologic change and development from infancy through adolescence. Children, especially infants, lack immunity to many pathogens because they have not been exposed through infection or immunization. They are prone to multiple viral infections during any year and naturally share them. Young children are not developmentally capable of understanding or performing good self-hygiene.

The nature of a children's hospital can also put children at risk of developing an HAI. Open design wards and critical care units rather than single-room design, shared toys, pet visiting, and communal play areas provide many opportunities for transmission of infection.

Once admitted to the ICU, children become more vulnerable to infection because of the interventions needed to provide life-sustaining care as well as the close contact of multiple care providers. An infectious agent that is a harmless or helpful commensal in a normal host can become a life-threatening pathogen in the ICU patient. Because of frequent antibiotic use, the spectrum of infecting microorganisms in the hospital, particularly the ICU, are usually more pathogenic that those acquired in the community setting. Finally, the route of transmission of infection in the ICU is facilitated through frequent patient contact by health care workers, use of mechanical devices and medical therapies that disrupt natural defenses, and inadequate attention to infection prevention and control measures that prevent spread of infection to and between patients (Box 97-1).

BOX 97–1 Factors that Influence Risk of Infection in the PICU

Factors that Influence Exposure

Host Factors
- Loss of skin integrity (e.g., intravascular devices)
- Loss of respiratory defenses such as cough, cilia propulsion (e.g., intubation, sedation)
- Loss of gastrointestinal defenses such as low pH, motility (e.g., use of H2 blockers, nasogastric tubes)
- Anatomic defect (e.g., surgical site)

Environmental Features
- Crowding in the ICU
- High patient/health care worker ratios (decreased time for infection prevention measures)
- Use of prophylactic antibiotics (alters colonizing normal flora, allows overgrowth of pathogens)
- Infection prevention and control practices of ICU health care workers
- Immunization status of health care workers
- Visitor policies
- Reservoirs of infectious organisms in the ICU (e.g., health care workers who are carriers, environmental reservoirs)

Factors that Influence Likelihood of Infection if Exposed

Host Factors
- Age
- Gender
- Genetic makeup
- Coexisting infection
- Nutritional status
- Use of immunosuppressive agents, including systemic steroids
- Immunization status
- Immune deficiency

Infectious Agent
- Virulence
- Antimicrobial resistance

Routes of Infectious Disease Transmission

Infectious diseases, whether bacterial, viral, protozoal, fungal, or helminthic, are transmitted via one or more of three routes, usually categorized for infection control purposes as contact (direct or indirect), droplet, or airborne (Table 97-1).[3]

Contact transmission includes direct contact and indirect contact. *Direct contact* transmission occurs when organisms are transferred through physical contact from an infected or colonized person to a susceptible host. *Indirect contact* transmission occurs when microorganisms are passively transferred to a susceptible host via an intermediate object, such as a contaminated medical device, inanimate objects in the patient's physical environment, or contaminated hands.

Droplet transmission is the transfer of microorganisms through large droplets (≥5 μm in diameter) generated from the respiratory tract of an infected or colonized person (the source) that are propelled 1 to 2 meters from the source and land on the nasal or oral mucosa of the susceptible host or in the immediate environment. The droplets can be propelled from the respiratory tract in the course of coughing, sneezing, vomiting, or singing or during procedures such as suctioning. These large droplets are propelled a distance of less than 2 meters through the air but do not remain suspended in the air; that is, they do not become aerosolized.

Airborne transmission refers to the spread of microorganisms in particles that are very small (<5 μm) and can therefore remain suspended in the air and widely dispersed by currents to places far from the host. Airborne particles are created through the evaporation of large droplets or may exist in dust particles containing skin squames and other debris.

Infection Prevention and Control Measures

The Infection Prevention and Control team

Prevention of infection in patients receiving health care is the responsibility of all health care providers. Although Infection Prevention and Control Professionals (ICP) provide an essential expertise,[4] it is important that the PICU team establish ongoing multidisciplinary processes to reduce infection risk. Among the activities the multidisciplinary team will address are the integration of surveillance data into formal plans for

Table 97–1 Modes of Transmission of Microorganisms in the ICU

Mode of Transmission	How Organisms Are Transmitted	Example
Direct	Direct physical contact between an infected or colonized individual and a susceptible host.	Visitor asymptomatically shedding herpes simplex virus kisses postoperative transplant patient.
Indirect	Passive transfer of microorganisms to a susceptible host via an intermediate object such as contaminated hands that are not washed between patients or contaminated instruments or other inanimate objects in the patient's immediate environment.	Health care worker provides care to patient with *Clostridium difficile* diarrhea, does not perform adequate hand hygiene, then enters room of a noncolonized patient and handles bedding and bedrails, leaving *C. difficile* spores in susceptible patient's environment.
Droplet	Large droplets (≥5 μm in diameter) generated from the respiratory tract of the source (infected individual) during coughing or sneezing or during procedures such as suctioning or bronchoscopy. These droplets are propelled a distance of <1 m through the air and are deposited on the nasal or oral mucosa of the new host (newly infected individual) or in the immediate environment. These large droplets do not remain suspended in the air; therefore special ventilation is not required since true aerosolization (see below) does not occur.	Health care worker with influenza virus infection sheds respiratory secretions on the face of a PICU patient.
Airborne	Dissemination of microorganisms by aerosolization. Organisms are contained in droplet nuclei, airborne particles <5 μm in size that result from evaporation of large droplets, or in dust particles containing skin squames and other debris that remain suspended in the air for long periods. Such microorganisms are widely dispersed by air currents and inhaled by susceptible hosts who may be some distance away from the source patients or individuals, even in different rooms or hospital wards.	Patient with measles is housed on an open ward in the emergency department; airborne virus particles are carried throughout the department and inhaled by susceptible hosts.

improvement of patient care at regular intervals and designing and implementing quality improvement initiatives. The collaborators in these initiatives can be infection control practitioners, the hospital epidemiologist or medical director of infection control, a clinical pharmacist, members of quality and patient safety departments, and representatives from nursing, ICU physicians, and respiratory therapy. Others may be needed depending on the issue at hand, such as housekeeping or information technology.

Isolation Practices: Standard Precautions and Additional (Transmission-Based) Precautions

Schema to classify infection prevention and control techniques have evolved over time from systems in which a microbiologic laboratory isolate was required (e.g., disease-specific *Salmonella* diarrhea isolation), to systems focused on preventing transmission of blood-borne diseases to health care workers (Universal Precautions), to the present system in which certain practices are followed continuously with all patients and supplemented based on syndromic presentation and/or specific laboratory diagnoses. In Canada and the United States, the procedures and practices that should be continuously practiced in health care settings are termed *Standard Precautions* and *Routine Practices,* respectively, and are briefly outlined in Table 97-1. The concept of Standard Precautions, in which the health care worker has a responsibility to practice certain behaviors (e.g., hand hygiene) or use certain interventions (e.g., wear a mask when face-to-face with a coughing patient) based on a recognition of the need to do so rather than because they were asked to do so, has not yet been universally adopted in health care settings. Training in these skills should be considered an essential component of health care worker competency.

Types of isolation practices (routine, additional) are based on the scientific understanding of how infectious diseases are transmitted from a host or inanimate reservoir to a susceptible host and aim to control or eliminate the reservoir or infectious agent, interrupt transmission, and protect susceptible persons.

If a patient has symptoms that could be caused by an infection (e.g., cough, diarrhea, rash) or diagnosis of a communicable infectious disease, then Additional Precautions may be required in addition to Standard Precautions.[3] The three types of Additional Precautions are contact, droplet, and airborne. A full description of the rationale for these precautions and the specific information needed to apply them is beyond the scope of this chapter; readers are referred to comprehensive guidelines available from public health agencies such as the U.S. Centers for Disease Control and Prevention (CDC)[3] or from the relevant agency in the jurisdiction in which they practice. A useful guide when deciding which type of precautions to use for an individual patient is the "Red Book" of the Infectious Diseases Committee of the American Academy of Pediatrics[5]; each institution will also have its own infection control manual.

The basic components of Standard Precautions are hand hygiene, use of personal protective equipment (PPE) (e.g., gowns, gloves, masks, face shields) based on the nature of the health care worker-patient interaction and the extent of anticipated body fluid exposure, respiratory/cough etiquette, and safe injection practices. As previously emphasized, Standard Precautions are to be integrated into all patient care activities, regardless of the clinical status of the patient. Additional, or transmission-based, precautions are used when the route(s) of transmission are not completely interrupted by using Standard Precautions alone.[3]

Respiratory Etiquette/Cough Hygiene are measures to contain respiratory secretions and include covering one's cough (e.g., coughing into a tissue or the elbow), promptly disposing of tissues, and performing hand hygiene after touching respiratory secretions.

Safe Injection Practices are basic principles of aseptic technique in the preparation and delivery of parenteral medication that limit the risk of infectious disease transmission for both the health care provider and the patient. They include preferential use of single-dose over multidose vials and use of sterile, single-use, disposable needles (needleless access devices) and syringes.

Infection Control Practices for special lumbar puncture procedures are the donning of a face mask and sterile gloves by the health care worker when placing a catheter or injecting material into the spinal space. These recommendations were made after a number of postmyelography meningitis cases occurred without such precautions.

Contact Precautions are intended to prevent transmission of infectious agents, including epidemiologically important microorganisms, that are spread by direct or indirect contact with the patient or the patient's environment. In addition to Standard Precautions, for example, gloves are required for all entries to a patient's room rather than just when patient interaction will occur.

Droplet Precautions are intended to prevent transmission of pathogens through close respiratory or mucous membrane contact with respiratory secretions. In addition to Standard Precautions, for example, health care workers and others coming within 3 to 6 feet of a patient on Droplet Precautions would be required to wear facial protection (mask, goggles, and/or face shield), a gown, and gloves. A child on Droplet Precautions would generally be placed in a room alone to avoid contact with other children. (Note: Some guidelines refer to a 3-foot perimeter of an infectious person on Droplet Precautions, and others refer to a 6-foot distance. The worldwide experience with the severe acute respiratory syndrome (SARS) virus, in which droplet transmission may have occurred up to 6 feet from the source, has led some jurisdictions to implement a 6-foot perimeter for droplet precautions.)

Airborne Precautions prevent transmission of infectious agents that remain infectious over long distances when suspended in the air. A patient on Airborne Precautions must be placed in a room alone with special air handling and ventilation capacity. PPE that should be donned by health care workers entering the room of a patient on Airborne Precautions includes a gown, gloves, and a surgical (procedure) mask or respirator depending on the disease encountered.

Patient placement is the determination of which physical setting is safest for the child while minimizing risk of transmission of infectious disease from a potentially or definitely infected patient. Within Additional Precautions recommendations include guidance about the need for a single room (e.g., whether shared rooms are acceptable) or whether a room with special air handling is required.

There are inherent safety risks associated with isolation practices. Isolation practices such as single rooms and PPE may limit the number and type of encounters health care workers have with patients because of the cumbersome nature of entering a room, breaking coverage, the discomfort of certain PPE, and the need to come and go to bring equipment, documentation, and other materials.[6] Limited encounters may inhibit the critical care team's ability to access and assess accurately the child and family. Adult studies have demonstrated a negative correlation between patient safety and isolation[7] as well as increased HAI with lower nurse/patient ratios.[8] Although no conclusions can be drawn regarding recommended staffing levels for isolated patients in the PICU, this evidence suggests that increased vigilance is warranted for these critically ill children.

Hand Hygiene

Contaminated hands of health care workers have been shown in many studies to transmit health care–associated pathogens.[2,9] The World Health Organization Patient Safety initiative on hand hygiene emphasizes five moments for hand hygiene: before touching a patient, before clean/aseptic procedures, after body fluid exposure/risk, after touching a patient, and after touching patient surroundings.[9]

The advent of waterless hand hygiene agents has been a particularly important development for the critical care setting because of superior antimicrobial killing, time saved compared with water-based handwashing, rapid action, no risk of antimicrobial resistance, and the ease with which waterless agents can be stationed close to the point of patient care. Alcohol-based hand rubs are in general the preferred hand hygiene product for all health care settings.[2,9] When hands have visible dirt or organic matter (e.g., blood) they must be cleaned with water and soap.

Although the benefits of proper hand hygiene far outweigh the risks, skin irritation and health care worker attitudes about hand hygiene products can be an impediment to compliance and satisfaction with hand hygiene agents and must be considered when choosing a particular product in a specific health care setting.[9,10]

Personal Protective Equipment

PPE consists of clothing or devices donned by health care workers for their safety or protection while performing potentially hazardous patient care activity. To interrupt infectious disease transmission, eye protection (goggles or face shield), masks, gowns, and gloves may be worn as a part of Standard Precautions and Transmission-Based Precautions.

A surgical (procedure) mask provides adequate facial protection against droplets generated from the respiratory tract. Surgical masks are also used for source control (e.g., on a coughing patient) as a part of respiratory hygiene/cough etiquette. To protect against airborne particles, a particulate filtering face piece respirator is required because it is thought to filter at least 95% of the smaller airborne particles.[11] Airborne particles are known to be produced in certain infectious diseases (e.g., tuberculosis, varicella, measles) or may be produced during aerosol-generating procedures in the ICU (e.g., intubation) in patients with respiratory infections (e.g. influenza, SARS). The choice of mask type became a controversial topic during the influenza A H1N1 pandemic that began in 2009, with different jurisdictions recommending procedure masks for health care worker protection during non–aerosol-generating procedures in patients with suspected influenza and others recommending respirators. There is little evidence to suggest that influenza is transmitted through the airborne route; in a recent randomized controlled trial surgical masks

were not inferior to respirators in preventing influenza transmission.[12] Readers are referred to local public health and infection control authorities for jurisdiction-specific guidance.

Surveillance

Surveillance for HAIs in a PICU is a process in which information about infections acquired after admission are summarized and given back to the care team in a timely manner so that problems can be identified for action. Surveillance has been defined as "a systematic method of collecting, consolidating, and analyzing data concerning the distribution and determinants of a given disease or event, followed by the dissemination of that information to those who can improve outcomes."[13]

Although an HAI could occur in any body system to a patient admitted anywhere in the hospital, historical systems of total hospital surveillance are no longer seen as wise use of scarce resources. Surveillance "by objective" was introduced in the 1980s and has led to systems focused on "targets" that cause the most morbidity or mortality, are frequent, or are remediable.[14] In the PICU, the most important are BSIs and ventilator-associated pneumonia.[15,16] Other important surveillance targets in the PICU are urinary tract infection associated with catheterization, surgical site infections such as mediastinitis, and acquisition of epidemiologically important pathogens such as methicillin-resistant *Staphylococcus aureus* (MRSA) or vancomycin-resistant enterococcus (VRE).

The National Health Safety Network (NHSN) of the CDC is a national surveillance system that collects data from a sample of health care facilities that voluntarily submit data on the occurrence of certain HAIs. Because standardized methodology and definitions and risk-adjusted data are used in the NHSN, the surveillance data permit recognition of trends, identification of practices associated with prevention of HAIs, and comparison of rates within and between facilities.[17] Relevant to the PICU setting, NHSN reports central line–associated BSI (CLA-BSI) rates (number of infections per central line days), central line utilization ratio (central line days per patient days), urinary catheter–associated infection (UTI) rate and utilization ratios, and ventilator-associated pneumonia (VAP) rate (VAP days per ventilator days) and utilization. It is important to note that these rates are device specific and therefore incorporate the effect of exposure to an important risk factor. Surveillance results from the NHSN are updated periodically and published in medical journals and on the CDC website.

Standard surveillance definitions have been developed by the CDC (Table 97-2).[18] The CDC definitions incorporate subcategories for children younger than 1 year in recognition of the variable clinical presentation of infection by age. However, CDC definitions may be difficult to apply in children, and alternative approaches have been explored.[19-23] Surveillance definitions fulfill a different purpose than inclusion/exclusion criteria for clinical trial enrollment, or than the diagnosis of illness by a clinician. Surveillance definitions consistently identify indicators of HAI over time and between settings.

Identification, synthesis, interpretation, and report generation of HAI surveillance data in the health care setting are performed by infection control professionals.[4] These professionals have completed certification requirements, have achieved competence in infection prevention and control practice,[24] and have been shown to perform HAI surveillance more accurately than do quality assurance personnel.[25]

Screening

Patient Screening

Screening of patients for colonization with certain antibiotic-resistant organisms (AROs) such as MRSA has been proposed as a method to contain spread of these organisms in colonized or infected patients. Several types of ARO screening programs have been described, including admission screening based on risk factors (e.g., hospitalization in the last 6 months, patient from a long-term care facility), universal screening on admission, and weekly point prevalence screening surveys. The pretest likelihood of colonization, the cost of the test, the timeliness of test reporting, the ability to isolate screened patients, and the degree to which MRSA transmission is occurring are all factors that influence the feasibility and usability of the type of screening program chosen.[26] Although increased frequency of screening will identify more colonized patients, it is not clear if this practice reduces the frequency of transmission in the PICU setting.[27] An active MRSA surveillance testing program is recommended when MRSA transmission continues to occur despite the implementation of basic practices for prevention and monitoring of transmission.[28]

Visitor Screening

The importance of family-centered care and visitation by siblings as well as parents means that PICUs must establish mechanisms to identify visitors who may have communicable infections before they enter patient care areas. Education of visitors regarding signs and symptoms of illness and recommendations to remain away are used in many PICUs. Visitor self-screening was widely used during the 2009 H1N1 influenza pandemic. Brochures, posters, telephone messages, and videos may be used to communicate these messages.

Occupational Health

Occupational health programs play an essential role in the protection of health care workers from infectious diseases through prevention and management of unintended communicable disease exposures. These interventions reduce the risk of infectious occupational hazards to health care workers as well as opportunities for health care workers to spread infectious diseases to patients. Occupational health programs ensure health care workers are offered immunization against vaccine-preventable infectious diseases of importance in the health care setting, perform fitness-to-work assessments, assist in educational programs so that health care workers can protect themselves and their families from acquiring infectious diseases while at work (e.g., respiratory protection programs, respirator fit testing), and provide postexposure counseling and care (e.g., blood exposures during phlebotomy; unprotected intubation of a patient with meningococcemia or group A *Streptococcus* toxic shock syndrome). Occupational health programs collaborate closely with infection prevention and control programs.[29]

Table 97–2 Summary of CDC/NHSN Definitions for HIA (2008)

Bloodstream infection	Laboratory confirmed *(infections must be primary)*	*Regardless of age:* • Recognized pathogen from ≥1 blood culture, *or* • Common skin contaminant in ≥2 blood cultures associated with symptoms (fever, chills, hypotension)
		≤1 Year of age: • Common skin contaminant in ≥2 blood cultures, *and* • Associated with symptoms (fever >38° or <37° C, apnea, bradycardia)
	Clinical sepsis	*Applies only to ≤1 year of age:* • Symptoms (fever >38° or <37° C, apnea, bradycardia), *and* • Negative or no blood culture done, *and* • Physician initiates sepsis treatment *and* • No primary infection elsewhere
Systemic infection	Disseminated infection	• Infections, usually of viral origin, without an apparent single site of infection and involving multiple organs and systems (e.g., varicella)
UTI	Symptomatic	• $\geq 10^5$ Microorganisms/mL urine, not >2 species, and symptoms (at least one of the following: fever >38° C, urgency, frequency, dysuria, suprapublic tenderness)
		• Symptoms (at least two of the following: fever >38° C, urgency, frequency, dysuria, suprapublic tenderness) *and* at least 1 of 5 urinary laboratory criteria *or* physician diagnosis *or* treatment for UTI • Separate criteria are available for children ≤1 year without nonspecific symptoms (not referent to the urinary tract) *and* 1 of 7 laboratory criteria
	Asymptomatic	• Indwelling urinary catheter within 7 days before urine culture, *and* • $\geq 10^5$ Microorganisms/mL urine, not >2 species, *and* • Asymptomatic, *or* • No indwelling urinary catheter within 7 days of urine culture, *and* • $\geq 10^5$ Microorganisms/mL urine, not >2 species in two urine cultures with same organism(s)
Pneumonia *(Alternate criteria are used for the diagnosis of pneumonia in adults.)*	Clinically defined (infants and children)	• Serial chest radiographs (one or more for patients without underlying disease and two or more for patient with underlying disease) with new or progressive and persistent infiltrate or consolidation or cavitation, or pneumatocoeles (in ≤1 year old), *and* • Clinical signs and symptoms (vary according to the patient age: ≤1 year or ≥1 year and ≤12 years)
Lower respiratory tract, not pneumonia	Bronchitis, tracheobronchitis, other lung infection	• No clinical or radiographic evidence of pneumonia, *and* • Two or more symptoms or signs (fever >38° C, cough, new or increased sputum production, rhonchi, wheezing), *and* • One or more positive cultures from deep tracheal aspirate or bronchoscopy *or* positive antigen test on respiratory secretions, *or* • Child ≤1 year with no clinical or radiographic evidence of pneumonia, *and* • Two or more symptoms or signs (fever >38° C, cough, new or increased sputum production, rhonchi, wheezing, respiratory distress, apnea or bradycardia), *and* • One or more of the following: positive culture from deep tracheal aspirate or bronchoscopy *or* positive antigen test on respiratory secretions, *or* serologic diagnosis
Ear, eye, nose, throat, mouth	Conjunctivitis	• Pathogen cultured from purulent exudate from conjunctiva or contiguous tissues, *or* • Patient has redness or swelling of conjunctiva or periorbital area and white blood cells and organisms on gram stain *or* purulent exudate, positive antigen test on exudate, *or* conjunctival scraping, positive viral culture, serologic diagnosis, or multinucleated giant cells on microscopic examination of conjunctival exudate
	Sinusitis (Separate criteria exist for oral cavity, ear and mastoid infections, eye infections other than conjunctivitis, and pharyngitis, laryngitis, and epiglottitis.)	At least one of the following: • Organism cultured from purulent material from sinus cavity, *or* • One or more of the following signs or symptoms with no other recognized cause: fever >38° C, pain or tenderness over the involved sinus, headache, purulent exudate, or nasal obstruction, *and/or* • Positive transillumination or positive radiographic examination
Central nervous system	Intracranial infection	At least one of the following: • Organisms cultured from brain tissue, *or* • Abscess or intracranial infection seen during surgical operation, *or* • Selected central nervous system symptoms without another cause *and* 1 of 4 laboratory criteria, *or* • Patient ≤1 year with at least 1of 5 selected symptoms *and* 1 of 5 laboratory criteria

Continued

Table 97–2 Summary of CDC/NHSN Definitions for HIA (2008)—Cont'd

	Meningitis or ventriculitis	• Organisms cultured from cerebrospinal fluid, *or* • At least one of the following symptoms: fever, headache, stiff neck, meningeal signs, cranial nerve signs, irritability, *and* • 1 of 5 laboratory criteria, *or* • Patient ≤1 year with at least of 1 of 5 selected symptoms *and* 1 of 5 laboratory criteria
	Spinal abscess without meningitis	• Organisms cultured from abscess in the spinal epidural or subdural space, *or* • Abscess in spinal epidural or subdural space seen during surgery, autopsy, or in histopathologic examination
SSI	Superficial incisional, primary or secondary	• Occurs within 30 days of operative procedure, *and* • Involves only skin and subcutaneous tissue of the incision, *and* • At least one of the following: purulent drainage from incision, organisms isolated from aseptically obtained incisional fluid or tissue, one sign or symptom (pain, tenderness, redness, swelling, heat), *and* • Surgeon opens incision and incision is not cultured or is culture positive
	Deep incisional, primary or secondary	• Occurs within 30 days of operative procedure or within 1 year if an implant is left in place, *and* • Involves deep soft tissues of the incision, *and* • At least one of the following: purulent drainage from the deep incision but not from the organ/space of the surgical site, spontaneous dehiscence of surgical site or symptomatic patient has site opened by surgeon and incision is not cultured or is culture positive, abscess found on direct examination (radiologic, histopathologic, or during operation), or surgeon diagnosis
	Organ space, primary or secondary, indicated specific type (e.g., cardiac)	• Occurs within 30 days of operative procedure or within 1 year if an implant is left in place, *and* • Infection involves any part of the body, excluding superficial or deep incisional areas, opened or manipulated during the operative procedure, *and* • Patient has one of the following: purulent drainage via a drain placed into organ/space; organisms cultured from aseptically obtained specimen from organ/space; abscess found on direct examination, during reoperation, or by radiologic or histologic examination or surgeon diagnosis
Bone and joint infection (Separate criteria exist for joint or bursa infection and disc space infection.)	Bone (osteomyelitis)	*At least one of the following:* • Organisms cultured from bone, diagnosis based on direct examination during surgery or on histopathologic examination, *or* • Two or more symptoms (fever >38° C, localized swelling, tenderness, heat, or drainage at bone site), *and* • One laboratory finding (positive blood culture or blood antigen test or radiographic evidence of infection)
Cardiovascular system	Mediastinitis (Separate criteria exist for endocarditis, myocarditis, pericarditis and vascular infection.)	*At least one of the following*:* • Organisms isolated from mediastinal tissue or fluid obtained by aspirate or during surgery, *or* • Diagnosis during surgical procedure or by histopathologic examination, *or* • Presence of one or more of the following signs or symptoms: fever >38° C, chest pain, or sternal instability, *and* • One or more of the following: mediastinal widening on chest radiograph, purulent drainage, or organism cultured from drainage
Gastrointestinal (Separate criteria exist for hepatitis, sgastrointestinal tract infections and intra-abdominal infection.)	Gastroenteritis	*At least one of the following:* • Acute onset liquid stools for >12 hours with or without vomiting or fever and no likely noninfectious cause, *or* • Two or more of following signs and symptoms: nausea, vomiting, abdominal pain, fever >38° C, or headache, *and* • One or more of the following: enteric pathogen detected in stool or rectal swab (by culture, routine or electron microscopy, or cytopathic change in tissue culture), or enteric pathogen detected by antigen or antibody assay on blood or feces
	Necrotizing enteritis	• In infants, two or more signs and symptoms (vomiting, abdominal distension, prefeeding residuals) and no other recognized cause, *and* • Persistent microscopic or gross blood in stools, *and* • More than one radiologic abnormality (e.g., pneumoperitoneum, pneumatosis intestinalis, unchanging rigid loops of small bowel)

This summary of the CDC/NHSN surveillance definitions for HAIs and criteria is not comprehensive. The reader is referred to Horan TC, Andrus M, Dudeck MA, et al: CDC/NHSN surveillance definition of health care–associated infection and criteria for specific types of infections in the acute care setting, *Am J Infect Control* 36:309-332, 2008.

Primary, First infection; *secondary,* infection as a result of another previous infection in the patient.

*For infants ≤1 year of age, the symptoms and signs above are adapted to fever (>38° C rectal), hypothermia (<37° C rectal), apnea, bradycardia, or sternal instability.

Vaccine-preventable diseases of particular importance in the PICU setting are hepatitis B, pertussis, influenza, bacterial agents that cause meningitis and bacteremia *(e.g., Neisseria meningitidis, Haemophilus influenzae),* measles, mumps, rubella, and varicella. Critical care settings may present unique challenges because of the intensity and frequency of health care worker/patient contact and the likelihood of health care worker exposure to body fluids while manipulating invasive devices.

Selected Topics in Policy, Procedure, and Program Development to Prevent Health Care–Associated Infection

Intervention Bundles

Care "bundles" are a group of evidence-based interventions that, when executed together, result in better patient care than when implemented individually[30] and can reduce HAIs or colonization.[31,32] Intervention bundles to prevent BSIs and VAP in the ICU setting have been included in national patient safety campaigns such as the United States' Institute for Healthcare Improvement's "Saving 100,000 Lives" and the Canadian Patient Safety Institute's "Safer Healthcare Now."

Characteristics of care bundles are their scientific grounding, all-or-none implementation (the process is not completed if one step is left out), goal of improved reliability of processes needed for effective care, and potential to contribute to improved teamwork and interprofessional communication in a care area.[30,33] Strategies include team generation of ideas as to how to implement bundle components, development of educational approaches for acquisition of new knowledge and/or sharing of information, and creation of reliable processes and methods of measurement, such as a daily goals sheets incorporated into daily bedside rounds.

Antibiotic Stewardship

Judicious use of antimicrobials is now seen as an essential component of preventing the emergence of multidrug-resistant organisms.[34] The overuse and inappropriate use of antibiotics is associated with the emergence of AROs. Principles of judicious antibiotic use include restriction of antibiotics (e.g., stop orders, restricted hospital formulary, requirement for infectious disease consultation for use of certain drugs), including antimicrobial susceptibility reporting and educational efforts aimed at changing physician prescribing practices.

Antibiotic stewardship begins with empiric treatment of the newly admitted patient. Although a suspected infection should initially be treated with broad-spectrum antibiotics, therapy should be changed to the most narrow spectrum agent once culture results are available or discontinued if there is no further evidence of bacterial infection. The clinical pharmacist is an integral member of PICU daily bedside rounds. They should participate in the one-on-one education of resident and nursing staff, be available for consultation, and assist in the development of evidence-based antibiotic prescribing guidelines for specific hospital acquired infections, updated regularly and combined with regular surveillance knowledge of local offending pathogens and their susceptibilities. Approval of certain antibiotics by an infectious disease consultant reduces antibiotic use, costs, and the emergence of AROs.

Antibiotic Prophylaxis

Some surgical procedures may be performed in the ICU rather than the operating room. Antibiotics given within 2 hours before certain surgical procedures (e.g., implantation of biomedical devices, central nervous system surgeries) and continued for less than 24 hours decrease the incidence of surgical site infection.[35-37] There is no evidence that antibiotic prophylaxis before the placement of central venous catheters (CVCs) or external ventricular drains reduces infection rates. Antibiotic prophylaxis while these devices remain in place only leads to resistant colonizing organisms without reducing infection rates.

Antibiotic Cycling

Antibiotic cycling refers to a scheduled rotation of antibiotics with similar spectrums of bacterial coverage for a specified period, with the aim of limiting the emergence of resistance to any single agent. Although this strategy has been proposed as a potential method to decrease antimicrobial resistance,[34,38] there is insufficient evidence to recommend its widespread application at this time.[39]

Antibiotic Gastric Decontamination

Normal gut flora have an important role in nutrition, metabolism, and immune regulation. The normal balance of organisms is altered when a child becomes ill or receives antibiotics, leading to infection by endogenous flora. Selective decontamination of the digestive tract was first introduced in 1983 and extensively studied in adult ICU patients.[40] Selective decontamination protocols involve a short course of intravenous antimicrobials (e.g., third-generation cephalosporin) and oropharyngeal and enteral nonabsorbable antimicrobials (e.g., colistin, amphotericin B, tobramycin) in addition to routine infection control practices. Variable effectiveness has been demonstrated in clinical studies. In a recent large randomized controlled trial of almost 6000 adults, oral decontamination and selective gut decontamination were associated with decreased mortality rate compared with standard care.[41] There are insufficient data on selective decontamination in children to recommend its use at this time.

An alternate strategy to reduce the development of potential AROs is the oral administration of probiotics (nonpathogenic microorganisms) such as lactobacillus. Their main role appears to be the prevention of pediatric antibiotic-associated diarrhea, the prevention of necrotizing entercolitis in premature infants, and the treatment of *Clostridia difficile*–associated diarrhea. Although apparently not associated with harm, the role of probiotics remains unclear in the critically ill child as an infection control strategy or therapy.[42]

Specific Infection Syndromes in the Pediatric Intensive Care Unit

Bloodstream Infections

BSIs are usually the most common HAI acquired in the PICU setting[43] and are associated with morbidity, excess length of stay, and mortality,[44] with an attributable cost of up to $46,000 per patient.[44,45] Most BSIs are associated with intravascular catheter use and commensal skin flora that gain access to the bloodstream through the device. The scope of intravascular

device–associated infections includes laboratory-confirmed bacteremia, infections of the skin and subcutaneous tissues around the device (exit site and tunnel infections), clinically defined sepsis,[46] septic thrombophlebitis and thrombosis, and right-sided endocarditis.

Epidemiology

The median rate of CLA-BSIs in 71 pediatric medical/surgical ICUs, in the most recent report of the NHSN was 2.1 infections per 1000 central line days, with a 25th percentile of 0.0 and a 90th percentile of 6.0. The pooled mean in these medical/surgical ICUs was 2.9 infections per 1000 line days; in 10 medical PICUs the mean rate was 1.0. The median utilization ratio was 0.41 (central line days per patient days), which is comparable to adult ICUs.[17] In 2007, the Canadian ICU Collaborative reported a cumulative rate of 2.8 CLA-BSIs for six PICUs,[47] with rates ranging from 0 infections per 1000 line days to 10 over the 3-year surveillance period (Figure 97-1).

The most common infecting organism in CLA-BSI is the gram-positive bacteria coagulase-negative *Staphylococcus* (CONS), a group of about 20 species, including *Staphylococcus epidermidis,* that are normal flora of human skin.[48] Gram-negative bacteria, including enterobacteraciae, and nonfermenting gram-negative bacteria such as *Pseudomonas* spp., *Acinetobacter* spp., and *Stenotrophomonas* spp. account for about 25% of infections. *Candida* spp. infections are increasingly recognized.

There are many types of intravascular devices, including CVCs, arterial catheters, and peripherally inserted catheters. Catheters can also be classified according to the site of insertion, the expected duration of placement (e.g., long vs. short term), and the path to the vessel (e.g., tunneled or not).[46] To date, surveillance for HAI associated with these devices has focused on central venous lines. For surveillance purposes, BSIs are categorized as primary (no other identifiable source of infection) or secondary (the BSI occurred as the result of an infection at another site).[18,21] Surveillance definitions used for CLA-BSI can be found in Table 97-2.

Migration of skin flora along the catheter to the blood vessel is thought to be the pathogenesis of most CLA-BSIs.[46] The reduction in rates of CLA-BSI studies using maximal sterile barrier precautions and careful antisepsis[31,49] during catheter insertion and care support this hypothesis. Infection can also result from contamination of the catheter hub with endoluminal migration, be hematogenously seeded from another source, or occur because of contaminated infusate.[46]

Prevention

Successful programs to reduce the incidence of CLA-BSIs have been reported in the last decade; all use multimodal team-based, systematic approaches in which combinations of effective preventive interventions are introduced into a care setting.

The central line bundle is a compilation of eight components broken into two separate bundles for insertion and maintenance. The bundle components described in the following sections are from the Canadian Safer Healthcare Now campaign and align with other improvement bundle packages for reduction of CLA-BSIs. The Canadian ICU Collaborative PICU teams reduced their collective CLA-BSI rate from 5.6 per 1000 line days to 2.8 per 1000 line days.[47] Other PICUs that have implemented the central line bundle have seen dramatic reductions in CLA-BSIs rates of up to 75%.[50]

The insertion bundle components include hand hygiene, maximal barrier precautions, and skin antisepsis. Maximal sterile barrier precautions for the inserter mean strict compliance with hand hygiene, a cap that covers all hair, a mask that covers the mouth and nose securely, a sterile gown, and sterile gloves. The patient is covered from head to toe with a sterile drape except for a small opening for the insertion site and to maintain the airway. Chlorhexidine skin antisepsis is recommended over other antiseptic agents.[46] With regard to the optimal site for a line, practitioners are urged to consider what is best for the patient based on current and future needs, anatomic features, and the inserter's technical competence.

Other components of success include empowering nurses to enforce the use of a central line checklist that incorporates inclusion of all components of the insertion bundle and constraining practice by creating central line insertion kits or carts that include the required equipment needed to maintain asepsis (e.g., only one antiseptic offered: chlorhexidine).

Antibiotic-impregnated CVCs are not recommended for routine use unless the concerted efforts to implement a strategy

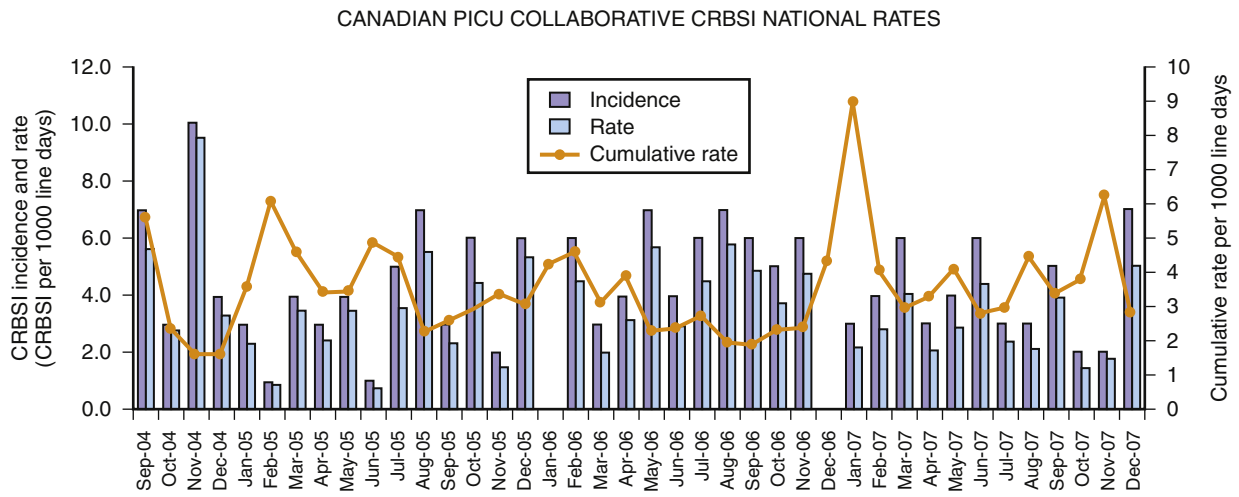

Figure 97–1. Canadian PICU Collaborative catheter-related bloodstream infection national rates. *(From Northway T, Folz E, Gavin S, et al: Success of a national pediatric critical care collaborative in reducing central line blood stream infections: an update of our progress,* Dynamics *19(2):40, 2008.)*

fail to reduce a local institution's infection rates below benchmark levels. They may be considered in specific patient populations such as the immunosuppressed requiring long-term CVC use, although their superiority over standard CVCs in this population has never been proven.

Ultrasound guidance for placement of CVCs to reduce insertion-related complications was identified by the Agency for Healthcare Research and Quality in 2001. In 2002, the National Institute for Clinical Excellence in the United Kingdom issued recommendations for the use of two-dimensional ultrasound guidance for insertion. The associated decrease in insertion-related complications might contribute to a reduction in CLA-BSIs through less-traumatic catheter placement, but this remains to be proven.

The maintenance bundle to prevent CLA-BSIs incorporates, in addition to hand hygiene, multimodal education and training programs, aseptic access to the lumens (scrubbing the hub), regular checks of the entry site for inflammation with each dressing change (at minimum), daily review of line necessity with removal if deemed unnecessary, and a dedicated total parenteral nutrition line.

Emerging trends in maintenance of CVCs include chlorhexidine-impregnated transparent dressings and biodiscs (which hug the catheter at the insertion site) and are intended to reduce the quantity of bacteria at the skin entry site.[51] Evidence of the safety and efficacy of this intervention in children is lacking, and it is not routinely recommended.

Practitioners are urged to check for recent updates in CLA-BSI reduction quality improvement strategies from Safer Healthcare Now (www.saferhealthcarenow.ca) or the Institute for Healthcare Improvement (www.ihi.org) or their national or local equivalents because these strategies change over time based on evolving evidence.

Management

Clinical diagnosis of BSI in the ICU based on clinical signs and symptoms is insensitive and nonspecific.[21] Laboratory confirmation should be sought and broad-spectrum antimicrobial therapy initiated early and targeted at likely pathogens until microbiologic results are available. If the device is suspected to be the source of infection or to have been secondarily infected, the clinician will need to decide if the infection can be eradicated with the device in place. The need for catheter removal will depend on the infecting organism and the availability of another route for parental antibiotic administration. Although CONS infections can often be treated without catheter removal,[52] this is likely not possible or wise if the infection is due to fungal infection or infection with *Pseudomonas* spp. or *S. aureus*. Current Infectious Disease Society of America guidelines recommend at least 10 to 14 days of therapy if the device remains in place along with consideration of antibiotic lock therapy.[53] The possibility of secondary seeding of the heart or thrombophlebitis should also be considered.

Respiratory Infections and Ventilator-Associated Pneumonia

Respiratory Infections

Respiratory tract infections are the most common illness in children in the community as well as the most common reason for admission to hospital, with young healthy children having an average of 6 to 8 infections each year. Respiratory infections acquired during health care encompass a broad range of illness of the upper and lower respiratory tract (see Table 97-2). In the child with high-acuity illness requiring admission to the PICU, some respiratory infections are particularly associated with increased morbidity, mortality, and health care cost. The following section focuses on viral respiratory tract infections, VAP, and sinusitis.

Epidemiology

Respiratory syncytial virus (RSV) is the most common cause of lower respiratory tract infection in young children in the community and occurs in yearly outbreaks during the winter in temperate climates.[54] Hospital-acquired RSV is associated with prolonged length of stay, increased morbidity and mortality rates,[55] and, if acquired around the time of cardiac surgery, worse postoperative outcomes.[56] Outbreaks of various respiratory virus infections in the PICU have been reported with attack rates of up to 30%.[57] Outbreaks of RSV and influenza provide useful information on the burden of illness associated with this HAI, but rates of HAI-associated respiratory virus infection determined by surveillance programs are infrequently reported.[58]

Like RSV, influenza virus HAI occurs at the same time as the local winter community epidemic. Multiple other respiratory virus infections (e.g., rhinovirus, adenovirus, parainfluenza virus) also spread by large droplets from the respiratory tract, the contaminated hands of care providers, or contact with contaminated nonporous surfaces on which the virus may survive.

Respiratory viral illness can increase the risk of secondary bacterial infection because the normal defensive function of the mucociliary apparatus is impaired and colonizing bacteria in the respiratory tract can invade through the nasopharynx or descend to the lower respiratory tree.

In the past 10 years, three novel respiratory viruses exposed severe gaps in hospital infection control practices. The SARS epidemic in Canada and Asia demonstrated the ability of a novel coronovirus to infect health care workers providing care for critically ill patients.[59] The avian influenza H5N1 virus and H1N1 influenza viruses spread predominately in community settings but forced health care centers to accelerate pandemic readiness and identified severe shortcomings in critical care capacity.[60] Transmission of these agents is thought to be by large droplet, but evidence for optimal occupational health protection is lacking.[12,61]

VAP is the second most common HAI in the PICU, estimated to occur in up to 10% of ventilated children.[62] In the most recent NHSN report pooling data from 50 pediatric medical-surgical ICUs, the median incidence was 0.7 episodes of VAP per 1000 ventilator days, and the mean frequency was 2.1.[17] Notably, the rate of VAP has decreased in the last decade from mean rates of 3.7 per 1000 ventilator days in 1998 in the Pediatric Prevention Network study[63] and 5.7 per 1000 ventilator days (median, 4.2 days) in participating PICUs.[64] VAP is a serious and life-threatening complication of PICU admission and is associated with prolonged ICU stay, need for ventilatory support,[65-67] and excess costs (more than $50,000 in one study[68]). VAP is also associated with increased mortality; in a prospective PICU study, Bigham et al.[69] observed a mortality rate of 19.1% in children with VAP compared with 7.2% in those without VAP ($P = .01$).

The preeminent risk factor for VAP in all age groups is the placement of an endotracheal tube, which provides a ready conduit to the lower respiratory tract and increases the risk of VAP 6-fold to 20-fold.[70] VAP is usually due to endogenous bacteria, and less commonly fungi, from the patient's oropharynx. VAP is often categorized into early (fewer than 5 days after intubation) and late (more than 5 days after intubation). Early VAP is usually caused by normal endogenous flora of the respiratory tract such as *H. influenzae, Moraxella* spp., *Streptococcus pneumoniae,* and alpha-hemolytic *Streptococcus* spp. These organisms are assumed to have gained entry around the time of intubation or to have been aspirated early in the course of treatment. During hospitalization, the normal endogenous flora of the nasopharynx are replaced within days by gram-negative bacteria such as *Pseudomonas* spp., *Escherichia coli, Acinetobacter,* and *Stenotrophomonas* spp., and various *Enterobacteraciae* spp. *S. aureus* is also a cause of HAI lower respiratory tract infection. For practical reasons, many studies base their laboratory diagnosis on specimens obtained from the endotracheal tube rather than invasive sampling of the lower respiratory tract; hence isolated microorganisms could be present in the nasopharynx, colonizing the endotracheal tube, or actually be the cause of infection in the lung.

In addition to its role as a conduit, the endotracheal tube also serves as a foreign body. As with other biomedical devices, an endotracheal tube interferes with normal defense mechanisms (e.g., cough, mucociliary apparatus) and acts as a nidus for adherence of microorganisms, which create a biofilm. Tracheal suctioning can cause mucosal denudation and detachment and aspiration of adherent biofilm aggregates that become a pulmonary inoculum. Not surprisingly, the length of respiratory assistance and endotracheal intubation—and therefore the device-related risk—remain significant risk factors of nosocomial pneumonia.[62,68,71,72]

Other risk factors for HAI pneumonia include immune deficiency, use of neuromuscular blocking agents, reintubation, transport outside the ICU, multiple organ dysfunction, shock, multiple-organ trauma, severe head trauma, and burns.[66,73-75] More rarely, VAP is associated with inhalation of contaminated aerosolized fluids or medications or hematogenous seeding (e.g., right-sided bacterial endocarditis).

Prevention

Respiratory Viruses. Prevention of HAI respiratory virus infection in the PICU can be accomplished through a collaborative effort between the PICU and the organization's infection prevention and control and occupational health programs. The goal of this effort is to avoid contact between persons with probable or definite respiratory infection (including family members) and PICU patients and prompt institution of isolation practices (Standard Precautions and Additional Precautions) in symptomatic patients, regardless of laboratory confirmation.

Occupational health programs assess fitness-to-work in health care workers with possible respiratory illness. An employee with new-onset cough and rhinorrhea, for example, could be deployed to a non–patient care assignment rather than the PICU or sent home. The occupational health program should ensure immunization status for employees is current and offer annual influenza vaccine programs in addition to ensuring access to vaccines against other infections that can be transmitted in the health care setting (hepatitis B, pertussis, measles, mumps, rubella, varicella, diphtheria). Regular education in the use of Standard Precautions/Routine Practices is recommended so that health care workers will use hand hygiene appropriately, understand how to use PPE, implement isolation practices when they suspect a communicable infection in a patient, and be aware of organization-wide and unit-specific infection prevention and control policies and procedures.

As part of the hospital and PICU admission process, screening of the patient for symptoms and signs of infectious illness should be conducted to determine appropriate placement. In the winter respiratory season, screening of all symptomatic children for viral infections and placing them on contact and droplet isolation until results are available have been reported to limit nosocomial spread. Screening admitted children with suspected viral infection is now done, and depending on the local laboratory capabilities, covers RSV, metapneumovirus, influenza A and B, parainfluenza, adenovirus, and rhinoenterovirus.

Ventilator-Associated Pneumonia. Strategies of prevention are directed against the three mechanisms by which VAP is thought to occur: aspiration of secretions, colonization of the aerodigestive tract, and use of contaminated equipment. General recommended measures are to conduct active surveillance for VAP, minimize the duration of ventilation and use noninvasive ventilation whenever possible, perform daily assessments of readiness to wean from ventilation, and educate health care workers who care for ventilated patients about VAP.[71]

Effective individual interventions that prevent VAP have been combined into bundles by the Institute for Healthcare Improvement.[76] Implementation of the bundles has shown documented evidence of a reduction in pediatric VAP; in one center a reduction of 5.6 to 0.3 infections per 1000 ventilator days over a 3-year period was observed.[69]

Recommended practices to prevent VAP are mostly based on studies conducted in adult patients.[71] The strategies to prevent VAP prepared by the Society for Healthcare Epidemiology and the Infectious Disease Society of America[71] highlight practical recommendations focused on this device-specific infection. Comprehensive recommendations published by the CDC provide background scientific rationale and guidance for detecting and preventing HAI pneumonia.[77] The original bundles included general care strategies for critically ill patients not related to VAP prevention (e.g., peptic ulcer prophylaxis and deep venous thrombosis prophylaxis). Oral hygiene protocols may reduce colonization by pathogenic bacteria in the oropharynx and are recommended.[77] Meta-analyses of trials conducted to date in adults indicate reduced risk of VAP in patients treated with oral chlorhexidine.[78] The CDC guidelines make no recommendation for routine use of chlorhexidine or antimicrobials for this purpose.[77]

Most recent pediatric VAP bundles have removed the general care strategies along with the adult-based recommendations of a daily sedation holiday and use of continuous aspiration of secretions above the endotracheal tube cuff.[77] Safety concerns for children (daily sedation) and tube design limitations in pediatrics are the rationale for elimination of the latter strategies. The pediatric bundle has recently been updated and published by Safer Healthcare Now. Specific

precautions of the pediatric VAP bundle are hand hygiene before and after circuit manipulation, elevation of the head of the bed (angle varies based on positioning limitations of the child based on age), proper positioning of the oral or nasogastric tube, elimination of the routine use of instillation before suctioning of the endotracheal tube, changing in-line suctioning catheters only when visibly soiled or malfunctioning, regular oral care for all children,[72] and maintaining the ventilator tubing in a dependent position.

Management

Lower Respiratory Tract Infection: Respiratory Syncytial Virus and Influenza. Management of RSV infection in the PICU is mainly supportive. Inhaled ribavirin has minimal efficacy in altering patient outcomes and is difficult to administer, particularly since particulate drugs may block the endotracheal tube. It may be used in the immunocompromised patient with altered cell mediated immunity who may otherwise be unable to clear infection. Laboratory confirmation is made by isolation of RSV from a nasopharyngeal aspirate or swab using molecular techniques, immunoassay, or viral culture. Monoclonal anti-RSV antibodies provide passive immunization for certain high-risk infants (e.g., hemodynamically significant heart disease, oxygen-dependent bronchopulmonary dysplasia) during the RSV season in the first year or two of life[79] but are not used for treatment of established infection. Evidence regarding cost-effectiveness of RSV passive immunization is conflicting.

Influenza infection can be treated with neuraminidase inhibitors (oseltamivir, zanamavir), which shorten the period of viral shedding and duration of fever. Practitioners are advised to be aware of seasonal public health guidance regarding antiviral susceptibility, which can change over time. The adamantine class of antivirals, for example, has not been used in recent years because of influenza virus resistance to these drugs.

Ventilator-Associated Pneumonia. The surveillance definition of VAP (see Table 97-2) permits comparison of HAI rates over time and between institutions but serves a different purpose than for diagnosis and clinical treatment.[23] VAP is difficult to diagnose accurately because of the inaccessibility of the lower respiratory tract. The gold standard for diagnosis is microbiologic confirmation from a lower respiratory tract specimen, such as lung biopsy.[80] Obtaining uncontaminated lower respiratory tract specimens in children by bronchoalveolar lavage, lung biopsy, or transthoracic biopsy are procedures with inherent risks, but diagnostic criteria have been proposed.[62,81-83] Despite the accepted shortcomings, tracheal aspirates remain the most common specimen for guiding initial empiric antibiotic therapy in a child with suspected VAP.

Aggressive and prompt treatment is required when nosocomial pneumonia is suspected in a critically ill patient because it is a life-threatening illness. Initial empiric therapy for VAP should be broadly based, with consideration of local microbiologic data on antibiotic resistance and a plan to reevaluate and narrow antibiotic selection when results of cultures or other diagnostic information is available. If aspiration is suspected, coverage for anaerobes can be considered (e.g., ticarcillin-clavulanate or clindamycin). If methicillin-resistant *S. aureus* is suspected, vancomycin or linezolid should be used. The appropriate duration of therapy for VAP in children is not known. Most experts recommend a 7- to 14-day course of therapy for VAP.

Sinusitis

Although acute viral rhinosinusitis (inflammation of the nose and paranasal sinuses) is a common infection in childhood,[84] data on its occurrence in the PICU are scarce. Care in the ICU was first associated with increased risk of sinusitis in adult ICU patients in the 1970s, following case reports of sinusitis ipsilateral to the nasotracheal tube.[85] Since that time, observational studies have supported this finding and indicate that prolonged nasal cannulation is associated with increased incidence of sinusitis, that larger nasal cannulae appear to accelerate this process, and that fewer devices in the nose decrease risk of infection.[85]

Epidemiology

There are few reports of sinusitis complicating the care of critically ill children in the ICU setting,[86] and active surveillance for this HAI is not done by most programs.[17,63,67] In one retrospective review, 1 of 98 children ventilated for at least 7 days had sinusitis noted in a follow-up visit that resolved spontaneously.[87]

Sinusitis can be categorized as acute or subacute bacterial, recurrent acute bacterial, chronic, or acute on chronic in nature. Although the ethmoid and maxillary sinuses are present at birth, the sphenoid and frontal sinuses are not pneumatized until age 5 and 7 years, respectively.[84] Diagnosis of sinusitis is challenging in children, particularly in the intubated child. Direct sinus puncture to permit microbiologic identification of infecting organisms is the gold standard for diagnosis, although it is rarely performed because it is invasive, time-consuming, and painful.[84] Normal sinus radiographs and CT scans provide evidence that sinusitis is absent, but mucosal thickening is a nonspecific finding.[88] The surveillance definition of health care–associated sinusitis is seen in Table 97-2.

Acute sinusitis is most commonly caused by respiratory flora such as *S. pneumoniae, H. influenzae,* and *Moraxella* spp. In ventilator-associated sinusitis, *S. aureus, Pseudomonas aeruginosa*, enteric gram-negative bacilli, and streptococcal infection need to be considered.

Prevention

The paranasal sinuses are contiguous with the nasopharynx and mostly lined with pseudostratified ciliated respiratory epithelium.[89] The normal defense of the sinuses against infection is the mucociliary apparatus; secretions capture particulate matter that is then propelled by cilia to the sinus ostia. Factors that would be expected to predispose to sinus obstruction or decreased mucociliary function include foreign bodies in the nasopharynx (e.g., nasogastric or endotracheal tubes), previous viral respiratory infection, preexisting abnormalities such as cilial disorders or cystic fibrosis, and craniofacial anatomic abnormalities or facial trauma. Orotracheal intubation is recommended over nasotracheal intubation because the latter increases the risk of sinusitis, which in turn may increase the risk of VAP.[71,77] Judicious use of antibiotics in the ICU would be expected to decrease the risk of colonization of the respiratory tract with gram-negative and antibiotic-resistant organisms.

Management

Because of their proximity to the brain, bacterial or fungal infection of the sinuses may be complicated by contiguous spread. If microbiologic confirmation obtained by sinus puncture is not possible, systemic antimicrobial therapy should be directed broadly to cover anaerobic respiratory flora, gram-positive and gram-negative bacteria such as *Pseudomonas* spp., and enteric flora. Options for antibacterial coverage include a third-generation cephalosporin or monobactam or an extended-spectrum penicillin–clavulanic acid combination with the addition of vancomycin to cover MRSA or penicillin-resistant pneumococcus, depending on antimicrobial susceptibility and epidemiology.

An otolaryngologist should be consulted in the care of children with complicated sinusitis to determine if surgery is necessary to remediate ostial obstruction or drainage of abscesses. Involvement of the central nervous system requires neurosurgical intervention. The infectious disease team should also be involved to assist in determining optimal antibiotic combinations and duration of therapy in these complicated cases with central nervous system involvement.

Urinary Tract Infections

The spectrum of illness associated with urinary tract infection (UTI) in the PICU can range from asymptomatic bacteruria in the presence of a catheter to a funguria that becomes a source of life-threatening disseminated fungal infection.

Epidemiology

A mean of 5.0 catheter-associated UTIs (CA-UTIs) occurred per 1000 catheter days (median, 3.0 per 1000 catheter days) in the U.S. National Health Safety Network surveillance system, with 37 pediatric medical-surgical ICUs reporting.[17] This rate is very similar to the CA-UTI frequency of 5.4 infections per 1000 urinary catheter days determined 10 years earlier in a survey of 35 PICUs and 33 NICUs.[63] In a recent review, secondary bacteremia occurs in about 3% of catheterized critically ill children.[22]

A urinary catheter is both a foreign body in the urinary tract and a conduit for microorganisms to ascend to the bladder, ureters, and kidney and potentially to the bloodstream. Voiding is an important defense mechanism for the urinary tract in which periurethral flora are flushed out regularly. Because of the urethra's anatomic location in the perineum, the most common organisms causing community and health care–associated UTI are normal periurethral or perirectal flora such as *E. coli* and *Klebsiella pneumoniae.* However, enterobacteriaceae such as *Pseudomonas* spp. and opportunistic organisms such as *S. aureus, S. epidermidis,* and *Candida* spp. also can be involved.

In addition to the general factors that increase risk for HAI in the PICU, children at increased risk for UTI include those with preexisting uropathies, especially neurogenic bladder.

Prevention

Guidelines for the prevention of CA-UTI in acute care hospitals focus on certain key strategies, all related to urinary catheter use: (1) recommendations for which patients should receive indwelling urinary catheters, (2) recommendations for catheter insertion, (3) recommendations for catheter maintenance, and (4) quality improvement programs to achieve appropriate placement, care, and removal of catheters.[90] The most important action that PICU staff can take to prevent CA-UTIs is to limit the use of urinary tract instrumentation, particularly indwelling urinary catheters. Systemic morphine infusions are not a contraindication to the removal of the urinary catheter.

Proper technique for catheter insertion includes hand hygiene before and after any manipulation of the device, use of aseptic technique, use of the smallest bore catheter needed, and proper securement of the catheter after insertion to prevent movement.[90] The catheter should be maintained as a closed drainage system with unobstructed urine flow. The catheter and collecting system should be replaced if the system is disconnected or leaks occur. Standard Precautions should be used for any manipulation of the catheter or collecting system (e.g., use of gloves and gowns as appropriate). Neither systemic antimicrobials, bladder irrigation with antimicrobials, nor complex drainage systems with antiseptics are recommended to prevent CA-UTIs. Special catheter materials (e.g., antimicrobial impregnation) are only recommended if a comprehensive strategy to reduce CA-UTI rates is unsuccessful.

A number of quality improvement resources are available to assist with systemic approaches to the prevention of CA-UTI. The Association for Professionals in Infection Control[91] produced the "Guide to the Elimination of Catheter-Associated Urinary Tract Infection" in 2008, and the Institute for Healthcare Improvement[92] has developed a program for the prevention of CA-UTI. Overall approaches for reduction of CA-UTI rates include the avoidance of unnecessary urinary catheters, use of aseptic technique when inserting urinary catheters, maintenance of urinary catheters based on recommended guidelines, and prompt daily review of urinary catheter necessity.[92]

Management

Surveillance definitions for UTI acquired in the health care setting are found in Table 97-2. Of note, infection may be asymptomatic or symptomatic. In the critically ill PICU patient diagnosis of UTI may be difficult because of inability to determine symptoms and signs; therefore laboratory criteria from aseptically obtained urine specimens are essential.[22]

For CA-UTI, the catheter should be removed as soon as possible because it is an ongoing source of infection. Once removed, intermittent catheterization may be required if spontaneous voiding does not occur. Therapy should be the narrowest spectrum agent that will treat the offending pathogen; appropriate empiric choices before availability of antimicrobial susceptibility should include consideration of common infecting organisms in that PICU, but appropriate initial choices include aminoglycosides, an extended-spectrum penicillin, or a third-generation cephalosporin.

Skin and Surgical Site Infections

Although almost all surgical procedures are performed in the operating room, a substantial component of care in the PICU is postoperative care for critically ill children. Procedures may also need to be performed in the PICU in patients who are too unstable for transport to the surgical suite or do not have primary closure of the surgical wound (e.g., open chest after cardiac surgery). The integument is the largest organ in the human body; it is a barrier to invasion of microorganisms and

plays a role in thermal regulation and fluid homeostasis. Disruption of the skin, whether by surgery, insertion of biomedical devices, or pressure sores, interrupts a key defense against infection.

Epidemiology

In an NNIS study of 61 U.S. PICUs from 1992 to 1999, skin and soft tissue and surgical site infections (SSIs) combined accounted for one quarter to one third of nosocomial infections in PICUs.[43] The NNIS reports SSIs according to operative procedure and risk index category but does not report the ward where the patient was cared for (e.g., ICU or not) or patient age.[17] In a prospective 6-month surveillance project in 17 European PICUs, postsurgical infections accounted for 7% of all HAIs.[67] A national Canadian pediatric point prevalence survey identified approximately 3% of the population with an SSI.[93] Complications of SSIs include contiguous or systemic spread and, in adults, an increased length of stay of 7 to 10 days and increased risk of death.[94] Depending on preexisting comorbidities, site, and severity of infection, the estimated costs of SSIs are between $3000 and $29,000.[94]

Surgical sites have bacterial contamination by the end of the procedure despite appropriate skin antisepsis.[95] Most commonly, the source of infection is the patient's own flora that migrate into the wound, but other sources include the surgical staff and contaminated instruments. The probability of a wound becoming infected is thought to result from the interaction of four key clinical variables: the inoculum of bacteria, the virulence of the infecting organism, the microenvironment of the wound (e.g., foreign body), and the state of host defenses.[95] Given this pathogenesis, it is not surprising that skin flora are the most common infecting organisms. *S. aureus* is the most common pathogen in SSIs without biomedical device placement, but *P. aeruginosa* and other gram-negative bacteria have been found.[72,96,97] Often a single microbiologic cause is not identified because the surgical site is open and contiguous with skin or mucosa. In procedures in which a device is implanted (e.g., neurosurgical cerebrospinal fluid shunts), the most common organism isolated is CONS. Of growing importance are infections caused by multidrug-resistant organisms, such as MRSA, and fungi.

Risk for an SSI can be predicted in adult patients by using the National Nosocomial Infections Surveillance System index, which combines the traditional four-category wound classification system of clean, clean-contaminated, contaminated, and dirty or infected with the American Society of Anesthesiology score and duration of procedure time.[95] An equivalent validated scoring system to identify high-risk children has not been developed. Multiple variables associated with increased risk for SSI in various studies include intrinsic factors (e.g., age, glucose control, obesity/malnutrition, smoking, steroid use, prolonged preoperative hospital stay, preoperative nares colonization with *S. aureus,* perioperative transfusion and immunosuppressive medications, presurgical comorbidity) and extrinsic factors (e.g., preoperative antiseptic showering, preoperative hair removal, patient skin preparation in the operating room, preoperative hand/forearm antisepsis, management of infected or colonized surgical personnel, antimicrobial prophylaxis). In pediatric cardiac surgery patients, an open sternum is a risk factor for SSIs.[96,97] Operative risk factors are surgical scrub by the team, skin preparation of the patient, appropriate and timely antibiotic prophylaxis, surgical drapes and attire, surgeon skill and technique, asepsis, and operative time. Operating room characteristics are also considered extrinsic factors. They include ventilation, traffic, and sterilization of surgical equipment. Postoperative factors incorporate incision care and discharge planning.

Prevention

Prevention of SSIs is directed at addressing the clinical variables that increase the probability of infection, as previously mentioned.[95] For example, patient skin preparation, health care worker hand hygiene, and antimicrobial prophylaxis affect the inoculum of bacteria into the wound. Optimal glucose and temperature control enhance the capacity of the host to deal with invading organisms. CDC recommendations for the prevention of SSIs are available,[36] and a compendium of strategies to prevent SSIs in acute care hospitals has been published.[94]

Surgical Site Infection Bundle

Most SSI bundles include measures to improve timing and choice of antimicrobial prophylaxis, appropriate hair removal, and prospective surgical wound infection surveillance with provision of feedback to individual surgeons. The surveillance definitions for SSI are provided in Table 97-2.

A considerable body of research has demonstrated that perioperative antibiotic prophylaxis is most effective when given 1 hour before the incision to maximize tissue concentration during cut time—when the antibiotic (as narrow spectrum as possible and as short a course as possible) is active against the likely contaminating organisms. Although the duration of administration varies by procedure, the optimal duration ranges from the operative period to the 24 hours after the surgery. Doses beyond this interval do not prevent infection and put the patient at risk of developing infections with resistant bacteria and fungi. The choice and duration of antibiotic prophylaxis depends on the surgical procedure, degree of wound contamination, emergency or elective surgery, and patient allergy.[36] Vancomycin should not be routinely used as prophylaxis but instead reserved for specific clinical situations such as an MRSA-positive patient with a SSI.[94]

Postoperative surgical site care includes regular observations and documentation of the integrity of the site. Recommendations for postoperative incision care include protecting a primary closure incision with a sterile dressing for 24 to 48 hours postoperatively, adhering to hand hygiene principles, applying sterile technique when changing dressings, promoting proper incision care, and identifying complications by educating patients and families.[36]

Management

Recognition of SSIs requires regular wound inspection for the usual signs of inflammation, with or without pus. Microbiologic confirmation of infection is often not possible or definitive because of contamination of the operative site by contiguous external surfaces. Treatment of SSIs includes appropriate empiric antimicrobials directed at the likely infecting organisms and subsequent narrowing of the spectrum when organism identification and susceptibility are available. Drainage of the infected area should be facilitated (e.g., removal of staples), and wound debridement may be required. Foreign bodies may need to be removed.[95] The extent of the infection will determine the wound care requirements, which

may involve packing the wounds or use of a negative-pressure wound therapy.

Ventriculostomy-Related Infections

The incidence of ventriculostomy-associated infection varies widely in the literature and is influenced by both patient characteristics and system factors, such as infection control policies and procedures pertaining to placement and maintenance of external ventricular drains. The risk increases with increasing duration of catheterization and with repeated insertions, but routine replacement is not recommended. The use of local antibiotic irrigation or prophylactic systemic antibiotics is not recommended. Routine surveillance cultures of cerebrospinal fluid are not more likely to detect infection than are cultures obtained when clinically indicated.[98,99]

Hospital-Associated Diarrhea

Clostridium difficile–associated diarrhea is a potentially life-threatening illness that can range in clinical presentation from diarrhea to colitis and megacolon. Although less common in children, it can cause problematic illness in oncology patients. Outbreaks of rotavirus and norovirus can occur in critical care settings, where close health care worker/patient contact can facilitate spread of secretions. Prevention of diarrheal illness is accomplished by prompt isolation of patients with diarrhea before laboratory results are available, careful hand hygiene, and regular and thorough environmental cleaning focusing on high-touch surfaces.

VI Chapter 98

Autoimmune Diseases: Diagnosis, Treatment, and Life-Threatening Complications

Jonna D. Clark and Helen M. Emery

PEARLS

- Approximately 1 child in 250 has a rheumatologic disease.
- Children may present to the intensive care unit with life-threatening manifestations of an undiagnosed rheumatologic disease or life-threatening complications of known rheumatologic diseases.
- A high index of clinical suspicion for rheumatologic disease is necessary when children present with:
  - Persistent fevers of unknown origin and constitutional symptoms
  - Multisystem involvement, including dermatologic, renal, pulmonary, gastrointestinal, cardiac, hematologic, or central nervous system pathology
  - Abnormal joint examination findings (can help decide whether child needs further evaluation for a rheumatic disease)
  - Unexplained elevated inflammatory markers
- Infectious and oncologic processes may mimic rheumatologic diseases and should be considered and/or excluded.
- The diagnosis of rheumatologic diseases requires a high index of clinical suspicion as few diagnostic tests are confirmatory and few clinical features are pathognomonic. While elevated inflammatory markers, abnormal serologies, and pathologic examination of a biopsy from an affected organ can aid in confirming a clinical suspicion, performing a careful history and physical exam, and considering a broad differential provides the basis for making these diagnoses.
- Life-threatening complications of rheumatologic diseases may affect any organ system. These complications include:
  - Severe infections secondary to immunosuppression
  - Adrenal insufficiency secondary to chronic steroid therapy
  - Airway compromise, pneumonitis, interstitial lung disease, pleuritis, pleural effusions, and acute alveolar hemorrhage
  - Pericarditis, myocarditis, valvular disease, arrhythmias, and acute coronary syndromes including myocardial infarction
  - Peritonitis, intestinal perforation, severe pancreatitis, and gastrointestinal hemorrhage
  - Renal insufficiency, severe nephrotic syndrome, and malignant hypertension
  - Cerebral infarction and hemorrhage, seizures, and psychosis
  - Prothrombotic states related to:
    - Antiphospholipid antibody syndrome
    - Thrombotic thrombocytopenic purpura
  - Immune dysregulation causing overwhelming cytokine storm:
    - Macrophage activation syndrome
- Therapies for rheumatologic diseases are often initiated in the intensive care unit, including: high dose corticosteroids; chemotherapeutic agents such as cyclophosphamide; "biologic" agents including tumor necrosis factor blockers and rituximab; intravenous immunoglobulin; and plasma exchange. These often present unique management challenges, given the complexities of potential interactions between the disease processes and complications of treatment.
- While waiting for studies to return and specific treatments to work, intensive support and coverage for alternative etiologies such as infection are critical.

Approximately 1 child in 250 has a rheumatologic condition. In the adult rheumatology patient population, approximately 10% to 25% of all patients who visit emergency departments for a rheumatic disease require hospital admission, and approximately one third of the hospitalized patients need intensive care.[1] Although the number of pediatric patients with rheumatologic diseases who require intensive care management is unknown, early diagnosis and rapid treatment can significantly decrease mortality and morbidity.[2,3] Patients may present to the intensive care unit (ICU) with life-threatening manifestations of new-onset disease, and a high index of suspicion is necessary in patients who present with

constitutional symptoms, unexplained elevated inflammatory markers, and multisystem involvement. Patients with known rheumatologic diseases may be admitted to the ICU with life-threatening complications of the disease process itself or complications secondary to therapies.[4] This chapter provides an overview of the most common pediatric rheumatologic diagnoses followed by a discussion of the most common conditions encountered by the intensivist.

Rheumatologic Diseases: Clinical Presentation, Diagnosis, and Treatment

Rheumatic diseases in children are best diagnosed by careful history and physical examination. Although laboratory changes may be consistent with and confirm clinical suspicions, they are frequently not diagnostic and must always be placed within the context of the patient's clinical picture.

Juvenile Idiopathic Arthritis

Juvenile idiopathic arthritis (JIA) is the most common childhood rheumatic disease (Box 98-1).[5] Most children are managed as outpatients, but the disease or its complications occasionally require intensive care.

Systemic juvenile idiopathic arthritis (S-JIA) accounts for only approximately 10% of children with juvenile arthritis; however, it is the type most likely to present with severe extra-articular multisystem disease.

Clinical Presentation

Classic features include fever, which by definition is a temperature higher than 38.5° C in a quotidian pattern for at least 2 weeks. Pleural and pericardial effusions occur in up to two thirds of patients and may compromise respiratory effort and rarely cause cardiac tamponade. Unwillingness to lie down, distant heart sounds, chest dullness to percussion, and reduced air entry are physical findings consistent with effusions. Friction rubs may be absent. Other clinical findings include diffuse lymphadenopathy and hepatosplenomegaly, sometimes so prominent as to lead to the consideration of malignancy and infectious processes, which must always be excluded. One helpful sign is the presence of the rheumatoid rash, which usually occurs with fever spikes, is nonpruritic and rapidly migratory, and often disappears completely when the temperature normalizes. Arthritis may not be the most prominent feature, although there is usually a history of morning stiffness, limp, or avoiding particular activities. A careful joint exam is essential.

Laboratory Studies

No diagnostic studies are specific, but tests consistent with systemic onset juvenile arthritis include anemia (often hemoglobin levels in the range of 6 to 8 g/dL); elevated white blood cell counts, sometimes into the leukemoid range; and platelet counts may rise to 1,000,000/μL or more. Low white blood cell and platelet counts should lead to consideration of macrophage activation syndrome (MAS), which is discussed in the following section, or malignancy. C-reactive protein and erythrocyte sedimentation rate (ESR) are usually markedly elevated, although in the setting of MAS the ESR may drop because of lowered fibrinogen levels. Antinuclear antibodies (ANAs) and rheumatoid factor are typically absent.

Box 98–1 Criteria for Juvenile Idiopathic Arthritis

JIA is a disease of childhood onset characterized primarily by arthritis persisting for at least 6 weeks with no known cause.

Systemic Arthritis

Arthritis with or preceded by daily fever of at least 2 weeks' duration, which is documented to be quotidian for at least 3 days, and accompanied by one or more of the following:

- Evanescent, nonfixed, erythematous rash
- Generalized lymph node enlargement
- Hepatomegaly or splenomegaly
- Serositis

Oligoarthritis or Polyarticular Arthritis

Arthritis affecting one to four joints during the first 6 months of disease. Two subcategories are recognized:

- Persistent oligoarthritis: affects no more than four joints throughout the disease course
- Extended oligoarthritis: affects a cumulative total of five joints or more after the first 6 months of disease

Polyarthritis (Rheumatoid Factor Negative)

Arthritis affecting five or more joints during the first 6 months of disease; tests for rheumatoid factor are negative.

Polyarthritis (Rheumatoid Factor Positive)

Arthritis affecting five or more joints during the first 6 months of disease associated with positive rheumatoid factor tests on two occasions at least 3 months apart.

Psoriatic Arthritis

Arthritis and psoriasis or arthritis and at least two of the following:

1. Dactylitis
2. Nail abnormalities (pitting or onycholysis)
3. Family history of psoriasis confirmed by a dermatologist in at least one first-degree relative

Enthesitis-Related Arthritis

Arthritis and enthesitis or arthritis or enthesitis with at least two of:

- Sacroiliac joint tenderness and/or inflammatory spinal pain
- Presence of HLA-B27
- Family history in at least one first- or second-degree relative of medically confirmed HLA-B27–associated disease
- Anterior uveitis that is usually associated with pain, redness, or photophobia
- Onset of arthritis in a boy after 8 years of age

Other Arthritis

Children with arthritis of unknown cause that persists for at least 6 weeks but that either:

- Do not fulfill criteria for any of the other categories, *or*
- Fulfill criteria for more than one of the other categories

HLA, Human leukocyte antigen.

From Petty RE, Southwood TR, Manners P et al: International League of Associations for Rheumatology classification of juvenile idiopathic arthritis: second revision, *J Rheumatol* 31:390–392, 2001.

Complications

Chest radiographs may show cardiomegaly or pleural effusions. An echocardiogram may detect subclinical effusions and identify signs of cardiac wall compromise. Most will respond to medical management, but occasionally aspiration and drainage of effusions is necessary.

The cervical spine may be affected, usually in children with systemic or polyarticular disease, and lead to loss of range or instability. Between the odontoid process and the transverse ligament is a synovial bursa that may become inflamed and cause erosions, leading to instability of C1 on C2 with actual or potential neurologic impairment. The facet joints of the lateral spinous processes of the cervical vertebrae are also synovial and inflammation at this site may lead to loss of range of motion or fusion of the c-spine. Limitation and instability may be problematic if hyperextension is attempted for intubation, or has occurred with a whiplash injury, and fracture and paralysis have been reported. Any patient with juvenile arthritis who has a history or findings of cervical spine disease should have careful flexion/extension views taken before intubation is attempted for any reason. If changes are identified, alternate airway management methods such as fiber optic visualization or even tracheostomy should be considered. Temporomandibular joint arthritis causes diminished mouth opening, also leading to difficulty in airway management. Cricoarytenoid arthritis may present as a sore throat with localized tenderness over the joints, or stridor and airway obstruction secondary to limitation of vocal cord mobility.

Rarely, fewer than 10% of children with JIA who exhibit polyarticular rheumatoid factor positive disease have complications such as progressive lung disease or other extra-articular manifestations of their disease.

Many children with previously diagnosed S-JIA are treated with steroids and immunosuppressives such as methotrexate, tumor necrosis factor (TNF) inhibitors, and other biologic agents. Therefore heightened awareness of the risks of adrenal suppression and infection is essential.

Management

Children with complications of active S-JIA should be treated aggressively with pulse methylprednisolone, usually 30 mg/kg/day up to 1 g/day administered over 1 hour for 3 consecutive days, then maintained at 2 to 3 mg/kg/day divided into 2 to 3 doses/day until symptoms resolve or until other steroid sparing agents are introduced with consultation from a pediatric rheumatologist. It is prudent to cover for infections at the same time because these massive doses of steroids compromise neutrophil function. Sodium and fluid retention, hypertension, gastric upset, and hyperglycemia are other short-term complications.[6]

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a multisystem disease characterized by loss of self-tolerance resulting in development of autoantibodies and formation of immune complexes.[7] The organs targeted by the autoantibodies and sites of immune complex deposition determine the disease presentation. Females in peripubertal and postpubertal years are most likely to be affected; however, both males and younger children can develop the disease. To make a diagnosis of SLE, 4 of 11 criteria must be met (Box 98-2).[8] However, lupus can be regarded as a medical example of Murphy's law—what can go wrong, will—so any organ system may be affected and in ways not always listed in the criteria. Therefore a thorough evaluation of all organ systems and serologic tests for antibodies and other markers commonly found in SLE is essential if this diagnosis is being considered.

Box 98–2 Revised SLE Classification Criteria

For the purpose of identifying patients in clinical studies, a person shall be said to have SLE if any of four or more criteria are present, serially or simultaneously, during any interval of observation.

1. Malar rash: Fixed erythema, flat or raised, over the malar eminences, tending to spare the nasolabial folds
2. Discoid rash: Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring (may occur in older lesions)
3. Photosensitivity: Skin rash as a result of unusual reaction to sunlight, by patient's history or physician's observation
4. Oral ulcers: Oral or nasopharyngeal ulceration, usually painless, observed by a physician
5. Arthritis: Nonerosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion
6. Serositis
   a. Pleuritis, a convincing history of pleuritic pain, or rub heard by a physician or evidence of pleural effusion *or*
   b. Pericarditis with or without documentation by electrocardiogram or rub or evidence of pericardial effusion
7. Renal disorder
   a. Persistent proteinuria >0.5 g/day or greater than 3+ if quantitation not performed, *or*
   b. Cellular casts (may be red cell, hemoglobin, granular, tubular, or mixed)
8. Neurologic disorder
   a. Seizures in the absence of offending drugs or known metabolic derangements (e.g., uremia, ketoacidosis, or electrolyte imbalance), *or*
   b. Psychosis in the absence of offending drugs or known metabolic derangements (e.g., uremia, ketoacidosis, or electrolyte imbalance)
9. Hematologic disorder
   a. Hemolytic anemia with reticulocytosis, *or*
   b. Leukopenia <4000/mm^3 total on two or more occasions, *or*
   c. Lymphopenia <1500/mm^3 on two or more occasions, *or*
   d. Thrombocytopenia <100,000/mm^3 in the absence of offending drugs
10. Immunologic disorder
    a. Anti-DNA: Antibody to native DNA in abnormal titer, *or*
    b. Anti-SM: Presence of antibody to Sm nuclear antigen, *or*
    c. Positive finding of antiphospholipid antibodies based on:
       1. An abnormal serum level of immunoglobulin G or immunoglobulin M anticardiolipin antibodies, *or*
       2. A positive test result for lupus anticoagulant using a standard method, *or*
       3. A false-positive serologic test result for syphilis known to be positive for at least 6 months and confirmed by *Treponema pallidum* immobilization or fluorescent treponemal antibody absorption test
11. An abnormal titer of ANA by immunofluorescence or an equivalent assay at any point in time and in the absence of drugs known to be associated with drug-induced lupus syndrome.

From Hochberg MC: Updating the American College of Rheumatology revised criteria for the classification of systemic lupus erythematosus, *Arthritis Rheum* 40:1725, 1997.

Clinical Presentation

Mucocutaneous Findings. Malar rash, discoid rash, photosensitivity, and oral (especially hard palate) and nasal mucous membrane ulcerations are classically included. However, almost any kind or rash, including bullous lesions, may be seen. Skin biopsy with immunofluorescence to demonstrate immune complex deposition can be helpful.

Central Nervous System Disease. Seizures and psychosis are included in the criteria; however, strokes, severe migraines, and an encephalopathic picture are among other central nervous system (CNS) findings. CNS disease can occur with minimal serologic changes.[9] CNS disease is related to antiphospholipid (APL) antibodies that can cause either thrombotic or embolic phenomena. These findings may be mistaken for or occur concurrently with infections, including opportunists such as nocardia. The eye can be involved in a number of ways (conjunctivitis, scleritis, episcleritis, uveitis, retinal vasculitis), and a careful eye exam is warranted in any possible rheumatic disease.

Pulmonary Involvement. Many patients have pulmonary signs and symptoms.[10] Pleuritis is included in the clinical criteria and may be severe, causing respiratory compromise. Pulmonary hemorrhage is one of the most serious complications of pulmonary involvement in SLE and may be precipitated by vasculitis or infection. Dyspnea, hemoptysis, and an otherwise unexplained drop in hemoglobin make this diagnosis obvious, but are not always present. More subtle hemorrhage may be detected by pulmonary function testing, specifically elevation of the diffusion capacity if the patient is stable and able to cooperate. Radiographs or chest computed tomography (CT) of the lungs will reveal patchy ground glass infiltrates.

Pulmonary embolism maybe related to APL antibodies or other hypercoagulable states such as nephritic syndrome or inborn errors. These may be massive and immediately life-threatening, and are best diagnosed by CT imaging, often at the time of interventions to lyse the clots. Smaller and recurrent emboli are thought to be a major contributor to pulmonary hypertension. Rarely, progressive interstitial disease, and possibly chronic pleural inflammation and fibrosis, lead to a "shrinking lung" syndrome.

Gastrointestinal Involvement. Sterile peritonitis may be present as part of a polyserositis picture. Hepatitis and pancreatitis may be primarily caused by lupus**,** but many commonly used therapies such as corticosteroids, azathioprine, and mycophenolate (MMF) may also cause liver and pancreatic side effects.

Cardiovascular Disease. Any layer of the heart including the pericardium, myocardium, and valves (e.g., Libmann-Sacks endocarditis) may be inflamed. Vasculitis may target the coronary vessels, and the increased risk of myocardial infarction and other premature vascular diseases are related to chronic inflammation, disease and drug-related hyperlipidemia, hypertension, and sometimes steroid-related diabetes. The role of generalized chronic inflammation in premature cardiovascular disease is under study. Vasculitis may affect other organs such as the gastrointestinal (GI) tract and brain with risk of thrombotic and hemorrhagic complications.

Raynaud phenomenon is unusual in children and is often a clue to an underlying rheumatic disease. If the vascular spasm persists, it may cause compromise of digits and require ICU intervention with vasodilating agents such as iloprost.

Renal Involvement. Renal disease is more common and more severe in children with SLE, occurring in about 80% of all cases. The spectrum varies from a silent disease identified only by abnormal urinalysis or by kidney biopsy to renal failure, severe nephrotic syndrome and malignant hypertension. Both nephritic and nephrotic patterns occur, loosely correlating with diffuse proliferative disease and membranous disease, respectively.[11]

Hematologic Involvement. Antibodies against specific cells usually reflect hematologic involvement. Anemia maybe related to Coomb positivity, but blood loss and marrow suppression should also be considered. Leukopenia is one of the criteria for SLE. If the white blood cell count is high in the context of what appears to be active SLE, then infection must be seriously considered. High-dose steroids demarginate neutrophils and therefore may also cause an elevated white cell count. Thrombocytopenia may be profound and life-threatening and may be mediated by antiplatelet antibodies or APL antibodies

Musculoskeletal Manifestations. Arthritis occurs in about 80% of patients with SLE and is a helpful clue to the diagnosis. Although a joint exam is not a regular part of the intensivist's repertoire, it can be very useful in deciding who needs further rheumatologic evaluation. Myositis is less common. Avascular necrosis can result from the disease itself, especially if the patients have APL antibodies, or as a complication of steroids.

Endocrine Issues. Thyroid disease may present as hyperthyroidism or hypothyroidism. Diabetes is usually a complication of steroid treatment, although rarely insulin resistant diabetes related to insulin receptor antibodies causes hyperglycemia refractory to therapy. Adrenal insufficiency is usually iatrogenic secondary to adrenal suppression from exogenous steroids.

Immune Dysfunction. Many factors reduce the immune response in patients with SLE. They are intrinsically immunosuppressed related to: altered B- and T-cell function; low complement levels that impair opsonization encapsulated organisms; and both hypergammaglobulinemia and hypogammaglobulinemia. In addition, immunosuppressive agents used to control their disease increase their risk of handling infections poorly. Furthermore, many patients with immunodeficiency can present with autoimmune phenomena, particularly those with chronic granulomatous disease, common variable immunodeficiency and T-cell abnormalities such as di George syndrome and ataxia telangiectasis.

Laboratory Studies. A hallmark of lupus is a positive test for ANAs in over 95% of cases; however, a positive ANA is found in many other conditions, including other rheumatic diseases and infections. It is therefore essential to support the diagnosis with clinical features and evidence of other autoantibodies

and immune complex formation.[12] Antibodies to double-stranded DNA (ds-DNA) are found in about 40% of patients at onset of their lupus and about 80% during the course of disease. These are quite specific to lupus and correlate with renal disease as the size and charge of the immune complex they form is filtered and deposited in the kidney, triggering an inflammatory response.

Smith antibodies (antiribonucleoprotein antibodies) are not quite as specific but are still part of the diagnostic criteria. Complement levels are low in active disease, reflecting consumption during immune complex formation. A total hemolytic complement should be screened to check the total complement pathway, and if zero, a search for complement component deficiency should be initiated. However, C3 and C4 are relatively quick and convenient screens of both the classic and alternate pathways and are used to monitor disease activity.

Full laboratory and imaging evaluation of all organ systems is essential to establish which organ systems are affected and the severity of the disease. A thorough clinical, laboratory, and radiographic evaluation is necessary to help guide treatment decisions.

Management

In patients ill enough to require intensive care, pulses of corticosteroids (methylprednisolone 30 mg/kg/day administered over 1 hour with careful monitoring of blood pressure, fluid and electrolyte status, and hyperglycemia for 3 days), are often indicated, with subsequent maintenance at 2 to 3 mg/day methylprednisolone divided every 8 hours. Simultaneous coverage for infection is usually advisable. Steroid-sparing agents such as cyclophophosphamide are often initiated, especially in the case of significant renal and CNS disease. Renal failure and dialysis can affect metabolism and clearance of many medications used to treat SLE, and consultation with nephrology and pharmacology services can assist in proper dosing. Careful attention to management of individual organ involvement such as hypertension, seizures, cardiac or pulmonary compromise, and hematologic abnormalities is just as important as overall disease treatment.

Neonatal Lupus Syndromes

Mothers who have autoantibodies, whether or not they are symptomatic, may transmit antibodies to the fetus causing antibody-related disease even before infants have the capacity to make antibodies of their own.[13] usually causes neonatal heart block that is irreversible and requires a pacemaker. Anti-La, which mediates neonatal cutaneous lupus syndrome, usually causes a rash that erupts after light exposure, but is sometimes associated with hepatitis and other organ system involvement. Other maternal antibodies, such as antiplatelet or Coomb antibodies, may cause neonatal thrombocytopenia and hemolytic anemia. As the maternal antibody levels in the infant's circulation decline, the signs usually resolve; however, exchange transfusion can remove antibodies causing serious adverse events.

Juvenile Dermatomyositis

Clinical Presentation. Juvenile dermatomyositis is an inflammatory disease characterized by rashes over the eyelids, face, "shawl" area, and extensor surfaces of the small joints of the hand, knees, and elbows (Gottron papules).[5,14] The inflammation affects striated muscle, proximal more than distal muscle groups, and can cause profound weakness of hip and shoulder girdle groups as well the palate, pharynx and upper third of the esophagus, resulting in dysphagia, dysphonia, and aspiration risk. Respiratory failure may not be obvious as muscle weakness may mask typical signs. Nailfold capillary dilatation and dropout are markers for systemic vasculitis. Vasculitis targets the GI tract and may cause bleeding, necrosis and perforation. Pulmonary hemorrhage is another complication of systemic vasculitis, and the fundi and skin may also be affected. Cardiac muscle may be inflamed, and rarely myocarditis and conduction defects have been reported. The kidneys are not usually a primary target of vasculitis, but rhabdomyolysis with secondary renal impairment rarely occurs. Severely ill patients may also demonstrate findings of MAS. An underlying malignancy is extremely rare, unlike adult-onset dermatomyositis.

Laboratory Studies. A typical rash, muscle weakness, and evidence of vasculitis usually makes this diagnosis obvious. However, laboratory studies can confirm the diagnosis, monitor disease activity, and guide management. Acute phase reactants and muscle enzymes, including creatine phosphokinase, aldolase, and lactate dehydrogenase are usually markedly elevated. A video swallowing study establishes whether aspiration risk is high enough to suggest alternative feeding methods. Electrocardiogram, echocardiogram, chest radiograph, chest CT, and pulmonary function studies establish the extent of cardiopulmonary involvement. Stool should be checked for occult blood and abdominal CT performed if there is any suggestion of GI involvement. A magnetic resonance image of proximal muscles will show muscle edema and inflammation and can be used to identify a site of biopsy if there is concern for other causes of a myositic or myopathic process.

Management. Besides airway and respiratory support and close monitoring for GI complications, an aggressive medical approach is essential. High-dose pulse steroids, methotrexate and intravenous gammaglobulin should be initiated immediately, not only to keep the patient alive, but to prevent permanent muscle destruction and reduce the risk of long term complications such as calcinosis. Other agents, such as cyclosporine, MMF mofetil, and rituximab may be used. Because of GI involvement, medications administered orally may not be reliably absorbed, and accordingly parenteral administration is preferred. Physical therapy should be initiated early to prevent joint contractures. After muscle enzymes start normalizing, physical therapy should emphasize strengthening muscles and regaining function.

Mixed Connective Tissue Disease (Overlap Syndrome)

This condition displays features of more than one rheumatic disease, for example a rash and arthritis like lupus, muscle inflammation like dermatomyositis, and fibrosing lung disease like scleroderma. Serologically, these patients usually have very high titer ANAs and antibodies only to ribonucleoprotein. Management, besides general control of inflammatory features, depends on the clinical features identified and the organs affected.

Antiphospholipid Antibody Syndrome

Catastrophic thrombotic syndromes are caused by hypercoagulable states. Some are related to primary hematologic diseases, such as deficiencies of protein C and protein S, 5,10-methylene tetrahydrofolate reductase polymorphisms and factor V Leiden. However, APL antibody syndrome, either primary or secondary to autoimmune disease, is also a common cause of hypercoagulability.[16] The syndrome is defined by recurrent arterial or venous thrombosis (often deep vein thrombosis and pulmonary emboli), thrombocytopenia, or, in women of child-bearing age, recurrent fetal loss. APL antibody syndrome also should be considered in the setting of severe neurologic manifestations such as stroke, transverse myelitis, seizures, or mononeuritis multiplex.

Laboratory Studies

Laboratory findings include prolongation of the partial thromboplastin time (PTT) that does not correct with a 1:1 mix (the antibody binds to the substrate, and adding normal serum with clotting factors does not affect this), false-positive syphilis test result, and the presence of antibodies to cardiolipin and associated proteins measured by either functional coagulation assays (lupus anticoagulant) or antibody titers (anticardiolipin and β_2-glycoprotein). Sometimes transient APL antibodies can be triggered by intercurrent infectious illnesses, and abnormal values three months apart are required to confirm APL syndrome.[16]

Management

The treatment of thrombotic episodes related to APL is anticoagulation with unfractionated heparin as the agent of choice.[17,18] Heparin acts as an anticoagulant within the clotting cascade in addition to preventing binding of C5a to endothelial cells and inhibiting release of factors triggering clotting at the vascular wall level. Monitoring for therapeutic anticoagulation may be difficult in the context of an already prolonged PTT and therefore, anti-factor Xa levels may be more reliable. If the thrombosis is acute or subacute, tissue plasminogen activator may facilitate breakdown. Use of Greenfield filters is controversial. If APL is identified in the context of a diagnosis such as SLE or vasculitis, additional immunosuppression is indicated.

Vasculitic Syndromes

Vasculitis is a generic term for inflammation of blood vessels, and is classified as either primary, or secondary to another rheumatic disease, such as lupus or dermatomyositis. Primary vasculitis is then classified according to size of affected vessels, although there may be overlap (Table 98-1). Diagnosis is usually made either by biopsy of affected tissue, or imaging showing characteristic changes in medium or large vessels. In some cases, serologic studies are helpful. With current treatment approaches, the prognosis has markedly improved.[19] The most common forms of vasculitis in children are Henoch Schönlein purpura and Kawasaki disease, but children can also develop Wegener granulomatosis (WG), microscopic polyangiitis (MPA), polyarteritis nodosa, and Takayasu arteritis.[20] Occasionally only one organ system is affected, for example, isolated CNS vasculitis.

Small Vessel Vasculitis Syndromes

Henoch-Schönlein Purpura

Clinical Presentation. Henoch-Schönlein purpura is an immunoglobulin A–mediated small vessel vasculitis, often triggered by a preceding infectious illness. Most cases are mild and resolve without treatment. However, rapidly progressive glomerulonephritis and GI complications including intussusception, necrosis and perforation may occur. Rarely pulmonary hemorrhage and CNS involvement have been reported. Classic clinical features include palpable purpura predominantly in the lower extremities, arthritis or arthralgias, abdominal pain, and hematuria.

Laboratory Studies. Laboratory tests are nonspecific, usually showing only mild elevation of inflammatory markers and white blood cell counts. Coagulation studies should be normal. On biopsy, immunoglobulin A may be deposited in the skin and kidney.

Management. Treatment is primarily supportive, but high-dose corticosteroids have been used for serious organ involvement, especially threatened or actual intussusception. Immunosuppression with cyclophosphamide, azathioprine, cyclosporine, intravenous immunoglobulin (IVIG), and plasmapheresis has been described for more severe or unresponsive disease.

Wegener Granulomatosis

Clinical Presentation. WG is a systemic granulomatous vasculitis that targets the head and neck, especially sinuses and middle ear, kidneys, and lungs (both airways and parenchyma).[21] Serious components of this disease include pulmonary hemorrhage, necrotizing cavitating lung lesions, and subglottic stenosis with symptoms of shortness of breath and stridor. The renal disease is a rapidly progressive pauci-immune glomerulonephritis. Table 98-2 lists the clinical syndromes causing severe nephritis and hemoptysis that should be considered in the differential of WG.[22] Neurologic manifestations occur in a significant portion of patients and include peripheral nervous system disease, mononeuritis multiplex, cerebral involvement with seizures, infarction, hemorrhage, (stroke or mass lesions), and transverse myelitis.

Laboratory Studies. Positive antineutrophil cytoplasmic antibodies (p-ANCA) in the setting of a compatible clinical picture are strongly suggestive of WG. Antibodies against proteinase-3 are quite specific for WG and may correlate with disease activity. Complete evaluation of the lungs and airways is essential, including a CT to identify cavitating lung lesions, pulmonary hemorrhage, or narrowing of the trachea, bronchi and bronchioles. Sinus disease may be silent and identified only by imaging. Renal biopsy shows pauci-immune necrotizing glomerulonephritis. Cutaneous vasculitis and thrombotic episodes secondary to APL antibodies are reported.

Management. Immunosuppression with a combination of cyclophosphamide and corticosteroids has been shown to decrease mortality and to induce remission in the majority of patients. Cyclophosphamide is given at 2 mg/kg/day orally or as an intravenous pulse dose of 250 mg/m^2 weekly in the setting

Table 98–1 Autoantibody Profiles for Vasculitis Associated with Various Autoimmune Diseases

	ANA	Ds-DNA	Smith	ANCA	Complements
SLE	+++	+ in 40%–80%	+ 50%–60%	Usually –	Low
WG	– or weakly +	–	–	0% + (PR3)	Normal
MPA	– or weakly +	–	–	90% + (MPO)	Normal
Polyarteritis	–	–	–	Usually –	Normal
Takayasu arteritis	–	–	–	–	Normal
S-JIA	–	–	–	–	Normal–high

+, Positive; –, negative; *MPO,* myeloperoxidase.

Table 98–2 Organ Involvement and Typical Laboratory Findings in Various Autoimmune Diseases

Diagnosis	Pulmonary Findings	Renal Findings	Other Organ System Involvement	Laboratory Findings
WG	Cavitating lung lesions, pulmonary hemorrhage	Pauci-immune necrotizing glomerulonephritis	Sinus, airways	Usually ANCA positive (PR3)
MPA	Pulmonary hemorrhage	Pauci-immune necrotizing glomerulonephritis	Skin, CNS	Usually ANCA positive (MPO)
Goodpasture syndrome	Pulmonary hemorrhage	Anti-GBM positive glomerulonephritis	None	Anti-GBM positive
SLE	Pulmonary hemorrhage	Proliferative or membranous changes; marked immune complex deposition	Multisystem disease	ANA positive, ds-DNA positive, Sm positive, low complements
Scleroderma	Fibrosing lung disease	Sclerosing glomerular and interstitial disease	Skin, GI tract	Scl-70 positive

GBM, Glomerular basement membrane; *MPO,* myeloperoxidase.

of serious, life-threatening disease. Pulse corticosteroids may be given in conjunction with this regimen until the inflammation and clinical setting improve, but steroids alone are not sufficient to maintain long term remission. More recently, rituximab (anti-CD20) has been used to target the B lymphocytes thought to be pathogenic in this disease. Antibiotic coverage for sinusitis and surgical intervention to improve sinus drainage can be helpful. Patients with WG are at increased risk of fungal infections such as aspergillus species, and care must be taken to differentiate infection from flare of disease.

Microscopic Polyangiitis

Clinical Presentation. The kidneys, lungs, GI tract, central and peripheral nervous system, skin and muscles are most frequently affected. Typically the patient exhibits constitutional symptoms such as fever, fatigue, weight loss, and symptoms of affected organs. Clinical presentations include pulmonary hemorrhage, GI bleeding or infarction, strokes, and kidney failure.

Laboratory Studies. Diagnosis of MPA is primarily clinical. Tests for p-ANCAs are often positive, especially for the neutrophil component myeloperoxidase. However, antibody testing is neither sensitive nor specific. It can be positive in other rheumatic diseases and in conditions such as inflammatory bowel disease. A positive biopsy of affected vessels confirms the diagnosis but is negative in almost half of cases. Renal biopsy shows pauci-immune necrotizing glomerulonephritis.

Management. Management includes supportive care and the use of corticosteroids. The addition of cytotoxic agents, such as cyclophosphamide or MMF, is associated with a lower mortality rate. Some cases with pulmonary hemorrhage have required extracorporeal membrane oxygenation treatment in addition to management of the underlying vasculitis. Plasmapheresis may be helpful in severe cases or in the setting of pulmonary hemorrhage.

Medium Vessel Vasculitis

Polyarteritis Nodosa

Clinical Presentation. Classic polyarteritis nodosa affects medium sized vessels. It is a rare disease in childhood but should be considered in any patient who has a combination of hypertension, GI involvement, rash, and fever. As in other forms of vasculitis, nonspecific muscle tenderness, arthritis, arthralgia and constitutional symptoms may occur. CNS signs include psychosis, seizures, strokes, or neuropathy. Skin manifestations can be varied, with painful nodules, purpura, petechiae, or patchy edema. GI vasculitis usually presents with abdominal pain, hemorrhage, necrosis or perforation. Cardiac involvement, including coronary arteritis, is more common in children.

Diagnosis. Diagnosis is confirmed by pathologic findings of medium sized vessels (those with a muscularis layer) on biopsy of affected tissues or angiography, either conventional or by magnetic resonance or CT contrast studies, that demonstrate

aneurysms, post stenotic dilatation and "rat tailing" changes in vessels. These may be patchy and multiple vessels, including renal, cerebral and celiac axes, may need to be studied to identify changes.

Management. Management includes high-dose corticosteroids and cyclophosphamide. *Streptococcus*-associated disease can trigger the disease and flare-ups. Appropriate antibiotic therapy and antibiotic prophylaxis may be warranted.

Large Vessel Vasculitis

Takayasu Arteritis

Clinical Presentation. Takayasu arteritis is an inflammatory disease that affects the aorta and its major branches. Early, in the inflammatory phase, the patient may have fever, fatigue, and weight loss and nonspecific organ findings. Later, after the inflamed vessels have begun to fibrose and stenose, symptoms related to compromised blood flow, such as absent pulses, angina, abdominal pain, visual changes, syncope, or stroke, will occur.

Diagnosis. Diagnosis is made by arteriography of the aorta and adjacent large vessels, although ultrasound, magnetic resonance imaging, or CT may be useful diagnostic procedures.

Management. High-dose corticosteroids are the primary treatment modality, augmented by cyclophosphamide, methotrexate, azathioprine, or in some cases, anti-TNF-α therapy. Surgical interventions may be indicated to bypass tight stenoses or replace a compromised aortic valve.

Primary Vasculitis of the Central Nervous System

Clinical Presentation. Primary vasculitis or angiitis of the CNS is characterized by inflammation of vessels within the CNS and by exclusion of vasculitis in other organ systems. This diagnosis is often considered in a child with unexplained CNS deterioration, especially after other diagnoses such as infections or metabolic conditions have been excluded.[23] Manifestations can be quite variable and include seizures, headache, hemiparesis, vertigo or dizziness, and aphasia.

Diagnosis. Diagnosis may be made by angiography, but small vessel disease may require brain or leptomeningeal biopsy. However, pathologic examination is prone to lower sensitivity if the biopsy sample does not capture an affected vessel area.

Management. Corticosteroids and cyclophosphamide have been shown to improve survival.

Kawasaki Disease

Clinical Presentation

Kawasaki disease is a childhood illness characterized by acute onset of fever at least 5 days, conjunctivitis, cervical lymphadenopathy, enanthem, exanthem, and extremity changes with redness, edema, and later desquamation.[24] Although acute myocarditis may occur during the acute febrile phase, the predominant morbidity results from the risks associated with development of coronary artery aneurysms and thrombosis peaking approximately six weeks after onset. Other peripheral arteries may develop aneurysms. Not all patients fulfill the classic clinical criteria, and so-called *atypical* or *incomplete Kawasaki disease* can include significant coronary artery involvement. The aneurysms of Kawasaki disease are at greater risk for stenosis or obstruction than are unaffected vessels and are prone to thrombosis and resultant morbidity. Furthermore, children with a history of Kawasaki disease have a higher incidence of premature myocardial infarction, even in the absence of known aneurysms.

Laboratory Studies

ESR and CRP are usually markedly elevated. After IVIG is administered, ESR is no longer an accurate marker of inflammation and CRP is a better marker for disease activity. Platelet counts can rise to more than 1,000,000/μL. High platelet counts are a maker of greater risk of thrombosis risk. Anemia and elevation of liver function tests also are common. Serial echocardiograms are the best way of monitoring the coronary vessels for signs of inflammation and development of aneurysms.

Management

Prompt initial diagnosis and treatment with 2 g/kg IVIG and high dose aspirin help prevent aneurysm formation. In the clinical scenario with concomitant myocarditis, supportive care including inotropes, fluid management with diuretics, and/or pacemaker may be necessary. Long-term use of low-dose aspirin is recommended once the acute illness is resolved. For cases refractory to IVIG, the addition of pulse steroids and TNF blockers such as infliximab and etanercept has been effective. Anticoagulants should be considered in the setting of large aneurysms to prevent further cardiovascular sequelae.

Scleroderma (Systemic Sclerosis)

Clinical Presentation

This is a rare condition causing vascular changes and fibrosis in multiple organ systems, especially lungs, kidneys, and GI tract.[25-27] Problems likely to be encountered in the ICU are renin mediated renal crises, which are best managed by use of angiotensin-converting inhibitors. Severe Raynaud phenomenon usually responds to vasodilators, including calcium channel blockers, alpha adrenergic blocking agents such as prazolol, or prostaglandin E agents such as iloprost. Progressive pulmonary fibrosis may result in respiratory failure. Prevention of microaspiration secondary to esophageal dysfunction and proton pump inhibitors to control gastroesophageal reflux may help. Cor pulmonale is a common terminal complication and is thought to be a result of microangiopathy and microthrombi, in which APL antibodies may play a role. Cardiac catheterization may demonstrate elevated pulmonary artery pressures, and trial of agents such as calcium channel blockers and bosentan (an endothelin-1 inhibitor) may result in reduction of right ventricular and pulmonary artery pressures. Pneumothorax from rupture of blebs in sclerodermatous lungs may require sclerosing of the pleura to prevent lung collapse. Rarely, pneumatosis intestinalis can result in intestinal perforation.

Critical Rheumatic Disease–Related Events in the Intensive Care Unit

Infections

Severe Infections

Life-threatening infections account for approximately 50% of ICU admissions in patients with systemic rheumatic disorders. They are the leading cause of mortality for patients with SLE, and affect a significant proportion of patients with other rheumatologic diseases.[28,29] The inflammatory disease process and chronic immunosuppression secondary to corticosteroids, chemotherapeutic agents, and biologic therapies reduce the ability of the innate immune system to fight infection, significantly increasing the risk for severe infections, including pneumonitis, sepsis, and necrotizing fasciitis.[28-35] A high index of suspicion for infection and the early judicious use of broad spectrum antimicrobial therapy are warranted, because many immunosuppressed patients may not be able to manifest the classic signs and symptoms of infection, including leukocytosis, fever, and erythema. Infectious organisms include community acquired bacteria such as *Staphylococcus aureus*, *Streptococcus pneumoniae*, and *Haemophilus influenzae*, gram-negative enteric organisms, and opportunistic agents, such as *Pneumocystis carinii*, *Mycobacterium tuberculosis*, mucormycosis, *Aspergillus* spp., and cytomegalovirus. Common organisms may be found in unusual sites, such as staphylococcal endocarditis, whereas opportunistic organisms may be identified in common locations including sinuses and airways, such as *Aspergillus* pneumonitis. Before the initiation of antimicrobial therapy, body fluids and specimens should be obtained, cultured, and examined for the presence of both common and opportunistic infectious etiologies. In the setting of infectious pulmonary disease processes, high-resolution chest CT scans and bronchoscopy with bronchoalveolar lavage should be considered early in the course of illness while the patient is stable enough to tolerate them, as lung lesions can rapidly progress into severe, acute lung injury without adequate therapy.[1] In addition, soft tissue infections may not be obvious; however, may rapidly progress as necrotizing fasciitis, requiring extensive debridement.[31,33,34] *Pneumocystitis carinii* pneumonia prophylaxis should be considered for patients receiving immunosuppressive agents. In patients with history of *Herpes zoster* or fungal infections, antiviral and antifungal prophylaxis should also be considered.

Endocrine Involvement

Adrenal Insufficiency

Chronic corticosteroid therapy in patients with rheumatologic diseases increases the risk of inability of the adrenal system to respond to states of physiologic stress. Rapid initiation of stress dose corticosteroids in the setting of acute illness or surgery is essential. Chronic corticosteroid therapy may not be the only etiology for adrenal insufficiency, as basal serum cortisol levels were reported to be low in children with active JIA off corticosteroid therapy.[36]

Airway Compromise

Childhood rheumatologic conditions may present with airway problems related to obstruction from inflammation within the airway, compression from outside the airway, or the inability to protect the airway secondary to muscle weakness. This may be indolent or very rapid in onset. Sometimes intubation can be difficult and otolaryngology should be notified early in case a tracheostomy is required.

Disease processes that cause airway obstruction secondary to a pathologic process within the airway include SLE, JIA, WG, and relapsing polychondritis. Oropharyngeal obstruction is uncommon, but rarely occurs in SLE from acute mucosal swelling of the pharyngeal and laryngeal tissues related to an acquired inhibitor causing an angioedema type picture.[37] Cricoarytenoid arthritis and airway obstruction from decreased mobility of the vocal cords can occur in JIA and SLE.[38,39] Subglottic stenosis affects 10% to 20% of patients with WG and is five times more common in pediatric than adult-onset disease. If the patient's condition allows, a conservative approach with medical therapy and topical approaches such as intralesional steroid injections and dilation may be attempted before surgical intervention.[4,39,40] Rarely, relapsing polychondritis, that causes recurrent cartilage inflammation, affects both small and large airways and may cause either upper or lower airway obstruction.[4,39]

Airway compromise secondary to external compression may occur in sarcoidosis. Children may present with dysphagia and dyspnea from enlarged nodes compressing the airway or supraglottic stenosis

Finally, in juvenile dermatomyositis, weakness of muscles in the palate, pharynx, larynx, and upper third of the esophagus leads to dysphagia, dysphonia, inability to manage secretions and airway compromise, requiring intubation.[4] As noted, signs of distress may be absent because of muscle weakness.

Pulmonary Involvement

Although infectious etiologies are the most common cause of lung involvement in pediatric patients with rheumatologic disease, noninfectious pneumonitis, interstitial lung disease, pulmonary fibrosis, acute alveolar hemorrhage, and pleuritis with pleural effusion frequently occur. The severity of these pathologic processes is highly variable; however, patients who suffer from significant respiratory compromise need supportive care with positive pressure ventilation. Patients may require chest tubes while pharmacologic and cytotoxic therapies are initiated.[41-45]

Pneumonitis

In addition to infectious etiologies, patients with rheumatologic diseases may develop pneumonitis with no identifiable infectious agent. In these cases, aggressive immunosuppressive therapy may decrease pulmonary inflammation, leading to improved outcomes. In WG, up to 80% of patients have pulmonary involvement. The most common findings on chest CT include pulmonary nodules, ground-glass appearance, and air opacifications. Plain chest radiographs may not reveal these changes.[19,21] Systemic sclerosis targets the lower third of the esophagus and may result in incompetence of the gastroesophageal junction. Resulting reflux and microaspiration may also contribute to the interstitial lung disease frequently seen in this

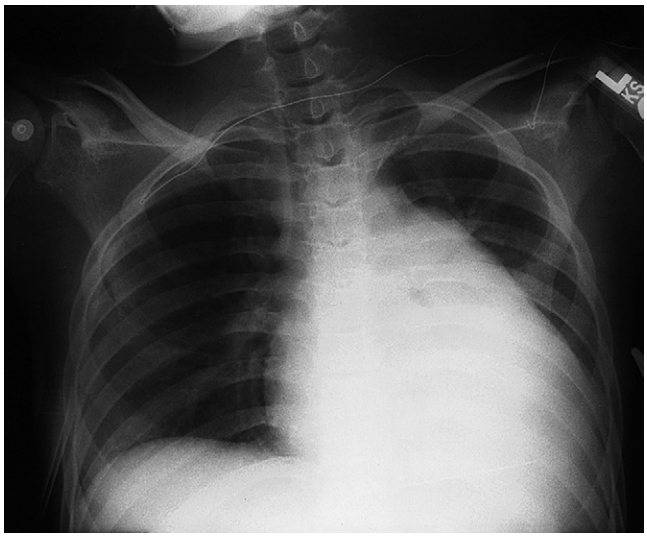

Figure 98–1. Portable chest radiograph of a 12-year-old female patient with scleroderma. The patient arrived at the ICU with sudden onset of orthopnea and thrombocytopenia. Cardiomegaly was observed. Echocardiography revealed pericardial effusion. However, pulmonary vascularity was normal in this patient. Physical examination revealed sclerodactyly. The patient eventually developed cor pulmonale as a result of pulmonary hypertension. Inflammatory changes suggestive of other collagen vascular diseases may be seen in the early course of scleroderma. Use of pulse intravenous methylprednisolone reduced these early inflammatory changes, although as an outpatient the patient maintained stable right-sided heart disease that was not responsive to immunosuppressive medication, consistent with scleroderma.

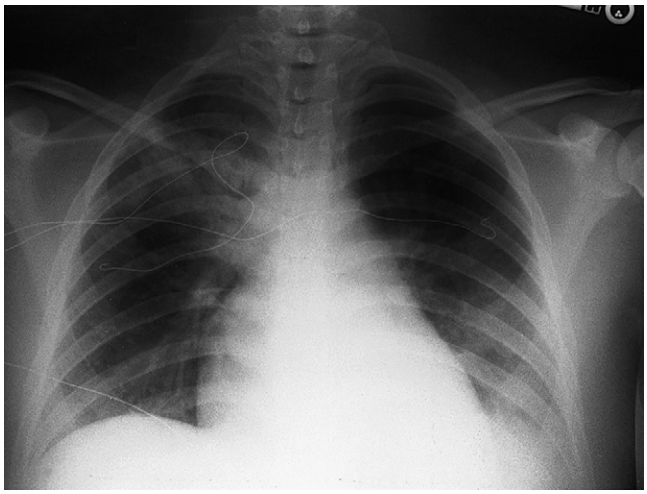

Figure 98–2. Portable chest radiograph of a 16-year-old female patient with SLE. Lupus pneumonitis is reflected by infiltrate in the right upper lobe and bilateral diffuse interstitial changes. Pleural fluid suggested by haziness over the left lower lobe, as well as blunted left costophrenic angle (not shown), was confirmed by bilateral decubitus films.

condition. A range of 40% to 80% of patients with systemic sclerosis exhibit interstitial lung disease based on several case series reports.[26,27] In these patients, pulmonary arterial hypertension can be associated with the interstitial lung disease, requiring pharmacologic vasodilator therapies (see Figure 98-1).[27] Although rare, severe interstitial lung disease has also been reported in juvenile dermatomyositis, requiring intensive immunosuppression and supportive therapy with extracorporeal membrane oxygenation.[25] Similarly, interstitial lung disease is rarely reported in SLE as acute lupus pneumonitis and idiopathic juvenile arthritis (see Figure 98-2).[4] Patients with interstitial lung disease secondary to autoimmune disease are at increased risk for developing pulmonary fibrosis.

Pleuritis and Pleural Effusions

Pleuritis, with or without pleural effusions, is a common manifestation of autoimmune disorders in children. Approximately 30% of patients with SLE and S-JIA demonstrate pleuritis that may cause pleural effusions sufficiently large to compromise pulmonary function.[45] Drainage with chest tubes may be required.

Pulmonary Hemorrhage

Systemic vasculitides, including WG, MPA, Goodpasture syndrome, and SLE place patients at risk for acute alveolar hemorrhage, causing significant morbidity and a mortality rate as high as 90%.[46] Acute pulmonary hemorrhages are not always preceded by hemoptysis and may be catastrophic, leading to acute hypoxemic respiratory failure and hemorrhagic shock. Chest radiographs typically reveal diffuse alveolar airspace filling defects, although patients with milder disease may have only focal abnormalities. Chest CT scans are more sensitive than chest radiographs and typically reveal ground glass opacities.[47] If the patient is able to cooperate with pulmonary function testing, an elevated diffusion capacity value is a good marker for pulmonary hemorrhage. Supportive care includes positive pressure ventilation with high positive end-expiratory pressure to reduce the hemorrhage, rapid blood transfusions, and close monitoring for hemodynamic stability. Although extracorporeal membrane oxygenation requiring anticoagulation therapy may be considered contraindicated in these settings, case reports in the literature demonstrate that extracorporeal membrane oxygenation can be safe and lifesaving.[48,49] Treatment of the cause of acute pulmonary hemorrhage requires high-dose corticosteroids and appropriate immunosuppressive therapies. Plasma exchange has also been shown to improve outcomes in Goodpasture syndrome and possibly other forms of vasculitis.[50] Evaluation for bacterial, viral, and fungal infections and treatment with antimicrobial therapy should be considered, as concurrent pulmonary infections such as mucormycosis may trigger pulmonary hemorrhage. Long term consequences of acute pulmonary hemorrhage include the development of pulmonary fibrosis and rarely, bronchiolitis obliterans, although many children recover without sequelae.[44,47]

Pulmonary Embolism

Patients with APL antibody syndrome, either primary or secondary to conditions such as SLE or vasculitis are at increased risk for the development of thrombotic events, including pulmonary embolism. Pulmonary embolism can also be associated with nephrotic syndrome from multiple conditions including SLE because of the renal loss of anticoagulant factors.[51,52] Patients typically present with pleuritic chest pain, tachypnea, tachycardia, and hypoxia, but some may be silent. Chest CT scans with angiography are the best studies. Treatment requires supportive care and early intervention with systemic thrombolytics, including unfractionated heparin and tissue plasminogen activator, especially for hemodynamically significant pulmonary emboli.[4,53] Occasionally, intrapulmonary thrombolytics are indicated to attempt to dissolve large clots if there is significant hemodynamic compromise.[54]

Cardiovascular Events

Pericarditis and Pericardial Tamponade

Pericarditis affects from 12% to 48% of patients with SLE, who present with positional precordial chest pain, fever, tachycardia, diminished heart sounds, and sometimes a friction rub.[55] Similarly, 8% to 42% of children with JIA are reported to have pericardial involvement.[4] Acute pericarditis with large effusions may lead to tamponade, characterized by tachycardia, a narrow pulse pressure, diminished heart sounds on exam, and clinical signs of poor cardiac output. Emergent pericardiocentesis is indicated when there are clinical signs of poor cardiac output or if there is concern for an infectious etiology.[56]

Chronic pericarditis may cause restrictive cardiac disease. Evaluation for pericarditis includes an echocardiogram and electrocardiogram. Medical management in the setting of systemic inflammatory disease includes nonsteroidal anti-inflammatory drugs, corticosteroids, and immunosuppression.

Myocarditis

Although rare, patients with rheumatic diseases, including SLE, JIA, dermatomyositis, and vasculitis may present with clinical evidence of poor cardiac output and congestive heart failure secondary to myocarditis.[4,57-59] Patients report fatigue and exercise intolerance and have tachycardia, respiratory distress with bilateral rales, and hepatomegaly on physical exam. The chest radiographs may reveal cardiomegaly with pulmonary edema, whereas the echocardiogram shows diminished ventricular systolic function. Management involves diuresis, inotropic support, and escalation of immunosuppressive therapy. Inflammatory myocarditis may be very sensitive to agents such as digitalis, resulting in arrhythmias, so these should be used judiciously if at all.

Valvular Disease

The most common valve disease associated with autoimmune diseases is verrucous endocarditis, or Libman-Sacks disease, found in up to 10% of patients with SLE.[45] Fibrinoid nodules may form on any of the cardiac valves, with the mitral and aortic valves most commonly involved.[4] Vegetations and valvular thickening may lead to severe regurgitation and occasionally stenosis. In addition to the hemodynamic complications associated with valvular regurgitation and stenosis, Libman-Sacks endocarditis may be complicated by thromboembolism, especially in the presence of APL antibodies, and infective valvulitis. Diagnosis requires an echocardiogram. As transthoracic echocardiograms have been shown to have low sensitivity and specificity, a transesophageal study should be considered. Some patients respond to conservative treatment, but others require valve replacement surgery.[60]

Arrhythmias

SLE is associated with an increased risk for conduction abnormalities. In one case series, approximately 12% of patients with lupus suffered from arrhythmias, including premature atrial beats, supraventricular tachycardia, atrioventricular blocks, and right bundle branch blocks. Diagnosis requires an electrocardiogram and echocardiogram. Patients usually respond to pharmacologic antiarrhythmics. Pacemakers are indicated for complete atrioventricular block, particularly in neonatal lupus.[4,45]

Acute Coronary Syndromes

The increased risk for acute myocardial infarction secondary to premature atherosclerosis, resulting from disease-related dyslipidemia, coronary artery inflammation or arteritis, and side effects of pharmacologic therapies is well recognized in SLE.[61]

Pediatric patients are especially at risk because of increased disease severity and lengthy disease burden. Approximately 60% to 85% of children and adolescents with lupus have dyslipidemia, compared with 5% to 10% of healthy children and adolescents. A randomized clinical controlled trial (APPLE trial) is studying the safety and efficacy of the use of statins to prevent premature atherosclerosis in pediatric patients with lupus.[62,63]

The 15% to 25% of patients with Kawaski disease who have delayed diagnoses, and those resistant to medical therapy are at increased risk for acute myocardial infarction secondary to the development of coronary artery aneurysms. These aneurysms are the site of thrombosis, stenosis, or rupture, causing myocardial ischemia. Giant aneurysms (>8 mm in diameter) have the poorest prognosis. Surgical intervention with bypass grafting is indicated when there is reversible ischemia on stress imaging tests with no coronary disease distal to the planned bypass graft site.[64] Occasionally, an older patient with a history of Kawasaki disease as a child may have a myocardial infarction as an adolescent or young adult.

Gastrointestinal Involvement

Gastrointestinal Hemorrhage

Vascularities and other systemic inflammatory diseases increase the risk for acute or subclinical GI hemorrhage. If GI bleeding is suspected during the initial assessment, large-bore intravenous access should be obtained and blood products should be readily available. Early GI and surgical consultation is advisable. Embolization under radiologic guidance controls the hemorrhage in some occasions. In patients with Henoch-Schönlein purpura, up to 30% of patients develop GI hemorrhage, although severe hemorrhage, irreducible intussusception and perforation are rare.[65]

Acute Surgical Abdomen: Peritonitis and Intestinal Perforation

Patients with autoimmune disease processes and vasculidites are at increased risk of morbidity and mortality from acute abdominal pathology, including intestinal perforation and bacterial peritonitis with abscess formation. Approximately 20% of patients with SLE report recurrent abdominal pain. A high index of suspicion for severe pathology is necessary, because immunosuppression may blunt the clinical signs and symptoms of an acute surgical abdomen.[66,67] Delayed intervention is common and leads to an increased mortality rate from abdominal complications

Pancreatitis

In addition to an acute surgical abdomen, severe acute pancreatitis is reported in SLE. This may be disease related or secondary to the use of high-dose steroids and other immunosuppressive agents.[68-70] Mortality rates secondary to pancreatitis in the setting of systemic disease have been reported as

high as 59%.[4] Children with Henoch-Schönlein purpura and Kawasaki disease have also been reported to suffer from pancreatitis.[4] In patients complaining of nonlocalizing abdominal pain in the setting of autoimmune disease, serum amylase and lipase levels should be obtained. If these enzymes are elevated, imaging studies including ultrasound and abdominal CT should be performed to evaluate for evidence of inflammation, stones and pseudocysts. Treatment involves pain control, non-enteral nutrition, close monitoring of electrolytes, and avoidance of refeeding too early. In cases caused by drug toxicity, inciting drugs should be avoided if possible.

Renal Involvement

Renal Failure and Malignant Hypertension

Most autoimmune disorders, including SLE, WG, microscopic polyarteritis, and Henoch-Schönlein purpura affect the kidneys. Renal findings include oliguria/anuria, hypertension, hematuria, proteinuria, elevated creatinine, low albumin and electrolyte imbalance. These may be present initially or evolve as the disease process progresses.[71,72] Evaluation of the renal status should include a urinalysis, electrolytes, blood urea nitrogen, creatinine, spot urine protein/creatinine ratio, 24-hour urine protein and creatinine collection, complete blood count, ANAs, complement levels including C3 and C4, and antineutrophil cytoplasmic antibodies. If the patient is stable and does not have contraindications such as a bleeding diathesis or severe hypertension, a renal biopsy should be performed early in the course of the disease process to aid in diagnosis and staging of disease. Although specific treatment depends on the etiology of renal insufficiency, all patients require close monitoring for hypertension, electrolyte abnormalities, and volume overload.

Adjunctive therapies with corticosteroids, cyclophosphamide, MMF mofetil or cyclosporine have been shown to improve remission rates.[73] In rapidly progressive glomerulonephritis, management includes high-dose corticosteroids, immunosuppression, and occasionally plasma exchange. Dialysis may be required for renal failure, but some patients will recover from acute renal injury if treated with aggressive medical therapy. However, some will not, and will need management for end-stage renal disease. Renal transplantation can be successful in the context of good control of active disease.[74,75]

Central Nervous System Involvement

Seizures are a feature of several rheumatic diseases, usually a result of small vessel vasculitis. They should be managed with standard agents in conjunction with antiinflammatory agents. Although some anticonvulsants have been associated with induction of a lupuslike picture, there is no evidence that these exacerbate lupus itself. Cerebral infarction is usually result of vasculitis or thrombosis related to APL. Hemorrhage can also result from vasculitis, but thrombocytopenia and anticoagulation for APL can also be factors.

Psychosis is most commonly seen in SLE. Often, markers usually abnormal in active lupus may be normal. An antibody, antiribosomal-p, may be a marker for psychosis in some patients.[76,77] It should be managed with antipsychotic agents as well as control of active disease. Rarely, steroids may cause psychosis, and the choice might be between reducing steroids to see if symptoms improve, or adding stronger immunosuppressants.

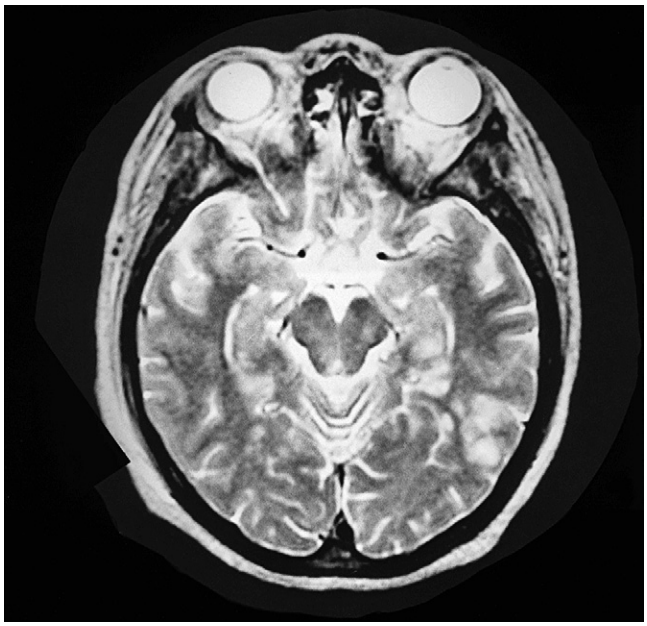

FIGURE 98–3. Magnetic resonance image of the brain of a 16-year-old female patient with SLE. This image was obtained after the patient was stabilized. Multiple areas of increased signal are scattered throughout both cerebral hemispheres, consistent with ischemic infarctions resulting from lupus cerebritis. Other views demonstrated similar infarcts in the brainstem and cerebellar hemisphere. Magnetic resonance angiography obtained at the same time revealed normal vasculature, suggesting pathologic involvement of brain tissue but sparing of vessels. The patient responded well to pulse intravenous methylprednisolone and cyclophosphamide, with no residual neurologic deficit.

Encephalopathy with altered state of consciousness should always raise concerns for infection, however may also be a result of active disease. Standard imaging may demonstrate abnormal findings (Figure 98-3) or may be normal even in the context of what appears to be active disease.

In SLE, lumbar puncture may yield spinal fluid with a mildly elevated white cell count with lymphocyte predominance, elevated protein and low glucose levels. Complement levels in the spinal fluid are difficult to interpret and not recommended.

Hematologic and Immunologic Involvement

Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura (TTP) is a rare, life threatening hematologic disorder that can be inherited or acquired. It is associated with SLE, especially in pediatric patients. Diagnosis is based on a clinical pentad: (1) thrombocytopenia and disseminated platelet aggregation, (2) microangiopathic hemolytic anemia, (3) neurologic abnormalities, (4) fever, and (5) renal disease. The reasons for the association between SLE and TTP is unknown; however, up to 50% of pediatric patients diagnosed with TTP also meet criteria for SLE.[78] The pathophysiology is explained by a malfunction of ADAMTS-13, that cleaves von Willebrand multimers. This lack of cleavage leads to binding of von Willebrand multimers to platelets, creating aggregates of platelets that bind to the endothelium, causing hemolysis and ischemia of affected

organs. In hereditary TTP, there is an absence of ADAMTS-13, whereas in secondary TTP, an inhibitory antibody inactivates ADAMTS-13. In patients with clinical TTP, demonstrating reduced levels of ADAMTS-13 activity (<5%) is confirmatory.[79] Treatment for TTP requires plasma exchange, which significantly decreases the mortality rate, and immunosuppression with corticosteroids and cyclophosphamide.[78-82]

Macrophage Activation Syndrome

MAS is a severe, life-threatening complication of childhood systemic inflammatory diseases, primarily S-JIA. It typically occurs during an acute flare of the disease, change in medical therapy, or with a concurrent infection. The diagnosis of MAS can be difficult, as findings can be confused with intercurrent infections, sepsis, and acute exacerbations of the underlying disease process. Therefore, a high index of clinical suspicion is necessary.

Patients typically become acutely ill with unremitting high fevers (different from the quotidian pattern of S-JIA), lymphadenopathy, hepatosplenomegaly, intravascular coagulation abnormalities causing possible purpura, easy bruising, and mucosal bleeding, and neurological changes, including lethargy, irritability, disorientation, headaches, seizures, or coma. Laboratory evaluation typically reveals pancytopenia, elevated liver transaminases, coagulopathy, hyponatremia, elevated triglycerides, elevated lactate hydrogenase, and most importantly, a significantly elevated ferritin level, usually greater than 10,000 ng/mL. The pathognomic feature of the disease is a bone marrow examination that reveals numerous macrophages phagocytosing hematopoietic cells.[83-87]

The pathogenesis of the disease process is not entirely understood; however, MAS is associated with an uncontrolled expansion of T lymphocytes and hemophagocytic macrophages. The hemophagocytic macrophages express CD163, a scavenger receptor that recognizes haptoglobin-hemoglobin complexes. Uptake of these complexes by macrophages leads to an upregulation of heme-oxygenase enzymatic activity that degrades the subunit of hemoglobin into biliverdin, carbon monoxide and free iron and leads to increased synthesis of ferritin. Hence, a significantly elevated ferritin level is typically associated with MAS. In addition to rapid expansion of macrophages, diminished cytotoxicity of CD8 T cells and natural killer cells has been found in MAS. The etiology of this diminished cytotoxicity is not entirely understood, however defects in the function of perforin, a protein expressed in lymphocytes, macrophages, and other bone marrow precursors that forms pores in the cell membranes of target cells, leading to osmotic lysis, has been associated with both familial hemophagocytic lymphohistiocytosis and MAS.[83-87]

Treatment for MAS requires parenteral administration of high doses of corticosteroids. Patients who are refractory to corticosteroids may be managed with cyclosporine A. Although the mechanism of cyclosporine A is not entirely understood, it suppresses the early steps in T-cell activation by inhibiting the activation of transcription for genes encoding for cytokines, decreases macrophage production of interleukin-6, interleukin-1, and TNF-α, and inhibits the expression of cell surface costimulatory molecules, altering the antigen-presenting function of dendritic cells for T cell activation. In addition to corticosteroids and cyclosporine A, etanercept, a TNF-α inhibitor, has been shown to have efficacy.[88] IVIG, plasma exchange, cyclophosphamide, and etoposide may be effective in some patients, but relevant studies have reported conflicting results.[85,86]

Complications of the Treatment of Rheumatologic Diseases

Although aggressive management of rheumatic diseases is necessary to control active inflammation and prevent further organ system damage, therapies have risks of their own.[89] High-dose steroids exacerbate hypertension, cause electrolyte imbalance (particularly sodium and fluid retention, shift of potassium from intracellular matrix to plasma, and transient rise in creatinine) and hyperglycemia. White cell changes include lymphopenia, demargination of neutrophils with elevated peripheral count, and decreased neutrophil function. Increased susceptibility to infection is related to these factors. Long-term effects of steroids include loss of bone density resulting in risk of compression fractures, and striae and thinning of the skin potentiating the risk of breakdown and loss of skin integrity. Several medications cause gastric irritation, liver abnormalities, and pancreatitis. GI prophylaxis with proton pump inhibitors and monitoring pancreatic and liver enzymes is recommended. The newer biologic agents used in managing rheumatic disease may trigger hypersensitivity reactions, and patients receiving them should be monitored. Sometimes a patient may be admitted to the ICU for desensitization to allow them to tolerate a needed treatment.[90]

Managing medications can be very complex in seriously ill patients with rheumatic diseases. Because many medications are cleared through the kidneys or affected by dialysis, metabolized in the liver, or affect protein binding, careful attention to dosing and possible drug interactions is critical (see Chapter 118).

Summary

In summary, rheumatologic diseases manifest themselves in numerous ways and can affect all organ systems. Pediatric intensivists should have a basic understanding of the most commonly diagnosed conditions, including S-JIA, lupus, juvenile dermatomyositis, vasculidities, and scleroderma, as critically ill children may present to the ICU with new onset disease or with complications from previously diagnosed conditions. In addition, many of the therapies for autoimmune diseases have clinically significant side effects or require technical skills (such as plasmapheresis) that may require close monitoring in the intensive care setting. The diagnosis of rheumatic diseases requires a high index of suspicion, a broad differential diagnosis, and a thorough history and physical exam, because there are few tests that are exclusively diagnostic or pathognomonic for the disease processes. Early diagnosis and intervention can significantly reduce morbidity and mortality, and hence the intensivist plays a crucial role in providing life saving therapies to children with rheumatologic diseases.

Genomic and Proteomic Medicine in Critical Care

David Jardine, Mary K. Dahmer, and Michael Quasney

PEARLS

- The DNA of two unrelated humans is more than 99.9% identical.
- Human genetic variation most commonly comes from single-nucleotide polymorphisms or copy number variations. Copy-number variations are stretches of DNA of greater than 1 kb that show differences in the expected number of copies of the DNA in greater than 1% of the human population. One single-nucleotide polymorphism is believed to occur in every 100 to 300 bases.
- Although high-throughput screening technology is not commonly utilized for individual patients, in the future these technologies will likely be used to provide information on an individual patient's disease or response to therapy.
- Gene expression arrays are providing new insights into sepsis and acute lung injury. Studies of genetic variation are helping us to better understand response to medications such as opiates and β-agonists.
- Genomic medicine will provide us with tremendous benefits and challenges. Perhaps one of the greatest benefits will be the understanding that human similarities and differences transcend the racial and ethnic categories that have proved so contentious in the past.

The recently developed disciplines of genomics, proteomics, and metabolomics are producing significant change in the biologic sciences. In the next decade, these disciplines are projected to have a major effect on clinical medicine, both in speeding the development of new therapies and in helping to create individualized therapies that are specifically tailored to the disease and drug metabolism characteristics of each patient.

One of the hallmarks of these new technologies is that they produce enormous quantities of data, so they often are described as "high-throughput" technologies. These data simultaneously reveal details about many components of a biologic system rather than focusing on a single pathway or product. To meet the challenge of extracting meaningful information from such large quantities of data, the new discipline of systems biology is being developed. The goals of systems biology are to integrate information from a variety of sources and to develop a comprehensive picture of the relationships and interactions between the components of a biologic system. This chapter will focus on these disciplines and describe their potential impact on patients in the intensive care unit.

Genomics

From the Discovery of the Double Helix to the Human Genome Project

In 1953, in a manuscript that scarcely exceeded one page,[1] the double helical structure of deoxyribonucleic acid (DNA) was described. This brief report opened the door for a new understanding of heredity and gene function. As a direct result of this discovery, the field of molecular biology emerged and the task of deciphering the genetic code began. Initially, progress was slow, depending mostly on methodical detective work and a certain measure of luck. It was not until 1983, with the localization of the mutation for Huntington's disease to chromosome 4, that a gene was unequivocally linked to a physical location within the human genome (Figure 99-1). Another 10 years would elapse before the sequence of this gene was known and the molecular abnormality causing Huntington disease was identified. The cystic fibrosis gene was among the earliest disease-causing genes to be sequenced in 1989. Among the insights gained was that the disease was genetically heterogenous. Only 70% of patients with this illness had the most common mutation (ΔF508); the remaining patients could have any of hundreds of mutations in the chloride-channel protein encoded by this gene. Knowledge of variation in the gene's sequence helped to explain the tremendous diversity in the clinical manifestations of this disease.

Gene Expression and Microarrays

High-throughput automated DNA sequencing was developed in the late 1980s, allowing rapid determination of DNA sequences. This development has led to new challenges, because managing the large volumes of sequence data demanded new technologies. Fortunately, the rapid increase in computing power in mainframe and desktop computers and the availability of the Internet to link investigators to public databases provided a solution to this problem. A fusion of these technologies greatly accelerated the pace of gene sequencing.

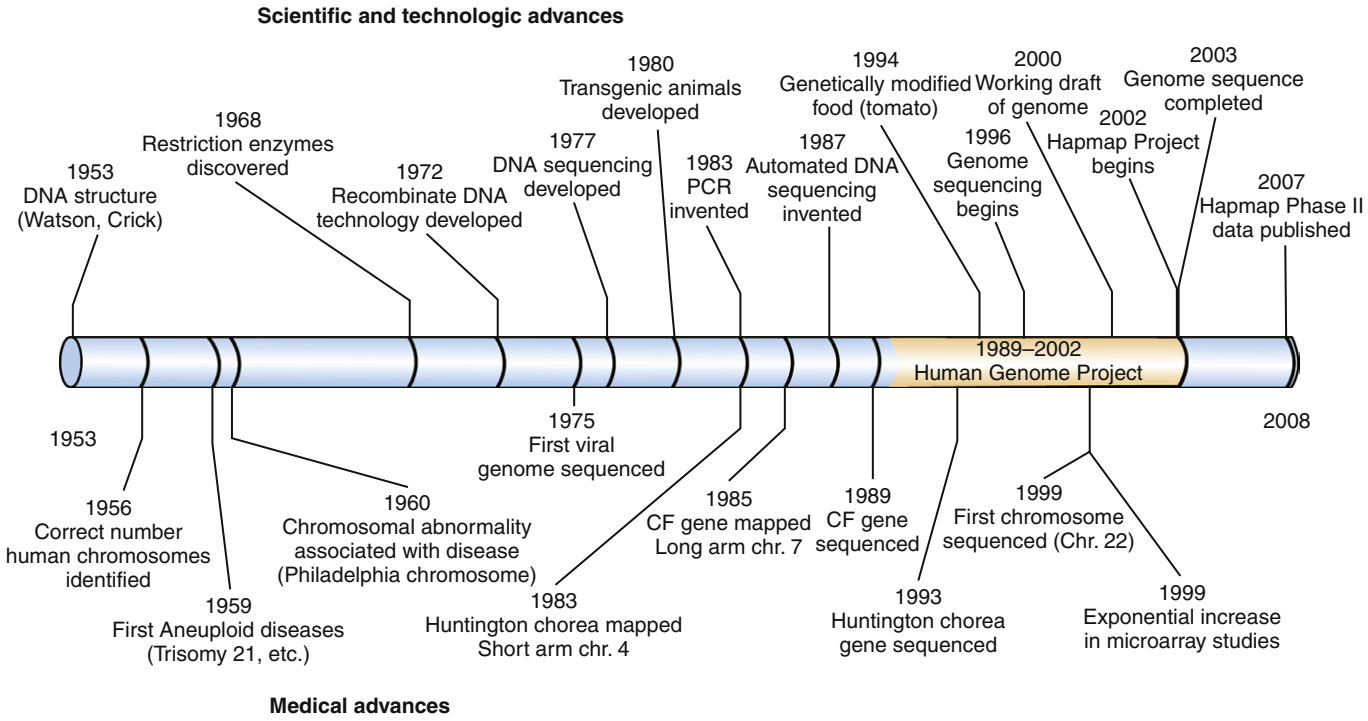

Figure 99–1. Milestones in molecular biology and sequencing of the human genome.

In the late 1980s and early 1990s, leaders from the National Institutes of Health and the Department of Energy began to create the infrastructure necessary for large-scale sequencing of the human genome. Although the Human Genome Project began in the early 1990s, the international effort to sequence the entire genome did not begin until 1998.[2] Remarkably, this massive project was completed just 5 years later.[3] Scientists throughout the world who participated in the human genome project contributed DNA sequence data to public databases so that the entire sequence of the human genome is freely available to the scientific community.

In the early 1990s, as the DNA sequence of an increasing number of genes became available, investigators began to experiment with gene expression microarrays. These investigators made microarrays from slides with a series of spots, in which each spot contained the DNA from a single gene. As the technology improved, the investigators were able to examine the expression of an increasingly larger number of genes in a single experiment. In the earliest published experiments, the investigators examined expression patterns of 45 yeast genes.[4] Less than a decade later, commercially produced gene expression microarrays were available with more than 30,000 human genes on each array.[5] The field of functional genomics emerged when gene expression microarrays made it feasible to study the expression of thousands of genes at once. Gene expression microarray use has increased rapidly since 1995, when the first gene expression microarray publications appeared in the literature. These powerful tools are readily available to laboratory investigators and are beginning to find their way into clinical practice. Within the next few years, gene expression microarrays and other high-throughput technologies will find increasing numbers of applications in clinical medicine.

Gene Expression Microarrays

All gene expression microarrays start with known gene sequences bound to some kind of a platform. These DNA sequences are obtained from public databases. As new information about the sequence and function of genes becomes available, it is added to the database so that the latest information is readily available to investigators who are using microarrays. Gene expression microarrays depend on the property of a single strand of DNA in solution to hybridize (bind) with a complementary strand of DNA that is bound to the microarray slide.

The oligonucleotides chosen for the microarray are selected based upon their ability to bind tightly with the DNA from a single gene, thus making each oligonucleotide highly selective for one gene with little cross-reactivity for other genes. Each oligonucleotide is printed onto a known location (spot) on the surface of the slide such that the various genes are arrayed in rows and columns. This spot is the "address" of the oligonucleotide and is an important piece of information in collecting and interpreting data from microarrays.

Quantifying Gene Expression

Microarray experiments usually are designed so that gene expression from two tissue samples may be compared either directly or indirectly.[6] This allows investigators to learn how different conditions can alter gene expression. For example, much has been learned about the biology of cancer by comparing gene expression from cancer cells to gene expression from normal cells in the same tissue.

When a gene is expressed in a cell, the DNA from that gene is transcribed into messenger ribonucleic acid (mRNA). This is transported out of the nucleus and then used as a template to guide the synthesis of proteins in the cell. At any given

time, the mRNA content of a cell represents a snapshot of the genes being expressed and the proteins being made in the cell. If a gene is turned on (upregulated), more mRNA will be produced from that gene. Conversely, if a gene is turned off (downregulated), less mRNA will be produced from that gene. To quantify gene expression, mRNA is extracted from the cell and reverse transcribed to make cDNA that is labeled with a fluorescent dye. The labeled cDNA is then incubated on a microarray slide to permit the hybridization with complementary DNA oligonucleotide probes that are bound to the surface of the slide (Figure 99-2). The amount of labeled cDNA hybridized to each oligonucleotide spot will be proportional to the quantity of mRNA that was expressed from the target gene.

When hybridization is complete and the labeled target DNA is bound to the oligonucleotide probes, the microarray is ready for analysis. The relative amount of mRNA produced from each gene is quantitated by exposing the microarray to blue laser light and capturing the image. A strong fluorescence signal from an oligonucleotide spot indicates a large quantity of mRNA was present from that gene. The strength of signals can be compared under different experimental conditions to determine how the conditions affect gene regulation. The signal intensity for each spot is quantitated and saved in a database. Because the position of each spot corresponds to a specific oligonucleotide, the database links the information about the image intensity to information about the gene. It now is possible to assemble a profile of the gene expression in the tissue.

Large, high-density microarrays contain thousands of spots, each of which corresponds to a different gene. Managing and analyzing this data would be nearly impossible if not for the substantial power available from desktop computers and the use of specialized software packages designed for microarray data analysis. Using this technology, it is possible to track the expression patterns of sets of genes and observe how these patterns change under different conditions. Analysis of gene expression patterns can provide new insights into how tissues and organs respond to a disease or a therapy.

Knowledge gained from expression microarray studies has greatly enhanced our understanding of the mechanisms organisms employ in response to environmental stresses, diseases, metabolic challenges, and therapeutic interventions. At the cellular level, maintenance of homeostasis often means altering gene expression to compensate for changes in a cell's environment. Learning which genes are activated or suppressed by changes caused by disease can suggest new targets for therapies directed specifically at correcting the molecular changes created by a disease state.

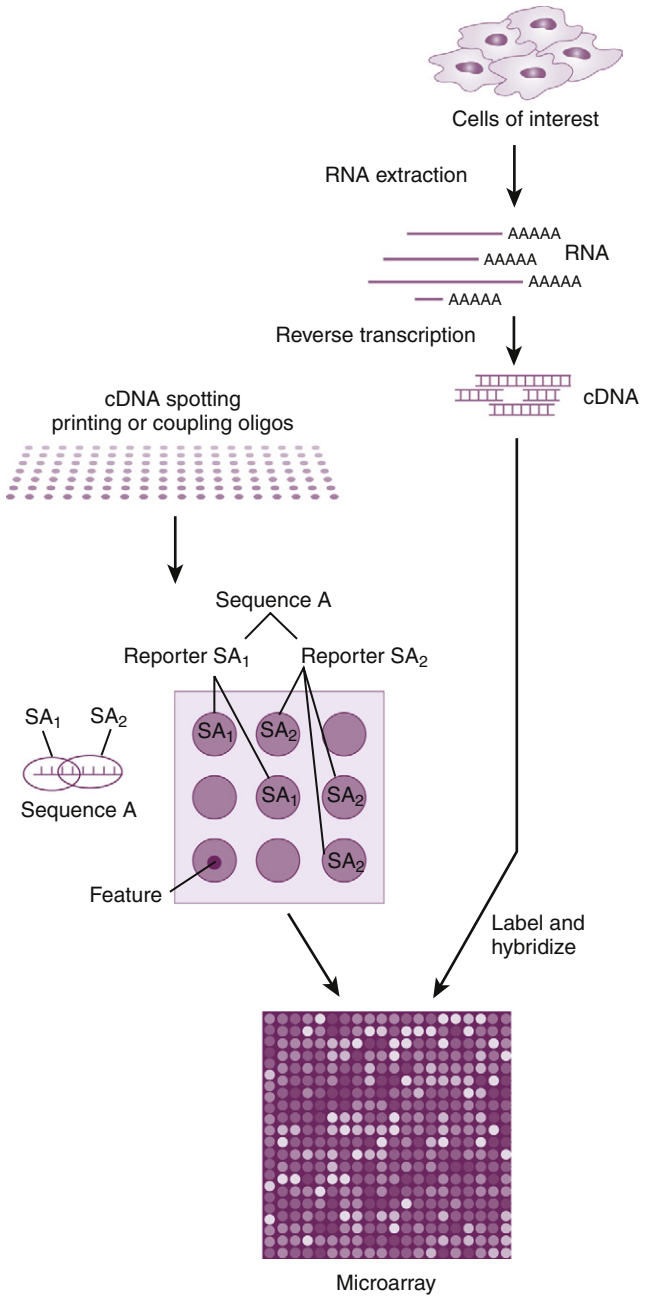

Figure 99–2. Making of a microarray. Ribonucleic acid (RNA) is isolated from a cell and reverse transcribed into labeled complementary deoxyribonucleic acid (cDNA). This is placed on the surface of a slide, which is covered with spots of oligonucleotides that are complementary to the cDNA. Under carefully regulated conditions, the labeled cDNA specifically hybridizes with a complementary oligonucleotide. Under a fluorescent laser, the brightness of each oligonucleotide spot is proportional to the quantity of cDNA bound to it. The brightness is measured to determine the relative amounts of RNA from each gene in the cells.

Genes and Human Variation

When contemplating the great diversity among humans, it is somewhat surprising to realize that the DNA of two unrelated humans is more than 99.9% identical.[7] Although the vast majority of nuclear DNA is identical from one person to the next, a small fraction of DNA sequence (~0.1%) varies between individuals and is responsible for the genetically determined variation in our physical characteristics and physiology. Genetic variability also appears to be involved with susceptibility to some diseases, as well as therapeutic responses to treatment.

The sequencing of the human genome (actually now several individuals' genomes) and the advent of high-throughput sequencing and genotyping technologies has revolutionized the understanding of gene structure and genetic variation. Many genes are polymorphic; that is, there are small differences in DNA sequence between individuals. Polymorphisms are sites in DNA in which variation at a specific nucleotide or DNA region is found in greater than 1% of the general population, and in some instances in as much as 50% of the population. (Mutations are considered to be sites at which

variation occurs in 1% or less of the population.) Polymorphisms may alter protein level or function in several ways. For example, altering a single base can alter an amino acid in a protein, which may lead to a change in protein function. Polymorphisms can also have significant effects without altering proteins. A polymorphism occurring in a promoter region, that controls gene expression through controlling mRNA synthesis, may lead to increased or decreased synthesis of that protein, which may have significant effects. Although polymorphisms are still being mapped and the function of most polymorphisms is still being defined, it is clear that these genetic variations account for the vast majority of inherited human phenotypes, from differences in hair color to differences in response to medications.

Polymorphic sites within a gene do not necessarily affect the expression or the function of the gene product. However, polymorphisms are not only of interest because of the subset which are responsible for genetic variability, but also because they occur fairly frequently in the human genome and can be used as markers to map genes involved with disease to specific regions of the genome. To be used as a marker, a polymorphism does not have to change the expression or function of a protein product but rather only needs to be linked to the gene involved with the disease of interest.

Single-Nucleotide Polymorphisms

Polymorphisms in DNA sequence may exist in several forms with the most common form due to the substitution of one nucleotide for another. These single nucleotide substitutions are called single-nucleotide polymorphisms (SNPs). For example, the sequences GATCACA and GATTACA differ because one of the cytosines (C) in the first sequence has been replaced by a thymine (T) in the second sequence. This example represents the most common human SNP, which involves the substitution of T for C.

Although such substitutions may occur spontaneously and represent a new mutation, the vast majority of the observed substitutions are stable variations in the human gene pool. SNPs are the most common type of polymorphism, and are thought to account for approximately 90% of human variation.[8] One SNP is believed to occur in every 100 to 300 bases. Although most of the SNPs in the human genome remain to be identified, if this figure holds true for the entire genome, then more than 20 million SNPs exist in our genome, and constitute an enormous source of variation.

Copy-Number Variations

In addition, polymorphisms within genes may be due to insertions or deletions of fragments of DNA, or to the presence of a variable number of tandem repeats (VNTRs) of short, repetitive DNA sequences. Some of these insertions or deletions, although submicroscopic, can be relatively large, resulting in gene copy-number variations (CNVs). CNVs are generally defined as stretches of DNA of greater than 1 kb that show differences in the expected number of copies of the DNA (that generally would be two due to the presence of one copy on each chromosome) in greater than 1% of the human population.[9,10] Very recently it has become clear that CNVs are common in human genomes and contribute significantly to human genetic variation.[11,12] In addition, CNVs have been demonstrated to be associated with a number of diseases including Williams-Beuren syndrome, DiGeorge syndrome, mental retardation, and autism.[9,10] It is thought that alterations in phenotypes due to CNVs are due to differences in gene dosage or to gene disruption that may be caused during the duplication or deletion. This is a new and rapidly expanding field and the next 10 years will likely determine how large a role CNVs play in human variation and disease.

Genotyping and Microarrays

DNA microarrays have been designed for both SNP and CNV genotyping. SNP microarrays are similar to those used for gene expression studies, but the oligonucleotides on SNP arrays have each been designed to selectively hybridize with one form of an SNP. Some of these microarrays have probes for almost a million different SNPs from throughout the genome and can quickly reveal the genotypes of an individual at these sites. Many of these same arrays also have the ability to genotype the individual for almost a million CNVs. Such arrays have been used for genome-wide association studies to identify genes associated with complex diseases such as asthma[13-16] and diabetes.[17-19] The ability to define the genetic components of variation with speed and precision is more than a valuable research tool. In the near future, this information will be used to identify disease and to help select therapies for illness, taking into consideration the individual variations that can be predicted on the basis of a patient's SNP and CNV genotype. As more polymorphisms are identified and their function understood, this technology will probably become an integral part of clinical practice. In the future, this new technology likely will permit physicians to plan highly individualized therapy for each patient, taking into account issues such as individual disease susceptibility and variations in drug metabolism.

Proteomics

Genes are the main sites of biologic information, but proteins are the main centers of biologic activity, which gives proteins a unique importance. The discipline of proteomics encompasses the study of all the proteins encoded by the genome present in specific tissues, cells, or fluids. Proteomics encompasses not only the study of differences in protein levels but also the study of the modifications that occur after protein synthesis. Study of the proteome is particularly important because levels of mRNA often do not correspond to levels of the protein product.[20] In addition, it is estimated that there are over a million proteins encoded by only about 30,000 genes, suggesting that there is substantial protein processing and modification involved in generating the proteome.[21] In clinical medicine, proteomic studies often examine differences in proteins between normal and diseased—or between untreated and treated—cells, tissues, or body fluids. Often the goal is to identify biomarkers associated with disease, or to identify novel targets for drug development.

Because the protein complement within a cell can vary widely over time in response to intracellular and extracellular influences, any picture of the proteome must consider these influences. Knowing which genes are expressed or suppressed by a given disease state is important but is only part of the picture. After proteins are synthesized, they can be modified in a number of ways that can dramatically alter their function. Such alterations are generally due to activation of a signaling cascade or enzyme pathway. Because activation of these cascades and pathways can occur without the activation of gene expression,

gaining a full picture of the functioning of a cell, particularly during differentiation, development of disease, or response to extracellular signals or drugs, will require determination of protein levels, protein modifications, and protein interactions.

Unfortunately, proteins are much more complex than DNA and RNA in a variety of ways. Proteins are composed of 20 amino acids rather than the four nucleotides that constitute DNA and RNA. The three-dimensional structure of proteins, which is critical to their function, usually is much more complicated than the three-dimensional structure of DNA. Finally, after proteins are synthesized, they undergo a variety of modifications (e.g., cleavage, phosphorylation, and glycosylation) termed posttranslational modifications. In contrast, DNA undergoes relatively little modification after synthesis. Proteomic methods are being developed to detect and measure posttranslational modifications.[22,23] The complexity of proteins has slowed the development of high-throughput methods for examining large numbers of proteins simultaneously. Nevertheless, great progress has been made in this field and a number of new techniques are being developed to enhance the use of proteomics for studying disease.[21] Some of the techniques bear a resemblance to DNA-based microarrays, except that proteins or ligands rather than oligonucleotides are spotted on a slide.[24,25] Other approaches, including mass spectrometry-based analysis of proteins, are also showing considerable promise.[21,25,26]

Metabolomics

Perhaps the newest of the "omic" fields is metabolomics, the study of all the small molecules, primarily metabolites, within cells, tissues, organs, or biological fluids. The goal is to provide a comprehensive picture of the metabolic state of a cell or tissue by measuring the full suite of metabolites and small molecules. The metabolites produced in a cell can vary widely depending on external influences, including the environment, and can reflect the health of the cell. In a sense, metabolites are at the end of the cellular information chain (because they are dependent on genes, gene expression, and proteins), but the metabolic state of the cell often drives mRNA and protein synthesis through feedback loops.

Because metabolites are a heterogeneous group of small molecules, many of which are structurally unrelated, this field presents great challenges. Substantial progress is being made in measuring the metabolic state of a cell using the technologies of gas and liquid chromatography coupled to mass spectrometry.[27-30] Recently, relatively high-throughput metabolomics approaches have been utilized to identify metabolomic signatures for a number of disease processes including cancer, motor neuron disease, and type 2 diabetes, and have demonstrated that metabolomic signatures are also useful in identifying drug-response phenotypes.[27,29] Metabolomics studies in cancer patients have resulted in the use of this technology for tests for diagnosis of breast and prostate cancer that are paid for by insurance providers.[29] Future metabolomic studies will likely help elucidate disease processes, identify biomarkers, and identify new drug targets.

Systems Biology

Together, the fields of genomics, proteomics, and metabolomics characterize biologic processes at a level of detail that was almost unimaginable 20 years ago. However, amalgamating these details into a meaningful narrative is one of the greatest challenges facing scientists (the genomic data alone can have more than 30,000 data points per experiment). The ambitious goal of systems biologists is to integrate data from all the "omic" disciplines, identify important components, and assemble the knowledge into a meaningful whole that can be validated (Figure 99-3).[31] Integrating information about system structures, system dynamics, the control method, and the design method can lead to a systems-level understanding of an organism.[32] Because of the obvious technical challenges in such an undertaking, this field is still relatively new. Nevertheless, a systems biology approach has already produced novel biologic insights regarding the regulation of innate

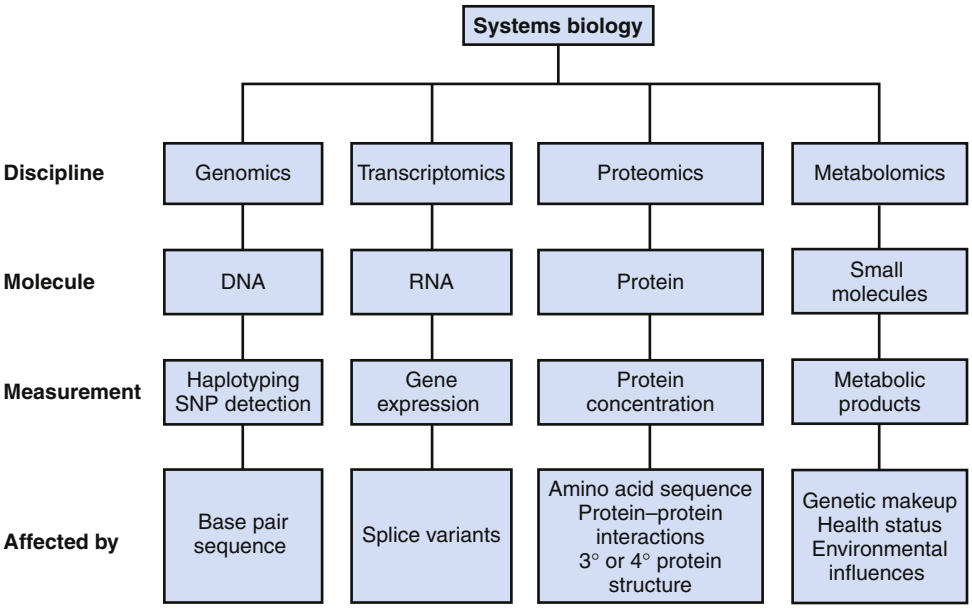

Figure 99–3. The goal of systems biology is to provide an integrated picture of all cellular functions. Each of the "omic" fields provides a comprehensive picture of one aspect of cellular function. *(Modified from Minie ME:* Module 7, expression resources, NCBI Advanced Workshop for Bioinformatics Information Specialists. *Available at http://www.ncbi.nlm.nih.gov/Class/NAWBIS/.)*

immunity[33,34] and protein kinases.[33] As expertise in this field continues to grow, there is optimism that it will lead to new insights in such diverse areas as drug discovery,[35,36] synthetic transgene control networks,[37] and neurologic diseases,[38] to name a few.

Metabolic control analysis is another discipline dedicated to the development of an integrated overview of genetic, enzymatic, and substrate control mechanisms in biologic systems.[38,39] When a metabolic control analysis is fully developed, a control coefficient is assigned to each step in an enzymatic pathway.[40] These coefficients reflect the magnitude of change that is induced in a pathway compared with the change in the state or level of an enzyme. Enzymes with high coefficients are logical targets for therapeutic intervention (drug design). Identification of important regulatory points also can help with the understanding of carcinogenesis and can provide new insights into genetic disorders.

Clinical Applications

The new technologies described above offer great promise for clinical medicine. At the research level, new biologic insights already are becoming available as a result of high-throughput technologies. Clearly, genomic screening of tumors can aid in diagnostic classification, and SNP analysis of enzymes involved in drug metabolism can characterize an individual's response to some drugs. Although high-throughput screening technology has not yet been implemented routinely for individual patients, almost certainly in the near future high-throughput technologies will provide information about an individual patient's disease or response to therapy.

Cancer

Oncologists have made extensive use of gene expression profiling to revise and more accurately classify the prognostic categories of malignancies.[41-44] One of the earliest uses of microarray technology for prognostic purposes was to study lymphomas using a specialized microarray, the "Lymphochip." Using this microarray, investigators were able to identify different histologic classes of lymphoma by their gene expression patterns, indicating that histologically distinguishable tumors differ in their gene expression, so these tumors can be distinguished at a molecular level. More importantly, the investigators found patients with gene expression patterns that permitted them to separate B-cell lymphomas into two groups: one group that resembled germinal center B cells and another that resembled activated B lymphocytes. Although these subgroups had identical histology, patient survival was significantly altered by the gene expression patterns. The lymphomas that exhibited gene expression patterns similar to germinal center B cells had a 5-year survival of 76%, whereas lymphomas that demonstrated gene expression patterns similar to activated B cells had a 5-year survival of 16%.

The promise of expression arrays to help define the prognosis of tumor types has also been used effectively in classifying breast cancers according to risk of metastasis. Use of microarray analysis of gene expression patterns permitted grouping of patients into high- and low-risk groups with greater accuracy than currently used clinical parameters.[45,46] Although these investigations were performed with high-density microarrays containing thousands of genes, the investigators found that expression levels of just 70 genes were sufficient to distinguish risk groups.[45] The authors believed that these results indicate the propensity to metastasize was an inherent genetic property of certain tumors and that this was not necessarily something that developed late in tumorigenesis. In the near future, these tools may be used to select patients who will require adjuvant therapy and to spare patients in the low-risk group who will not benefit from therapy.

Proteomic and metabolomic studies have also been utilized to characterize cancers. As described earlier (in the Metabolomic section), a specific metabolomic signature has been identified that is now used diagnostically to identify patients with breast and prostate cancer. Proteomic approaches have also been utilized in cancer research. Such studies have generally focused either on better understanding the cancer process with the goal of identifying novel therapeutic targets or on identifying biomarkers that can be used clinically. Proteomics studies have provided significant insight into understanding the mechanism of cancer development and currently much effort is targeting the use of proteomics to identify biomarkers that can be utilized in clinical oncology.[47,48]

Pharmacology

High-throughput genomic and proteomic technologies are currently being used in the field of pharmacology to speed the discovery of new drug targets, learn more about the mechanisms of drug action, and identify genetic polymorphisms that alter efficacy or increase risk of toxicity (see Chapter 117).[49] Gene expression arrays have identified genes that are differentially regulated in disease and provided clues about possible pathways and proteins that may be targets for drug therapy.[50,51] The combination of genomic technology with pharmacology has led to the new field of *pharmacogenomics,* a term that is often used interchangeably with *pharmacogenetics,* to refer to studies examining the contribution of genetic variation to drug response.[52,53]

The goal of pharmacogenomics/pharmacogenetics has been individualization of drug therapy to optimize therapeutic effect and minimize toxicity. Historically, attaining these goals has been difficult because it has often been impossible to predict an individual's response to therapy before treatment was initiated. Instead, using pharmacodynamic data (drug levels), optimization was attempted after therapy was started. It was clear that inheritance played an important role in individual responses to drug therapy; however, until recently it has been impossible to easily identify variations in an individual's genetic makeup that would determine therapeutic responses. Pharmacogenomics uses genetic markers (specific variants such as SNPs or CNVs) that determine a patient's course and/or response to therapy to tailor therapy according to an individual's genetic makeup.[54] Current examples where this new paradigm is utilized is in determining safe and effective therapeutic doses when treating with thiopurines or warfarin.[55-59] The new paradigm will allow optimal individualization of therapy on the basis of a patient's genetic profile and will be useful for improving outcomes and risk stratifying patients.[55]

Are there examples in the critical care environment in which genetic variations influence the pharmacologic treatment of critically ill children? Variations in genes coding for drug transporters, receptors, components of signal transduction pathways, and proteins involved in the metabolism

of drugs can alter the overall response to a given drug. The following discussion highlights some drugs used relatively frequently in the ICU for which genetic variations may potentially be involved in response, yet much more research is needed to support the widespread use of pharmacogenetics in this patient population.

The use of opiates, the mainstay for treating pain in the ICU, is an example of an instance where the influence of genetic variations on the efficacy of drug therapies is well documented. The mechanism of action of opioids involves a number of processes, including enzymatic conversion to active metabolites, transport across various barriers including the blood-brain barrier, binding to various receptors, and secondary involvement of catecholamines, such as dopamine and norepinephrine. Genetic variations in a number of the proteins involved in these processes have been demonstrated to influence the clinical efficacy of opiates.[60,61] For example, many opiates are metabolized by the CYP2D6 enzyme encoded for by the highly polymorphic *CYP2D6* gene. This metabolic step is required to convert the prodrug to the active metabolite. Genetic variations in *CYP2D6* contribute to four general phenotypes characterized by the rate of opiate metabolism: poor, intermediate, extensive, and ultrarapid. Individuals with one or two copies of the wild type *CYP2D6* gene are phenotypically classified as extensive metabolizers and tend to have better responses to opioids than poor metabolizers. Individuals who are poor metabolizers are at greatest risk for treatment failure.

Another example of a step in opiate response that is subject to genetic variability is opioid receptors. Of the three opioid receptors the primary target for the opioid drugs is the mu (μ) receptor encoded for by the opioid receptor mu-1 (*OPRM1*) gene. *OPRM1* has a SNP at position 118 (adenine to guanine substitution) found in 10% to 15% of Caucasians that results in a substitution of an asparagine for aspartate at amino acid position[40] in the extracellular domain of the μ receptor.[62] Individuals with the wild-type μ receptor (A allele) who have cancer or are in the perioperative period have significantly reduced requirements for analgesia compared with those individuals with the less common G allele.[62-65]

In addition to receptor binding and CYP2D6 activity to generate active metabolites, opiates such as methadone are a substrate for the P-glycoprotein 170 (P-gp 170) that transports drugs from the intracellular to the extracellular compartments in tissues that act as barriers such as the blood-brain barrier. P-gp 170 is encoded for by the highly polymorphic ATP-binding cassette sub-family B member 1 (*ABCB1*) gene in which over 100 SNPs have been identified. Many studies have been performed examining the role of ABCB1 genetic variations on function, including one in which a three SNP haplotype in the *ABCB1* gene was shown to be associated with the need for a higher methadone requirement in a cohort of heroin-dependent adults; however, the field has not yet reached a consensus on the contribution of variation in *ABCB1* on drug opioid effects.[61,66]

Finally, catecholamines are also involved in the mechanism of opioid action, and thus, catecholamine metabolism can affect opiate efficacy. Variability in the gene coding for catechol-*O*-methyltransferase enzyme (COMT) has also been demonstrated to be associated with the need for lower morphine dose in a cohort of adults receiving morphine for cancer-associated pain.[67]

Thus, individual genetic variability appears to influence the efficacy of opiate use, but studies involving children in the ICU setting have yet to be done. While the response to opiates is likely the best-characterized example of the role pharmacogenomics may play in the ICU setting, there are other studies that suggest that genetic variations influence the response to drugs commonly used in the ICU. For example, genetic polymorphisms in the gene coding for butyrylcholinesterase, an enzyme involved in hydrolysis of succinylcholine to its inert form, result in decreased enzyme activity. Individuals with these genetic polymorphisms exhibit a prolonged paralytic effect of succinylcholine.[68] Another example is the use of β_2-adrenergic receptor (β_2-AR) agonists, particularly in children with severe acute asthma exacerbations. Variability in response to inhaled β-agonist treatment between individuals is well documented and approximately 60% of such variability is estimated to be due to genetic differences.[69] A number of studies indicate that polymorphisms in the gene for the β_2-AR, the target of β-agonists, may affect response,[70-74] although there are conflicting reports. Future studies will clarify the contribution of genetic variation in the β_2-AR in variable response to treatment in children. Lastly, genetic variations have been described in the genes coding for the family of cytochrome P450s, which are involved in the metabolism of a large number of drugs that are commonly used in the ICU setting. Such drugs include proton pump inhibitors, antiepileptics, angiotensin II blockers, β-blockers, and nonsteroidal anti-inflammatory agents. Clearly the above described examples demonstrate that pharmacogenomics and pharmacogenetics will provide opportunities to refine treatment strategies and enhance medication efficacy and safety. However, much work is still needed to identify the optimal use of pharmacogenomics and pharmacogenetics data in critically ill children.

Drug Discovery

The pharmaceutical research industry has already been changed by the technologies discussed in this chapter. Drug discovery has been enhanced by the application of gene expression arrays, which have revealed previously unsuspected therapeutic targets. Gene expression array and other high-throughput technologies have proved invaluable in the screening of novel compounds for activity against disease. High-throughput technologies have also revealed new biomarkers of disease that can be used for diagnosis, or to monitor response to therapy. The recent discovery of a genetic variant that is highly associated with the development of age-related macular degeneration[75] illustrates the power of these technologies to identify potential new targets of therapy as well as to aid in the molecular diagnosis of diseases. Recently, a new technique that is capable of identifying extremely rare genetic variants has been developed.[76] It is only a matter of time before these technologies shed light on the diseases that we commonly encounter in pediatric critical care. It is reasonable to anticipate that we may begin to see these discoveries in the relatively near future.

These new technologies are also reshaping our perception of certain diseases, in much the same way that sequencing of the cystic fibrosis gene led to the realization that the cystic fibrosis phenotype could be caused by any one of a large group of genetic variations within the cystic fibrosis gene. For example, although a single gene causing schizophrenia

has yet to be identified, a recent investigation indicates that schizophrenic patients have an unusually high proportion of genetic abnormalities within a group of genes known to be involved in signaling networks that control neurodevelopment.[77] This suggests that the schizophrenia phenotype, like the cystic fibrosis phenotype, may be caused by any one of a group of genetic abnormalities rather than by a single flaw in one gene. Consequently, it is possible that rather than a single therapeutic target for schizophrenia treatment, there may be multiple targets, each of which may show a different response to a given therapeutic agent. If this concept is found to be correct, it may help to explain why the response to therapy is so variable in this illness. Novel insights such as this may ultimately contribute to better diagnosis and therapy for a variety of illnesses.

Biomarkers

A biomarker is a biologically derived indicator of the presence or progression of a process or condition such as an illness. Many genomic, proteomic, and metabolomic studies are designed to identify biomarkers of disease or response to treatment for a variety of illnesses. These markers should enable physicians to better identify the presence and progression of various conditions. In turn, this should help in targeting the optimal therapy, and/or the optimal time point for delivery of therapy, during the course of an illness.

Historically, proteins have been used as biomarkers. In the past, protein biomarkers were usually proteins which were known to be elevated during the disease process and studies were performed to determine whether the protein could be used as a prognostic marker of disease. Protein biomarkers have been identified for a number of disease processes including sepsis (procalcitonin[78]), pneumonia (soluble triggering receptor on myeloid cells-1 [sTREM-1][79-82]), and neurologic outcomes after cardiac arrest (neuron specific enolase and S-100B).[83,84] Currently a substantial body of research is focusing on disease-related functional proteomics in the hopes of developing novel protein biomarkers or protein biomarker signatures.[22]

Microarray technology has also been utilized for identification of biomarkers. In breast cancer treatment, expression array analysis has led to the identification of new prognostic biomarkers, given novel insights into the biology of the tumors, and suggested new therapeutic targets.[85] A similar approach has been used to identify new potential biomarkers for hepatocellular carcinoma[44] and bladder cancer.[86] Investigators seeking to identify novel biomarkers for low doses of radiation have used microarray technology to identify a set of genes whose regulation is altered by exposure to sublethal levels of radiation.[87]

In addition to single biomarkers, genomic and proteomic technologies open the possibility of using multiple biomarkers as a "molecular signature." One example of such an application is the development of pathogen chips, which are microarrays containing genes from viral or bacterial pathogens. These chips can be used to identify genes and gene expression patterns that will identify a pathogen and tell us about the drug sensitivity of the organism.[88] Another example is that results from expression arrays can be used as a molecular signature of a disease state. This is probably best exemplified by the use of expression arrays in typing cancers as described above under the section on Cancer.[41-44] It is likely that in the future, genomic, proteomic, and metabolomic studies will generate biomarker profiles indicative of many disease processes.

Critical Care

The above sections provide a framework for understanding of how the new "omic" fields of study are relevant in the pediatric intensive care unit. Currently, in the field of critical care these types of studies have been utilized primarily for research. Some of these studies are described in more detail below to highlight their relevance to critical care and the potential for use in diagnostics.

Gene Expression Microarrays

Gene expression studies in the PICU setting have primarily been utilized to examine expression profiles in children with sepsis. The value of such studies is twofold; first, they provide a better understanding of the host response to severe infection by indicating what genes are turned on and off in sepsis; and second, they may be useful for predicting which children are at risk of developing more severe disease or stratifying children into groups most likely to benefit from specific treatments. Wong and colleagues have pioneered this field and have studied the largest cohort of children with sepsis in whom gene expression profiles have been generated.[89-91] Several important observations have been made; first, many genes involved in zinc homeostasis are downregulated in children with septic shock; however, metallothionein, a metal-binding protein, is upregulated in nonsurvivors.[91] Nonsurvivors of sepsis demonstrated lower serum levels of zinc, which is consistent with the ability of metallothionein to sequester zinc intracellularly. Further support for the importance of metallothionein in sepsis is the observation that metallothionein knockout mice demonstrate a survival advantage over wild-type mice in a sepsis model.[91] In addition, similar studies examining longitudinal expression of signaling pathways in children with septic shock indicated that expression profiles of genes involved in immunity and inflammation appear to change over time, and gene networks involved with T cell and major histocompatibility complex (MHC) antigen-related biology are persistently downregulated.[89,90] Other gene networks are also differentially regulated in those children with septic shock compared with those with systemic inflammatory response syndrome or sepsis (see Chapter 103). For example, genes in the human leukocyte family are repressed in children with septic shock, while those involved in the signaling pathway for transforming growth factor-beta (TGF-β) are upregulated.[90] Recently a genomic signature related to repression in genes related to zinc homeostasis and lymphocyte function has been validated for pediatric septic shock.[92]

Gene expression profiles have also been used to identify expression patterns that are associated with the development of ventilator-associated pneumonia (VAP) using transcriptional profiles of circulating leukocytes in a cohort of severely injured adults.[93] Using these profiles, patients who developed VAP could be identified several days prior to the actual confirmatory diagnosis of VAP. If these results are confirmed, the use of gene expression profiling could help eliminate the use of antibiotics in those patients that are only colonized.

Genetic Variation

Recent studies in both critically ill adults and children have suggested that the clinical presentation, treatment, and outcome from critical illnesses are influenced in part by the

genetic makeup of the patient. Sepsis and acute lung injury (ALI) have been two areas of intense research, with the primary objective in both areas being to investigate whether new or previously identified genetic variations are associated with the susceptibility to, or outcome from, disease (sepsis or ALI). These studies have the potential to impact of clinical practice because they (1) may help identify those patients who have an increased susceptibility to, or an increased risk of worse outcome from, critical illnesses, thereby allowing tailoring of treatment or monitoring in the ICU to the specific risk of the individual; and (2) may identify novel genes or pathways involved in a specific illness, thereby generating the potential for novel therapies. This section will briefly highlight some of the studies supporting the concept that genetic variations influence the susceptibility to or outcome from critical illnesses. These studies are generally designed to determine whether specific genetic variants are associated with susceptibility or outcome of critical illness. In the last 10 years, many genetic-association studies have been reported, and often, such studies fail to replicate previously reported results. There are many reasons for this lack of consistent results including inadequate power (resulting from small cohorts and/or examination of multiple polymorphisms), population stratification (resulting from inclusion of multiple races and/or ethnicities in the study group), different study populations, and different definitions of response.[94,95] Currently, most journals are requiring that the authors demonstrate that their study does not suffer from such weaknesses. In addition, replication of any association is important to document that any observed association is not spurious.

The ability of the host to recognize a pathogen and respond with a well-measured and balanced response is crucial in the clinical course of patients with sepsis. However, individuals vary in the ability to recognize a pathogen and mount a response. Some of this variability may be accounted for by genetic variations. This idea is supported by the observation that an early death of a biologic parent from infection is associated with a much greater risk of death of a child from infection than the death of an adoptive parent from infection on the risk of death from a similar infection of an adoptee.[96] Identification of genetic variations which contribute to the susceptibility to and outcome from sepsis is important given the major impact of sepsis on the morbidity and mortality in neonatal, pediatric, and adult ICUs.

The innate immune response enables the host to recognize pathogens and provide a rapid inflammatory response. This response includes the production of cytokines, chemokines, and effector molecules allowing for the interaction with the adaptive immune response.[97] These two components of the innate immune system, recognition and response, utilize a large number of receptors and accessory proteins, signaling molecules, and transcription factors and proteins involved in protein synthesis. Any part of the recognition and response components that is altered in quantity or functional activity by the presence of genetic variations in the genes coding for them may ultimately influence the final response to a pathogen. Thus, the number of possible genes in which variation might influence the innate immune response, and, thereby, the susceptibility to and outcome from sepsis is quite large. The recognition component of the innate immune system consists of a large repertoire of receptors and binding proteins that recognize pathogen-associated molecular patterns. These include such proteins as the family of cell surface toll-like receptors, intracellular accessory proteins CD14 and MD-2, and circulating mannose-binding lectin (MBL). Discussed below are studies examining whether genetic variations in MBL are associated with susceptibility to, or severity of, infection as an example of how genetic variation may be important in individuals with critical illnesses.

Several genetic variations in the gene coding for MBL (*MBL2*) or its regulatory region have been described, and three are noted for resulting in changes in amino acids at positions 52, 54, and 57 (referred to as variants D, B, and C, respectively). These amino acid changes diminish the ability of the helical tails to polymerize, resulting in an increased degradation of MBL and reduced serum levels of MBL.[98] Studies have demonstrated associations between the three MBL structural variants D, B, and C and susceptibility to or outcome from infections in humans. These include associations with an increased risk for meningococcal infections,[99,100] with pneumonia and sepsis in neonates,[101] with acute respiratory infections in children,[102] with hospitalizations due to infections in children,[103] and with viral coinfections in adults with pneumococcal pneumonia.[104]

The influence of genetic variation on the development of acute lung injury (ALI) and acute respiratory distress syndrome (ARDS) is another area of intense research in the intensive care unit (hereafter, the term ALI will be used to reflect both ALI and ARDS). Genetic variations in over a dozen genes have been shown to be associated with either the development of ALI or the outcome from ALI.[105] The pathophysiology of ALI involves a number of critical processes that occur during various stages[106,107] and include inflammation, breakdown of the vascular endothelial cell barrier, impairment of normal surfactant function, alveolar fibrin deposition, interstitial fibrosis, and matrix deposition, to name just a few. The strategy utilized thus far in the study of genetic variation and ALI has been to select candidate genes whose gene products are thought to play a central role in the development of ALI. These include genes involved in innate immunity and inflammation, surfactant proteins, vascular barrier integrity, and regulation of lung endothelial and epithelial cell death, and oxidative stress. To date, the strongest evidence for the association of genetic variations with ALI exists for the genes encoding surfactant protein B,[108-111] angiotensin converting enzyme,[112-114] and interleukin-6.[115-118] Although considerable progress has been made in identifying genetic variants associated with ALI, further studies are warranted.

The above discussion demonstrates that these new technologies have great promise for critical care medicine. These technologies may help us to diagnose disease and to select appropriate medications and doses for our patients. Some of the earliest benefits to critical care patients likely will come from a systems biology approach to understanding inflammation. As the effects of genomic and proteomic components of the inflammatory cascade are understood in an integrated fashion, researchers/physicians should be able to identify critical points in selected pathways that will permit favorable alteration of the inflammatory response. Multigene studies should provide new insights into the mechanisms and prognosis of diseases such as sepsis, ALI, and hypoxic injury. Intriguing examples of potential applications of this technology to the field of critical care are already appearing.

Patients in critical care units are extensively monitored. In the future, this monitoring probably will include genomic, proteomic, and even metabolomic monitoring of responses to therapy as well as the previously mentioned pharmacogenomic monitoring.[119] Using genomic, proteomic, and metabolomic markers of disease, physicians will have a powerful set of tools to identify who is at risk for developing an illness or complication before clinical signs become apparent and will allow the use of therapies to minimize the disease burden, delay the onset of clinical symptoms, or decrease the risk of complications. Managing the volumes of information that will result from these tests will be a challenge to physicians, but these challenges will provide us with an opportunity to optimize our patients' therapies in ways that could not have been imagined a decade ago.

Ethical Issues

The technologies discussed in this chapter have prompted a wide public discussion about the ethics of genetic testing. In the past, genetic testing was infrequently performed and was usually limited to the identification of a very limited number of genetic variants. With the current high-throughput technologies, it is feasible and increasingly inexpensive to sequence an individual's entire genome. This feat can easily be performed on a tiny amount of DNA; theoretically, the DNA content of a single cell is sufficient for this purpose. A sufficient quantity of DNA for genotyping an individual can be obtained from a small amount of blood, sputum, or epithelial cells lining the mouth. There are several ways that an individual's genetic makeup may be characterized. The most commonly employed analysis is to perform SNP genotyping utilizing efficient high-throughput methods. The ease with which such information can be generated has led to concern about misuse of this information, especially with regard to genetic discrimination, particularly in regard to employment or insurance. In the 1970s, a well-documented example of genetic discrimination was the denial of health insurance to some African-Americans who carried the sickle cell trait.[120]

It has been argued that genetic information is special or "exceptional" for several reasons[121]: (1) Such information can be used for eugenic purposes. In theory, this information could be used to select for or against certain traits. (2) An individual's genetic information may provide the individual with unique and perhaps unwelcome insights with regard to his/her parents or siblings. For example, nonpaternity may be revealed. (3) Genetic information is immutable. The test, if correctly done, provides one with information about one's genetic status forever. This is unlike other medical information, which often changes with age or disease status. (4) For many conditions, genetic information is probabilistic and provides ambiguous risk assessments. Such information may be unnecessarily frightening to individuals and if revealed to employers or insurers could lead to genetic discrimination. Although these arguments for genetic exceptionalism may appear to be compelling, most authorities feel that genetic information is not clearly and distinctly different from nongenetic medical information.[122,123]

Legislation passed prior to 2000 provided limited protection with regard to genetic discrimination. The Americans with Disabilities Act (1990) prohibits discrimination against symptomatic disabilities, but it does not protect against discrimination based on unexpressed abnormalities. This left open the possibility that an individual could be discriminated against based upon an as-yet-unexpressed genetic trait. HIPAA legislation (1996) protected an individual's right to enroll in a health insurance plan without discrimination based upon expressed or unexpressed abnormalities. This legislation, however, did not address these issues in employer-provided health plans. In response to the public's concern regarding the potential misuse of genetic information, almost every state has issued legislation regarding genetic privacy.[124,125] Despite opposition from the National Association of Manufacturers, the National Retail Federation, the Society for Human Resource Management, and United States Chamber of Commerce, the Genetic Information Nondiscrimination Act of 2008 easily passed the United States House and Senate. This law (H.R. 493) prohibits insurers from denying coverage to individuals based solely upon a genetic predisposition to develop a disease in the future. Employers are prohibited from making decisions about hiring, firing, or promotion based upon such information.

The protection provided by both state and federal legislation has addressed some of the concerns raised by arguments for genetic exceptionalism. Increasingly, genetic information is being treated in the same manner as other medical information. Institutional review boards are finding it easier to craft policies regarding the use of genetic information in investigations, as these boards are increasingly guided by federal and state legislation as well as by precedents from other institutional review boards. Much work remains to be done in this area and we must remain vigilant to protect the rights of individuals. Nevertheless, the protections and precedents that have been established are already serving to facilitate appropriate use of genetic information in clinical care and research.

Molecular Foundations of Cellular Injury: Necrosis, Apoptosis, and Autophagy

Jared T. Muenzer and Craig M. Coopersmith

PEARLS

- As an "accidental" form of death, necrosis is an uncontrolled process.
- Apoptosis is a controlled, evolutionarily conserved process.
- Alterations in the balance between cellular proliferation and death can lead to disease.
- Altered apoptosis is estimated to play a role in half of all medical illness for which prevention is lacking.
- Apoptosis appears to play a role in critical illness, both in septic and noninfectious inflammatory states.
- Autophagy is a reversible form of cell death used to recycle intracellular organelles and is increased in states of starvation, inflammation, and infection.

Cell Death

Each day, the human body produces and eradicates 60×10^9 cells, a rate of cell death of nearly 1 million per second.[1] Cells die by one of three mechanistically distinct processes: apoptosis, autophagy, or necrosis (Table 100-1).[2,3] These three forms of cell death can be distinguished by both morphologic and molecular biologic criteria.

In necrosis, an overwhelming acute injury is followed by cell and organelle swelling, with early dissolution of the plasma membrane and subsequent cell lysis. As the cell bursts, its contents enter the interstitial space, leading to an accompanying inflammatory response to the toxic enzymes and proteases released. Morphologically, cells undergoing necrosis show swelling of the entire cell and its internal organelles. Deoxyribonucleic acid (DNA) fragmentation has no characteristic pattern and exhibits a random pattern on electrophoretic gel analysis. As an "accidental" form of death, necrosis has always been described as an uncontrolled process. However, more recent evidence suggests that necrosis may be more controlled than previously thought.[3]

In contrast, apoptosis (also known as *programmed cell death type I* or *cell suicide*) is a well-controlled, evolutionarily conserved process.[4,5] Following an appropriate trigger, a cell's apoptotic machinery leads to orderly death of the cell. This is characterized by cell and organelle shrinkage (pyknosis), nuclear fragmentation (karyorrhexis), and cytoplasmic blebbing with retention of plasma membrane integrity. Ultimately, there is fragmentation of the cell into small apoptotic bodies that are phagocytosed by neighboring cells. Orderly DNA fragmentation is identifiable on electrophoretic gels as a characteristic "ladder" pattern. Because cytosolic contents are not released into the interstitial space, there is no accompanying inflammatory response.

Apoptosis is critical to the existence of virtually all multicellular organisms and is involved in widely divergent physiologic processes, including embryonic development, maturation, immunity, repair, and cellular homeostasis. However, alterations in the balance between cellular proliferation and death have been proposed to be involved in the etiology of cancer and autoimmunity[6,7] and excessive apoptosis has been noted in the origins of neurodegenerative disease, osteoarthritis, allograft infection, graft-versus-host disease, type 1 diabetes, and heart failure.[1,8] Importantly, apoptosis is increasingly recognized as playing a role in critical illness, in both septic and noninfectious inflammatory states. Because of the importance of apoptosis in multiple disease states, a number of ongoing phase II and phase III trials targeting apoptotic pathways are currently ongoing.[1,9]

Autophagy (also known as *programmed cell death type II*), is the only cell death process thought to be reversible and functions to allow cells to degrade cytoplasmic contents, including dysfunctional intracellular components, for either recycling or removal.[10] Autophagy is characterized by formation of autophagosomes or large double-membrane vesicles that engulf intracellular organelles. Autophagosomes subsequently are trafficked to the lysosomal system for degradation. In times of starvation or stress, the breakdown of intracellular components provides the cell with a much-needed energy source. Autophagy, much like apoptosis, has been shown to be involved in a diverse number of physiologic processes, including embryonic development and immunity.[11] Furthermore, over the last 5 years increases in autophagy have been associated with several disease states, including sepsis, cancer, heart disease, and Alzheimer disease.[10] Finally, autophagy has been

closely linked to apoptosis by the fact that both forms of cell death use many of the same signaling mechanisms and are induced by overlapping stimuli.[12]

Pathways of Apoptosis and Autophagy

Apoptosis is initiated by two main pathways: a receptor-mediated pathway and a mitochondrial-mediated pathway (Figure 100-1).[13-16] The receptor-mediated pathway can be activated by a number of ligands, including Fas and tumor necrosis factor (TNF)-α. The mitochondrial pathway can be activated by a number of different stimuli following DNA damage, including reactive oxygen species, radiation therapy, and chemotherapy. Within the mitochondrial pathway, the Bcl-2 family of molecules plays a critical role. This group of proteins includes more than 20 proapoptotic and antiapoptotic molecules, many of which physically interact with each other.[1,15,17,18] Their primary function appears to be regulation of cytochrome c release from the mitochondria, with proapoptotic family members promoting and antiapoptotic family members suppressing its release. The prototypical antiapoptotic proteins are Bcl-2, Bcl-xL, and Mcl-1, whereas the prototypical proapoptotic family members are Bax and Bak.

Both receptor-mediated and mitochondrial-mediated pathways activate specific members of the cysteine aspartyl-specific protease (caspase) family.[19] Produced as inactive precursors, caspases are triggered by proteolytic processing as part of a cascade that produces their active counterparts. Depending on their location in the apoptosis cascade, caspases can be either upstream "initiators" or downstream "effectors" of cell death. Although several pathways for inducing these molecules exist, the receptor-mediated pathway acts by inducing caspase-8. In the mitochondrial pathway, cytochrome c binds to apoptotic protease-activating factor-1 (APAF-1), which in turn induces caspase-9. Both caspase-8 and caspase-9 converge on the final common pathway of apoptosis via induction of the death effector caspase-3, leading to the ultimate death of the cell.[18] Crosstalk between the mitochondrial and receptor-mediated pathways of death can occur via the molecule Bid.

The pathways and regulation of autophagy are much less understood, but ongoing research is beginning to unravel some of the complex signals that lead to autophagy. Autophagy is known to occur at basal levels and is important in the maintenance of cellular homeostasis.[10] Importantly, like apoptosis, autophagy can be a double-edged sword, in that too little or exaggerated levels can lead to unwanted consequences to the host. Key regulators of autophagy include ATG proteins and beclin-1, which are important in both formation of autophagosomes and autophagy signaling. It is important to note that many of the same genes that regulate apoptosis also regulate autophagy, the most studied of these being the Bcl-2 family and beclin-1. Antiapoptotic members of the Bcl-2 family inhibit beclin-1 function and proapoptotic family members disrupt this inhibition, thus promoting autophagy.[20,21] Although a complete understanding of the relationship between these two forms of cellular death is not yet clear, there is growing evidence that both are important in a multitude of human diseases.

Table 100–1 Differences Between Necrosis and Apoptosis

Autophagy	Necrosis	Apoptosis
Cell shrinkage	Cell and organelle swelling	Cell shrinkage
Double-membrane vesicles	Early loss of membrane	Preservation of membrane integrity until late
Organelle degradation	Organelle swelling Random DNA fragmentation Accompanied by inflammation	Organelle shrinkage (pyknosis) Nuclear fragmentation (laddering) No accompanying inflammation

Human Studies

Several human studies have shown alterations in apoptosis, necrosis, and autophagy in critical illness. The potential functional importance of these alterations has led to the development of agents aimed at manipulating cell death for therapeutic benefit currently undergoing preclinical and clinical trials.[1,9]

Sepsis

A prospective analysis by Hotchkiss et al.[22] of 37 patients who died in a surgical intensive care unit and underwent immediate autopsy demonstrated increased lymphocytic and gut

epithelial apoptosis in approximately 50% of septic patients with multiple organ dysfunction syndrome compared with essentially no alterations of cell death in critically ill, nonseptic patients (Figure 100-2). In addition, necrosis was detectable in 35% of patient livers but was minimal or absent in all other tissues examined. Similar findings have been shown in both neonates and pediatric patients with sepsis.[23,24] Increased apoptosis in septic patients has been demonstrated to be associated with an increase in active caspase-3 activity. Further studies from this same group showed that B and $CD4^+$ T lymphocytes are disproportionately lost in septic patients.[25] B and $CD4^+$ T-lymphocyte apoptosis is caspase-9 dependent, with the degree of cell death greater the longer the patient is septic. Antigen-presenting dendritic cells are also decreased in the spleens of septic patients.[26] Apoptosis is significantly decreased, however, in macrophages obtained by bronchoalveolar lavage (BAL) in septic patients compared with nonseptic controls.[27] This decrease in apoptosis is associated with lower levels of Bcl-2 than in control patients. An inverse correlation appears to exist between the severity of sepsis and the percentage of apoptotic alveolar macrophages. Minimal macrophage necrosis has been detected in BAL fluid.

Apoptosis is also decreased in neutrophils in patients who become septic after an initial traumatic insult, through upregulation of tyrosine phosphorylation by circulating mediators.[28] This appears to be related to the septic insult because neutrophil apoptosis is not significantly different between noninfected trauma patients and healthy volunteers.[28] In addition, circulating neutrophil apoptosis is decreased in infected patients with the systemic inflammatory response syndrome compared with controls. The decrease in neutrophil death is not associated with alterations in caspase-3 levels. Of note, however, levels of apoptosis are similar to those seen in patients who underwent elective abdominal aortic aneurysmectomy.[29]

Although there are few studies evaluating the role of autophagy in patients with sepsis, a recent study by Watanabe et al.[30] showed a significant increase in autophagy in patients with sepsis. In this study, liver sections from six patients who died from sepsis were compared with four control patients. The patients who died from sepsis showed a threefold increase in autophagic vacuoles compared with controls.[30] The significance of this finding is not entirely understood, and further studies are needed to determine the pathologic significance of increased autophagy in sepsis.

Noninfectious Inflammation

Similar to sepsis, tissue lymphocyte and intestinal epithelial apoptosis are increased in patients who have undergone shock and trauma. Intestinal specimens resected from 10 patients following motor vehicle collisions or gunshot wounds revealed extensive crypt epithelial and gut lymphocytic apoptosis, whereas control patients who underwent elective bowel resections had no obvious change in levels of cell death.[31] Apoptosis was detectable within 2 hours of traumatic injury, and patients with the highest injury severity score had the most severe apoptosis. Importantly, patients with high apoptosis on initial evaluation following trauma had no evidence of increased cell death at follow-up elective laparotomy.

Increased apoptosis has also been demonstrated to be present in circulating T lymphocytes of patients following blunt trauma or burn injury.[32,33] Although increased apoptosis of lymphocytes in the bloodstream was not directly associated with a negative outcome in the 30 individuals studied, patients with very high levels of apoptosis prior to complete activation

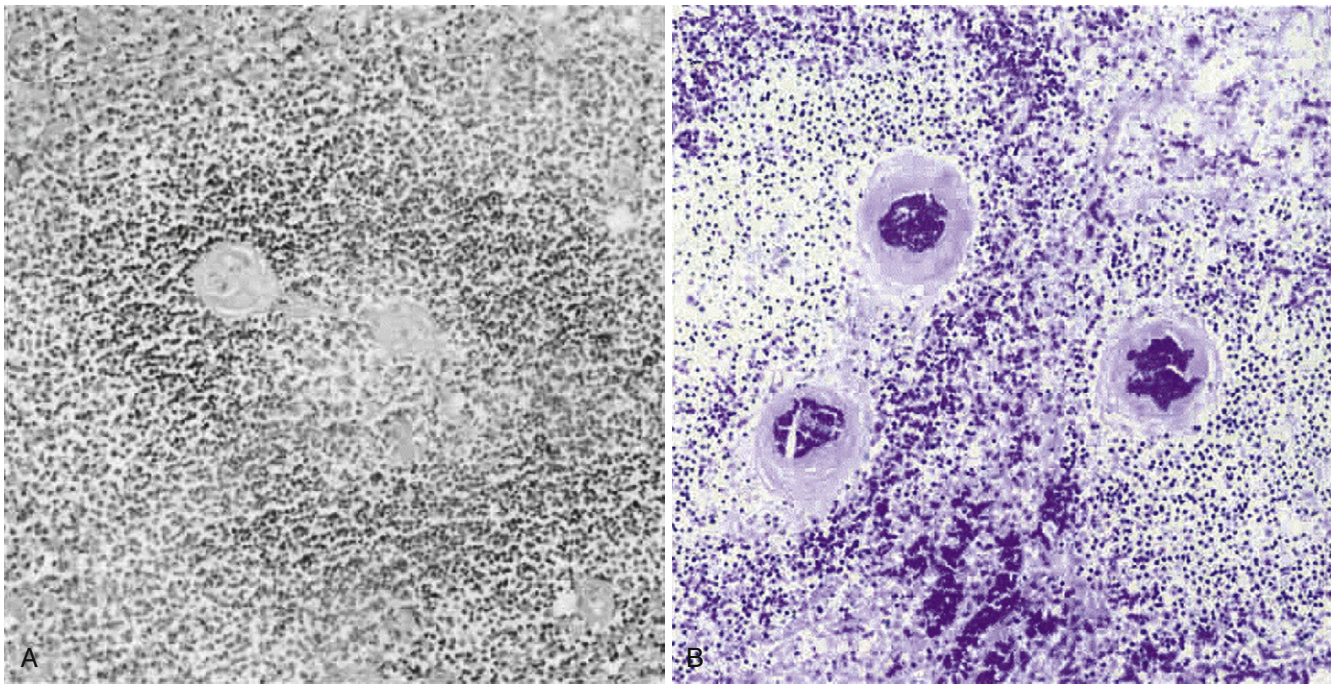

Figure 100–2. Spleen from a control patient (**A**) demonstrating a normal lymphoid follicle and from a septic patient (**B**) with substantial depletion in the lymphoid follicle. *(From Hotchkiss RS, Swanson PE, Freeman BD, et al: Apoptotic cell death in patients with sepsis, shock, and multiple organ dysfunction,* Crit Care Med *27:1230–1251, 1999.)*

and expansion of the T-cell response appear to be predisposed to anergy and organ failure. T-cell anergy leading to immunosuppression is further supported by Miller-Graziano et al.,[34] who recently showed increased apoptosis in circulating T cells of trauma patients and that high levels of T-cell apoptosis correlated with T-cell anergy.

The apoptotic response of polymorphonuclear leukocytes to trauma has not been fully elucidated. Ogura et al.[35] reported that apoptosis is decreased in this cell type for as long as 3 weeks following trauma. This contrasts with data showing that neutrophil apoptosis is decreased in septic trauma patients but is not significantly different between patients 24 hours after traumatic injury and control volunteers.[28]

Neutrophil apoptosis is low in BAL fluid from patients with acute respiratory distress syndrome (ARDS) as well as those at risk for ARDS.[36,37] Levels of apoptosis did not correlate with patient survival. Interestingly, in vitro human polymorphonuclear leukocytes from healthy volunteers have less apoptosis when incubated with BAL fluid from ARDS patients compared with BAL fluid from healthy controls.

Further evaluation of this antiapoptotic effect on normal neutrophils showed it to be highest during the early stages of ARDS, with subsequent decreases over time. This change in apoptotic response to BAL fluid from ARDS patients correlates with levels of granulocyte colony-stimulating factor and granulocyte-macrophage colony-stimulating factor.[38]

Soluble Fas ligand is present in BAL fluid before and after onset of ARDS.[39] However, its concentration is higher at the onset of ARDS in patients who eventually die. Of note, BAL fluid from patients with ARDS induces a Fas-dependent apoptosis in distal lung epithelial cells, whereas BAL fluid from patients at risk for ARDS but without the disease does not have an effect on distal lung epithelial cell death. BAL fluid also has elevated concentrations of the apoptosis-related molecules perforin, granzyme A, and granzyme B in critically ill patients with early ARDS compared with those not having lung injury or late ARDS.[40]

Although autophagy is thought to play a role in the human response to trauma and hemorrhage, there are currently no studies showing autophagy in humans. However, there is extensive literature on the role of autophagy in other noninfectious inflammatory conditions. Several groups have now shown a correlation between genetic mutation in autophagy genes and the development of inflammatory bowel disease.[40,41] The exact mechanisms by which these specific mutations lead to inflammatory bowel disease are not known, but the role these autophagy genes play in inflammation is thought to be at least partially responsible.[41] There is also growing evidence that autophagy is increased in atherosclerotic heart disease; however, it is unclear if this increase is detrimental or protective.[43-45]

Animal Studies

Although human studies demonstrate that apoptosis, autophagy, and necrosis are altered in critical illness, the functional importance of these descriptive associations has not yet been studied in patients. Animal models of sepsis and noninfectious inflammation can help determine whether altered cell death is harmful in critical illness and offer mechanistic insights into the pathways underlying changes in cell death.

Sepsis

Similar to human autopsy studies, apoptosis is primarily localized to lymphocytes, dendritic cells, and the gut epithelium in animal models of sepsis. In cecal ligation and puncture (CLP), a murine model of ruptured appendicitis, as well as in overwhelming infection from *Pseudomonas aeruginosa* pneumonia, sampling of multiple cell and tissue types shows that maximal lymphocytic and intestinal apoptosis occurs 24 hours after onset of septic insult without substantial necrosis reported (Figure 100-3).[46-51]

As outlined above, apoptosis occurs via two main pathways: a receptor-mediated pathway and a mitochondrial-mediated pathway. In animal models, it appears that both pathways play a role in sepsis-induced apoptosis. Animals with gene-specific knockouts of proapoptotic Bcl-2 family members (mitochondrial pathway) or Fas-associated death domain transgenic mice (receptor-mediated) demonstrate significant decreases in sepsis-induced splenocyte apoptosis.[17,52] Intestinal epithelial lymphocytes and lamina B lymphocytes undergo Fas ligand-dependent (receptor), endotoxin-independent apoptosis.[53,54] However, thymic apoptosis is mainly Fas independent (mitochondrial) and is related to release of endogenous steroids, potentially acting via Bcl-2 expression.[55] Sepsis-induced apoptosis, whether initiated by the mitochondrial or the receptor-mediated pathway, converges into a single common pathway mediated by caspase-3. It should be noted that there are likely alternate pathways that are independent of caspase-3, given that caspase-3 knockout mice exhibit only a small degree of apoptosis.[56]

Increased lymphocytic apoptosis appears to be detrimental to survival in sepsis. Overexpression of Bcl-2 in transgenic mice overexpressing either T lymphocytes or B lymphocytes improves survival twofold to fourfold in three different strains of inbred mice subjected to CLP.[56,57] Similar increases in survival have been shown in mice where the proapoptotic Bcl-2 family member Bim has been knocked out.[17] Administration of the polycaspase inhibitor N-benzyloxycarbonyl-Val-Ala-Asp(O-methyl) fluoromethyl ketone (z-VAD) or the caspase-3 specific inhibitor M-971 result in similar improvements in outcome.[57,58] The beneficial effects of caspase inhibitors on survival in murine sepsis require the presence of lymphocytes; there is no survival benefit conferred to Rag-1 mice treated with caspase inhibitors. Adoptive transfer of T lymphocytes that overexpress Bcl-2 into Rag-1 animals improves survival similar to that seen in transgenic mice that overexpress Bcl-2 in their lymphocytes.[57]

The mechanisms that account for worse outcomes with increasing lymphocytic apoptosis appear to involve immunosuppression. Although immunosuppression in sepsis is multifactorial, the ongoing loss of immune effector cells in both the innate and adaptive compartments likely plays a significant role. In addition to the loss of cells, there is an upregulation of T regulatory cells and myeloid-derived suppressor cells.[58] This upregulation of immunosuppressive cells is driven in part by the production of interleukin (IL)-10, an antiinflammatory, immunosuppressive cytokine. IL-10 has been shown by several researchers to be an important mediator of immune function and is known to downregulate monocyte and neutrophil function as well as decrease inflammatory cytokine production by T cells.[59-62]

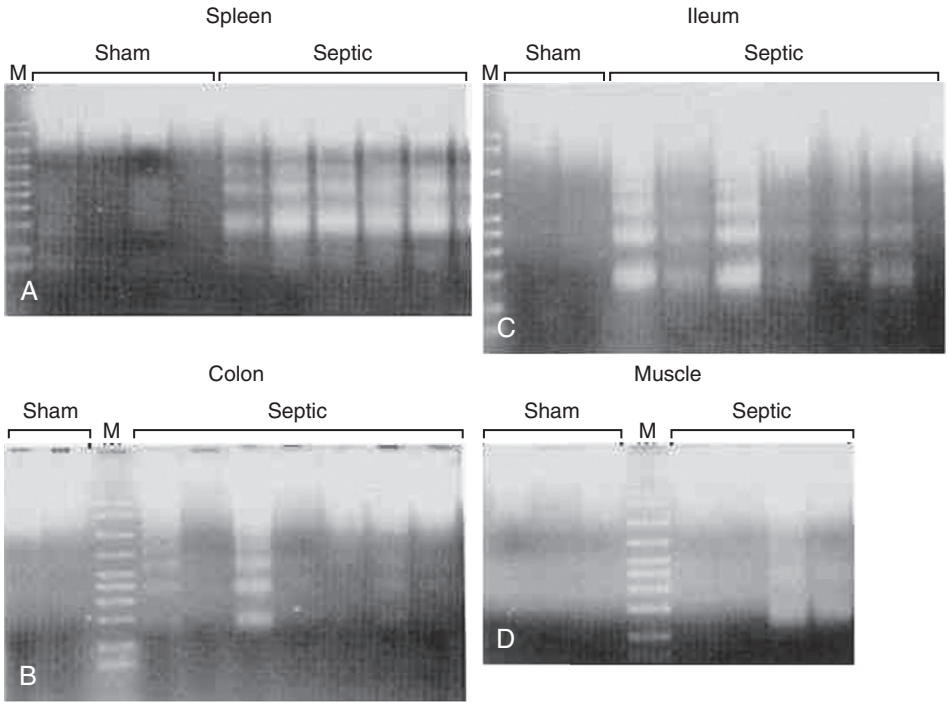

Figure 100–3. DNA agarose gel showing characteristic "laddering" pattern in spleen (**A**) and colon (**B**) in septic but not sham mice. *(From Hotchkiss RS, Swanson PE, Cobb JP, Jacobson A, et al: Apoptosis in lymphoid and parenchymal cells during sepsis: findings in normal and T- and B-cell-deficient mice,* Crit Care Med *25:1298–1307, 1997.)*

Gut epithelial apoptosis is increased in CLP, *P. aeruginosa* pneumonia,[49] and in vitro after infection with invasive enteric pathogens *Salmonella dublin* and *Escherichia coli*.[63] Intestinal cell death appears to be detrimental in polymicrobial or monomicrobial sepsis originating in the peritoneal space or the lungs because overexpression of Bcl-2 in the gut epithelium of transgenic mice confers a twofold survival advantage in CLP[51] and a tenfold survival advantage in *P. aeruginosa* pneumonia (Figures 100-4 and 100-5).[49] The mechanism underlying the improvement in survival caused by decreasing gut epithelial apoptosis is unclear, although it appears to be related to crosstalk with lymphocytes. However, bacterial translocation is similar between transgenic and nontransgenic animals with sepsis-induced pneumonia despite widely varying survival, and there are no statistically significant differences in cytokine levels between septic mice that overexpress Bcl-2 in their gut epithelium and their nontransgenic littermates.

Understanding of the role of lung apoptosis in sepsis is evolving. Respiratory epithelial cells are highly resistant to apoptosis when exposed to *P. aeruginosa*, undergoing cell death in vitro only under culture-specific conditions when treated with virulent bacteria capable of expressing both adhesins and cytotoxins.[64] In addition, lung epithelial apoptosis reportedly is absent in *P. aeruginosa* pneumonia in mice.[47] However, Grassme et al.[65] reported that *P. aeruginosa* pneumonia induces respiratory epithelial apoptosis in mice through activation of the Fas/Fas ligand system. Respiratory apoptosis appeared to be essential for survival in this study, with rapid sepsis-induced mortality in Fas or Fas ligand-deficient mice that lacked bronchial apoptosis. Alveolar and bronchiolar apoptosis were present in rats 8 hours after pneumonia was induced with *Streptococcus sanguis* (which resolves after 1 week) or *Streptococcus pneumoniae* type 25 (which progresses to pulmonary fibrosis).[66,67] Apoptosis was widespread for the first 4 days following either type of pneumonia. Eight days following *S. sanguis* pneumonia, apoptosis was localized to lung abscesses, implying a role for cell death in the resolution of injury.[66] By contrast, apoptosis was widespread and actually increased in intensity after *S. pneumoniae* type 25 pneumonia. Lung apoptosis has also been demonstrated following CLP in multiple mouse strains.[46,47]

Few animal studies demonstrate sepsis-induced apoptosis in other cell types. One exception is an increase in murine hepatocyte apoptosis following infection with *Listeria monocytogenes*.[68] Liver apoptosis is greatest at the edge of microabscesses and is independent of endotoxin, Fas, and nitric oxide. Apoptosis is also increased in murine granulocytes after CLP through a TNF-dependent pathway.[69] In contrast, blood leukocyte apoptosis is decreased in mice 24 hours after the same insult.[69]

Despite the paucity of literature supporting the role of autophagy in human sepsis, there is a growing body of literature characterizing the role of autophagy in animal models of infection. Liver autophagy in mice following cecal ligation and puncture.[30] Multiple researchers have also shown the importance of autophagy in the response to infection to a variety of bacteria and viruses including *S. pyogenes*, *M. tuberculosis*, *S. flexneri*, and Herpes simplex virus 1.[42] To date, autophagy has been shown to be important in both innate and adaptive immunity, inflammation, and immune homeostasis.[11,12,42] Some of these functions include degrading intracellular pathogens, delivering foreign material to MHC class II compartments, regulating T-cell homeostasis and directing viral genetic material to cell surface receptors.[70]

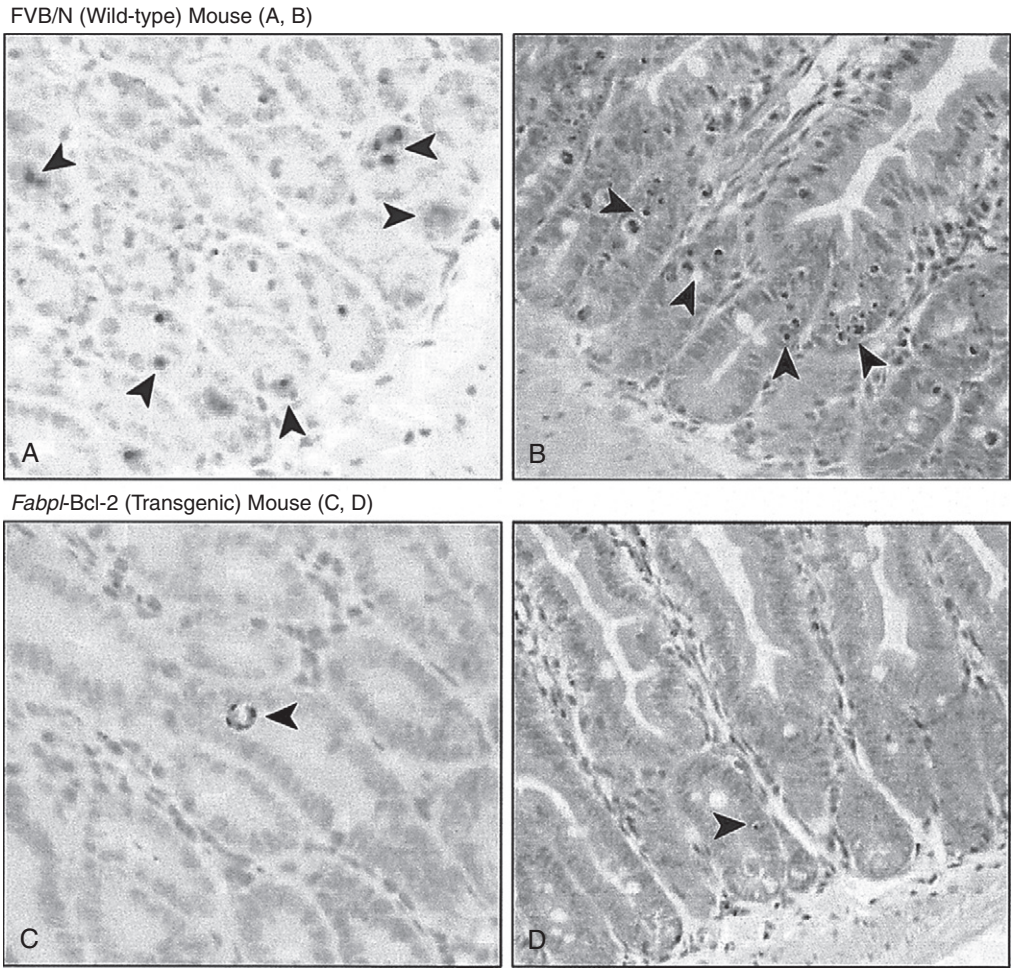

Figure 100–4. Intestinal epithelial sections from wild-type (**A** and **B**) and Bcl-2 transgenic (**C** and **D**) mice with sepsis from *Pseudomonas aeruginosa* pneumonia. Bcl-2 decreases apoptosis when assessed by active caspase-3 (**A** and **C**) or hematoxylin and eosin (**B** and **D**). *(From Coopersmith CM, Stromberg PE, Dunne WM, et al: Inhibition of intestinal epithelial apoptosis and survival in a murine model of pneumonia-induced sepsis,* JAMA *287:1716–1721, 2002.)*

Survival 7 days after sepsis from *Pseudomonas aeruginosa* pneumonia in transgenic mice that overexpress Bcl-2 in their intestinal epithelium and wild-type mice. *(From Coopersmith CM, Stromberg PE, Dunne WM, et al: Inhibition of intestinal epithelial apoptosis and survival in a murine model of pneumonia-induced sepsis,* JAMA *287:1716–1721, 2002.)*

Noninfectious Inflammation

Similar to sepsis, significant lymphocyte and intestinal epithelial apoptosis are present in human and animal studies of noninfectious inflammation; however, in noninfectious inflammation, cell death is also increased in a number of other tissues. Both thymocyte apoptosis[71,72] and B-cell Peyer patch apoptosis[73] are increased following either trauma/hemorrhage or hemorrhage alone. Both injuries decrease the release of the myeloid stimulating cytokine IL-3 from thymocytes,[71] whereas increased thymus-derived granulocyte-macrophage colony-stimulating factor (GM-CSF) is only seen following hemorrhage alone. Lymphocyte apoptosis in Peyer patches also occurs following either trauma/hemorrhage or hemorrhage alone and is associated with elevated Fas expression, consistent with the Fas-dependent apoptosis seen in animal models of sepsis.[73] Thymocyte, splenocyte, Peyer patch, and intraepithelial lymphocyte apoptosis are all increased following thermal injury.[74-79] Thymocyte and splenocyte apoptosis are associated with increased levels of active caspase-3 but are independent of endotoxin as evidenced by high levels of apoptosis in lipopolysaccharide-nonresponsive transgenic mice.[75,76] Cell death is also dependent upon corticosteroids, as pretreatment with the glucocorticoid receptor antagonist

mifepristone significantly reduced both apoptosis and active caspase-3 activity following burn injury.[76] Mifepristone also reduces apoptosis in intraepithelial lymphocytes.[78] The roles of both TNF-α and Fas ligand in burn-induced lymphocyte apoptosis are more complicated. TNF-α levels are elevated following thermal injury in both thymus and spleen in C57BLK6/J mice; however, TNF-α protein levels are disproportionately elevated in thymic tissue, which is associated with elevated thymic but not splenic apoptosis.[79] The finding of elevated thymus and spleen apoptosis in TNF-α knock-out mice further complicates its role in burn-induced apoptosis.[75] Thymocyte, splenocyte, and $CD8^+$ T-cell Peyer patch apoptosis all are Fas ligand independent,[76,78] whereas B-cell Peyer patch cell death depends on the presence of this molecule because burn-induced apoptosis is eliminated in C3H/HeJ-FasL(gld) mice that lack functional Fas ligand.[78]

As in human studies, gut epithelial apoptosis is increased in multiple animal models of noninfectious inflammation including trauma, LPS administration, ischemia reperfusion, and thermal injury.[80-87] Gut epithelial apoptosis appears to be in large part induced through the mitochondrial-mediated pathway. Apoptosis is suppressible in murine ischemia reperfusion by overexpression of Bcl-280 in gut epithelia cells. In addition, the administration of the poly (ADP-ribose) synthetase inhibitor 3-aminobenzamide decreases LPS-induced apoptosis and is associated with a preservation of Bcl-2 expression by gut epithelial cells.[82] In contrast, thermal injury–induced gut epithelial apoptosis appears to be in part regulated through the receptor-mediated pathway because treatment with insulin-like growth factor 1, in combination with its binding protein, decreases apoptosis by downregulation of the Fas pathway.[88]

Acute lung injury (ALI) causes increased death in multiple cells within the lung.[67,89] Intratracheal injection of LPS induces apoptosis in alveolar cells, neutrophils, and macrophages.[89] This process is associated with upregulation of Fas in alveolar and inflammatory cells, and lung injury can be blocked by administration of an anti-Fas antibody. Respiratory apoptosis is also increased in a diffuse fashion in a hyperoxia model of ALI and in a patchy distribution in ALI caused by intravenous injection of oleic acid.[65] ALI has been shown to cause both epithelial and endothelial apoptosis in the lung.[90,91] Recent work by Barlos et al.[91] showed in a rat trauma-hemorrhagic shock model that both epithelial and endothelial apoptosis occur in the lung and that epithelial apoptosis occurs in a caspase-3–dependent fashion, whereas endothelial apoptosis is caspase-3 independent. The endothelium also plays a role in influencing neutrophil apoptosis.[92] Rat lung neutrophil apoptosis shows a significant delay following intratracheal LPS instillation. The mechanism underlying the delay is unrelated to LPS; a similar delay is seen following the addition of the potent apoptosis-inducer TNF-α. The process of endothelial transmigration appears to play a major regulatory role in regulating neutrophil apoptosis. Adhesion molecules from the integrin and selectin families also have a role in modulating neutrophil cell death.[93]

Extensive hepatocyte apoptosis is seen in animal models of trauma/hemorrhage and depends on the severity of shock induced with increasing apoptosis correlating with duration of shock.[94,95] In addition, apoptosis is only seen following resuscitation, and the introduction of IL-6 at the time of resuscitation completely prevents trauma/hemorrhage-induced apoptosis.[95] Apoptosis of hepatocytes is also seen in animal models of thermal injury.[96]

Other organ tissues susceptible to apoptosis, particularly through thermal injury, include cardiac and skeletal muscle.[85,97] Cardiac apoptosis appears to be predominantly located in the subendocardial region of the left ventricle.[85] Increased skeletal muscle apoptosis is seen up to 7 days after thermal injury and was found in muscle tissue below the site of injury as well as in remote areas.[97] Similar to infectious models, increasing mortality in noninfectious inflammation is related to host immunosuppression. Apoptosis of immune effector cells, epithelial cells, and endothelial cells is a likely contributor to the overall immune status of the host.

Autophagy has also been implicated in the pathophysiology of noninfectious inflammation, most notably in animal models of cardiac ischemia and reperfusion. Increased autophagy has been found in multiple animal models of cardiac ischemia and reperfusion with mixed results. Matsui et al.[98] evaluated autophagy in mice with a defect in a key autophagy genes and found decreased autophagy in these mice was associated with decreased cell death and decreased infarct size. Alternatively, Hamacher-Brady et al.[99] found that increased autophagy in mice leads to decreased ischemia/reperfusion-induced myocyte death and protects the myocardium.

Chapter 101

Endotheliopathy

Yves Ouellette and Jan A. Hazelzet

PEARLS

- Because of their location, endothelial cells have the ability to interact with blood components, such as flow, soluble factors, and other cells. Endothelial cells integrate these signals into a cohesive regulation of vascular responses.
- The endothelium controls the vascular tone of the underlying smooth muscle cells through the production of vasodilator and vasoconstrictor mediators.
- Endothelial cell activation in response to inflammation changes endothelial cellular physiology and results in altered vascular function.

Until recently, scientists and clinicians considered the endothelium, the cell layer that lines the blood vessels, as an inert barrier separating the various components of blood and the surrounding tissues. The vascular endothelium is now recognized as a highly specialized and metabolically active organ performing a number of critical physiologic, immunologic, and synthetic functions. These functions include regulation of vascular permeability, fluid and solute exchange between the blood and interstitial space, vascular tone, cell adhesion, homostasis, and vasculogenesis.[1]

The normal vascular endothelium is only one cell layer thick, separating the blood and vascular smooth muscle. The endothelium responds to physical and biochemical stimuli by releasing regulatory substances affecting vascular tone and growth, thrombosis and thrombolysis, and platelet and leukocyte interactions with the endothelium. Normal endothelial functions include control over thrombosis and thrombolysis, platelet and leukocyte interactions with the vessel wall and regulation of vascular tone and growth. Of particular interest to intensivists is the fact that the endothelium secretes both powerful vasorelaxing (e.g., nitric oxide [NO]) and vasoconstricting substances (e.g., endothelin-1 [ET-1]). Since normal endothelial function plays a central role in vascular homeostasis, it is logical to conclude that endothelial dysfunction contributes to disease states characterized by vasomotor dysfunction, abnormal thrombosis, or abnormal vascular proliferation.

The endothelium lies between the lumen and the vascular smooth muscle, where it is uniquely positioned to "sense" changes in hemodynamic forces or blood-borne signals by membrane receptor mechanisms. The endothelial cells can respond to physical and chemical stimuli by synthesis or release of a variety of vasoactive and thromboregulatory molecules and growth factors. Substances released by the endothelium include prostacyclin, NO, endothelins, endothelial cell growth factors, interleukins, plasminogen inhibitors, and von Willebrand factor (vWF). The vascular endothelium possesses numerous enzymes, receptors, and transduction molecules, and it interacts with other vessel wall constituents and circulating blood cells. In addition to these universal functions, the endothelium may have organ-specific roles that are differentiated for various parts of the body, such as gas exchange in the lungs, control of myocardial function in the heart, or phagocytosis in the liver and spleen. From a structural perspective, endothelial cells from different sites of the vascular tree differ in size, shape, thickness, and nuclear orientation. For example, endothelial cells that line the pulmonary artery of the rat are larger and more rectangular than those lining the aorta, whereas endothelial cells in the aorta are thicker than their counterparts in capillaries or veins.[2]

Studies of endothelial structure and function have been accomplished by a variety of techniques, including ultrastructural studies, in vitro experiments for endothelial cell isolation and culture, physiologic studies in animals, and, most recently, clinical studies in humans. This knowledge has facilitated the development of treatment strategies based on administration of endothelial products, such as prostacyclin and NO, or their antagonists.

Normal Endothelial Function

Endothelial Cell Heterogeneity

Many vascular diseases appear to be restricted to specific vascular beds. For example, thrombotic events are often localized to single vessels. It is also common for certain vasculitides to specifically affect certain arteries, veins, or capillaries, or to affect certain organs. Tumor cells will often metastasize more commonly within particular vascular beds. The basis for this variability in vascular disease is poorly understood, but may be explained in the heterogeneity of endothelial cells. Recently, there has been a greater understanding of how endothelial cell heterogeneity may contribute both to the maintenance of organ-specific function and to the development of disorders restricted to specific vascular beds.[1-3]

The morphological appearance of capillary endothelium from different vascular beds may explain differences in tissue function. For example, the brain microcirculation is lined by endothelial cells connected by tight junctions that maintain the blood-brain barrier. By contrast, sinusoids found in the liver, spleen, and bone marrow are lined by endothelial cells that allow transcellular trafficking between intercellular gaps. Similarly, fenestrated endothelial cells found in the intestinal villi, endocrine glands, and kidneys facilitate selective permeability, which is required for efficient absorption, secretion, and filtering. [4]

Another example of endothelial cell heterogeneity lies in the expression of cell surface receptors involved in cell-to-cell signaling and cell trafficking. For example, in the mouse, lung-specific endothelial cell adhesion molecules are exclusively expressed by pulmonary postcapillary endothelial cells and some splenic venules. Similarly, specific mucosal cell adhesion molecules are expressed primarily on endothelial venules in the Peyer patches of the small intestine.[5,6] Tumor cells may show clear preferential adhesion to the endothelium of specific organs paralleling their in vivo metastatic propensities.[7] Distinct subsets of endothelial cells often exist within a single organ. In in situ studies, two distinct sinusoidal endothelial cell phenotypes can be recognized in the adult human liver: hepatic periportal vessels express specific cell surface molecules such as PECAM-1 and CD34, whereas sinusoidal intrahepatic endothelial cells do not.

Cultured microvascular endothelial cells express surface markers, protein transporters, and intracellular enzymes specific to their tissue of origin such as brain, liver, or other organs. These tissue-specific phenotypic differences can be maintained for some time under identical tissue culture conditions. Endothelial phenotype can be manipulated by changing the microenvironment, a phenomenon that has been referred to as transdifferentiation. For example, aortic endothelial cells cultured on lung-derived extracellular matrix are induced to express lung-specific endothelial cell adhesion molecules, whereas the same cells develop fenestrae when cultured on matrix derived from the kidney-derived MDCK cells. Similarly, endothelial cells grown on extracts of basement membrane from different organs have been observed to develop preferential adhesivity for tumor cells prone to metastasize to that organ.

Endothelial Progenitor Cells

In the last decade, a significant amount of literature has shown that maintenance and repair of vasculature in ischemic diseases may be at least partially mediated through recruitment of endothelial progenitor cells (EPCs) from the bone marrow to areas of vascular injury.

EPCs are a specific subtype of hematopoietic stem cells that have been isolated from circulating mononuclear cells, bone marrow, and cord blood. EPCs migrate from the bone marrow to the peripheral circulation, where they contribute to vascular repair.[8,9] When injected into animal models of ischemia, EPCs are incorporated into sites of neovascularization,[8,10,11] and have contributed to improved outcomes in patients with ischemic vascular disorders.[12] In addition, there has been accumulating evidence for the function of EPCs in critical illnesses such as sepsis.

Recruitment of EPCs to areas of endothelial and vascular damage may have prognostic implications and be associated with clinical outcome. The pathophysiologic changes associated with critical illness, notably sepsis and sepsis-related organ dysfunction, may lead to apoptosis and necrosis of endothelial cells from the vasculature and recruitment of EPCs from the bone marrow. Whether recruitment and mobilization of EPCs is associated with clinical outcomes in critically ill patients, thus serving as a prognostic biomarker, remains uncertain.

In various models of vascular injury and organ dysfunction, only a few studies have emerged regarding EPCs in particular as a therapeutic strategy. Transplanted EPCs have been shown to improve survival of mice following liver injury.[13] Infusion of EPCs also restored blood flow in a mouse model of hindlimb ischemia.[9] A recent prospective randomized trial compared the effects of EPC transplantation in patients with idiopathic pulmonary arterial hypertension versus conventional therapy and showed that after 12 weeks, patients who had received EPCs had a significant improvement in their 6-minute walk test, mean pulmonary artery pressure, pulmonary vascular resistance, and cardiac output.[14]

Coagulation and Fibrinolysis

A normal physiological function of the endothelium is to provide an antithrombotic surface inhibiting platelet adhesion and clotting, thus facilitating normal blood flow. Under pathophysiological conditions, the endothelium transforms into a prothrombotic surface. A dynamic equilibrium exists between both states that permits a rapid response to an insult and a rapid recovery.[15]

Anticoagulant Mechanisms

The endothelium has anticoagulant, antiplatelet, and fibrinolytic properties.[16] Endothelial cells are the major site for anticoagulant reactions involving thrombin. Thrombin plays a key role in coagulation, including activation of platelets, activation of several coagulation enzymes and cofactors, and stimulation of procoagulation pathways on the endothelial cell surface. In the normal state, there is little thrombin enzyme activity. The surrounding endothelial cell matrix contains heparin sulfate and related glycosaminoglycans that activate antithrombin III. In addition, the subendothelial cell matrix contains dermatan sulfate which promotes the antithrombin activity of heparin cofactor II. Furthermore, microvascular endothelial cells release tissue-factor pathway inhibitor that inhibits the factor VIIa/tissue factor complex, and further contributes to anticoagulation (Figure 101-1).

Thrombin activity is also modulated by endothelial cell synthesis of thrombomodulin.[17,18] The binding of thrombin to thrombomodulin facilitates the enzyme's activation of the anticoagulant protein C. Activated protein C (APC) activity is enhanced by cofactor C, also called protein S, which is synthesized by endothelial cells as well as by other cells (see Figure 101-1). APC inhibits factor Va and factor VIIIa. Thrombomodulin (TM) also inhibits prothrombinase activity indirectly by binding factor Xa (Figure 101-2). Protein C has a special receptor on the endothelial cells: endothelial protein C receptor (EPCR). EPCR augments protein C activation approximately twentyfold in vivo by binding protein C and presenting it to the thrombin-TM activation complex. Both EPCR and TM can be found in plasma as soluble proteins. Activated protein C retains its ability to bind EPCR, and this complex appears to be involved in some of the cellular signaling mechanisms

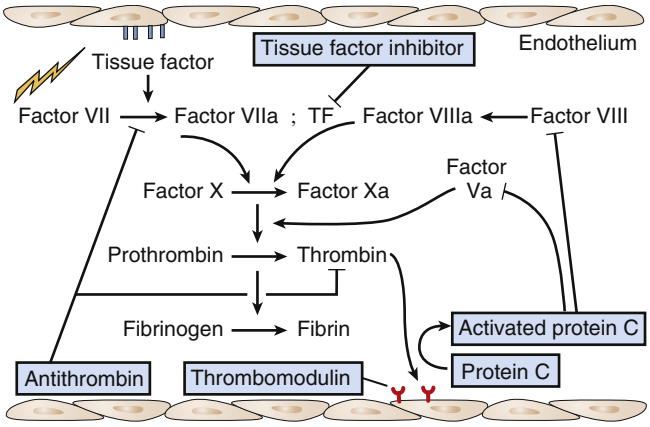

Figure 101–1. Endothelium control of the coagulation cascade. An inflammatory stimulus upregulates the interaction of tissue factor (TF) with factor VII, which generates activated factor VII (factor VIIa). The TF–factor VIIa complex then leads to the conversion of factor X to factor Xa. The interaction of factors Xa and Va results in the conversion of prothrombin to thrombin, and the conversion of fibrinogen to fibrin. Three key anticoagulant pathways can inhibit this process. Protein C is activated through its interaction with cell-surface thrombomodulin, and inhibits the activities of factors Va and VIIIa. Antithrombin blocks the activation of multiple factors including factor X and thrombin. Tissue factor pathway inhibitor interferes directly with the tissue factor–factor VIIa complex.

that downregulate inflammatory cytokine formation (tumor necrosis factor, interleukin-6). Activated protein C has a variety of antiinflammatory activities. As said, it suppresses inflammatory cytokine during sepsis, inhibits leukocyte adhesion, decreases leukocyte chemotaxis, reduces endothelial cell apoptosis, helps maintain endothelial cell barrier function through activation of the sphingosine-1 phosphate receptor, and minimizes the decrease in blood pressure associated with severe sepsis.[19] Another interesting effect of APC is its PAI-1 neutralizing effect. PAI-1 (plasminogen activator inhibitor-1) is a glycoprotein that acts as an acute-phase protein during acute inflammation. Its primary role in vivo is the inhibition of both tissue- and urokinase-type plasminogen activators. PAI-1 is the most efficient inhibitor of activated protein C and thrombin in the absence of heparin. PAI-1 competes with TM for binding with thrombin, which, in combination with its inhibition of activated protein C, makes it a strong local procoagulant by a combined action of displacing and inactivating anticoagulant thrombin from thrombomodulin. In this way PAI-1 has important pathophysiological effects in acute and chronic diseases.[20] The thrombin-TM complex also activates thrombin-activatable fibrinolysis inhibitor, a procarboxypeptidase that renders fibrin resistant to clot lysis and neutralizes vasoactive molecules such as complement C5a.[21]

In addition, platelet adhesion to endothelial cells is markedly inhibited by endothelium-derived prostacyclin.[22] The same stimuli that activate platelets, such as thrombin and adenosine diphosphate and adenosine triphosphate (ATP), also act to release prostacyclin from the endothelium, which allows the endothelium to limit the extent of platelet plug formation. The interactions between platelets and endothelium regulate platelet function, coagulation cascades, and local vascular tone.

Microvascular endothelial cells may secrete tissue-type plasminogen activator (t-PA), the powerful thrombolytic agent in frequent clinical use for treatment of coronary thrombotic occlusion.[23] t-PA release is stimulated in vivo by norepinephrine, vasopressin, or stasis within the vessel lumen. Thrombin may also stimulate t-PA release, providing a further endothelium-mediated safeguard against uncontrolled coagulation.

Procoagulant Mechanisms

The expression and release of tissue factor is the pivotal step in transforming the endothelium from an anticoagulant to a procoagulant surface.[24,25] Tissue factor accelerates factor VIIa-dependent activation of factors X and IX (see Figure 101-1). The synthesis of tissue factor is induced by a number of agonists, including thrombin, endotoxin, several cytokines, shear stress, hypoxia, oxidized lipoproteins, and other endothelial insults. Once endothelial cells expressing tissue factor are exposed to plasma, prothrombinase activity is generated and fibrin is formed on the surface of the cells. Tissue factor can also be found in plasma as a soluble protein. Its role there is not well understood, but it probably plays a role in the initiation of coagulation.

Endothelium-Derived Vasodilators

The important role that the endothelium plays in controlling vascular tone has only recently been appreciated. Clinicians and researchers have come to appreciate that the endothelium controls underlying smooth muscle tone in response to certain pharmacological and physiological stimuli. This response involves a number of luminal membrane receptors and complex intracellular pathways and the synthesis and release of a variety of relaxing and constricting substances, described in the following sections.

Nitric Oxide

Furchgott and Zawadzki first postulated the existence of an endothelial derived relaxing factor (EDRF) in 1980, when they noticed that the presence of endothelium was essential for rabbit aortic rings to relax in response to acetylcholine.[24] Later, it was determined that the biologic effects of EDRF are mediated by NO.[26]

NO is generated from the conversion of L-arginine to NO and L-citrulline by the enzyme nitric oxide synthase (NOS).[27] There are two general forms of NOS: constitutive and inducible. In the unstimulated state, NO is continuously produced by constitutive NO synthase (cNOS). The activity of cNOS is modulated by calcium that is released from endoplasmic stores in response to the activation of certain receptors. Substances such as acetylcholine, bradykinin, histamine, insulin, and substance P stimulate NO production through this mechanism. Similarly, shearing forces acting on the endothelium are another important mechanism regulating the release of NO. The inducible form of NOS (iNOS) is not calcium-dependent, but instead is stimulated by the actions of cytokines (e.g., tumor necrosis factor-α [TNFα], interleukins) and/or bacterial endotoxins (e.g., lipopolysaccharide). Induction of iNOS occurs over several hours and results in NO production that may be more than a thousandfold greater than that produced by cNOS. This is an important mechanism in the pathogenesis of inflammation (see Figure 101-2). Inhibition of NOS using competitive analogs of L-arginine drastically reduces endothelium-dependent relaxation in vitro, particularly in large conduit arteries, thereby evoking vasoconstriction.

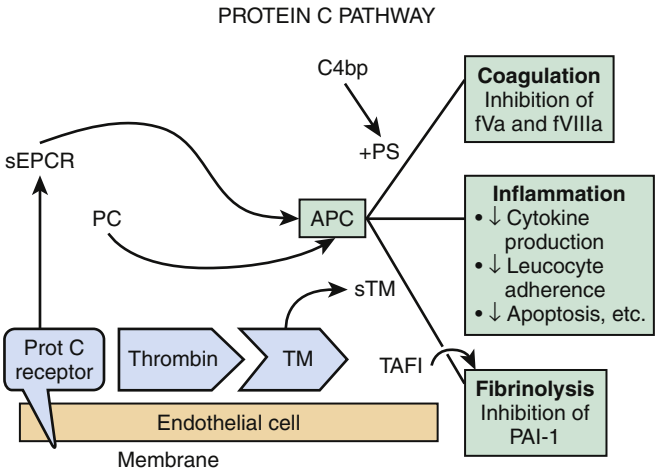

Figure 101–2. The interaction of the protein C system with the endothelium: thrombin bound to thrombomodulin (TM) modifies protein C bound to the endothelial protein C receptor on the cell surface to generate activated protein C (APC). APC acts as a natural anticoagulant by inactivating activated factors V (fVa) and VIII (fVIIIa), modulating inflammation by downregulating the synthesis of proinflammatory cytokines, leukocyte adherence, and apoptosis, and enhancing fibrinolysis by inhibiting thrombin-activatable fibrinolysis inhibitor (TAFI) and plasminogen activator inhibitor type-1 (PAI-1). *C4Bbp,* C4b binding protein (binds protein S); *+PS*, in the presence of protein S; *sTM,* soluble thrombomodulin; *sEPCR*, soluble endothelial cell protein C receptor. *(Modified from Hazelzet J: Pathophysiology of pediatric sepsis. In Nadel S:* Infectious diseases in the pediatric intensive care unit, *London, 2008, Springer.)*

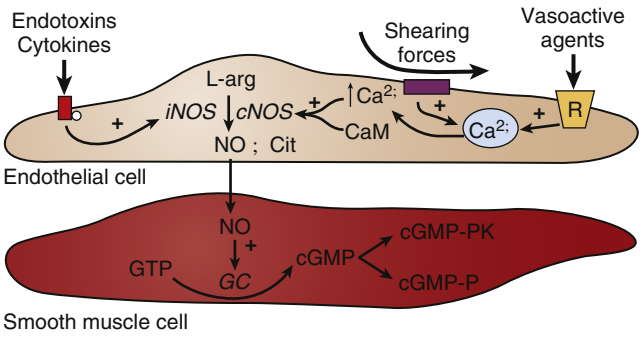

Figure 101–3. Nitric oxide (NO) is generated from L-arginine (L-arg) by the action of nitric oxide synthase (NOS). In the resting state, constitutive NOS (cNOS) is modulated by intracellular Ca^{2+} and calmodulin (CaM). Stored Ca^{2+} is released in response to vasoactive agents (acetylcholine and bradykinin, for example) and other external stimuli such as shearing forces. Cytokines' and endotoxins' activation of endothelial cells results in increased expression of inducible NOS (iNOS). Citrulline (Cit) is a byproduct of NO production. NO has a half-life of only a few seconds in vivo and quickly diffuses to surrounding cells such as smooth muscle cells. NO stimulates the production of the intracellular mediator cyclic GMP (cGMP). Increased cGMP activates a series of cGMP-dependent protein kinases (cGMP-PK) and cGMP-dependent phosphatases (cGMP-P).

Chronic treatment of animals with NOS inhibitors or suppression of the cNOS gene is reported to induce hypertension.[28-30]

Once NO is formed by an endothelial cell, it readily diffuses out of the cell and into adjacent smooth muscle cells where it binds and activates the soluble form of guanylyl cyclase, resulting in the production of cyclic guanosine-monophosphate (cGMP) from guanosine-triphosphate.[31] cGMP in turn activates a number of cGMP-modulated enzymes (Figure 101-3). Increased cGMP activates a kinase that subsequently leads to the inhibition of calcium influx into the smooth muscle cell, and decreased calcium-calmodulin stimulation of myosin light-chain kinase. This, in turn, decreases the phosphorylation of myosin light chains, thereby decreasing smooth muscle tension development and causing vasodilation. There is also some evidence that increases in cGMP can lead to myosin light chain dephosphorylation by activating the phosphatase. In addition, cGMP-dependent protein kinase phosphorylates K^+ channels to induce hyperpolarization and thereby inhibits vasoconstriction.[32,33] Interestingly, NO inhibition of platelet aggregation is also related to the increase in cGMP. Drugs that inhibit the breakdown of cGMP such as inhibitors of cGMP-dependent phosphodiesterase (for example, sildenafil) potentiate the effects of NO-mediated actions on the target cell.

NO therefore contributes to the balance between vasodilator and vasoconstrictor influences that determine vascular tone.[34] The exogenous nitrovasodilators sodium nitroprusside and nitroglycerin use the same pathways. The generation of NO from L-arginine can also be specifically blocked by arginine analogues, such as N^G-monomethyl-L-arginine (L-NMMA), which has recently proven to be a useful tool in clinical research, allowing investigation of the biologic distribution and role of NO.

Prostacyclin

Another major endothelium-derived vasodilator is the prostaglandin prostacyclin (PGI_2), a derivative of arachidonic acid synthesized through the action of the enzyme cyclooxygenase. Endothelium cells are capable of producing a variety of vasoactive substances that are products of arachidonic acid metabolism. Among these are prostaglandins, PGI_2, leukotrienes, and thromboxanes. These substances act as either vasodilators or vasoconstrictors, amongst their other biological activities. PGI_2 is a potent vasodilator and is active in both the pulmonary and systemic circulations. In addition to its vasodilatory effects, prostacyclin also has antithrombotic and antiplatelet activity. Its release may be stimulated by bradykinin and adenine nucleotides. Like NO, it is chemically unstable with a short half-life.[35] However, unlike NO, PGI_2 activity in arterial beds depends on its ability to bind to specific receptors in vascular smooth muscle. Its vasodilator activity is therefore determined by the expression of such receptors. PGI_2 receptors are coupled to adenylate cyclase to elevate cyclic AMP levels in vascular smooth muscle.[36] The increase in cAMP results in (1) stimulation of ATP-sensitive K^+ channels resulting in hyperpolarization of the cell membrane and inhibition of the development of contraction; and (2) increase efflux of Ca^{2+} from the smooth muscle cell and inhibition of the contractile machinery.

In addition, PGI_2 facilitates the release of NO by endothelial cells and the action of PGI_2 in vascular smooth muscle is potentiated by NO. Interestingly, NO may also potentiate the effects of prostacyclin. The NO-mediated increase in cGMP in smooth muscle cells inhibits a phosphodiesterase that breaks down cAMP, and therefore indirectly prolongs the half-life of the second messenger of PGI_2.[37]

Endothelium-Derived Hyperpolarizing Factor

Endothelium stimulation by acetylcholine also produces hyperpolarization of the underlying smooth muscle and thereby induces vasorelaxation. This process is not mediated

by NO, but is instead mediated by another endothelium-derived factor. This factor acts by increasing K^+-channel conductance in smooth muscle cells, resulting in smooth muscle cell relaxation. The resulting vasodilation is not inhibited by L-NMMA, the specific antagonist of NO, but is inhibited by ouabain, a Na^+/K^+-ATPase inhibitor. In addition, in most medium- to resistance-sized arteries, electrophysiological studies have established that endothelium-dependent hyperpolarization of vascular smooth muscle is resistant to the combined inhibition of both NOS and cyclooxygenases. Accordingly, a component of the endothelium-dependent relaxation in these arteries is mediated by a substance different from NO and PGI_2. This component of endothelium-dependent vasodilatation has been attributed to a yet unidentified diffusible endothelium-derived hyperpolarizing factor (EDHF).[38]

EDHF acts by opening K^+ channels in vascular smooth muscle. Hyperpolarization inhibits vasoconstriction by closing voltage-sensitive Ca^{2+} channels, impairing the receptor-dependent activation of phospholipase C and the subsequent release of Ca^{2+} from intracellular stores, as well as by reducing the Ca^{2+} sensitivity of the contractile proteins. Of significant clinical importance is the fact that EDHF-mediated effect increases as the arterial diameter decreases, such as in resistance arteries. EDHF likely plays a significant role in the regulation of peripheral vascular resistance and local hemodynamics. Unfortunately, in the absence of selective inhibitors of the EDHF pathway, it is not possible to evaluate the relevance of EDHF in vivo.[38]

Endothelium-Derived Vasoconstrictors

Endothelins (Endothelium-Derived Contracting Factors)

Endothelin is a 21-amino-acid peptide and is one of the most potent vasoconstrictors yet identified. Endothelial cells synthesize the prohormone big endothelin and express endothelin-converting enzymes to generate endothelin. There are three isoforms of endothelin, but only one (ET-1) has been shown to be released from human endothelial cells. ET-1 is synthesized in the endothelial cells and its release is mediated by a variety of stimuli. ET-1 release is stimulated by angiotensin II, antidiuretic hormone, thrombin, cytokines, reactive oxygen species, and shearing forces acting on the vascular endothelium. ET-1 release is inhibited by nitric oxide as well as by PGI_2 and atrial natriuretic peptide.[39,40]

ET-1 has a short half-life, suggesting that similarly to NO, ET-1 is mainly a locally active vasoregulator. Once released by endothelial cells, ET-1 binds to a membrane receptor (ET_A) found on adjacent vascular smooth muscle cells. This binding leads to calcium mobilization and smooth muscle contraction. The ET_A receptor is coupled with a G-protein linked to phospholipase-C, resulting in the formation of IP_3. Interestingly, ET-1 can also bind to an ET_B receptor located on the vascular endothelium, which stimulates the formation of NO by the endothelium. This release of NO appears to modulate the ET_A receptor-mediated contraction of the vascular smooth muscle. Its physiological role includes maintenance of basal vascular resistance, and it is present in healthy subjects in low concentrations. Elevated endothelin levels have been found in systemic and pulmonary hypertension, coronary artery disease, and heart failure, although the role of ET-1 in the pathophysiology of these conditions has been postulated but not proven.[39,40]

Reactive Oxygen Species

Endothelial cells secrete oxygen-derived free radicals and hydrogen peroxide in response to shear stress and endothelial agonists such as bradykinin. Such reactive oxygen species are reported to inactivate NO, resulting in vasoconstriction. Reactive oxygen species may also facilitate the mobilization of cytosolic Ca^{2+} in vascular smooth muscle cells and promote Ca^{2+} sensitization of the contractile elements. Endothelium-derived superoxide anion, under conditions of hyperoxia, may combine with NO with diffusion-limited kinetics to generate peroxinitrite, negating NO-mediated vasodilation, an effect inhibited by superoxide dismutase, which metabolizes superoxide anion to hydrogen peroxide.[41]

Vasoconstrictor Prostaglandins

The metabolism of arachidonic acid by cyclooxygenase in endothelial cells may lead to the secretion of precursors of thromboxanes and leukotrienes. These prostaglandins act on receptors in vascular smooth muscle to induce vasoconstriction. PGI_2, however, is the major endothelial metabolite of arachidonic acid that is generated through the cyclooxygenase pathway. Thus, under normal circumstances, the influence of the small amounts of vasoconstrictor prostanoids released by endothelial cells is masked by the production of PGI_2, NO, and EDHF.[42,43]

Endothelium and Blood Cell Interactions

In addition to the interactions of the endothelium with blood coagulation factors, endothelial cells also express cell-surface molecules that orchestrate the trafficking of circulating blood cells. These cell-associated molecules help direct the migration of leukocytes into specific organs under physiologic conditions and accelerate migration towards sites of inflammation. They have also been implicated in the adhesion of platelets and erythrocytes in several common disorders associated with homeostasis.

Interactions of Leukocytes with the Vessel Wall

It is now well established that flowing leukocytes may adhere to specific regions of the endothelium in response to tissue injury or infection. These multicellular interactions are essential precursors of physiologic inflammation. Leukocytes interact with vessel surfaces through a multistep process that includes (1) initial formation of usually reversible attachments; (2) activation of the attached cells; (3) development of stronger, shear-resistant adhesion; and (4) spreading, emigration, and other sequelae.[44] (Figure 101-4)

Selectins are key molecules in the interaction of leukocytes and endothelial cells. They are transmembrane glycoproteins that recognize cell-surface carbohydrate ligands found on leukocytes, and initiate and mediate tethering and rolling of leukocytes on the endothelial cell surface. Selectins constitute a family of three known molecules. L-selectin is expressed on most leukocytes and binds to ligands constitutively expressed

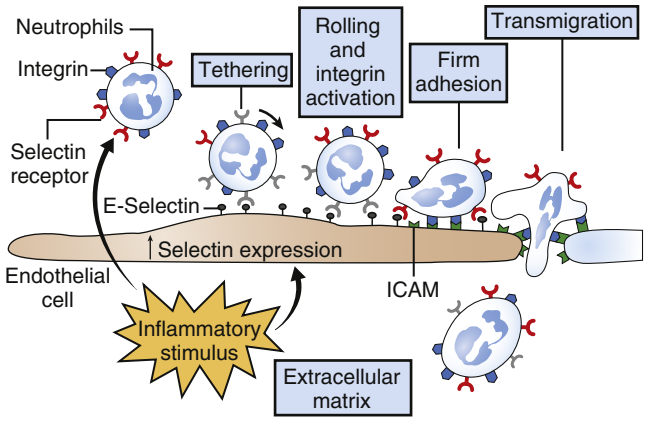

Figure 101–4. Leukocyte recruitment process and transmigration. The multistep model for leukocyte recruitment at sites of inflammation begins with the activation of neutrophils and endothelial cells. Once activated, endothelial cells express selectins, whose binding to neutrophils initiates rolling and adhesion of neutrophils to the endothelium. Activated integrins on the surface of neutrophils bind to endothelial cell ICAMs, facilitating a firm adhesion. Transmigration through the endothelium further involves interactions with other molecules such as PECAMs and cadherins on the surface of endothelial cells.

on endothelial cells found in venules of lymphoid tissues. Its expression is induced on endothelium at sites of inflammation. E-selectin is expressed on activated endothelial cells and leukocytes. P-selectin is rapidly redistributed from secretory granules to the surface of platelets and endothelial cells stimulated with thrombin. Both endothelial cells E-selectin and P-selectin bind to ligands on leukocytes.[45]

With stimulation, leukocytes usually attach to postcapillary venule endothelial cells, where shear stresses are lowest. Leukocytes adherent to the endothelium can make contact with flowing leukocytes through the L-selectin molecule, resulting in amplification of leukocyte recruitment to sites of inflammation. It is generally understood that selectins initiate inflammatory, immune, and hemostatic responses by promoting transient multicellular interactions.[46]

Proinflammatory molecules presented on the surface of the endothelium proceed to activate a second family of adhesion molecules, the integrins, and cause cells to firmly adhere. After the initial tethering of leukocytes to endothelial cells, leukocytes then must roll prior to transmigrating through the endothelium. Inhibition of leukocyte adhesion does not reduce leukocyte rolling, suggesting that rolling and adhesion are distinct molecular events. In addition, inhibiting rolling reduces adhesion, suggesting that rolling is a prerequisite of leukocyte adhesion/recruitment and ultimately the inflammatory response.

Leukocytes subsequently migrate between endothelial cells into tissues by mechanisms that are not completely understood but which we know are affected by gradients of chemokines, integrins activation states, and interactions with PECAM-1, an Ig-like receptor. This migration requires disruption of endothelial-cell-to-endothelial-cell interaction of cadherins at tight junctions. Leukocyte recruitment to lymphoid tissues or inflammatory sites requires the coordinated expression of specific combinations of adhesion and signaling molecules. Diversity at each step of the cascade ensures that the appropriate leukocytes accumulate for a restricted period in response to a specific challenge.[4,46]

Platelet Adhesion

Endothelial cells and circulating platelets normally do not interact with each other due to the release of PGI_2, the release of NO, and the expression of CD39 on the surface of endothelial cells.[47] During vascular injury and inflammation, platelets adhere to exposed subendothelial components, and are rapidly activated. Circulating platelets interact with the adherent platelets, producing a hemostatic plug that promotes thrombin generation and development of a stable fibrin clot. High shear stress, as seen in arteries, increases platelet adherence to the subendothelium where unactivated platelets attach to the subendothelium through interactions of platelet glycoproteins with immobilized vWF, a large, multimeric protein with binding sites for several other molecules, including subendothelial collagen. Flowing platelets attach transiently to vWF, resulting in continuous movement of the cells along the surface. Under the lower shear stresses found in veins, unactivated platelets interact with integrins to attach to and immediately arrest on immobilized fibrinogen.[48]

Once platelets adhere to either vWF or fibrinogen, they are activated by secreted products such as adenosine diphosphate or epinephrine, or by surface molecules such as collagen that crosslink the integrins and other platelet receptors. The activated platelets spread and adhere more avidly to the subendothelial surface, which recruits additional platelets into aggregates. Shear-resistant adhesion may be further enhanced by interactions of other integrins or receptors with laminin, fibronectin, and thrombospondin. As thrombin is generated, converting bound fibrinogen to fibrin, the aggregated platelets contract to strengthen the clot.[48]

Endothelial Permeability

Transport across the endothelium can occur via two different pathways: through the endothelial cell (transcellular) or between adjacent cells, through interendothelial junctions (paracellular) (Figure 101-5). The endothelial cell is able to dynamically regulate its paracellular and transcellular pathways for transport of plasma proteins, solutes, and liquid. The semipermeable characteristic of the endothelium (which distinguishes it from the epithelium) is crucial for establishing the transendothelial protein gradient (the colloid osmotic gradient) required for tissue fluid homeostasis. The transcellular pathway, also known as transcytosis, is defined as vesicle-mediated transport of macromolecules, such as plasma proteins, across the endothelial barrier in a caveolae-dependent manner. The paracellular pathway is formed by the minute intercellular space between contacting cells. Its primary function is to restrict free passage of macromolecules in the range of 3 nm and above through interendothelial junctions (IEJs), while allowing the convective and diffusive transport of molecules of less than 3 nm in diameter. Permeability of the IEJs is determined by the adhesive properties of the proteins that comprise the tight junctions and adherens junctions. However, the junctional barrier is a dynamic structure. It responds to permeability-increasing agonists and migrating leukocytes with disassembly of IEJs and to barrier-stabilizing mediators by increasing the surface expression and adhesiveness of junctional proteins in order to strengthen IEJs. There are extensive reviews available on this topic.[49-51]

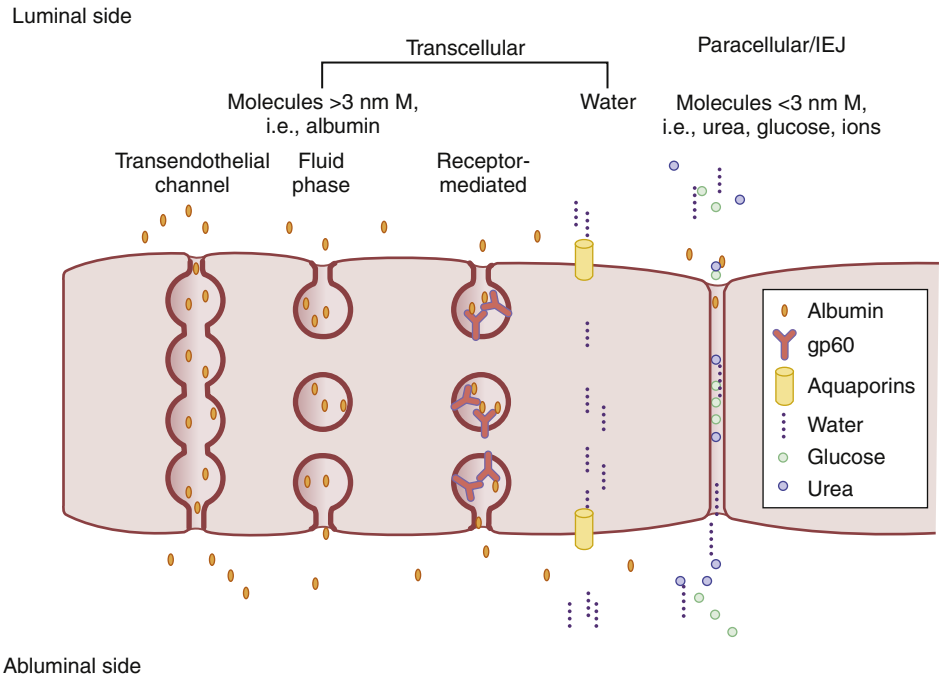

Figure 101–5. Schematic of transport pathways in continuous endothelium. Under basal conditions, the transcellular pathway can mediate the transport of plasma proteins (>3 nm Mr) such as albumin by caveolae via an absorptive (receptor-mediated) or fluid-phase pathway. Transcellular channels can also form transiently in endothelial cells by fusion of multiple caveolae and allow albumin transport. Aquaporins form channels across the lipid bilayer that are highly selective for water molecules and allow their movement across the luminal or abluminal endothelial membrane, thus creating a transendothelial pathway for water. Small molecules including urea and glucose (<3 nm Mr) are transported around individual endothelial cells via the paracellular, i.e., interendothelial junction (IEJ) pathway. *Mr*, Molecular radius. *(Modified from Mehta D, Malik AB: Signaling mechanisms regulating endothelial permeability,* Physiol Rev *86:279–367, 2006.)*

Endothelial Cell Dysfunction

Ischemia-Reperfusion Injury

Recently, it has become apparent that reperfusion of previously ischemic tissues can place the organs at risk for further cellular injury, thereby limiting the recovery of function. The microvasculature, particularly the endothelial cells, is very vulnerable to the deleterious consequences of ischemia and reperfusion (I/R). It is now recognized as a potentially serious problem that is encountered during a variety of standard medical and surgical procedures such as thrombolytic therapy, organ transplantation, and cardiopulmonary bypass.[52]

The molecular and biochemical changes in the vascular wall during I/R are characteristic of an acute inflammatory response (Figure 101-6). The intensity of this inflammatory response can be so severe that the injury response to reperfusion is also manifested in susceptible organs such as in the lungs and cardiovascular system. The resulting systemic inflammatory response syndrome (SIRS) and multiple organ dysfunction syndrome (MODS) are both associated with significant increases in mortality and morbidity.[53]

Microvascular dysfunction associated with I/R is manifested as impaired endothelium-dependent dilation in arterioles, enhanced fluid filtration, leukocyte plugging in capillaries, and the trafficking of leukocytes and plasma protein extravasation in postcapillary venules. During the initial period following reperfusion, activated endothelial cells in the microcirculation produce more oxygen radicals and less nitric oxide. The resulting imbalance between superoxide and nitric oxide in endothelial cells leads to the production and release of inflammatory mediators (e.g., platelet-activating factor, TNF-α) and

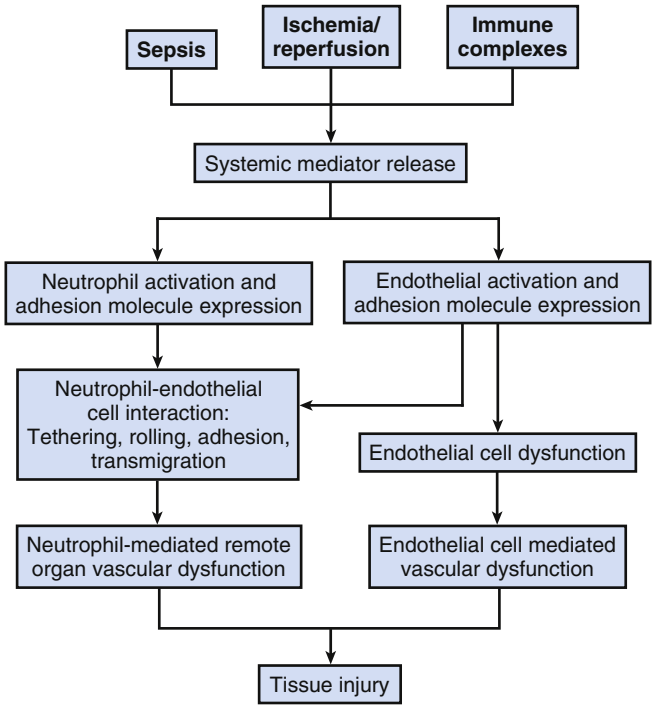

Figure 101–6. Mechanisms that underlie the development of local and remote organ injury following an initial inflammatory event. The activation of endothelial cells and circulating neutrophils lead to the expression and activation of adhesion molecules that facilitate neutrophil invasion of vascular beds, resulting in local and remote organ dysfunction.

enhances the biosynthesis of adhesion molecules that mediate leukocyte-endothelial cell adhesion.[53]

The inflammatory mediators released as a consequence of reperfusion also appear to activate endothelial cells in remote organs that are not exposed to the initial ischemic insult. Oxidants and activated leukocytes have been implicated as mediators of remote organ injury in I/R. This distant response to I/R can result in leukocyte-dependent microvascular injury that is characteristic of SIRS and MODS. The pulmonary damage associated with MODS can range from mild dysfunction as seen in acute lung injury (ALI), to severe failure as in acute respiratory distress syndrome (ARDS). The pulmonary injuries associated with ALI and ARDS include increased pulmonary microvascular permeability and the accumulation of neutrophil-rich alveolar fluid. Respiratory failure is often associated with cardiovascular, hepatic, gastrointestinal, and renal dysfunction as well as central nervous system involvement. MODS is associated with dysfunction of the coagulation cascade and the immune system, resulting in thrombosis, disseminated intravascular coagulation, and immunocompromise. The initiation of MODS may also lead to further tissue ischemia, resulting in further insult.[54]

Sepsis

Sepsis is a generalized systemic response to an infectious insult and manifests itself as SIRS (see Chapters 103 and 104). The clinical syndrome is characterized by a series of circulatory disturbances, including decreased vascular resistance and maldistribution of blood flow in association with impaired oxygen utilization. As a consequence, focal tissue hypoxia and cell injury soon follow the onset of sepsis. Despite aggressive volume resuscitation, systemic administration of antibiotics, vasopressors, and other sophisticated intensive-care measures, sepsis is frequently associated with multiple organ dysfunction and the death of the patient (see Chapter 104).

Although the pathophysiologic process of multiple organ dysfunction is multifactorial, one common feature is the dysfunction of the microcirculation, including the resistance arteries, capillaries, and postcapillary venules. The microcirculation cannot be considered a simple passive conduit. Rather it is a functionally active system of interactions between the vascular wall, circulating, and tissue-associated cells such as leukocytes, platelets, and mast cells, and extracellular mediators that contribute to the regulation of local, downstream, and upstream vascular tone. Sepsis is particularly associated with microvascular endothelial cell dysfunction leading to (1) the breakdown of endothelial barrier function, leading to tissue edema and uncontrolled inflammatory cell infiltration; (2) vasomotor dysfunction, leading to the formation of arteriovenous shunts in association with loss of peripheral resistance; and (3) disturbance of oxygen transport and utilization by tissue cells.[55]

Another major mechanism during sepsis is the change from anticoagulant to procoagulant and the contribution of microthrombi to the disturbance of the microcirculation. Lipopolysaccharide (LPS), an important pathogen product, is recognized by pathogen recognition receptors like toll-like receptors on cells of the innate immune system. This will lead to intracellular signaling and to the production of cytokines and other potent chemokines (see Chapter 90). Cytokines can upregulate tissue factor leading to (over)production of thrombin, downregulation of the protein C pathway, and an increase in PAI-1. The net result is increase in the production of fibrin, depression of the fibrinolysis, and, ultimately, increased microthrombi.

Septic shock is often associated with the loss of fluid from the intravascular into the extravascular space with the potential progressive loss of circulating blood, eventually leading to a depression of cardiac output. Similarly, loss of fluid into the extravascular space can lead to life-threatening edema in the lungs, kidney, and brain of septic patients. The loss of fluid is not believed to be associated with changes in hydrostatic and/or osmotic pressures within the vascular compartment, but rather to the breakdown of endothelial barrier function. The permeability of the vascular barrier can be modified in response to specific stimuli acting on endothelial cells. Many inflammatory agonists mediate endothelial hyperpermeability via a calcium-dependent mechanism. Multiple cascades of intracellular signaling reactions are initiated when an inflammatory agonist binds to its respective receptor expressed on the endothelial surface (e.g., thrombin binds the protease-activated receptor-1, histamine binds its receptor H1, and vascular endothelial growth factor binds its receptor VEGFR-2). This breakdown allows migration of water and macromolecules, including proteins, into the extravascular space. The pathophysiological mechanisms proposed include the separation of tight junctions between endothelial cells, as well as cytoskeleton contraction, rather than destructive changes of endothelial cells leading to defects in the endothelium.[49,56] In animal models of sepsis, a loss of vasoconstrictor response of resistance arterioles to catecholamines is observed and the vasorelaxing response to the microcirculatory segment is blunted. Although in vitro experiments demonstrate decreased biosynthesis of NO by endotoxin-exposed cultured endothelial cells, the overriding reaction with respect to NO synthesis is the upregulation of smooth muscle NO synthase. The ensuing overproduction of NO is the essential factor in the massive peripheral vasodilatation characteristic of the septic state. However, it has also been suggested that endotoxin-induced NO synthesis and consequently increased levels of NO in the septic organism decrease the sensitivity to the relaxing effect of acetylcholine. In septic rats, the vasoconstrictor response to a variety of vasopressor agents (vasopressin, endothelin, angiotensin) was attenuated. The microvascular response could be partially or completely restored by administration of inhibitors of NO, suggesting that NO plays a key role in mediating the vasomotor dysfunction in sepsis.[57]

Recent studies on the microcirculation of the gut have shown the development of a gap between microvascular and venous oxygen tension, suggesting enhanced shunting of the microcirculation. Defects in distributing blood to regional vascular beds or the microcirculation could be responsible for tissue hypoxia and limited oxygen extraction. Recent clinical evidence of decreased microvessel density in the sublingual microcirculation of fluid-resuscitated septic patients is consistent with findings of decreased functional capillary flow in the gut, liver, and skeletal muscle microcirculation in animal models of sepsis. This clinical finding raises the possibility that abnormal microvascular O_2 transport develops in multiple organs despite fluid resuscitation, leading to heterogeneous microvascular dysfunction and local tissue hypoxia in severe cases of sepsis.

Hemolytic-Uremic Syndrome

Thrombotic thrombocytopenic purpura (TTP) and the hemolytic-uremic syndrome (HUS) are related disorders characterized clinically by microangiopathic hemolytic anemia and thrombocytopenia. Pathologically, both conditions include the development of platelet microthrombi that occlude small arterioles and capillaries. Endothelial dysfunction plays a prominent role in the pathogenesis of both disorders. HUS commonly occurs in early childhood (approximately 90% of cases). It often follows an episode of bloody diarrhea caused by enteropathic strains of *Escherichia coli* that release an exotoxin, verotoxin-1 (VT-1) (see also Chapter 71). VT-1 binds with high affinity to receptors expressed in high density on renal glomerular endothelial cells. VT-1 is directly cytotoxic to endothelial cells where it promotes neutrophil-mediated endothelial cell injury. VT-1 induces the production of TNF-α by monocytes and cells within the kidney. In turn, TNF-α, in synergy with interleukin-1, increases VT-1 receptor expression and exacerbates the sensitivity of the endothelium to toxin-mediated and antibody-mediated cytotoxicity. It also promotes vWF release and impairs fibrinolytic activity.[58]

There is considerable evidence to suggest that endothelial cell injury plays a role in the pathogenesis of TTP. Platelet microthrombi in TTP contain abundant vWF but little fibrinogen, in contrast to those seen in disseminated intravascular coagulopathy. A subgroup of patients has been identified who suffer from chronic, relapsing TTP and whose plasma continues to contain elevated levels of unusually large vWF multimers (ULvWF) between relapses. ULvWFs may exacerbate microvascular thrombosis through their ability to aggregate platelets at high levels of shear stress. The secretion of ULvWF by cultured endothelial cells is stimulated by many agonists, including Shiga toxin. However, elevated levels of vWF occur in other thrombotic microangiopathies, and their exact role in TTP/HUS requires further study. Endothelial damage plays a pivotal role in the pathogenesis of the disease. The events that initiate TTP remain unknown. More recently, plasma from patients with TTP and HUS has been reported to induce apoptosis in microvascular endothelial cells. Interestingly, cells from dermal, renal, and cerebral origin were most susceptible, whereas pulmonary and coronary arterial cells were less susceptible.[59]

Vasculitic Disorders

Vasculitis is a disease that targets all levels of the arterial tree from aorta to capillaries, and also affects venules, with leukocyte infiltration and necrosis. Different forms of vasculitis attack different vessels and are classified accordingly. The inflammatory process may target vessels of any type throughout the vascular system, although distinct clinicopathological entities preferentially involve vessels of particular sizes and locations. Small vessels anywhere in the body may be affected by focal necrotizing lesions where extravasation of leukocytes drives the inflammatory responses, resulting in vasculitis. Leukocyte adhesion molecules participating in the interactions with endothelial cells belong to three major families: selectins, sialomucins, and integrins. Interestingly, it is recognized that these interactions participate in tissue specificity in various vasculitic conditions. For instance, specific selectin interactions mediate cutaneous tropism in several inflammatory disorders including graft-versus-host disease and dermatomyositis.[60]

Conclusions

The endothelium can no longer be viewed as a static physical barrier that simply separates the blood for tissue. Rather, the endothelium coordinates key functions of different tissues in normal and pathophysiological conditions. This is accomplished by the interaction of endothelial cells with circulating factors and cells and its ability to transmit biochemical and biophysical signals to surrounding tissues. Increasing understanding of endothelial physiology will lead to novel therapeutic approaches in complex clinical conditions.

Neuroendocrine–Immune Mediator Coordination and Disarray in Critical Illness

Kate Felmet and Joseph A. Carcillo

PEARLS

- Activation of the hypothalamic-pituitary-adrenal axis is normal during stress. Lack of activation in the acute setting causes many of the signs and symptoms of critical illness.
- Relative adrenal insufficiency should be suspected in any patient with catecholamine-resistant shock and in patients with prolonged critical illness.
- Lymphopenia and monocyte dysfunction occurs commonly in the intensive care unit and may result from unopposed immunosuppressive stress hormones.
- Dopamine use suppresses prolactin and growth hormone release and may suppress the immune system and anabolic pathways.
- Opioids used for analgesia may have immunosuppressive effects.
- The neuroendocrine state in prolonged critical illness differs from acute stress and may be dysfunctional.

Clinically relevant cross-talk occurs among the central nervous system, the endocrine system, and the immune system. For example, psychological stress leads to release of cortisol, a potent inhibitor of immune function, whereas immune activation initiates central nervous system pathways generating fever, pain sensation, and behaviors associated with recovery. These neuroendocrine-immune (NEI) interactions are relevant in critical illness. A normally functioning hypothalamic-pituitary-adrenal (HPA) axis, the primary efferent limb of the NEI system, is essential to surviving critical illness. Certain disease states such as septic shock are strongly associated with dysfunction of the NEI system. Drugs used to resuscitate shock, including catecholamines, vasopressin, and glucocorticoids, are mediators for the efferent limb of this system. Dopamine infusion profoundly affects release of the neuroendocrine products growth hormone and prolactin. Molecules of the afferent limb of the NEI system, primarily cytokines, have been targets for adjuvant therapies for severe sepsis.

This chapter distills a broad range of data from the fields of immunology, endocrinology, and neuroscience into clinically useful concepts. We provide a conceptual framework, building on the concept of the stress response and focusing on the best-understood aspects of neuroendocrine mediators and their relevance to critical care. The authors describe situations in which breakdown of the NEI system plays a role in the development of critical illness, and discuss situations in which physicians, using common intensive care unit (ICU) therapies, may inadvertently interfere with NEI function.

Organization of the Stress Response

The stress response has been considered an extension of the fight-or-flight response, which halts growth, digestion, and other daily activities in order to ready the body for immediate action. These signals, namely, activation of the sympathetic nervous system, the HPA axis, and endogenous opioids, are primarily antiinflammatory. If this were the whole of the stress response, then humans, after fleeing their aggressor or delivering their babies, would be left with disrupted epithelial barriers and a suppressed immune system. Modern science has shown that the stress response is a complex dynamic process that can be initiated by the immune system or the central nervous system.

Stress can be understood as any threat to an organism's homeostatic internal milieu. An organism must defend itself against two types of threats. Macroscopic threats, such as an encounter with a predator, an episode of hypotension, or a traumatic hemorrhage, threaten the whole organism at once. The central nervous system response to macroscopic threats has been recognized for decades. Microscopic threats attack epithelial and endothelial barriers that are essential to organ function. To maintain integrity against microscopic threats, the organism must be vigilant against microbial invasion in the face of the wear and tear of daily activities such as digestion, excretion, and procreation. The central stress response to macroscopic threats puts housekeeping on hold as the vital functions are marshaled against an assault. The response to microscopic threats is a matter of day-to-day housekeeping and is primarily the responsibility of the immune system. They are equally important and must balance each other; they are the yin and the yang of the response to stress.

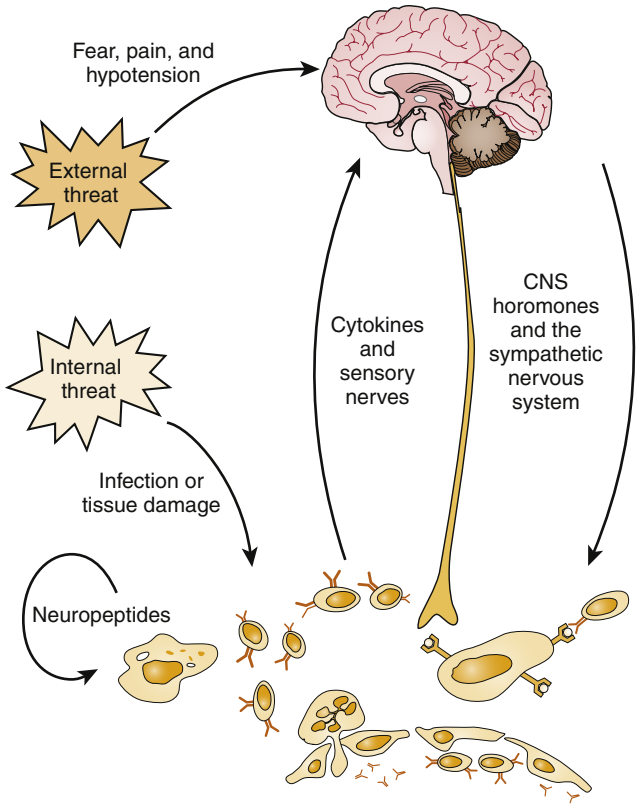

Figure 102–1. Neuroendocrine immune loop. Stimulation of the central stress axis generates immunosuppressive signals (activation of the hypothalamic-pituitary-adrenal axis, sympathetic nervous system, endogenous opioids) and immunosupportive signals (release of proinflammatory peptides, e.g., vasopressin and prolactin). A threat to the homeostatic milieu, in the form of trauma or infection, activates the immune system. Activated immune cells produce cytokines such as tumor necrosis factor-α, interleukin-1, and interleukin-6, which in turn activate the central stress response. Some immune cells produce neuropeptide hormones for autocrine or paracrine action. *CNS,* Central nervous system.

Central Stress Response

All types of stress—physical, emotional, or immune—cause stimulation of the sympathetic nervous system, activation of the HPA axis, and release of hypothalamic hormones, including vasopressin, prolactin, and growth hormone (Figure 102-1). The HPA system is the major humoral coordinator of the central stress response (see Chapter 77). Hypothalamic release of corticotropin-releasing hormone occurs in response to cortical signals generated by fear, pain, or hypotension, as well as in response to immune-derived signal molecules, especially interleukin (IL-1β), tumor necrosis factor (TNF-α), and IL-6.[1] Corticotropin-releasing hormone in the brain stimulates sympathetic outflow and causes release of adrenocorticotropic hormone (ACTH) by the pituitary. Vasopressin, that is also released in response to immune signals and stress, is powerfully synergistic with corticotropin-releasing hormone in promoting ACTH secretion.[2] Circulating ACTH reaches the adrenal cortex, where it stimulates conversion of cholesterol to the steroid hormone cortisol. Cortisol release suppresses further ACTH secretion within minutes and more slowly feeds back to suppress secretion of corticotropin-releasing hormone.[3] Cortisol and its synthetic analogues, the glucocorticoids, act in tandem with the sympathetic nervous system to prepare a body for action by putting growth and housekeeping functions on hold, making fuel substrates available, and supporting blood pressure and intravascular volume. Failure of this normal stress response leads to cardiovascular collapse.

Cortisol inhibits growth in all tissues, decreases deoxyribonucleic acid and ribonucleic acid synthesis, and increases protein catabolism, except in the liver, where protein synthesis is enhanced. Cortisol increases the availability of glucose, amino acids, and free fatty acids for immediate use. Cortisol increases vascular tone and increases expression of adrenergic receptors, potentiating the vasoconstrictive action of catecholamines. Cortisol also regulates the distribution of total body water. It activates the renin-angiotensin system, causing hypertension, and is necessary for secretion of a water load.[3] In suppressing the body's maintenance functions, cortisol suppresses immune responses. Cortisol reduces circulating numbers of lymphocytes, monocytes, and eosinophils by stimulating apoptosis. It stabilizes lysosomal membranes, decreases capillary permeability, impairs demargination of white blood cells and phagocytosis, and decreases release of IL-1, preventing fever. Cortisol supports a T_H2 (humoral immunity) over a T_H1 (cellular immunity) phenotype.[3]

Activation of the sympathetic nervous system complements the actions of cortisol. The impact of sympathetic nervous system stimulation on the immune system is complex and imperfectly understood and is discussed later in this chapter. The parasympathetic limb of the autonomic nervous system plays an important role in regulating the immune response. Fibers from the vagus nerve innervate liver macrophages, called *Kupffer cells,* as well as other abdominal lymphoid organs. Efferent signaling from the vagus nerve decreases the production of inflammatory cytokines by Kupffer cells, macrophages, and other cytokine producing cells, an effect that has been termed the *cholinergic antiinflammatory pathway.*[4] This pathway may be a protective mechanism that blunts the response to sterile endotoxin translocation from the gut. Alternatively, parasympathetic activation may complement the stress response in restraining the magnitude of an inflammatory response to real infection.

In the short term, the immunosuppressive effects of the central stress response may be allowed to predominate, but once the acute danger has passed, the ability to fight infection must be restored and even potentiated. Release of prolactin, growth hormone, vasopressin, and substance P into the bloodstream occurs in tandem with HPA and sympathetic nervous system activation. By binding to specific receptors on immune cells, these peptide hormones function as counter-regulatory mechanisms to the immunosuppressive limb of the stress response.

Prolactin and growth hormone share structural homology with each other and with the immune-derived cytokines granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-2, and IL-7.[5,6] Together these hormones support immune response by stimulating cytokine expression, antibody production, and clonal expansion of lymphocytes. Prolactin and growth hormone directly oppose the lymphocyte apoptosis promoted by cortisol. Growth hormone also affects metabolism, which may be important in critical illness. The overall impact of vasopressin on the immune system is less well understood, but its function in direct interaction with lymphocytes appears to be supportive.

Immune Response to Microscopic Threats

The immune system is a sensory organ that allows early recognition of, and response to, microscopic threats. Day-to-day activities result in wear and tear on epithelial barriers, leading to microbial and other nonself invasion. These peripheral stressors initiate a cascade of molecules and activated cells that amplify the initial signal and stimulate the central stress response. The central stress response, in turn, downregulates and eventually terminates the immune response.

Inflammation and phagocytic cells comprise the first line of defense and recognition. Tissue damage caused by microbial invasion or trauma initiates the nonspecific cascade called the inflammatory response (see Chapters 90 and 91). It leads to vasodilatation, increased capillary permeability, and an influx of phagocytes. Histamine and kinins are important mediators of the inflammatory response. Phagocytic cells may be blood monocytes, neutrophils, or tissue macrophages. Macrophages engulf foreign matter and bacteria, break them down into large molecules, and present these as antigens to T lymphocytes, thus activating the specific adaptive immune response.

Phagocytic cells also produce proinflammatory cytokines, primarily IL-1, IL-6, and TNF-α, which amplify the immune response locally. Cytokines help determine whether the specific immune response takes on a T_H1 or T_H2 phenotype. Cytokines carry messages between different cell types within the immune system and between the immune system and other organ systems. In the latter role, they are thought to comprise the most important afferent limb of the NEI system. Cytokines circulating in the bloodstream reach the central nervous system, where receptors for IL-1α and IL-1β, IL-2, IL-4, IL-6, TNF-α, and interferon (IFN-γ) are found. Afferent nerves also carry inflammatory signals to the brain. When stimulated by cytokines and endotoxin, signals from the vagus lead to HPA axis activation.[7]

Binding of cytokines to their specific receptors in the brain can activate the full spectrum of the central stress response, including release of corticotropin-releasing hormone and other hypothalamic hormones, activation of the sympathetic nervous system, and release of endogenous opioids from the hindbrain and spinal cord. Hypothalamic hormones lead to release of effector molecules such as cortisol and insulin-like growth factor. In general, hypothalamic hormones such as prolactin and growth hormone support the immune response, whereas corticotropin-releasing hormone, ACTH, and cortisol suppress the immune response. NEI mediators also may play a role in determining the predominance of a T_H1 or T_H2 phenotype.

Interestingly, neuroendocrine mediators that trigger the antiinflammatory cascade in the central nervous system, such as vasopressin and corticotropin-releasing hormone, may have the opposite effect when they are released in tissues. Both corticotropin-releasing hormone and vasopressin are clearly immunosupportive in peripheral tissues. Corticotropin-releasing hormone is found in high concentrations at inflammatory sites, although plasma levels may be undetectable.[8,9] Corticotropin-releasing hormone augments T-lymphocyte proliferation and IL-2 expression in vitro, augments cytokine expression by macrophages, and triggers mast cell degranulation.[8,10] Immunoneutralization of corticotropin-releasing hormone decreases inflammation as effectively as neutralizing antibodies to TNF-α.

The normal pathways that lead to increased local concentrations of hypothalamic hormones and their clinical relevance in peripheral tissues are not completely understood. Corticotropin-releasing hormone is a neurotransmitter of postganglionic sympathetic nerves, some of which innervate lymphoid organs and may be a mediator of autonomic control of inflammation. In some cases, immune cells actually secrete neuropeptides for autocrine or paracrine action. Immune cell secretion of neurotransmitters may affect peripheral nerve activity and may represent a second method by which the immune system alerts the central nervous system to the presence of microbial invasion.

Acute Versus Chronic Stress

The body's response to stress has been studied mostly as an acute event occurring in normal healthy people. Through the use of advanced therapies and machines, we have created in the modern ICU a state of prolonged critical illness that does not exist in nature and to which the neuroendocrine system must adapt. The state of prolonged stress is not well understood, but the hormonal milieu that exists and which we intentionally create in the acute phase of resuscitation—that of catecholamine and cortisol excess—likely will not be appropriate later. In chronic critical illness, the excess of ACTH, prolactin, growth hormone, and thyroid hormone observed initially is reversed, and the normal pulsatile pattern of pituitary hormones is diminished or lost.[11] It is unclear whether this represents a beneficial adaptation to critical illness or an unrecognized organ failure.

The neuroendocrine system in critically ill patients cannot be judged by reference to established norms. It may not be possible to know what levels of these hormones are "natural." In studying the NEI system in critical illness, the appropriate hormone level is that associated with the best outcome. In the future, dysfunction of the NEI system that occurs in prolonged critical illness may be recognizable as an organ failure and part of the multiple organ dysfunction complex.

Neuroendocrine–Immune Dysfunction Causing Critical Illness

Some categories of critical illness are caused by dysfunction of the NEI system. Breakdown of the central stress response leads to a shock state. The most obvious example is the autonomic instability associated with spinal shock. Complete adrenal failure with breakdown of the HPA axis causes shock, but this phenomenon is relatively rare. More important to critical care is the syndrome of critical illness–related corticosteroid insufficiency. An acquired, reversible adrenal insufficiency can occur in any critically ill patient but is particularly associated with sepsis and septic shock. A syndrome of inadequate circulating vasopressin also has been implicated in the pathogenesis of shock, particularly vasodilatory or warm shock.

Hypothalamic-Pituitary-Adrenal Axis

In general, critically ill patients have elevated cortisol levels that correspond to the severity of illness. In the acute phase of critical illness, adequate cortisol is necessary for maintenance

of vascular tone and normal catecholamine responsiveness.[12] In some critically ill patients, cortisol levels may be inadequate for their degree of illness or inadequate relative to the ACTH levels measured in their blood. The incidence of relative adrenal insufficiency varies according to author and definition criteria. The reported incidence ranges from 0% to 75% and is higher in patients with septic shock than other ICU patients. Relative adrenal insufficiency is associated with poor outcomes in adults and children.[13,14]

During the prolonged phase of critical illness, the normal association between ACTH and cortisol often is strikingly reversed. In the face of ongoing stress, cortisol levels in critically ill patients tend to remain elevated despite a decline in ACTH levels.[15] Sustained cortisol production may result from direct autonomic innervation of steroidogenic cells, paracrine action of the products of the adrenal medulla, or the action of cytokines, which can directly stimulate cortisol production.[16-18] Decreased cortisol clearance by the liver may contribute to elevated cortisol levels in prolonged critical illness.[15]

Adrenal insufficiency should be suspected in any patient with catecholamine-resistant shock and in patients with prolonged critical illness. Pathologic scenarios that may produce relative or absolute adrenal insufficiency include suppression of corticotropin-releasing hormone or ACTH secretion, adrenal unresponsiveness, increased cortisol clearance, or end-organ unresponsiveness to cortisol (Table 102-1). For a thorough discussion of the causes of relative adrenal insufficiency, the reader is referred to the excellent review by Beishuizen and Thijs.[19]

Defining what constitutes a normal cortisol response to critical illness is difficult because the range of cortisol levels observed in critically ill patients is so broad, varying from the healthy normal level to 20 times normal. Additionally, measured cortisol levels may overestimate biologically active free cortisol in the acute phase of critical illness because levels of cortisol-binding globulin are low.[20,21] Most authors agree that a "normal" level of cortisol in the face of shock probably is inadequate.[19]

The ACTH stimulation test can be used to identify absolute adrenal failure but may fail to identify a clinically significant adrenal insufficiency. The ACTH dose used in the standard test (250 mg for adults and children older than 2 years, 125 mg for children younger than 2 years) produces plasma ACTH levels 100 to 200 times the physiologic maximum stress levels of ACTH. A 1-mg test has been suggested but has not been standardized for adults or children. Beishuizen et al.[22] demonstrated that patients with a normal response to the standard test but an inadequate response to the 1-mg test improved clinically with decreased pressor requirement in response to hydrocortisone treatment. In adult patients with septic shock, a random cortisol level less than 25 μg/dL was a better predictor of a hemodynamic response to hydrocortisone than either the 1-mg or the 250-mg ACTH stimulation test.[23] Most recently, in a study of 30 children with septic shock, a change in cortisol of greater than 9 μg/dL in response to a 1 mg ACTH stimulation test identified patients at increased risk of catecholamine refractory shock but not increased risk of mortality.[24]

Standard reference ranges for normal healthy subjects accept minimum peak values after ACTH stimulation of 18 to 22 mg/dL (500-600 nmol/L) or a minimum change in cortisol level of 7 to 9 mg/dL (200-250 nmol/L). Failure according to these requirements is associated with a high 28-day mortality in adults.[13] ACTH stimulation tests should be interpreted in light of the basal cortisol level, because the change in serum cortisol after ACTH stimulation is a measure of adrenal reserve.

It may be impossible to rely on results of an ACTH stimulation test in the acute setting of severe catecholamine-unresponsive shock, when time is of the essence. Because the criteria for diagnosis of relative adrenal insufficiency in the critical care setting are imprecise, some authors believe a negative or inconclusive result should not prohibit use of glucocorticoids. Instead, a rapid hemodynamic response to glucocorticoids may be the best clue to the diagnosis of relative adrenal insufficiency. One author suggests that, at present, we have no choice but to rely on clinical assessment of the severity of stress and make "an educated guess of the adequacy of the measured serum cortisol concentration."[21]

Table 102–1 Causes of Adrenal Insufficiency

Nervous System	Condition	Comments
Central	Hypothalamic or pituitary disease	
	Brain injury	
	Recent steroid use	Follows the "rule of ones": 1 day of steroid use may suppress adrenal function for 1 week; 1 week for 1 month; 1 month for 1 year
Peripheral	Preexisting adrenal failure	Associated with increased pigmentation, hypoglycemia, mild hyponatremia, and hyperkalemia
	Acute adrenal failure	Adrenal hemorrhage or autoimmune adrenalitis
	Inadequate substrate	Low cholesterol[48]
	P450 impairment	From ketoconazole, etomidate, sepsis, prematurity, or age <6 months[77-79]
	Increased clearance	Occurs with rifampin, phenytoin, and phenobarbital[80]
	End-organ unresponsiveness	Cytokines can change glucocorticoid receptor sensitivity[19,80]
Other	Sepsis/inflammation	Circulating inflammatory mediators can cause hypothalamic-pituitary-adrenal axis suppression, particularly in patients with fungal infection or human immunodeficiency virus[18]

Although several studies on administration of pure glucocorticoids to septic shock patients have failed to demonstrate a survival advantage, the use of steroids with both glucocorticoid and mineralocorticoid activity has shown some benefit.[26,27] Annane et al.[25] reported a large, prospective, placebo-controlled, randomized clinical trial in adults with septic shock, demonstrating that treatment with hydrocortisone (50 mg every 6 hours) and fludrocortisone (50 mg/day) decreased 28-day mortality in all patients. Most of the survival benefit was seen in patients in whom relative adrenal insufficiency was identified by standard-dose corticotropin stimulation test with change in stimulated minus baseline cortisol response of less than 9 μg/dL.[25] A large, international, multicenter trial (CORTICUS trial) investigating this effect found that hydrocortisone given without fludrocortisone hastened resolution of shock but had no impact on mortality.[28] A high percentage of patients in the Annane study were treated with etomidate, an inhibitor of the cytochrome P-450 enzymes responsible for the final step in cortisol synthesis. An *a priori* subgroup analysis of the patients in the CORTICUS trial who received etomidate for intubation found an increased risk of adrenal insufficiency and mortality in these patients. Treatment with hydrocortisone did not change the mortality of patients who received etomidate.[29]

A recent meta-analysis of clinical trials of steroids in septic shock concluded that low-dose long-duration corticosteroids may have an advantage over high doses and shorter duration.[30] Current recommendations for adult sepsis recommend use of low-dose steroids (<300 mg/day of hydrocortisone) for shock that is resistant to fluid resuscitation and catecholamines, without use of the ACTH stimulation test.[31,32] An excellent historical review of the use of steroids for septic shock reminds us that there is still need for clinical equipoise on the use of steroids for septic shock in children.[33] At present, the American College of Critical Care Medicine clinical practice parameters for the hemodynamic support of pediatric and neonatal septic shock recommend the use of hydrocortisone in patients with catecholamine resistance and suspected adrenal insufficiency. Risk factors that should alert the clinician to high risk for adrenal insufficiency include physical examination findings suggestive of absolute adrenal insufficiency, disseminated intravascular coagulation or purpura fulminans, and history of steroid use. The authors would add to this list a history of prolonged stress (i.e., decompensation in a patient during a long ICU stay), severe septic shock, and risk of P-450 impairment as a result of drugs and extreme youth.

The physiologic replacement dose of hydrocortisone is 12.5 mg/m^2/day. In critical illness, dosing ranges from 50 mg/m^2/day in stress states to 50 mg/kg/day in severe shock have been reported, although dosing greater than 300 mg/day of hydrocortisone equivalent is associated with worse outcomes.[31,32] Hydrocortisone has a short half-life and should be given as a bolus, followed by continuous infusion or dosing every 6 hours as per most recent interventional trials. Although critically ill patients may receive steroids for a variety of indications, steroids that lack mineralocorticoid activity may not be sufficient for adrenal replacement in shock. Table 102-2 gives a comparison of the relative glucocorticoid and mineralocorticoid potency of steroids commonly used in the ICU. Glucocorticoids given over a prolonged period are associated with an increased risk for superinfection, gastrointestinal bleeding, hyperglycemia, polyneuropathy of critical illness, and prolonged adrenal insufficiency. Exogenous hydrocortisone should be tapered or discontinued as soon as hemodynamics allow.

Table 102–2 Comparison of Common Corticosteroid Dosing

Dosage	Glucocorticoid Potency (as Hydrocortisone Equivalent Dose)	Mineralocorticoid Potency
Stress dose hydrocortisone: 50 mg/m^2/day	Approximately 2 mg/kg/day	++
Shock dose hydrocortisone: 50 mg/kg/day	50 mg/kg/day	++
Annane study[3]: hydrocortisone 50 mg q6h and fludrocortisone 50 mg/day	Approximately. 3 mg/kg/day	++++
Dexamethasone for postextubation stridor: 0.5 mg/kg q8h	35 mg/kg/day	0
Methylprednisolone in severe asthma: 1 mg/kg q6h	20 mg/kg/day	0
Methylprednisolone in spinal cord injury: 30 mg/kg load followed by 5.4 mg/kg/h over 23 hours	770 mg/kg/day	0

Vasopressin

Vasopressin is a hormone of the posterior pituitary that is secreted in response to high serum osmolarity. Excitation of atrial stretch receptors inhibits vasopressin secretion. Vasopressin is also released in response to stress, inflammatory signals, and some medications. Hypotension, morphine, nicotine, angiotensin II, glucocorticoids, and IL-6 all stimulate release of vasopressin.[2] Circulating vasopressin levels are usually high in the early phase of septic shock, but vasopressin deficiency as been described in vasodilatory shock states in both adults and children.[34,35] The level of vasopressin that is normal in the late phase of sepsis is unclear.[36]

In general, vasopressin decreases water excretion by the kidneys by increasing water reabsorption in the collecting ducts, hence its other name of antidiuretic hormone. Vasopressin also has a potent constricting effect on arterioles throughout the body.[6] Vasopressin potentiates ACTH release leading to cortisol release, which may contribute to its salutary effects in cardiac arrest and vasodilatory shock.[2] Vasopressin has been proposed as a replacement or adjunct to epinephrine in the resuscitation of cardiac arrest and of catecholamine-unresponsive shock. The interest in vasopressin for resuscitation is based on the fact that vasopressin may increase coronary perfusion without increasing myocardial oxygen demand and without the arrhythmogenic effects of epinephrine. Also, repeated doses of vasopressin tend to support blood pressure after the epinephrine response wanes.[37] When given as the first drug in cardiac arrest, vasopressin has been shown to confer a survival advantage in out-of-hospital arrest but not in arrests occurring in stressed, hospitalized patients.[38,39] Vasopressin's

effects on NEI mediators may explain this discrepancy. In a person with normal adrenal reserves of cortisol, exogenous vasopressin may cause a surge of endogenous cortisol, which should improve catecholamine responsiveness. Hospitalized patients with decreased adrenal reserves may not experience this benefit of vasopressin.

Vasopressin is a powerful vasoconstrictor, even in patients with catecholamine unresponsiveness. Because vasopressin dilates the pulmonary, cerebral, and myocardial circulations, it may help to preserve vital organ blood flow. Vasopressin and its synthetic analogue, terlipressin, have also been used as a rescue therapy for severe shock. Case series of the use of vasopressin in patients with catecholamine refractory shock have described the use of doses in the range of 0.00001 to 0.08 units/kg/min.[40-43] Vasopressin has also been used as a catecholamine-sparing hormone replacement, with a goal of restoring high-normal levels rather than titrating to clinical effect. A recent, large, randomized controlled trial of low-dose vasopressin infusion in adult patients found a good safety profile but no impact on mortality when compared with norepinephrine alone.[44] The only pediatric randomized controlled trial so far showed used a dose of 0.0005 units/kg/min, similar to adult trials, and found an increase in mean arterial pressure but no differences in time to hemodynamic stability or other clinical outcomes.[45]

High doses of vasopressin are associated with unacceptable side effects, such as gut and digital ischemia and decreased urine output. However, several small clinical studies have suggested that these problems do not occur at physiologic doses.

Vasopressin has effects on the immune system independent of its effect in stimulating the HPA axis. When given intraventricularly to rats, vasopressin decreases the T-cell response to mitogen independently of the HPA axis, probably via the sympathetic nervous system.[46] Like CRH, vasopressin stimulates immune responses in peripheral tissues. Circulating or local vasopressin enhances lymphocyte reactions and potentiates primary antibody responses.[47] Elevated vasopressin levels are found in a mouse model of autoimmune disease, and antibody neutralization ameliorates the inflammatory response in these mice.[2] Vasopressin can potentiate the release of prolactin, a proinflammatory peptide hormone.[48]

Because vasopressin has immunosuppressive effects when present in the central nervous system and immunosupportive effects when present in peripheral tissues, predicting which effect would predominate during vasopressin infusion in the ICU is difficult.

Intensive Care Unit Therapies That Interfere with the Neuroendocrine–Immune System

The NEI system is so crucial in the maintenance of blood pressure that the most powerful therapies available to resuscitate shock are analogues of naturally occurring NEI mediators. Catecholamines, glucocorticoids, vasopressin, and somatostatin are all hormonal therapies. These molecules are often used without a full understanding of the role they play in the balance between promoting and suppressing immune responses. The incidental effect of most of these therapies is immune suppression (Figure 102-2 and Table 102-3). Prolactin and growth hormone, the NEI mediators that counterbalance the immunosuppressive effect, are particularly subject to suppression by catecholamines, especially dopamine. A prolonged imbalance between the immunosuppressive and immunosupportive elements of the NEI system can lead to development of lymphopenia, which in turn is associated with considerable morbidity and mortality.[49]

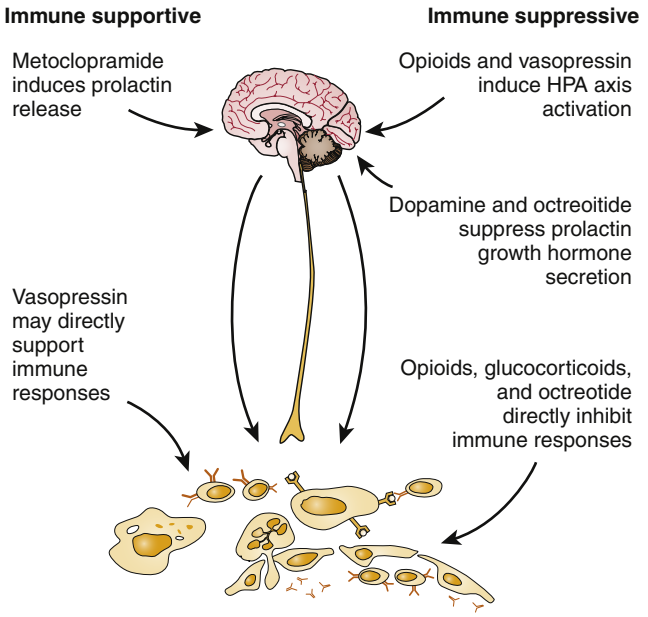

Figure 102–2. Neuroendocrine-immune impact of commonly used intensive care unit (ICU) therapies. Common drug infusions in the ICU influence immune function by altering neuroendocrine secretory activity and by binding to immune cells directly. Opioids and vasopressin activate the hypothalamic-pituitary-adrenal *(HPA)* axis, leading to cortisol release. Dopamine and octreotide block the release of the immunosupportive hormones prolactin and growth hormone. Opioids and octreotide have direct effects on immune cells, decreasing lymphocyte proliferation, primary antibody responses, and monocyte and macrophage function. All of these effects are immunosuppressive. Only vasopressin in the periphery, which supports lymphocyte function, and metoclopramide, which induces prolactin release, are immunosupportive.

Catecholamines and Autonomic Control of Inflammation

Catecholamines are the most important immediate effector molecules of the fight-or-flight response. These drugs impact the NEI system by directly influencing immune responses and by altering the release of other NEI mediators. Norepinephrine is the primary effector molecule for the sympathetic nervous system. Epinephrine is secreted into the bloodstream by the adrenal gland in response to sympathetic nervous system activation. Together they regulate cardiovascular and respiratory function, smooth muscle contraction, and secretions. Like cortisol, they put the housekeeping functions of the body, including digestion, growth, and reproduction, on hold in favor of blood pressure support and mobilization of fuel substrates.[6]

The sympathetic nervous system innervates the immune system. Bone marrow, thymus, spleen, lymph nodes, and gut-associated lymphoid tissue receive adrenergic, dopaminergic,

Table 102–3 Summary of the Effects of Neuroendocrine–Immune Mediators on Immune Cell Types

	T-Cell Proliferation and Cytokine Release	B-Cell Antibody Production	Monocyte Activation	Natural Killer Cell Function	Macrophage Function and Cytokine Release	Neutrophil Chemotaxis
Circulating catecholamines	–	–	±			
Dopamine	–	–	–	–	–	
Prolactin	+	+	+	+	+	?
Opioids	–	–	–		–	
Somatostatin	–	?	?			
Hypothalamic-pituitary-adrenal axis/cortisol	–	–	–		–	–
Vasopressin peripheral	+	+				
CRH peripheral	+				+	

and peptidergic input.[49] T cells and other immune cells have β-adrenergic receptors, as well as specific receptors for dopamine and a variety of neuropeptides (acetylcholine, substance P, neuropeptide Y, somatostatin, prolactin).[34] Sympathetic nerve terminals are in direct apposition to T cells, B cells, and dendritic cells. During development, immune-derived neurotrophic factors may direct the growth of innervating fibers.[50]

The effects of catecholamines on the immune system are complex. Catecholamines increase the production of some proinflammatory cytokines and increase the number of circulating lymphocytes and natural killer (NK) cells.[51] Adrenergic receptor activation inhibits neutrophil function, decreases mitogen-induced T-cell proliferation and decreases both IL-2 production and IL-2R expression on T cells.

The overall impact of sympathetic nervous system activation on immune responses may depend partly on its inhibitory effect on the cholinergic antiinflammatory pathway. Although this pathway is incompletely understood, it is clear that both vagal nerve stimulation and systemically administered agonists to the nicotinic cholinergic receptor attenuate inflammatory cytokine release and organ damage and improve survival in animal models of sepsis.[4] In humans, there is a significant correlation between depressed vagus nerve activity and increased morbidity and mortality in inflammatory states.[52] For a review of the current understanding of the choinergic antiinflammatory pathway, the reader is referred to the recent review by Rosas and colleagues.[4]

The degree to which circulating catecholamines given in the ICU can mimic the effects of sympathetic outflow is unclear. Of more certainty is that catecholamines in pharmacologic dose impact the release of other NEI mediators in vivo. Dopamine has a powerful inhibitory effect on release of the proinflammatory mediator prolactin and has been shown to decrease lymphocyte proliferation.[53,54] Dopamine inhibits pulsatile release of growth hormone, thus contributing to the catabolic state observed in critical illness.[54] Other catecholamines have similar effects, albeit to a much lesser degree.

Growth and Lactogenic Hormone Family

Prolactin

Prolactin is a hormone produced by anterior pituitary cells and lymphocytes that has been shown to have immunoregulatory function. It is best known for its role in promoting milk secretion. Although it is produced in both sexes, prolactin levels are highest in lactating mothers and newborns. Prolactin release is stimulated by suckling, IL-1β, IL-2, IL-6, oxytocin, serotonin, and thyrotropin-releasing hormone. A prolactin secretory response to psychological and physical stress is reported.[5,55,56] In the normal state, prolactin secretion is tonically inhibited by hypothalamic dopamine.

Prolactin may be the most important counterbalance to the immunosuppressive effects of the central stress response. Prolactin supports circulating lymphocyte numbers as a necessary cofactor for IL-2 and mitogen-stimulated proliferation[5] and by opposing glucocorticoid-induced apoptosis.[57] Prolactin increases IL-2 production by T cells and is necessary for expression of the IL-2 receptor. Prolactin increases antibody production by B cells and increases cytokine release capacity of macrophages and NK cells.[5]

Disturbances of prolactin have clinically significant effects on immune function. Prolactin levels are increased in some autoimmune diseases and in association with episodes of organ rejection.[58] The immunosuppressive drug cyclosporine exerts its effect through the prolactin receptor on lymphocytes.[59] Bromocriptine, an oral agent that prevents prolactin release, has shown promise in the treatment of autoimmune disease and in animal models of organ transplantation.[60] Prolactin levels are suppressed in critically ill patients in response to hemorrhage.[61,62] Hemorrhage has been associated with lymphopenia, decreased T-cell proliferative response, and increased risk of sepsis and multiple organ failure.[61] Prolactin administration has been shown to improve cytokine release and survival in posthemorrhage mice subjected to the cecal ligation and puncture experimental model of sepsis.

Pituitary prolactin production is strongly inhibited by exogenous dopamine at doses as low as 1 μg/kg/min.

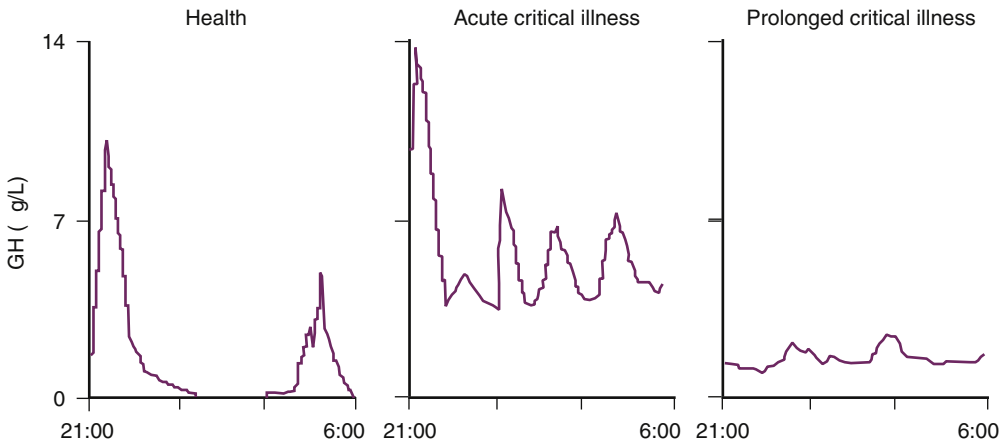

Figure 102–3. Secretion profile of growth hormone in health and illness. A healthy person has robust, predictable nocturnal growth hormone release. In the acute phase of critical illness, both peak levels and interpulse levels are significantly elevated. In prolonged critical illness, growth hormone secretion becomes chaotic, and the mean growth hormone levels are decreased. *(Modified from Van den Berghe G: The neuroendocrine response to stress is a dynamic process,* Best Pract Res Clin Endocrinol Metab *15:407, 2001.)*

Dopamine-associated hypoprolactinemia has been associated with decreased T-cell response to mitogen *ex vivo*, decreased circulating lymphocyte numbers, and increased risk of secondary infection in the ICU.[53,63] Adrenergic agents other than dopamine have a similar, albeit much less potent, effect on prolactin release. Prolactin release may be inadvertently inhibited by somatostatin, serotonin, corticosteroids, and histamine (H_1) blockers. Metoclopramide and vasopressin increase pituitary prolactin release.[55]

Given that prolactin is one of the few antagonists to the overwhelmingly immunosuppressive effects of the stress response, use of therapies that inhibit its release, particularly dopamine, should be carefully considered. Recombinant human prolactin may have therapeutic potential to reverse lymphopenia observed in the ICU and to speed hematopoietic reconstitution after bone marrow transplant.[64]

Growth Hormone and Insulin-like Growth Factor

Growth hormone is a large peptide hormone produced by the anterior pituitary. It is structurally similar to prolactin. Like prolactin, growth hormone has immune stimulatory effects and is suppressed by catecholamines.[65] In states of health, growth hormone increases protein synthesis, gene transcription, and the size and mitosis of somatic cells. It decreases glucose uptake and utilization and promotes differentiation. Growth hormone induces liver production of insulin-like growth factor-1, which mediates many of the effects of growth hormone.[6]

Growth hormone supports the immune response. Animal models suggest an important role for growth hormone in the development of the immune system. In growth hormone–deficient humans, growth hormone increases the differentiation of B-cell and NK-cell activity. Growth hormone increases IL-2 production by lymphocytes and increases IL-1, TNF-α, and superoxide production by monocytes in animal models and in growth hormone-deficient subjects.[58,65] Growth hormone also improves phagocytic cell function. Like prolactin, growth hormone is produced by cells throughout the immune system.[65]

The hypercatabolic state seen in critically ill patients has been attributed in part to growth hormone dysfunction. Trauma, sepsis, and surgery are thought to induce a state of growth hormone resistance.[64,66] Dopamine infusion and prolonged critical illness are associated with lower mean levels of growth hormone and a pronounced flattening in the normal pattern of pulsatile growth hormone release[54,66] (Figure 102-3). The hyperglycemic catabolic state induced by growth hormone depletion and resistance is compounded by the normal stress response, the effects of immune-derived cytokines, and inadequate calorie delivery in the ICU.[67] Use of exogenous growth hormone to preserve muscle and improve healing has received some interest. Administering growth hormone perioperatively improves nitrogen balance, increases liver protein synthesis, increases muscle strength and lean body mass, and decreases postoperative fatigue over controls. Growth hormone also increases the rate of healing in burn patients and increases the rate of protein synthesis in sepsis and trauma patients.[68]

Unfortunately, an elevated growth hormone level in critically ill patients is associated with increased mortality. In two large European studies of growth hormone use in critically ill adults, patients treated with growth hormone had a 1.9- to 2.4-fold relative risk of mortality, mostly due to multiple organ dysfunction syndrome, shock, or uncontrolled infection. Growth hormone-treated patients also had increased morbidity as measured by prolonged mechanical ventilation and longer ICU stay.[69] Increased endogenous growth hormone is associated with increased mortality in children with meningococcemia.[70] A consensus statement from the Growth Hormone Research Society recommends against use of growth hormone in the acute phase of critical illness.[71]

The reasons behind this association between elevated growth hormone and increased morbidity and mortality are not clearly understood. Growth hormone treatment is associated with an increase in blood glucose concentration, which may support bacterial growth.[67] This hypothesis is supported by evidence that tight glycemic control is associated with a decreased risk of death from sepsis in adult surgical patients.[66] Growth hormone's effects on the immune system may play a role. At very high levels, growth hormone binds in significant quantities to the prolactin receptor. Both of these hormones, at 10 to 20 times physiologic levels, may mediate immunosuppressive effects in vitro.[5,6] At more moderate doses, excessive growth hormone may cause

overshoot of the immune/inflammatory response, which could be detrimental.

For more information on growth hormone and insulin-like growth factor in the ICU, the reader is referred to the excellent reviews by Carroll[67] and G. Van den Berghe.[20]

Morphine and Other Opioids

Almost every pediatric ICU patient is given morphine or one of its relatives. The hypotensive effects of exogenous opioids are well known. Endogenous opioids or endorphins are released in response to stress and play a role in the development of shock. The opiate antagonist naloxone attenuates the hypotensive response to endotoxin in animal models. Endorphins decrease sympathetic outflow, whereas exogenous opiates injected intraventricularly result in sympathetic nervous system activation.[72,73]

Opioids have immunosuppressive effects. Opioid abusers and their animal model counterparts have increased susceptibility to infection and sepsis-related mortality. In animal models, this effect is blocked by naloxone.[74] Opioid use increases metastases and decreases survival in tumor-bearing animals.[75,76] Acutely, centrally acting morphine activates the sympathetic nervous system, which in turn innervates immune tissue. Good evidence indicates that most of the observed immunosuppressive effects of morphine occur via this pathway.[77,78] Morphine also activates the HPA axis, which may lead to cortisol-mediated immune suppression, particularly during chronic administration. Opioids induce immune suppression at analgesic doses by binding to classic, naloxone-sensitive opioid receptors in the brain. In addition, both classic and nonclassic opioid receptors are present on immune cells, but the extent to which morphine interacts directly with these cells to cause immune suppression in vivo is unclear.[79-81]

Morphine reduces the T-cell proliferative response to mitogen, increases T-cell apoptosis, and decreases IL-6 levels in vitro. Morphine decreases B-cell antibody production. In vitro, morphine acts directly to decrease T-cell responsiveness by suppressing IL-2 gene expression, but the extent to which this mechanism is important in vivo is unclear.[79-81] Acute and chronic exposure to morphine decreases splenic and peripheral NK cell activity.[80] NK cells have significant tumoricidal activity, and decreased NK cell function may be associated with an increase in tumor cell dissemination and growth of micrometastases.[76]

Treatment with morphine for as little as 36 to 72 hours impairs macrophage response to macrophage colony-stimulating factor in mice and may affect phagocytosis and superoxide production ex vivo. Macrophages from morphine-treated animals are still sensitive to GM-CSF, a recombinant form of which is available for clinical use. This may represent one of the few methods by which clinicians might antagonize the immunosuppressive effects of morphine.[80]

Opioid use is ubiquitous in critical care and may contribute to lymphocyte depletion observed in the ICU. Because many of the effects of opioids on the immune system occur via the μ receptor, morphine derivatives such as fentanyl likely have the same effect. There are no clinical trials examining the impact of opioid treatment on outcomes from infection. Unfortunately, there is no known analgesic with efficacy comparable to the opioids. When the desired effect is anxiolytic, nonopioid alternatives should be considered. More research on this topic is necessary before therapy can be changed. Patients who are dependent on morphine for pain control may someday be candidates for immune stimulants.

Somatostatin

Somatostatin was first discovered as a potent inhibitor of growth hormone release, but it now is known to also inhibit insulin release, decrease secretion and absorption in the gastrointestinal tract, and decrease splanchnic blood flow.[6] Somatostatin analogues (octreotide) are used for treatment of gastrointestinal hemorrhage.

Somatostatin has direct immunosuppressive effects in vitro. Somatostatin receptors are expressed on peripheral T and B lymphocytes, on activated monocytes, and in hematopoietic precursors.[82] The function of these receptors is under investigation. In the bone marrow, somatostatin inhibits proliferation, particularly in response to granulocyte colony-stimulating factor (G-CSF).[83] Somatostatin also decreases prolactin release by the pituitary, and some of its immunosuppressive effects may occur via this mechanism.[55] The effect of octreotide infusions on immune function in critically ill patients has not been studied.

Other Neuroendocrine–Immune Mediators

Researchers are still discovering new neurotransmitters, hormones, and cytokines, and they continue to recognize new NEI roles for well-known molecules. The molecules described here are examples of this interface. At the time of this writing, there are no known therapies targeting these molecules, but they may someday have clinical relevance. If nothing else, they serve as a reminder of the layers of complexity to the NEI system that we do not yet understand.

Macrophage Migration Inhibitory Factor

Macrophage migration inhibitory factor (MIF) was discovered in the 1950s on the basis of its ability to inhibit the migration of macrophages in capillary tubes. More recently, MIF has been recognized as the unique protein hormone released by the anterior pituitary and the adrenal gland in tandem with HPA axis activation. It also is produced by activated macrophages in response to levels of bacterial lipopolysaccharide that are lower than the levels that stimulate TNF-α production, making it a very early mediator of inflammation.[85]

Like prolactin and substance P, MIF antagonizes some of the peripheral effects of glucocorticoids. It appears to play a major role in the amplification of the immune response. MIF promotes cytokine expression by macrophages and T cells. MIF upregulates the expression of toll-like receptors, which are cell surface receptors involved in recognition of bacterial endotoxin by the innate immune system. MIF levels are elevated in septic shock patients compared with nonseptic critically ill patients and correlate with decreased adrenal responsiveness, and MIF levels increase with the development of ARDS.[86,87]

No therapies for modulating the expression or actions of MIF are available. Drugs that oppose MIF may someday play a role in inflammatory conditions such as ARDS and asthma.

Substance P, Neuropeptide Y, and Calcitonin Gene-Related Peptide

Substance P, a neuropeptide present in afferent nerves in the dorsal horn of the spinal column, was originally discovered to be a mediator of pain sensation. Substance P plays a role in inducing inflammation in response to a variety of irritants and may be part of the CNS pathways involved in psychological stress.[67] Immune cells contain receptors for substance P in addition to other neuropeptides. The actions of substance P in the immune system appear to be proinflammatory and immunosupportive. It induces mast cell degranulation, stimulates lymphocyte proliferation and cytokine release, and may play a role in chronic inflammation.[88,89] In vitro and in vivo, substance P counteracts glucocorticoid-mediated apoptosis.[88]

Substance P is one of a growing group of neuropeptides that have been shown to have immune regulatory function. Others include calcitonin gene-related peptide, neuropeptide Y, vasoactive intestinal peptide, ghrelin, pro-opiomelanocortin-related peptides, and β endorphins.[65] Whether the actions of neuropeptides on immune cells is stimulatory or inhibitory may depend on the activation state of the cells and the T-cell phenotypes.[90] At the time of this writing, little is known about their function in the normal state or the stress response. Currently, there are no known therapeutic agents directed at them. Further research may prove the importance of these molecules.

Clinical Relevance

The acute phase of critical illness is characterized by supranormal release of neuroendocrine mediators from the hypothalamus and pituitary. As a consequence of this secretory activity, short-term goals of blood pressure support and mobilization of fuel substrates are met at the expense of neglecting homeostatic mechanisms, immune function, growth, and repair. When a patient's own fight-or-flight response is insufficient to maintain perfusion, shock ensues. For intensivists, the NEI system represents a set of tools for influencing the hemodynamic, metabolic, and immune/inflammatory state of the patient. In the first hours to days of critical illness, replacement of an inadequate neuroendocrine response with catecholamines, vasopressin, and/or steroids may be lifesaving.

During the acute phase of critical illness, the antiinflammatory effect of steroids and catecholamines may be beneficial in many patients. Although clinical trials of antiinflammatory therapies in sepsis have generally been disappointing, most authors agree there is a subset of patients whose robust inflammatory response puts them at increased risk for early death from septic shock. During the prolonged phase of critical illness, the effects of fight-or-flight mediators, whether endogenous or exogenous, may be harmful.

Decreased levels of anterior pituitary hormones and loss of the normal pattern of pulsatile release of these hormones characterize the prolonged phase of critical illness (see Figure 102-3). ACTH, growth hormone, thyroid-stimulating hormone, prolactin, and luteinizing hormone are all similarly affected. Cortisol levels remain elevated in chronic critical illness despite a decrease in ACTH release. The metabolic consequence of this neuroendocrine milieu is an impaired ability to use fatty acids as fuel substrates and a tendency to store fat and to waste protein from muscle and organs. The immune consequences are impaired lymphocyte and monocyte function and increased lymphocyte apoptosis. In patients who fail to recover but go on to develop multiple organ dysfunction, the state of catabolism and immune suppression persists even in the absence of dopamine, glucocorticoids, or other well-known suppressors of the somatotropic axis.

Because dysfunction of normal homeostatic mechanisms may occur independently of ICU therapies, it may be tempting to label the neuroendocrine profile of chronically critically ill patients "normal." In fact, prolonged critical illness does not occur without medical intervention, and in the natural state these patients would not survive. In some chronically critically ill patients, the neuroendocrine system may fail as other organ systems fail. Investigators must ask what neuroendocrine milieu is associated with the best outcomes, including recovery of organ function, effective wound healing, and freedom from nosocomial infection.

Prolonged use of steroids, opioids, or hemodynamic support likely plays a role in the immune suppression and the suppression of anabolic pathways seen in chronic critical illness. Duration of immune suppression correlates strongly with the incidence of related infection, so even a low-grade immune suppression may become clinically significant over time. Lymphopenia and monocyte deactivation are associated with increased risk for poor outcomes, including nosocomial infection, prolonged hospital stay and mechanical ventilation, multiple organ dysfunction, and death.[91] In a review of autopsies of children who died of multiple organ failure, among those who were admitted with a diagnosis of sepsis, 75% had persistent infection at autopsy, suggesting that some patients with multiple organ failure have clinically significant immune depression.[10]

After the first week of ICU care, as patients move into the chronic phase of critical illness, it is important to begin to think about restoring the capacity to grow, heal wounds, build muscle, and fight infection. Steroids should be tapered as soon as hemodynamics or underlying conditions allow. Morphine and other opioids should be used no more than necessary to control the patient's pain. In situations where catecholamines have no proven benefit, as in the case of "renal dose" dopamine, it may be appropriate to consider whether the negative effects on the immune system and on metabolism outweigh the potential benefits of the drug.

Clinicians should be vigilant for the acquired immune deficiency that occurs in prolonged critical illness. When lymphopenia is persistent, indicators of T- and B-cell function should be measured. Patients with low CD4 counts may benefit from early prophylaxis against fungus or *Pneumocystis carinii* pneumonia. Patients with low immunoglobulin levels may benefit from intravenous immunoglobulin. In the prolonged phase of critical illness, patients may be candidates for immune stimulants, including G-CSF or GM-CSF. Investigational therapies targeting lymphopenia may be available in the near future.

Sepsis

Hector R. Wong, Jeffrey E. Nowak, Stephen W. Standage, and Cláudio Flauzino de Oliveira

PEARLS

- The typical patient with septic shock has simultaneous derangements of cardiovascular function, intravascular volume status, respiratory function, immune/inflammatory regulation, renal function, coagulation, hepatic function, and/or metabolic function.
- The complexity and heterogeneity of septic shock warrants a systematic and multifaceted approach on the part of the pediatric intensivist.
- Although some overlap exists among the terms spanning the sepsis spectrum (systemic inflammatory response syndrome, sepsis, sever sepsis, and septic shock), each term is intended to define a particular patient population.
- Sepsis is now viewed as a dysregulation of the immunologic and inflammatory pathways normally directed toward pathogen eradication and restoration of homeostasis.
- From a clinical standpoint, the treatment of sepsis entails four important goals: initial resuscitation, elimination of pathogen, maintenance of oxygen delivery, and (in the future) carefully directed modulation of the inflammatory response.
- Genomic medicine and systems biology represent novel approaches for studying complex processes such as septic shock.
- The development of robust stratification and phenotyping strategies has the potential to more effectively manage the intrinsic heterogeneity of septic shock, and thus improve the effectiveness of both clinical research and individual patient care.

Management of the patient with septic shock embodies the discipline of pediatric critical care medicine. The typical patient with septic shock has simultaneous derangements of cardiovascular function, intravascular volume status, respiratory function, immune/inflammatory regulation, renal function, coagulation, hepatic function, and/or metabolic function. The degree to which any one of these derangements manifests in a given patient is highly variable and influenced by multiple host and nonhost factors, including developmental stage, presence or absence of comorbidities, causative agent of septic shock, immune/inflammatory status, genetic background, and variations in therapy. These factors combine to profoundly influence the course and ultimate outcome of septic shock.

The complexity of septic shock warrants a systematic and multifaceted approach on the part of the pediatric intensivist. Optimal management requires a strong working knowledge not just of cardiovascular physiology and infectious diseases, but also of multiple organ function/dysfunction, inflammation-related biology, immunity, coagulation, pharmacology, and molecular biology. The pediatric intensivist also needs a working knowledge of genomic medicine for the future management of patients with septic shock. This chapter provides a comprehensive description of the many aspects that influence the development and outcome of septic shock, pathophysiology at the physiologic and molecular levels, contemporary management of septic shock, and what we believe to be the next important future directions in the field. Ultimately, this information must be integrated with bedside experience and clinical acumen, which cannot be supplanted by a book chapter.

Epidemiology

A true picture of the epidemiology of septic shock is clouded by the lack of a reliable case definition. This is true for both the adult and pediatric populations. A few pediatric-specific studies, however, illustrate the importance of septic shock in today's modern intensive care unit (ICU). Proulx et al. analyzed the incidence and outcome of the systemic inflammatory response syndrome (SIRS), sepsis, severe sepsis, and septic shock (see next section for definitions) in a single institution.[1] A total of 1058 admissions were analyzed over a 1-year period. SIRS was present in 82% of patients, 23% had sepsis, 4% had severe sepsis, and 2% had septic shock. The overall mortality rate for this patient population was 6%, with the majority of deaths occurring in patients with multiple organ dysfunction syndrome (MODS). Among the patients with MODS, distinct mortality rates were associated with SIRS (40%), sepsis (22%), severe sepsis (25%), and septic shock (52%). Later studies by Watson et al. provide the most comprehensive epidemiologic surveys of pediatric septic shock to date.[2] By linking 1995 hospital records from seven large states (representing 24% of the United States population) with census data, they estimated an incidence of 42,371 cases of severe sepsis in individuals younger than 20 years of age (0.6 cases/1000 population). The

highest incidence was in neonates (5.2 cases/1000 population), compared with children ages 5 to 14 years who had an incidence of 0.2 cases/1000 population. The overall mortality rate in this population was 10.3% (4364 deaths per year nationally). In addition, patients younger than 1 year of age and patients with comorbidities had higher mortality rates than patients between 5 and 14 years old and patients without comorbidities, respectively. Their study also estimated an annual national health care cost of $1.7 billion associated with severe sepsis.

In a follow-up study, Watson et al.[3] compared the epidemiology of severe sepsis between 1995 and 1999. Using a similar strategy as described for their earlier study, they found a 13% increase in the absolute number of cases of severe sepsis during this time period. The majority of the increase was accounted for by severe sepsis in children younger than 1 year of age. In contrast, the overall mortality rate for severe sepsis decreased from 10.3% to 9.0% during this time period.

In the most recent report on the epidemiology of pediatric sepsis, Czaja and colleagues used the discharge diagnosis of severe sepsis for Washington State to investigate the readmission rates and late mortality for children (1 month to 18 years old) following severe sepsis.[4] From 1990 through 2004, 7183 children were diagnosed with severe sepsis and 6.8% of these patients died during the sentinel admission or within 28 days of discharge. Importantly, death certificates confirmed that an additional 434 (6.5%) of the initial survivors died during the follow-up period with the highest late death rate occurring within 2 years of the initial hospitalization. Although most of the early, as well as the late deaths occurred in children with comorbidities (8% early death, 10.4% late death), 8% of children with no comorbidities died during their initial hospitalization with 2% of the 28-day survivors being classified as late deaths.

Collectively, these data illustrate that septic shock continues to present a major public health problem in terms of incidence, mortality, and health care costs. Nevertheless, there is an ongoing need for quality epidemiologic studies of septic shock in children. Quality epidemiologic studies are necessary for our understanding not only of incidence, but also of the impact of new knowledge and therapies. One major issue that must be addressed is the development of more meaningful and consistent case definitions. Consistent case definitions will also facilitate and improve the design of more effective interventional trials specific to the pediatric population. Equally important is objectively measuring long-term outcomes in these patients (i.e., quality of life) beyond the dichotomy of "alive" or "dead." Progress in this important area is steadily coming to fruition.[5-8]

Definitions

Intuitively, the experienced pediatric intensivist knows when he or she encounters a patient with septic shock. Thus strict definitions of sepsis and septic shock could be viewed as having relatively limited value in daily practice. Despite this common perception, there is a clear need for standard definitions of sepsis and septic shock for three primary reasons. First, with the development of standard definitions, we will be able to more accurately characterize the epidemiologic features of septic shock in the pediatric population. Second, as novel, expensive, and potentially higher risk therapies are developed, it will be important to accurately identify and stratify patients early in the course of septic shock if we are to apply those therapies to the most appropriate groups and realize a more favorable risk/benefit ratio in a given patient population. Finally, standard definitions are crucial to the design of much needed, pediatric-specific interventional trials.

Box 103–1 Criteria for SIRS

The presence of at least two of the following four criteria, one of which must be abnormal temperature or leukocyte count:

1. Core temperature (rectal, bladder, oral, or central catheter) over 38.5° C or under 36° C.
2. Tachycardia, defined as a mean heart rate more than two standard deviations above normal for age in the absence of external stimulus, chronic drugs, or painful stimuli; or otherwise unexplained persistent elevation over a 0.5-hour to 4-hour time period; OR for children less than 1 year old: bradycardia, defined as a mean heart rate under tenth percentile for age in the absence of external vagal stimulus, β-blockers, or congenital heart disease; or otherwise unexplained persistent heart rate depression over a 0.5-hour time period.
3. Tachypnea, defined as mean respiratory rate over ninetieth percentile for age; or the need for mechanical ventilation for an acute process not related to underlying neuromuscular disease or the receipt of general anesthesia.
4. Leukocyte count elevated or depressed for age (not secondary to chemotherapy-induced leukopenia); or more than 10% immature neutrophils.

The International Consensus Conference on Pediatric Sepsis and Organ Dysfunction was convened in 2002 to develop pediatric-specific definitions for SIRS, sepsis, severe sepsis, septic shock, and organ failure, and the results of this conference were subsequently published.[9] The standard terms to describe the sepsis spectrum are systemic inflammatory response syndrome (SIRS), sepsis, severe sepsis, and septic shock. Each term is intended to describe a clinical syndrome having increasing illness severity and relatively increasing specificity, which in turn drives important clinical decision and therapeutic processes.

SIRS is not a diagnosis. The term is intended to represent a state of relative inflammatory/immune activation in a given patient, and is said to be present when a patient meets at least two of the four criteria listed in Box 103-1, one of which must be abnormal temperature or abnormal leukocyte count. Thus, patients with diverse clinical conditions, such as sepsis, pancreatitis, burns, or hypermetabolism following major trauma or surgery, can meet criteria for SIRS. *Sepsis* is defined as SIRS secondary to an infection, either documented by microbiology cultures or in the presence of other clinical evidence of infection. *Severe sepsis* is defined by sepsis criteria plus either cardiovascular dysfunction or acute respiratory distress syndrome, or at least two other dysfunctional organ systems. *Septic shock* is defined by sepsis criteria, plus cardiovascular dysfunction. Importantly, each criterion takes into account the influence of developmental age on physiological variables. The reader is referred to the original publication by Goldstein et al.[9] for further details and definitions of organ dysfunction.

Clinical Presentation

As a syndrome that potentially affects the entire body, the clinical presentation of sepsis is highly heterogeneous. The most common clinical manifestations of sepsis include fever or hypothermia, tachypnea, tachycardia, leukocytosis or leukopenia, thrombocytopenia, and change in mental status. It should be noted however that, in the absence of meningitis, changes in mental status are relatively late manifestations of septic shock and should not be relied upon for early recognition of shock. One of the earliest signs that alerts caregivers to the possibility of infection is fever. A number of the cytokines elicited in response to infection are pyrogens, particularly interleukin (IL)-1β and tumor necrosis factor (TNF)-α. Patients can also have hypothermia, which is more common in infants than older children. Finally, petechiae and/or purpura can be present and are potentially ominous signs of purpura fulminans.[10]

Shock states can be grouped into four broad categories: hypovolemic, cardiogenic, obstructive, and distributive shock. Septic shock is unique in that all four forms of shock may be involved simultaneously. The patient may have hypovolemic shock resulting from capillary leak, increased insensible water losses, poor intake, and/or decreased effective blood volume secondary to venodilation and arterial dilation (i.e., increased vascular capacitance). Cardiogenic shock manifests as depressed myocardial contractility and low cardiac output secondary to myocardial-depressant effects of bacterial toxins and inflammatory cytokines. Obstructive shock can result indirectly from diffuse microvascular thrombosis, or directly from abdominal compartment syndrome. Distributive shock can result directly from abnormally low systemic vascular resistance, leading to maldistribution of blood flow; or can result indirectly from the inability of tissues to adequately use oxygen at the mitochondrial level (i.e., cytopathic hypoxia).

The degree to which an individual patient manifests these physiologic perturbations is highly variable. In some cases, patients display increased cardiac output with diminished systemic vascular resistance. The presenting symptoms in this type of patient are tachycardia, a hyperdynamic precordium, bounding pulses, and warm, flushed skin characteristic of the distributive mode of shock or the so-called "warm" shock state. Despite this clinical appearance, the perfusion of major organs during warm shock may remain highly compromised secondary to maldistribution of blood flow. Alternatively, a patient with depressed cardiac output and elevated systemic vascular resistance has cool, mottled skin with diminished pulses and poor capillary refill characteristic of the "cold" shock state. Limited data and our collective anecdotal experience suggest that this latter presentation, cold shock, is more common in younger children compared to teenagers and adults.[11] Recently, it has been suggested that patients who develop community-acquired septic shock more commonly present to the ICU with signs of "cold" shock; whereas patients that develop septic shock secondary to catheter-related infections more commonly present to the ICU with signs of "warm" shock.[12] It is important to recognize that a given patient may transition from one shock state to another, and that recognition and reassessment of these classes of shock are absolutely central to the choice of cardiovascular medications.

Patients with sepsis often have presenting symptoms of respiratory abnormalities, including tachypnea and hypoxia. Tachypnea alone can reflect a compensatory, respiratory alkalosis aimed at counteracting a metabolic acidosis secondary to shock. Chest radiograph in this setting often reveals a relatively small cardiac silhouette (potentially reflective of relative hypovolemia) with few vascular markings. However, in the face of capillary leak and decreased myocardial function, patients with septic shock often develop pulmonary edema and acute respiratory failure as fluid resuscitation proceeds. Alternatively, respiratory abnormalities can reflect pneumonia as the primary source of infection, and/or the development of acute respiratory distress syndrome (ARDS). In these situations, chest roentgenography will display patterns of pulmonary infiltrates characteristic of the respective scenarios.

All organ systems can be adversely affected by poor perfusion and decreased oxygen delivery. In addition, all organ systems can be directly or indirectly injured by bacterial toxins, circulating cytokines, and the products of activated white blood cells. The end result of these complex and interrelated pathologic mechanisms is multiple organ dysfunction syndrome, which describes the serial and progressive failure of various organ systems, and is associated with increased morbidity and mortality.[13-15]

Pathogenesis

A large number of clinical and basic science studies have focused on the mechanisms underlying the development of sepsis. At least three major hypotheses have been proposed to explain the development of sepsis and its sequelae. The first hypothesis attributes the development of sepsis to an excessive or uncontrolled host inflammatory response. This "proinflammatory" hypothesis is broadly consistent with the concept of SIRS, and is generally well supported by experimental and clinical data. However, a large number of clinical trials aimed directly at inhibition of various components of this putative excessive inflammatory response have failed, thus leading to the development of alternative hypotheses. One such alternative hypothesis states that sepsis is not directly the result of excessive inflammation, but rather a more direct manifestation of failed antiinflammatory responses. Thus in this alternative hypothesis there is direct failure of the compensatory antiinflammatory response syndrome (CARS), which subsequently permits unchecked proinflammatory responses. Related to the CARS concept is the concept of immunoparalysis, which embodies the third overall hypothesis to account for the clinical manifestations of sepsis. The hypothesis of immunoparalysis postulates that sepsis is not a manifestation of too much or too little inflammation, but rather a form of acquired immunodeficiency (both innate and adaptive immunity), leading to an inability to effectively clear pathogens and their products, which thereby cause direct tissue and organ injury.[16,17]

A conceptual framework for integrating these three hypotheses/paradigms is provided in Figure 103-1. All three paradigms are biologically plausible and supported by the existing literature.[18] While seemingly vastly different in concept, they are not mutually exclusive in the context of a highly heterogeneous syndrome such as human sepsis. That is, it is plausible that all three paradigms are valid across a given cohort of heterogeneous patients with sepsis. In addition, each paradigm has the potential to influence all of the other paradigms, as indicated in Figure 103-1. The following sections review the

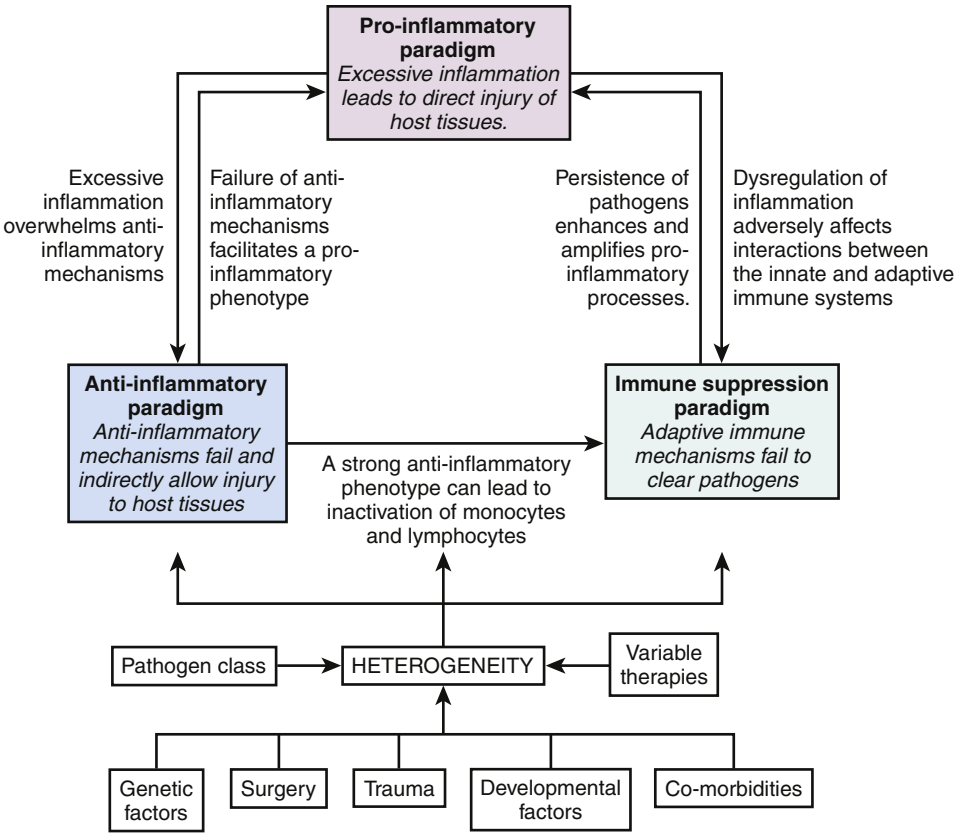

Figure 103–1. The three major paradigms for understanding the pathophysiology of sepsis and septic shock. Although the three paradigms are mechanistically distinct, they are not mutually exclusive. Each paradigm has the potential to influence the other paradigms, and all are potentially operative in a heterogenous patient cohort. Heterogeneity is a major component of septic shock and results from multiple host and environmental factors.

existing literature supporting these three paradigms and will serve to frame the important concept of heterogeneity in sepsis. A major challenge in the field of sepsis is to more effectively understand how a given patient fits into one of these three paradigms (i.e., stratify or phenotype).

Pathogen Recognition and Signal Transduction

The fundamental role of the immune system is to detect, contain, and eradicate invading pathogens. The first step in this process involves pathogen recognition, which is achieved by the activation of pattern recognition receptors (PRRs) on immune cells by pathogen-associated molecular patterns (PAMPs).[19] Examples of PAMPs include lipopolysaccharide from the cell walls of gram-negative bacteria; lipoteichoic acid from the cell walls of gram-positive bacteria; mannans from the cell walls of yeast; double-stranded RNA of viruses; and unmethylated, CpG-rich DNA unique to bacterial genomes. The most well studied PRRs include the family of toll-like receptors (TLRs), which can have relatively specific recognition of PAMPS.[19] For example, TLR-4 recognizes lipopolysaccharide, wherease TLR-2 recognizes lipoteichoic acid. Other examples of PRRs or PRR components include CD-14, scavenger receptors, NOD receptors, pentraxins, and collectins.[20]

Engagement of PRRs on the cell surface of immune cells, by PAMPS, leads to activation of the immune system in the form of phagocytosis, proliferation, and production/secretion of cytokines. The latter process, cytokine expression, serves to orchestrate, direct, and amplify the innate and adaptive immune response toward pathogen eradication. However, if this process becomes dysregulated, this same production of cytokines, though required for pathogen eradication, can inadvertently lead to auto-injury of the host.

Much of the activation of the immune system upon PRR activation relies upon signal transduction mechanisms, which serve to transfer the signal of pathogen recognition at the cell surface to the intracellular compartment in order to induce new gene expression or a change in cellular function. One of the major signal transduction mechanisms of the immune system is the NF-κB pathway, which serves as a master "switch" for the expression of a wide variety of genes involved in inflammation and immunity. Indeed, activation of the NF-κB pathway is a major signaling pathway in the pathophsiology of sepsis, and may represent a potential therapeutic target.[21,22] Another major signaling pathway for the regulation of genes involved in inflammation and immunity is the mitogen-activated protein kinase (MAPK) signaling pathway. The MAPKs consist of three major families: p38 MAPK, extracellular-regulated protein kinase (ERPK), and c-Jun N-terminal kinases (JNK). These major kinase families are also referred to as a stress-activated protein kinases (SAPKs). Similar to the NF-κB pathway, the MAPKs are also regarded as potential therapeutic targets in the context of sepsis.[21,23,24] Finally, there is now increased attention on the phosphatase family of intracellular signaling molecules in the

Box 103–2 Common Features of Cytokines

- Cytokine secretion is relatively brief and self-limited.
- Secretion of many cytokines requires new mRNA transcription and new protein translation.
- Expression and secretion is regulated by specific cellular signals.
- A given cytokine can have multiple cellular sources.
- A given cytokine can have multiple cellular targets.
- A given cytokine can have multiple functions regarding cellular function or activation.
- Cytokines can have redundant activities/functions with other cytokines.
- Many cytokines regulate the activity and expression of other cytokines.

context of sepsis. Whereas kinases direct cellular signaling by adding phosphate groups to intracellular signaling proteins, phosphatases serve to remove phosphate groups from these same intracellular signaling proteins and can thus serve to modulate proinflammatory cell signaling.[25,26]

Cytokines as Principal Mediators of the Sepsis Response

Cytokines represent a broad family of proteins that have paracrine, autocrine, and endocrine properties, and the ability to regulate and modulate virtually all aspects of immunity and inflammation. Common features of cytokines are provided in Box 103-2. Herein we will review a selected group of cytokines thought to play an important role in the pathophysiology of sepsis.

Tumor Necrosis Factor-α

Tumor necrosis factor alpha (TNF-α) is perhaps the most well-studied cytokine that is causally linked to sepsis. Evidence for TNF-α mediation of sepsis includes the observations that TNF is produced by hematopoietic cells; its expression is temporally related to the development of shock; it can by itself induce experimental septic shock in animals; and passive immunization against TNF blunts the endotoxin-induced sepsis response.[27] The proinflammatory effects of TNF include leukocyte-endothelial cell adhesion, transformation to a procoagulant phenotype, induction of inducible nitric oxide synthase, and functioning as a principal "early" cytokine that induces the subsequent cascade of mediators and cytokines promulgating the septic response. Despite a plethora of preclinical studies demonstrating the important proximal role of TNF-α in the pathophysiology of sepsis, multiple clinical trials targeted at neutralization of TNF-α activity have thus far failed to demonstrate efficacy.[28]

Interleukin-1β

Interleukin (IL)-1β has many redundant biological properties to those of TNF-α, and is also considered to be a major early cytokine in the sepsis response.[29] IL-1β leads to inflammatory and immune cell activation via the NF-κB and MAPK pathways. Also, similar to TNF-α, clinical trials targeted at neutralization of IL-1β activity have thus far failed to demonstrate efficacy despite promising preclinical data.

Interleukin-6

Interleukin-6 expression is highly dependent on TNF-α and IL-1β, and is consistently found to be elevated during the course of sepsis.[30] IL-6 is a pleiotropic cytokine possessing a number of functions including driving the acute-phase response in hepatocytes, differentiating myeloid cells, stimulating immunoglobulin production, and activating T-cell proliferation.[31] Because increased IL-6 admission levels have been correlated with death in the context of sepsis, there has been interest in using IL-6 as a stratification biomarker for interventional clinical trials in sepsis. While this stratification approach has been highly effective in animal models of sepsis,[32] it has thus far failed when applied in the clinical setting.[33]

Interleukin-8

Interleukin-8 is a canonical member of the chemokine subclass of cytokines.[34] The term "chemokine" refers to the ability of certain cytokines to serve as chemoattractants, which direct leukocyte movement to sites of infection and inflammation (chemotaxis). Both TNF-α and IL-1β can induce IL-8 production from a variety of cells, including endothelial cells, macrophages, neutrophils, and epithelial cells. IL-8 is the principal human chemoattractant for neutrophils, and appears to play a major role in the recruitment of neutrophils to the lungs in patients with sepsis-induced acute respiratory distress syndrome.[35] Recently, it was demonstrated that serum IL-8 measurements within 24 hours of presentation to the ICU can robustly predict good outcome in children with septic shock receiving standard care.[36] Other chemokines relevant to the pathophysiology of septic shock include monocyte chemoattractant protein 1 (MCP-1) and macrophage inflammatory protein-1 (MIP-1).[34]

Macrophage Migration Inhibitory Factor

Macrophage migration inhibitory factor (MIF) has recently emerged as an important cytokine in the pathophysiology of sepsis, and high levels of MIF in patients with septic shock and ARDS correlate with poor outcome.[37,38] MIF possesses a number of biological activities generally directed toward a proinflammatory phenotype, including skewing of naive T cells toward a Th1 phenotype. An unusual feature of MIF is that its secretion is enhanced by glucocorticoids, whereas the expression and activity of many cytokines are suppressed by glucocorticoids. In turn, MIF has the ability to antagonize the antiinflammatory effects of glucocorticoids.

Interleukin-18

Interleukin-18 has also recently emerged as an important cytokine in the pathophysiology of sepsis.[39] Depending on the local cytokine milieu, IL-18 has the ability to skew naive T cells toward either a Th1 or Th2 phenotype. In addition, it appears that IL-18 may serve as an early biomarker to distinguish between gram-positive and gram-negative sepsis.

Interleukin-10

Interleukin-10 is the best studied and most well known antiinflammatory cytokine.[40,41] As an antiinflammatory cytokine, IL-10 serves to antagonize the proinflammatory effects of other cytokines and can thereby keep inflammation "in check." IL-10 inhibits expression of cytokines such as TNF-α, IL-1β, and IL-8, and can inhibit expression of adhesion molecules. In

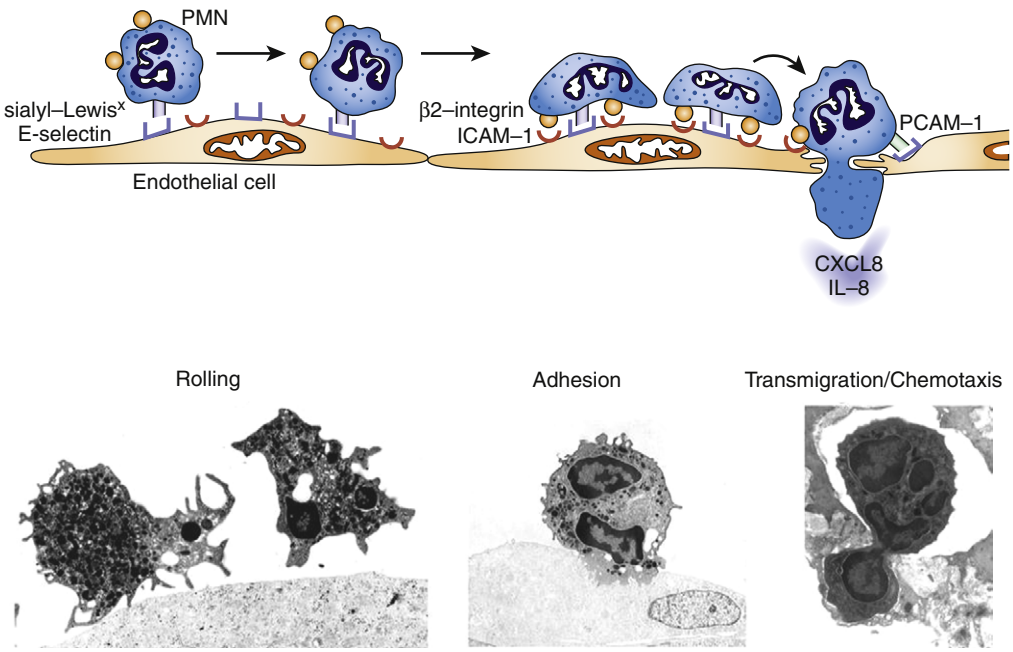

Figure 103–2. Schematic and corresponding electron micrographs highlighting the process of leukocyte-endothelial cell adhesion and leukocyte transmigration from the intravascular compartment to the extravascular compartment. Cytokine-mediated activation of the selectin family of endothelial cell adhesion molecules mediate neutrophil "rolling," followed by ICAM-1-mediated adhesion. After adhesion, neutrophils transmigrate across "openings" between enothelial cell junctions to enter the extravascular space. The transmigration process is directed by chemokines that serve as homing signals for neutrophils and other leukocytes. *(Courtesy Thomas P. Shanley, MD, University of Michigan.)*

addition, IL-10 can "deactivate" monocytes by downregulating the expression of MHC surface molecules. Thus IL-10 has a number of interesting properties that could potentially be leveraged therapeutically to limit excessive inflammation during sepsis. This theoretical consideration must be tempered by the ability of IL-10 to deactivate monocytes and thereby potentially impair the ability to adequately clear infection (i.e., the immune suppression paradigm depicted in Figure 103-1). Indeed, it has been reported that in children with multiple organ dysfunction syndrome, higher plasma IL-10 levels correlate with higher mortality, and higher monocyte mRNA levels of IL-10 correlate with increased length of stay in the ICU.[42] Similar observations have been reported in adult patients with septic shock.[43]

High-Mobility Group Box 1

High-mobility group box 1 (HMGB-1) has long been known as a nonhistone DNA-binding protein. More recently, it has been recognized that HMGB-1 also exists in the extracellular compartment, appears to have proinflammatory properties that may play a role in the pathophysiology of sepsis, and may represent a potential therapeutic target for sepsis.[44] The attraction of HMGB-1 as a therapeutic target in sepsis stems from the observation that it may be a "late mediator" of sepsis in as much as it appears in the extracellular compartment within a time frame that is considerably later than that seen with the canonical sepsis cytokines such as TNF-α and IL-1β. Thus the kinetics of HMGB-1 expression provide a potential therapeutic window that is clinically feasible to exploit. This temporal observation is evident in both experimental models of sepsis and in humans with established septic shock.[45] The biologic properties of HMGB-1 appear to involve activation of toll-like receptors and the receptor for advanced glycation end products (RAGE). More recently, it has been suggested that HMGB-1 intrinsically possesses very little proinflammatory biological activity, but forms highly proinflammatory complexes with cytokines (e.g., IL-1β) and PAMPS (e.g., bacterial DNA and lipopolysaccharide).[46]

HMGB-1 is also a prime example of a class of molecules known as "alarmins" or danger/damage-associated molecular patterns (DAMPs).[47] Broadly speaking, DAMPs represent a class of molecules that normally exist in the intracellular compartment at baseline, but are released from damaged cells into the extracellular compartment during conditions such as trauma or sepsis. DAMPs appear to signal through many of the same PRRs that recognize pathogens, and therefore have the ability to activate the immune/inflammatory system. Because DAMPs are released from damaged cells, they can serve to "alert" the inflammatory system of systemic "damage" or "danger" and can therefore induce appropriate and adaptive activation of defense mechanisms. Alternatively, excessive DAMP-mediated activation of PRRs can lead to unnecessary and maladaptive amplification of inflammation that is damaging to host tissues. Other examples of PAMPs include calgranulins, hepatoma-derived growth factor, heat shock proteins, and uric acid. In this regard, heat shock proteins have been reported to be substantially elevated in the serum of children with septic shock.[48,49]

Adhesion Molecules

An important breakthrough in the molecular understanding of sepsis-induced organ dysfunction came with the identification of the processes responsible for the infiltration of leukocytes into tissues.[50] The "leukocyte-endothelial cell adhesion cascade" (Figure 103-2) is characterized by early cytokine-mediated activation of the selectin family of endothelial cell adhesion molecules that can mediate a process of neutrophil

"rolling," whereby sialyated moieties constitutively present on neutrophils interact with selectins on the endothelial cell membrane (e.g., E-selectin). In the second phase, activation of the "rolling" neutrophil causes increased expression and activation of the integrin family of adhesion molecules that interact with the similarly upregulated intercellular adhesion molecule (ICAM)-1 on the endothelial cell surface. This ligand interaction facilitates firm adhesion of the neutrophil to the endothelium. Subsequently, in response to a variety of chemotactic molecules, neutrophils transmigrate through the endothelial junctions to the site of inflammation. Release of a variety of radical species, both oxygen- and nitrogen-based, and proteases by the activated neutrophils can contribute to pathogen eradication, but paradoxically can also cause endothelial and tissue injury.

Nitric Oxide

Nitric oxide (NO) was discovered in the 1980s to be the molecule responsible for endothelial-derived relaxation of blood vessels.[51,52] Since that time, NO has received tremendous attention as a potential mediator of septic shock.[53] NO is produced by the enzyme nitric oxide synthase (NOS), which converts arginine and oxygen to NO and citrulline. Human NOS exists as three different isoforms (NOS 1, 2, and 3) and each isoform has relatively unique tissue localizations, requirements for NO production, and kinetics of NO production. Several features of NO-related biology support an important role in the pathophysiology of sepsis. First, NOS2 (also referred to as *inducible NOS*) is expressed in response to proinflammatory signals (e.g., lipopolysaccharide, TNF-α, and IL-1β) and produces large amounts of NO for prolonged periods of time. Second, NO can induce pathologic vasodilation and can function as a myocardial depressant. Third, NO can function as an oxidant either alone or by contributing to formation of other highly oxidizing, reactive molecules such as peroxynitrite. Fourth, NO has the potential to negatively affect mitochondrial function. Finally, elevated levels of NO metabolites have been well documented in children with septic shock and the levels correlate with the degree of cardiovascular dysfunction.[54,55] Despite these intriguing biological properties, and a wealth of preclinical data testing the efficacy of NOS inhibition, clinical trials targeted at NOS inhibition have failed to demonstrate efficacy.[56] Because NO has a myriad of biological properties important for maintenance of homeostasis (particularly when NO is produced by the NOS1 and NOS3 isoforms), this lack of efficacy may represent the timing and specificity of NOS isoform inhibition.

The Coagulation Cascade

It is now well established that the inflammatory cascade is directly linked to the coagulation cascade, and that the coagulation cascade can be pathologically activated in the context of sepsis.[57,58] This pathological activation leads to disseminated intravascular coagulation, which subsequently leads to endothelial cell dysfunction and microvascular thrombosis. If the endothelial dysfunction and microvascular thrombosis progress to a critical threshold, end-organ failure ensues.

A complex network of multiple mediators takes part in this pathologic process, including proinflammatory cytokines, tissue factor, antithrombin III, protein C, protein S, tissue factor pathway inhibitor, and plaminogen activator inhibitor type 1 (PAI-1). Increased PAI-1 levels are a particularly strong feature of severe cases of meningococcemia and may be causally linked to a polymorphism in the promoter region of the PAI-1 gene.[59,60] Depressed levels of the endogenous anticoagulants, antithrombin III, protein C, and protein S are consistently documented in the context of septic shock. These observations have led to multiple clinical trials in which recombinant forms of these endogenous anticoagulants have been administered to patients with septic shock. Thus far the only strategy that has been shown to reduce mortality is activated protein C (APC), which now has Food and Drug Administration (FDA) labeling specifically for adult patients with septic shock.[61] The beneficial affects of APC in septic shock are thought to be secondary to both prevention of microvascular thrombosis and an antiinflammatory effect.[62] Unfortunately, a Phase III trial of APC therapy in children with septic shock (the RESOLVE trial) failed to demonstrate efficacy.[63] The RESOLVE trial was terminated after the second interim analysis due to little chance of reaching the primary efficacy endpoint. In addition, there was an increased risk of serious bleeding events in patients younger than 2 months of age. Nonetheless, the RESOLVE trial represents the largest and best-organized pediatric septic shock trial to date and provides an important context and reference point for all future interventional trials in the field of pediatric critical care medicine.

Related to the paradigm of altered coagulation playing an important role in the pathophysiology of sepsis is the concept of thrombocytopenia-associated multiple organ failure (TAMOF).[64] New-onset thrombocytopenia in critically ill patients, including patients with sepsis, correlates with the evolution of persistent organ failure and poor outcome. The mechanistic link between thrombocytopenia and organ failure is thought to involve a form of microangiopathy analagous to thrombotic thrombocytopenic purpura, involving substantial decreases of ADAMTS-13 (A Disintegrin and Metalloprotease with ThromboSpondin motifs). ADAMTS-13 regulates microvascular thrombosis by cleaving the large thrombogenic von Willebrand factor multimers into smaller, less thrombogenic forms. Prelminary experience indicates that plasma exchange restores ADAMTS-13 levels and restores organ function in children with TAMOF.[65] The future conduct of large, multicenter, randomized trials will be imperative to objectively establish the potentially exciting role of plasma exchange in this patient population.

The Peroxisome Proliferator-Activated Receptor-γ Pathway

The peroxisome proliferator-activated receptor-γ (PPARγ) is a member of the PPAR nuclear receptor superfamily and a ligand-activated transcription factor having well-known effects on lipid metabolism and cell proliferation.[66] The thiazolidinedione class of insulin-sensitizing drugs are well known PPARγ ligands (activators) and are currently widely used in the management of type II diabetes. Recently, it has become evident that pharmacologic activation of PPARγ has important antiinflammatory effects that are of significant benefit in experimental models of critical illness, including sepsis.[67-71] The recent demonstration that PPARγ expression and activation is indeed altered in children with septic shock, coupled with the availability of FDA-approved PPARγ ligands,

opens up the realistic possibility of conducting clinical sepsis intervention trials focused on PPARγ activation in the near future.[72]

The Paradigm of Sepsis as an Adaptive Immune Problem

Our conceptual framework of the pathophysiology of septic shock has evolved over the last decade to include the concept of immune paralysis. Whereas septic shock has been traditionally viewed as being a reflection of uncontrolled hyperinflammation (i.e., an innate immunity problem), it is now thought that septic shock also has a strong, perhaps predominant, "antiinflammatory" component that can be manifest as immune suppression and the relative inability to effectively clear an infectious challenge (an adaptive immunity problem).[16,17,73,74] For example, monocyte deactivation related to decreased major histocompatibility complex (MHC) gene mRNA expression and decreased surface expression of MHC molecules have been previously demonstrated in patients with septic shock, including children.[42,43,75,76] With regard to lymphocyte dysfunction, Heidecke and colleagues demonstrated that adult patients with intraabdominal infections and septic shock have defective T cell proliferation and defective T cell–dependent cytokine secretion, all of which is consistent with anergy/immune suppression.[77] Felmet and colleagues identified prolonged lymphopenia and apoptosis-associated depletion of lymphoid organs as independent risk factors for the development of nosocomial infections and multiple organ failure in critically ill children.[78] Animal studies have well documented the requirement of an intact T-cell system to adequately combat a septic challenge.[74,79] More recently, animal-based experiments have demonstrated that experimental septic shock is characterized by widespread apoptosis of T cells, and that preventing T-cell apoptosis positively impacts the outcome of experimental sepsis.[80-87] Importantly, the concept of T-cell apoptosis in human sepsis has been indirectly corroborated by autopsy studies, including children,[78,88] and lymphocyte-based immunophenotyping was recently demonstrated to effectively stratify septic shock outcome in adults.[89] Finally, it has been recently demonstrated in experimental models that alterations of the adaptive immune system in sepsis can persist well beyond the acute period (up to at least 6 weeks) via epigenetic mechanisms affecting dendritic cells.[90,91] Despite these data, formal studies of T-cell function and adaptive immunity in pediatric septic shock have never been conducted in a systematic and comprehensive manner. Such studies hold the promise of radically changing our conceptual approach to the long sought, but not yet realized, goal of rational immune modulation in septic shock.

Genomic Medicine and Sepsis

The initial completion and publication of the human genome, the development of molecular biology tools for efficient high-throughput data generation, and the evolution of the field of biomedical informatics, have combined to generate a new field termed "genomic medicine" and the related field of "systems biology." All aspects of medicine are potentially amenable to the concepts of genomic medicine and systems biology, including pediatric sepsis. One skeptical perspective of this concept is that clinical pediatric sepsis is overly heterogeneous and multifactorial to be credibly interrogated by the current genomic and systems biology approaches. An alternative, and more optimistic, perspective is that the concepts of genomic medicine and systems biology are ideally suited to more effectively address the complex syndromes that we encounter in pediatric critical care medicine, such as septic shock. Herein we will address the two areas of genomic medicine that have been most well developed in the field of pediatric septic shock: candidate-gene association studies and genome-wide expression profiling.

Genetic Influence and Septic Shock

Susceptibility to sepsis and the clinical course of patients with sepsis are both highly heterogeneous, thus raising the strong possibility that the host response to infection is, at least in part, influenced by heritable factors (i.e., genetics).[92] A landmark study by Sorensen et al., published more than 20 years ago, provides strong evidence linking genetics and susceptibility to infection.[93] This study involved a longitudinal cohort of more than 900 adopted children born between 1924 and 1926. The adopted children and both their biologic and adoptive parents were followed through 1982. If a biologic parent died of infection before the age of 50 years, the relative risk of death from infectious causes in the child was 5.8 (95% confidence interval, 2.5 to 13.7), which was higher than for all other causes studied, including cancer and cardiovascular/cerebrovascular disease. In contrast, the death of an adoptive parent from infectious causes did not confer a greater relative risk of death in the adopted child.

More recently, investigations attempting to link genetics with sepsis have largely focused on candidate-gene association studies and gene polymorphisms. A gene polymorphism is defined as the regular occurrence (>1%) in a population of two or more alleles at a particular chromosome location. The most frequent type of polymorphism is called a single nucleotide polymorphism (SNP): a substitution, deletion, or insertion of a single nucleotide that occurs in approximately 1 per every 1000 base pairs of human DNA. SNPs can result in an absolute deficiency in protein, an altered protein, a change in the level of normal protein expression, or no discernible change in protein function or expression. There is a growing body of literature linking SNPs within several genes that regulate inflammation, coagulation, and the immune response with critical illness, and several excellent reviews exist on the topic.[94-97]

The signaling mechanisms involved in pathogen recognition, the immune response, and inflammation were described in previous sections. Herein, we will provide an overview of relevant SNPs that have been described in many of the genes involved in these signaling mechanisms. TLR-4 (the primary receptor for recognition of lipopolysaccharide) mutations have been described in humans, all of which increase susceptibility to infections secondary to gram-negative organisms.[98] While several SNPs in the TLR-4 receptor gene have been described, few have been found to be associated with an increased risk of septic shock or septic shock-related mortality in children. For example, an adenine for guanine substitution 896 base pairs downstream of the transcription start site for TLR-4 (+896) results in replacement of aspartic acid with glycine at amino acid 299 (Asp299Gly). The Asp299Gly polymorphism has been associated with reduced expression

and function of the TLR-4 receptor in vitro.[98,99] Furthermore, adults who carry the Asp299Gly polymorphism appear to be at increased risk for septic shock and poor outcome in several cohort studies.[100-102] While children who carry the Asp299Gly polymorphism appear to be at increased risk of urinary tract infection, this SNP does not appear to influence either the susceptibility or severity of meningococcal septic shock in children.[103,104] These results were further corroborated in a cohort study involving over 500 Gambian children.[105]

SNPs related to other members of the LPS-receptor complex (e.g., CD14, MD-2, and MyD88) have been studied in adult populations, but no such studies have yet to be performed in children.[101,106-109] SNPs in other classes of toll-like receptors have also been studied. For example, gene polymorphisms of TLR-2, the primary pattern recognition receptor for gram-positive bacteria, have been associated with increased risk of infection in children and adults.[110-112]

Several SNPs affecting cytokine expression have been described, but the corresponding gene association studies in critically ill adults with septic shock have been conflicting.[96,97,113] For example, two allelic variants of the TNF-α gene have been described: the wild-type allele TNF1 (guanine at –308A), and TNF2 (adenosine at –308A). The TNF2 allele has been associated with higher expression of TNF-α and increased susceptibility to septic shock and mortality in at least one study involving critically ill adults.[114] Nadel and colleagues found an increased risk of death in critically ill children with meningococcal septic shock who carried the TNF2 allelic variant.[115] Several additional SNPs in TNF-β, IL-1, IL-6, IL-8, and IL-10 have also been shown to influence susceptibility to and severity of septic shock in children.[116-122]

Because dysregulation of the coagulation cascade plays an important role in the pathophysiology of septic shock, several studies have examined polymorphisms of key genes involved in coagulation. For example, the 4G allele of a deletion/insertion (4G/5G) SNP in the promoter region of the plasminogen-activator inhibitor type-1 (PAI-1) gene has been associated with higher plasma concentrations of PAI-1. The 4G allele increases susceptibility to and severity of septic shock, as well as increasing the risk of mortality in children with meningococcal septic shock.[59,123-125] In addition, an SNP in the protein C promoter region has been associated with susceptibility to meningococcemia and illness severity in children.[126]

SNPs in genes involved in phagocytosis and the complement cascade have also been studied in the context of septic shock. For example, SNPs that affect function have been described in virtually all family members of the Fcγ receptor (important for phagocytosis), and several of these SNPs have been associated with susceptibility to meningococcal sepsis, severity of meningococcemia, and poor outcome from meningococcal septic shock.[127-133] In addition, an association between the FcγRIIa polymorphism and infection with other encapsulated bacteria has also been reported.[134,135] Several SNPs in the mannose-binding lectin (MBL) gene have been associated with increased susceptibility to infection, as well as increased illness severity.[136-141] Finally, an SNP of the bactericidal/permeability-increasing protein (BPI) gene has also been associated with increased mortality from septic shock in children.[142] This polymorphism is particularly interesting given that a well-conducted Phase III trial of recombinant BPI in children with septic shock failed to demonstrate efficacy.[143]

It is likely that many more studies are forthcoming in the future that will attempt to link SNPs with the susceptibility and/or outcome of pediatric septic shock, and all need to be carefully considered and evaluated. With respect to validity and wide clinical acceptance, the ideal candidate-gene association study requires several important qualities including biological plausibility, large sample sizes, a priori hypothesis statements and power calculations, accounting for confounding factors, and independent validation.[144]

Genome-Wide Expression Profiling in Children with Septic Shock

The development of microarray technology has provided an unprecedented opportunity to efficiently measure genome-wide mRNA expression patterns in clinical samples. Recently, this approach has been leveraged to understand more comprehensively the pathophysiology of pediatric septic shock, and as a means of discovery and hypothesis generation.

The first publication involving genome-wide expression patterns in pediatric septic shock consisted of 42 children with septic shock that were compared to 15 normal controls.[145] RNA samples were derived from whole blood samples obtained within 24 hours of admission to the pediatric intensive care unit with septic shock. As would be predicted, this comparison between two biological extremes (i.e., normal vs. septic shock), demonstrated a large number of genes (>2000) that were differentially expressed/repressed in patients with septic shock, relative to normal controls. Also as would be expected, the upregulated genes in the patients with septic shock corresponded significantly with functional annotations (i.e., attaching biological information to genomic elements) related to immunity and inflammation.

The most novel finding of this initial genome-wide expression profiling study surrounded the genes that were significantly repressed in the patients with septic shock, relative to controls (more than 1000 genes). Surprisingly, a large number of these repressed genes significantly corresponded to functional annotations and ontologies (i.e., gene attributes across all species) related to zinc biology. Thus, this initial approximation of the genomic response of pediatric septic shock suggested that pediatric septic shock is characterized by repression of a large number of genes that either directly participate in zinc homeostasis, or directly depend on zinc homeostasis for normal functioning. Consistent with this observation, the patients with septic shock that did not survive had significantly lower serum zinc levels compared to the patients with septic shock that survived. These data have generated the testable hypothesis that altered zinc homeostasis may play a role in the pathophysiology of septic shock, and is consistent with the known links between zinc and immune function.[146] Recently, Knoell and colleagues[147] independently corroborated the potential validity of this hypothesis by demonstrating that zinc depletion leads to increased death in a murine model of sepsis, and that zinc supplementation partially reverses this phenotype.

The second microarray-based study in pediatric septic shock focused on longitudinal expression profiles, which consists of comparing gene expression patterns in the same patient cohort over time.[148] RNA samples were obtained within 24 hours of admission to the PICU ("day 1"), and 48 hours later ("day 3"). Thirty children having complete microarray data

on day 1 and day 3 were compared to 15 normal controls. The upregulated genes in the patients with septic shock again corresponded to multiple signaling pathways and gene networks associated with inflammation and immunity. One of the most notable signaling pathways represented by the upregulated gene lists was the IL-10 signaling pathway. As described above, IL-10 is a canonical antiinflammatory signaling molecule for the adaptive immune system in that it represses Th1 cytokine production (lymphocyte inactivation), MHC class II-mediated antigen presentation, and costimulatory molecules for macrophages.[149] A large number of genes corresponding to the IL-10 signaling pathway were persistently upregulated in children with septic shock on both days 1 and 3.

The downregulated gene expression patterns in this longitudinal study again demonstrated large-scale repression of genes corresponding to zinc-related biology. This pattern of repression persisted, to a similar degree, from day 1 to day 3. Another notable gene repression pattern involved T cell receptor signaling and the antigen presentation pathway. Again, this pattern of gene repression was evident as early as day 1, and persisted well into day 3.

In summary, this follow-up study focused on longitudinal genome-wide expression profiles demonstrated persistent repression of genes corresponding to the adaptive immune system. This observation suggests that the pathophysiology of pediatric septic shock may represent a failure of the adaptive immune system and is well in line with the paradigm of "sepsis as an adaptive immune problem," as described above.[16,17,78,79,85,86,88,150-152]

The third microarray-based study in pediatric septic shock focused on validation of previous observations by way of formal class prediction modeling and by the application of alternative filtering and statistical approaches.[153] This study made use of the original data as the "training data set" and a new cohort of patients with septic shock as the "test" or "validation" data set. Using two distinct class prediction algorithms, the gene list derived from the training data set was able to identify the separate cohort of patients with septic shock in the validation data set with 100% accuracy. In addition, the application of alternative gene filtering and statistical approaches to the validation cohort of patients yielded similar observations to that derived from the original data. Namely, the validation data cohort of children with septic shock was also characterized by large-scale repression of genes corresponding to zinc-related biology and adaptive immunity.

The most recent microarray-based studies in pediatric septic shock have addressed two distinct questions: (1) Are the reported gene expression profiles discussed above specific to patients with septic shock, or are they more generic manifestations of critical illness? and (2) Can gene expression profiling be leveraged to identify subsets or subclassifications of children with septic shock?

The first question of specificity was addressed by comparing the gene expression profiles between children with SIRS, children with sepsis, and children with septic shock.[154] These comparisons identified some patterns of conserved gene expression across the pediatric SIRS, sepsis, and septic shock spectrum, particularly with regard to upregulation of genes corresponding to innate immunity and inflammation. There were, however, several notable gene expression patterns that were unique and persistent in the patients with septic shock, relative to the patients with SIRS or sepsis. Specifically, the patients with septic shock had the most prominent and persistent upregulation of genes corresponding to the IL-10 signaling pathway. In addition, repression of zinc biology-related and adaptive immunity-related genes was most prominent and persistent in the patients with septic shock. These data indicate that the previous observations surrounding zinc biology and adaptive immunity are relatively specific to pediatric septic shock, rather than being generic manifestations of critical illness, or even of the sepsis spectrum as a whole.

The second question of subclassification was addressed by using microarray data from 98 children with septic shock.[155] Through a discovery-oriented gene filtering approach and unsupervised hierarchical gene clustering, three putative subclasses of children with septic shock were identified solely based on the gene expression profiles. One of these three expression-based subclasses was characterized by significantly greater repression of genes corresponding to zinc biology and adaptive immunity, compared to the other two putative subgroups. Notably, this subclass of patients had a significantly higher severity of illness and a significantly higher mortality rate compared to the other two subclasses. These data suggest that molecular subclassification, with clinical significance, may be possible through gene expression profiling.

Treatment Strategies

As the biologic response to sepsis becomes better understood and as we refine our ability to phenotype/stratify patients, the approach to treatment of sepsis will become more specific and more sophisticated. At present, however, clinical treatment of sepsis entails four important goals, which for the most part rely on purely supportive measures founded upon the fundamental principles of critical care medicine: initial resuscitation, pathogen elimination, maintenance of oxygen delivery, and carefully directed regulation of the inflammatory response. An update of pediatric and neonatal specific guidelines for sepsis management was recently published.[156]

Initial Resuscitation

As in any disease process, the first step in the treatment of sepsis is the initial stabilization of the patient. In this regard, children present many of the same challenges as adult patients, including respiratory and cardiovascular stabilization. The primary goals of therapy in the first hours are to maintain oxygenation and ventilation, achieve normal perfusion and blood pressure, and reestablish appropriate urine output and mental status.[156]

Children with signs of sepsis may have significantly decreased mental status, raising concern about the ability to protect their airway. Also, in septic shock the work of breathing can represent a significant portion of oxygen consumption (as much as 15% to 30%). Because children with septic shock also receive large amounts of fluid to restore intravascular volume in the context of capillary leak, they are at increased risk for developing pulmonary edema. Consequently, lung compliance decreases and the work of breathing can increase substantially. Together, these respiratory abnormalities often necessitate tracheal intubation and mechanical ventilation. Arterial blood gas analysis often reveals, in early sepsis, respiratory alkalosis from centrally mediated hyperventilation. As sepsis progresses, patients may have hypoxemia and

respiratory acidosis, secondary to parenchymal lung disease and/or hypoventilation due to altered mental status.[156] However, the decision to initiate mechanical ventilation support should not necessarily be contingent on laboratory findings; rather, the decision should be primarily based on clinical findings of increased work of breathing, hypoventilation, and/or impaired mental status. Mechanical ventilation provides the added benefit of reducing work of breathing, therefore decreasing overall oxygen consumption, especially when combined with sedation and paralysis. If early tracheal intubation is chosen, consideration of volume loading and inotropic/vasoactive support is recommended. Sedative agents for induction should be selected to maintain hemodynamic stability. The 2007 pediatric guidelines for septic shock specifically recommend against the use of etomidate due to its adrenal-suppressive effects, and suggest the use of ketamine as a suitable agent to maintain hemodynamic stability.[156] Subsequent studies, however, suggest no effect on mortality or length of stay in adults with septic shock that were intubated with etomidate.[157,158]

For a variety of reasons, patients with sepsis almost universally have decreased effective intravascular volume. Many had poor oral intake of fluid for a period of time prior to developing sepsis. With the development of increased vascular permeability, intravascular volume has been lost because of third spacing. Finally, vasodilation partially related to excessive NO production (see earlier section) results in abnormally increased vascular capacitance, thereby decreasing the effective intravascular volume. When sepsis is suspected, vascular access should be obtained and 20 mL/kg of isotonic fluid administered as quickly as possible. A second peripheral vascular access is recommended, and difficulties in attaining venous access can be overcome with the use of an intraosseous catheter. Intraosseous access can temporarily be the primary route for volume infusion, medications, and blood products when an intravascular access is not readily obtained. While following clinical examination for signs of overly aggressive volume resuscitation (e.g., new onset of rales, increased work of breathing, development of a gallop, abdominal distension, or hepatomegaly), fluid should be administered quickly with the goal of improving blood pressure and tissue perfusion. Administration of more than 60 mL/kg of isotonic fluid in the first hour of resuscitation is associated with improved survival.[159-161] However, volumes up to 200 mL/kg may be required during the first few hours. The importance of vigorous, early, goal-directed therapy (volume repletion, attainment of a target blood pressure, central venous oxygen saturation ≥70%, urine output >1 mL/kg/h) in significantly reducing sepsis mortality has been demonstrated in both adult and pediatric patients.[162,163] A pediatric algorithm for early goal-directed therapy, based on central venous oxygen saturation measurements, is provided in Figure 103-3.

Cardiovascular agents are indicated for fluid-refractory septic shock, and specific agent selection should ideally be predicated on the cardiovascular state of the patient. Patients with septic shock can present with low cardiac output and elevated systemic vascular resistance, high cardiac output and low systemic vascular resistance, or low cardiac output and low systemic vascular resistance. The incidence of sepsis-induced cardiac dysfunction in children is thought to be considerably higher than in adults, potentially representing up to 80% of fluid-refractory patients.[11]

Cardiovascular agents used to support circulation can be classified as inotropes, vasopressors, vasodilators, and inodilators. Inotropes improve cardiac contractility and can increase heart rate. Vasopressors increase systemic and pulmonary vascular resistance. Vasodilators reduce systemic and pulmonary vascular resistance and, although not directly affecting myocardial contractility, improve cardiac output by decreasing afterload. Inodilators simultaneously improve cardiac contractility and reduce afterload. Purely by tradition, the most common initial agent selected for vasoactive support is dopamine, which provides both inotropic support at lower doses (5 to 10 μg/kg/min) and increased vasomotor tone at higher doses (>10 μg/kg/min). Often it is necessary to escalate the dopamine dosage to high levels (up to 20 μg/kg/min), at which point additional agents should be strongly considered. The decision of which second agent to start should be based on the following determinations: whether the cardiovascular compromise is related to inadequate cardiac output from direct cardiodepressant effects, which requires increased inotropy; decreased vascular tone, which requires vasopressors; or increased afterload from vasoconstriction, which requires peripheral vasodilators. Afterload reduction in the context of septic shock is unlikely to be of benefit in a patient who is not adequately fluid-resuscitated. There is not a single strategy meeting the needs of all patients. Consequently, the therapeutic options must be individualized and adjusted according to patient's response.[12,164] In this regard, the clinician often can be assisted by garnering additional data on the basis of invasive monitoring.

Invasive Monitoring

The final step in the initial resuscitation of a child with sepsis is placement of appropriate and necessary vascular access and monitors. However, attention to the clinical examination as part of the ongoing assessment is imperative. In sepsis, the primary clinical endpoints to assess are changes in level of consciousness, decreased urine output, and poor peripheral perfusion characterized by delayed capillary refill and diminished distal pulses. Unfortunately, children with sepsis can be difficult to examine because they often are tracheally intubated and sedated, and may not have produced any initial urine because of severe hypovolemia. Also, they frequently are receiving vasopressors (sometimes excessively), which can make examination of the skin for assessment of perfusion less reliable. For these reasons, invasive monitoring often is necessary and helpful.

Central venous access is a necessity for the child in septic shock. The decision to place a central venous catheter in the internal jugular, subclavian, or femoral position is dictated by a number of factors, such as the experience level of the operator, the presence of coagulopathy, and the possibility of monitoring central venous pressure and central venous oxygen saturation. Central venous catheters provide access for reliable delivery of vasoactive medicines and large volumes of fluid. However, they also can be used to obtain a measurement of central venous pressure (CVP) and, depending on location, may provide an approximate measurement of the mixed venous oxygen saturation.[164-166] Femoral catheters, in the absence of abdominal pathology, can be used to estimate CVP with good correlation.[166] Although use of CVP is very common in clinical practice, the measurement of CVP in isolation

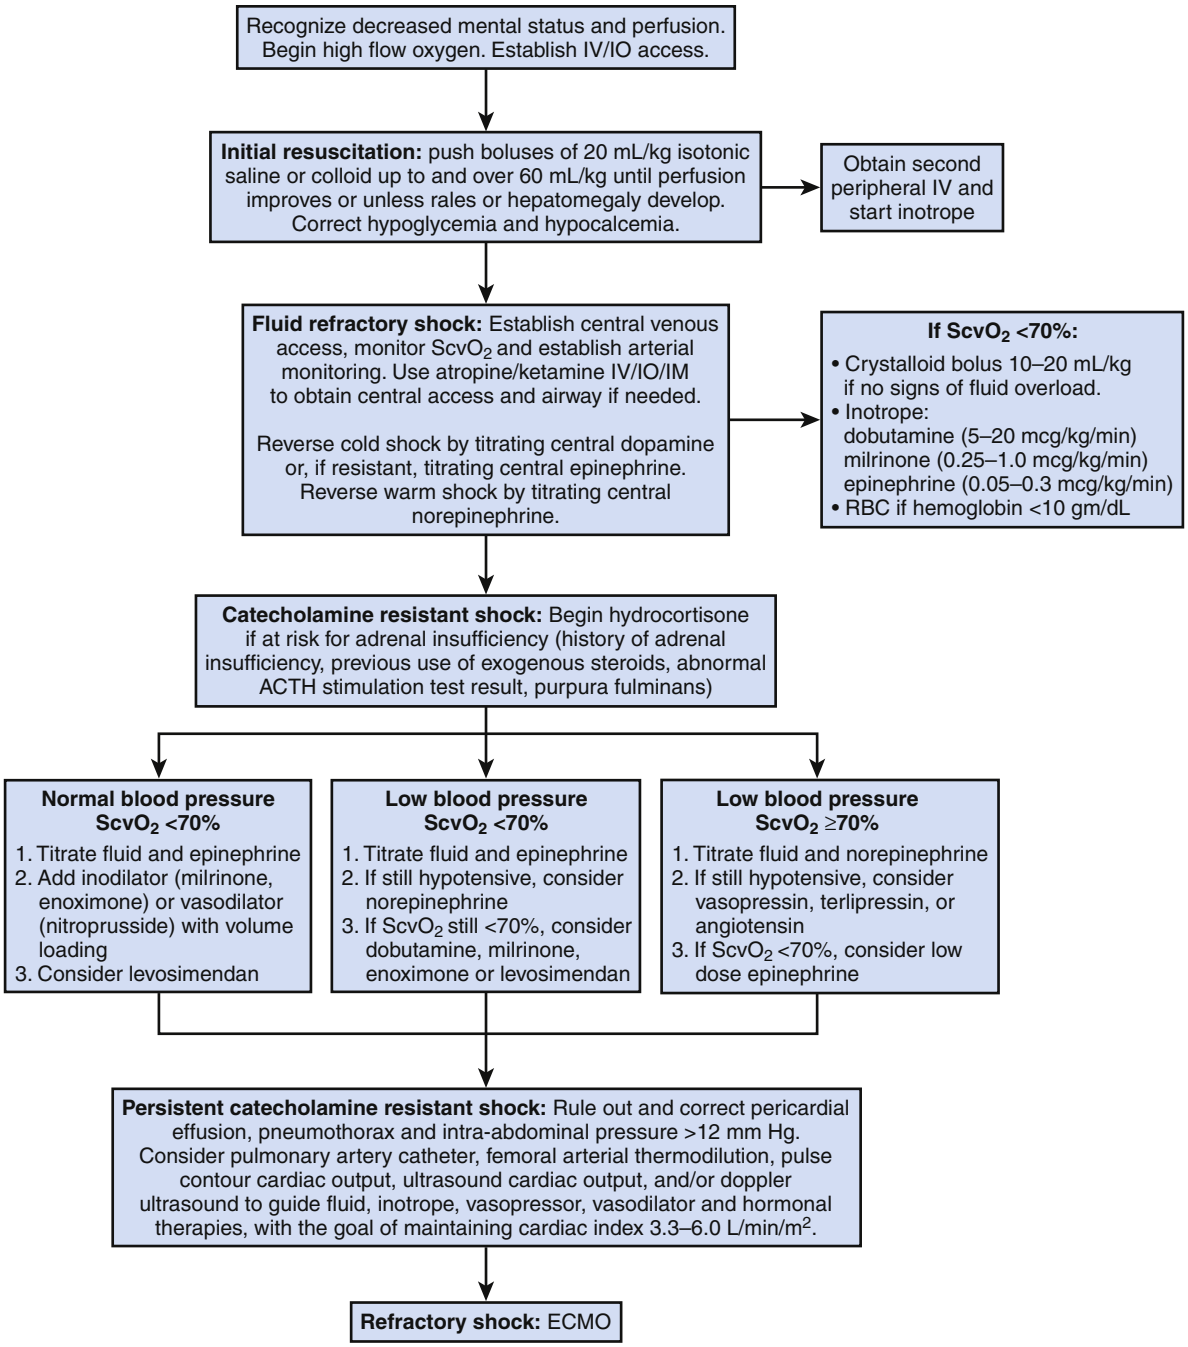

Figure 103–3. Algorithm for early goal directed therapy, guided by central venous saturation, in pediatric septic shock.

cannot reliably estimate volume status or preload of the heart, as it depends on the interactions of cardiac function, cardiac compliance, and intravascular volume.[167,168] For example, a low CVP may be present with hypovolemia and normal cardiac function, but may also be present in a patient with normovolemia and a hyperdynamic status. On the other hand, a high CVP can be observed in hypervolemic patients, but also in normovolemic, or even hypovolemic, patients with cardiac dysfunction. Factors that can elevate CVP even in the presence of hypovolemia include pulmonary hypertension, right ventricular dysfunction, tricuspid regurgitation, high positive end-expiratory pressure, high abdominal pressure, cardiac tamponade, and intracardiac left-to-right shunts. Thus, CVP measurements need to be interpreted in the context of the specific clinical situation and patient.

The measurement of CVP without corresponding direct or indirect measurement of cardiac output also may not discriminate fluid responsiveness.[167] The hemodynamic response to fluid load can be estimated with the application of a fluid challenge, which is the rapid infusion of a fluid bolus of sufficient magnitude to increase CVP by approximately 2 mm Hg. A change of CVP of this magnitude will typically produce, in fluid-responsive patients, a significant change in cardiac output. When a direct measure of cardiac output is not available, other surrogates, such as central venous oxygen saturation, should be followed. A practical maneuver that simulates a fluid

challenge procedure is passive leg-raising. Passive leg-raising to 30° increases venous return and transiently increases cardiac output and blood pressure in a fluid-responsive patient.[169,170] It is important to emphasize, however, that the identification of a fluid-responsive patient does not necessarily mean that the patient needs additional large volumes of fluid.[169]

Accurate determination of the true mixed venous saturation in the pulmonary artery requires a pulmonary arterial catheter (PAC), but approximations of the saturation can be provided by a catheter tip at or near the right atrium. Values of oxygen saturation measured at the right atrium or superior vena cava are slightly different from true mixed venous saturation, but there is a good trend correlation between the two measurements.[164,171,172] Therefore, the use of central venous (right atrium or superior vena cava) oxygen saturation is more practical and feasible as it avoids the requirement for pulmonary artery catheterization. Because of significant differences in oxygen extraction between the upper extremities, abdomen, and lower extremities, venous saturations from a femoral venous line do not accurately correlate with those measured in the pulmonary artery.[166] Measurements of central venous saturation can be achieved through the analysis of blood samples collected from correctly positioned catheters (intermittent), or continuously with the utilization of an indwelling fiberoptic catheter. A superior vena cava oxygen saturation greater than 70%, and therapeutic maneuvers targeted at achieving this goal, are associated with improved outcome in children and adults with septic shock.[162,163]

In the face of severe sepsis and septic shock, an intraarterial catheter becomes necessary. An arterial catheter becomes both a source of continuous clinical information regarding blood pressure, pulse pressure, hemodynamic variation with respiration (i.e., pulsus paradoxus), and an access for frequent blood draws. Whereas blood pressure alone does not always equate to tissue perfusion because of differences in regional perfusion and vasoconstriction, a fluid-resuscitated child with normal or high systolic blood pressure will be more tolerant of manipulations to increase perfusion (i.e., afterload reduction) than children with lower blood pressures. This condition occurs in children who have poor ventricular ejection and high systemic vascular resistance. Therapeutic maneuvers to actively decrease afterload can be more rationally conducted with continuous blood pressure monitoring via an intraarterial catheter.

The arterial blood also provides the most accurate information regarding arterial oxygen content that can be used to both assess the function of the lungs and to maximize oxygen delivery. Additionally, the analysis of the arterial pulse wave can provide a continuous monitoring of the cardiac output. Recent studies reveal that this cardiac output estimation technique can be safely applied in children, and has reasonable correlation with thermodilution or echocardiography-based techniques.[173,174]

Use of PACs to optimize left ventricular preload, monitor changes in cardiac index, and provide accurate measurements of oxygen delivery and consumption is now controversial. Interpretation of PAC data requires the absence of intracardiac shunting and the presence of normal mitral valve function, as either shunting or mitral regurgitation alters cardiac index determination and pulmonary capillary wedge pressure measurements. Because data from critically ill adults showed no benefit of routine PAC use,[175] the use of PACs has substantially declined in critical care medicine, but is thought to be of potential benefit in selected patients.[176] In light of studies showing that the information obtained from PAC can be important in identifying clinically meaningful cardiovascular conditions that are different from what is suspected by clinical impression,[11,176] PAC placement may be considered for pediatric patients who remain in shock after resuscitation and initiation of the usual cardiovascular agents, and in patients having unclear fluid status and cardiac function. Other methods of measuring cardiac output, such as arterial pulse wave analysis, femoral artery thermodilution, Doppler ultrasound, or ultrasound cardiac output monitoring, may be effective substitutes to the use of PAC.

Elimination of Pathogens

Identification of the source of a possible offending organism in septic shock dictates the choice of antimicrobial coverage and is important to long-term outcome, as early administration of appropriate antibiotics is associated with improved survival.[177] While the imperative nature of prompt antibiotic treatment may seem intuitively obvious, it has been well documented that delays in appropriate antibiotic administration have a greater adverse impact on septic shock outcome than do cytokine polymorphisms.[178] Therefore, antibiotic therapy should be started within the first hour of recognition of sepsis, ideally after appropriate cultures have been readily obtained. However, antibiotic administration should not be delayed if obtaining appropriate cultures is technically problematic.

The offending organism and the site of infection also affect prognosis. Fungal infections are associated with the lowest survival rates, followed by bacterial infections, especially meningococcal and pneumococcal infections.[2] It is important to note, however, that the epidemiology of pediatric sepsis is changing, particularly in populations where vaccination policies incorporate immunization against *Haemophilus influenzae*, *Streptococcus pneumoniae* and *Neisseria meningitidis* serotype C. While infections caused by these agents have decreased, there are now more cases of nosocomial infections, especially caused by staphylococci and fungi. The majority of infections causing severe sepsis are respiratory or primary bacteremia, with respiratory cases being more common among older children and in community-acquired infections, and primary bacteremia more frequently affecting neonates, children with neoplastic disorders, or those with other comorbidities. Lower survival rates are associated with endocarditis and infections of the central nervous system.[2]

Initial empirical antimicrobial therapy should include one or more drugs that have activity against the likely pathogens (bacterial or fungal) and that penetrate into the presumed source of the sepsis. The choice of drugs should be guided by the susceptibility patterns of microorganisms in the community and in the hospital.[177] Because of the importance of appropriate antimicrobial therapy, the decision regarding which agents to empirically start must balance potential side effects against maximizing coverage. Initially, broad antibiotic coverage should be started. Neonates should be given ampicillin and either gentamicin or a third-generation cephalosporin such as cefotaxime. In infants and children older than 4 to 6 weeks, the decision to begin vancomycin therapy empirically, in addition to the standard third-generation cephalosporin, should be considered in light of the increasing antibiotic resistance of *Streptococcus pneumoniae*, as well as methicillin-resistant

Staphylococcus aureus. Nosocomial infections and infections in immunocompromised patients require additional coverage for the possibility of *Pseudomonas* species and other resistant organisms. Acyclovir should be given if there is a clinical presentation or suspicion of an overwhelming viral (herpetic) infection, particularly in neonates and infants. Starting antifungal medicines initially in an immunocompetent child usually is not necessary. However, this decision should be reconsidered if the child does not improve over the first 2 days or in case of higher risk for fungal infection (presence of indwelling devices, immunosuppression, or other significant comorbidities). The antimicrobial regimen should be reassessed after 48 to 72 hours on the basis of microbiological and clinical data with the goal of narrowing the antibiotic spectrum to prevent the development of resistance and to reduce toxicity. Once a causative pathogen is identified, there is no evidence that combination therapy is more effective than monotherapy for most bacterial infections. The duration of therapy should typically be 7 to 10 days and guided by clinical response.[177]

Maintenance of Oxygen Delivery

After initial resuscitation and attention to pathogen elimination, ongoing management of sepsis remains primarily supportive, with particular attention to maintenance of adequate oxygen delivery. While this is a fundamental tenet of critical care medicine, the approach may be relatively ineffective in a subset of patients having impaired utilization of oxygen despite adequate oxygen delivery (i.e., cytopathic hypoxia). The assessment of adequate oxygen delivery should be viewed as a dynamic and ongoing process as measured by a combination of parameters including clinical assessment of perfusion, blood pressure, serial lactate measurements, urine output, central/mixed venous oxygen saturation, and, in selected cases, PAC-derived measurements.[162]

Adequate preload is necessary for adequate cardiac output, and consequently for adequate oxygen delivery. Children with sepsis can remain at risk for hypovolemia after an appropriate initial resuscitation because of persistent increased insensible fluid loss, increased vascular capacitance, and capillary leak with third spacing. Anecdotally, some well-resuscitated children have such vigorous urine output after the initial resuscitation that reassessment of fluid balance after the first 24 hours of presentation to the ICU reveals that the fluid balance may actually be close to "even." Thus, providing adequate preload to the patient in septic shock may require increased fluid administration for several days after the initial resuscitation. The choice of fluid to be used in this process is controversial, although there is general agreement that the fluid choice should be isotonic. The three broad choices of fluids are crystalloid, non-blood colloid, and blood products. As evident when calculating the arterial content of oxygen, maintaining an adequate hemoglobin level is an important factor in providing adequate oxygen delivery. Although there is no clear recommended hemoglobin level for children with sepsis, one recent study showed that in patients with central venous oxygen saturation less than 70%, transfusion of packed red blood cells, in combination with other measures to increase oxygen delivery, is associated with improved outcomes.[162]

After initial resuscitation, ongoing myocardial dysfunction and altered vascular tone are likely to persist and will therefore require ongoing titration of cardiovascular drugs to maintain adequate oxygen delivery. Many patients will require titration of inotropes and vasopressors simultaneously, and it must be emphasized that this will likely be a dynamic process requiring constant reassessment of the aforementioned indicators of adequate oxygen delivery. It is important to recognize that blood pressure alone as a goal may not correlate with optimal tissue perfusion and oxygen delivery. This concept is best illustrated by the subset of patients with septic shock who benefit from afterload reduction (i.e., vasodilation). Patients with high systemic vascular resistance (SVR) and low cardiac output, who have adequate preload, can benefit tremendously from inodilators such as milrinone.[179,180] Alternatively, this subset of patients can also benefit from pure vasodilators such as the NO donor, nitroprusside (in combination with a pure inotrope). After institution of afterload reduction, these types of patients may actually have lower blood pressures than one would typically target, but will have enhanced tissue perfusion and oxygen delivery.

A subset of patients will have refractory shock despite optimization of the above management strategies. In this subset, the institution of extracorporeal membrane oxygenation (ECMO) is recommended as a consideration in the context of refractory shock.[156] Our anecdotal and subjective experiences suggest that institution of ECMO support for refractory septic shock can be lifesaving in a subset of patients. The challenges that come with institution of ECMO include the definition of refractory septic shock, timing of ECMO initiation before the onset of irreversible end organ failure, and ensuring that ECMO support is not prematurely or unnecessarily instituted in patients that can be effectively managed with conventional support (i.e., not exposing patients to unnecessary risks).

A summary of approaches to improving the relationship between oxygen delivery and oxygen consumption is provided in Box 103-3.

Box 103–3 Means of Altering the Relationship Between Oxygen Delivery and Oxygen Consumption

Means of Improving Oxygen Delivery:

- Increase cardiac output
  - Increase stroke volume
  - Increase preload (volume resuscitation)
  - Increase contractility (administration of inotropes)
  - Decrease afterload (administration of vasodilators)
  - Increase heart rate (rarely a therapeutic goal in sepsis management)
- Increase arterial oxygen content
  - Increase arterial oxygen tension (administer oxygen, apply positive-pressure ventilation, etc.)
  - Increase arterial oxygen carrying capacity (transfusion of packed red blood cells)
- In select cases, cardiac output and arterial oxygen content can both be increased through the institution of venoarterial extracorporeal membrane oxygenation.

Means of Decreasing Oxygen Consumption:

- Avoid/manage hyperthermia
- Remove work of breathing
- Administer sedation
- Administer paralytics

Additional Management Considerations

Patients with sepsis may have poor nutrition prior to presentation and often are not fed during the first few days of illness. Because of an increased metabolic rate and poor nutrition, patients with sepsis are frequently catabolic and at risk for development of protein-calorie malnutrition.[181] Intestinal ischemia in association with loss of the mucosal barrier from malnutrition is associated with translocation of bacteria and endotoxin from the intestine into the bloodstream. Use of enteral feeding in critically ill patients has been shown to improve survival and decrease hospital stay.[182] The benefit of enteral feeding should be balanced with the risk of stressing intestinal function in the face of poor splanchnic perfusion, especially in the presence of vasopressors such as epinephrine and norepinephrine.[183] Regardless of the feeding mode, adequate nutrition and nitrogen balance are important for maintaining adequate host immune function and achieving homeostasis, as malnutrition adversely affects immune function. Finally, in the absence of enteral feedings, pharmacologic prophylaxis against stress-related gastrointestinal bleeding is recommended by the most recent guidelines.

Fluid overload, as a consequence of aggressive fluid resuscitation and capillary leak, is an important issue that eventually needs to be addressed in virtually all patients with septic shock. General signs of clinically significant fluid overload include hepatomegaly; rales/pulmonary edema; a substantially positive fluid balance; ascites and, potentially, intraabdominal hypertension; and/or 10% increase in body weight. For many patients, institution of diuretic therapy is a simple and effective approach to dealing with fluid overload, in the context of hemodynamic stability and adequate renal function. However, acute kidney injury/renal failure commonly occurs in septic shock and may require institution of some form of renal replacement therapy such as peritoneal dialysis, hemodialysis, or continuous renal replacement therapy (CRRT).

Variations of CRRT are commonly viewed as the most ideal choice for these patients, given the potential ability to meticulously titrate fluid removal in patients with hemodynamic instability. In addition, CRRT has the potential to achieve more than simple fluid removal; inasmuch as high ultrafiltration rates can also provide clearance of standard waste products of metabolism, as well as "mediators" of sepsis (i.e., immune modulation). However, CRRT is also well documented to be associated with clinically significant complications (e.g., hemodynamic instability and electrolyte imbalances) in critically ill children.[184] Thus "timing" and "dose" are important considerations for institution of CRRT in patients with septic shock, and both considerations are predicated on the concept that CRRT represents more than just simply fluid removal and management of uremia.[185] "Timing" refers to the concept of instituting CRRT before the onset of overt renal failure and clinically significant fluid overload. "Dose" refers to the concept of ultrafiltration rates and the potential ability of high filtration rates to achieve more effective immune-modulation. These important concepts represent major challenges in the field that need to be addressed by well-designed, pediatric-specific multicenter trials. Importantly, a recent trial compared high ultrafiltration rates (high-intensity CRRT) to standard ultrafiltration rates (low-intensity CRRT) in over 1500 critically ill adults.[186] There was no difference in the primary outcome variable (90 day mortality) between the two treatment groups. However, there was an intriguing trend toward improved survival in the subset of patients with sepsis that underwent high-intensity CRRT.

Hyperglycemia is well recognized to be associated with increased morbidity and mortality in critically ill patients, including children with sepsis.[187,188] In 2001, van den Berghe and colleagues[189] published a landmark study demonstrating that aggressive insulin therapy to normalize glucose levels to within a very narrow range significantly increased survival in a large cohort of critically ill adult surgical patients. This study strongly suggested that hyperglycemia is not merely a stress-related epiphenomenon of critical illness, but rather a pathologic process that can be addressed by an intensive insulin-based protocol targeting normalization of glucose levels. However, the inability to consistently replicate these findings has led to a great deal of controversy in the field. A recent meta-analysis concluded that tight glucose control does not significantly reduce mortality in critically ill adult patients, but is associated with an increased risk of hypoglycemia.[190] An even more recent, randomized, multicenter trial compared intensive glucose control (81 to 108 mg/dL) to conventional glucose control (<180 mg/dL) in over 6000 critically ill adults.[191] This study concluded that intensive glucose control increased mortality in critically ill adults, relative to conventional glucose control. Finally, another recent trial focused on intensive insulin therapy in adults with sepsis demonstrated no survival benefit, but an increased risk of clinically significant hypoglycemia.[192]

The most current pediatric-specific sepsis guidelines recommend insulin therapy to maintain glucose levels less than or equal to 150 mg/dL, and avoiding hypoglycemia by keeping glucose levels greater than or equal to 80 mg/dL.[156] This is a level 3 recommendation (adequate scientific evidence is lacking but widely supported by available data and expert opinion), but was generated prior to the publication of a recent trial investigating intensive insulin therapy specifically in critically ill children.[193] The majority of patients in this trial (approximately 75%) were surgical patients undergoing correction of congenital heart malformations. Intensive insulin treatment resulted in improved short-term outcomes (decreased ICU length of stay and decreased parameters of inflammation), but also resulted in a 25% rate of hypoglycemia. There are no large pediatric-specific trials addressing insulin-based glucose control specifically in the context of septic shock. Therefore, in light of the current data, and taking into consideration the risks of hypoglycemia in children, a glucose level of no greater than 180 mg/dL seems to be a reasonable target, pending a formal study.

Immune Modulation

Since immune/inflammatory dysregulation is a well-accepted pathophysiological concept in septic shock, there has been a great deal of effort in developing treatment strategies directly targeted at immune/inflammatory modulation. Steroids have long been proposed as a general antiinflammatory strategy. In many clinical settings, patients with septic shock demonstrate worsening of their shock temporally associated with antibiotic administration. It is thought that this phenomenon results from a massive release of bacterial toxins after antibiotic-mediated bacterial killing, and a subsequent inappropriately

exuberant immune/inflammatory response. However, the use of high-dose steroids to blunt this response is now universally accepted to be of no benefit and potentially harmful.[194,195]

A more recent approach to using steroids in septic shock involves the concept of relative adrenal insufficiency, and an association between adrenal insufficiency and catecholamine-refractory shock.[196,197] A landmark study by Annane and colleagues demonstrated a substantial benefit in adults with septic shock having "relative adrenal insufficiency" (based on cortisol levels and ACTH stimulation testing) and treated with replacement hydrocortisone.[198] However, a subsequent trial did not demonstrate the efficacy of hydrocortisone replacement, thus leading to an ongoing, unresolved controversy in the field.[199,200] Conflicting data and controversy also exist in the pediatric septic shock population.[201,202] The role of hydrocortisone replacement in pediatric septic shock represents another major challenge in the field that must be directly addressed by a large, multicenter, randomized trial. Current barriers to conducting this important trial include lack of equipoise in the pediatric critical care community and lack of consensus regarding the definition of relative adrenal insufficiency. Thus, at present, the treatment guidelines suggest hydrocortisone replacement therapy be considered for patients who appear refractory to resuscitative measures, have a known history of adrenal insufficiency, have already received exogenous steroids, or have an abnormal ACTH stimulation test result.[156]

Because the pathophysiology of septic shock is directly linked to circulating pathogen-derived toxins and circulating inflammatory mediators, removal of these molecules via hemofiltration or exchange transfusion (i.e., plasmapheresis) has been hypothesized to improve outcome. Both hemofiltration and plasmapheresis were discussed in previous sections. The fact remains that these approaches, while theoretically well-founded, remain to be proven and cannot be recommended routinely in the absence of more objective data. Both strategies carry significant risks that must be weighed against the potential theoretical benefits. These include difficult vascular access in smaller children, fluid and electrolyte imbalance, hypothermia, anticoagulation requirements because of extracorporeal circuits, and acutely altered hemodynamics when instituting therapy. In addition, beneficial proteins such as albumin, immunoglobulins, clotting factors, and counter-regulatory cytokines may be removed to the detriment of the patient.

Part of the inflammatory response involves cytokines that cause widespread activation of the coagulation cascade with suppression of fibrinolysis, as described in previous sections. Disseminated intravascular coagulation has been implicated in the etiology of multiple organ injury leading to MODS, and is directly linked to alterations of endogenous anticoagulants such as antithrombin III and protein C. While recombinant forms of these anticoagulants are available, they have not been demonstrated to be efficacious in the pediatric population and carry significant risks of serious adverse events due to bleeding.

As previously described, multiple antiinflammatory strategies have been attempted and some are now being reconsidered. These include anti-TNF, anti-IL1, anti-endotoxin, and anti-PAF strategies. Thus far none of these strategies have proven to be of sufficient clinical benefit in septic shock to warrant formal approval as standard of care. It is hoped that better designed studies that carefully stratify patients, consider the presence or absence of an offending pathogen, and possibly identify genetic factors influencing outcome will provide insight into the appropriate immunomodulating agents that will be clinically beneficial to pediatric patients with septic shock. Of note, there are currently two ongoing phase III trials based on a TLR-4 antagonist strategy in adults with septic shock.[203]

An alternative approach to immune modulation in septic shock focuses on immune "enhancement" rather than inhibition of inflammation. As emphasized in previous sections, the paradigm of sepsis as an adaptive immune problem is increasingly gaining credence in the field. Thus there is now growing attention to the use of potentially immune-enhancing agents such as interferon-γ, granulocyte-macrophage colony stimulating factor, zinc, selenium, prolactin, agonist antibody to CD40, and interleukin 7.[17,204-206] Thus, the next major advance in the clinical septic shock may involve one or more of these immune-enhancing approaches, rather than an anti-inflammatory approach.

The Case for More Effective Stratification in Pediatric Septic Shock

The vast majority of interventional clinical trials in septic shock have failed to demonstrate efficacy of the particular test agent. We propose that the reason for failure in these trials is not because the biological/physiological principle being tested was fundamentally flawed. Rather, the primary reason for failure lies in the inability to effectively address the substantial heterogeneity that characterizes the syndrome of septic shock. As indicated throughout this chapter, septic shock is a heterogeneous syndrome with the potential to negatively and directly affect all organ systems, and this heterogeneity has consistently challenged multiple investigators attempting to evaluate the efficacy of various experimental interventions. As astutely stated by Marshall, a key challenge in the field is to reduce and manage this heterogeneity by more effectively stratifying patients for the purposes of more rational and effective clinical research and clinical management.[207] The concept of preintervention stratification in sepsis, and its positive impact on the efficacy of an experimental therapy, was very recently corroborated by the Remick laboratory in a murine model of polymicrobial sepsis.[32]

One potential strategy for stratifying children with septic shock involves early identification of septic shock subclasses based on genome-wide expression patterns. As described above, putative subclasses of children with septic shock have been identified based exclusively on gene expression profiling conducted within 24 hours of admission, and these expression-based subclasses have highly relevant differences in illness severity and mortality.[155] A similar strategy was recently demonstrated in adult patients suffering from trauma.[208] As high-throughput technologies evolve and validation studies are rigorously performed, the ability to conduct expression-based subclassification of pediatric septic shock could very well become a clinical reality.

Another potential strategy for stratifying children with septic shock (and perhaps more readily feasible at present) is biomarker-based stratification. Many biomarkers can be readily measured in the blood compartment, thus providing

a clinically feasible strategy for early stratification of patients. For example, interleukin-8 (IL-8) can be readily and rapidly measured in small volume blood samples. Recently, IL-8 was found to be a very robust outcome biomarker in children with septic shock.[36] Specifically, an IL-8 level, measured within 24 hours of admission to the pediatric intensive care unit, was found to have a 95% negative predictive value for mortality in a derivation cohort of patients. In other words, this particular IL-8 level was able to predict survival in pediatric septic shock with standard care with 95% probability and very narrow confidence intervals. The reliability of this assertion is supported by prospective, formal validation in an independent validation cohort of patients (the RESOLVE database), which demonstrated an identically robust negative predictive value.[36] More recently, a similar observation (98% negative predictive value for mortality) was found by measuring chemokine (C-C motif) ligand 4 (CCL4) serum protein levels within 24 hours of admission to the PICU with septic shock.[209]

It has been proposed that these types of sepsis-outcome biomarkers (i.e., biomarkers having high negative predictive values for mortality) could be used to stratify patients eligible for interventional septic shock trials.[36,209] Patients having a high likelihood of survival with standard care, but otherwise meeting entry criteria for a given interventional trial, could be potentially excluded from the trial based on these biomarkers. Such a stratification strategy would serve to derive a study population with a more optimal risk-to-benefit ratio, thus improving the ability to demonstrate efficacy for a given test agent. This type of strategy would be particularly useful for a test agent carrying more than minimal risk.

While single biomarker-based patient stratification is clinically appealing, it may not be sufficiently robust to meet all clinical and research needs from the combined standpoints of specificity, sensitivity, and positive predictive values. Indeed, the aforementioned studies involving IL-8 and CCL4 had clinically unacceptable specificities, sensitivities, and positive predictive values, relative to the very high negative predictive values. The ideal biomarker-based stratification tool, which would meet a wide range of clinical and research needs, would simultaneously have high specificity, high sensitivity, high positive predictive value, and high negative predictive value.

Given the biological complexity of pediatric septic shock, a stratification strategy based on a panel of multiple biomarkers has more potential to meet the needs of the aforementioned ideal biomarker-based stratification tool. To this end, we have recently derived a panel of 15 biomarkers using a genome-wide expression database of nearly 100 children with septic shock. The database focuses on the gene expression patterns representing the first 24 hours of admission to the pediatric intensive care unit, which is an ideal time-frame for clinically useful stratification. An initial working list of candidate biomarkers was systematically and objectively derived using two complementary statistical tools: analysis of variance (ANOVA) to determine genes differentially regulated between survivors and nonsurvivors, and support vector machines-based class prediction modeling targeted at identification of "survivor" and "nonsurvivor" classes. The final panel of 15 biomarkers was refined from the initial working list based on biological plausibility in the context of sepsis, and the ability to readily measure the biomarkers (proteins) in blood samples. The resulting 15 biomarker list will be used to derive the pediatric sepsis biomarker risk model (PERSEVERE: PEdiatRic SEpsis biomarkEr Risk modEl). PERSEVERE is intended to predict outcome and illness severity for individual patients with septic shock. PERSEVERE will be derived in a formal derivation cohort of patients using statistical modeling approaches, and subsequently validated prospectively in a separate validation cohort. If PERSEVERE comes to fruition, we expect that it will provide an unprecedented decision and stratification tool for the care of individual children with septic shock and for the conduct of interventional clinical trials.

Concluding Perspectives

Sepsis is and will continue to be an important challenge to the pediatric intensivist. Indeed, sepsis is one of the few disease processes for which the pediatric intensivist can claim "ownership." Although much is known about the biological and molecular mechanisms involved in sepsis, much of this knowledge has not directly translated to improved bedside care. At present, most of the therapeutic modalities for sepsis are fundamentally supportive and founded on the basic principles that define the discipline of critical care medicine. Although this approach has directly improved the outcome of sepsis in children, the fact that more than 4000 children per year in the United States alone continue to die in association with severe sepsis warrants further advances. Realization of this goal is feasible but requires further mechanistic insights at the physiological, molecular, and genetic levels, as well as the design of large-scale, pediatric-specific interventional trials complemented by evolving stratification strategies. As "owners" of pediatric septic shock, pediatric intensivists are well positioned to lead this effort on all fronts.

VI Chapter 104

Inflammation and Immunity: Systemic Inflammatory Response Syndrome, Sepsis, Acute Lung Injury, and Multiple Organ Failure

Joseph A. Carcillo, Yong Y. Han, Lesley Doughty, Mark Hall, Trung Nguyen, and Raj K. Aneja

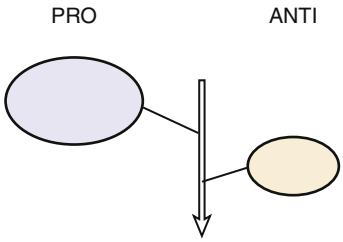
PEARLS

- Systemic inflammatory response syndrome, sepsis, severe sepsis, acute lung injury, acute respiratory distress syndrome, and multiple organ failure are defined by specific clinical criteria. Known outcomes and mechanisms have been evaluated using these clinical syndrome definitions.
- Multiple organ failure (MOF)/multiple organ dysfunction syndrome (MODS) has been classified as primary (occurring in the first 7 days) and secondary (occurring after 7 days). Ninety percent of these patients have MOF at presentation, whereas 10% develop sequential MOF over time with liver and renal involvement following initial lung dysfunction.
- MOF phenotypes include thrombocytopenia-associated MOF, immune paralysis/lymphoid depletion syndrome (predominant TH2 phenotype), viral/lymphoproliferative disorder associated sequential MOF (natural killer cell/cytotoxic T cell/B cell/T-regulatory cell dysfunction), iron overload cardiac/hepatic/pancreatic MOF (secondary hemochromatosis), and hyperleukocytosis MOF (pertussis leukocyte proliferating factor).
- Nonspecific and specific therapies can be successfully directed to patients with MOF/MODS according to these phenotypes, including intensive plasma exchange therapy for thrombocytopenia-associated MOF, rapid tapering of immunosuppressants and administration of low-dose granulocyte-macrophage colony-stimulating factor for immune paralysis, rituximab and intravenous immunoglobulin for posttransplantation proliferative disease, protocols for primary hemophagocytic lymphohistiocytosis, pulse steroids for rheumatologic disease–associated macrophage activation syndrome, interferon-α and intravenous immunoglobulin for secondary hemophagocytic lymphohistiocytosis, iron chelation for iron overload MOF, and leukapheresis for hyperleukocytosis-associated MOF.
- Early goal-directed therapy (time-sensitive achievement of normal blood pressure, capillary refill less than 2 seconds, and central venous oxygen saturation >70%) has been demonstrated as being successful in improving outcomes and reducing the incidence of MOF/MODS. Biomarker goal directed therapy holds similar promise in children with inflammation/immunologic dysfunction-based MOF.

Systemic inflammation can lead to systemic inflammatory response syndrome (SIRS) or sepsis syndrome (when infection is suspected), recognized and defined by the presence of two of the following: tachycardia, tachypnea, fever, and abnormal white blood cell count. Increased systemic inflammation with the compensatory antiinflammatory response syndrome can further mediate severe sepsis (sepsis + single organ failure) and with *immunologic dissonance*, the development of multiple organ failure (MOF) with acute lung injury (bilateral infiltrates with hypoxemia and a partial pressure of oxygen [Pao_2]/fraction of inspired oxygen [Fio_2] ratio <300) or acute respiratory distress syndrome (ARDS) (bilateral infiltrates with hypoxemia and a Pao_2/Fio_2 ratio <200).

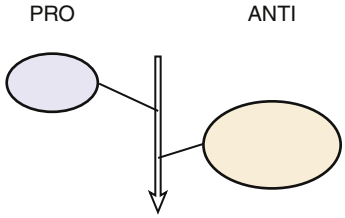
The Inflammation/Coagulation/Immune Dysfunction/Dysregulated Metabolism Hypothesis

Roger Bone popularized the notion that systemic inflammation led to the development of sepsis syndrome and MOF in the 1990s. According to this theory, an initial proinflammatory cytokine response to foreign or self-antigen caused SIRS, a systemic inflammatory response characterized by two of four criteria: tachycardia, tachypnea, fever, and leukocytosis. This syndrome was thought to be mediated



• Temperature changes, tachypnea, tachycardia, acidosis, signs of specific end organ dysfunction.

Figure 104–1. SIRS shows proinflammation self-limited by antiinflammation and eradication of the source of inflammation.



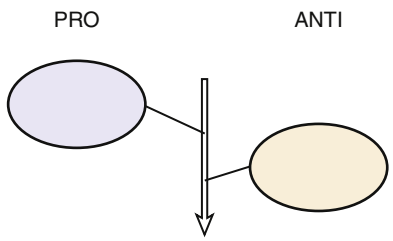
CARS: Compensatory anti-inflammatory response syndrome

• Retaliatory surge of anti-inflammatory mediators released in response to SIRS.

Figure 104–2. The compensatory antiinflammatory response syndrome occurs when the antiinflammatory response is prolonged, leading to increased susceptibility to nosocomial infection.

by increased interleukin (IL)-1 and tumor necrosis factor (TNF)-α levels (Figure 104-1). It could be blunted by nonsteroidal antiinflammatory drugs and hence was prostaglandin mediated. A systemic inflammatory response was called *sepsis* if related to infection and *SIRS* if related to surgery, pancreatitis, or other noninfectious processes. This syndrome was self-limited when antibiotics were used to kill the infection or time allowed recovery from surgery, pancreatitis, and other noninfectious causes. This proinflammatory response was turned off by an antiinflammatory response led by the antiinflammatory cytokine IL-10. When IL-10 resulted in reduction of IL-1 and TNF-α to normal control values, sepsis or SIRS stopped and organ failure did not occur (Figure 104-2). In patients who developed severe sepsis and MOF, the compensatory anti-inflammatory response was unsuccessful in turning off inflammation. Instead, these patients had persistent elevation of the cytokine IL-6 along with IL-10. Bone coined the term *immunologic dissonance* to describe this process. He viewed MOF as an inflammatory condition in which the normal antiinflammatory response was unable to turn off the proinflammatory process (Figure 104-3).

Proulx and colleagues[1] defined pediatric MOF syndromes as primary and secondary. Primary MOF occurred in 90% of children and was present at the time of admission, and secondary MOF occurred in 10% of children and was not present until 7 days after admission.[1] To evaluate the role of inflammation in pediatric sepsis-induced MOF, this group defined children as having no MOF (NMOF) if they had two-organ



Immunologic dissonance

• Massive amounts of both types of mediators are released, but balance cannot be restored.

Figure 104–3. *Immunologic dissonance* refers to patients at greatest risk of MODS/MOF-related death. These patients have uncontrolled proinflammatory and antiinflammatory features with an uneradicated source of inflammation and infection.

failure at presentation but never reached three-organ failure, resolved MOF (RMOF) if they had three-organ failure at admission that resolved to two-organ or less at 48 hours, persistent MOF (PMOF) if they had three or more organ failures at presentation that did not resolve by 48 hours, and sequential MOF (SMOF) if they had acute lung injury/adult respiratory distress syndrome at admission and then progressed to hepatorenal failure/dysfunction.[2] Similar to Proulx's classification, children in the latter investigation with SMOF represented 10% of the population. The mortality rates with NMOF, RMOF, PMOF, and SMOF were 2%, 8%, 35%, and 50%, respectively. The authors then investigated Bone's hypothesis in this categories and reported that patients with NMOF had an increase in IL-10 with subsequent turning off of inflammation; however, those with PMOF or SMOF had persistently high IL-6 and IL-10 levels—the hallmark of Bone's "immunologic dissonance."[2]

Bone's untimely death prevented him from further pursuing the mechanisms by which immunologic dissonance could mediate organ injury. However, Proulx et al. first reviewed the autopsy bank at their hospital and noted that children who died from sepsis-induced MOF exhibited two unsuspected findings compared with children who died of other causes: persistent or unrecognized infection and thrombotic and bleeding complications with organ infarctions. Accordingly, they pursued the notion that immunologic dissonance might lead to an inability to mediate coagulation homeostasis as well as an inability to clear infection. Proinflammatory cytokines including TNF-α and IL-1 induce endothelial activation in vitro with an increased prothrombotic and antifibrinolytic state and expression of adhesion molecules (Figures 104-4 to 104-6). Patients with PMOF had increased tissue factor and plasminogen activator-1 activity as well as circulating adhesion molecules, intercellular adhesion molecule, and vascular adhesion molecule consistent with the hypothesis that immunologic dissonance was associated with an activated prothrombotic/antifibrinolytic endothelium.[3,4] IL-6 also inhibits ADAMTS-13, the von Willebrand factor (vWF) multimer-cleaving protease, in vitro. PMOF patients also had deficient ADAMTS-13 activity compared with NMOF patients, consistent with increased risk of vWF multimer–mediated thrombosis.[5] Increased IL-10 is the hallmark of the TH2 antiinflammatory cytokine response. When the TH2 response is dominant, the TH1 response can be turned

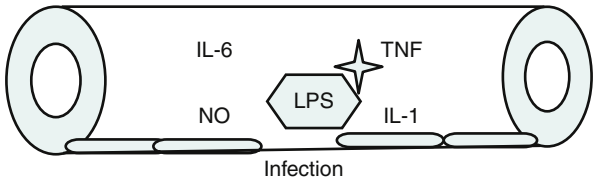


Figure 104–4. Infection evokes a proinflammatory cytokine response that brings blood flow to the site of infection. *LPS,* Lipopolysaccharide.

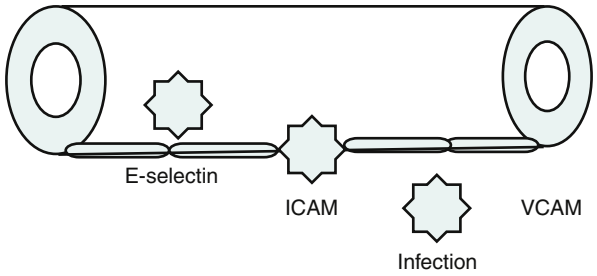

Figure 104–5. The proinflammatory cytokines stimulate expression of adhesion molecules that allow immune cells to roll, stick, and transmigrate to kill the infection. *E-selectin,* Endothelial selectin; *ICAM,* intercellular adhesion molecule; *VCAM,* vascular cell adhesion molecule.

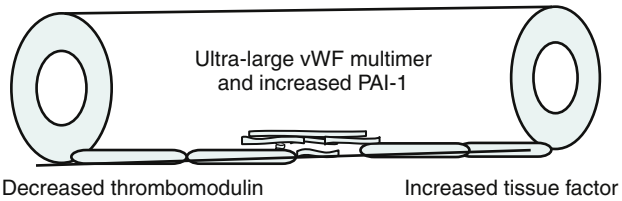

Figure 104–6. The proinflammatory cytokines increase expression of prothrombotic molecules and decrease expression of antithrombotic molecules to seal off endothelium at the site of infection. After the infection is killed and there is no longer a proinflammatory cytokine response, the endothelium returns to its usual antithrombotic, profibrinolytic state. *PAI-1,* Plasminogen activator inhibitor type 1.

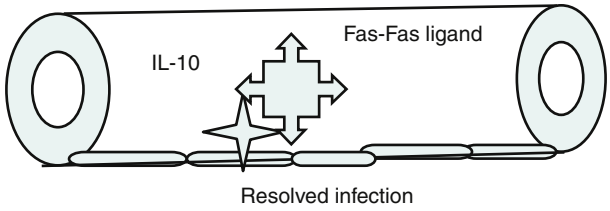

Figure 104–7. After the infection is killed, the antiinflammatory cytokines turn off expression of the proinflammatory cytokines. This results in reduction in monocyte/macrophage TNF production and apoptosis of activated immune cells.

off, a state known as *immune paralysis* (Figure 104-7). These patients have a diminished ex vivo ability to secrete TNF-α from endotoxin-stimulated monocytes or macrophages. Without this ability, infections cannot be terminated. PMOF patients exhibited immune paralysis more frequently than did NMOF patients.[6]

Cytokines and nitric oxide also inhibit cytochrome P450 activity and mitochondrial respiration in vitro. One study group found that patients with PMOF had reduced cytochrome P450 (10-fold) activity compared with patients with NMOF (twofold).[7] *Immunologic dissonance* in PMOF was associated with endotheliopathy, immune paralysis, and poor metabolism, but how was PMOF different from SMOF? The authors determined that patients with SMOF were more likely to have viral or lymphoproliferative disease with very high soluble Fas ligand (sFasL) levels. In vitro, sFasL levels greater than 500 pg/mL cause hepatocyte necrosis. Children with MOF with sFasL levels greater than 500 pg/mL demonstrated liver injury at autopsy.[8] The mechanism of injury in SMOF was different than in patients who presented with MOF (Figure 104-8).

In this decade, investigators from the United Kingdom have investigated the inflammation/immune dysregulation hypothesis in SIRS/sepsis, hypothesizing that reduced complement activity increases the risk of SIRS/sepsis.[9] Mannose-binding lectin (MBL) is the first complement component released and is required for the first 12 hours of complement activity. Approximately 30% of children are MBL deficient. Complement factor H inhibits complement activity. The complement H factor H Y402H polymorphism reduces this complement inhibition activity. Using genotype analyses, these investigators have demonstrated that children at risk for SIRS/sepsis more commonly have deficiencies in MBL production and a reduction in this H factor polymorphism. These two polymorphisms together lead to an even greater risk of SIRS/sepsis than either alone. The interpretation is that diminished complement function prevents rapid clearance of antigen, leading

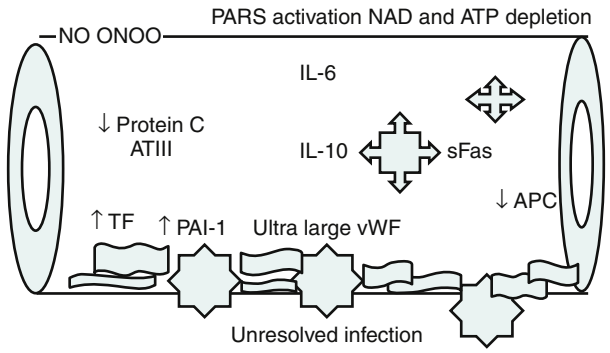

Figure 104–8. In immunologic dissonance, MOF patients are unable to resolve infection and inflammation. They remain in a prothrombotic/antifibrinolytic state with microvascular thrombosis and thrombocytopenia-associated MOF. They also have immunoparalysis with ineffective antigen-presenting cell activity mediated in part by increased IL-10. SMOF can occur when increased sFasL levels higher than 500 pg/mL induce liver injury. Metabolism is also adversely affected as nitric oxide plus superoxide anion lead to the formation of peroxynitrite radicals that inhibit cytochrome P450 activity and mitochondrial respiration. *TF,* Tissue factor; *PAI-1,* plasminogen activator inhibitor type 1; *AT III,* antithrombin III; *NO,* nitric oxide; *ONOO,* peroxynitrite; *PARS,* polyadenosylribose synthase; *APC,* antigen presenting cell.

to the SIRS/sepsis syndrome. The inflammation hypothesis is alive and well in SIRS, sepsis, severe sepsis, and MOF.

Definitions and Scoring

As previously noted, SIRS is defined by two of the following four criteria: tachypnea, tachycardia, fever, and leukocytosis. *Sepsis* is defined as SIRS plus suspected or documented infection. Severe sepsis is defined as sepsis plus organ failure. Acute lung injury is defined by bilateral pulmonary infiltrates and a Pao_2/Fio_2 ratio less than 300. MOF or multiple organ dysfunction

syndrome is defined by failure of more than one organ. Many definitions exist for defining organ failure. Wilkinson and Pollack[10] published the first definitions in pediatrics, which were subsequently modified by Proulx and then again by Doughty.[2] Goldstein and colleagues[11] subsequently developed two more sets of definitions. Doughty et al.[2] developed the organ failure index to score organ failure. This index is a simple integer score that assigns 1 point for each organ failure. Leteurtre and colleagues[12] reported two more MOF scores, the Pediatric Multiple Organ Dysfuction (PEMOD) and the Pediatric Logistic Organ Dysfunction (PELOD) scores.[12] The PEMOD score assigns 1 to 4 points per organ failure depending on severity. The PELOD score logistically weights these scores in the hope of allowing for prognostication. It remains unclear whether the PELOD score can be used in this manner.

Outcomes

In the United States, survival in the setting of SIRS/sepsis is almost universal. Odetola and colleagues[13] reported that survival in severe sepsis is 96%, 98% overall in previously healthy children and 92% in children with chronic diseases. Typpo and colleagues[14] reported that survival from MOF is 90%. Survival rates decrease as the number of organ failures increase.

Multiple Organ Failure/ Dysfunction Phenotypes, Respective Biomarkers, and Therapies

Thrombocytopenia-Associated Multiple Organ Failure

New-onset thrombocytopenia is a harbinger of thrombotic microangiopathy in MOF, especially when accompanied by increased lactate dehydrogenase and reduced renal function (Figure 104-9). Until the current decade, thrombotic microangiopathy of critical illness was believed to be mediated by fibrin, but more recent work suggests that vWF multimer–associated platelet thrombi are an unrecognized cause. If ADAMTS-13 activities (vWF-cleaving protease) are

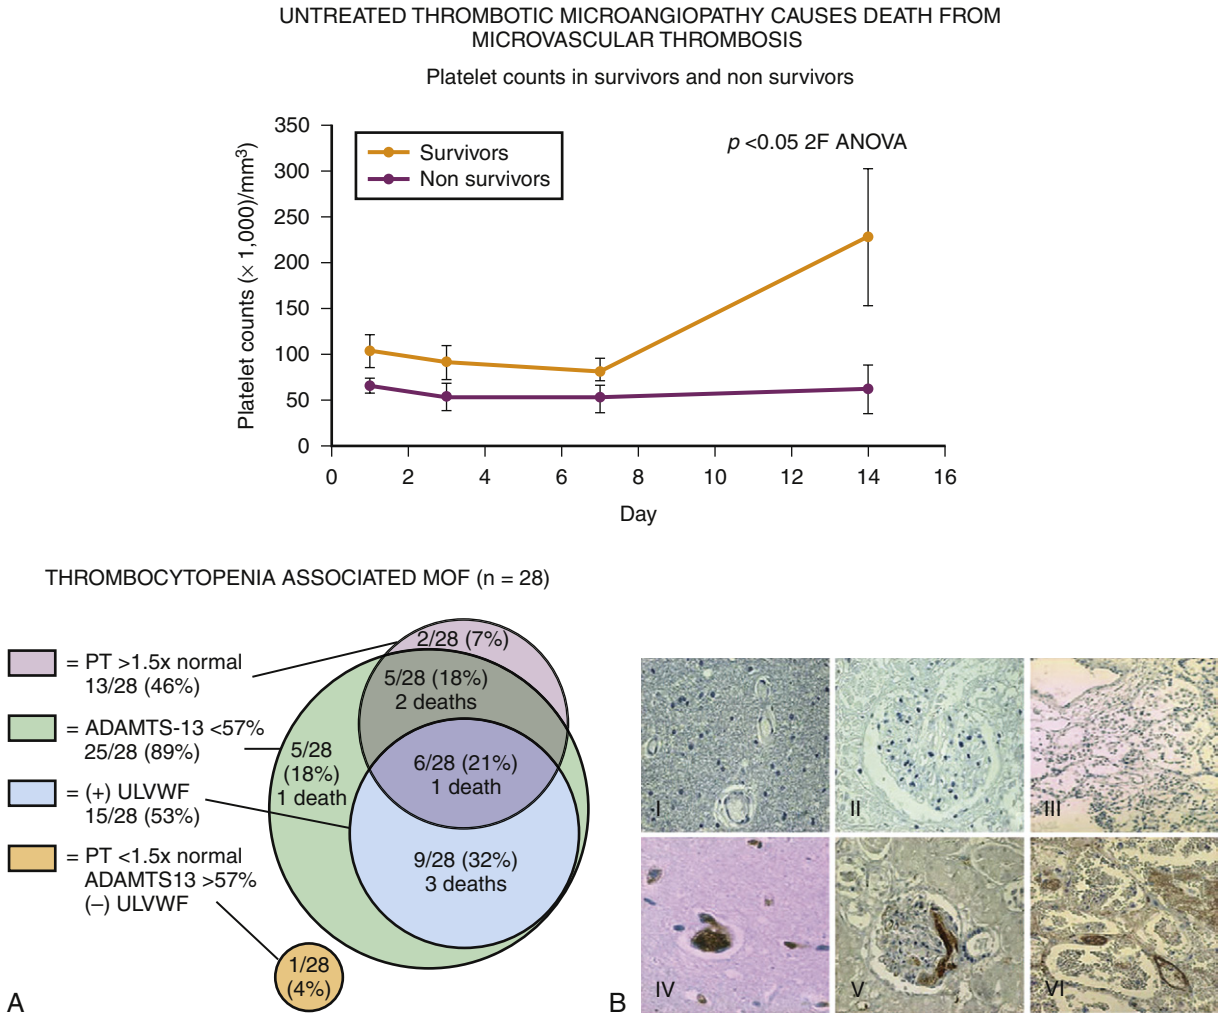

Figure 104–9. Thrombocytopenia-associated MOF is heralded by new-onset thrombocytopenia and MOF. Survivors recover platelet count and nonsurvivors do not. In this study, 89% of these patients had reduced ADAMTS 13 (**A**). At autopsy, patients had vWF multimer thrombi (**B**) in brain (*panel IV*), kidney (*panel V*), and lung (*panel VI*). These microthrombi can resolve with intensive plasma exchange therapy that removes thrombogenic ultralarge vWF multimers and replenishes ADAMTS-13.

less than 57% of control and vWF multimer antigen levels are increased, this form of thrombosis should be highly suspected. Intensive plasma exchange can be required to reverse this process because it removes the thrombogenic ultralarge vWF multimers and replenishes ADAMTS-13 (vWF-cleaving protease) activity.[5,15]

Immune Paralysis and Lymphoid Depletion Syndrome

Adult and neonatal investigators noted the associations among lymphocyte apoptosis, lymphoid depletion, and death from nosocomial sepsis. When dendritic cells, monocytes, or macrophages ingest these apoptotic bodies, a profound TH2 response ensues, with immune paralysis and death associated with uneradicated infection (Figure 104-10). Pediatric studies corroborate these findings with immunoparalysis and prolonged lymphopenia associated with nosocomial infection and death.[6] In transplant recipients, rapid tapering of immune suppressants can restore monocyte function and reverse immune paralysis. In non-immune-suppressed patients, low-dose subcutaneous granulocyte-macrophage colony-stimulating factor (GM-CSF) can reverse immune paralysis. If patients have hypogammaglobulinemia, intravenous immunoglobulin (IVIG) can be given. If the patient is severely lymphopenic, antimicrobial prophylaxis can be considered.

Viral/Lymphoproliferative Disease–Associated Sequential or Liver-Associated Multiple Organ Failure Syndrome

Viral/lymphoproliferative disease associated with SMOF or liver-associated MOF represents only 10% of MOF, but this diagnosis carries the worst prognosis (Figure 104-11). Liver injury is associated with high sFasL levels (>500 pg/mL).[8] In transplant recipients, the most common cause is post-transplant lymphoproliferative disease. Epstein-Barr virus intercalates the viral IL-10 genome into B cells, preventing activated immune cell death and promoting lymphoproliferation. This is treated by stopping immune suppression, administering the B-cell monoclonal antibody rituximab, and administering interferon-α if necessary. In nontransplant patients with a family history of a similar disease, primary hemophagocytic lymphohistiocytosis (HLH) must be considered. These patients have absent natural killer (NK)/cytotoxic T-lymphocyte (CTL) cell activity secondary to mutations in perforin signaling, rendering them unable to kill viruses and cancer cells. Furthermore, these patients cannot direct programmed cell death in activated immune cells. These patients are treated with chemotherapy and bone marrow transplantation to kill activated immune cells and replenish functioning NK/CTL cells. In patients with rheumatologic disease, this syndrome may be caused

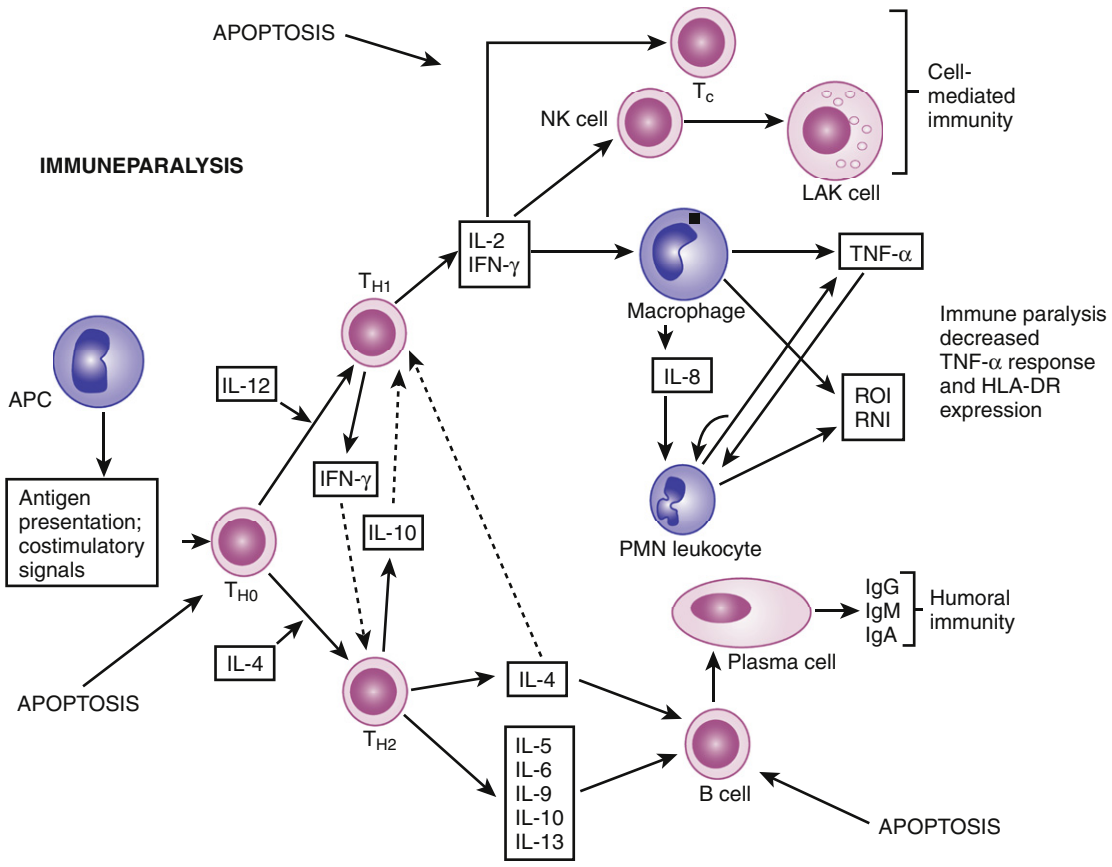

Figure 104–10. MOF patients who develop secondary infections commonly have immuneparalysis with an ex vivo TNF-α response to lipopolysaccharide <200 pg/mL and/or reduced monocyte human leukocyte antigen DR expression <30% or <8000 molecules/cell. Immune function can be restored by holding immunosuppressant therapy and low-dose GM-CSF therapy.

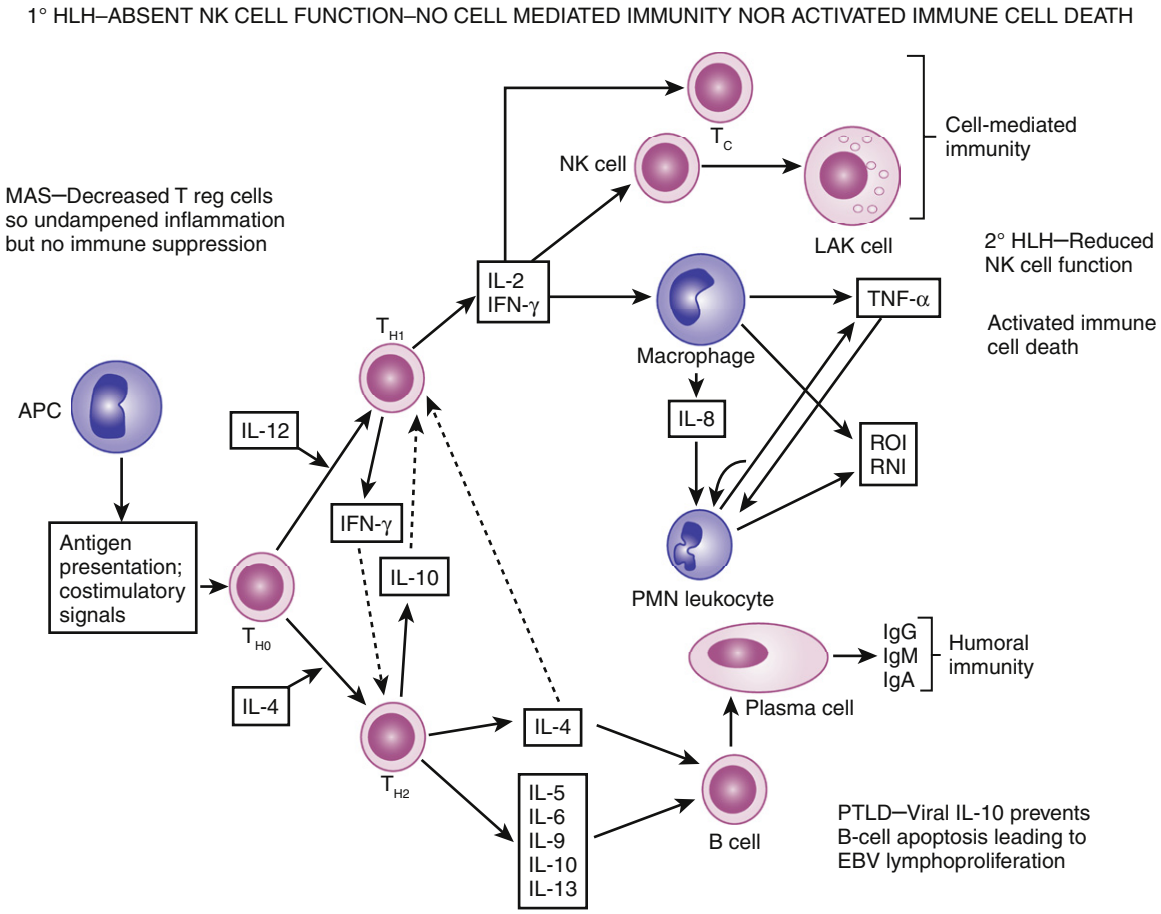

Figure 104–11. SMOF patients have a number of different immune system defects that can be present and require sorting because therapies differ according to cause. *PTLD,* Posttransplant lymphoproliferative disease.

by macrophage activation syndrome (MAS) as a result of decreased T-regulatory cell activity (see Chapter 98). These patients respond well to pulse steroids. Patients with infection-associated or secondary HLH will not have the rash, arthralgias, or serositis of MAS or the family history of primary HLH. These patients have decreased but not absent NK/CTL cell function. Therefore they can kill viruses and cancer cells and induce activated immune cell death, but at a slower rate. These patients respond well to eradication of infection with supportive therapy. In addition, IVIG, plasma exchange, and interferon-α have been reported as successful therapies.[16]

Secondary Hemochromatosis-Associated Cardiac Hepatopancreatic Multiple Organ Failure

Patients who have received multiple blood transfusions (including those with aplastic anemia, liver failure, or hemolytic anemia) develop iron overload with high ferritin level (>1000 μg/L) and iron-binding capacity <50%. Iron deposition can be diagnosed by liver magnetic resonance imaging. Infections thrive with this excess iron, and sepsis-induced MOF is common in this population. Chelation can be considered.

Hyperleukocytosis-Associated Multiple Organ Failure

Leukostasis syndrome is caused by pertussis-associated leukocyte proliferating factor and is predominantly found in infant pertussis. The time-sensitive treatment appears to be leukophoresis or whole blood exchange. These therapies remove toxin and reduce pulmonary leukosequestration.

Therapeutic Approaches to Systemic Inflammatory Response Syndrome, Sepsis, Acute Lung Injury, and Multiple Organ Failue

A patient with SIRS can be distinguished from a patient with sepsis by history. An antecedent history of surgery, pancreatitis, or trauma is supportive of SIRS. The prototype for SIRS can be found in the patient with a spinal fusion or the postoperative cardiac surgery patient. Tissue injury induces the inflammatory complement/cytokine-driven response of tachycardia, tachypnea, fever, and leukocytosis. If the systemic inflammatory response worsens or occurs de novo several days after the antecedent insult, sepsis should be considered and infection

Box 104–1 Nonspecific Therapies to Prevent and Resolve MOF

- Reverse shock in a time-sensitive fashion (ACCM/PALS guidelines)
- Provide effective antibiotics in time-sensitive fashion
- Remove nidus of infection
- Use antitoxins for toxin-mediated disease
- Fluid removal before fluid overload >10% body weight
- Use lung protection strategy of an effective tidal volume <8 mL/kg
- Control hyperglycemia
- Prevent drug toxicity by titrating drugs to liver/kidney function
- Remove toxic drugs as indicated
- Provide nutrition
- Prevent or stop systemic hemolysis

ACCM, American College of Critical Care Medicine; *PALS,* Pediatric Advanced Life Support.

suspected. SIRS is treated by watchful waiting, fluid resuscitation if hypovolemia is suspected, and temperature control as required. Acute lung injury should be treated with supplemental oxygen as needed. SIRS is thought to be a self-limited response that can be prolonged in the presence of decreased complement production found in one third of the population who have MBL and complement H polymorphisms. Of note, the rate of tachycardia and tachypnea decreases with time. If sepsis is suspected, antibiotics should be given.

If SIRS/sepsis progresses to organ failure or MOF, it is no longer a self-limited disease. Further support and interventions are needed (Box 104-1). If acute lung injury progresses, intubation and mechanical ventilation will be needed. Intubation with ketamine as an induction agent in this setting is antiinflammatory and will not interfere with the adrenal stress response. Pulmonary capillary and epithelium leak will result in indirect ARDS, and the patient will need positive end-expiratory pressure to facilitate adequate oxygenation. Protective lung ventilation is recommended. Use of high lung volumes results in increased systemic inflammation and immune paralysis. For this reason, an effective tidal volume of no more than 8 mL/kg/breath is recommended. Cardiovascular management should be goal directed in a time-sensitive manner. Fluid and inotrope administration targeting capillary refill of less than 2 seconds and normal blood pressure in the emergency department is associated with a 40% reduction in mortality rate.[17] Fluid, inotrope, and blood resuscitation directed to attaining superior vena cava oxygen saturation greater than 70% reduced the incidence of MOF (renal and neurologic failure in particular) and mortality rate fourfold in a randomized controlled trial.[18] The use of antibiotics and antitoxins in a time-sensitive and appropriate manner is paramount. In a retrospective cohort study involving 14 North American adult intensive care units, septic patients received effective antibiotics on average 6 hours after the onset of hypotension. Administration of an effective antimicrobial within the first hour of documented hypotension was associated with a survival rate of 79.9%. However, for each subsequent hour delay in administering an effective antimicrobial, average survival decreased by 7.6%.[19]

Careful attention should also be given to fluid balance. When patients have fluid overload greater than 10% total body weight (e.g., up 1 L in a 10-kg child), the risk of death from MOF increases. Diuretic and or extracorporeal therapies, including intermittent renal dialysis and continuous hemofiltration, should be used to remove fluid as needed after initial resuscitation specifically to prevent this level of fluid overload. Nutrition is also important and should be given enterally if possible; if this is not possible, administration should be parenteral. The delivery of a intravenous 10% dextrose solution at maintenance will ensure glucose delivery requirements. This provides all calorie needs on the first day. Feedings or total parenteral nutrition can be started subsequently. Although controversy exists regarding what glucose level should be targeted, there is consensus that glycemic control with insulin is required at some degree of hyperglycemia. Hyperglycemia causes monocyte deactivation, increases C-reactive protein levels and inflammation, reduces immune function globally, and increases risk of thrombosis and MOF. Insulin improves monocyte/macrophage function and reduces systemic inflammation and thrombosis.

Because cytochrome P450 activity is decreased during sepsis induced MOF (approximately 50% in sepsis, 25% with two-organ failure, and 10% with persistent three-organ failure), adjustment of cytochrome P450 metabolized medications is suggested when possible. Medications metabolized by the kidney should be adjusted as well according to creatinine clearance. One way to address reduced drug metabolism is to use drugs that can be followed pharmacokinetically by measured concentrations and pharmacodynamically by physiologic responses to titrated dosing. A nice rule of thumb when giving drugs that do not have pharmacokinetic or pharmacodynamic targets is to double the interval between doses for every doubling of creatinine or bilirubin depending on whether the drug is primarily metabolized through renal or hepatic pathways. Hormone synthesis can also be affected. Patients with adrenal insufficiency or thyroid insufficiency will require replacement.

Unresolving MOF should evoke suspicion that the source of infection is not being eradicated. Persistent inflammation with thrombosis and infection is the cause of PMOF. Careful review of the minimum inhibitory concentration profile of the infection should be performed and antibiotics with the lowest possible minimum inhibitory concentration should be used. If the infection is toxin producing, clindamycin should be given to stop production and IVIG administered to neutralize the toxic effects. The nidus of infection may need to be removed surgically. Barie and colleagues[20] found that surgical sepsis mortality rate was 96% with failed nidus removal compared with only 4% with successful removal. Primary or acquired immune deficiency syndromes can also be the cause of uneradicated infection. Primary immunodeficiencies are usually suspected in children younger than 5 years but can present at any time in life. Initial screening for these syndromes includes white blood cell count, lymphocyte subset, complement level, gammaglobulin level, and tests for chronic granulomatous disease. Secondary immune deficiencies include severe neutropenia (absolute neutrophil count <500) and severe graft-versus-host disease (grade III and above). Neutropenia is most commonly related to bone marrow suppression induced by chemotherapy. Infection eradication and subsequent resolution of MOF occur only after restoration of the neutrophil counts. The pathobiology of graft-versus-host disease is one of donor T cells being directed against host epithelial cells. This results in denudation of the epithelial cell barrier with secondary bacterial and fungal infections. Treatment is difficult but

is directed at stopping T cell–mediated epithelial destruction without concomitantly stopping the host's ability to kill infection. This is the most difficult MOF syndrome to treat.

Hemolysis is another cause of unresolving MOF. Free hemoglobin becomes hemoglobin peroxidase when exposed to superoxide and hydrogen peroxide generated by activated white blood cells. Hemoglobin peroxidase can lead to endothelial cell injury, microvascular constriction secondary to NO scavenging, and when bound to haptoglobin reduction in viable macrophages.[21] The prototype of this form of MOF is found in children with sepsis who are on poorly functioning extracorporeal membrane oxygenation (ECMO) support. If the ECMO circuit induces excessive hemolysis (free hemoglobin >10 μg/L), MOF can ensue. The approach should be to attempt to stop ongoing hemolysis by changing oxygenator circuits, adding a second venous cannula, and reducing ECMO flow. In hemolytic disease such as sickle cell anemia, plasma exchange can help reduce hemolysis and resolve MOF.

Rare medication toxicities can also contribute to unresolving MOF. Patients with intrathecal baclofen pump infusions can develop baclofen withdrawal infusion syndrome when infusions are stopped. This can be remedied by restarting intrathecal baclofen. Linezolid toxicity can also progress to overwhelming lactic acidosis and MOF. Linezolid's antimicrobial activity is mediated through bacterial ribosome poisoning. Unfortunately, human mitochondria can similarly be poisoned by linezolid. Baseline lactate levels should be obtained, and if lactate levels increase while on linezolid, the drug should be stopped before lactic acidosis ensues. Nitroprusside can induce cyanide poisoning. Cyanide levels should be followed when giving this medication. Propofol can cause fatty acid oxidation/mitochondria dysfunction–driven propofol infusion syndrome with overwhelming lactic acidosis. Propofol should not be used for long-term sedation in children younger than 3 years. Systemic drug reactions such as Stevens-Johnson syndrome and delayed hypersensitivity syndromes must also be considered. These scenarios call for discontinuation of the offending agent and watchful supportive care, which can sometimes be tricky. For example, the delayed hypersensitivity skin rash may be difficult to discern in children with more pigmentation. For patients with sulfa drug–related Stevens-Johnson syndrome, it is important to realize that furosemide is also a sulfonylurea.

Even in clinical settings without sophisticated research tests, patients with PMOF can be phenotyped (Table 104-1). New-onset thrombocytopenia with MOF, increase lactate dehydrogenase with or without schistocytes, and renal dysfunction likely reflect a thrombotic microangiopathy that resides within the disseminated intravascular coagulation/thrombotic thrombocytopenic purpura (DIC/TTP) continuum. This complex coagulopathy can be treated with plasma infusion or exchange, protein C, antithrombin III, pentoxifylline, prostacyclin, and/or heparin. New or persistent bacterial or fungal infections in a patient with MOF who does not have evidence of primary or secondary immune deficiency or an uneradicated nidus of infection is highly suggestive of immune paralysis/lymphoid depletion syndrome. Immune suppressant therapies should be rapidly tapered in these patients. Dexamethasone in particular should be stopped and transitioned to hydrocortisone. GM-CSF can be given subcutaneously at 125 μg/m^2 daily subcutaneously to reverse immunoparalysis. If immunoglobulin G levels are less than 500 mg/dL, IVIG should be considered. If the CD4 count is low, antifungal, antiviral, and antiprotozoal prophylaxis can be considered. Patients with SMOF that begins with ARDS and progresses to hepatorenal syndrome should be recognized and treated accordingly. If the child has EBV-related posttransplant lymphoproliferative disease (high EBV titers), rapid immune suppression tapering is recommended along with rituximab and IVIG therapy. If the ferritin level is higher than 500 μg/L, then MAS (rheumatologic signs), secondary hemochromatosis, or the HLH syndrome should be considered. History and physical exam findings of rash, serositis, and arthralgias support MAS and should be treated with pulse steroids. A long-term history of transfusions, a ferritin level greater than 1000 μg/L, and an iron-binding capacity less than 50% suggests secondary hemochromatosis. These patients should be treated with iron chelation therapy. These patients are prone to iron-loving *Aspergillus* infection during chelation therapy. Appropriate antifungal coverage is recommended in these children. In the absence of rheumatologic or secondary hemochromatosis disease, HLH should be considered. A positive family history should invoke evaluation for primary HLH. These patients should have no NK cell cytotoxicity activity and specific

Table 104–1 MOF Phenotypes

Phenotype	Diagnosis	Therapy
Thrombocytopenia-associated MOF	New-onset thrombocytopenia and MOF with increased LDH and renal involvement; ADAMTS 13 <57%	Intensive plasma exchange until resolution
Immunoparalysis MOF	Whole-blood TNF-α response to LPS <200 pg/mL or monocyte HLA DR expression <30% or <8000 molecules/cell for >3 days	Rapidly taper immunosuppressants; give low-dose GM-CSF at 5 μg/kg/day subcutaneously
SMOF	Respiratory then hepatorenal	
	PTLD: EBV disease posttransplantation	Stop immunosuppressants; give rituximab + IVIG
	MAS: rheumatologic disease + ferritin >500 μg/L	Pulse steroids
	Primary HLH: positive family history or consangunity + ferritin >500 μg/L	HLH protocols
	Secondary HLH: infection + ferritin >500 μg/L	Supportive therapies, plasma exchange, interferon-α + IVIG
Iron overload MOF	History of multiple transfusions, ferritin >1000 μg/L, Fe binding >505%	Iron chelation, coverage for *Aspergillus* during chelation
Hyperleukocytosis MOF	Pertussis + high white blood cell count + ARDS and pulmonary hypertension	Leukophoresis or whole-blood exchange

LDH, Lactate dehydrogenase; *HLA,* human leukocyte antigen; *PTLD,* posttransplantation lymphoproliferative disorder.

perforin mutations. Treatment includes chemotherapy followed by bone marrow transplantation. In patients without a family history who have bacterial/fungal infection, secondary HLH is a possibility. These patients have reduced NK cell activity but no perforin mutations. Successful treatment for this group of patients has included interferon-α plus IVIG, steroids plus plasma exchange, and supportive care with eradication of infection. Cancer patients with absent NK cell function and HLH have responded to the IL-2 receptor antibody daclizumab.

Time Course of Systemic Inflammatory Response Syndrome, Sepsis, and Multiple Organ Dysfunction

In general terms, SIRS and sepsis should resolve within 5 days. MOF resolves over 1 week to 3 months. MODS and MOF are related to epithelial cell and endothelial cell dysfunction, damage, and apoptosis. If significant hypoxia/ischemia is the causal event, MOF will not resolve until (1) reepithelialization of lung, liver, and kidney occurs; (2) reendothelialization of the organs occurs; and (3) canalization of microvessels occurs. These processes take 6 weeks to 3 months. Accordingly, health care providers should be patient and not give up on MOF-afflicted children too early.

Summary

Inflammation and immunity are the basis of SIRS, sepsis, acute lung injury, ARDS, and MOF. SIRS and sepsis occur more commonly in patients with reduced complement function. MOF and MODS occur in patients who have epithelial/endothelial cell injury and or microvascular thrombosis caused by unresuscitated shock, ischemia/reperfusion, unresolved inflammation, unresolved infection, and/or drug- or toxin-induced mitochondrial injury. SIRS and sepsis are managed with fluids, temperature control, and antibiotics if infection is present, which usually resolves within 5 days. This approach prevents the development MOF or MODS. If treatment is delayed, then MODS or MOF can occur. Treatment is then used to reverse shock, remove infection, resolve inflammation, and reverse microvascular thrombosis. Phenotype-specific therapies are directed to recovery of endothelial, epithelial, mitochondrial, and immune function. Survival can be 90% with a patient approach.

Principles of Toxin Assessment and Screening

Alan D. Woolf

PEARLS

- The diagnosis of unknown poisoning is based on obtaining a good history and performing a thorough physical examination. Rarely does a laboratory finding reveal a totally unexpected diagnosis.
- Some toxins (e.g., acetaminophen, *Amanita* mushroom poisoning, valproic acid, sulfonylurea medications) are notable for the delay between the time of ingestion to the onset of symptoms. Others, such as methadone or naltrexene, can have symptom recurrence hours after an apparent improvement in consciousness.
- The clinician can often predict the severity of medical outcomes from poisonings simply by noting the timing of progression of the poisoned patient's signs and symptoms of toxicity.

Despite significant progress in preventive measures, poisonings in children and adolescents continue to be common occurrences. More than 51% of almost 2.5 million poison center calls in the United States in 2007 involved children younger than 6 years of age.[1] Although many of these exposures are medically trivial, poisonings account for an important number of all pediatric hospital visits and hospitalizations. Not all children are equally at risk for serious poisoning. The incidence of poisoning is highest among children 1 to 3 years of age. Boys slightly outnumber girls as victims of unintentional exposures. Children with developmental delays and/or pica, as occurs with autistic spectrum disorders, have an increased risk for self-poisoning. A second peak of serious poisonings occurs in adolescence, when a suicide attempt by poisoning (with females disproportionately overrepresented) or a misadventure involving substance abuse becomes the common circumstance underlying a poisoning episode. Adolescents with anorexia nervosa or psychiatric conditions such as clinical depression are especially vulnerable to self-poisoning.

Childhood poisoning typically occurs around mealtime, when parents are preoccupied with food preparation or are otherwise distracted. Many poisonings involve medications or household products that are open and being used at the time of the poisoning. The second most common site of a poisoning other than the child's own home is that of the grandparents. Children in power struggles with parents, and those in socially isolated, stressed families, sometimes experience repeated poisoning events.

Common Agents Involved

The most common agents involved in preschooler poisonings are medications, such as analgesics, cough and cold preparations, and dermatological preparations; household products, such as cleaning agents, soaps, and detergents; and plants. Table 105-1 lists those agents responsible for the majority of calls to poison control centers. The agents most frequently involved in serious pediatric poisonings (those requiring intensive care) are prescription medications (tricyclic antidepressants, anticonvulsants, digitalis, and opiates), alcohol, and hydrocarbon-based household products. Lead poisoning and carbon monoxide poisoning related to house fires are less recognized, but frequent causes of poisoning hospitalization in childhood. International adoptees and children immigrating to the United States may have been exposed to lead, arsenic, or other toxins in a polluted environment in their home countries or by their family's use of poorly regulated remedies. Clinicians should ask caretakers about the types and doses of any medications, herbs, vitamins, diet supplements, or ethnic remedies being used to treat the child's other health problems. Such therapies may be interacting with the toxins responsible for the poisoning or otherwise contributing to the child's toxicity.

Resources for the Clinician

In making the diagnosis of an unknown poisoning, the physician must rely on observation, history-taking abilities, and clinical skills. Laboratory analyses and radiographic findings are sometimes helpful. References such as Drug Information (available annually from the American Hospital Formulary Service [AHFS], American Society of Hospital Pharmacists Bethesda, Md.) and the Poisindex computer database (Micromedex Cooperation, Greenwood Village, Colo.) can be helpful in identifying drugs and their actions and precautions. The regional poison control center (telephone: 800-222-1222) can

Table 105–1 Agents Most Frequently Involved in Childhood (<6 Years) Poisoning-Related Poison Center Calls in the United States (2007)

Toxic Agent	Number of Poison Center Calls	Percent (%) Total
Cosmetics and personal care	168,875	13.7
Cleaning substances	118,068	9.6

provide helpful consultative services by toxicologists. Such services may include:

1. Assistance with the differential diagnosis by citing toxins known to cause a particular constellation of symptoms and signs
2. Information about drug-drug, drug-chemical, and drug-herb interactions
3. Expected clinical course of the patient, given the known kinetics of the agents involved
4. Help with locating laboratories that can assay tissue samples for exotic drugs and chemicals
5. Advice about current management techniques for specific poisonings
6. Help in locating supplies of particular antidotes, antivenins, or other exotic poisoning medicines
7. Assistance with triage of patients to specialized regionalized therapeutic services for acute poisonings such as hemodialysis or hyperbaric oxygen chambers
8. Surveillance for clusters of poisoning in a community representing a public health hazard
9. Assistance in reporting adverse drug or dietary supplement reactions or medical errors to appropriate public health authorities
10. Assistance to first responders and other public health officials in a community-level hazardous materials emergency
11. Assistance with community-level public education programs and public service announcements aimed at poisoning prevention

General Assessment of the Poisoned Patient

History

An accurate history is vitally important in the diagnosis of unknown poisoning. Surprisingly, the physician in the intensive care unit (ICU) may be the first health professional who can sit with parents and carefully review the possible circumstances of the exposure. Poisonings may occur by various routes including ingestion, inhalation, ocular exposure, dermal exposure, mucous membrane involvement, or parenteral exposure. Once the child's condition has been stabilized, the pediatrician should query the family about the incident, with particular attention to the environmental, patient, and toxic agent factors as outlined in Table 105-2. In acute, unintentional exposures in young children, the time of exposure and toxin involved frequently are accurately known. The importance of obtaining the precise ingredients in the suspected toxic agents cannot be overemphasized. Parents should bring the product containers or medication labels. For estimations of liquid toxins, the average swallow of a young child is approximately 5 to 10 mL while that of the older child and adolescent is 10 to 15 mL. The clinician must appreciate the fact that parents frequently minimize the child's exposure to a toxin in an attempt to deny the threat of injury or to assuage their guilt that such an episode occurred. Therefore it is prudent to assume the worst possible scenario in calculating the maximum dose of a drug or household product a child could have swallowed in a poisoning and to treat the patient accordingly. Calculation of the dose the child might have received is sometimes helpful, using the maximum number of missing tablets or amount of liquid, the concentration of the drug or chemical, and the child's weight.

The latency between the time of ingestion and the onset of symptoms is important. The tempo of progression of symptoms and signs also may help the clinician gauge the severity of the intoxication and the urgency with which intervention is necessary. However there are some exceptions to this rule. Patients poisoned by some toxins, such as paraquat and the *Amanita* mushroom toxin, classically have a relatively asymptomatic period of 12 hours or more but then manifest life-threatening pulmonary or hepatic toxicity, respectively.[2,3] Some drugs, such as sulfonylurea hypoglycemics and valproic acid, can also have similar latency periods prior to the onset of severe toxicity.[4,5] Adolescent poisonings are confounded by

the intentionality of the episode and the frequent unreliability of the adolescent's history. Adolescents in distress may be evasive, misleading, or otherwise uncommunicative. Their ability to remember or provide a coherent account of what happened may be distorted by the effects of the drugs taken. The clinician cannot assume that the time of exposure, the dose, or even the toxic agents themselves are accurately recounted.

Physical Examination

The physical examination is crucial for assessment of the patient's medical stability and for identification of the unknown poison. Specific changes in vital signs and symptoms are associated with likely toxins or groups of toxins. Such characteristic clinical patterns of illness are sometimes termed toxidromes. Table 105-3 lists some of the more common toxidromes important in pediatric poisoning. Families are using herbs and diet supplements with increasing frequency to treat their children's illnesses or simply to promote their general well-being. However, serious poisonings in which herbs and dietary supplements are implicated are appearing in the medical literature.[6] Table 105-4 lists some examples of toxicities associated with particular herbal remedies.

Frequently, the gastrointestinal tract is involved early in a poisoning. Nonspecific findings after a drug or chemical overdose include nausea, vomiting, abdominal pain, and loose stools. A variety of drugs can cause fever. Overdoses with cocaine, phenothiazines, atropine, or salicylates often are associated with an elevated temperature. For specific discussions of the effects of toxins on other selected organ systems, the reader is referred to the general reviews listed in the additional readings at the end of this chapter and to other chapters in this textbook on toxicology and poisonings.

Table 105-5 lists examples of drugs and toxic agents associated with specific effects on the cardiovascular system. Drugs with cardiotoxic effects, especially those with membrane stabilizing activity, are among those most commonly associated with life-threatening toxicity. In one 10-year retrospective study, 15 out of 17 poisoned patients requiring extracorporeal life support measures for refractory shock or prolonged cardiac arrest had overdosed on cardiotoxic agents.[7] Toxins may cause hypertension or hypotension by direct effects on vascular smooth muscle, neurogenic effects on autonomic nervous centers governing vascular innervation, direct effects on the heart, or renal effects. Specific agents associated with hypertension include adrenergic stimulants, such as amphetamines, cocaine, phencyclidine, phenylpropanolamine, ephedrine, and phenylephrine. Although the hypertension caused by sympathomimetics frequently lasts only a few hours, it may be associated with acute encephalopathy and/or intracranial hemorrhage.

Acute hypotension frequently is associated with aconite, antiarrhythmic agents, antihypertensive agents, β-adrenergic antagonists, calcium channel antagonists, clonidine, tricyclic antidepressants, opiates, and phenothiazine overdose. Anaphylactic, anaphylactoid, or allergic responses may also result in hypotension.

Tachycardia frequently is associated with ingestion of any of the sympathetic nervous system stimulants listed in Table 105-5. A notable exception is phenylpropanolamine, which, as a pure α-adrenergic receptor agonist, causes peripheral vasoconstriction associated with reflex bradycardia or a normal pulse. Tachycardia also is associated with the ingestion of exogenous thyroid preparations, the early phase of poisoning with tricyclic antidepressants, theophylline overdoses, and caffeine or nicotine intoxications. Bradycardia may accompany exaggerated vagal responses to some compounds or direct negative chronotropic effects on the heart. Interference with the cardiac conduction system may cause a slowed pulse. Cardiac drugs associated with bradyarrhythmias include the calcium channel antagonists, digitalis, and β-adrenergic antagonists. Antiarrhythmic agents such as quinidine and procainamide can slow the pulse. Aconite, an herbal remedy, binds to site 2 of the open-state of voltage-sensitive sodium channels, which then becomes refractory to excitation.[8] Aconite is also arrhythmogenic due, in part, to both its anticholinergic effects and its activation of the ventromedial nucleus of the hypothalamus.

Many drugs and chemicals depress a patient's consciousness either directly or by hypoxia resulting from decreased respiratory drive or simple asphyxia. Table 105-6 provides a suitable scoring system for determining the level of consciousness in the intoxicated patient. The dynamic nature of a

Table 105–3 Common Toxidromes in Pediatric Poisoning

Signs and Symptoms	Agent
Dilated pupils, tachycardia, tachypnea, warm moist skin, flushing, increased sweating, agitation	Sympathomimetic syndrome
Miosis, salivation, diarrhea, bronchorrhea, lacrimation, seizures, respiratory failure, bradycardia	Organophosphate insecticides
Fever, tachypnea, hyperpnea, lethargy, metabolic acidosis	Salicylates
Seizures, metabolic acidosis, history of tuberculosis, hyperglycemia	Isoniazid
Dry mouth and skin, flushed appearance, dilated pupils, fever, ileus, urinary retention, disorientation	Anticholinergic syndrome
Oculogyric crises, dystonia, opisthotonus	Phenothiazines
Severe metabolic acidosis, sluggish pupils, hyperemic retina, blurred vision	Methanol
Hypoglycemia, lethargy, ataxia, seizures, characteristic breath odor	Ethanol
Lethargy or coma, metabolic acidosis, active urinary sediment, crystalluria	Ethylene glycol
Headache, flulike symptoms, lethargy, dizziness, coma	Carbon monoxide
Pinpoint pupils, coma, respiratory depression	Opiate
Hyperthermia, neuromuscular rigidity, autonomic dysfunction, agitation, delirium	Serotonin syndrome
Metabolic acidosis, prolonged QRS interval, coma, seizures, dilated pupils, dysrhythmias	Tricyclic antide pressants
Protracted vomiting, tremors, tachycardia, anxiety, seizures, hypotension	Theophylline
Feeling of impending doom, sudden coma, metabolic acidosis, hypotension, bitter almond odor	Cyanide
Rotatory nystagmus, delirium; "4 C's": combative, catatonia, convulsions, coma	Phencyclidine

Table 105–4 Herbs Associated with Toxicity

Herbal Product	Toxic Chemicals	Toxic Effects
Aconite (*Aconitum* spp.)	Aconitine alkaloids	Nausea, vomiting, paresthesias, weakness, hypotension, asystole, arrhythmias, bradycardia
Chamomile *(Matricaria chamomilla, Anthemis nobilis)*	Allergens	Anaphylaxis, contact dermatitis
Chapparal *(Larrea divaricata, Larrea tridentata)*	Nordihydroguaiaretic acid	Nausea, vomiting, lethargy, hepatitis
Cinnamon oil (*Cinnamomum* spp.)	Cinnamaldehyde	Dermatitis, abuse syndrome
Coltsfoot *(Tussilago farfara)*	Pyrrolizidines	HVOD
Comfrey *(Symphytum officinale)*	Pyrrolizidines	HVOD
Crotalaria spp.	Pyrrolizidines	HVOD
Echinacea (*Echinacea angustifolia, Compositae* spp.)	Polysaccharides	Asthma, atopy, angioedema, anaphylaxis, urticaria
Eucalyptus *(Eucalyptus globulus)*	1,8-cineole	Drowsiness, ataxia, nausea, vomiting, seizures, coma, respiratory failure
Garlic *(Allium sativum)*	Allicin	Dermatitis, chemical burns, oxidizing agent
Germander *(Teucrium chamaedrys)*		Hepatotoxicity
Ginseng *(Panax ginseng)*	Ginsenoside	Ginseng abuse, diarrhea, anxiety, insomnia, hypertension
Glycerated asafetida	Oxidants	Methemoglobinemia
Grousel *(Senecio longilobus)*	Pyrrolizidines	HVOD
Heliotrope, turnsole *(Crotalaria fulva, Heliotropium, Cynoglossum officinale)*	Pyrrolizidines	HVOD
Jin bu huan (*Stephania* spp., *Corydalis* spp.)	L-Tetrahydropalmitine	Hepatitis, lethargy, coma
Kava-kava *(Piper methysticum)*	Kawain, methysticin	Hepatic failure, "kavaism" neurotoxicity
Kelp	Iodine	Thyroid dysfunction
Laetrile	Cyanide	Coma, seizures, death
Licorice *(Glycyrrhiza glabra)*	Glycyrrhetic acid	Hypertension, cardiac arrhythmias, hypokalemia
Ma huang *(Ephedra sinica)*	Ephedrine	Cardiac arrhythmias, seizures, stroke, hypertension
Monkshood *(Aconitum napellus, A. columbianum)*	Aconite	Cardiac arrhythmias, weakness, coma, shock, paresthesias, vomiting, seizures
Nutmeg *(Myristica fragrans)*	Myristicin, eugenol	Hallucinations, emesis, headache
Nux vomica	Strychnine	Seizures, abdominal pain, respiratory arrest
Pennyroyal (*Mentha pulegium* or *Hedeoma* spp.)	Pulegone	Centrilobular liver necrosis, fetotoxicity, seizures, shock
Ragwort (golden) *(Senecio aureus, Echium)*	Pyrrolizidines	HVOD
Wormwood (*Artemisia* spp.)	Thujone	Seizures, dementia, tremors, headache

HVOD, Hepatic veno-occlusive disease.
Modified from Committee on Injuries & Poison Prevention: *Children's environmental health,* ed 2, Elk Grove Village, IL, 2003, American Academy of Pediatrics.

poisoning mandates serial assessments of consciousness using this objective scoring system to gauge accurately whether the patient's overall condition is deteriorating or improving. The effects of therapies such as naloxone or oxygen also can be assessed. In many serious intoxications, such as carbon monoxide or cyanide poisoning, the state of consciousness may be the single best guide to the patient's overall prognosis. Box 105-1 lists some of the agents that may cause coma in the pediatric patient. Box 105-2 lists some common causes of seizures.

Pupil size depends on the balance between dilating and constricting fibers and is under complex autonomic nervous system control. Both sympathetic and parasympathetic nerves regulate the iris and can be affected by a variety of toxins. Anticholinergic drugs such as tricyclic antidepressants, antihistamines, and belladonna paralyze the parasympathetic fibers leading to pupillary dilation. Conversely, agents that inactivate cholinesterase leading to accumulations of acetylcholine (e.g., organophosphate pesticides, physostigmine) constrict the pupil. Ethanol, phenothiazines, and barbiturates also constrict the pupils. Opiates act centrally to cause extreme pupillary constriction (miosis). Sympathomimetics, such as amphetamines and cocaine, cause extreme pupillary dilation (mydriasis). Pilocarpine directly stimulates the sphincter muscle of the iris, causing constriction. Toxins can also be responsible for unequal pupil size. Local instillation of atropine to the eye causes ipsilateral pupillary dilation. It is important to recognize that polydrug overdoses may include agents with opposite pupillary actions. Overreliance on pupillary size alone in deciding which poison is responsible for the patient's

Table 105–5 Toxins Associated with Cardiovascular Findings

Sign	Agents
Tachycardia	Amphetamines Antihistamines Anticholinergics Aconite Cocaine β-Adrenergic agonists (albuterol, terbutaline) Theophylline
Bradycardia	Aconite Antiarrhythmics β-Adrenergic blockers Calcium channel blockers Cardiac glycosides Clonidine Ergotamine Opiates Organophosphates Phenylpropanolamine Quinidine Sedative-hypnotics
Torsades des pointes	Amantadine Antiarrhythmics Amiodarone Arsenic Astemizole Chloral hydrate Chloroquine Cisapride Cyclic antidepressants Disopyramide Encainide Fluoride Lidocaine Mexiletine Organophosphates Terfenadine Quinidine Procainamide Pentamidine Phenothiazines Prenylamine Suxamethonium
Ventricular tachycardia	Aconite Amphetamines Antiarrhythmics (e.g., quinidine, flecainide) Carbamazepine Chloral hydrate Chlorinated hydrocarbons Cocaine Cyclic antidepressants Digitalis Theophylline Thioridazine

condition may lead to a misdiagnosis. Closed head trauma or central nervous system (CNS) hemorrhage, sometimes seen in the context of a poisoning with hypertension-inducing drugs such phenylpropanolamine or ephedrine,[9] can themselves cause pupillary effects.

When treating a disoriented, delirious pediatric patient, the clinician must consider which intoxications may be responsible. Because of their central anticholinergic effects and common availability, antihistamines (e.g., chlorpheniramine, diphenhydramine) must be considered.

Table 105–6 Reed Scale for Clinical Assessment of Consciousness

Grade	Description
0	Asleep, can be aroused, answers questions
1	Comatose, withdraws from painful stimuli, intact reflexes
2	Comatose, does not withdraw from painful stimuli, no respiratory or circulatory depression, intact reflexes
3	Comatose, reflexes absent, no respiratory or circulatory depression
4	Comatose, reflexes absent, respiratory or circulatory problems

Box 105–1 Agents Associated with Coma in the Pediatric Patient

Anticonvulsants
Aromatic hydrocarbons
Asphyxiant gases
Barbiturates
Benzodiazepines
Carbon monoxide
Clonidine
Cyanide
Cyclic antidepressants
Ethanol
Ethylene glycol
γ-Butyrolactone
γ-Hydroxybutyrate
Hypoglycemic agents
Ketamine
Lead (encephalopathy)
Lithium
Methanol
Nonbarbiturate sedative-hypnotics
Opiates
Organochlorine pesticides
Phenothiazines
Salicylates

Box 105–2 Agents Associated with Seizures at Presentation

Amphetamines
Camphor
Cocaine
Cyanide
Ephedrine
Gyromitra (mushroom species)
Insecticides
Isoniazid
Methylene dioxymethamphetamine (MDMA)
Monoamine oxidase inhibitors
Nicotine
Phenylpropanolamine
Propoxyphene
Salicylates
Strychnine
Theophylline
Tricyclic antidepressants
Water hemlock (plant)

Alcohol-containing household products or liquor may be responsible. In the adolescent, substances of abuse may cause delirium or hallucinations. Jimsonweed (*Datura stramonium*) plant seeds, containing atropine and other anticholinergic chemicals, can be intentionally chewed by adolescents for their euphoric (and delirium-producing) effects caused by a central anticholinergic syndrome. Hallucinogens include lysergic acid diethylamide (LSD), psilocybin, mescaline, "magic mushrooms," and some amphetamine congeners ("designer drugs," e.g., 3-methoxy 4,5-methylenedioxyamphetamine [MMDA], 3,4-methylenedioxy-*N*-methamphetamine [MDMA, "ecstasy"], or 3,4-methylenedioxy-*N*-ethylamphetamine [MDEA]). Both cocaine and amphetamines can cause an acute psychosis. Newer, smokable forms of methamphetamine (known as "crystal" or "ice") and phencyclidine (PCP) cause symptoms of agitation, aggression, and combativeness. Additionally, intensive care physicians should be alert for abstinence syndromes in adolescents suffering from chronic substance abuse. Drug withdrawal from opiates, benzodiazepines, or alcohol (delirium tremens) often causes agitation, irritability, or even delusional thinking in affected patients. Withdrawal from chronic γ-hydroxybutyrate use (GHB, a popular "designer drug") is characterized by anxiety, insomnia, tremor, confusion, delirium, hallucinations, cardiovascular changes, nausea, vomiting, and diaphoresis.[10] Other neurologic findings may be found depending on the drug or toxin ingested. Phenytoin and phencyclidine frequently cause nystagmus. Opsoclonus (saccadic eye movements) can be caused by drugs such as lithium. Tinnitus is associated with ingestions of ergot, quinine, salicylates, and streptomycin. Changes in color vision may be seen in chronic digitalis overdose or cinchonism (quinidine).

Many poisonings cause skin or cutaneous manifestations. Abusers of intravenous narcotics or other drugs may have needle tracks, characteristic tattoos, or scarring from "skin popping." Those suffering from inhalant abuse frequently have rashes around the nose and mouth as a result of defatting and irritative effects of inhaled solvents. Methemoglobinemia as a result of a variety of oxidizing agents causes acute cyanosis despite relatively normal blood gas values (Box 105-3). A variety of rashes can be seen with adverse drug reactions and allergic responses to drugs, plants, or chemicals. Typical chemical burns may result from dermal exposure to caustics. Alopecia is associated with exposures to antimetabolite medications and other antineoplastic agents and to overdoses of chemicals such as arsenic, thallium, and selenium. Jaundice may result from exposure to carbon tetrachloride, aniline dyes, quinacrine, or phenothiazines.

The physician must be alert to characteristic odors in containers found at the scene of the exposure, of substances spilled on the patient's skin or clothing, or on the patient's breath. Organophosphate insecticides or thallium impart the strong odor of garlic. Cyanide exposures have the characteristic aroma of bitter almond (although 50% of the population is of the genotype that cannot detect the odor of bitter almonds). Ethanol, kerosene, camphor, and gasoline impart their strong odors to the breath. Adolescents abusing glues or volatile organic compounds by inhalation may have a solvent smell on their breath and on their clothes. Table 105-7 lists some of the typical intoxications that can be diagnosed by the patient's breath odors.

Laboratory Tests and Toxin Screens

Although laboratory testing of the blood or urine occasionally reveals an unanticipated toxin involved in an overdose, more frequently it confirms the physician's clinical diagnosis on the basis of a careful history and physical examination. The pediatric intensive care physician is well advised to know which compounds are included in the toxicology screen performed by the institution because the menu of substances detectable by a commercial laboratory is variable and frequently based on cost, ease of detection, available technical equipment, relative frequency of the overdose in the community, and other considerations. Most hospitals include the following compounds on a toxicology screen: acetaminophen, ethanol, barbiturates, opiates, anticonvulsants, some benzodiazepines, phenothiazines, and salicylates. Some toxicology screens may or may not include drugs of abuse (e.g., amphetamines, cocaine, tetrahydrocannabinol), older tricyclic antidepressants (e.g., amitriptyline, imipramine), and methanol. Many common toxic agents, including carbon monoxide, cyanide, methemoglobin, iron, lithium, heavy metals such as lead or arsenic, and ethylene glycol, are never included on a toxicology screen and must be ordered specifically.

A "negative" toxicology screen result does not rule out the diagnosis of a toxic exposure. For example, some enzyme multiplied immunoassay technique (EMIT) assays routinely used to screen for opiates do not necessarily detect dextromethorphan, a chemically related compound commonly used in cough preparations and also abused by adolescents. An adolescent whose urine test is negative for opiates could, in fact, be suffering from the adverse effects of dextromethorphan intoxication. The more specific a clinician is in communicating with laboratory personnel about which toxins are suspected clinically, the more directed laboratory personnel can be in seeking specific answers through laboratory methods. Because some toxins (for example cocaine, other drugs of abuse, some heavy metals) are detected more easily in urine than in the blood, both specimens should be submitted when the toxicology screen is ordered. Gastric contents can be assessed when the patient is seen shortly after an ingestion, before absorption of the drug or chemical is likely.

Some toxicology screens include, as a first step, qualitative spot chromatography tests or thin-layer chromatography (TLC) in the analysis of an unknown sample of blood or urine. These tests are accurate for qualitative analysis of the presence of a toxin, but are imprecise for quantitative analysis. For many compounds, TLC or spot test analyses may have unacceptable false-positive rates or cross-reactions within a class of chemicals. For a more quantitative confirmation of the presence of a drug or chemical, EMIT can be performed as a screening test. An immunoassay positive for a drug must be confirmed by a second technique before the drug is considered present in the blood or urine. For more precise assays, as "second" techniques to confirm the results of screening assays, and for detection of more exotic drugs or chemicals, high-pressure liquid chromatography (HPLC) or gas-liquid phase chromatography/mass spectrometry (GLC-MS) are used. For detecting heavy metals and many salts, flame ionization spectroscopy or atomic absorption spectroscopy is the quantitative assay of choice. Reliability in the screening for drugs or toxins requires not only a sound analytic technique but also adequate sample collection, chain of custody (in cases involving judicial

Well water (elevated nitrates)

prosecution), and timely reporting of the results. Sources of error include delay in the time between sample collection and assay, problems with sample collection (wrong tube, loss of fluid, poor labeling), natural chemical reactions (volatilization, enzymatic degradation), purposeful sample alteration, technical limits on the detection threshold of the assay used, and misinterpretation of the units in reporting the results. Quantitative assessments of some toxins correlate with the severity of intoxication. Serum concentrations of acetaminophen, aspirin, barbiturates, carbamazepine, carbon monoxide, digoxin, ethanol, ethylene glycol, iron, isopropanol, lead, lithium, methanol, phenytoin, and theophylline are useful in guiding patient management. Co-oximetry can provide blood levels of abnormal hemoglobins caused by toxins, such as carboxyhemoglobin, sulfhemoglobin, and methemoglobinemia. Box 105-3 lists drugs, chemicals, and foods capable of causing methemoglobinemia in susceptible individuals.

Certain toxins (e.g., ethanol, ethylene glycol, isopropanol, methanol) introduce osmotically active particles into the serum. These particles increase serum osmolality, which can be measured by either vapor pressure or freezing point depression. However, vapor pressure techniques give falsely low values in the presence of volatiles (such as any of the alcohols) and should not be used in the monitoring of poisoning cases. The calculated serum osmolality is derived by the following equation: Calculated serum osmolality = [2 × Na (in mEq/L)] + [Blood urea nitrogen (in g/dL)/2.8] + [Glucose (in mg/dL)/18]. Calculated osmolality then is subtracted from the measured osmolality. The measured osmolality – calculated osmolality = Osmolar gap. A normal osmolar gap is between -3

Table 105–7 Toxins Associated with Characteristic Breath Odors

Toxin	Characteristic Odor
Acetone	Ketones
Arsenic	Garlic
Camphor	Mothballs
Chloroform	Sweet
Cyanide	Bitter almond
Ethanol	Alcohol
Hydrogen sulfide	Rotten eggs
Isopropanol	Ketones
Methyl salicylate	Wintergreen
Nicotine	Stale tobacco
Organophosphates	Garlic
N-3-pyridylmethyl-N′-p-nitrophenyl urea	Peanuts (rat poison)
Paraldehyde, chloral hydrate	Pears (urine)
Phenol, cresol	Phenolic
Phosphorus	Garlic
Salicylates	Acetone
Thallium	Garlic
Turpentine	Violets

Table 105–8 Osmolar Gap Conversions to Calculate Serum Concentration: Alcohols and Glycols

Toxin	Conversion Factor
Methanol	2.6
Ethanol	4.3
Ethylene glycol	5.0
Acetone	5.5
Isopropanol	5.9

Serum concentration (mg/dL) of given toxin divided by corresponding conversion factor equals serum osmolality (mOsm/kg H_2O) attributable to that toxin.

and 10 mOsm/kg H_2O. The presence of toxins listed in Table 105-8 is associated with an elevated osmolar gap. An estimate of the serum toxin concentration can be derived using the serum osmolality as measured by the freezing point depression technique, calculating the osmolar gap, and applying the conversion factors listed in Table 105-8. Intensivists are cautioned that elevated osmolar gaps also are seen in patients with lipemic blood or in those receiving therapies such as mannitol, glycerol, sorbitol, propylene glycol, or some types of contrast agents in preparation for diagnostic imaging studies. Conversely, a falsely low osmolar gap can be seen in ethylene glycol or methanol poisoning if the vapor pressure method of serum osmolarity determination is erroneously used.
