All of the randomized trials of HDC/ASCS exclude patients with markedly impaired renal function, as well as patients older than 65–70 years. The available data suggests HDC/ASCS is possible in these groups,^{97–102} though the potential for increased treatment-related toxicity should be recognized. For example, a preparative regimen of melphalan 140 mg/m² may be optimal for patients with impaired renal function.¹⁰³ It may also be desirable to use less intensive IV melphalan (i.e., 60–140 mg/m²) in older patients with MM to reduce toxicity.⁹⁷ Such regimens in older patients may be able to achieve results comparable to those seen with more intensive transplant regimens.¹⁰⁴

New issues related to HDC continue to emerge. Tandem autologous transplant has been shown in one randomized trial to yield superior outcome to single transplant,⁵ but there is evidence to suggest that the subset of patients actually benefiting from a second transplant are those not attaining a CR or nCR with the first one and who are able to undergo the second procedure within 6–12 months.^{5, 105} Given the mixed data on single HDC/ASCS, the role of tandem transplant in *any* patient group remains ambiguous. As allogeneic stem cell transplant techniques become increasingly refined, the potential role of this modality will need to be explored further. Finally, the rapid expansion of novel antimyeloma agents in recent years has led to vigorous debate as to how these agents should be incorporated into both transplant and nontransplant treatment paradigms.

NEWER REGIMENS AND NOVEL AGENTS

MELPHALAN-PREDNISONE-THALIDOMIDE

The results of two large randomized studies comparing MP to MPT, undertaken after an Italian Phase II of MP plus low-dose thalidomide (MPT) in patients with previously untreated MM demonstrated a remarkable 93% overall response rate (45% CR/nCR),¹⁰⁶ have recently reported. Palumbo et al. randomized 255 patients between the ages of 60 and 85 with newly diagnosed MM to either MP or MPT. All patients received six 4-week cycles of MP, and patients

randomized to the MPT arm also received thalidomide 100 mg daily until either disease progression or unacceptable toxicity.¹⁰⁷ Patients receiving MPT had a superior overall response rate (76% vs 48%), CR/nCR rate (28% vs 7%), and 2-year EFS rate (54% vs 27%; $p = 0.0006$). Three-year OS was also higher—80% for MPT versus 64% for MP—although this difference did not reach statistical significance. The increased efficacy of MPT came at the price of increased toxicity, particularly infectious and thrombotic complications. The incidence of grade 3-4 nonhematologic adverse events was 48% in the MPT arm, compared to 25% in the MP arm ($p = 0.0002$). Prior to the introduction of prophylactic enoxaparin, 20% of patients receiving MPT developed deep vein thromboses (DVTs). After enoxaparin 40 mg subcutaneously once daily was added, the incidence of DVTs dropped to 3%, resulting in an overall incidence of 12% on this trial. The IFM compared MP (12 cycles), MPT (thalidomide ≤ 400 mg/day through the end of MP), and a high-dose melphalan-based regimen (VAD $\times 2$, then cyclophosphamide 3 g/m² to mobilize stem cells, then MEL(100) with ASCS $\times 2$) in 476 patients between the ages of 65–75 with previously untreated MM.¹⁰⁸ The median progression-free survival for MPT was 29 months (compared to 17 months for MP ($p < 0.0001$) and 19 months for MEL(100) ($p = 0.0001$)). Median OS, which was 30 months for MP and 39 months for MEL(100), was not reached in the MPT arm after 56 months median follow-up ($p = 0.0008$ for MPT vs MP, $p = 0.014$ for MPT vs MEL(100)).

COMBINATION CHEMOTHERAPY WITH CONCURRENT THALIDOMIDE

The addition of daily thalidomide (50 mg/day initially, escalated to a maximum of 400 mg/day) to the DVd regimen (described above) appears to result in greatly enhanced antimyeloma activity in both the relapsed/refractory and up-front settings.¹⁰⁹ After a median of

six cycles of therapy, 46% of newly diagnosed patients had either a CR or nCR, a rate comparable to that seen with HDC/ASCS.³⁴ It remains to be seen whether the time to disease progression will be as long as that typically expected from HDC/ASCS. The regimen is clearly more toxic than DVd alone, requiring prophylactic antibiotics because of high rates of infection, particularly pneumonia, and also daily aspirin because of a high rate of DVTs.¹⁰⁹ The latter complication is not wholly unexpected, given the higher rate of thrombotic complications seen with TD.^{68, 69} Investigators at the University of Arkansas have published their extensive experience using combination chemotherapy with thalidomide in both the up-front and relapsed setting (Table 83.3).^{110–112} As in the other trials discussed, an increased rate of DVT was observed with these combinations, particularly during concomitant anthracycline and thalidomide administration.^{111, 112}

Based on the results of the two randomized studies discussed above, some clinicians have adopted MPT as the preferred regimen for newly diagnosed MM patients who are not going on to get HDC/ASCS and who are judged likely to be able to tolerate the added toxicity of the regimen compared to MP. Incorporation of thalidomide into other combination chemotherapy induction regimens will ultimately only be justified if there is proven, meaningful clinical benefit that outweighs increases in toxicity.

BORTEZOMIB (VELCADE)

Bortezomib is the first proteasome inhibitor approved by the FDA for treatment of relapsed-refractory MM. In Phase II trials involving heavily pretreated patients, including several with markedly impaired renal function, Bortezomib 1.3 mg/m² as an IV push twice weekly for 2 weeks followed by a week break demonstrated a 35% overall response rate, including 10% CR/nCR.¹¹³ Two Phase II studies in newly diagnosed

Table 83.3 Combination regimens containing thalidomide

Regimen	Drugs	Doses	Frequency
TD ^{68,69}	Dexamethasone Thalidomide	40 mg/day PO/IV, days 1–4, 9–12, 17–20 200–600 mg/day PO (start 100–200)	q 28–35 days
TD-PACE ¹¹⁰	Dexamethasone Thalidomide Cisplatin Doxorubicin Cyclophosphamide Etoposide	40 mg/day PO/IV, days 1–4 400 mg/day PO 10 mg/m ² /day, CIV, days 1–4 10 mg/m ² /day, CIV, days 1–4 400 mg/m ² /day, CIV, days 1–4 40 mg/m ² /day, CIV, days 1–4	q 28 days
DVd-T ¹⁰⁹	Liposomal Doxorubicin (Doxil) Vincristine Dexamethasone Thalidomide	40 mg/m ² , IVPB, day 1 2 mg IVP, day 1 40 mg/day, PO/IV, days 1–4 200–400 mg/day PO (start 50–100)	q 28 days
MP-T ¹⁰⁶	Melphalan Prednisone Thalidomide	4 mg/m ² PO, days 1–7 40 mg/m ² PO, days 1–7 100 mg/day PO	q 28–35 d

myeloma suggest that the response rate may be much higher when the drug is used in combination with dexamethasone earlier in the disease course. Jagannath et al. treated 32 patients with newly diagnosed MM with standard dose bortezomib and added pulse dexamethasone for patients who did not achieve at least a partial response after two cycles or a CR after four cycles.¹¹⁴ The response rate to bortezomib alone was 40% after two cycles, partial responses in almost all cases. Dexamethasone was added for 22 patients, leading to improved responses in 15 cases. The overall response rate for the study was ultimately 88%, with 25% attaining CR/nCR. An IFM study involving 52 newly diagnosed patients treated with bortezomib plus dexamethasone showed similarly impressive results: 66% overall response rate and 21% CR rate.¹¹⁵ In this study, subsequent stem cell collection was successful in 44 out of 44 patients in whom this was attempted, demonstrating that bortezomib can be used as initial therapy for patients planning to undergo HDC/ASCS. Peripheral sensory neuropathy occurred in just under a third of the patients enrolled on each of these two studies, and 14% of the enrollees in the French study had grade 2-3 neuropathy.^{114, 115} Bortezomib dose reduction results in improvement of treatment-related neuropathy in half or more of cases.¹¹⁴ Other investigators have explored adding bortezomib to cytotoxic chemotherapeutic combination regimens. The PAD regimen, which combines bortezomib (1.3 mg/m² days 1,4,8,11), infusional adriamycin (9 mg/m²/day CIV), and dexamethasone (40 mg/d days 1-4 every cycle, and days 8-11, 15-18 cycle 1 only), has been shown in a large Phase II study to be both feasible and exceptionally active, with an overall response rate of 95% (CR rate 24%).¹¹⁶ Based on the very high overall and complete response rates seen with the PAD regimen, some clinicians (including the author) are already using the PAD regimen rather than VAD for the initial treatment of MM patients presenting with renal failure. Similarly impressive response rates were noted in a Phase I-II study of MP plus bortezomib in previously untreated MM patients.¹¹⁷ For further discussion regarding bortezomib as treatment for relapsed-refractory MM, please refer to Chapter 92. If larger studies validate the promising results seen thus far, it is probable that in the future bortezomib will become widely used early in the course of disease management.

LENALIDOMIDE (CC-5013; REVLIMID)

Lenalidomide is a member of a class of thalidomide analogues called immunomodulatory drugs, or IMiDs. In vitro, lenalidomide modulates cytokine production and T-lymphocyte stimulation at least 100 times more potently than thalidomide.^{118, 119} Phase I trials in relapsed-refractory patients using doses ranging from 5 mg/day to 50 mg/day have shown response rates of 40–71%, even in patients previously treated with thalidomide.^{120, 121} The toxicity profile of lenalidomide

is very different than that of thalidomide, with thrombocytopenia and neutropenia predominating, and essentially no sedation, constipation, or neuropathy. The response rate among 34 patients with newly diagnosed MM treated with lenalidomide 25 mg daily for 21 out of every 28 days with pulse dexamethasone (40 mg/day on days 1–4, 9–12, 17–20) was 91% (CR 6%).¹²² ECOG has completed accrual to a large randomized study of lenalidomide with two different doses of dexamethasone, and the Southwest Oncology Group is currently conducting a 500-person randomized, double-blinded study comparing dexamethasone to dexamethasone plus lenalidomide (LD). The results of these two studies will establish whether LD could be an appropriate front-line regimen for patients with MM.

DURATION OF THERAPY

The risk of some chemotherapy-associated complications is related to cumulative lifetime dose of a given agent. Relevant examples include cardiomyopathy and anthracyclines,¹²³ neuropathy and vinca alkyloids or thalidomide,¹²⁴ and stem cell injury from melphalan.^{45–47} Thus, the benefit of ongoing treatment must be continuously weighed against the risk of developing potentially irreversible toxicities. In patients not undergoing HDC/ASCS, initial therapy is typically continued for at least two to four cycles beyond maximal response, unless concern over toxicity mandates stopping sooner. Indefinite “maintenance” with ongoing chemotherapy is not beneficial in the case of MP¹²⁵ and is not feasible with VAD. There is insufficient data to make a recommendation at this time on the optimal duration of TD therapy (NCCN Guidelines v.1 2006; www.nccn.org/professionals/physician_gls/PDF/myeloma.pdf), but most clinicians continue therapy until there is evidence of either disease progression or unacceptable toxicity. There is data to support benefit from ongoing corticosteroids as a form of maintenance. A SWOG trial showed that 50 mg of prednisone every other day after achievement of maximal response to chemotherapy extends median duration of both remission and survival by 9 months,¹²⁶ a modest benefit which must be weighed against the potential adverse effects of chronic steroid use in certain patients (e.g., diabetics). The preliminary findings of a trial comparing dexamethasone maintenance (40 mg/day for four consecutive days every month) to observation following induction therapy confirm a 9-month improvement in time to disease progression, but no survival advantage was found.¹²⁷ Maintenance therapy with Interferon- α (IFN) has been explored in a multitude of trials, the results of which are summarized in two published meta-analyses.^{128, 129} IFN maintenance prolongs both response duration and OS by only 4–6 months in a minority of patients with significant toxicity and cost, making it difficult for most clinicians to recommend with enthusiasm.

SUPPORTIVE CARE

Adjunctive measures addressing three complications of MM—skeletal disease, anemia, and thrombosis—deserve mention. For a more general discussion of palliative care issues in hematologic malignancies, please refer to Chapter 115.

MANAGEMENT OF SKELETAL DISEASE

Bone disease in the form of lytic lesions, pathological fractures, or osteoporosis are present at diagnosis over three-quarters of the time,¹³⁰ ultimately leading to significant morbidity in many patients with MM. While external beam radiation therapy is remarkably effective palliation for pain relief from existing lesions, it is the localized therapy without the potential to reduce the risk of skeletal complications outside of the radiation port.

Bone resorption in MM results occurs due to stimulation of osteoclasts, which in turn results predominantly from receptor activator of NF- κ B (RANK) signaling by RANK-ligand.^{131, 132} Bisphosphonates are synthetic pyrophosphate analogues that inhibit osteoclast function directly through disruption of intracellular biochemical pathways^{133, 134} or induction of apoptosis,¹³⁵ or indirectly by stimulating production of the inhibitory RANK decoy molecule, osteoprotegerin.¹³⁶ The two bisphosphonates currently approved for use in treating MM-related bone disease are pamidronate (Aredia) and zoledronic acid (Zometa). Pamidronate, 90 mg intravenously over 4 hours every 4 weeks, has been shown in randomized trials to significantly reduce the rate of skeletal complications associated with MM compared to placebo, 28% versus 44% at 12 months, as well as delaying the median time to first skeletal complication from 12 months to 21 months.¹³⁷ This effect persisted with treatment extended out to almost 2 years.¹³⁸ It should be noted that this dose of pamidronate can be given safely over 60–90 minutes. Zoledronic acid is a newer bisphosphonate with 1000 times the potency of pamidronate and an even shorter infusional time of 15 minutes. In a randomized trial with extended follow-up, comparing zoledronic acid 4 mg every 3–4 weeks to pamidronate 90 mg, comparable efficacy in preventing skeletal complications was observed.^{139, 140} As a result of these trials, the American Society of Clinical Oncology has released clinical guidelines recommending the routine use of either pamidronate or zoledronic acid for MM patients with lytic bone lesions or myeloma-related osteopenia.¹³ There is no consensus on the optimal duration of bisphosphonate therapy, but the widespread practice of indefinite monthly administration of these agents has recently come under scrutiny with the recognition of ONJ as an uncommon toxicity associated with prolonged bisphosphonate use.¹⁴ Patients with ONJ develop exposed areas of chronic, nonhealing necrotic

bone in their mouths, in many cases after tooth extraction. While much work remains to be done in terms of fully characterizing this problem, some groups have developed treatment guidelines which reflect the currently available information on ONJ and bisphosphonates.¹⁵ Newer approaches to treating myeloma-related bone disease include percutaneous kyphoplasty or vertebroplasty of vertebral compression fractures related to lytic lesions^{141, 142} or osteoporosis¹⁴³; utilization of radioactive Strontium-89¹⁴⁴; and recombinant osteoprotegerin or the soluble RANK-ligand receptor, RANK-Fc, to block the osteoclast-activating effects of endogenous RANK-ligand in the marrow microenvironment.^{145, 146}

MANAGEMENT OF ANEMIA

Several studies have been performed to assess the efficacy of recombinant erythropoietin (rHuEPO; Epogen, Procrit) administered subcutaneously to patients with MM with a hemoglobin value of less than 10 g/dL.^{147–150} Although there were methodological flaws making interpretation of the results of individual trials problematic, taken together they suggest that half or more of such patients may benefit in terms of increase in hemoglobin concentration^{147–150} and reduction in transfusion requirements.^{147, 150} Based on these results, the American Society of Clinical Oncology and the American Society of Hematology guidelines recommend consideration of rHuEPO use for myeloma patients with anemia that does not improve after initiation of therapy with chemotherapy or glucocorticoids.¹⁵¹ Concurrent use of rHuEPO with either thalidomide or lenalidomide may be associated with an increased risk of DVTs, and therefore caution is recommended when considering its use in this setting.¹⁵² The starting dose of rHuEPO should be 150 units/kg thrice weekly for a minimum of 4 weeks, with consideration of an increase to 300 units/kg/dose for an additional 4–8 weeks if there has been less than a 1–2 g/dL increase in hemoglobin. Forty-thousand units subcutaneously once weekly, with an increase to 60,000 units as needed, is an accepted and widely used alternative. A randomized study comparing an alternative erythropoietic agent, weekly darbepoetin alfa (Aranesp; dose: 2.25 μ g/kg/wk), to placebo was published after the release of these guidelines, and the results demonstrate comparable efficacy.¹⁵³ Studies evaluating administration of higher doses of darbepoetin every 2 to 3 weeks in patients with other cancers receiving chemotherapy suggest that less-frequent dosing is feasible,^{154, 155} but at present, there is insufficient data in patients with myeloma or other hematologic malignancies.

THROMBOSIS

Patients with MM have a high baseline incidence of thrombotic complications—perhaps as high as 10%.¹⁵⁶ Treatment with either thalidomide or lenalidomide in combination with either glucocorticoids^{69, 70, 157, 158} or chemotherapy^{111, 112, 159} appears to increase this risk.

All MM patients receiving these IMiD-containing combinations should receive some form of thromboprophylaxis. There is evidence to support the use of full-dose warfarin,⁶⁹ prophylactic dose enoxaparin,¹⁰⁷ and aspirin (ASA) 81–325 mg daily.^{122, 159, 158} These preventative agents have not been compared head-to-head. The favorable cost- and toxicity-profile of ASA has made this the most attractive option for patients and clinicians, though some experts have advocated full-dose warfarin or enoxaparin as preferred options.¹⁶⁰

SUMMARY

As our understanding of MM expands, treatment paradigms are changing. It is becoming increasingly apparent that tumor-specific biologic features, such as the presence of chromosome 13 abnormalities, or patient-specific clinical factors, such as renal failure

or advanced age, result in biologically or functionally distinct disease states, likely requiring “tailoring” of treatment. Although cure remains an elusive goal, it appears that for some subsets of patients, emerging therapies may finally be starting to have an impact on survival. For example, the addition of thalidomide to MP clearly improves survival in older patients who are not candidates for HDC/ASCS. Once optimal strategies for combining thalidomide and other new agents such as bortezomib and lenalidomide with traditional cytotoxic drugs are established, better quality (i.e., more complete) responses may be able to be obtained without having to use HDC/ASCS. The benefits of HDC/ASCS have recently been questioned with the negative results of a large randomized US intergroup trial, but high-dose therapy will likely remain a part of MM therapy for the foreseeable future, particularly as allogeneic transplant techniques evolve.

Chapter 84

VARIANTS OF MULTIPLE MYELOMA

Robert A. Kyle and S. Vincent Rajkumar

Variants of multiple myeloma consist of solitary plasmacytoma of bone, extramedullary plasmacytoma, multiple solitary plasmacytomas, plasma cell leukemia, smoldering multiple myeloma, nonsecretory myeloma, immunoglobulin (Ig) D myeloma, and POEMS syndrome (osteosclerotic myeloma).

SOLITARY PLASMACYTOMA OF BONE

Solitary plasmacytoma of bone is characterized by the presence of a tumor consisting of monoclonal plasma cells, identical to those in myeloma, and no other features of multiple myeloma.¹

CLINICAL FEATURES

Solitary plasmacytoma of bone is uncommon and occurs in 3–5% of patients with plasma cell neoplasms. It occurs more commonly in men than in women. The median age at diagnosis is approximately 55 years, which is a decade younger than that for multiple myeloma.

The most common symptom initially is pain at the site of the skeletal lesion. Severe back pain or cord compression may be the presenting feature. Pathologic fractures or a soft tissue extension of a solitary plasmacytoma, such as in a rib, may result in a palpable mass.

The axial skeleton is more commonly involved than is the appendicular skeleton.² Thoracic vertebrae are more often involved than are lumbar, sacral, or cervical vertebrae. Involvement of the distal axial skeleton below the knees or elbows is extremely rare. The recommended laboratory tests for identifying this entity are listed in Table 84.1.

DIAGNOSIS

The diagnosis is based on histologic evidence of a tumor consisting of monoclonal plasma cells and the absence of multiple myeloma on the basis of bone marrow, radiographic, and appropriate studies of blood and urine. Complete skeletal radiographs must show no other lesions of multiple myeloma (Table 84.2). If magnetic resonance imaging of the spine and pelvis

reveals skeletal lesions, the condition should be classified as smoldering multiple myeloma. Approximately one-fourth to one-third of patients with an apparently solitary plasmacytoma will have abnormalities on magnetic resonance imaging.^{5–7} These patients are at greater risk for progression to multiple myeloma. Immunofixation of serum and concentrated urine ideally should have no monoclonal (M) protein, but approximately half of the patients do have a small amount of M protein in the serum or urine. This often disappears after tumoricidal radiation. Most patients with solitary plasmacytoma of bone have normal, uninvolved immunoglobulin levels.¹ There is no anemia, hypercalcemia, or renal insufficiency that is related to the plasmacytoma. Although the bone marrow aspirate and biopsy must contain no evidence of multiple myeloma, a few plasma cells may be seen.

TREATMENT

Tumoricidal radiation is the treatment of choice. The patient should receive 4000–5000 cGy over approximately 4 weeks. Even if the plasmacytoma has been excised for diagnostic purposes, radiotherapy should also be given. The local response rate exceeds 80–90%.⁸ In one series, all solitary plasmacytomas less than 5 cm in size were controlled by radiotherapy.⁹

There is no convincing evidence that adjuvant or prophylactic chemotherapy will prevent the development of multiple myeloma.^{10–12} However, in an uncontrolled study, adjuvant chemotherapy delayed the time to progression to 59 months, compared with 29 months for patients treated with only radiation, but did not affect the rate of conversion.⁸ In another report of 53 patients with solitary plasmacytomas randomized to receive either radiotherapy plus melphalan and prednisone for 3 years or radiotherapy alone, disease-free survival and overall survival improved in the chemotherapy group. After a median follow-up of 8.9 years, 22 of 25 patients were alive and free of disease in the chemotherapy group, compared with 13 of 28 patients in the radiotherapy-only group ($P < .01$).¹³

Table 84.1 Laboratory tests recommended for solitary plasmacytoma

History and physical examination
Hemoglobin, leukocytes with differential and platelets
Serum calcium and creatinine
Serum protein electrophoresis and immunofixation, quantitative serum immunoglobulins
Electrophoresis of aliquot from 24-h urine specimen followed by immunofixation
β_2 -Microglobulin, C-reactive protein, and lactate dehydrogenase
Skeletal survey including humeri and femurs
Bone marrow aspirate and biopsy
Peripheral blood plasma cell count and labeling index, if available
Magnetic resonance imaging or computed tomography

However, on the basis of all available data, adjuvant therapy should not be given to patients with solitary plasmacytoma of bone.¹ The use of systemic chemotherapy may obscure recognition of patients cured by radiotherapy. In addition, early exposure to systemic treatment may increase the number of resistant subclones and restrict later therapeutic approaches. In one report, secondary leukemia developed in four of seven patients with solitary plasmacytoma of bone who had received adjuvant melphalan-based chemotherapy after completion of radiotherapy.¹⁴

NATURAL HISTORY

Overt multiple myeloma develops in at least 50% of patients with solitary plasmacytoma of bone.^{2,8,9,15} In our report of 46 patients, 77% of those who progressed did so within 4 years.² Dimopoulos et al.¹⁶ found that two-thirds of patients who progressed did so within 3 years.

The patterns of failure in our series included development of multiple myeloma in 54%, failure local recurrence in 11%, and development of new solitary bone lesions without evidence of myeloma in 2%. Four of the five local failures in our series occurred in the spine, and all the patients had received less than 45 Gy to the initial lesion.

The overall survival rate in a series of 46 patients was 74% at 5 years and 45% at 10 years. The 5- and 10-year disease-free survival rates were 43% and 25%, respectively. In a series of 12 patients with solitary plasmacytoma of the vertebral column, multiple myeloma developed in 50%.¹⁷ Fifty-eight percent patients were alive at 5 years and 25% at 10 years. An additional 72 patients with solitary plasmacytoma of the spine were identified in the English literature. The mean disease-free duration of survival for the 84 patients was 76 months. The average overall duration of survival was 92 months. The 5-year disease-free survival rate was 60%, and the 10-year disease-free survival rate was 16%.¹⁷

In one series, conversion to myeloma occurred in 9 of 11 patients (82%) who had lesions 5 cm or larger, whereas only 5 to 18 patients (28%) who remained stable had lesions that were 5 cm or larger (7).

PROGNOSTIC FACTORS

Relapse rates are higher in older patients⁹ and in patients presenting with axial lesions.¹⁸ The persistence of an M protein after radiation therapy is a predictor of subsequent development of multiple myeloma in several studies.^{8,16} In one series, persistence of the M protein for more than 1 year after radiation therapy was the only independent adverse prognostic factor for myeloma-free survival and cause-specific survival with multivariate analysis when included variables were resolution vs persistence of the M protein after radiation therapy, presence or

Table 84.2 Classification of plasma cell disorders

Category	Criteria
Solitary plasmacytoma (bone or extramedullary)	Absent or small monoclonal protein in serum or urine Single area of destruction Bone marrow not consistent with myeloma Normal skeletal survey
Multiple solitary plasmacytomas	Absent or small monoclonal protein in serum or urine More than one localized area of destruction Normal bone marrow
Monoclonal gammopathy of undetermined significance (MGUS)	Monoclonal protein <3 g/dL Bone marrow plasma cells < 10% No end-organ damage ^a
Smoldering (asymptomatic) multiple myeloma (SMM)	Monoclonal protein \geq 3 g/dL or bone marrow plasma cells \geq 10% No end-organ damage ^a
Symptomatic multiple myeloma (MM)	Monoclonal protein in serum or urine Clonal bone marrow plasma cells or plasmacytoma Presence of end-organ damage ^a

^aEnd-organ damage: anemia, lytic bone lesions, renal failure, or hypercalcemia thought to be related to plasma cell proliferative disorder. From Ref. 4, with permission from Mayo Foundation.

absence of an M protein at diagnosis, presence or absence of an associated soft tissue mass on computed tomography or magnetic resonance imaging, size of serum M protein at diagnosis, age, spinal vs nonspinal location, Karnofsky performance score, total radiation dose, and tumor size. In patients with an M protein persisting for more than 1 year, multiple myeloma developed within 2.2 years of therapy.⁵ Of the 60 patients in that series, 75% had an M protein at diagnosis. The 10-year myeloma-free survival rate was 91% in patients whose M protein disappeared, and 29% in those whose M protein did not disappear at 1 year after radiation therapy.

In contrast, we found no difference in the 5-year disease-free survival rate among patients with or without an M protein at diagnosis.² The failure rate was 75% in patients with a persistent M protein after radiation and 71% in those in whom the M protein disappeared. The median time to failure was 40 months for the patients with a persistent M protein and 36 months for those in whom the M protein disappeared with therapy.

We studied angiogenesis in 25 patients with solitary plasmacytoma of bone. High-grade angiogenesis was present in 64% of the plasmacytomas, whereas angiogenesis was low in the bone marrow of all 25 patients. The median vascular density was 26 (range 20–50) in the high-grade group ($n = 16$) and 11 (range 2–16) in the low-grade group ($n = 9$). Progression to myeloma occurred in 9 of the 16 patients in the high-grade angiogenesis group and in only 1 of the 9 patients with low-grade angiogenesis. The progression-free survival rate was significantly shorter in those with high-grade angiogenesis. There was no correlation between median vascular density and age, M-protein level, urinary light chain, β_2 -microglobulin level, or tumor location. In a multivariate Cox, analysis, persistence of M protein, angiogenesis grade, and spinal vs nonspinal tumor location were independently prognostic for progression. Patients who had both a persistent M-protein spike and high-grade angiogenesis (six patients) were five times more likely to have progression than did the rest of the group ($P = .01$).¹⁹

FOLLOW-UP

After radiation therapy, patients should have a complete blood count, serum calcium and creatinine determinations, and serum and urine immunofixation every 4–6 months for 1 year and annually thereafter. A metastatic bone survey or magnetic resonance imaging should be performed every year or sooner if an M protein develops, if a persistent M protein increases in size, or if any features suggestive of multiple myeloma occur.

EXTRAMEDULLARY PLASMACYTOMA

Extramedullary plasmacytoma is a plasma cell tumor that arises outside the bone marrow. Extramedullary plasmacytoma accounts for up to 3% of plasma cell malignancies.¹⁵ The median age of patients is about 60

years, and the majority of patients are male.¹⁵ Approximately 80% of tumors involve the upper respiratory tract, including the sinuses and nasal cavity, larynx, and nasopharynx. Epistaxis, rhinorrhea, and nasal obstruction are the most frequent symptoms.

In a review of 714 cases of extramedullary plasmacytoma, 82% involved the upper respiratory tract. Seventy-four percent of plasmacytomas involving the upper aerodigestive tract occurred in male patients. Extramedullary plasmacytomas in the 155 cases not involving the upper aerodigestive region were in the gastrointestinal tract (40%), urogenital region (25%), skin (17%), lung (10%), breast (4%), conjunctiva (2%), and retroperitoneum (1%).²⁰

In a review of the literature, Anghel et al.²¹ described 17 patients with a primary solitary testicular plasmacytoma at diagnosis. The median age was 53.5 years. Nine patients died of progressive disease, six were alive without evidence of disease, and two were alive with disease. Twenty-five patients with plasmacytoma localized to the lymph nodes were reported.²² Cervical nodes were involved in 56%, abdominal in 16%, and mediastinal in 12%. Bone marrow examinations and metastatic bone surveys showed no evidence of multiple myeloma. Ten patients had localized disease, and none had development of multiple myeloma.

Pulmonary involvement may occur. Koss et al.²³ reported two patients with extramedullary plasmacytoma involving the mediastinal lymph nodes and three with parenchymal involvement. When the authors considered their 5 cases in combination with 14 others from the literature, the overall 2-year survival rate was 66%, and the 5-year survival rate was 40%.²³

DIAGNOSIS

Extramedullary plasmacytoma is diagnosed on the basis of finding a monoclonal plasma cell tumor in an extramedullary site, in the absence of multiple myeloma in the bone marrow and on radiographic tests, without protein spikes using appropriate studies of blood and urine (Table 84.2). Poorly differentiated neoplasms and lymphoma may be difficult to differentiate from plasmacytomas. In this situation, immunohistochemistry and flow cytometry are helpful in making the diagnosis. There is a higher incidence of IgA M-protein subtype in extramedullary plasmacytoma.

TREATMENT

The treatment of choice for extramedullary plasmacytoma is tumoricidal radiation at a dosage of 4000 cGy over 4 weeks.

COURSE

Tsang et al.⁹ reported local recurrence in 7% of patients receiving tumoricidal radiation. All local failures were in patients with bulky tumors 5 cm or more in diameter. Progression to multiple myeloma occurs in 10–15% of patients, which is much less common than in patients with solitary plasmacytoma of bone.^{9,20,24,25}

In one review, the overall 5-year survival rate with pulmonary plasmacytoma was 40%,²³ whereas it was 60–82% in three separate series of patients with plasmacytoma mainly in the head and neck region.^{24–26} A detailed literature search found that there were more than 400 publications between 1905 and 1997.²⁰ The median overall duration of survival was more than 25 years for patients who received a combination of radiation and surgery. Median duration of survival for patients receiving surgical intervention only was 13 years, whereas it was 12 years for those receiving radiation therapy alone. Overall, 61% had no recurrence or development of multiple myeloma; 22% had recurrence of extramedullary plasmacytoma; and 16% had conversion to multiple myeloma.

Extramedullary plasmacytoma may be classified as low-, intermediate-, or high-grade, depending on histologic grading. In one study, local control after radiation therapy was achieved in 15 of 18 patients (83%) with low-grade disease and in only 1 of 6 patients (17%) with intermediate- to high-grade tumors.²⁴

MULTIPLE SOLITARY PLASMACYTOMAS

The condition termed *multiple solitary plasmacytomas* is characterized by the simultaneous or sequential occurrence of discrete lesions in either bone or soft tissue (extramedullary). In contrast to multiple myeloma, the bone marrow is normal and radiography and magnetic resonance imaging show no evidence of diffuse skeletal involvement (Table 84.2). There is no end-organ damage other than the localized bone lesions. Multiple plasmacytomas may be treated with tumoricidal radiation, when recurrent, if there is no evidence of multiple myeloma. Large numbers of solitary plasmacytomas or recurrent lesions at short intervals are an indication for systemic therapy similar to that for multiple myeloma, such as autologous stem cell transplantation.

PLASMA CELL LEUKEMIA

Plasma cell leukemia (PCL) is a rare form of plasma cell dyscrasia characterized by the presence of at least $2.0 \times 10^9/L$ and more than 20% plasma cells in the peripheral blood differential leukocyte count. PCL may be classified as primary, when it presents in the leukemic phase, or secondary, when there is leukemic transformation of a previously recognized multiple myeloma. Approximately 60% of patients with PCL have the primary type.^{27,28} Secondary PCL occurs in about 1% of patients with multiple myeloma.

PATHOPHYSIOLOGY

The reason that some patients present with PCL and others have evolution to it is unclear. Primary PCL is a distinct entity because its presenting features, response

to chemotherapy, and survival are different from those in multiple myeloma. In patients with primary PCL who respond to chemotherapy, PCL almost always reappears at relapse, whereas only 1% of patients with multiple myeloma evolve to a secondary PCL.³⁰

Primary PCL cells have a higher expression of CD20 antigen than do cells from multiple myeloma.²⁸ Plasma cells from both primary and secondary PCL usually lack CD56 antigen, which is important in anchoring plasma cells to the bone marrow stroma.³¹ One study showed that the expression of CD28 appears to differentiate primary from secondary PCL.³¹

In one report, more than 80% of patients with PCL were diploid or hypodiploid compared with 40% of patients with multiple myeloma, and 60% of patients with multiple myeloma were hyperdiploid (33). In another series, 17 of 20 (85%) patients were nonhyperdiploid, 2 were equivocal, and 1 was hyperdiploid.²⁹

Cytogenetic studies show a complex karyotype with multiple structural and numeric abnormalities in most cases. Fluorescence in situ hybridization showed monosomy of chromosome 13 in 12 of 13 patients.²⁸ In contrast, cytogenetic findings associated with a favorable outcome such as trisomy of chromosomes 6, 9, and 17 are absent in primary PCL.²⁸ In a report of 20 patients with PCL (13 primary and 7 secondary), 15 had IgH translocations. Two-thirds of the translocations were t(11;14)(q13;q32), which is an unfavorable prognostic feature. Fourteen patients (70%) had deletion of chromosome 13, whereas 10 had t(17;p13.1) (p53 locus), which are both unfavorable prognostic features.

Mutations of N- and K-*ras* oncogenes have been reported in up to 58% of patients with PCL.^{32,33} Amplification of the *c-myc* oncogene at the DNA level with concomitant overexpression has been reported.³⁴ In two series, 4 of 12 (33%) and 3 of 10 (30%) patients with PCL had p53 mutations.^{33,35} Hypomethylation of p16 has been reported in PCL.³⁶

Interleukin 6 (IL-6) is the major plasma cell growth factor in vitro and in vivo in patients with multiple myeloma.³⁷ In a series of 13 patients with PCL, all had significant spontaneous cell growth after 5 days in culture and all had significant growth when stimulated with exogenous IL-6.³⁸ The role of IL-6 is supported by blockage of plasma cell proliferation when treated with anti-IL-6 monoclonal antibody.³⁹

CLINICAL FEATURES

PCL is uncommon. Most reports consist of single cases or small series, with the exception of three reviews reporting at least 25 cases each. The main clinical and laboratory features, the response to therapy, and the duration of survival of patients with primary PCL in the three reviews are summarized in Table 84.3. Noel and Kyle²⁷ included patients with PCL diagnosed between 1960 and 1985, while another two series^{28,40} included patients with a more recent diagnosis of PCL.

Table 84.3 Primary plasma cell leukemia: clinical and laboratory features in three series including at least 25 patients each

Feature	Noel and Kyle ²⁷	Dimopoulos et al. ⁴⁰	Garcia-Sanz et al. ²⁸
No. of patients	25	27	26
Median age, years	53	57	55
Sex (M/F)	15/10	NR	12/14
Extramedullary involvement (%)	>50	37	23
Lytic bone lesions (%)	44	NR	48
Hemoglobin <10 g/dL (%)	>50	82	54

^aOne case was biclonal (IgA λ , IgE λ).

From Ref. 41, with permission from Elsevier.

The median age ranged between 53 and 57 years, which is a decade younger than that in a large recent myeloma cohort.⁴² Patients with primary PCL are younger and have a higher incidence of hepatosplenomegaly and lymphadenopathy, a higher platelet count, fewer lytic lesions, a lower serum M-protein level, and longer survival than do patients with secondary PCL.^{27,28} It is obvious from these series that primary PCL has a more aggressive clinical presentation than does multiple myeloma with a higher frequency of extramedullary involvement, anemia, thrombocytopenia, hypercalcemia, and renal impairment. The presence of lytic bone lesions is lower than that observed in multiple myeloma.

THERAPY AND SURVIVAL

In general, therapeutic options are similar to treatment of multiple myeloma, except that more intensive therapy is needed, and outcomes are significantly inferior.

The outcome of 68 patients from the literature with well-documented primary PCL treated before 1986 has been described.²⁷ Fifty-two of the patients received a single alkylating agent, mainly melphalan with or without prednisone, as initial therapy. A complete or partial response was documented in 28 patients (54%). The median duration of survival was slightly more than 1 year in patients who responded to therapy, but less than 1 month for nonresponding patients. The other 16 patients were treated with combination chemotherapy, which resulted in a response rate of 75% and a median duration of survival for all 16 patients of 9.5 months. In the Mayo Clinic series of 25 patients with primary PCL, 7 of 15 patients responded to melphalan with or without prednisone. Despite the response rate of 47%, the median time to progression or death in these 15

patients was 8.7 months. The median duration of survival for all 25 patients with PCL was 6.8 months, and only 4 patients survived for more than 2 years.

The overall response rate in the series by Dimopoulos et al.⁴⁰ was 37%. They noted that failure to achieve 50% clearing of peripheral blood plasma cells within 10 days after initiation of treatment was a predictor of no response. The median duration of survival was 12 months. A short survival was caused mainly by the large number of patients dying of disease complications during the first 2 months of treatment. In that series, patients treated with vincristine, doxorubicin (adriamycin), and dexamethasone (VAD) or with cyclophosphamide and etoposide had a response rate of 59% and a median duration of survival of 20 months. These improved results are probably due to a decrease in early mortality as a result of a rapid reduction of tumor mass, and due to improved supportive therapy. Garcia-Sanz et al.²⁸ reported an overall response rate of 38%. The response rate and survival were lower in patients treated with melphalan and prednisone than in those given alternating courses of vincristine, cyclophosphamide, melphalan, and prednisone (VCMP) or vincristine, 1,3-bis(2-chlorethyl)-1-nitrosourea (BCNU), doxorubicin (adriamycin), and prednisone (VBAP).

Treatment with a single alkylating agent plus prednisone is not adequate for patients with primary PCL. Combination chemotherapy with VAD, cyclophosphamide, and etoposide or alternating VCMP and VBAP yields better responses. High-dose therapy followed by autologous stem cell transplantation should be offered to responding patients if age and clinical condition do not preclude transplantation.⁴³ Thalidomide also may be a useful agent.⁴⁴

Secondary PCL usually is a terminal event in patients with relapsed or refractory myeloma. Unfortunately, the median duration of survival in these patients is about 1 month.²⁷ Thalidomide may be of some benefit in this situation.⁴⁵

SMOLDERING (ASYMPTOMATIC) MULTIPLE MYELOMA

The point of transition from monoclonal gammopathy of undetermined significance (MGUS) to smoldering multiple myeloma is not sharply defined biologically. By definition, MGUS consists of an M-protein value less than 3 g/dL, bone marrow plasma cell value less than 10%, and absence of anemia, renal insufficiency, hypercalcemia, or skeletal lesions attributable to the neoplastic plasma cell proliferation (Table 84.2). However, if the M-protein value is 3 g/dL or more or the bone marrow contains 10% or more plasma cells, the term *smoldering (asymptomatic) multiple myeloma* is used (Table 84.2).⁴ Frequently, a reduction of uninvolved immunoglobulins in the serum and a small amount of M protein in the urine are found. These findings are consistent with multiple myeloma, but anemia, renal insufficiency, and skeletal lesions are not present. That is, there is no evidence of end-organ damage. In addition, the plasma cell labeling index is low.

Smoldering multiple myeloma occurs in approximately 15% of all cases of newly diagnosed multiple myeloma.¹ The prevalence estimates of smoldering multiple myeloma are variable because many reports include asymptomatic patients with lytic lesions on skeletal survey. Some exclude skeletal lesions but include patients who have lytic lesions on magnetic resonance imaging. A true prevalence derived from strict criteria for smoldering multiple myeloma is not available. Most patients with smoldering multiple myeloma eventually have progression to symptomatic myeloma, and the risk of progression is higher than with MGUS.¹ Some patients may remain stable for many years.⁴⁶ The median time for progression to symptomatic disease is 1–3 years. One study found only a 20% risk of progression at 6 years, but patients were considered to have smoldering multiple myeloma only if they had no disease progression after 1 year of follow-up.⁴⁷

PREDICTORS OF PROGRESSION

Assessment of predictors of progression in smoldering multiple myeloma is hampered by varying diagnostic criteria used to define the condition. Several studies include patients with asymptomatic lytic lesions as well. Future studies of smoldering multiple myeloma will need to use more uniformly accepted criteria so that results can be compared.

Patients with an increase in the number of circulating peripheral blood monoclonal plasma cells are at higher risk for progression to myeloma. An increased

plasma cell labeling index of the bone marrow indicates that symptomatic multiple myeloma is present or will develop in the near future.

The three most important prognostic factors for progression in one series included a serum monoclonal protein concentration more than 3.0 g/dL, IgA subtype, and urinary M-protein excretion of more than 50 mg/day. Patients with more than two of these features had a median time to progression of 17 months; those with two factors had a median time to progression of 40 months; and patients who had none of these features had a median time to progression of 95 months.⁴⁸

Other studies have found that abnormalities on magnetic resonance imaging can predict disease progression in patients with smoldering multiple myeloma.¹ Whether patients who have abnormalities on magnetic resonance imaging should be considered as having smoldering multiple myeloma is debatable. Nevertheless, these patients can be considered to have low-grade multiple myeloma and can be observed without therapy, similar to those with smoldering multiple myeloma.

MANAGEMENT

The current standard of care in smoldering multiple myeloma is close follow-up every few months without any chemotherapy. This recommendation results from trials that found no significant improvement in overall survival in patients who received immediate treatment with melphalan plus prednisone for stage I or asymptomatic myeloma, compared with those who received treatment at progression. Hjorth and colleagues⁴⁹ assigned 50 patients with asymptomatic stage I myeloma to observation versus melphalan plus prednisone chemotherapy. No differences were found in overall survival between the two groups. In another series of 44 patients with asymptomatic myeloma, survival times were similar with immediate or deferred therapy.⁵⁰

Investigational approaches may be considered for selected patients in appropriate trials. Thalidomide is being studied as a single agent, and a partial response rate of approximately 35% has been noted. However, a phase III randomized study comparing no therapy with thalidomide or other agents such as bisphosphonates, IL-1 β inhibitors, clarithromycin, or dehydroepiandrosterone is required before making any recommendations concerning therapy of smoldering multiple myeloma.

POEMS SYNDROME (OSTEOSCLEROTIC MYELOMA)

POEMS (*polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes*) syndrome, or osteosclerotic myeloma, is characterized by chronic sensorimotor peripheral neuropathy with predominant motor disability.⁵¹ Additional features include scler-

rotic bone lesions, Castleman's disease, papilledema, edema, ascites, pleural effusion, erythrocytosis, and thrombocytosis.

CLINICAL FEATURES

Peripheral neuropathy was present in all of our 99 patients and usually dominates the clinical picture.⁵² Symptoms usually begin in the feet and consist of tingling or paresthesias. Motor involvement follows the sensory symptoms. Both begin distally and are symmetric and progress proximally. More than half of the patients have severe weakness and may have difficulty in climbing stairs, rising from a chair, or gripping objects firmly. In contrast to the neuropathy associated with primary amyloidosis (AL), autonomic symptoms are not a feature. Bone pain and pathologic fractures are major findings in symptomatic myeloma, but occur rarely in POEMS syndrome.

Physical examination reveals a symmetric, sensorimotor neuropathy involving the extremities. Muscle weakness is usually more marked than sensory loss. Touch, pressure, vibratory, and joint position senses are often involved, whereas loss of temperature discrimination and nociception occur less frequently. Papilledema was present in almost one-third of our patients. However, other cranial nerves are not affected.

Hepatomegaly, splenomegaly, and lymphadenopathy were present in about one-fourth of patients. Hyperpigmentation was present in almost one-half of patients, but it was easily overlooked. Hypertrichosis, manifested by coarse black hair, appeared on the extremities in one-fourth of our patients, and telangiectasia and hemangiomas were present in 10%. Peripheral edema was found in one-fourth of our patients, but ascites and pleural effusion were uncommon. Clubbing of the fingers has been noted but was infrequent in our series.

LABORATORY FEATURES

Almost 20% of our patients had polycythemia. Anemia was not a feature of the syndrome. Thrombocytosis was noted in more than half of our patients. Hypercalcemia and renal insufficiency were rare.

All of our patients had evidence of a monoclonal plasma cell proliferative process. Eighty-five percent had an M protein in the serum, but the level was modest and the median value was 1.1 g/dL. This is similar to the 75% reported by Nakanishi et al.⁵³ in a review of 102 patients with the syndrome. Forty patients had an M protein in the urine, but the amount was small and the median value was 100 mg/24 h.

All of our patients had a monoclonal λ -proliferative process. IgA λ was found in 44 patients, and IgG λ was found in 40. Only one patient had an IgM λ protein. A clonal λ plasma cell proliferative process was shown by immunohistochemical staining in all 12 patients who did not have an M protein in their serum or urine.

The bone marrow was most often nondiagnostic. Only 14% of patients had a bone marrow plasmacytosis of more than 10%, which is similar to the findings of Soubrier et al.⁵⁴ Only four of our patients had more than 20% plasma cells, but none of them had lytic bone lesions or anemia.

Endocrine abnormalities were found in two-thirds of our patients at presentation. Hypogonadism was the most common abnormality, and 71% of males had erectile dysfunction. Twenty-four of 28 patients who had serum testosterone levels measured had a reduction. Gynecomastia was found in 17 men. Prolactin levels were not increased. Hypothyroidism was found in 14% of patients. An additional 12% had a mild increase in the thyroid-stimulating hormone level but had normal thyroxin levels. Abnormalities of the adrenal-pituitary axis were present in 16%. In five additional patients, adrenal insufficiency developed during follow-up.

SCLEROTIC BONE LESIONS

Conventional radiographs showed osteosclerotic lesions in 95% of our patients. Lytic lesions without evidence of sclerosis are rare. Approximately half of our patients had mixed sclerotic and lytic lesions. Forty-seven percent of our patients had only sclerotic lesions. A single solitary lesion was found in 45%, and the remainder had multiple lesions. The pelvis, spine, ribs, and proximal extremities are most often involved. In rare instances, multiple myeloma is associated with diffuse osteosclerotic bone lesions, and affected patients must be differentiated from those with POEMS syndrome.

PATHOPHYSIOLOGY

The cause of POEMS syndrome is unknown. Patients frequently have higher levels of IL-1 β , tumor necrosis factor α , and IL-6 than do patients with multiple myeloma.⁵⁵ Levels of vascular endothelial growth factor are also frequently increased.⁵⁶ Antibodies to human herpesvirus 8 were reported in seven of nine patients with POEMS syndrome and Castleman's disease. Six of seven patients had human herpesvirus 8 DNA sequences.⁵⁷

Electromyography shows slowing of nerve conduction and severe attenuation of compound muscle action potentials.⁵⁸ Distal fibrillation potentials are found on needle electromyography. Both axonal degeneration and demyelination are found in sural nerve biopsy specimens. Ono et al.⁵⁹ reported a loss of demyelinated fibers and an increased frequency of axonal degeneration in teased fibers. Cerebrospinal fluid protein levels are increased in almost all patients. More than half of our patients had a cerebrospinal fluid protein value more than 100 mg/dL.⁶⁰

Castleman's disease (giant cell lymph node hyperplasia, angiofollicular lymph node hyperplasia) has also been associated with POEMS syndrome.⁶¹ In our experience, about 15% of patients with POEMS syndrome also have Castleman's disease.

Renal involvement may be a feature of POEMS syndrome. Nakamoto et al.⁶² reviewed 52 cases of POEMS syndrome with renal abnormalities. Approximately half of the patients had creatinine levels more than 1.5 mg/dL, and 10% required dialysis.

Pulmonary hypertension also has been noted in POEMS syndrome.⁶³ Pulmonary hypertension developed in 5 of 20 patients with POEMS syndrome, and increased levels of IL-1 β , IL-6, tumor necrosis factor α , and vascular endothelial growth factor were found in all cases.⁶⁴ Five of our patients had pulmonary hypertension and restrictive lung disease; respiratory failure developed in four of them. Respiratory disease was responsible for death in 17% of our patients.

Hyperpigmentation, hypertrichosis, and hemangiomas were the major dermatologic findings in our series.⁵² Four patients have been described with POEMS syndrome and a violaceous skin patch overlying a solitary plasmacytoma of bone, along with enlarged regional lymph nodes. One patient had POEMS syndrome, whereas in another, POEMS syndrome developed after excision of the plasmacytoma. The authors suggested the term *AESOP syndrome* for adenopathy and extensive skin patch overlying a plasmacytoma.⁶⁵

Forty-one thrombotic events occurred in 18 of our patients. These consisted of stroke, myocardial infarction, or Budd-Chiari syndrome. Four patients with POEMS syndrome have been reported with acute arterial thrombotic events.⁶⁶

DIAGNOSIS AND COURSE

POEMS syndrome must be considered in the differential diagnosis of a patient presenting with a sensorimotor peripheral neuropathy. A metastatic bone survey must be done in search for osteosclerotic lesions. These lesions can be subtle and easily confused with fibrous dysplasia or a vertebral hemangioma. The M-protein level in the serum and urine is low and may be easily overlooked. The diagnosis depends on the demonstration of increased numbers of monoclonal plasma cells and a biopsy specimen from the osteosclerotic lesion.

The natural history is one of progressive peripheral neuropathy over a period of years until the patient is bedridden. Death usually occurs from inanition or terminal pneumonia. The median overall duration of survival in our 99 patients was 13.7 years.

THERAPY

Radiation in a dose of 40–50 cGy is indicated for patients with single or multiple osteosclerotic lesions in a limited area. More than half of the patients show substantial improvement of neuropathy. Of our 13 patients who did not respond to radiation, 9 received less than 4000 cGy. The improvement may be slow and may not be apparent for 6 months or longer. Some patients continue to improve for 2–3 years after radiation therapy.

Systemic therapy is necessary if the patient has widespread osteosclerotic lesions. Melphalan and

prednisone were given to 48 of our patients, and improvement was noted in 44%. Combination chemotherapy induced responses in 27% of 15 treated patients. Prednisone or dexamethasone as a single agent was given to 41 of our patients, and there was an apparent improvement in only 15%. Plasma exchange, intravenous immunoglobulin, cyclosporine, and azathioprine were ineffective.

Autologous stem cell transplantation after high-dose melphalan should be seriously considered for patients younger than 70 years with widespread osteosclerotic lesions. The stem cells should be collected before the patient is exposed to alkylating agents because they will damage the hematopoietic stem cells. The mortality associated with the procedure is only 1–2%.^{67–70}

NONSECRETORY MYELOMA

Patients with nonsecretory myeloma have no M protein in either the serum or urine with immunofixation. This finding occurs in 1–5% of all patients with multiple myeloma.^{42,71–74} In 1027 patients with newly diagnosed myeloma, we found no M protein in the serum and urine with immunofixation in 29 (2.8%).⁴²

Immunoperoxidase and immunofluorescence studies on plasma cells should be performed in all patients with nonsecretory myeloma. A cytoplasmic M protein is identified in about 85% of patients; no M protein can be found in the remaining, and these patients are considered to have “nonproducer” nonsecretory myeloma.^{75–78}

Ultrastructural study of plasma cells shows the typical features observed in plasma cells of patients who have an M protein in the serum and urine.^{79,80} In contrast, in some cases of nonproducer or truly nonsecretory myeloma, ultrastructural studies show highly undifferentiated plasma cells.^{77,81} The lack of M protein in the serum and urine of patients with nonsecretory myeloma may be from (1) the inability of plasma cells to excrete the immunoglobulin, (2) the low synthetic capacity of immunoglobulin production, (3) increased intracellular degradation, or (4) rapid extracellular degradation of abnormal immunoglobulins. Interestingly, the light chain is of κ type in about 75% of patients with nonsecretory myeloma.

CLINICAL FEATURES

The main presenting features in four series of nonsecretory myeloma with at least seven patients are shown in Table 84.4. In the largest series, consisting of 29 patients, the median age was a decade younger than that of a usual patient with myeloma. In that series, almost 70% of patients had low tumor mass. No patient had a hemoglobin level less than 11 g/dL or renal failure, and only two patients had hypercalcemia. In the other series, the presenting features of nonsecretory myeloma were similar to those in patients with M

protein, except for the absence of renal insufficiency. Most patients had stage III disease, and the majority had a marked reduction of normal polyclonal immunoglobulins. Almost all patients had lytic lesions.

In the series of 29 patients, the condition remained nonsecretory throughout in 22 patients (76%). During follow-up, M protein developed in the serum in five patients (two with monoclonal heavy chain and three with monoclonal light chain). In two others, a monoclonal light chain developed in the urine. The uninvolved immunoglobulins were reduced in 92%. None of the patients with nonsecretory myeloma had a serum creatinine value more than 2 mg/dL. In contrast, the serum creatinine value was increased in 35% of the patients with light-chain myeloma. Median duration of survival was 38 months for patients with nonsecretory myeloma, 34 months for those with light-chain myeloma, and 33 months for the entire cohort of 1027 patients.⁴²

RESPONSE TO THERAPY AND SURVIVAL

Therapy is similar to that for multiple myeloma. The lack of a measurable M protein makes evaluation of response to therapy difficult. Evaluation of response is based on improvement in the symptoms of bone pain, correction of anemia and hypercalcemia if initially present, reduction of extramedullary plasmacytomas, no increase in lytic bone lesions, and decrease in the proportion of bone marrow plasma cells. The advent of free light-chain assays is useful for monitoring the progress of patients with nonsecretory myeloma. Drayson et al.⁹⁴ reported abnormal free light chains in 68% of patients with nonsecretory myeloma. Dreicer and Alexanian⁷³ reported that 80% of patients responded to initial chemotherapy.

In several series, survival of patients with nonsecretory myeloma was similar to that of patients with a measurable M protein.^{71,72,79,80} Dreicer and Alexanian⁷³ reported a median duration of survival of 39 months, whereas Bourantas⁸² noted 45 months. The median of 38 months in our study was not statistically different from that in patients with a measurable M protein.⁴²

IMMUNOGLOBULIN D MYELOMA

IgD myeloma accounts for about 2% of all cases of multiple myeloma.^{83,84} Although the presence of an IgD M protein is almost always indicative of a malignant plasma cell disorder such as multiple myeloma or primary amyloidosis, two well-documented cases of MGUS of the IgD type have been reported.^{85,86} Thus, the presence of a serum IgD M protein is not always associated with a malignant plasma cell proliferative process.

CLINICAL FEATURES

The data on IgD myeloma come from reports on a few cases and small series, two large reviews of the reported cases in the literature,^{87,88} and single-institution experience in 53 cases.^{89,90}

The main clinical and laboratory features reported in four series of IgD myeloma including at least 20 patients are summarized in Table 84.5.^{87,88,89,90,91} The median age at presentation was 55–60 years, which is slightly younger than that in a general myeloma population. The initial presenting symptoms were not different from those reported in usual myeloma cases. In two series, a moderate lymph node enlargement, a rare finding in multiple myeloma, was present in about 10% of patients.^{88,90} Although one series had a low incidence of extramedullary plasmacytoma,⁹¹ the reported incidence of extraosseous spread in IgD myeloma ranges from 19 to 63%.^{84,88,90} In one of the studies, 7 of 53 patients (13%) had extradural plasmacytomas at diagnosis.⁹⁰ Amyloidosis was reported in 44% of patients at autopsy.⁸⁷ In a single-institution series, however, the frequency of associated amyloidosis was 19%.⁹⁰ IgD myeloma has been associated with a higher frequency of PCL.^{87,88,92} The incidence of renal failure is higher in IgD myeloma.^{87,88,90,91}

The serum protein electrophoretic pattern differs in that only 60% of patients with IgD myeloma have an M-protein spike. Furthermore, the amount of the M protein rarely exceeds 2 g/dL.⁹⁰ Almost all patients

Table 84.5 Immunoglobulin D myeloma: clinical and laboratory features in four series including at least 20 patients^a

Feature	Jancelewicz et al. ⁸⁷	Fibbe and Jansen ⁹¹	Shimamoto et al. ⁸⁸	Bladé et al. ⁹⁰

with IgD myeloma have light-chain proteinuria, and more than half have more than 1 g/24 h.⁹⁰ In most series of IgD myeloma, increased λ light chain has been reported,^{87,88,91,93} but in a large single-institution series the frequency of λ light chain was 60%.⁹⁰ IgD myeloma should always be excluded in patients with a discrete M-protein spike on serum protein electrophoresis and only a monoclonal κ or λ light chain on immunofixation.

In summary, patients with IgD myeloma often present with a small band or no spike on serum protein electrophoresis and light-chain proteinuria. Almost one-fifth have associated amyloidosis. Because these features are also typical of light-chain myeloma, IgD can be considered a variant. The presence of IgD M protein and the predominance of the λ light chain are the major distinctive findings.

THERAPY AND SURVIVAL

Treatment and response to therapy in patients with IgD myeloma is similar to that in patients with myeloma of other immunologic types.^{87,90,95} In several series, the median duration of survival of patients with IgD myeloma ranged from 12 to 17 months.^{84,87,88,91} Fahey et al.⁹⁵ reported a median duration of 2 years in 15 patients. In the Mayo Clinic series of 53 patients, the median duration of survival was 21 months, but for the 26 patients in whom the diagnosis was made after 1980 the median survival was 31 months.⁹⁰ Three patients in that series survived for more than 10 years, and one of them was considered to have been cured.⁹⁶

Chapter 85

ALLOGENEIC STEM CELL TRANSPLANTATION FOR MULTIPLE MYELOMA

Edwin P. Alyea

INTRODUCTION

Multiple myeloma is a clonal neoplasm of terminally differentiated B cells which accounts for about 1% of new cancers.¹ Despite an increased understanding of the biology of the malignant plasma cell, myeloma remains incurable with current chemotherapy. Although multiple myeloma is highly sensitive to chemotherapy, combination chemotherapy regimens have not achieved better outcomes than achieved by melphalan and prednisone therapy.² Large comparative studies have demonstrated superior response rates, overall survival, and event-free survival using high-dose therapy and autologous Stem cell transplant (SCT) compared with conventional therapy.³ Despite the improved outcome after autologous transplantation, long-term disease-free survival remains disappointingly low at 15–20%, with disease relapse being the primary reason for treatment failure.⁴ Myeloablative allogeneic stem cell transplantation achieves long-term disease-free survival in 15–20% patients with myeloma. The curative potential of allografting is based upon two principles. First, high-dose myeloablative therapy may eradicate disease, and hematopoiesis is restored using a tumor-free stem cell allograft. Second, donor cells mediate an immunologic antitumor effect that eradicates minimal residual disease (MRD) posttransplant. This immunologic effect has been termed the “graft-versus-leukemia (GvL) effect” or, in multiple myeloma, the graft-versus-myeloma (GvM) effect. For allogeneic SCT to achieve its full potential in the treatment of patients with myeloma, efforts are now being directed toward both reducing the attendant toxicity of allogeneic SCT and enhancing the GvM effect after transplant. Identification of the mediators and targets of the GvM effect may allow for more directed immunotherapy for myeloma in the future.

STANDARD THERAPY AND AUTOLOGOUS STEM CELL TRANSPLANT IN MULTIPLE MYELOMA

Alkylating agents administered with corticosteroids have been the mainstay of therapy for patients with multiple myeloma over the last three decades. Most commonly, melphalan is combined with prednisone, and patients are treated every 6 weeks. Many attempts have been made to increase the intensity of standard therapy, but combination chemotherapy regimens have not led to an improvement in survival. Specifically, a meta-analysis of 6633 patients treated in comparative trials of melphalan and prednisone versus combination chemotherapy showed these treatments to be equivalent.⁵ Currently, the response rate to conventional chemotherapy is 40–60%, with a median survival of 3 years from diagnosis. Unfortunately, this disease remains incurable with conventional chemotherapy.

The demonstration that high-dose melphalan can induce higher remission rates in patients who are otherwise refractory to conventional-dose melphalan has provided the framework for multiple trials of autologous stem cell transplantation in this disease.^{3,6–8} A randomized trial of 200 newly diagnosed patients in France demonstrated an improved response rate (81% vs 57%) and 5-year probability of event-free survival (28% vs 10%) for patients undergoing high-dose therapy and autologous SCT, compared with standard-dose chemotherapy.³ A second randomized trial of 401 previously untreated patients demonstrated both an improved overall survival and progression-free survival for patients receiving intensive therapy, including an autologous transplant, compared with standard therapy.⁹ Other randomized studies have not demonstrated an improved overall survival or event-free survival, but have demonstrated a prolonged time to treatment failure and improved quality of life.¹⁰

Although response rates are high following autologous transplantation, long-term follow up demonstrates that few patients are cured using this approach.

Efforts continue to improve the results of autologous transplantation for patients with myeloma. A recent randomized trial demonstrated that sequential autologous transplantation resulted in a superior overall survival compared with a single autologous transplantation.¹¹ While results of autologous transplant in myeloma appear encouraging, relapse of disease is the principal reason for the failure of this approach. Reinfusion of tumor cells at the time of transplant may contribute to disease relapse in some patients, as has been demonstrated in other types of autologous transplantation.¹² In an effort to reduce relapse rates, attention has focused on allogeneic transplant as a method to provide a tumor-free stem cell source for patients. In addition, the recognition of the existence of a potent GvM effect has renewed interest in allogeneic transplantation for myeloma.

MONITORING OF PATIENTS AFTER TRANSPLANTATION

Criteria for defining a complete response (CR) in patients with myeloma undergoing transplantation have evolved over time and may account in some cases for the differing CR rates observed in clinical trials. Early trials from the European Stem cell Transplant Registry (EBMTR) defined CR as the disappearance of immunoglobulin in serum and light chains in the urine using conventional electrophoresis or immunofixation, as well as the absence of myeloma cells in the marrow.^{13,14} Using a more strict definition, investigators at Dana-Farber Cancer Institute (DFCI) and Fred Hutchinson Cancer Research Center (FHCRC) have required the absence of detectable monoclonal protein by immunofixation to define a CR. In an effort to establish uniform criteria for response, transplant registries have proposed criteria based upon immunofixation for defining CR, PR, relapse, and progressive disease in patients with multiple myeloma treated with high-dose therapy.¹⁵

Polymerase chain reaction (PCR) based techniques have also been used to evaluate MRD in patients with myeloma after high-dose therapy. PCR for MRD in multiple myeloma involves the amplification of the V_H family of primers to identify the patient-specific immunoglobulin complementarity-determining region (CDRIII) sequences. Patient-specific primers can then be used to follow patients over time. Using the V_H family primers alone, one myeloma cell in 10^3 – 10^4 normal cells can be detected. Increased sensitivity can be obtained using patient specific primers, to the degree that one myeloma cell in a background of 10^5 – 10^6 normal cells can be identified. Investigators are now using PCR to assess patients after transplantation and have reported in one study that molecular CR, defined

as PCR negativity, occurs more frequently after allografting (7 of 14 patients) than after autografting (2 of 15 patients).¹⁶ Quantitative PCR using “Real-Time” technology can now also be used to follow patients with myeloma and provide a better estimate of the burden of disease.¹⁷

CLINICAL TRIAL RESULTS OF MYELOABLATIVE ALLOGENEIC TRANSPLANTATION

Results from several large trials of myeloablative allogeneic SCT in patients with myeloma are available both from cooperative groups and several single institutions (Table 85.1). The EBMTR has reported the results of 162 patients receiving allogeneic Stem cell transplant for multiple myeloma at over 40 centers in Europe and South Africa.^{13,18,23} The median age was 43 years, and 52% of the patients had evidence of chemotherapy-sensitive disease at the time of transplant. Although the ablative regimens differed between centers, the majority (72%) of patients received high-dose chemotherapy, most commonly cyclophosphamide and melphalan, combined with total body irradiation (TBI). Graft-versus-host disease (GvHD) prophylaxis also varied by center. Cyclosporine was combined either with methotrexate (48%) or with other agents (20%). T-cell depletion, either alone or in combination with other agents, was used in 33% of patients. The overall treatment-related mortality (TRM) was 25%, with most patients succumbing to complications of infection, interstitial pneumonitis, or GvHD. The overall CR rate was 44%, and the overall actuarial survival rates at 4 years and 9 years after were 32 and 18%, respectively. Relapse-free survival was 34% at 6 years for those patients who attained a CR after transplant.

Similar results have been reported from several large single institutions. In the FHCRC experience, 80 patients underwent myeloablative allogeneic

Table 85.1 Results of allogeneic transplantation in multiple myeloma

	N	Treatment-Related mortality (%)	Complete remission rate following stem cell transplant (%)	References
EBMTR	162	25	44	13,18

Seattle	80	56	36	20
Dana-Farber	61	10	23	21
Vancouver	19	16	58	22

transplantation for multiple myeloma.²⁰ Sixty patients received marrow from HLA-identical sibling donors, and 20 patients from mismatched or unrelated donors. The majority of patients had chemotherapy-refractory disease. Ablative therapy consisted of busulfan and cyclophosphamide in 57 patients, and cyclophosphamide and TBI in 23 patients. The majority of patients (56%) received cyclosporine with methotrexate as GvHD prophylaxis and the remaining received cyclosporine and prednisone (37%). The TRM was 56%, with infection, veno-occlusive disease, and complications of GvHD being the most common causes of treatment failure. Despite the increased TRM, the CR rate was 36% in this highly refractory group of patients. Overall and progression-free survival was 20 and 16%, respectively, at 5 years after transplant.

Sixty-one patients with multiple myeloma have undergone allogeneic SCT at DFCI.^{21,24} The majority of patients had advanced Durie–Salmon stage II–III disease at diagnosis, and all patients had chemotherapy-sensitive disease at the time of transplant. The ablative regimen included cyclophosphamide and TBI in 80% of patients, and busulfan and cyclophosphamide in the remaining 20% of patients in whom prior radiation therapy precluded the use of TBI. All patients received marrow allografts from HLA-matched sibling donors which were T-cell depleted using anti-CD6 monoclonal antibody and complement lysis as the only form of GvHD prophylaxis. The overall TRM was low (10%), primarily due to the fact that only 17% of patients developed grade II or greater GvHD. The CR rate was 22%, and 60% of patients achieved PR. The median and progression-free survival was 22 months and 12 months, respectively.

Recently, Martinelli et al. reported the results of 68 patients receiving allogeneic transplantation. The majority (56) received bone marrow, while the remaining 16 patients received peripheral blood stem cells (PBSCs). Conditioning regimens included cyclophosphamide and TBI in 48 patients, and busulfan and cyclophosphamide in 20 patients. GvHD prophylaxis consisted of cyclosporine with or without methotrexate in 31 patients and T-cell depletion in 37 patients. Thirty-eight patients achieved a CR at a median of 36 months.²⁵ Twelve patients achieving a CR were evaluated by PCR and 9 (75%) were PCR negative. Only 1 of 4 patients who were PCR positive relapsed during the follow-up period.²⁶

Overall, the results of allogeneic SCT in patients with multiple myeloma demonstrate CR rates ranging from 22 to 50%. In many trials the treatment-related toxicity was high (25–56%), primarily related to complications of GvHD, infection, and disease relapse. To improve outcome, efforts have focused on methods to reduce both complications of GvHD and disease relapse.

TREATMENT-RELATED TOXICITY AND GvHD FOLLOWING MYELOABLATIVE ALLOGENEIC TRANSPLANTATION

While allogeneic transplantation following myeloablative therapy is associated with potent antitumor activity in patients with myeloma, most clinical trials have reported significant TRM, limiting the effectiveness of this approach. Acute and chronic GvHD contribute to the high TRM. The incidence of grade II–IV acute GvHD in patients receiving cyclosporine and methotrexate ranges as high as 78% in some studies, with an incidence of grade III–IV GvHD of 14–19%. In the EBMTR registry, patients with grades III and IV GvHD had an extremely poor survival.^{14,23}

Using selective T-cell depletion with anti-CD6 monoclonal antibody and complement lysis, investigators at DFCI have reduced the incidence of significant GvHD after transplant in patients with multiple myeloma. When T-cell depletion is used as the only means of GvHD prophylaxis, the incidence of severe grade III or IV acute GvHD is less than 7%, with no deaths attributable to GvHD.²¹ No evidence of GvHD was identified in 47% of patients, while 36% and 12% patients had grades I and II GvHD, respectively. Chronic GvHD was noted in only 20% of patients. Using an *in vivo* T-cell depletion approach, Kroger et al. reported a similar low incidence of severe GvHD and an overall 6-year progression-free survival of 31%.²⁷ Unfortunately, this reduction in toxicity related to GvHD has not been associated with an increased overall survival rate. As an example, a recent study using a partial T-cell depletion approach after myeloablative transplantation was associated with a low complete response rate (6%) after transplantation.²⁸ The EBMTR has reported that patients receiving T-cell depletion had a similar survival in comparison to patients receiving other methods of GvHD prophylaxis.^{14,23}

MYELOABLATIVE CONDITIONING REGIMENS

A variety of conditioning regimens have been explored using allogeneic transplantation for multiple myeloma. Cyclophosphamide, in combination with TBI or busulfan, has been used most commonly. No particular regimen has been identified to be superior in terms of CR rates, toxicity, or long-term outcome. As an example, EBMTR studies using a variety of conditioning regimens did not demonstrate any difference in response rates between regimens with or without TBI.^{13,14} Data from FHCRC support this finding: modified TBI added to busulfan and cyclophosphamide did not result in improvement of either relapse or survival of patients transplanted in the setting of advanced disease.²⁰

Melphalan has also been included in the conditioning regimen for allogeneic transplantation. A small study of 14 patients treated with melphalan in addition to busulfan and cyclophosphamide demonstrated a low TRM.²² In another study, 10 of 13 patients receiving melphalan 110–120 mg/m² in combination with TBI achieved a CR, and 9 patients remained disease free at 7–70 months after transplantation.²⁹ The overall disease-free survival with short follow-up in this study approached 70%.

PROGNOSTIC FACTORS AND OUTCOME AFTER MYELOABLATIVE ALLOGENEIC TRANSPLANTATION

Prognostic factors influencing outcome have been analyzed in patients with multiple myeloma receiving allogeneic SCT. The EBMTR analysis demonstrated improved survival associated with female gender (41% at 4 years), stage I disease at diagnosis (52% at 4 years), treatment with one regimen prior to ablative therapy (42% at 4 years), and achieving CR prior to SCT (64% at 3 years).^{13,14,23} IgA subtype and a low serum β_2 -microglobulin also conferred a favorable prognosis. Ability to achieve a CR following transplantation was the most favorable prognostic factor associated with prolonged survival.

In 80 patients receiving transplantation at FHCRC, time from diagnosis to transplant was found to be a significant prognostic factor.²⁰ Patients undergoing transplant more than 1–3 years after diagnosis had a 2.5 times greater 100-day mortality, compared with patients transplanted in the first year after diagnosis. Patients receiving transplantation beyond the first year after diagnosis or those with Durie–Salmon stage III disease had a 1.8 and 2.0 times greater risk of dying from any cause, respectively. Adverse factors predicting relapse or disease progression included female patients receiving marrow grafts from male donors, as well as extensive chemotherapy (greater than eight cycles) prior to transplant. Only Durie–Salmon stage at the time of transplant influenced relapse or progression-free survival, with stage III patients at increased risk, compared with stage I or stage II patients.

Analyzing the outcome of 62 patients undergoing allogeneic transplantation at DFCI, advanced disease was the factor associated with inferior progression-free survival and overall survival. Other factors, such as age less than 40, donor/patient sex, Ig isotype, or time from diagnosis to transplant, were not found to be significant.²⁴

These analyses demonstrate that advanced-stage disease is associated with inferior outcomes after transplant. Data from FHCRC suggest that transplant is more successful if performed early after diagnosis and prior to extensive therapy. Unfortunately, the TRM associated with myeloablative allogeneic transplantation at present is high in patients with myeloma, and

use of this modality in patients earlier in their disease course must, therefore, be considered carefully.

SYNGENEIC TRANSPLANTATION

The FHCRC and the EBMTR have reported long-term follow-up of patients receiving syngeneic transplants. Five of the nine evaluable patients treated at the FHCRC achieved a CR after transplant, three a PR, and one patient had no response. Of the five patients who achieved a CR, three relapsed and one died of myelodysplastic syndromes; one patient remains in remission with a small monoclonal spike at 15 years after transplant. Two patients died of treatment-related complications early after transplant.³⁰

The EBMTR has reported on 24 patients who received syngeneic transplant.³¹ Sixty-eight percent entered a CR. Three of 17 patients relapsed, and 2 died of transplant-related complications. The overall survival and progression-free survival are 73 months and 72 months, respectively. These data were compared with EBMTR results for autologous and allogeneic transplants. The relapse rate was lower after syngeneic than autologous transplant, but similar to that observed after allogeneic transplant. These results suggest that the higher relapse rate seen after autologous transplant compared to syngeneic transplant is related either to reinfusion of malignant cells in the autograft or to the presence of a GvM effect in the setting of syngeneic transplantation.

MYELOABLATIVE PERIPHERAL BLOOD STEM CELL TRANSPLANTATION

Use of allogeneic PBSCs has increased over the last several years. PBSC transplantation results in more rapid engraftment and requires shorter hospital stays than does SCT.³² Relatively few myeloablative allogeneic PBSC transplants have been performed to date in patients with multiple myeloma. In one small study, 10 patients received granulocyte colony-stimulating factor mobilized PBSCs (median of 9.7×10^8 mononuclear cells/kg and 14.3×10^6 CD34⁺ cells/kg) from HLA-identical siblings.³³ Engraftment was rapid, with a median time to both neutrophil and platelet engraftment of only 13 days. Four patients developed grade II or greater GvHD; two patients died, one of multiorgan toxicity. While follow-up is limited, the CR rate was 71%.

COMPARISON OF MYELOABLATIVE ALLOGENEIC AND AUTOLOGOUS STEM CELL TRANSPLANTATION

The results of myeloablative allogeneic and autologous transplant for patients with multiple myeloma have

Figure 85.1 Progression-free survival: comparison of patients receiving either autologous or myeloablative allogeneic transplantation for multiple myeloma

been compared.^{23,24,34–36} The EBMT performed a retrospective case-matched analysis comparing 189 patients treated with allogeneic transplantation with an equal number of patients undergoing autologous transplant.²³ The groups were comparable, except that the median age of patients receiving autologous transplants was 49 years, significantly greater than the median age of 43 years in patients undergoing allogeneic transplant. The CR rate was similar for both groups; however, the TRM was significantly higher for allogeneic transplant recipients (41% vs 13%). This difference in TRM resulted in a significantly improved median survival for patients treated with autologous transplant (34 months) versus allogeneic transplant (18 months). After 4 years of follow-up, the survival curves for the allogeneic and autologous patient cohorts come together, and thereafter the long-term survival rates in both groups were comparable.

Sixty-two patients receiving a myeloablative allogeneic transplantation were compared with 162 patients receiving autologous transplantation at DFCI.²⁴ The groups were comparable, with the exception that patients receiving autologous transplantation had a higher median age, 50 years versus 45 years; received

transplantation earlier after diagnosis; and had received fewer regimens prior to transplantation. Patients receiving autologous transplantation had a superior overall and progression-free survival at 2 years after transplantation, 74 and 48% respectively, compared with patients receiving allogeneic transplantation, 58 and 28%, respectively. By 4 years after transplantation, overall survival and progression-free survival were similar—41 and 23% for autologous recipients and 39 and 18% for allogeneic transplant recipients, respectively (Figure 85.1). The 4-year cumulative TRM was significantly higher for the allogeneic transplant patients, 24% versus 13% for autologous transplant patients. Relapse of disease was the most common cause of treatment failure for both transplant procedures, but was higher for patients receiving autologous transplantation, 56%, compared with 46% for those receiving allogeneic transplantation (Figure 85.2). Therefore, despite the lower incidence of relapse following allogeneic transplantation, the high TRM following allogeneic transplantation results in an inferior overall survival when compared with autologous transplantation. The lower relapse rate is in part related to the potent GvM effect mediated by the allogeneic immune system. Efforts are

Figure 85.2 Comparison of risk of relapse after myeloablative allogeneic transplantation and autologous transplantation

currently focused on reducing the treatment-related toxicity of transplantation using nonmyeloablative conditioning regimens while preserving the GvM effect.

GRAFT-VERSUS-MYELOMA EFFECT AND DONOR LYMPHOCYTE INFUSION

Similar to chronic myelogenous leukemia, there are several lines of indirect evidence supporting the existence of an alloimmune antimyeloma response, or GvM effect. This evidence includes the observation that molecular remissions are more common after allogeneic transplantation than after autologous transplantation in patients with myeloma.¹⁶ In addition, the relapse rates are lower after allogeneic transplant compared with autologous transplantation. Some patients with persistent evidence of disease after allogeneic transplantation gradually achieve complete remission without further therapy. Finally, it has been shown that vaccination of the allogeneic donor against the patient's idiotypic protein can facilitate transfer of donor immunity to myeloma at the time of transplantation.³⁷

Studies of donor lymphocyte infusion (DLI) provide direct evidence of the existence of a GvM effect³⁸⁻⁴¹ (Table 85.2). The overall response rate to DLI in patients with myeloma approaches 45%, with complete responses noted in about 25% of patients. Durable complete responses are noted in half of the patients who obtain a complete remission, with follow-up over 7 years in some patients. Interestingly, extramedullary recurrence has been noted in some patients.⁴⁵

DLI in patients with myeloma is associated with a high incidence of GvHD. In one study of 13 patients treated with DLI, 66% developed evidence of acute GvHD and 56% chronic GvHD.³⁸ Quantitative PCR has been used to follow patients after DLI and demonstrates the close correlation between the onset of GvHD and GvM.⁴⁶ Strategies explored to reduce GvHD following DLI include the infusion of lower numbers of donor cells, infusion of selective donor cell populations such as CD4⁺ cells,^{40,47} or use of T cells transduced with thymidine kinase, which allows for systemic treatment of the recipient with ganciclovir in

the event that severe GvHD develops.⁴⁸⁻⁵⁰ Lokhorst and colleagues reported responses in some patients with doses as low as 1×10^7 CD3⁺ cells/kg.⁵¹

There is a strong association between GvHD and a GvM effect, and whether GvHD and GvM are distinct remains unclear. A review of DLI studies in patients with multiple myeloma reported that 18 of 22 patients who developed GvHD responded to the infusion, while only 2 of 7 patients who did not develop GvHD responded.⁴¹ A second study of 54 patients demonstrated an overall response rate of 52%, with 73% of patients who developed evidence of chronic GvHD responding to DLI.⁵² Responses to DLI have occurred in the absence of clinical GvHD, and several patients remain in durable remission without evidence of GvHD, suggesting that GvM may indeed be separable from GvHD in some patients. In an attempt to prevent relapse and to induce a GvM effect in the minimal disease setting, prophylactic DLI after myeloablative transplantation has been explored.

INDUCTION OF GvM AFTER MYELOABLATIVE TRANSPLANT

Improvement in outcome of myeloablative allogeneic transplantation requires reducing TRM and maximizing the GvM effect. One strategy involves combining a myeloablative T-cell-depleted transplantation with DLI in hopes of reducing the TRM associated with the transplant procedure while augmenting the GvM effect. Twenty-four patients at DFCI were enrolled in a trial combining a T-cell-depleted myeloablative transplant with prophylactic DLI, 6 months after transplantation.⁵³ Twenty-one patients received cyclophosphamide and TBI ablative therapy; busulfan and cyclophosphamide were used in those three patients in whom prior radiation precluded TBI. The bone marrow was purged of T cells with anti-CD6 monoclonal antibody as the sole means of GvHD prophylaxis. Despite the use of T-cell depletion, just over half of the 24 patients were eligible to receive DLI. Reasons for not receiving DLI included rapid relapse, transplant-related complications such as interstitial pneumonitis, and GvHD. Nine of the 11 patients who were eligible to receive DLI at 6 months demonstrated a response,

MRD, matched related donor; MMRD, mismatched related donor; URD: unrelated donor; TBI, total body irradiation; ATG, antithymocyte globulin

with 6 complete responses and 3 partial responses. Six patients developed acute GvHD after DLI, and four patients progressed to chronic GvHD. This approach demonstrates that a significant GvM effect can be induced by the administration of DLI after transplant; however, its effect on overall outcome will require further follow-up. Ultimately, identifying the T cells mediating GvM and their target antigens will allow DLI with antigen-specific T cells to both enhance efficacy and avoid toxicity.

NONMYELOABLATIVE STEM CELL TRANSPLANTATION FOR MYELOMA

Nonmyeloablative stem cell transplantation (NST) has been explored as an alternative to myeloablative transplantation for patients with myeloma. A variety of conditioning regimens and GvHD prophylactic regimens have been employed⁵⁴⁻⁵⁸ (Table 85.3). Several of these studies have combined an autologous transplant procedure with a nonmyeloablative transplantation in order to achieve better disease control and greater host immune suppression prior to proceeding to nonmyeloablative transplantation. Overall, these studies report TRM at 100 days ranging from 0 to 19% and event-free survival rates at 2 years ranging from 19 to 55%. While initial results are encouraging, data are not yet available on the durability of these responses. Early attempts to reduce GvHD complications after nonmyeloablative transplantation using a T-cell depletion followed by DLI approach have not been encouraging.⁵⁹

Prognostic features associated with an improved outcome after nonmyeloablative transplantation include chemotherapy-sensitive disease, good performance status, complete remission after transplantation, and evidence of chronic GvHD.⁶⁰ Patients with deletions of 13q were at increased risk of relapse after NST, compared with patients without this abnormality.⁶¹ These

results demonstrate that induction of the GvM effect may lead to significant remissions in patients with myeloma. Identifying the targets of the GvM reaction may help make this therapy more efficacious and specific.

TARGETS OF GvM EFFECT

Several potential targets of the GvM effect have been proposed (Table 85.4). Previous studies have focused on targeting the immunoglobulin idiotype (Id) as a tumor antigen in myeloma, an approach that has also been used in B-cell non-Hodgkin's lymphoma.^{66,67} Investigators have generated specific anti-Id T-cell responses in patients with myeloma after high-dose chemotherapy or autologous transplantation. Demonstrating that this approach can be adoptively transferred, immunization of the donor against the patient's Id protein has resulted in the development of Id-specific T-cell responses in recipients after allogeneic transplantation.³⁷ Studies are attempting to use this strategy in nonmyeloablative transplantation as well.

Table 85.4 Potential target antigens of the graft-versus-myeloma effect

Potential targets	References	
Targets identified by T cells	Idiotype	37
	MUC-1	62
	MAGE family	63
	hTERT	64
	Targets identified by SEREX	BCMA
ROCK-1		
KIAA0053		
HOMER 3B		

Other candidates targeted by T cells include MUC-1 and members of the MAGE family of genes. MUC-1 is an immunogenic epithelial mucin present in several solid tumors and has also been identified on malignant plasma cells.^{62,68} MUC-1-specific cytotoxic T-cell lymphocytes have been isolated in the bone marrow of patients with myeloma.^{62,69} Vaccination trials in myeloma are underway, targeting the MUC-1 antigen.^{70,71} Genes of the MAGE family are expressed in myeloma and anti-MAGE CTL clones are identified and were able to kill myeloma cell lines in vitro.⁶³

Distinct populations of T cells may mediate GvHD and GvM. Specifically, clonal populations of T cells emerged in three of four patients after CD4⁺ DLI.⁷² The clones that were detected early after DLI correlated with GvM effect, while those clones appearing later were associated with the onset of GvHD. Interestingly, clones associated with GvM were often detectable prior to DLI and expanded up to 10-fold after DLI. In contrast, clones associated with GvHD were undetectable prior to DLI. These findings suggest that DLI may mediate GvM via an indirect effect on preexisting T-cell populations, while GvHD post-DLI is mediated by new T-cell populations that develop after DLI.

While much attention has focused on T cells, evidence is emerging that B cells and humoral immunity may also play an important role in the GvM effect. Animal studies have emphasized the importance of interactions between humoral responses and T-cell responses, both CD4⁺ and CD8⁺.^{73,74} Using SEREX, a technique in which the patient's serum is used to screen recombinant cDNA expression libraries, a large number of serologically defined tumor-associated antigens have been identified.⁷⁵⁻⁷⁸ Ten gene products have been identified in myeloma patients responding to CD4⁺ DLI using this tool.⁶⁵ Two of the genes identified were also weakly recognized in a patient with chronic GvHD, perhaps suggesting a link between GvM and chronic GvHD. Two antigens identified, BCMA and ROCK-1, are highly expressed in primary myeloma cells as well as in myeloma cell lines, and further characterization of these myeloma antigens is being pursued to determine if they may serve as rational therapeutic targets.

FUTURE DIRECTIONS

ADOPTIVE IMMUNOTHERAPY

Data demonstrate that DLI mediates a significant GvM effect, and this offers the potential to effectively and selectively treat MRD after transplantation.^{38,40} Defining the role and timing of DLI after nonmyeloablative transplantation is currently underway. Efforts to identify the mediators of GvM and their target antigens are in progress, and hopefully it will be possible to expand antigen-specific DLI ex vivo to treat patients while at the same time reducing the complications related to GvHD.

Strategies are also available for increasing the antigen-presenting capacity of myeloma cells and their ability to stimulate donor T cells targeting myeloma. CD40 activation of myeloma cells upregulates Class I and Class II HLA and costimulatory molecules,⁷⁹ and CD40-activated myeloma cells trigger a brisk allogeneic, as well as autologous, T-cell response.^{80,81} In preclinical studies, histocompatible donor cells can be expanded ex vivo using CD40-activated patient myeloma cells as stimuli.

Another strategy for ex vivo expansion of T cells for adoptive immunotherapy is directed toward a novel, widely expressed tumor antigen derived from the telomerase catalytic subunit (hTERT).⁶⁴ hTERT is a ribonucleoprotein expressed in high levels in more than 85% of human cancers, including multiple myeloma, but is expressed in few normal tissues. In preliminary studies using donor cells, this expansion strategy has been used to generate MHC Class I restricted CTL that are specific for an hTERT peptide and kill hTERT-bearing myeloma cells. These studies will establish the conditions for testing the efficacy and safety of allogeneic, as well as autologous, hTERT CTL immunotherapy, and may provide the framework for a subsequent clinical treatment protocol in myeloma.

VACCINATION

Vaccination is another promising area for inducing antimyeloma immunity. T-cell recognition of myeloma is suggested by the restricted usage of V α and V β segments in the peripheral blood⁸²; the presence of activated Id-reactive CD8⁺ cells⁸³ as well as CD4⁺ cells⁸⁴; the growth of T-cell clones by stimulation with IL-2 and F(ab')₂ fragments derived from autologous Id⁸⁵; as well as the production of cytokines such as interferon γ (IFN- γ), interleukin 2 (IL-2), and IL-4 after stimulation with autologous Id.^{86,87} The Id-reactive population includes T cells that are not MHC restricted and that recognize conformational epitopes on Ig, as well as CD4⁺ and CD8⁺ cells, which recognize Id-derived peptides in association with MHC Class I and Class II molecules.⁸⁸ The Id-reactive T-cell expansion has been correlated with tumor load,^{83,87} and a shift from type I to type II T-cell response has been correlated with disease progression.⁸⁵ It has been shown that vaccination with Id^{67,89} or the use of Id-pulsed dendritic cells⁹⁰ can trigger Id-specific humoral and T-cell response in some patients with myeloma, even after high-dose therapy and autologous transplantation.

As discussed previously, it is possible to vaccinate the donor against the patient's idiotype protein prior to transplant and transfer specific donor immunity at the time of allografting.^{37,91} This strategy is under active investigation, coupling donor immunization pretransplant with patient vaccination following transplantation to boost antitumor immunity. Activated tumor cells, such as CD40-activated myeloma cells, or

possibly tumor-associated antigens, such as MUC-1, or BMCA, may be used to vaccinate donors prior to transplantation.

CONCLUSIONS

Allogeneic transplantation in patients with multiple myeloma can achieve high response rates, and long-term remission in some patients. Unfortunately, the toxicity associated with myeloablative transplantation has limited the success of this approach. The recogni-

tion of the existence of the GvM myeloma effect has renewed interest in allogeneic transplantation in patients with myeloma, now using a nonmyeloablative approach in hopes of reducing toxicity related to the transplant procedure. DLI remains an effective method for inducing a GvM effect, and the role of DLI after nonmyeloablative transplant is being defined. Efforts to identify the targets, mechanism of action of the GvM effect, as well as methods to enhance the GvM effect are underway. Identification of targets and an understanding of the mechanism of action may lead to more specific allogeneic immune therapies in the future.

Chapter 86

DEFINITION OF REMISSION, PROGNOSIS, AND FOLLOW-UP

S. Vincent Rajkumar and Angela Dispenzieri

INTRODUCTION

Multiple myeloma is typically incurable, with a median survival of 3–4 years.^{1–3} Conventional chemotherapy with melphalan and prednisone (MP) produces a response rate of approximately 50%, with complete responses (CRs) in less than 10% of patients.⁴ Combination chemotherapy with additional cytotoxic agents improves response rates (60–70%), but without significant survival benefit compared to MP.^{4–6}

The careful evaluation of the efficacy of the various therapeutic options and their impact on patient outcome has implications for both practice and research. In this chapter, we review the current criteria for evaluating response to therapy in myeloma, summarize established and novel prognostic factors for the disease, and briefly outline the recommended follow-up for patients.

DEFINITION OF REMISSION (RESPONSE) CRITERIA

Strict remission (response) criteria are required to monitor effectiveness of therapy in patients and to evaluate new drugs and interventions. Response criteria are also required to compare various therapeutic alternatives, both in clinical practice and in prospective trials. In some, but not all instances, response to therapy also serves as a marker for a good clinical outcome. In addition to response rates, other estimates of successful therapy in myeloma include measurements such as progression-free (PFS) and overall survival (OS).

BASIC PRINCIPLES

The goals of assessing response differ between clinical practice and clinical trials. In practice, clinicians use various parameters to make an informed judgment about whether a given therapy is effective in a patient with myeloma, and to adjust therapy as needed. This includes assessment of M-protein levels on the basis of published response criteria, as well as other clinical variables. There is room for discretion when certain

results are not available or are deemed clinically unnecessary. In clinical trials, however, there is a need to adhere to strict criteria to ensure that reported results are reliable and reproducible, as well as to ensure that results can be compared across clinical trials.

Several well-established response and survival criteria have been developed for myeloma over the years, primarily for use in clinical trials, though they have also been used to guide clinical practice. These criteria define various categories of response. They also define progressive disease, which is important in calculating PFS and event-free survival (EFS). The four most commonly used response criteria are those of the Chronic Leukemia-Myeloma Task Force,⁷ Southwest Oncology Group (SWOG),^{8,9} Eastern Cooperative Oncology Group (ECOG),¹⁰ and the European Group for Blood and Bone Marrow Transplant/International Bone Marrow Transplant Registry/American Bone Marrow Transplant Registry (EBMT/IBMTR/ABMTR).¹¹ Recently the International Myeloma Working Group has published uniform response criteria.^{11a}

CRITERIA FOR RESPONSE AND PROGRESSION

Serum and urine M-protein levels should be determined by electrophoresis rather than by quantitative immunoglobulin measurement. Exceptions are made in cases in which the M-protein value may be unreliable. In these cases, quantitative immunoglobulins should be used. To assess response and progression, however, serum protein electrophoresis (SPEP) values should be compared only to SPEP values and quantitative immunoglobulin values only to quantitative immunoglobulin values.

The international uniform response criteria^{11a} are the standard criteria for clinical trials and have been adopted recently by cooperative groups such as ECOG. These criteria partially take into account hemoglobin, calcium, bone changes, and bone marrow plasmacytosis for assessment of response, but rely heavily on measurement of serum and urine M protein.

For clinical trial purposes certain arbitrary levels of serum and urine M-protein values are considered

“measurable,” to ensure that a decrease in the M protein meeting requirements for response would be of sufficient magnitude to not be considered a laboratory variation. A “measurable” serum M protein is typically defined as ≥ 1 g/dL and a “measurable” urine M spike is defined as ≥ 200 mg/24 h. Responses cannot be reliably ascertained using M-protein measurements if the baseline values are below the “measurable” threshold.

Standard definition of response and progression

By definition, the criteria require that M-protein reductions be confirmed by consecutive determinations. Responding patients should also have no evidence of progressive disease.

Bone marrow biopsies are not required to confirm PR or MR, but are required for the definition of CR and to evaluate response in patients with nonsecretory myeloma. Skeletal radiographs are not required to confirm response, but should not show evidence of progression if performed. A summary of the criteria listed below is provided in Table 86.1.

Complete response Patients who have complete disappearance of M protein (negative immunofixation on the serum and urine) and 5% or fewer bone marrow plasmacytosis are considered to have achieved a CR. In addition, any soft-tissue plasmacytomas should disappear, and there should be no known increase in the size or number of lytic bone lesions. Patients meeting criteria for CR who have no clonal cells in the bone marrow and have a normal free light chain ratio are categorized as “stringent CR.”

Very good partial response The VGPR category is a useful measure of response that has gained clinical signifi-

cance, as patients who achieve at least a VGPR with the first autologous stem cell transplant do not benefit from a second (tandem) transplant. For practical purposes, it distinguishes patients who have had near disappearance in their M spike but are still immunofixation positive from those who merely have a 50% reduction in their serum M spike. To be considered VGPR, patients must meet all of the following criteria:

- greater than or equal to 90% reduction of M protein from serum (also includes achievement of a detectable but not quantifiable monoclonal protein by SPEP or by immunofixation only);
- urine M spike to be ≤ 100 mg/24 h (also includes achievement of a detectable but not quantifiable monoclonal protein by urine protein electrophoresis or by immunofixation only);
- no increase in size or number of lytic bone lesions.

Partial response To be considered a PR, patients should have a $\geq 50\%$ reduction in the level of the serum monoclonal protein and a reduction in 24-h urinary light-chain excretion either by $\geq 90\%$ or to < 200 mg/24 h. If present at baseline, there should also be a $\geq 50\%$ reduction in the size of any soft-tissue plasmacytomas (by radiography or clinical examination), and there should be no increase in the number or size of lytic bone lesions. (Development of a compression fracture does not exclude response.) FLC criteria are used in patients without measurable disease.

In patients with nonsecretory myeloma, a $\geq 50\%$ reduction in plasma cells in a bone marrow aspirate and on trephine biopsy must be documented in place of the M-protein and FLC requirements provided baseline bone marrow plasma cell percentage is 30% or

Table 86.1 Response criteria for myeloma

Response category ^a	Monoclonal protein/plasmacytoma	Bone marrow
Complete response (CR)	<ul style="list-style-type: none"> ■ Negative immunofixation on the serum and urine and ■ Disappearance of any soft-tissue plasmacytomas 	$\leq 5\%$ plasma cells
Very good partial response ^b	<ul style="list-style-type: none"> ■ $\geq 90\%$ reduction of serum M protein and ■ Serum and urine M protein detectable on immunofixation but not on electrophoresis, or ■ Urine M protein < 100 mg/24 h and ■ Disappearance of any soft-tissue plasmacytomas 	
Partial response	<ul style="list-style-type: none"> ■ $\geq 50\%$ reduction of serum M protein and ■ Reduction in 24-h urinary M protein by $\geq 90\%$ or to < 200 mg/24 h ■ If present at baseline, a $\geq 50\%$ reduction in size of soft-tissue plasmacytomas ■ If serum and urine M protein unmeasurable, a $\geq 50\%$ decrease in the difference between involved and uninvolved free light-chain (FLC) levels is required in place of the M-protein criteria^b 	Not a response requirement except in nonsecretory myeloma where a $\geq 50\%$ reduction in plasma cells is required in place of M protein

^aThe criteria for response require M-protein reductions to be confirmed by consecutive determinations and that there be no known increase in the size or number of lytic bone lesions on skeletal imaging.

^bShould not be used to assess response if serum and/or urine M protein are measurable. Baseline involved FLC level must be 10 mg/dL (100 mg/L) or higher and serum FLC ratio must be abnormal for FLC criteria to be used to assess response.

higher. At Mayo Clinic, these bone marrow criteria are also used for patients in whom neither the serum nor the urine M-protein levels are “measurable” at baseline, i.e., patients with oligosecretory myeloma.

Stable disease Failure to meet response criteria for CR, VGPR, PR, or progressive disease is considered as stable disease.

Relapse from CR Patients in CR are considered to have “relapse from CR” if there is reappearance of serum or urine M protein by immunofixation or electrophoresis, development of $\geq 5\%$ plasma cells in the bone marrow, or appearance of any other sign of progression (i.e., new plasmacytoma, lytic bone lesion, or hypercalcemia). Relapse from CR is used only to calculate disease free survival (DFS).

Progressive disease Progressive disease for patients not in CR is defined by the presence of one or more of the following features, and is used to calculate time to progression (TTP) and progression free survival (PFS):

- increase in serum M protein to $>25\%$ above the lowest response level, which must also be an absolute increase of at least 0.5 g/dL;
- increase in 24-h urine M protein to $>25\%$ above the lowest remission value, which must also be an absolute increase of at least 200 mg/24 h of urine M protein;
- increase in bone marrow plasmacytosis by $>25\%$ above the lowest remission value, which must also be an absolute increase of at least 10% bone marrow plasma cells;
- development of new soft-tissue plasmacytomas or bone lesions. Compression fracture does not exclude continued response and may not indicate progression;
- definite increase in size of existing plasmacytomas or bone lesions. At Mayo Clinic, a definite increase is defined as a 50% (and at least 1 cm) increase as measured serially by the sum of the products of the cross diameters of the measurable lesion; and
- development of hypercalcemia as defined by serum calcium >11.5 mg/dL (not attributable to any other cause);
- progression based on FLC criteria (see below).

The Bladé criteria require that M-protein levels for relapse from CR and progression listed above be confirmed by at least one repeat investigation.

Definitions for response using the free light-chain assay

The serum free light-chain (FLC) assay is of particular use in monitoring response to therapy in patients who have oligosecretory or nonsecretory myeloma, in whom serial bone marrow biopsies are often impractical and cumbersome.

The test is highly sensitive and consists of two separate assays: one to detect free kappa (normal range 0.33–1.94 mg/dL) and the other to detect free lambda (normal range 0.57–2.63 mg/dL) light chains.¹² In addition to measuring the levels of free-light chain, the test also allows assessment of clonality based on the ratio of kappa/lambda light-chain levels (normal reference range 0.26–1.65).¹³ Patients with a kappa/lambda FLC ratio <0.26 are typically defined as having monoclonal lambda FLC, and those with ratios >1.65 are defined as having a monoclonal kappa FLC. The monoclonal light-chain isotype is referred to as the “involved” FLC isotype, and the opposite light-chain type is the “uninvolved” FLC type. Thus, a patient with a ratio of >1.65 on the FLC ratio has a monoclonal kappa FLC isotype, where the kappa is the “involved” FLC and the lambda is the “uninvolved” FLC.

When using the FLC assay, the FLC levels vary considerably with changes in renal function and do not solely represent monoclonal elevations. Thus, both the level of the involved and the uninvolved FLC isotype (i.e., the involved/uninvolved ratio or involved/uninvolved difference) should be considered in assessing response. The criteria listed below take this factor into account.

Until further validation, the serum FLC assay criteria should be used in assessing response and progression only if the baseline serum and/or urine M proteins are not “measurable” by the traditional criteria discussed earlier. In addition, the baseline level of the involved FLC should be at least ≥ 10 mg/dL and the FLC assay should have an abnormal ratio (clonal).

Complete response To be considered a CR, normalization of the FLC ratio and negative serum and urine immunofixation are required. In addition, patients should meet other nonparaprotein requirements for CR.

Partial response To be considered a PR, a 50% decrease in the difference between involved and uninvolved FLC levels, is required in place of the M-protein criteria. Other requirements of PR must also be met.

Progressive disease The following change qualifies as progression:

- a 50% increase in the difference between involved and uninvolved FLC levels from the lowest response level, which must also be an absolute increase of at least 10 mg/dL.

ESTIMATES OF SURVIVAL

Several estimates of survival have been developed to assess the efficacy of therapy and to describe prognosis in clinical cancer research. These include OS, disease-free survival (DFS), PFS, and EFS. OS is the gold standard for comparing therapeutic strategies, but has limitations because even in randomized trials patients often cross over to treatment offered in the opposing arm when discontinuing assigned therapy.

PFS, usually defined as time from start of therapy to disease progression or death,¹⁴ can serve as a surrogate for OS. EFS, which is the duration from start of therapy to predefined events such as disease progression or relapse, death, or serious toxicity, can also be used as an important endpoint. When EFS is defined from start of therapy to death from any cause or progression (whichever occurs earlier),^{15,16} it is the same as PFS. On the other hand, time to progression (TTP)¹⁷ is usually measured from start of therapy to disease progression, with deaths due to causes other than progression not counted as an event, but censored at that time point.

Response duration, which is measured only in responding patients, also provides an estimate of drug efficacy. In myeloma, often only a subset of patients respond to a specific drug, and although TTP or PFS for the entire cohort may appear small, the benefit in responders may be substantial.^{17,18}

DFS applies only to patients achieving a CR, and refers to the duration from onset of CR to first evidence of relapse. Since it applies to only a small subset of patients with myeloma, it is probably not a good endpoint in this disease.

COMPARING RESPONSE RATES AND SURVIVAL

A comparison of response and survival between patients receiving different therapeutic strategies can be reliably made only in the context of a randomized (phase III) trial. As a general rule, response rates and estimates of survival should not be compared between trials, e.g., comparing two separate phase II (nonrandomized, single-arm) trials, except as a hypothesis generating exercise, even if the same response and survival criteria are used in the trials being compared.

PROGNOSTIC FACTORS

There is significant variation in survival of patients with myeloma; though median survival is 3 years,¹ some patients can live longer than 7–10 years.^{19–22} Several prognostic factors that identify groups of patients with significantly different survival probabilities have been identified, and have become indispensable for patient care and counseling (Table 86.2). These factors are also increasingly used for risk stratification in clinical trials to ensure that treatment arms are truly comparable.

Age, stage, hemoglobin concentration, creatinine, calcium, albumin, immunoglobulin class subtype, and extent of bone marrow involvement are all significant predictors of survival.^{23–25} However, they add minimal additional prognostic value, once the major independent prognostic factors are known.^{26,27} These include serum β_2 -microglobulin (β_2 M), bone marrow plasma cell labeling index (PCLI), karyotypic chromosome 13 deletion or hypodiploidy, plasmablastic morphology, lactate dehydrogenase (LDH), and C-reactive protein (CRP).^{24,28}

Table 86.2 Prognostic factors in myeloma

Clinically useful, major prognostic factors

Performance status
 Stage (by the ISS staging system)
 Cytogenetic studies (conventional cytogenetics and/or interphase FISH)
 ■ Deletion 13
 ■ Hypodiploidy
 ■ t(4;14), t(14;16), or deletion 17p
 Lactate dehydrogenase
 Plasmablastic morphology
 Plasma cell labeling index (limited availability)
 Circulating plasma cells (limited availability)

Biologically relevant prognostic factors, with limited clinical utility

Microvessel density
 Ras and p53 mutations
 Immunophenotyping
 Serum IL-6 and soluble IL-6 Receptors

STANDARD CLINICAL AND LABORATORY FACTORS

Age

As expected, age has an influence on the outcome of patients with myeloma.^{26,27} In particular, patients younger than 40 years of age have a median survival that exceeds 50 months.²⁹ In a recent cohort study, OS was 41 months in patients less than 70 years of age, compared to 26 months in older patients.¹ However, age does not seem to add major prognostic information once the β_2 M and PCLI are known.²⁷ Age also does not appear to be a significant variable for predicting survival after autotransplantation for myeloma, though age restrictions in the larger randomized transplant trials have been to 60 or 65 years.^{15,16} Retrospective analyses of subsets of older patients transplanted at other large transplant centers suggest that a specific age limit need not be imposed in selecting patients for autologous stem cell transplantation.³⁰

Performance status

Performance status is probably the single most powerful predictor of outcome in myeloma, but its value has not been highlighted in the literature. Kyle and colleagues reported on a study of 1027 consecutive patients with newly diagnosed myeloma seen at the Mayo Clinic, in which performance status of 3–4 (using the ECOG scoring system) had a more adverse impact on outcome than any other single variable including PCLI and β_2 M.¹ One of the reasons performance status is not on the list of many studies evaluating prognosis is that most of these studies use cohorts of patients from clinical trials. Most clinical trials automatically exclude those with performance status 3–4 from participating. In contrast, the study by Kyle et al. included all patients with myeloma seen at the Mayo Clinic between 1985 and 1998, not just patients enrolling in clinical trials. The relative risk of a performance status of 3–4 was 1.9 [95% confidence

interval (CI) 1.6–2.4], compared to 1.5 for PCLI (95% CI 1.3–1.7) and $\beta_2\text{M}$ (95% CI 1.3–1.8). In that study, which predated the era of new active agents against myeloma, patients with good performance status had a median survival of 36 months, compared to 11 months for those with performance status of 3–4.

Stage

Since 1975, the Durie–Salmon staging system (Table 86.3) has been used to stage multiple myeloma. The median survival is about 5 years for those with stage IA disease and 15 months for those with stage IIIB disease using this system. The Durie–Salmon staging essentially measures tumor burden and is limited in the categorization of bone lesions.^{24,31} Some studies have also failed to confirm the prognostic value of the Durie–Salmon stage.^{26,31} The Durie–Salmon staging largely loses prognostic value once the PCLI and $\beta_2\text{M}$ are known.²⁷

Table 86.3 Durie–Salmon staging for multiple myeloma

Stage I
All of the following:
Hemoglobin >10 g/dL Serum calcium <12 mg/dL
On radiograph, normal bone structure or solitary bone plasmacytoma only
Low M-component production rates
IgG <5 g/dL
IgA <3 g/dL
Urine light-chain M-component on electrophoresis <4 g/24 h
Stage II
Fitting neither Stage I nor III
Stage III
One or more of the following:
Hemoglobin <8.5 g/dL
Serum calcium >12 mg/dL
Advanced lytic bone lesions
High M-component rates
IgG >7 g/dL
IgA >5 g/dL
Urine light-chain M-component on electrophoresis >12 g/24 h
Subclassification
A: Serum creatinine <2 mg/dL
B: Serum creatinine \geq 2 mg/dL

Modified from Durie BG, Salmon SE: A clinical staging system for multiple myeloma. Correlation of measured myeloma cell mass with presenting clinical features, response to treatment, and survival. *Cancer* 36:842–854, 1975; with permission of John Wiley & Sons, Inc.

Table 86.4 International staging system for multiple myeloma

Stage	Median survival (months)
Stage I $\beta_2\text{M}$ <3.5 and albumin \geq 3.5	62
Stage II Not meeting criteria for Stage I or III	44
Stage III $\beta_2\text{M}$ >5.5	29

Adapted from Greipp PR, San Miguel JF, Durie BG, et al.: A new International staging system (ISS) for multiple myeloma (MM) from the International Myeloma Working Group. *J Clin Oncol* 23(15): 3412–3420, 2005; with permission of the American Society of Clinical Oncology.

Recently, Greipp et al. have developed a new staging for myeloma built with international consensus as a replacement to the Durie–Salmon staging. The new International Staging System (ISS) was a collaborative effort by investigators from 17 institutions worldwide and involved data from 11,171 patients. It overcomes some of the drawbacks of the Durie–Salmon staging and is extremely simple to use. The ISS divides patients into three distinct stages and prognostic groups based solely on the $\beta_2\text{M}$ and albumin levels in the serum (Table 86.4).

C-reactive protein

The CRP is an acute-phase reactant. It is produced by hepatic cells in response to interleukin 6 (IL-6). The serum CRP is a widely available, inexpensive assay, and has been proposed as a surrogate for measurement of IL-6 levels.

Several studies have shown that the CRP has prognostic value in myeloma.^{32,33} However, Mayo Clinic and ECOG studies have failed to confirm the value of CRP as an independent prognostic factor.^{26,27}

Other miscellaneous clinical and laboratory parameters

Several readily available clinical and laboratory parameters, such as hemoglobin concentration, creatinine, calcium, albumin, immunoglobulin class subtype, and extent of bone marrow involvement, are also predictors of survival.^{23–25,34} Some, such as hemoglobin, albumin, and creatinine, are already incorporated into staging systems. When independent factors are known, they do not add significant additional prognostic information.^{26,27}

MAJOR INDEPENDENT PROGNOSTIC FACTORS

Plasma cell labeling index and measures of plasma cell proliferation

PCLI is a measurement of the proliferative activity of the neoplastic plasma cells in myeloma.^{27,35} The assay is done on the bone marrow aspirate, using a

slide-based immunofluorescence method. The principle underlying the PCLI is that cells in the S phase of the cell cycle incorporate bromodeoxyuridine, which is then recognized by a specific monoclonal antibody (BU-1) directed against it.

Several studies have demonstrated the prognostic value of PCLI in myeloma. A high PCLI predicts both poor OS and PFS. On multivariate analysis, PCLI has consistently demonstrated independent prognostic value.^{33,36–42} Most investigators use a cutoff value of 1 or 2% to identify those with a poor prognosis. At the Mayo Clinic, a cutoff of 1% or higher has been defined as a high value. In one study, Greipp et al. found the median survival of patients with a PCLI $\geq 1\%$ to be 17 months, compared to 42 months in those with a PCLI $< 1\%$.²⁷ In another study, the median survival was 21 and 43 months in patients with a PCLI $< 2\%$ versus those with values $\geq 2\%$, respectively.⁴³

One of the limitations of the PCLI is that only a few laboratories in the United States are presently performing the test. To overcome this limitation, flow cytometric methods of estimating the proportion of plasma cells in S phase have been developed. San Miguel and colleagues analyzed the cell cycle distribution of plasma cells in 120 untreated multiple myeloma patients, using simultaneous CD38 and DNA staining.⁴⁴ A high percentage ($> 3\%$) of plasma cells in the S phase was an independent prognostic factor for poor survival.

β_2 -microglobulin

β_2 M is a small protein that forms the light chain of the human leukocyte antigen, and has a molecular weight of 11,800.⁴⁵ It is normally excreted by the kidney, and its serum concentration is elevated in renal failure. There is an excellent correlation between serum β_2 M levels and myeloma tumor burden in the absence of renal failure.⁴⁶

A high serum β_2 M level is an established predictor of poor survival in patients treated with conventional chemotherapy for myeloma.^{27,47,48} β_2 M is also an independent predictor of CR, OS, and EFS after transplantation for myeloma.^{22,49–51} As discussed earlier, it has been incorporated into the ISS, and hence does not need to be considered independent of the staging in the future.⁵² The utility of serial β_2 M is undefined, and it should not be used as a marker for evaluating disease course or response to therapy.

Cytogenetic abnormalities

Cytogenetic abnormalities are of major prognostic significance in acute leukemias and myelodysplastic syndromes. Among myeloma patients treated with standard-dose or high-dose chemotherapy, the presence of cytogenetic abnormalities has significant prognostic value.^{24,53,54} Cytogenetic abnormalities are usually complex (> 3 abnormalities) in myeloma.^{53,55} Approximately 20% of patients with newly diagnosed disease have abnormalities on conventional karyotypic analysis.⁵³ In contrast, the incidence of such abnormalities in relapsed

myeloma increases to 40% or higher.^{53,56–58} Recent studies show that cytogenetic abnormalities are present in most, if not all, patients with myeloma if sensitive interphase fluorescent in situ hybridization techniques (FISH) are used.^{59–61} The most common cytogenetic changes include deletion of chromosome 13 (30–55% of patients), deletion of 17p13.1 (10%), t(11;14)(q13;q32) (15–20%), t(4;14)(p16.3;q32) (15%), and t(14;16)(q32;q23) (5%).⁵⁴ The discrepancy is due to the low proliferative activity of neoplastic plasma cells and the resulting lack of metaphases, which are essential for karyotypic analysis but not for interphase FISH, which does not require dividing cells.^{54,62}

Several groups have reported on the prognostic value of cytogenetic abnormalities detected by karyotyping in myeloma.^{49,58,63} Tricot and colleagues studied 427 patients undergoing transplantation and found that patients with chromosomal abnormalities had a significantly worse outcome compared to those with normal cytogenetics: OS 29 months versus 55 months, and EFS 19 months versus 36 months, respectively. Similar results are seen in patients with relapsed and refractory myeloma as well.⁵⁸

There is a significant correlation between the presence of cytogenetic abnormalities and a high PCLI.^{55,64} Since the two variables are correlated, the PCLI may not add significant predictive value to a model that already contains cytogenetics, and vice versa. However, there are trends that suggest that the two variables may achieve independent prognostic significance if studies are done with a larger sample size.

Deletion of chromosome 13 Several studies show that deletion of chromosome 13 [Figure 86.1(a) and 86.1(b)] has a particularly adverse prognostic effect.^{21,22,65–67} The abnormality is monosomy for the chromosome in approximately 85% of cases, while in 15% it represents interstitial deletions involving mainly 13q14.^{68,69}

When present, the prognostic effect of deletion 13 detected by conventional karyotypic analysis is highly significant. In a study of 1000 patients with myeloma who received autologous stem cell transplantation, the 5-year survival rate was 16% in those with karyotypic deletion 13 (163 patients), compared to 44% in those without the abnormality (830 patients) ($P < 0.001$). Five-year EFS was 0% versus 28% ($P < 0.001$), respectively.²²

The adverse prognostic effect is also demonstrable (although to a slightly lesser extent) when deletion 13 is recognized using interphase FISH studies.^{70–73} In four different studies, median OS ranged from 15 to 35 months among patients with deletion 13 by interphase FISH, compared to 50–65 months in those without the abnormality.^{70,72–74} Importantly, in contrast to karyotypic deletion 13, which is detected in only 15% of patients, approximately 35–55% of patients have abnormalities that can be detected by interphase FISH.⁵⁴

Figure 86.1 FISH showing (a) normal plasma cell with two copies of chromosome 13 (two probes for each copy), and (b) plasma cell in myeloma with deletion of one copy of chromosome 13

The abnormality may also have therapeutic implications, since patients who demonstrate the presence of deletion 13 by karyotypic analysis appear to receive minimal benefit from single or tandem autologous stem cell transplantation.^{22,73} Unfortunately, nonmyeloablative transplantation does not appear to overcome the poor prognostic effect either.^{75,76}

Other cytogenetic changes The presence of t(4;14)(p16.3;q32), t(14;16)(q32q23), and 17p13, which are usually detected by molecular genetic studies such as interphase FISH or metaphase spectral karyotype imaging, are associated with a markedly adverse prognosis.^{71,77–79}

Plasmablastic morphology

Based on well-defined morphologic criteria, it is possible to identify a subgroup of patients with myeloma who have plasmablastic features on bone marrow examination.⁸⁰

Plasmablastic morphology is considered to be present (plasmablastic myeloma) when $\geq 2\%$ plasmablasts comprise the bone marrow plasma cell population.²⁶

Using the above criteria, a large study of 453 newly diagnosed patients by the ECOG demonstrated that plasmablastic morphology is a powerful, independent adverse prognostic factor for survival.²⁶ In this study, median OS was 1.9 years in patients with plasmablastic myeloma, compared to 3.7 years in those with nonplasmablastic morphology.

One limitation of using plasmablastic morphology as a prognostic factor is that the interpretation is subjective, and significant interobserver variation may be present.

Circulating plasma cells and peripheral blood labeling index

Circulating myeloma cells are difficult to find in routinely stained peripheral blood slides in most patients with myeloma. However, with the use of multiparameter

flow cytometry, or by using the slide-based immunofluorescence method (similar to that described for the PCLI), these cells can be easily detected and quantified (Figure 86.2).^{81–84} Witzig and colleagues have shown that the presence of large numbers of circulating plasma cells is associated with poor prognosis.⁸⁵ In a study of 254 patients with myeloma, OS was poorer among those with a high level of circulating peripheral blood plasma cells: median survival, 2.4 years (high levels) versus 4.4 years (low or undetectable levels), and $P < 0.001$.⁸⁵

Circulating plasma cells also predict for patients with smoldering multiple myeloma (SMM) that are likely to progress sooner to active disease.⁸³ In a study of 57 patients with SMM, the median TTP for patients with abnormal circulating plasma cells was 0.75 years, compared to 2.5 years for the rest ($P < 0.01$).

Although powerful prognostic factors, circulating plasma cells, and peripheral blood labeling index are limited by their availability. Flow cytometric methods to detect circulating plasma cells are being studied and can be readily incorporated into clinical practice once well validated.

Figure 86.2 Circulating plasma cells as seen on fluorescent microscopy after staining for cytoplasmic immunoglobulin light chains

Lactate dehydrogenase

LDH is a powerful, independent prognostic factor in myeloma.^{64,86,87} One limitation of the LDH is that only a small proportion of patients with myeloma (5–11%) have an elevated level.⁸⁸ Nevertheless, when elevated, it predicts for a markedly adverse prognosis.

OTHER PROGNOSTIC MARKERS WITH BIOLOGICAL IMPORTANCE

Numerous other prognostic factors have been identified, many of which are of major biological importance, as they shed light on the mechanisms of disease progression in myeloma. However, their impact on outcome is minimal once the major independent factors described above are known, thus limiting their clinical utility as prognostic tools.

Microvessel density

Studies in myeloma indicate that bone marrow angiogenesis is increased in myeloma (Figure 86.3).^{89–92} There is also evidence that bone marrow angiogenesis correlates with the proliferation of neoplastic plasma cells and may be important in disease progression and activity.^{89,90} Several studies now show that increased angiogenesis measured by microvessel density is a significant adverse prognostic factor in myeloma.^{93–96} In the ECOG study, OS was significantly longer in patients with low-grade angiogenesis (53 months), compared to those with high-grade (24 months) or intermediate-grade angiogenesis (48 months) ($P = 0.18$).⁹⁷

Interleukin 6

Although IL-6 is an important growth factor in the differentiation of normal B lymphocytes to plasma cells,^{98,99} it does not generally induce proliferation of normal B lymphocytes or plasma cells.¹⁰⁰ In contrast, IL-6 can induce a significant proliferative response in myeloma cells.⁹⁸ It appears to have both an autocrine and paracrine role in the growth and proliferation of

myeloma cells.^{98,101} The proliferative response of myeloma cells to IL-6 is a major factor that distinguishes malignant proliferating from normal nonproliferating plasma cells.¹⁰⁰

Serum IL-6 levels are elevated in about one-third of myeloma patients, and are more frequently elevated in plasma cell leukemia. IL-6 levels correlate with bone marrow plasmacytosis, serum LDH, β_2M , and calcium.^{102,103}

Soluble IL-6 receptors

The activity of IL-6 in myeloma appears to be modulated by the expression of soluble IL-6 receptors (sIL-6R).^{100,104,105} In the presence of IL-6, sIL-6R associates with glycoprotein 130 (gp130), and leads to signal transduction and augmentation of the IL-6 proliferation effect.¹⁰⁶ sIL-6R potentiates the proliferative effect of IL-6 on myeloma cells up to 10-fold.^{104,105}

An elevated sIL-6R level has independent poor prognostic value in myeloma.^{28,33} A multivariate analysis of 388 patients showed independent prognostic significance for a sIL-6R >300 .³³ The sIL-6R level did not correlate with PCLI or other prognostic variables. Adding sIL-6R to PCLI and β_2M allowed improved prognostic classification, doubling the proportion identified as high risk.

Immunophenotyping

Certain immunophenotypic features have been suggested to have prognostic value. CD20⁺ plasma cells in myeloma have been associated with a more aggressive course of disease.¹⁰⁷ Initial reports suggested that the presence or coexpression of CD10 or surface immunoglobulin may represent poor prognostic features in myeloma. However, the prognostic value of CD10 in myeloma is unclear, as others have reported conflicting results.^{107–109} Further, only 15% of myeloma cells are positive for CD10, limiting its role as a prognostic factor. The presence of surface immunoglobulin may be indicative of more immature plasma cell clone. It does not appear that any of these immunophenotypic characteristics of plasma cells have independent prognostic value in myeloma.

Oncogenes and tumor suppressor genes

Mutations in the *ras* oncogene have been noted in plasma cells of myeloma, more commonly in the advanced phase of the disease.^{110,111} Liu and colleagues examined the mutational status of the N- and K-*ras* genes in 160 newly diagnosed multiple myeloma patients enrolled on the ECOG phase III clinical trial E9486.¹¹² The incidence of *ras* mutations was 39%. Patients with K-*ras*, but not N-*ras*, mutations had a significantly shorter median survival, 2.0 years versus 3.7 years, $P < 0.02$.¹¹²

Mutations of the tumor suppressor gene p53 have also been studied. The incidence of p53 point mutations

Figure 86.3 Increased bone marrow microvessels in myeloma bone marrow as visualized by immunohistochemical staining for CD34

in myeloma in one study was 13%.¹¹³ Mutations were more common (43%) in the more advanced and clinically aggressive forms of the myeloma.

Alternative measures of plasma cell proliferation

Besides the PCLI and S-phase estimations, other methods are available to evaluate the proliferative activity of the plasma cells. Immunohistochemical staining of bone marrow using the Ki-67 antibody has been proposed as a surrogate marker for the PCLI, because it identifies plasma cells undergoing active cell division.¹¹⁴ The correlation between the results of this assay and disease activity is good, but comparisons suggest a wider variation of results and lack of correlation with the PCLI.¹¹⁵

Similarly, the use of the proliferating cell nuclear antigen (PCNA) monoclonal antibody has been proposed as a surrogate marker of cell proliferation.¹¹⁶ The results of PCNA correlate more closely with PCLI than with the Ki-67 assay.

T- and B-cell levels

Several studies have shown that baseline and posttreatment levels of T and B lymphocytes may be important to outcome in myeloma. San Miguel and colleagues demonstrated that loss of CD4⁺ T cells is associated with a worse prognosis in myeloma patients.¹¹⁷ Similarly, an elevated level of T cells with activation markers or plasma cell markers has been associated with an unfavorable outcome.¹¹⁸ Kay and colleagues showed that approximately 20% of patients with myeloma have increased levels of circulating CD19⁺ B cells.¹¹⁹ Low numbers of circulating CD19⁺ B-cell level (<125 μ L) were associated with more advanced disease (clinical stage III, $P = 0.033$). Survival was better in

patients with higher levels of circulating CD19 cells (≥ 125 μ L, $P < 0.0001$). CD19 was found to be an independent prognostic factor.

Recently, Kay and colleagues have confirmed the above findings in an ECOG phase III trial involving 504 newly diagnosed patients with myeloma treated with standard-dose chemotherapy.¹²⁰ Higher baseline levels of CD3(+), CD4(+), CD8(+), and CD19(+) cells were each associated with improved survival. Porrata and colleagues have demonstrated that early lymphocyte recovery is important for survival, postautologous transplantation in myeloma.¹²¹

Other novel factors

An association between high serum levels of the carboxy terminal of telopeptide of type I collagen (ICTP) and survival has been suggested in newly diagnosed myeloma patients.¹²² In one study, patients with high serum level of ICTP had poorer OS compared to those with low levels with a median survival of 3.5 years versus 4.1 years, respectively ($P = 0.001$).¹²³

Serum levels of thymidine kinase also have prognostic value in myeloma.¹²⁴ Thymidine kinase may identify a small subset of patients with a high PCLI. An elevated IL-2 level is associated with a better prognosis.¹²⁵

COMBINING INDEPENDENT PROGNOSTIC FACTORS TO PREDICT OUTCOME

A combination of independent prognostic factors provides greater prognostic information than any one prognostic factor alone. Table 86.5 provides two other models in which readily available prognostic factors have been combined to provide powerful prognostic information.

Table 86.5 Combining major prognostic factors to predict outcome in myeloma

Series	Prognostic factors	Combination	No. of patients	Overall survival (OS)	Event-free survival (EFS)
Facon et al. ⁷³	Deletion 13 by FISH	None high	110	Median not reached at 111 month	Median 37 months
	β_2 -microglobulin	One high Both high		Median 47 months Median 25 months	Median 27 months Median 15 months
Desikan et al. ²²	β_2 -microglobulin Karyotypic deletion 13	None abnormal Any 1–3 abnormal with exception of deletion 13	1000	62% at 5 years 20–52% at 5 years	41% at 5 years 12–34% at 5 years
	More than 12 months therapy prior to transplant	Deletion 13 present		5–35% at 5 years	0% at 5 years
	C-reactive protein	All 4 factors abnormal		5% at 5 years	0% at 5 years
Greipp et al. ¹²⁶	Plasma cell labeling index	None high	493	46% at 5 years	Not available
	β_2 -microglobulin	Either one high Both high		31% at 5 years 9% at 5 years	Not available Not available

FOLLOW-UP

The follow-up of patients with multiple myeloma is dependent on a number of factors, including phase of disease (early untreated vs relapsed refractory), the stage, presence or absence of ongoing therapy, mode of therapy, and comorbidity. Patients are typically evaluated every 4–6 weeks during active therapy, and every 3–4 months when in the plateau phase of disease on no therapy or only maintenance therapy. Patients with active treatment or disease-related complications may need more frequent monitoring.

The suggested clinical and laboratory evaluations to be performed at follow-up are given in Table 86.6. These are guidelines and need to be modified according to clinical need.

Acknowledgments

This work is supported by grants CA 107476, 62242, 100080, and 93842 from the National Cancer Institute, National Institutes of Health, Bethesda, MD.

Table 86.6 Standard tests for follow-up

Routine tests to be done at each follow-up

- Complete blood counts
- Serum chemistries (include serum creatinine, electrolytes, and calcium)
- Serum protein electrophoresis
- Urine protein electrophoresis

Every 6–12 months

- Skeletal survey

Based on clinical situation

- Serum and urine protein immunofixation (at baseline and to document complete response)
- Bone marrow biopsy (at baseline, as needed to clarify clinical state, and if needed to confirm Progression/response)
- β_2 -microglobulin, plasma cell labeling index, cytogenetics, circulating plasma cells, LDH, CRP (at base line, and as needed to clarify clinical state)

Chapter 87

TREATMENT OF RELAPSED OR REFRACTORY MULTIPLE MYELOMA AND NEW FRONTIERS IN MULTIPLE MYELOMA THERAPY

Manmeet Ahluwalia and Mohamad A. Hussein

INTRODUCTION

Despite several recent therapeutic advances, multiple myeloma (MM) remains incurable, and unfortunately most patients experience relapse after responding to initial therapies, including high-dose chemotherapy and stem cell transplantation (SCT). Long-term remissions are rare. With conventional chemotherapy, the 5-year median survival rate is approximately 25%, and approximately 10% of patients live longer than 10 years.¹ Multiple regulatory pathways involving cytokines, adhesion molecules, angiogenesis, and resistance mechanisms contribute to the development and progression of the disease. The complex pathophysiology of MM makes it difficult to manage the disease successfully. Over the past 5 years, remarkable improvement in the understanding of the disease biology has resulted in the development of targeted therapy interrupting single or multiple survival pathways for the disease. Newer agents have been developed that have provided hope for better management of relapsed and refractory MM. Further research is ongoing to target multiple pathways of the disease simultaneously for more efficient and durable treatment of the disease.

THE BIOLOGY OF MULTIPLE MYELOMA

The bone marrow microenvironment consists of extracellular matrix proteins, stromal cells, monoclonal myeloma cells, vascular endothelial cells, osteoblasts, osteoclasts, and lymphocytes. The interactions among the myeloma cells, stromal cells, adhesion molecules, cytokines, and the factors involved in angiogenesis play a key role in the pathogenesis of MM and in the refractoriness of the disease.

Multiple regulatory pathways are involved in the development and progression of MM. Interleukin 6 (IL-6) is an important cytokine in myeloma cell growth and proliferation.² Close cell-to-cell contact between myeloma cells and the bone marrow stromal cells triggers a large amount of IL-6 production that supports the growth of these cells and protects them from apoptosis induced by dexamethasone or other chemotherapeutic agents.³ In addition, IL-6 can enhance the effect of other osteoclastogenic factors, such as receptor activator of nuclear factor (RANK) ligand (RANKL), parathyroid-hormone-related peptide (PTHrP), macrophage inflammatory protein 1 α (MIP-1 α), IL-1, and tumor necrosis factor α (TNF α).

Nuclear factor kappa B (NF- κ B) is a protein that is believed to be central to the pathophysiology of MM. The Rel/NF- κ B family of proteins includes inducible dimeric transcription factors that recognize and bind a common sequence motif in nuclear DNA.⁴⁻⁷ NF- κ B, the major transcription factor in this family, is a p50/RelA heterodimer (p50/p65) present in the cytoplasm of almost all cells.^{7,8} NF- κ B regulates cell growth and apoptosis, as well as the expression of various cytokines, adhesion molecules, and their receptors.⁹ NF- κ B is normally bound in the cytoplasm to its inhibitor I- κ B.⁷ Stimulation of cells by cytokines, stress, or chemotherapy can trigger signaling cascades that lead to activation of I- κ B kinase (a heterodimeric protein kinase that catalyzes I- κ B phosphorylation). I- κ B is then degraded by the proteasome pathway, releasing free active NF- κ B. After release from I- κ B, activated NF- κ B translocates to the nucleus and binds to the promoter regions of several target genes, thereby triggering their transcription. This in turn leads to increased expression of various cytokines and chemokines, adhesion molecules, and cyclin D, which promote cell growth and survival.⁶ NF- κ B activation also leads to increased expression of

adhesion molecules, such as ICAM-1 and VCAM-1 by MM cells, thus facilitating the binding of the myeloma cells to stroma, in turn causing NF- κ B-mediated upregulation of IL-6 secretion by the stromal cells and contributing to drug resistance.^{10,11} Therefore, treatment strategies targeting NF- κ B, the malignant cell–stroma interaction, and the complex cytokine network could result in regulation of the growth and development of the MM cells.

DRUG RESISTANCE MECHANISMS

MM cells, unlike the cells of most other hematologic malignancies, are highly resistant to chemotherapy. The membrane cell survival proteins, Bcl-2 and Bcl-X_L, are overexpressed in most MM cells through interaction with the environment and are associated with inhibition of apoptosis. Upregulation of these antiapoptotic members of Bcl-2 contribute to the drug resistance seen in MM cells.^{12,13} In a study by Tu et al., Bcl-X_L overexpression in bone marrow biopsy samples strongly correlated with decreased patient response to melphalan, vincristine, doxorubicin, and dexamethasone.¹³ Response rates were 83–87% in non-Bcl-X_L-expressing patients, compared to 20–31% in Bcl-X_L-expressing patients.¹³

Drug resistance continues to pose considerable challenge to successful treatment of MM patients.¹⁴ Tumor cells develop resistance to cytotoxic agents due to several mechanisms, including those mediated by drug transporter proteins, such as P-glycoprotein (P-gp),¹⁵ increased activity of the transcription factor, NF- κ B,¹⁶ or lung-resistance-related protein (LRP; a major vault protein).¹⁷ Acquired drug resistance in MM cells usually manifests as a multidrug-resistant phenotype.^{15,18}

The expression of P-gp has not been shown to be elevated in patients who have not received any chemotherapy or who have been treated only with melphalan.¹⁹ P-gp expression may be elevated in approximately 75% of patients treated with vincristine, doxorubicin, and dexamethasone (VAD).^{19,20} The degree of P-gp expression in myeloma cells correlates with the cumulative dose of doxorubicin and vincristine given to the patient.

LRP is a major nuclear vault protein that blocks the transport of drugs from the cytoplasm to the nucleus by forming central plugs of the nuclear pore complexes. Its spectrum of cross-resistance is wide, covering not only the classical multi-drug resistance (MDR) phenotype, but also the platinol- and melphalan-resistant phenotypes.^{17,21} P-gp can be expressed in up to half of patients with MM, and is associated with a poor response to melphalan-based induction chemotherapy and shorter overall survival duration.²² The response rate was lower in patients expressing LRP (54%) compared to those lacking it (87%). Thus, LRP has been proposed as an important genetic marker for predicting poor therapeutic response and outcome.²² There is increased expression of LRP in patients with p53 deletion and P-gp. LRP and P-gp might share a similar regulatory mechanism

mediated by p53, and further research exploring the role of these genes is underway.²²

PROTEASOME INHIBITOR: BORTEZOMIB

Bortezomib (*N*-pyrazine carbonyl-L-phenylalanine-L-leucine boronic acid, previously known as PS-341 or MLN-341), a boronic acid dipeptide, is a specific inhibitor of the proteasome pathway.^{23,24} Bortezomib inhibits the proteasome pathway in a rapid and reversible manner by binding directly with the 20S proteasome complex and blocking its enzymatic activity. The proteasome pathway regulates the degradation of the NF- κ B inhibitor, I- κ B.^{25,26} Several effects of bortezomib, including the induction of apoptosis in the malignant plasma cell, appear to be mediated through inhibition of NF- κ B. Bortezomib prevents the degradation of I- κ B and thereby inhibits NF- κ B activation.⁵

In view of encouraging *in vitro* data, a phase I study using bortezomib was initiated in patients with refractory hematologic malignancies (MM, lymphoma) to determine the maximum tolerated dose (MTD), dose-limiting toxicity (DLT), and pharmacodynamics of the molecule.²⁷ Bortezomib was administered at doses ranging from 0.4 to 1.38 mg/m², twice weekly for 4 weeks, followed by a 2-week rest. DLTs, including grade III hyponatremia, fatigue and malaise, and hypokalemia, were observed at the highest dose levels (1.38 mg/m² and 1.20 mg/m²); 1.04 mg/m² was considered the MTD. Although grade IV events did occur, none was felt to be related to bortezomib. Evidence of antineoplastic activity was observed in patients with MM and non-Hodgkin's lymphoma. Of the nine evaluable patients with plasma cell dyscrasias, a complete response was observed in one patient, and the remaining eight showed evidence of decreased paraprotein levels or bone marrow plasmacytosis. In another phase I trial, DLTs were nonhematologic and included diarrhea and painful sensory neuropathy. Grade III sensory neuropathy was experienced by two of 12 patients treated at the highest dose level (1.56 mg/m²).²⁸ Based on the pre-clinical and phase I activity in MM, a phase II study (SUMMIT) was initiated in patients with relapsed and refractory MM.²⁴ The dose established for bortezomib in the treatment of relapsed/refractory myeloma was 1.3 mg/m² given twice weekly on days 1, 4, 8, and 11 every 21 days.²⁴ This schedule of at least 72 h between the dosages of bortezomib allows for the recovery of the inhibited proteasome, thus minimizing the incidence of significant and severe side effects. Dexamethasone (20 mg the day of and after each bortezomib dose) was permitted if progressive disease was observed after two cycles, or in the presence of stable disease after four cycles. A total of 202 heavily pretreated patients were enrolled. Of the 202 patients entered, 193 were evaluable for response. The overall response rate [complete remission (CR) + partial response (PR) + minimal response (MR)] was 35% (67 of

193 patients). Seven patients (4%) had a CR, and 12 (6%) had a near-CR (NCR) (myeloma protein undetectable by electrophoresis but immunofixation positive). An additional 34 patients (18%) achieved a PR, and 14 (7%) others an MR.²⁴ The median time to disease progression for bortezomib as a single agent was 7 months, compared with 3 months that was reported for the patients' previous therapy ($P = 0.01$). In a landmark analysis, patients who achieved a CR or PR by the end of the second cycle survived significantly longer than those achieving other types of responses. Additional clinical benefits observed in these patients included increases in hemoglobin levels and platelet counts, resulting in a reduction in transfusion requirements. Moreover, levels of unaffected immunoglobulins improved. The factors that predicted poor response to bortezomib were older age (≥ 65 years) and $\geq 50\%$ plasma cells in the bone marrow. In this bortezomib trial, serum β_2 -microglobulin level, number or type of previous therapies, and chromosomal abnormalities, including chromosome 13 deletions, did not predict for poor response. This observation might be important for future development of bortezomib therapy in combination with other agents or strategies, especially in patients with poor prognosticators.^{24,29,30}

Drug-related adverse events of any grade occurring in $>25\%$ of patients included nausea (55%), diarrhea (44%), fatigue (41%), thrombocytopenia (40%), peripheral neuropathy (31%), vomiting (27%), and anorexia (25%). The most common grade III adverse events included thrombocytopenia (28%), fatigue (12%), peripheral neuropathy (12%), and neutropenia (11%). The most common grade IV events included thrombocytopenia (3%) and neutropenia (3%). Peripheral neuropathy was more likely to occur in patients who suffered from neuropathy at baseline (80%). Among the 33 patients who did not have evidence of peripheral neuropathy on study entrance, 17 developed peripheral neuropathy during the course of therapy. Most of the adverse events reported during the trial were manageable with standard supportive symptomatic therapy.

Bortezomib is an active agent in the management of relapsed/refractory MM, with responses occurring relatively quickly (within 6 weeks of the initiation of therapy). In view of its ability to sensitize myeloma cells to other biologics and chemotherapeutic agents,^{22,31,32} further development using the agent in combination with other agents at low dosages is in progress. A maintenance strategy is being investigated as part of the phase III, APEX (Assessment of Proteasome Inhibition for Extending Remissions) trial. Studies defining the dose and the frequency are urgently needed to maximize the benefits of this drug's mechanisms of action.

THALIDOMIDE

Thalidomide is unique in that it is the only anticancer agent in the treatment of MM that maintains the same

high response rate in newly diagnosed as well as in the relapsed and refractory MM patients.^{33,34} Thalidomide, also known as alpha-(N-phthalimido) glutarimide, consists of a two-ringed structure with an asymmetric carbon in the glutarimide ring that exists as an equal mixture of S- (-) and R- (+) enantiomers that interconvert rapidly under physiologic conditions. This makes attempts at isolation of the dextro form, in an effort to eliminate teratogenicity, unsuccessful. As it is sparingly soluble in water and ethanol, there is no intravenous formulation.³⁵ Thalidomide undergoes rapid pH-dependent hydrolysis in aqueous solution. Mean terminal half-lives for a 200-mg dose range from 4 to 9 h, whereas higher doses of 800 mg have a substantially longer terminal half-life of approximately 8 h.³⁶ Pharmacokinetics in renal and hepatic dysfunction is not well established; in patients with renal failure secondary to MM, however, similar dose levels to those for patients with non-impaired renal function are used.

Thalidomide inhibits angiogenesis and induces apoptosis of established neovasculature in experimental models.^{37,38} The bone marrows of MM patients show prominent vascularization, which correlates positively with high plasma cell labeling index disease activity and independently confers a poor prognosis.³⁹⁻⁴² Moreover, the plasma levels of various angiogenic cytokines, such as basic fibroblast growth factor and vascular endothelial growth factor (VEGF), are elevated in patients with active myeloma.⁴⁰⁻⁴²

The first study of thalidomide in MM by Singhal et al.⁴³ consisted of 84 previously treated patients with refractory myeloma, 76 of whom had relapsed after high-dose chemotherapy. Oral thalidomide was administered as a single agent for a median of 80 days (range 2-465). The starting dose was 200 mg daily, and this was increased by 200 mg every 2 weeks to a maximum of 800 mg/day. The response was assessed based on a reduction of myeloma protein in serum or urine that lasted for at least 6 weeks. The serum or urine levels of paraprotein were reduced by at least 90% in eight patients, two had a complete remission (CR), six patients had a 75% reduction of paraprotein, seven patients had a 50% reduction, while six had a 25% reduction, accounting for a total rate of response of 32%. Reductions in the paraprotein levels were apparent within 2 months in 78% of the patients who responded to therapy. This was associated with increased hemoglobin levels and decreased numbers of plasma cells in the bone marrow. The microvascular density of bone marrow, however, did not significantly change in responding patients. After 12 months of follow-up, Kaplan-Meier estimates of the mean (\pm SE) rates of event-free survival and overall survival for all patients were $22 \pm 5\%$ and $58 \pm 5\%$, respectively.⁴³ A more recent follow-up included 169 patients with advanced myeloma, in whom 67% had abnormal cytogenetics (CG) and 76% a prior autotransplant.⁴⁴ A 25% reduction in the M protein was noted in 37% of

Table 87.1 Thalidomide in relapsed/refractory multiple myeloma

Mileshkin et al. ⁴⁵	75	600	28	50	5.5 months	50	15 months
Neben et al. ⁴⁷	83	400	20	45	1 year	86	1 year

EFS, event-free survival; OS, overall survival.

the patients, and $\geq 50\%$ reduction in 30% of the patients; NCR or CR occurred in 14%, more frequently in patients with low plasma cell labeling index and normal CG. Two-year event-free and overall survival rates were $20 \pm 6\%$ and $48 \pm 6\%$, respectively. Superior 2-year event-free and overall survival was seen in patients with normal CG, normal plasma cell labeling index, and β_2 -microglobulin of 3 mg/L or less. The therapy was well tolerated considering that most of the patients were previously heavily treated for their advanced disease. At least one third of patients had mild or moderate constipation, weakness or fatigue, or somnolence. More severe adverse effects were infrequent (occurring in fewer than 10% of patients), and hematologic effects were rare.⁴³ Similar findings have been reported by other study groups (Table 87.1).

COMBINATION THERAPY

Pegylated doxorubicin (Doxil), vincristine, and dexamethasone (DvD) is an active combination used in the management of newly diagnosed MM with equivalent response rates and quality of responses to those of VAD therapy.^{48,49} Moreover, in the relapsed/refractory setting, the response rates are modest and durable only when patients achieve a NCR or better, which is a rare occurrence (overall response rate is 22% and NCR is $< 5\%$).⁵⁰ DvD significantly reduces the amount of abnormal angiogenic activity in treated patients; however, this finding does not impact progression-free survival.⁴⁸ Thalidomide has a direct antimyeloma effect in addition to its ability to modulate integrins, rendering the myeloma cell vulnerable and sensitized to different chemotherapeutic agents. It was combined with DvD in newly diagnosed active MM as well as in advanced progressing relapsed/refractory disease, with the primary objective of improving the response rate, quality of response, and of maintaining the antiangiogenic activity achieved with the DvD regimen. The overall CR/NCR rate was 47% in relapsed/refractory patients, compared to 46% in newly diagnosed disease.⁵⁰ Time to best response was similar for both groups. Stable disease or improvement occurred in 89% of the patients with relapsed/refractory disease.

Early studies from the University of Arkansas have shown that patients with β_2 -microglobulin of 3mg/dL or less, normal CG, and normal plasma cell labeling

index were the most sensitive to thalidomide therapy.⁴⁴ A phase II study evaluated the role and efficacy of thalidomide in combination with interferon alpha-2B.⁴⁶ In this trial, a multivariate analysis for overall survival demonstrated that age greater than 65 years (median, 9.2 months vs longer than 26 months; $P = 0.011$), raised serum lactate dehydrogenase levels ($P = 0.002$), and raised serum creatinine ($P = 0.007$) predicted inferior outcomes. Those factors could have been influenced by the addition of interferon to the therapy.

Overall, thalidomide as a single agent or in combination is well tolerated. Tolerability depends on the starting dose of therapy, the maximal target dose, the cumulative dose, and the type of agents with which thalidomide is combined and the intensity of the schedule for those agents. The most critical side effect that is noted is the increased incidence of deep venous thrombosis. Plasma cell dyscrasia appears to be associated with a high incidence of thrombotic events.⁵¹ This finding is supported by the increased incidence of thrombotic events in patients with monoclonal gammopathy who are not receiving any active therapy. Of interest is the absence of any significant increase in the incidence of those events with the use of thalidomide in combination with dexamethasone, when the latter was used in a less intense schedule compared to the more frequent, intense steroid timetable.^{33,34,52} When used in combination with chemotherapy, particularly anthracyclines, the incidence of deep venous thrombosis is significantly increased and can be reduced to baseline by the use of low-dose aspirin or low-molecular-weight heparin.^{50,52} In summary, when thalidomide is used as a single agent or in combination with a nonintense steroid schedule (dexamethasone at 40 mg/day for 4 days with 10 days off), prophylactic anticoagulation is not warranted. When used in combination with anthracycline-based regimens, low-dose aspirin prevents deep venous thrombosis with no side effects.

In patients with relapsed or refractory disease who are slowly progressing, it is reasonable to consider the use of thalidomide as a single agent, starting with a low dose of 50 mg daily and incrementing this dose by 50 mg a week to a maximum of 400 mg/day. This dose strategy allows patients to develop tolerance to the side effects, especially somnolence, and capitalizes on

the data suggesting that the cumulative dose in the first 3 months of therapy could influence the outcome of therapy.^{45,47} If patients do respond to monotherapy, then progress at a later time, the addition of steroids provides another chance at a response that could be as high as 50%.⁵³ In patients with more advanced disease or with quickly progressing MM, the use of thalidomide in combination with steroids or chemotherapy is reasonable. In this population, the time to achieve a response is approximately 0.7 months, and the response rates are around 70%.⁵³ The use of thalidomide in combination with DVd improves the response rate and the quality of response. The progression-free survival at 14 months is significantly improved when compared to DVd alone, and the results appear to be better than what was noted with thalidomide and dexamethasone alone.^{50,53} A phase III trial is in progress to compare dexamethasone and thalidomide to DVd-T.

IMMUNOMODULATORY ANALOGS OF THALIDOMIDE

The efficacy of thalidomide has been limited by adverse effects, which include sedation, neuropathy, constipation, and deep vein thrombosis. This spurred the development of thalidomide-derived immunomodulatory analogs, known as immunomodulatory drugs (ImiDs). Like thalidomide, IMiDs inhibit angiogenesis and act directly on MM cells to induce both apoptosis and growth arrest in resistant cells. They also block the adhesion of myeloma cells to bone marrow stromal cells and the associated protection against apoptosis, and thus affect myeloma cell growth, survival, and migratory factors such as IL-6, tumor necrosis factor α (TNF α), and VEGF. In addition, they expand natural killer cell and T-cell numbers, and improve function against human myeloma cells and enhance their susceptibility to antibody-dependent cell-mediated cytotoxicity *in vivo*.⁵⁴⁻⁵⁶ The addition of an amino group at position 4 of the phthaloyl ring in thalidomide structure led to the generation of CC-4047, and with the further removal of a carbonyl on the ring CC-5013 (lenalidomide) was created. ImiDs are up to 50,000 times more potent at inhibiting TNF α than is the thalidomide parent compound *in vitro*, and are markedly more stable.⁵⁷

Promising preclinical data led to the first phase I study of thalidomide analog CC-5013 in 2001, when 25 patients with relapsed and refractory MM were treated with 5–50 mg/day of CC-5013. Patients enrolled in this study had received a median of three prior regimens, including autologous SCT and prior thalidomide in approximately two thirds of the patients. Grade III myelosuppression developed after 28 days in all 13 patients treated at the highest dose level of 50 mg/day. In 12 of these patients, dose reduction to 25 mg/day was well tolerated and was consid-

ered the maximum-tolerated dose.⁵⁸ No significant constipation or neuropathy was seen in any cohort, and encouragingly, responses were seen in 17 (71%) of 24 assessable patients, including 11 patients (46%) who had received prior thalidomide.⁵⁸ Further studies evaluating CC-5013, either alone or in combination with dexamethasone, have shown encouraging results in patients with MM at first relapse, or for relapsed/refractory MM.⁵⁹ Further studies, including a phase III trial, are ongoing in evaluating the efficacy of CC-5013 (with and without dexamethasone) in patients with relapsed or refractory disease.⁶⁰

In a recently published phase I trial of 24 patients with relapsed or refractory disease treated with CC-4047, Schey et al. reported encouraging results. Sixty-seven percent of patients achieved greater than 25% reduction in paraprotein, 13 patients (54%) had greater than 50% reduction in paraprotein, and four (17%) of 24 patients entered a CR.⁶¹

ARSENIC TRIOXIDE

Arsenic trioxide is an antitumor agent with a multifaceted mechanism of action that induces apoptosis *in vitro* in MM cell lines and freshly isolated cells from MM patients. In preliminary studies, it has demonstrated good clinical activity in patients with late-stage MM. Arsenic trioxide affects myeloma cell survival, possibly through the inhibition of glutathione peroxidase, inducing apoptosis and inhibiting the proliferation of MM cell lines and primary MM cells in a dose-dependent manner.^{62,63} Unlike the antitumor activity of dexamethasone, which is inhibited by IL-6, arsenic trioxide-induced apoptosis is not prevented by IL-6.⁶³ Arsenic trioxide induces apoptosis through activation of caspases 8 and 10 in mutated p53 myeloma cells, while it does so by activation of caspase 9 in the mitochondrial apoptotic pathway in myeloma cells with functional p53.⁶⁴ In addition, it inhibits TNF α -induced cell adhesion, inhibits secretion of IL-6 and VEGF, and increases dexamethasone-induced apoptosis.^{65,66} The cytotoxic action of arsenic trioxide is increased when administered with ascorbic acid *in vitro*.⁶⁷

Cross-resistance to other chemotherapeutic agents is less likely with arsenic trioxide because it can induce dose-dependent apoptosis in drug-resistant MM cell lines.⁶⁸ Antiangiogenic properties, such as inhibition of VEGF production and capillary formation, also promote the antitumor efficacy of arsenic trioxide.⁶⁸ In addition, treatment with arsenic trioxide increases lymphokine-activated killer cell activity and upregulates CD38 ligand and CD38 on immune effector cells and myeloma cells, indicating that immunomodulation may contribute to its antitumor activity.⁶⁹ A recent phase II, multicenter, open-label study of arsenic trioxide (ATO) was conducted in 24 MM patients (eight with relapsed disease and 16 refractory to prior therapy).⁶⁸

Patients received ATO 0.25 mg/kg/day for 5 days/week during the first 2 weeks of each 4-week cycle. Sixteen patients had grade III or IV neutropenia and one required antibiotics. Eight of 24 (33%) patients had reductions in serum M-protein levels in excess of 25%, while an additional 6 (25%) patients had stable disease.⁶⁸ The median time to response was 67.5 days, with a median duration of response of 130 days.⁶⁸ Arsenic trioxide therapy lowered serum creatinine levels in two patients with high baseline values. These data show that ATO is active and reasonably well tolerated as a single-agent salvage therapy, even in patients with late-stage, relapsed and refractory MM.

TRANSPLANTATION

The role of the autologous hematopoietic progenitor cell transplant in the management of relapsed MM evolved in the late 1980s and early 1990s. This is covered in greater detail in Chapter 83.

NOVEL AGENTS

FARNESYLTRANSFERASE INHIBITORS

Farnesylation is the first and most important step in the posttranslational modification of Ras proteins, which are mutated in up to 30–40% of patients with MM.⁷⁰ Mutated Ras activates Ras-dependent pathways, including the MAPK (mitogen-activated protein kinase) and the PK13 cascades, to form cross-linked complexes that favor cell survival. In preclinical trials, R115777 inhibited the growth and survival of MM cells even in the presence of IL-6.⁷¹ In a phase II trial, R115777 was used to treat 43 patients who had previously received treatment for MM. Disease stabilization (defined as 0–25% decrease in the level of paraprotein) occurred in 64% of patients. Fatigue was the most common side effect.⁷²

HISTONE DEACETYLASE INHIBITORS

Histone deacetylase (HDAC) inhibitors are a new class of chemotherapeutic reagents that cause growth arrest and apoptosis of neoplastic cells. In a recent study, depsipeptide, a new member of the HDAC inhibitors, induced apoptosis in myeloma cell lines in a time- and dose-dependent fashion, and in primary patient myeloma cells.⁷³ Another HDAC inhibitor, suberoylanilide hydroxamic acid (SAHA), potently induced apoptosis of human MM cells.⁷⁴ SAHA treatment has been shown to suppress the activity of the proteasome and expression of its subunits, thereby enhancing MM cell sensitivity to proteasome inhibition by bortezomib (PS-341).⁷⁴ SAHA also enhances the anti-MM activity of other proapoptotic agents, including dexamethasone, cytotoxic chemotherapy, and thalidomide analogs.⁷⁴ This agent has shown encouraging results in a phase I trial.⁷⁵

INHIBITORS OF VEGF RECEPTOR

VEGF stimulates autocrine and paracrine growth of MM cells. VEGF achieves its action through its binding to three tyrosine kinase receptors—VEGF receptor 1 (also called FMS-like tyrosine kinase receptor 1), VEGF receptor 2 (also called kinase insert domain containing receptor), and VEGF receptor 3 (also called FMS-like tyrosine kinase receptor 4).⁷⁶ VEGF receptor 1 is the most commonly expressed VEGF in MM patients. In a phase II study, no objective response was seen in patients with refractory MM when treated with VEGF receptor 2 (SU5416).⁷⁷ However, antiangiogenic properties of SU5416 can be used in combination with other agents in treating relapsed/refractory MM.

BISPHOSPHONATES

Bisphosphonates have a widely recognized antiosteoclastic activity and have been shown to decrease skeletal events in patients with MM.⁷⁸ There is growing evidence of direct antitumor action of bisphosphonates on MM cells. Bisphosphonates act through inhibition of the ubiquitous mevalonate pathway, inducing apoptosis of tumor cells, suppressing proliferation and migration of endothelial cells, and by inhibiting angiogenesis.⁷⁶ In addition, bisphosphonates decrease IL-6 production and induce apoptosis of osteoclasts through inhibition of farnesyl and geranyl transferase activity. Bisphosphonates increase $\gamma\delta$ T cells, which cause increased apoptosis of the MM cells.⁷⁹ Immunomodulatory effects of bisphosphonates are further being explored.

OTHER AGENTS

Other agents that are under investigation for their role in the treatment of MM include those that act by interrupting intracellular signaling pathways, including the inhibitors of insulin-like growth factor 1 (IGF-1) receptor, inhibitors of the heat-shock protein 90, and the soluble RANKL antagonist, which decreases bone resorption. Inhibitors of lysophosphatidic acid acyltransferase β (CT-32176, CT-32458, and CT-32615) in combination with HDAC inhibitors are under study for their role in MM treatment.⁷⁶ Table 87.2 lists new agents now under study for treatment of relapsed or refractory MM.

SALVAGE THERAPIES

Traditionally, salvage therapies included combination chemotherapy, such as vincristine, doxorubicin, and dexamethasone (VAD). VAD was the first effective treatment for melphalan-resistant myeloma.⁸⁰ Other agents that have shown efficacy in relapsed or refractory myeloma, especially myeloma with high proliferative activity, include combinations such as DCEP (dexamethasone pulsing and 4-day continuous infusion

Table 87.2 Novel agents under study in treatment of relapsed/refractory multiple myeloma

Proteasome inhibitor (PS-341, bortezomib)
Thalidomide
Immunomodulatory derivatives (ImiDs)
Arsenic trioxide
Heat-shock proteins
Anti-VEGF antibodies
Farnesyltransferase inhibitors
Histone deacetylase inhibitors
Bcl-2 antisense molecules
2-Methoxyestradiol
Bisphosphonates
IGF-1 receptor inhibitors
RANKL antagonist
Lysophosphatidic acid acyltransferase β inhibitors
Vaccines

of cyclophosphamide, etoposide, and cisplatin) or DT-PACE, in which thalidomide and doxorubicin are added to DCEP.⁸¹

SUMMARY

Disease progression in MM is associated with complex biologic pathways and processes, making it difficult to manage the disease successfully, and increasing the probability of relapse. The pathophysiology of MM contributes to the development of resistance to standard therapy. Over the past 2–3 years, there has been a remarkable expansion in drug development for MM that will probably result in a positive impact on survival. This has included development of bortezomib, lenalidomide, and “rediscovering” thalidomide and arsenic trioxide, agents that have shown promise in treatment of relapsed and refractory myeloma.

Novel treatment strategies are further needed to target the underlying pathogenic mechanisms, but they must be safe for a predominantly older patient population. Nontraditional therapeutic agents having novel mechanisms of action are under investigation. The current approach is to target the progression of myeloma at multiple different pathways simultaneously. It is probably time to proceed on two simultaneous developmental tracks: one, the continuation of the current strategy to develop targeted therapy; the other, to properly define the dose, frequency, and combination strategies of the available new agents. Combination of novel agents with established therapy may fill an unmet need in the management of relapsed/refractory MM.

Section **2****SPECIAL TOPICS IN
MULTIPLE MYELOMA**Chapter **88****HYPERVISCOSITY SYNDROME***Marcel N. Menke and Steve P. Treon***INTRODUCTION**

Hyperviscosity syndrome (HVS) can be caused by various clinical conditions. It can be observed in conditions where the hematocrit is raised, such as polycythemia vera and pseudopolycythemia, or where serum proteins are increased or their composition is altered, such as in paraproteinemias, hyperfibrinogenemia, or hypoalbuminemia, as well as in inflammatory syndromes, hypothermia, increased red blood cell aggregability, and reduced red cell deformability due to various congenital and acquired conditions, such as sickle cell anemia, hyperlipoproteinemia, thrombosis, or diabetes.¹⁻⁸

The most common cause of HVS encountered by hematologists is monoclonal and occasional polyclonal paraproteinemias, particularly those characterized by large molecular compounds with a high intrinsic viscosity, such as immunoglobulin M (IgM). Therefore, among cases of HVS caused by paraproteinemias the most frequent diagnosis is Waldenström's macroglobulinemia (WM), a B-cell disorder characterized by overproduction of monoclonal IgM. Approximately 17% of all WM patients show clinical symptoms related to hyperviscosity (HV).⁹ HVS can also occur in patients with multiple myeloma, malignant lymphoproliferative diseases, lymphoma, monoclonal gammopathy of undetermined significance (MGUS), and primary amyloidosis.^{2,10-12} These diseases can occur as a result of a monoclonal paraproteinemia of either IgM, IgG, or IgA.

PATHOPHYSIOLOGY OF HVS**IMMUNOGLOBULINS**

Paraproteinemias due to excess concentrations of immunoglobulin molecules represent the main disorder of blood that primarily contribute to HVS. Excess concentrations of immunoglobulins are primarily present in the plasma. There are five immunoglobulin classes: IgG, IgA, IgM, IgD, and IgE.

Immunoglobulin M, with which HVS is most commonly observed, is a large molecular compound that is secreted in a pentamer form and weighs approximately one million daltons. IgM may bind water through its carbohydrate component and can also form aggregates. Due to its large size, 70–95% of the IgM produced is found in the intravascular compartment.^{13,14} As a result of its osmotic draw, IgM leads to expanded blood volume, and can surreptitiously lead to a factitious anemia. Paraproteinemias due to smaller sized immunoglobulins, such as IgG and IgA, can also cause HVS, but usually at much higher serum levels than IgM due to their capacity to diffuse across blood barriers. Immunoglobulins, which are cationic, can also lower the repulsive forces between normally anionic erythrocytes and further contribute to HVS through rouleaux formation.¹⁵

SYMPTOMATIC THRESHOLD OF VISCOSITY

Serum viscosity is often measured in centipoises (cp), which is a measure of viscosity relative to water. The normal range of serum viscosity is between 1.2 and 1.8 cp. Patients with nonmalignant inflammatory disorders can

display elevated serum viscosities above 1.8 cp, but generally are under the symptomatic threshold leading to HVS. Fahey et al.¹⁶ first reported on the “symptomatic threshold” of viscosity in 1965 in patients with monoclonal gammopathies. While acknowledging in their studies that the serum viscosity at which symptoms occurred varied between patients, no patient exhibited symptoms at a serum viscosity of less than 4 cp. Similarly, Crawford et al. reported in a series of 126 patients with monoclonal gammopathies that patients usually became symptomatic at serum viscosity levels of >4 cp, whereas, none of the patients in this series who had a serum viscosity of <3 cp exhibited HVS.¹⁷ In a study of 56 patients with malignant paraproteinemias, retinopathy was always associated with serum viscosities ≥ 3.8 cp, though in some patients with serum viscosity levels between 2 and 3 cp, bleeding and neurologic symptoms were observed.¹⁸ Numerous additional studies have also confirmed the appearance of symptoms at serum viscosity levels of 4–5 cp.^{19–22}

While many investigators have focused on the use of serum viscosity levels to evaluate HVS, others have emphasized the use of whole blood viscosity wherein both immunoglobulin and hematocrit levels are taken into account.²³ However, in follow-up studies, MacKenzie et al. demonstrated that serum viscosity levels were as reliable as whole blood viscosity levels in identifying HVS in patients with monoclonal gammopathies.²⁴ This is probably due to the high concentration of immunoglobulins present in serum. However, HVS was reported in a patient with low immunoglobulin levels, in whom a high whole blood viscosity level was detected, which likely was due to extensive red cell paraprotein interactions. It therefore appears that evaluation of the whole blood viscosity may reveal in certain individuals the presence of HVS.

CLINICAL FINDINGS

The clinical findings for HVS are summarized in Table 88.1. Symptoms due to HV can be categorized into (1) general symptoms, such as tiredness, fatigue, weight loss, and anorexia, (2) neurologic symptoms, such as headaches, nausea, vertigo, dizziness, ataxia, paresthesia, decreased hearing, and rarely coma, and (3) vascular disturbances, such as epistaxis, gingival and gastrointestinal hemorrhages or menorrhagia, congestive heart failure, retinopathy (including retinal hemorrhages), papilledema, dilated retinal veins and visual disturbances, and perfusion-related renal problems. The typical ophthalmologic changes in a WM patient with HVS are depicted in Figure 88.1.

ASSOCIATED MANIFESTATIONS OF HVS

Retinal findings

Circulatory disturbances due to HV can be best appreciated by ophthalmoscopy. Approximately 10% of

Table 88.1 Clinical symptoms of hyperviscosity

(1) General symptoms
– Tiredness/fatigue
– Loss of weight
– Anorexia
(2) Neurologic symptoms
– Headache
– Nausea
– Vertigo
– Dizziness that can rarely lead to coma
– Ataxia
– Paresthesia
– Decreased hearing
(3) Vascular disturbance
– Epistaxis
– Gingival and gastrointestinal hemorrhages or menorrhagia
– Congestive heart failure
– HV-related retinopathy
– HV-related kidney problems

patients with HV due to WM have symptoms of visual disturbance, and up to 50% of these patients will demonstrate ocular changes.^{25–27} The percentage of retinal involvement in patients with HV due to other paraproteinemias is unknown, but such cases have been reported.^{28,29} In a recent study, Menke et al. examined 46 patients with WM by indirect ophthalmoscopy and the laser Doppler blood flow technique, which assessed retinal vessel diameter and blood flow.³⁰ These studies showed a relationship between retinal vessel caliber, particularly retinal veins, and serum viscosity, with increases in the caliber of vessels accompanying increases in serum viscosity.^{28,30} Fluorescein angiography has also been used to investigate retinal microcirculation, with finding of increased arteriovenous passage times and vessel diameters in WM patients with increased serum viscosities.^{28,29}

Figure 88.1 Ocular exam of a patient with Waldenström's macroglobulinemia depicting typical findings of hyperviscosity

Among the first clinical signs of HV is the appearance of peripheral and mid-peripheral dot- and blot-like hemorrhages in the retina, which are best appreciated with indirect ophthalmoscopy and scleral depression.^{30,31} In more severe cases of HVS, dot, blot, and flame-shaped hemorrhages can appear in the macular area, and may be accompanied by retinal edema and visual disturbance. Although visual acuity usually improves with plasmapheresis treatment, irreversible visual loss has been reported.³² Some patients with HVS show papilledema and markedly dilated and tortuous veins with focal constrictions, predominantly at the arterio-venous junctions (i.e., venous sausageing). Other clinical findings associated with HVS can include intraretinal exudates resulting from more severe leakage from retinal vessels and retinal detachments.³³ Fluorescein angiography may be helpful in cases of intraretinal exudates in identifying areas of leakage.

Corneal and conjunctival findings

Slitlamp examination frequently reveals sludging of red blood cells in the conjunctival vessels. Keratoconjunctivitis associated with HV in patients with WM has also been reported. In some cases, corneal and conjunctival crystals consisting of immunoglobulin deposits can be found in patients with paraproteinemia.³⁴

Neurologic findings

Common neurologic symptoms of HVS include headaches, nausea, vertigo, and dizziness, which rarely can progress to coma.^{1,14,35,36} Some patients with HVS can show sensorineural hearing loss.³⁷ In most cases, neurologic symptoms usually appear at higher viscosity levels (i.e., >4 cp), though early appearance before retinal findings at lower serum viscosity levels (i.e., 2–3 cp) has also been reported.¹⁸

Several animal models have been used to investigate the neurologic consequences of HVS. The effects of blood hyperviscosity on functional integrity in the brain stem have been investigated using brain stem auditory evoked potentials.³⁸ Animals with elevated blood hyperviscosity showed either a total lack of any waveforms, or a prolongation of waves, indicating a severe disturbance in functional brain stem integrity, which could be improved partially with hemodilution therapy. In a study investigating the cerebral cortical blood flow and oxygen metabolism in newborn piglets with hyperviscosity, cerebral cortical blood flow and oxygen delivery were found to be decreased.³⁹ Moreover, in studies of the cerebral microcirculation in macroglobulinemic mice, decreased plasma velocities in the presence of increased serum viscosities were observed, whereas red blood cell velocities were within normal limits or even elevated. These findings suggest that alterations of viscosity can lead to disturbances in the microcirculation of the cerebral cortex, and are likely to account at least in part for the neurologic manifestations of HVS.⁴⁰

Kidney findings

Renal failure is an uncommon manifestation of HVS, and may result from perturbations in renal perfusion, leading to ischemic injury of the kidney. In experimental animal models, the influence of blood rheology on glomerular hemodynamics has been investigated. Elevation of either serum or whole blood viscosity resulted in renal vasodilation and decreased renal blood flow.^{41,42} Ischemic acute tubular necrosis as a result of HVS has also been reported in a patient with WM.⁴³ In HVS-related renal dysfunction, decreased urine output, defects in concentrating and diluting urine, and increased serum creatinine may be observed.⁴³ In such cases, a kidney biopsy can be considered. Increased mesangial matrix, cytoplasmic vacuolation of the epithelial cells lining the proximal tubules, foci of atypical lymphoplasmacytoid infiltration in the interstitium, and mitosis in the tubules as a sign of regenerative activity may be observed in biopsy specimens from a patient with HVS-induced renal injury.

TREATMENT OF HYPERVISCOSITY SYNDROME

PLASMA EXCHANGE/PLASMAPHERESIS

Plasmapheresis can be successfully used as an emergent therapy for patients with immunoglobulin-related HVS. Typically, two to four courses of plasmapheresis are required to achieve symptomatic control. However, marked improvement in HVS can occur even after the first course of plasmapheresis. The benefit of plasmapheresis usually lasts 4–6 weeks in patients with immunoglobulin-related HVS, and should be considered a temporizing measure until definitive therapy can be initiated to control disease.⁴⁴ Plasmapheresis can also be effective in reverting HV-associated retinopathy.^{28,30,45,46} Improvements in renal function after plasmapheresis have also been reported in patients with hyperviscosity-related renal failure.⁴³

In general, the response of patients to plasmapheresis depends on three main factors: (1) the intravascular component of the protein; (2) the volume exchanged; and (3) the synthesis rate of the protein being removed. The IgM molecule is large, with 70–95% localized in the intravascular compartment. A single plasma exchange can result in a reduction in serum IgM by 35%, with a concomitant decrease of 50–60% in serum viscosity.⁴⁷ In contrast to IgM, only 40% of IgG and IgA immunoglobulins are intravascular. Therefore, plasmapheresis is more likely to be successful in patients with WM, as opposed to multiple myeloma. There is no evidence that regular removal of monoclonal proteins accelerates or reduces their rate of synthesis. Concurrent systemic chemotherapy is therefore required for long-term management. However, plasmapheresis may be rarely indicated on a long-term

basis in patients with hyperviscosity who are drug resistant or whose only clinical problem is due to the

paraprotein (e.g., immunoglobulin-related neuropathy) rather than tumor burden.¹⁴

Chapter 89

MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE

Shaji Kumar, Philip R. Greipp

BACKGROUND AND DEFINITIONS

Presence of small amounts of monoclonal protein in the serum detected by protein electrophoresis, in the absence of clinical or laboratory evidence of multiple myeloma (MM), Waldenström macroglobulinemia, light chain amyloidosis, or related disorders, was described over half a century ago. Since Waldenström's initial description of "essential hyperglobulinemia," this entity has been described by multiple terms, including idiopathic paraproteinemia and idiopathic, asymptomatic, benign, or nonmyelomatous, monoclonal gammopathy. The common theme to all these early descriptions was the presumed "benign" nature of the abnormality and the relatively stable levels of paraprotein in these patients. However, long-term follow-up of these patients has proven that "benign monoclonal gammopathy" is a misnomer. These patients have a definite risk of progression to MM, macroglobulinemia, or amyloidosis, and at the time of diagnosis it is impossible to predict with any degree of confidence as to who will have disease progression. This led to coining of the term monoclonal gammopathy of undetermined significance (MGUS), highlighting the uncertain nature of the abnormality at the time of initial detection.

The hallmark of MGUS is the presence of monoclonal protein (M protein) in individuals with no clinical or laboratory evidence of MM, macroglobulinemia, light chain amyloidosis, or related plasma cell disorders. It is characterized by M protein less than 3 gm/dL in the serum with an absence or small amounts of M protein in the urine; fewer than 10% clonal plasma cells in the bone marrow; absence of bony lytic lesions, anemia, hypercalcemia, or renal insufficiency related to the paraproteinemia. While some of the abnormalities, such as anemia and renal insufficiency, are common in this patient population, it is imperative that an alternate cause for the abnormality be identified prior to making the diagnosis of MGUS. The stability of the paraprotein over time and lack of development of

additional abnormalities are important for the definition of MGUS, though at the time of initial detection of the M protein these factors are indeterminate. Some studies that followed these patients for long term have required demonstrated stability of the M protein for at least 1 year for inclusion in the study.

EPIDEMIOLOGY

There appear to be some variation in the prevalence of this disease, based on geography and race. In a study from a small southeastern Minnesota community, M protein was found in 15 of the 1200 adults (1.25%) aged 50 years or older.¹ In a study from Sweden, of 6995 adult patients aged 25 years or older, Axelsson reported presence of an M protein in 1%.² Saleun et al. detected a monoclonal protein in the sera of 334 persons, from among 30,279 French adults studied, translating to a prevalence of 1.1%.³ In a study from Greece, a paraprotein was detected in 75 of the 1564 patients (aged 50–95 years) studied, of whom 60 were classified as having MGUS.⁴ Among Japanese patients older than 50 years, Kurihara reported the presence of M protein in 71 of 2007 samples (3.5%).⁵ In a convenience sample of community-dwelling elderly subjects aged 63–95 years seen for health screening examinations, Bowden found an M protein in 2.7% of Japanese, compared to 10% of Americans.⁶ African Americans have been reported to have a higher prevalence of M proteins compared to that reported in Caucasians.⁷ In a study of 1732 elderly subjects (>70 years) selected by stratified random household sampling, Cohen found 106 (6.1%) with a monoclonal gammopathy.⁸ African Americans (8.4%) had a greater than twofold prevalence of monoclonal gammopathy compared to whites (3.8%).

The prevalence of monoclonal gammopathy increases with age, and is greater in men than women.⁹ In the Japanese study, 11% of those from 80 to 89 years had detectable paraprotein in the sera.⁵ In the study by

Cohen, the incidence of MGUS among those older than 70 years was 3.6%.⁸ In a study of residents from a retirement home, the prevalence of monoclonal gammopathies was 6% in those younger than 80 years, compared to 14% in those older than 90 years.¹⁰ Lighthart et al. reported the presence of M protein among 23% of 439 patients aged 75–84, compared to a control group aged 25–34 years, of whom none had a detectable paraprotein.¹¹ There is a slight preponderance of male gender among MGUS patient populations (Male:Female ratio of 1.1 to 1.2).^{8,12–14} A familial occurrence of monoclonal gammopathies has been reported.¹⁵

DIAGNOSIS

The detection of a paraprotein in the serum is often an incidental finding in a healthy individual undergoing routine testing, or in someone undergoing evaluation for an unrelated disorder. An agarose gel electrophoresis is the preferred method for evaluation of M protein in the serum, and is more sensitive than cellulose acetate. The monoclonal protein appears as a localized band on the agarose gel electrophoresis, and when converted to a densitometric tracing appears as a tall spike or peak (Figure 89.1). The M spike is usually seen in the β or γ region of the densitometer tracing, though occa-

sionally it can occupy the α_2 -globulin region. In contrast, a polyclonal increase in the gamma globulin is manifested as a broad peak in the γ region. Once an electrophoretic abnormality suggestive of M protein is seen on the electrophoresis, immunofixation should be performed to confirm the presence of the monoclonal protein as well as to characterize the heavy-chain class (G, A, M, E, or D) and the type of light chain (κ or λ). In addition to identifying the presence of the monoclonal protein, the protein can be quantitated by rate nephelometry, which is important for the follow-up of these patients. Nephelometry results may be higher than those expected on the basis of the densitometry tracing from serum protein electrophoresis, especially in the case of IgM.

An M protein may also be present in the urine, which should be examined in patients with monoclonal gammopathies. Similar techniques are used for urine protein electrophoresis, and should be performed on 24-h collections. The percentage of M protein on the densitometer tracing, and the total protein excretion over a 24-hour period, will allow calculation of the M protein excreted during this time period.

Once an M protein is identified, the next step is to rule out the presence of another plasma cell disorder, such as MM, amyloidosis, or macroglobulinemia (see differential diagnosis, below). A complete blood count

Figure 89.1 Serum protein electrophoresis and immunofixation. The left side panels show the protein electrophoresis and immunofixation pattern from a normal serum sample. On the right is a patient with myeloma and IgG kappa monoclonal protein. The monoclonal protein appears as an abnormal band on the agarose gel electrophoresis that is converted to an M-spike in the gamma region on the densitometric tracing. The immunofixation demonstrates the type of M-protein as an IgG kappa

and chemistry panel, including calcium and creatinine, should be obtained in all individuals. C-reactive protein and β_2 -microglobulin levels should be obtained as well. The presence of anemia or renal insufficiency points toward a more advanced plasma cell proliferative disorder, unless another explanation is found. A bone marrow biopsy to estimate the plasma cell percentage is not necessary for the diagnosis of MGUS, and should be reserved for those with higher amounts of M protein (>1.5 gm/dL) or if there is a strong clinical suspicion for another plasma cell disorder. A skeletal survey that includes films of the long bones and skull should be obtained, especially in those with larger M-protein levels and in those whom clinical suspicion for MM is high.

CLINICAL AND LABORATORY FEATURES

The majority of patients with MGUS are asymptomatic. Exceptions are the patients in whom associated disorders develop, the strongest association being neuropathy, as described below (Associated Disorders). The median age at diagnosis of MGUS was 72 years in the Mayo Clinic series and 63 years (24–91 years) in the Italian series.^{12,13} Laboratory findings include the M protein in serum, which is less than 3 gm/dL by definition. The median M-protein concentration in the 1384 patients reported by Kyle et al. was 1.3 gm/dL (range: unmeasurable to 3 gm/dL). The M protein was an IgG subtype in nearly two-third of the patients, IgA in 12%, and IgM in 15%.¹³ IgD MGUS is rare, and isolated case reports can be seen in the literature.^{16,17} Given the rarity of this class of immunoglobulins among MGUS patients, finding an IgD spike should raise suspicion of MM, amyloidosis, or plasma cell leukemia. A biclonal gammopathy (presence of two distinct monoclonal proteins) was seen in about 3% of patients. The light chain was kappa in nearly 60% and lambda in the remaining 40%. The levels of the polyclonal uninvolved immunoglobulins were decreased in nearly a third of the patients in this study. Other studies have reported lesser proportions of patients with reductions in the polyclonal immunoglobulins.¹² Light chains were detectable in 31% of patients with MGUS, with only 17% having 24-h light chain excretions of over 150 mg. The bone marrow plasma cell percentage, when evaluated, varies between 0 and 10%, with median values of 3–5% in different studies.^{12,13} The plasma cell labeling index (PCLI), a measure of the plasma cell proliferative rate, is characteristically low. Anemia may be present in some of the patients, and is usually related to iron deficiency, renal insufficiency, or myelodysplasia, which are common in this population. Nearly 23% of patients in the Mayo study had hemoglobin values of less than 12 gm/dL.

Conventional cytogenetics fail to demonstrate any significant chromosomal abnormalities in the plasma cells in MGUS, which is likely a reflection of the low proliferative rate of these cells. More recently, several authors have reported the presence of chromosomal abnormalities in MGUS, similar to that seen in myeloma, using interphase fluorescence in situ hybridization techniques.^{18–21} Fonseca et al. studied 59 patients with MGUS in whom 27 (46%) had IgH translocations. A t(11;14)(q13;q32) was found in 15 (25%) of 59 patients, a t(4;14)(p16.3;q32) in 9% of the patients, and a t(14;16)(q32;q23) in 5% of the patients. Deletion 13 was noted in nearly half of the patients with MGUS who were studied. Patients with a chromosome 13 deletion may be at a higher risk of progression to myeloma.¹⁹

Long-term follow-up studies have provided valuable information about the outcome of these patients. It is not clear if the life expectancy of this population as a group is changed compared to those without MGUS. Blade et al., in his study of 128 persons with MGUS, did not find any significant difference in the survival probability of persons with MGUS compared to a control population, even though progression to malignancy was clearly associated with a shorter survival.²² In the initial Mayo Clinic series of 241 patients, the overall survival was shorter among those with MGUS compared to an age- and sex-adjusted population.²³ Among the 1384 patients from southeastern Minnesota, evaluated at Mayo Clinic between 1960 and 1994, the median survival among those with MGUS was clearly shorter (8.1 years) compared to the expected survival (11.8) for an age- and sex-matched population.¹³ Among the 1324 cases of MGUS identified between 1978 and 1993 in North Jutland County, Denmark, a twofold higher mortality rate was observed compared to the expected rate for that population.²⁴ Malignant transformation explained only 20% of the excess mortality in this group. The rest was likely due to other coexisting medical conditions in this patient population, especially during the period immediately following diagnosis.

Patients with MGUS can go on to develop other plasma cell proliferative disorders, such as MM, amyloidosis, Waldenström's macroglobulinemia, or a lymphoproliferative disorder. Direct progression to plasma cell leukemia also has been reported.²⁵ The risk of progression persists throughout the course of the disease. Among the 1384 patients seen at Mayo Clinic since 1970 and followed for a total of 11,009 person-years (median 15.4 years; range 0–35 years), 115 patients (8%) developed one of the above-mentioned disorders.¹³ These included 75 patients with myeloma, 19 with lymphoma, 10 with primary amyloidosis, 7 with macroglobulinemia, 3 with chronic lymphocytic leukemia (CLL), and 1 with a plasmacytoma. The cumulative risk of progression was 10% at 10 years, 21% at 20 years, and 26% at 25

years, translating to a 1% annual risk. In addition, there were 32 patients in whom the M-protein level rose to over 3 gm/dL or the bone marrow plasma cell percentage increased to >10% without development of overt symptomatic myeloma. The risk of development of MM was calculated to be over 25 fold among these patients, and that of macroglobulinemia and amyloidosis 46 and 8.4 fold, respectively. The risk of developing lymphoma or CLL, though higher, was not as dramatic as that for the plasma cell disorders. The majority of patients with MGUS (70%) died of unrelated causes during the follow-up period, with no evidence of progression. The risk of progression is remarkably similar across multiple studies. Among the 1104 patients with MGUS reported by Cesana et al., at a median follow-up of 65 months, the M protein remained stable in 907 patients (82%); 111 patients (10%) died from unrelated causes and 64 patients (5.8%) had a malignant transformation.¹² This included myeloma (43 patients), macroglobulinemia (12), lymphoma (6), plasmacytoma (1), and CLL (1). Baldini et al. reported a 6.8% rate of malignant transformation among the 335 patients who were followed for a median of 70 months.²⁶ Among the 128 patients with MGUS studied by Blade et al., progression was seen in 10.2% at a median follow up of 56 months.²² Carter reported a 6.2% rate of transformation among 64 patients studied for over 3 years.²⁷ Among the 313 patients reported by Paladini et al., 14% of the patients followed for 5–8 years and 18% of those with more than 8 years of follow-up developed a malignant B-cell dyscrasia.²⁸ The mean duration to progression was 63 months (27–138 months) from initial recognition of the paraprotein. Similar results have been reported by others.^{29,30} In a study of 1229 patients from the Danish Cancer Registry, the relative risk of developing MM, Waldenström's macroglobulinemia, and non-Hodgkin's lymphoma was significantly increased, and the increase was independent of the time from diagnosis.³¹ However, the relative risk of CLL was not significantly increased.

Spontaneous disappearance of the M protein has been reported, and was seen in 27 patients (2%) in the Mayo Clinic study. Most of these patients had low levels of M protein at the time of diagnosis. In the Italian study, spontaneous disappearance was noted in 19 patients (1.7%).¹² Similar rates of spontaneous disappearance have been reported in other series, as well.²⁷

RISK FACTORS FOR PROGRESSION

Identifying patients with MGUS who are at high risk of progression is important; both from the standpoint of prognostication as well as for design and implementation of trials aimed at preventing progression. At the time of diagnosis, it is difficult to predict the disease

Table 89.1 Factors associated with increased risk of progression

1. Higher M-protein levels at diagnosis
2. IgA or IgM
3. Higher percentage of plasma cells in bone marrow
4. Suppression of un-involved immunoglobulins
5. Presence of circulating plasma cells or clonal B cells
6. Bone density abnormalities
7. Advanced age
8. Bence Jones Proteinuria
9. Elevated ESR
10. Abnormal free light chain ratio

ESR, erythrocyte sedimentation rate.

course for an individual, even though several clinical and laboratory markers have been suggested based on results from large groups of prospectively followed patients with MGUS (Table 89.1). In the Mayo Clinic study of 1384 patients with MGUS, factors associated with a higher risk of progression included higher M-protein levels and non-IgG (IgA or IgM) subgroups.¹³ The risk of progression to MM or a related disorder at 10 years after diagnosis of MGUS was 6% for an initial M-protein level of 0.5 g/dL or less, 7% for a level of 1 g/dL, 11% for 1.5 g/dL, 20% for 2 g/dL, 24% for 2.5 g/dL, and 34% for 3.0 g/dL. The initial concentration of the M protein appears to be one of the most important risk factors, and similar results have been observed in other large studies. In the Italian series reported by Cesana et al., patients with MGUS who had more than 1.9 g/dL of M protein had twice the rate of progression compared to those with less than 0.95 g/dL.¹² In a Danish study reported by Gregersen et al., the risk of progression increased with increasing M-protein concentration.¹⁴ The type of immunoglobulin also appears to have predictive value, with those having an IgG paraprotein being at lower risk of progression compared to those with an IgA or IgM M protein. In the Italian study, patients with an IgA or IgM M protein had nearly twice the rate of progression compared to those with IgG. In a series of 128 persons with MGUS reported by Blade et al., the IgA type of MGUS was the only variable associated with a higher probability of progression.²² In the Danish study, the relative risk of progression for IgA and IgM were 1.8 and 1.1, respectively, compared to IgG type paraprotein.¹⁴ The proportion of plasma cells in the bone marrow may help predict the risk of progression. Cesana et al. noted an event rate of 0.64/100 person-years among those with 0–5% plasma cells in the marrow, compared to 1.35 and 5.96/100 person-years for those with 6–9% and ≥10% plasma cells, respectively.¹² Baldini et al. reported a transformation rate of 6.8% among those with a plasma cell percentage of <10%, which increased to over 30% in those with 10–30% plasma cells in their marrow. Similar results have been seen in other studies.³² Suppression of uninvolved immunoglobulins (immunoglobulin classes other than

the M protein), characteristically seen in myeloma, can also be seen in patients with MGUS. In the Mayo study, nearly 38% of the patients with MGUS had reduction in the uninvolved immunoglobulin.¹³ Baldini et al. reported a 3.6 fold elevated risk of progression with suppression of one uninvolved immunoglobulin and a 13.1 fold increased risk when two of the polyclonal immunoglobulins were decreased.²⁶ Cesana et al. reported a relative risk of 1.6 for reduction in one normal immunoglobulin, and 7.6 for reduction in two normal immunoglobulins. Similar predictive values for suppression of polyclonal immunoglobulins have been reported by others.¹⁴ Clonal plasma cells can be detected in the peripheral blood in up to 20% of the patients with MGUS using immunofluorescence microscopy. Presence of circulating clonal plasma cells in these patients appears to predict for an increased risk of progression. In one study, patients who had circulating plasma cells were twice as likely (relative risk of 2.2) to progress, most commonly to myeloma, compared to those without circulating plasma cells.³³ Increased numbers of clonal B cells in the circulation has also been associated with a higher risk of progression.³⁴ Quantification of free light chains (FLCs) in the serum offers a new method for disease assessment in patients with paraproteinemias. The presence of an abnormal kappa/lambda FLC ratio (kappa/lambda ratio <0.26 or >1.65) in the serum may help identify those at a higher risk of progression of their underlying MGUS.³⁵ In a study of 1384 patients with MGUS, an abnormal ratio was detected in 379 patients (33%). The risk of progression in these patients was significantly higher (hazard ratio 3.5, 95% CI 2.3–5.5; $p < 0.001$) compared to those with a normal ratio. The presence of Bence Jones proteinuria nearly tripled the rate of progression in two large studies, and may help predict risk of progression.^{12,26} Increased rates of bone resorption have been reported in MGUS patients who are at high risk of progression.³⁶ Modern imaging techniques, such as whole-body positron emission tomography (¹⁸F-FDG PET), may predict patients with stable disease, though further studies are needed to validate these findings.³⁷ Increased age has been reported as a risk factor in a few studies. Baldini et al. reported a 3.6 fold higher risk of progression for

those older than 70 years.²⁶ In one study, a low sCD16 (soluble Fc gamma receptor type III) level in patients with MGUS indicated a high likelihood of rapid progression to MM.³⁸

DIFFERENTIAL DIAGNOSIS

Once the presence of an M protein is detected on protein electrophoresis or immunofixation, it is important to consider and rule out other plasma cell proliferative disorders, including MM, amyloidosis, and macroglobulinemia. The presence of anemia without another explanation, hypercalcemia, lytic bone lesions, renal insufficiency that cannot be attributed to another cause, M protein > 3 gm/dL, large amounts of paraprotein in the urine, bone marrow plasma cells of over 10%, or a high bone marrow PCLI should all raise the suspicion of MM, rather than MGUS. However, no one clinical feature distinguishes one from the other with certainty, and differentiation of myeloma from MGUS may be difficult (Table 89.2) There is a distinct group of patients with features consistent with MGUS except for an M-protein concentration of ≥ 3 gm/dL and $\geq 10\%$ plasma cells in the marrow, for whom the term smoldering (asymptomatic) multiple myeloma (SMM) has been coined.^{39,40} This group of patients has also been referred to as having monoclonal gammopathy of borderline significance (MGBS).²⁶ These patients often have small amounts of M protein in the urine and a reduction of uninvolved immunoglobulins, as well as a low labeling index. At the time of diagnosis, it is often difficult to predict the course of these patients, and this condition is difficult to distinguish from symptomatic myeloma and needs to be closely followed. Patients with SMM are at a higher risk of progression to another plasma cell disorder compared to those with MGUS. In the group of patients reported by Baldini et al., the risk of malignant transformation for the MGBS group was 37% at a median follow-up of 53 months, compared to 6.8% for those with MGUS. Cesana et al. reported a higher risk of progression for patients with SMM (19.7%), compared to 5.8% among those with MGUS, at a median follow-up of 65–72

Table 89.2 Diagnostic features of MGUS, SMM, and MM

Disease stage	Diagnostic Features
Monoclonal gammopathy of Undetermined significance (MGUS)	<ul style="list-style-type: none"> ■ Serum monoclonal protein <3 g/dL ■ Bone marrow plasma cells <10% ■ Absence of anemia, renal failure, hypercalcemia, and lytic bone lesions
Smoldering multiple myeloma (SMM)	<ul style="list-style-type: none"> ■ Serum monoclonal protein ≥ 3 g/dL or bone marrow plasma cells $\geq 10\%$ ■ Absence of anemia, renal failure, hypercalcemia, and lytic bone lesions
Symptomatic multiple myeloma (MM)	<ul style="list-style-type: none"> ■ Presence of a serum or urine monoclonal protein ■ Bone marrow plasmacytosis ■ Anemia, renal failure, hypercalcemia, or lytic bone lesions

months. This group of patients may need immediate treatment for their disease, though many have a relatively stable course for several years.

While high serum levels of M protein and large amounts of M protein in the urine increases the likelihood of myeloma, MGUS patients can occasionally have high levels of Bence Jones protein in their urine, and there is no cutoff value that can be reliably used for discrimination. As many as 17% of patients with MGUS can have urinary monoclonal proteins of more than 150 mg/24 h.¹³ While reduction of uninvolved immunoglobulin points toward myeloma, these findings can be seen in as many as 38% of the patients with MGUS.¹³ While >10% plasma cells in the bone marrow points toward myeloma, some of these patients can have a stable clinical course, as previously mentioned. Atypical plasma cells, especially those with a plasmablastic morphology, point toward myeloma, even though they may occasionally be seen in patients with MGUS or SMM. In a study of 566 patients enrolled in a multicenter trial (MGUS = 295; myeloma = 266), consistent differences were observed in the bone marrow histology between patients with MGUS and MM.⁴¹ Changes in bone marrow composition from MGUS to early MM and to advanced MM followed a precise pattern which, in addition to increasing plasma cell percentage, included a shift from plasmocytic to plasmablastic cytology, an increase in bone marrow cellularity and fibrosis, a change in bone marrow infiltration (becoming diffuse rather than interstitial), a decrease in residual hematopoiesis, and an increase in osteoclasts. Patients with MGUS generally have plasma cell labeling index values close to 0, which may be a valuable discriminator when other features are equivocal.⁴² A value of over 0.4% raises the likelihood of myeloma or impending transformation to one. However, nearly a third of patients with symptomatic myeloma can have normal labeling index values. The value of the labeling index in differentiating benign monoclonal gammopathy from myeloma has been reported by others.^{43,44} The ratio of the plasma cell cytoplasmic light chains has been suggested as a useful differentiating feature, with a ratio of 8 or below pointing toward MGUS.⁴⁵ Circulating clonal plasma cells can be detected using immunofluorescence microscopy, flow cytometry, or more sensitive techniques, such as allele specific oligonucleotide-polymerase chain reaction (ASO-PCR) in patients with monoclonal gammopathies, and are seen in higher numbers in patients with myeloma compared to those with MGUS.⁴⁶ In patients with MGUS and SMM, the presence of these cells predicts for a higher risk of progression.

While the presence of lytic bone lesions in the setting of a monoclonal protein points to myeloma, this patient population is at risk for other malignancies, and the bone lesions may be related to metastatic disease. Occasional patients have one or more sclerotic bone lesions, M protein in the serum or urine (typically

lambda), endocrine and skin abnormalities, and often debilitating neuropathy—a syndrome referred to as osteosclerotic myeloma or POEMS syndrome. More sensitive imaging of the bone using techniques such as MRI or whole body PET imaging may help distinguish patients with MGUS from those with other disorders. Bellaiche et al. performed MRIs of the thoracolumbar spine in 24 patients with MGUS comparing the results to those in 44 patients with myeloma.⁴⁷ All findings on magnetic resonance examination were normal in those with MGUS, whereas findings on 38 patients (86%) with MM were abnormal. CT evaluations of the thoracolumbar spine, iliac crests, and sacrum showing lacunae larger than 5 mm with trabecular disruption have been reported in myeloma—a finding not observed in any of the patients with MGUS.⁴⁸ Durie et al. found that a normal whole-body ¹⁸F-FDG PET reliably identified patients with stable MGUS.³⁷ Others have reported that markers of increased bone turnover, such as carboxy-terminal telopeptide of type I collagen (ICTP) and deoxypyridinoline (Dpd), may help distinguish patients with MGUS.⁴⁹ Bataille et al., using histomorphometric parameters of bone resorption, demonstrated decreased levels of bone resorption in MGUS compared to active MM.³⁶

Levels of cytokines either in the serum or those demonstrated in the plasma cells have been suggested as having diagnostic value. Interleukin (IL)-1 β is produced by plasma cells from patients with MM, whereas those from patients with MGUS rarely do.⁵⁰ IL-1 β is thought to be an important player in the osteoclast-mediated bone destruction seen in myeloma. Serum levels of IL-6 have been reported to be higher in patients with myeloma compared to in those with MGUS. In one study, significant serum IL-6 levels were detected in only 3% of the MGUS/SMM group, compared to 35% of the overt MM group and 100% of those with plasma cell leukemia.⁵¹ Serum levels of IL-2 have been reported to be higher in MGUS patients compared to those with myeloma.⁵² Serum β_2 microglobulin, while increased in myeloma compared to MGUS, does not have enough discriminatory power to be of clinical value in differentiating between MGUS and myeloma.⁵³⁻⁵⁵

Increased bone marrow angiogenesis is a prominent feature of MM and is a prognostic factor for overall survival. Patients with MGUS do not have any significant increase in the bone marrow microvessel density, though the clinical applicability of this test is low given that many patients with myeloma can have normal findings.⁵⁶ Presence of cytoplasmic 5' nucleotidase (c5NT) in plasma cells has been reported to discriminate between MGUS and myeloma.⁵⁷

An M-protein can be detected in the presence of many lymphoproliferative disorders, including non-Hodgkin's lymphoma and CLL, and should be kept in mind when evaluating these patients. Over a ten year period, Malacrida et al. performed protein electrophoresis on

102,000 samples, detecting 730 cases of M-protein, of whom 114 could be classified as B cell malignancies and 261 as monoclonal gammopathy of undefined significance.⁵⁸

DISEASE ASSOCIATIONS

Several hematological and non-hematological conditions have been associated with monoclonal gammopathies. Many of these conditions are likely to occur with increased frequency in this older patient group, making it difficult to identify true associations.

Various lymphoproliferative disorders have been described in the context of monoclonal gammopathies. In a long-term study of 430 patients with a monoclonal IgM in the serum, Kyle et al. found 28 patients (7%) with lymphoma, 21 (5%) with CLL, and 62 (14%) with other malignant lymphoproliferative diseases. Among those with an apparently benign monoclonal gammopathy, nearly a fifth subsequently progressed to have a lymphoid malignancy.⁵⁹ In a study of 1144 patients, using serum protein electrophoresis, Alexanian et al. found an M-protein (IgG) in 2.3% of the 400 patients with CLL and lymphocytic lymphoma.⁶⁰ IgM peaks were seen in 4.5% of patients with lymphomas. Noel et al. reported on 100 patients with CLL seen over a fourteen year period, all of whom had an M-protein in the serum or urine. IgG (51%) was noted most often, followed by IgM (38%) and IgA (1%), with light chains alone in the remainder.⁶¹ Monoclonal gammopathy has also been reported in association with hairy cell leukemia, adult T-cell leukemia, and chronic myeloid leukemia, though the strength of the association remains indeterminate.

Acquired von-Willebrand disease has been described in association with monoclonal gammopathies as well as other malignant disorders.^{62,63} Bleeding time is prolonged in most patients, and is associated with marked reductions in plasma von Willebrand factor antigen and ristocetin cofactor activity, and a type 2 pattern of von Willebrand multimer distribution. Other hematological disorders that have been associated with monoclonal gammopathies include polycythemia vera, myelofibrosis, myelodysplastic syndrome, and pernicious anemia. Lupus-like anti-coagulant activity has been associated with the monoclonal protein in patients with monoclonal gammopathies.⁶⁴

Another common association that has been seen with monoclonal gammopathies is peripheral neuropathy.⁶⁵⁻⁶⁸ Nearly 10% of patients with idiopathic peripheral neuropathy have a monoclonal protein detectable in their serum or urine, a prevalence rate nearly five times of that seen in general population.⁶⁹ The frequency of the neuropathy in different series varies widely, likely a reflection of the criteria used to identify it as well as the thoroughness of the search for a monoclonal protein and the clinical or electrophysiologic cri-

teria used to diagnosis neuropathy.⁷⁰ The neuropathy seen in association with MGUS is typically a peripheral neuropathy, and autonomic nerve or cranial nerve involvement is not usually seen. The association appears to be the strongest with IgM monoclonal gammopathies.^{71,72} In one study, the prevalence of peripheral neuropathy among patients with IgM monoclonal gammopathies was as high as 32%.⁷³ The monoclonal protein binds to myelin associated glycoprotein (MAG) in nearly half of the patients with an IgM-MGUS associated neuropathy.⁷⁰ Among the 65 patients with MGUS and sensorimotor peripheral neuropathy seen at Mayo Clinic, 31 patients had IgM, 24 had IgG, and 10 had IgA.⁶⁵ IgM-MGUS associated neuropathies were characterized by a higher frequency of sensory loss and ataxia, higher frequency of nerve conduction abnormalities, and a higher frequency of dispersion of the compound muscle action potential. Neither the amount of IgM nor the estimated size of the monoclonal peak was associated with the severity of neuropathy. The type and severity of IgM-MGUS neuropathies associated with anti-MAG antibodies were not significantly different from those without anti-myelin-associated glycoprotein antibodies. Patients with IgM-associated neuropathy had more severe demyelination on nerve conduction studies compared to IgG associated neuropathy in one small study, though clinical feature were indistinguishable.⁷⁴ Patients with IgM associated neuropathy may have a more progressive course, with significantly more weakness and sensory signs.⁷⁵

Patients with MGUS associated neuropathy often present with a clinical picture resembling chronic inflammatory demyelinating polyneuropathy (CIDP). Simmons et al. compared a group of 77 patients with idiopathic CIDP with 26 patients in whom CIDP was associated with MGUS.⁷⁶ Patients with CIDP and MGUS had, on average, a more indolent course and less severe weakness, despite similar findings on electrophysiological studies. These patients also demonstrated less functional impairment, more frequent sensory loss, and more abnormal sensory conduction studies. However, given the greater improvement of idiopathic CIDP patients with treatment, both groups had similar outcomes from their initial episodes of weakness. However, nerve conduction studies may not always be helpful in distinguishing between demyelinating neuropathies associated with a paraprotein and idiopathic demyelinating polyneuropathy.⁷⁷ Diagnostic criteria for demyelinating neuropathy associated with monoclonal proteins have been proposed.⁷⁸ Even though the neuropathy associated with MGUS is typically a predominantly demyelinating process which can have additional features of axonal degeneration, pure or predominant axonal degeneration also has been reported.⁷⁹ Axonal neuropathy in this setting presents as a mild, symmetric, slowly progressive, predominantly sensory, neuropathy usually limited to the legs. When compared with

MGUS neuropathy of demyelinating type, the axonal process was associated with less vibration and proprioceptive loss, did not include leg ataxia, less often had generalized areflexia, had less prevalence of IgM gammopathy and anti-MAG antibodies, and had lower CSF protein concentrations. Even though fewer patients with axonal neuropathy improved with therapy, the illness was generally milder with less disability.

The treatment of MGUS associated neuropathy is difficult. Plasmapheresis has been studied by many, with variable benefit. In a double blind trial from Mayo Clinic, significant benefit was seen with plasma exchange, especially among those with IgG or IgA MGUS.⁸⁰ Intermittent cyclophosphamide and prednisone has been reported to produce improvements or stabilization of the neuropathy in a small study.⁸¹ Fludarabine has been used with some benefit in patients with IgM associated peripheral neuropathy.⁸² There are scattered reports of benefit from high dose therapy in patients with debilitating peripheral neuropathy.⁸³

The association of neuropathy and monoclonal gammopathy in the presence of osteosclerotic bone lesions is a distinct entity. The constellation of Polyneuropathy, Organomegaly, Endocrinopathy, M protein and Skin changes or POEMS syndrome, also known as osteosclerotic myeloma, Crow Fukase syndrome, or Takasaki syndrome is a poorly understood phenomenon.⁸⁴ These patients usually have sclerotic bone lesions on skeletal survey. Other clinical findings include papilledema, pedal edema, hyperpigmentation, hypertrichosis, gynecomastia, hepatosplenomegaly, and lymphadenopathy. Laboratory testing may reveal abnormalities of multiple endocrine glands, including the thyroid, parathyroid, and adrenals, as well as polycythemia and thrombocytosis. Almost all patients have small amounts of M-protein in the serum, and the associated light chain is lambda in virtually every patient. Patients with single osteosclerotic lesion can often be treated with radiation therapy to the lesion with significant benefit. Patients with multiple lesions often need systemic therapy, and autologous stem cell transplantation has been successful in selected patients.⁸⁵

Motor neuron disease has been associated with MGUS. In a study of 56 patients with motor neuron disease, 6 (10.7%) were found to have a monoclonal protein (4 with IgG and 2 with IgA), compared to a control group of 121 age-matched patients with other neurological disorders, in whom only 5 patients (4.1%) had a monoclonal protein.⁸⁶ Presence of gammopathy in this study appeared to correlate with the absence of marked upper motor neuron involvement and with elevated CSF protein concentration.

Autoimmune disorders such as rheumatoid arthritis,⁸⁷ lupus erythematosus,⁸⁸ and polymyositis⁸⁹ have been reported in association with monoclonal gammopathies. Paraproteins with activity against rheumatoid factor, as well monoclonal anti-nuclear antibodies, have been

reported.⁹⁰ A higher prevalence of anti-phospholipid antibodies have been reported in association with monoclonal gammopathy.⁹¹

DISEASE VARIANTS

Biclonal gammopathies: The simultaneous presence of more than one type of M-protein can be seen in as many as 5% of patients with monoclonal gammopathies. This likely represents the proliferation of two separate clones of plasma cells, producing M-proteins of different immunoglobulin classes. Patients with three different types of M-proteins also have been reported. Most of these were associated with malignant lymphoproliferative disorders, though a few were of undetermined significance. Kyle et al. reported on 57 patients with biclonal gammopathy, of whom 37 had a biclonal gammopathy of undetermined significance.⁹² These patients had clinical features indistinguishable from those with monoclonal gammopathies. The remaining patients with a biclonal gammopathy had myeloma, macroglobulinemia, or another lymphoproliferative disorder. Nilsson et al. found 20 patients (2%) from among 1034 patients with monoclonal gammopathy, who had two distinct monoclonal spikes; 3 were associated with lymphoma, 7 with myelomatosis, 9 with monoclonal gammopathy of undetermined significance (MGUS), and 1 with lupus erythematosus disseminatus.⁹³

Idiopathic Bence Jones Proteinuria: Patients may present with isolated monoclonal FLCs in the urine, or Bence Jones proteinuria. Several patients have been reported with Bence Jones proteinuria, with disease that has remained stable over long periods of follow up. Kyle reported nine patients with Bence Jones proteinuria of over 1 g/24 hours with no serum M-protein and no evidence of another plasma cell proliferative disorder.^{94,95} While symptomatic myeloma developed in three of these patients at 8–21 years of follow up, two were followed for 12 years with no evidence of progression. Similar outcomes have been reported by others.⁹⁶ While patients with idiopathic Bence Jones proteinuria can stay stable over long periods, some studies have suggested an increased risk of progression in patients with light chain proteinuria, and they need to be followed closely.

MANAGEMENT

The cornerstone of the management is regular follow up, so that any disease progression can be detected and appropriate therapy can be instituted. At the time of initial diagnosis, other plasma cell disorders should be ruled out, as mentioned before. Patients with small amounts of M-protein in their serum (< 0.5 g/dL) may

not require a bone marrow examination or skeletal survey, given the low risk of progression seen in this group. However, the choice of tests should be dictated by the clinical assessment, and if suspicion is high, a complete workup, including bone marrow examination, skeletal survey, and urine protein electrophoresis, should be performed. The serum protein electrophoresis should be repeated at least annually to demonstrate stability of the M-protein. Patients with higher levels of M-protein, especially those with over 2 gm/dL, should have metastatic bone survey, quantitation of immunoglobulins, 24 hour urine examination for monoclonal protein, and a bone marrow aspirate and biopsy. A bone

marrow PCLI, if available, should be performed, as this will provide valuable prognostic information. Serum β_2 microglobulin and C-reactive protein should be obtained. If these tests are consistent with the diagnosis of MGUS, serum protein electrophoresis should be performed in three months. If results do not indicate any progression, they should be repeated every 6–12 months. Patients who, at diagnosis, have factors predicting higher risk of progression, will need closer follow up. They should be re-evaluated for progression in the interval period if clinical symptoms or signs raise suspicion for progression. The risk of progression never disappears, and patients need lifelong follow up.

Chapter 90

AMYLOIDOSIS

Madhav V. Dhodapkar

DEFINITION

The term *amyloidosis* is used to describe a heterogeneous group of protein deposition diseases in which misfolding of proteins plays a prominent role.^{1,2} This process generates insoluble toxic fibrillar protein aggregates that are deposited in tissues in a characteristic β -pleated structure. These deposits are identified based on their apple-green birefringence under a polarizing light microscope after staining with Congo red dye, and by the presence of rigid nonbranching fibrils 7–10 nm in diameter on electron microscopy. Historically, the amyloidoses were classified as “primary” when no apparent etiology was evident, and “secondary” when resulting from chronic infectious or inflammatory states.³ In 1971, Glenner demonstrated the presence of immunoglobulin (Ig) light chains in primary amyloid fibrils.⁴ Since then, several other proteins have been characterized, and the chemical nature of the amyloidogenic protein forms the basis of the current classification (Table 90.1).⁵

Pathologically, all amyloid deposits share some common constituents, such as amyloid P component and glycosaminoglycans, but differ in the nature of the precursor protein. Clinically, the amyloidoses are still classified as localized to a single organ, or systemic.⁶ The most common localized form is Alzheimer’s disease, which affects more than 12 million people worldwide.⁷ In the western world, the two most common forms of systemic amyloidosis are AL (or Ig light chain) amyloidosis and reactive amyloidosis due to chronic inflammatory diseases (e.g., rheumatoid arthritis). Hereditary amyloidosis is an ever expanding group of disorders that pose difficult diagnostic problems.⁸ In this chapter, we will largely focus on AL amyloidosis as it is associated with hematologic diseases.

MOLECULAR PATHOGENESIS

PROPERTIES OF AMYLOIDOGENIC PROTEINS

To date, at least 21 different proteins have been recognized as causative agents of amyloid diseases.⁵ Despite

heterogeneous structure and function, all these proteins generate morphologically indistinguishable amyloid fibrils. The current nomenclature for amyloidosis is based on this diversity of precursor proteins. For example, amyloidosis involving Ig light chains (L) or transthyretin (TTR) is classified as AL or ATTR, respectively. The conversion of the native protein into a β -sheet structure is a pathologic process closely linked to physiologic protein folding. The pathogenically misfolded proteins may form in several ways. The protein may have an intrinsic property to assume a pathologic conformation that becomes evident with ageing (e.g., normal transthyretin in patients with senile systemic amyloidosis),⁹ or with persistently high concentrations in the serum (e.g., β -2 microglobulin in patients undergoing long-term hemodialysis).¹⁰ Other mechanisms include mutations in the protein, as in many hereditary amyloidoses, or proteolytic remodeling of the precursors, as in β -amyloid precursors in Alzheimer’s disease. The mechanisms can act independently or together. Other environmental influences, such as proteolysis, pH, and oxidation states, also seem to play important roles in the formation of amyloid fibrils.¹¹

AMYLOIDOGENICITY OF IG LIGHT CHAINS

Only a small proportion of Ig light chains are amyloidogenic. For example, AL amyloidosis occurs in only about 12–15% of patients with myeloma.¹² Certain structural features are related to amyloidogenicity: the λ isotype and the V λ 6 variability subgroup.¹³ Two V λ gene segments, 6a and 3r, seem to contribute to nearly 40% of the amyloidogenic λ light chains.^{14,15} There is some evidence that some of the amyloidogenic light chains undergo antigen-driven selection and mutations.¹⁴ Development of mutations in these proteins can then lead to destabilization of key structural domains and generation of an aggregation prone state.¹⁶ Improved understanding of the mechanisms of amyloidogenicity of the Ig light chains may allow the development of targeted therapies.

MECHANISMS OF TISSUE DAMAGE AND SPECIFICITY

A remarkable aspect of amyloidoses is the diversity of organ distribution. Specific proteins aggregate

Table 90.1 Major types of amyloidosis: Classification and clinical presentation

Type	Precursor	Distribution	Syndrome
AL	Ig light chain	Systemic or localized	Primary amyloidosis
AA	Serum amyloid A	Systemic	Secondary amyloidosis reactive to chronic infections or inflammation, including periodic fever syndromes
ATTR	Transthyretin	Systemic	Prototypic familial amyloid polyneuropathy
		Localized	Senile cardiac amyloidosis
A β	A β precursor	Localized	Alzheimers; ageing
APrP	Prion protein	Localized	Prion associated disorders
ACys	Cystatin C	Localized	Icelandic amyloid angiopathy
AFib	Fibrinogen A α chain	Systemic	Hereditary, renal
A β 2M	β -2 microglobulin	Systemic	Chronic hemodialysis
AApoA1	Apolipoprotein A1	Systemic	Liver, kidney, heart
AApoAII	Apolipoprotein AII	Systemic	Liver, kidney, heart
A Lys	Lysozyme	Systemic	Kidney, liver, spleen
A Gel	Gelsolin	Systemic	Finnish hereditary amyloidosis
AIAPP	Islet-associated peptide	Localized	Amyloid of the islets; Type II diabetes

predominantly in defined target organs: β -2 microglobulin in the joints, fibrinogen A α in the kidney, and the transthyretin Met30 variant in the peripheral nerves.¹⁷ In AL amyloid, virtually every organ may be involved, most commonly the heart, kidneys, nerves, and liver. Importantly, the pattern of organ involvement may differ greatly between patients and seems to determine outcome. The reasons behind differences in organ tropism in different patients is not clear, but may be due to properties of the light chains themselves, or to their interactions with specific tissue glycosaminoglycans or cell-surface receptors, such as the receptor for advanced glycation end products (RAGE).¹⁸

An equally important, but poorly understood aspect of this disease is the mechanism by which the deposited amyloid fibrils cause tissue damage or organ dysfunction. For example, amyloid deposition in the heart due to either light chain or transthyretin-related amyloid leads to different clinical outcomes.¹⁹ Several possible explanations for the mechanism of tissue injury have been put forth. These include interactions with RAGE receptors,¹⁸ inflammatory response due to fibrillar intermediates, or direct cytotoxicity of oligomeric precursors.²⁰ Several clinical clues suggest that some of these mechanisms may be operative in AL amyloid as well. For example, significant improvement in organ function may occur after chemotherapy has halted the production of amyloidogenic light chains, but before the expected resolution of the amyloid deposits in the involved tissues.^{11,21} Improved understanding of the mechanism of amyloid-associated tissue injury may allow novel approaches to

preserve organ function and prolong survival in these patients.

CLINICAL FEATURES

Clinical features in this group of diseases is highly diverse and depends on the nature of the organs involved. The nature of the amyloid (e.g., AL, ATTR) is a key determinant of pattern of organ involvement and dysfunction. Clinically, it is still useful to think in terms of localized or systemic forms of amyloidosis.⁶

LOCALIZED AMYLOIDOSES

Localized deposits of amyloidosis in the genitourinary tract (e.g., bladder, ureter) or tracheobronchial tree (e.g., vocal cords) are nearly always localized, even though the fibrils themselves are often AL.^{22,23} Skin amyloid is often localized and can be classified into lichen, macular, or nodular. The lichen and macular forms are easily treated with surgical resection. A common presentation of localized soft-tissue amyloid is carpal tunnel syndrome, which is generally treated with surgical release. These patients do not have systemic plasma cell dyscrasia and do not require systemic therapy.

SYSTEMIC AMYLOIDOSIS

Immunoglobulin light chain-associated amyloidosis (AL)

AL is derived from Ig light chains, and most patients have plasma cell dyscrasia.^{24,25} Patients regularly have free light chains detectable in the serum or the urine.

The clonal burden of plasma cells, however, is low and most patients have less than 10% plasma cells. Presence of lytic bone lesions and significant marrow plasmacytosis (more than 30%) should lead to a diagnosis of associated myeloma. However, in most instances, the clonal plasma cell burden in AL amyloidosis is nonprogressive, analogous to monoclonal gammopathy of undetermined significance or smoldering myeloma. It is the unique biologic properties of the light chain that leads to organ dysfunction and shortened survival.

Patients with AL generally present with one of the following seven syndromes:

1. Cardiomyopathy, with or without congestive heart failure,
2. Nephrotic range proteinuria, with or without renal insufficiency,
3. Hepatomegaly with elevated serum alkaline phosphatase,
4. Axonal peripheral neuropathy,
5. Autonomic neuropathy manifest as orthostatic hypotension,
6. Small intestinal involvement leading to pseudo-obstruction and alternating constipation and diarrhea, and
7. Soft-tissue involvement leading to arthropathy, macroglossia, and jaw or limb claudication.

These clinical features are consistent with AL, but there is significant overlap with other forms of amyloid, including AA, AF, or dialysis-associated amyloid.^{24,25} It is therefore critical to establish the correct type of amyloid before initiation of therapy.

The dominant organs/systems involved in AL are cardiac, renal, neurologic, and gastrointestinal. Symptomatic cardiac involvement occurs in up to 25–50% of patients.⁶ Cardiac manifestations mainly reflect myocardial involvement, and patients present with restrictive cardiomyopathy and diastolic dysfunction. Echocardiography is the most important tool in the diagnosis of cardiac involvement. The major echocardiographic features are increased left ventricular wall thickness, left atrial enlargement, and diastolic dysfunction, though these are not specific for AL amyloidosis.²⁶ Serum levels of troponins and brain natriuretic peptide appear to correlate with cardiac involvement and prognosis in early studies.^{27,28} Renal involvement is generally manifest as nephrosis or renal insufficiency, and present in over half of the patients at diagnosis.²⁹ Sensorimotor peripheral neuropathy is present at diagnosis in about 15–30% of patients.³⁰ Autonomic neuropathy often co-exists with peripheral neuropathy and may present as orthostasis, or gut/bladder motility disturbances.

Secondary amyloidosis (AA)

The most common manifestations of secondary (AA) amyloidosis are nephrotic range proteinuria and bowel

involvement with diarrhea. AA may therefore be difficult to distinguish from AL.³¹ In the west, AA mostly occurs in the setting of chronic inflammatory conditions (such as poorly controlled rheumatoid arthritis or ankylosing spondylitis), or chronic infections (e.g., osteomyelitis).²⁵ In the developing countries, AA is much more common as a complication of tuberculosis, leprosy, or malaria. In the Middle East, familial Mediterranean fever (FMF) is a common cause of AA. Although most patients do have an antecedent history of attacks of polyserositis, rash, or arthritis, there are genetic pedigrees of FMF, wherein AA can develop without antecedent symptoms.³²

Familial amyloidosis (AF)

Familial forms of amyloid are more common than AA. The most common presentation is progressive axonal peripheral and autonomic neuropathy.¹⁷ However, patients can present with cardiomyopathy or with hepatic or renal amyloid. The most common forms of familial amyloidoses are due to mutations in the transthyretin (TTR) molecule.⁹ To date, more than 60 mutations in the *TTR* gene have been described and associated with amyloid neuropathy. Nearly half of these patients do not have a family history. Therefore, an absence of family history does not exclude the diagnosis of AF. A distinct type of AF is seen in African American men. An allele of TTR called isoleucine 122 (*Ile122*) is carried by 3.9% of African-Americans.¹⁹ The inheritance of this allele is a major cause of cardiac amyloidosis in elderly African American men. Cardiac amyloidosis can also occur from the deposition of wild type, as opposed to mutant, TTR. This form, referred to as “senile cardiac amyloidosis,” occurs in 10–25% of people older than 80 years. Inherited forms of renal amyloid also occur, generally manifest as nephrosis. The amyloid in these instances may be a mutant fibrinogen-A- α chain, mutant lysozyme, apolipoprotein-A-I, or A-II. The distinction between AF and AL is critical and of more than academic importance. For example, liver transplantation done before the development of severe neuropathy or cardiomyopathy can produce durable regressions in patients with transthyretin-related amyloidosis.³³

DIAGNOSTIC WORKUP

The diagnosis of amyloidosis depends on the pathologic demonstration of typical congophilic deposits. The most common strategy is to take the biopsy from the most easily available tissue. Small amyloid deposits often occur in subcutaneous tissue of most people with AL or AA amyloidosis. For this reason, an abdominal fat aspirate is often used as an initial screen. However, a negative result does not exclude a diagnosis of AL, and other sites, such as rectal mucosa, marrow, and particularly the involved organ may need to be sampled.

The most important element of the diagnosis is typing of the amyloid deposit, as several amyloid states can have overlapping features. The presence of serum or urine monoclonal protein strongly supports AL amyloid. However, monoclonal proteins can be incidental in 3% of elderly patients.³⁴ Therefore, there would be a small false positive rate if this were the only criterion used. Most amyloid treatment centers recommend typing of the tissue with commercial antisera for AA, TTR, and κ and λ light chains. Antisera are also available for other proteins such as fibrinogen, lysozyme, or apolipoprotein, but are reserved for more complex cases.

Once the diagnosis and type of amyloid have been established, the next step is to determine the extent of organ dysfunction. In AL amyloidosis, evaluation of renal function (e.g., 24-hour urine collection for immunofixation and total protein) and cardiac involvement (e.g., echocardiogram, holter monitor, serum troponin, and brain natriuretic peptide) should be undertaken even in the absence of symptoms. Studies to evaluate the underlying clone in AL amyloid should include bone marrow biopsy, studies to quantify monoclonal Ig in the serum and urine, serum-free light chains, serum β -2 microglobulin, and a skeletal survey to exclude lytic bone disease. Other evaluations, such as electromyogram and stool studies for malabsorption, are based on the nature of disease-related symptoms. Radiolabeled serum amyloid P component (SAP) has been used to image amyloid involvement, but this test has limited availability.³⁵ Approaches to visualize AL deposits in a noninvasive fashion are an area of active research.

PROGNOSTIC FACTORS

The heterogeneity of clinical features and outcome in AL amyloidosis have inspired attempts to identify key determinants of prognosis in these patients. Presence of congestive heart failure and the total number of organs/systems involved are predictive of adverse outcome in several studies.²⁵ However, these features are quite subjective and may depend on the extent of evaluation of organ involvement. More recent studies have begun to test more objective criteria based on laboratory tests that have predictive value in other plasma cell diseases. These studies have identified serum level of β -2 microglobulin and markers of cardiac involvement (brain natriuretic peptide and troponins) as dominant predictors of outcome.^{27,28,36,37} Assessment of prognostic factors is likely to assume major importance in the therapy of AL, as patient selection has a major effect on the outcome with some newer approaches (such as high-dose chemotherapy). Ongoing research will help clarify the impact of light chain variable region (VL) usage and other features of the amyloidogenic protein as predictors of outcome in AL.³⁸

EVALUATION OF RESPONSE

Evaluation of response to therapy in AL amyloidosis is largely based on surrogate measures that assess improvement in the underlying plasma cell clone and in AL-related organ dysfunction.³⁹ The hematologic response definition is quite comparable to that used in multiple myeloma, though the level of the monoclonal Ig in AL is quite low compared to myeloma. Most AL treatment centers also follow serum levels of free light chains as surrogate markers,⁴⁰ although this assay has not yet been fully incorporated or compared with the traditional response criteria used in most published studies with AL amyloid. Currently, improvement in AL-related organ dysfunction remains the gold standard by which the clinical efficacy of therapies against AL amyloid is judged. Although a consensus is beginning to emerge, these criteria are somewhat arbitrary. It is notable that histologic evidence of regression of AL deposits has not been documented in most studies. Indeed, improved organ function can occur without actual regression of amyloid deposits.²¹

PRINCIPLES OF THERAPY

Most of the current therapies in AL and other amyloidoses are targeted toward the amyloidogenic precursor. The underlying principle is that deposition/resorption of amyloid is a dynamic process. Reduction in precursors or inhibition of amyloid formation will therefore shift the balance toward regression of deposits. A greater degree of reduction in precursors may lead to more durable responses. As the precursors themselves may be responsible for organ dysfunction, this approach may also help preserve organ function.

For example, therapies targeted to the underlying plasma cell clone may lead to reduction in amyloidogenic light chains, and thereby improved organ function.¹ Improvement in dialysis-related β -2 microglobulin can occur with renal transplantation to reduce the levels of serum β -2 microglobulin. In patients with ATTR, liver transplantation has been pursued to provide a source of normal TTR from the transplanted liver. Durable regressions have been observed in several patients in whom liver transplantation was done before the development of severe neuropathy or cardiomyopathy.³³ Patients who receive such transplants late in the disease course, however, can show disease progression due to the deposition of wild type TTR in the heart that already has a nidus of mutant TTR.

SUPPORTIVE CARE

Another important advance has been the improvements in supportive measures for AL-related organ

dysfunction.⁶ Careful attention to intravascular volume and cardiac function is essential. Many patients with renal involvement require assistance in the form of dialysis, although renal transplants have also been performed in some patients with otherwise good risk disease. Amyloidosis can develop in the graft if the precursor protein is not well controlled. Orthostasis can be treated with elastic stockings, fluorocortisone, and midodrine. Refractory diarrhea has been treated with antidiarrheals, somatostatin analogs, and even diverting colostomies.

SPECIFIC THERAPY FOR AL AMYLOIDOSIS

MELPHALAN AND PREDNISONE

The use of melphalan and prednisone (MP) to treat AL amyloidosis followed their establishment as effective therapy for multiple myeloma. A three-arm trial randomized 219 patients to colchicine alone, oral melphalan (0.15 mg/kg per day for 7 days) and prednisone (0.8 mg/kg per day for 7 days) every 6 weeks, or a combination of melphalan, prednisone, and colchicine (MPC).⁴¹ The median survival for patients receiving MP was 17 months, compared to 8.5 months for colchicine alone. Another trial comparing MPC to MP found improved survival with MP-based therapy.⁴² These studies have helped establish MP as one of the standard approaches to treat AL. However, most patients do not respond to this therapy, with objective responses seen in only 15–20% of patients. Most of these responses are limited to the patients with renal-only disease with preserved renal function. The median time to response is long (12 months), which necessitates prolonged therapy. This, however, has other consequences, such as the development of myelodysplasia or acute leukemia (actuarial risk of 21% at 3.5 years).⁴³ In spite of these limitations, MP is used frequently in the therapy of AL, particularly in older patients, as it is relatively well tolerated.

DEXAMETHASONE BASED THERAPIES

In 1997, Dhodapkar et al. first described the clinical activity of dexamethasone (DEX) in AL amyloidosis.⁴⁴ Several studies have since confirmed this finding.^{45–48} In a recent US Intergroup trial, 93 patients were treated with induction therapy with pulsed DEX, followed by DEX and alpha interferon as maintenance.³⁷ Complete hematologic remissions (CHR) were observed in 24%. Improvement in AL-related organ function was seen in 45% of patients. Overall survival in the entire cohort was 31 months. The presence of congestive heart failure (CHF) and elevated serum β -2 microglobulin were dominant adverse prognostic factors. Patients with both of these features do poorly with DEX and should not be treated with this regimen. DEX has also been administered as a part of regimens that include melphalan⁴⁹ or doxorubicin-vincristine,⁴⁵ with promising

results. However, whether the addition of these agents adds significantly to DEX alone remains unclear. The use of melphalan may have an impact on stem cell collection in patients eligible for stem cell transplantation, and should therefore be avoided before stem cell collection.

The tolerance to DEX in AL amyloid is lower than that in myeloma. This has prompted investigators to use reduced doses at the initiation of therapy, with dose escalation based on tolerance. Controlled studies are needed to compare DEX-based regimens to MP and to stem cell transplantation. Recent studies have identified the activity of several new drugs, such as thalidomide and bortezomib in combination with DEX in myeloma.^{50,51} These regimens are currently undergoing active evaluation in the therapy of AL amyloidosis.

STEM CELL TRANSPLANTATION IN AL AMYLOIDOSIS

The utility of high-dose melphalan and autologous stem cell transplantation in myeloma has been demonstrated through controlled studies. This has prompted several investigators to pursue this form of therapy in AL amyloidosis. Most of the published data are from a few amyloid centers.^{52–54} The largest experience is from Boston University Medical Center. In the last update, 394 of 701 patients evaluated were eligible for this form of therapy.²¹ Hematologic complete remissions (HCR) were observed in 40% of patients. Improvement in at least one organ was seen in 66% of patients with HCR and 30% of those without HCR. Median survival of the entire cohort was 4.6 years, but the early mortality was 13%. These data suggest that durable improvements in AL-related organ function can be achieved in AL amyloid using high-dose chemotherapy. Due to the higher transplantation-related mortality, some investigators are now pursuing risk-adapted approaches to melphalan dosing.⁵⁵

Although the data with autologous stem cell transplantation (ASCT) are promising, the degree to which they are impacted by patient selection factors remains unclear. Survival of patients eligible for transplantation, but treated with other approaches, is comparable to that reported in the ASCT experience in at least two, but not all studies.^{37,56,57} These data underscore the need for controlled trials to address the value of high-dose melphalan and ASCT in AL amyloid. We recommend that the application of high-dose chemotherapy and stem cell transplantation in AL amyloidosis be carried out only in the context of clinical trials, or by groups experienced in this approach.⁵⁵

NEWER INVESTIGATIONAL APPROACHES

In view of the activity of several new agents in myeloma, these agents are now also being tested in patients with AL amyloidosis. However, the tolerance to drugs such as thalidomide is lower in this patient

population.⁵⁸ Based on its binding to amyloid fibrils in vivo, iododeoxydoxorubicin was tested in a phase I/II trial, but yielded a low (15%) response rate as a single agent.⁵⁹ Hrnčić et al. reported on an experimental model in which injection of antibody directed against amyloidogenic light chains led to regression of amyloid deposits.⁶⁰ This has not yet been tested in humans. Another approach in early clinical testing involves targeted pharmacologic depletion of serum amyloid P component, which may have broad utility in several amyloid states.⁶¹

CONCLUSIONS

The amyloidoses are a diverse group of disorders characterized by pathologic protein folding, conformation, and deposition.^{1,2} These disorders exhibit considerable clinical heterogeneity but share many pathogenic mechanisms. Current therapies are directed mostly toward reducing the supply of precursor proteins. Improved understanding of the pathogenic mechanisms is likely to yield novel approaches to therapy of these diseases.

Chapter 91

TREATMENT OF COMPLICATIONS IN MULTIPLE MYELOMA

Paul Masci

Although multiple myeloma (MM) is classified under the heading of indolent non-Hodgkin's lymphomas, the pathophysiologic mechanisms of this disease often cause significant morbidity. Long-term survival rates for patients with MM have consistently improved over the last 30 years.¹ Thus, managing the acute and chronic complications of this disease can be challenging. This chapter will review the basic mechanisms of target organ complications of MM and provide a summary of literature-based recommendations for managing such complications.

ANEMIA

Anemia in the patient with MM is defined by a hemoglobin value 2 gm/dL below the institutional limits of normal or a hemoglobin concentration less than 10 gm/dL.² It is present in approximately two-thirds of newly diagnosed patients and will eventually occur in nearly all patients.² The causes are multifactorial and include the replacement of normal hematopoietic cells by the expanding plasma cell burden, myelosuppression related to chemotherapy, and an increase of plasma volume secondary to high serum M-protein levels, which may lead to spurious declines in hemoglobin concentration.³ Importantly, overproduction of interleukin-6 (IL-6) in the bone marrow microenvironment can cause an attenuated response to erythropoietin.⁴ This process may be exacerbated in patients who have compromised renal function and lower endogenous erythropoietin levels.

The use of exogenous recombinant erythropoietin has been studied in patients with MM. Small, single institution studies suggested benefit in those patients with low endogenous levels.^{5,6} Subsequent randomized trials have confirmed this benefit.^{7,8} In a double-blinded study, 25 patients were randomized to receive placebo or erythropoietin 150 U/kg three times per week for 6 weeks.⁷ The dose was doubled in nonresponders after 6 weeks in the erythropoietin group; patients in the placebo arm were

crossed over to receive erythropoietin in an open label fashion if no response was observed after 12 weeks on study. Although the number of evaluable patients was small ($n = 20$), the results were significant. Sixty percent of the patients receiving erythropoietin had a complete response, whereas no responses occurred in the placebo group. Thirty percent of these patients did have a complete response when crossed over to receive erythropoietin. The median dose for the responding group was 120 U/kg. The type of chemotherapy and pretreatment serum erythropoietin levels did not predict response to exogenous erythropoietin.⁷

A second trial included 120 transfusion-dependent patients with either MM or low-grade non-Hodgkin's lymphoma. Patients were randomly assigned to receive either a fixed dose or an escalating dose of erythropoietin, or placebo.⁸ Response, defined by elimination of transfusion need and an increase in hemoglobin by at least 2 gm/dL, occurred in 60% of those patients receiving erythropoietin. No difference in response was found for the fixed versus escalating dose of erythropoietin.⁸ Multivariate analysis did suggest that endogenous erythropoietin level was the most important predictor of response.⁸

As these trials included small numbers of patients, the current consensus guidelines do not recommend the routine use of erythropoietin in MM patients not receiving chemotherapy. For those MM patients receiving chemotherapy, or with no improvement in hemoglobin following control of disease, erythropoietin use is recommended if a hemoglobin level ≤ 10 gm/dL is observed.⁹ Guidelines for recombinant erythropoietin use are presented in Table 91.1.

A large retrospective study suggested that approximately 14% of newly diagnosed plasma cell dyscrasia patients have serologic evidence of B₁₂ deficiency.¹⁰ Newly diagnosed MM patients should be screened for B₁₂ deficiency by use of serum B₁₂ and methylmalonic acid (MMA) levels. In the absence of renal insufficiency, a serum B₁₂ level < 200 pg/mL or a serum B₁₂ level 200–300 pg/mL with an elevated MMA are diagnostic

Table 91.1 Recommendations for erythropoietin use in multiple myeloma

- Consider for all MM patients receiving chemotherapy with a hemoglobin level ≤ 10 g/dL. There is no satisfactory data to support routine erythropoietin use in MM patients in the absence of chemotherapy.
- Most trials have studied multiple doses per week. The recommended starting dose is 150 U/kg three times per week for a minimum of 4 weeks. The dose may be escalated to 300 U/ μ g three times weekly for up to 4–8 more weeks if no response to initial dose. The evidence for once weekly dosing, i.e., 40,000 units, is less strong, but acceptable clinically.
- The dose can be titrated to maintain hemoglobin levels at or near 12 g/dL. Erythropoietin may also be held and restarted once hemoglobin levels decline 10 g/dL. Patients who do not respond to optimized doses by 6–8 weeks are unlikely to do so and erythropoietin should be discontinued.
- The use of erythropoietin in patients with isolated plasmacytoma, or other plasma cell dyscrasia is not recommended. Anemia in these patients should prompt further work-up for underlying MM.

Adapted from Ref. 9

of B₁₂ deficiency.¹⁰ Such patients should receive vitamin B₁₂ replacement therapy.

HYPERCALCEMIA

Hypercalcemia may be observed in approximately 15–30% of newly diagnosed patients with MM.^{11,12} The mechanism of hypercalcemia is likely due to increased osteoclastic resorptive activity.¹³ Calcium levels should be corrected for serum albumin. Furthermore, some patients may have spurious elevations of serum calcium because of increased binding by paraproteins. Therefore, ionized serum calcium levels should be measured to aid in the diagnosis of hypercalcemia for patients with high monoclonal protein levels.³

Clinically, hypercalcemia is associated with lethargy, confusion, polydipsia, polyuria, constipation, and nausea.¹¹ Untreated hypercalcemia will lead to renal insufficiency, a problem to which patients with MM are already prone. Therefore, prompt treatment once recognized is essential.

Urgent treatment of hypercalcemia is accomplished through increased urinary calcium excretion by volume expansion with intravenous saline. The addition of diuretics to aid in maintaining adequate urine output and calciuresis may cause other electrolyte abnormalities and exacerbate volume depletion. Therefore, diuretics are probably best avoided in the initial management of hypercalcemia. Some investigators recommend corticosteroids, i.e., prednisone 25 mg daily as an adjunctive treatment.¹²

Bisphosphonates inhibit the resorptive action of osteoclasts (see the next section on skeletal complications) and can be effective in the management of hypercalcemia in the patient with MM.^{14,15} Two bisphosphonates, pamidronate (Aredia; Novartis Pharmaceuticals, East Hanover, NJ) and zoledronate (Zometa; Novartis Pharmaceuticals, East Hanover, NJ) have been studied for the treatment of hypercalcemia of malignancy.¹⁶ One large randomized trial suggested that zoledronate (4 mg or 8 mg) may be superior to pamidronate (90 mg) in achieving corrected serum calcium levels to less than 10.8 mg/dL, time to response, and duration of response.¹⁶ However, this study, which included 275 eligible patients with hypercalcemia of malignancy, enrolled only 23 (8.4%) with MM.¹⁶ Therefore, it is reasonable to treat MM patients with hypercalcemia with either agent.

RENAL COMPLICATIONS

Renal insufficiency is found in up to 20% of patients with MM at the time of diagnosis and about 10% of all patients will eventually develop severe renal failure.^{2,17} The morbidity and mortality of this complication is significant; MM patients account for approximately 0.9% of the dialysis patients in the United States and up to 2% of dialysis patients in Great Britain.^{17,18} A review of the United States Renal Data System reveals that the 2-year all-cause mortality for dialysis patients with MM/light chain disease is higher than for all other dialysis patients (58% vs 31%; $P < 0.01$ by log-rank test).¹⁸

Several independent mechanisms are responsible for the acute and chronic renal insufficiency observed in patients with MM: direct tubulointerstitial damage and cast nephropathy caused by filtered free light-chain proteins (Bence-Jones proteins), light chain deposition disease, primary amyloidosis, hypercalcemia, and, rarely, type I myeloma associated cryoglobulinemia.

Filtered light-chain proteins (both κ and λ) can cause an acute or chronic renal insufficiency by two pathophysiologic mechanisms.^{19,20} In vitro studies suggest that human-derived light-chains are directly toxic to proximal tubular cells in rat nephrons causing both altered function and morphology in a perfusion, time-dependent fashion.¹⁹ This mechanism is believed to underlie the tubulointerstitial nephropathy found in patients with MM.¹⁹ Light-chain proteins may also form intraluminal proteinaceous casts through noncovalent binding with the normally present Tamm-Horsfall glycoproteins.²¹ These casts can obstruct the distal tubules, leading to an obstructive cast nephropathy (“myeloma kidney”).²⁰ Increasing calcium, sodium, and chloride concentrations in the tubule fluid can augment the aggregation of light-chains and Tamm-Horsfall protein.²² Dehydration can cause both decreased filtrate flow and increased light-chain concentration, further

accelerating cast formation.²³ Therefore, obstructive cast nephropathy usually manifests as acute renal insufficiency with nonnephrotic clinical features.

Multiple myeloma patients with acute renal insufficiency may benefit from plasma exchange or plasmapheresis. A small randomized trial was conducted in which patients with MM and Bence-Jones proteinuria (> 1 g/day) were randomly assigned to receive plasma exchange or control.²⁴ Twenty-nine patients were enrolled, 24 of whom initially required dialysis; the five not requiring dialysis had serum creatinine levels in excess of 5 mg/dL. All patients received concurrent therapy with cytotoxic drugs and corticosteroids. Those in the plasma exchange group underwent a 3–4 L exchange per day for five consecutive days. Patients in the plasma exchange group had a significant reduction in proteinuria ($P < 0.01$) associated with a significant increase in urine output ($P < 0.001$) compared to the control group.²⁴ Thirteen of the 15 patients (87%) allocated to plasma exchange no longer required dialysis at the end of the study period, with an average serum creatinine recovery of 2.6 mg/dL, while only two of the 14 patients (14%) in the control group improved with cytotoxic treatment alone.²⁴ Importantly, a significant improvement in 1 year overall survival was observed when compared to the control group (66% vs 28%; $P < 0.01$).²⁴

The importance of the tubular cast burden in a similar population of patients was described in a trial of plasmapheresis.²⁵ Twenty-one patients with overt MM all received cytotoxic therapy, corticosteroids, and forced diuresis. Eleven were randomly assigned to receive plasmapheresis three times per week for 1 to 4 weeks. Renal biopsies were performed on nine of the patients in the plasmapheresis group and seven of the patients in the control group. The patients in the two groups had similar outcomes, with no differences observed between groups for improved serum creatinine value, need for long-term hemodialysis, or overall median survival (approximately 18 months for both).²⁵ However, blinded evaluation of renal biopsy specimens (available from 16 patients on trial) for myeloma cast formation and tubulointerstitial changes consisting of inflammation, atrophic loss, and fibrosis was performed. Five out of seven patients (71%) with 2–3+ cast formation went on to require hemodialysis, while only two of nine (22%) with $\leq 1+$ cast formation became dialysis dependent.²⁵

The results of these two small studies may seem conflicting. However, they differed in choice of pheresis technique and cytotoxic regimen. Also, patients in the second study had an average time from recognition of renal impairment to study entry of 1.21 months.²⁵ This suggests that patients with acute renal insufficiency caused by myeloma kidney with low disease burden may benefit from plasma exchange if it is instituted with cytotoxic chemotherapy soon after recognition of impaired renal function. Indeed, an

empiric trial of plasmapheresis in any MM patient with acute renal failure not initially responsive to volume replacement is warranted as renal biopsy is logistically impractical in all patients.¹²

Light-chain (rarely heavy chain) deposition disease and primary amyloidosis are pathophysiologically similar. Both are histologically characterized by the deposition of immunoglobulin (Ig) light or heavy chains within various body tissues. Amyloid protein (usually λ light chain) deposition is histologically and molecularly unique in the formation of characteristic β -pleated fibrils identified by an apple-green color when stained with Congo red dye. Light-chain (usually κ light chain) and the rare heavy-chain deposition diseases lead to a nonfibrillary accumulation of light (or heavy) chains. In the kidney, light chain deposition is detected by immunohistochemical staining and found in a linear distribution within the glomerular and/or tubular basement membranes.²⁶ Electron microscopy may reveal granular electron dense deposits in the same places.²⁶

Generally, the clinical manifestation of renal light chain or amyloid deposition is nephrotic range proteinuria with a nonoliguric, chronically progressive renal insufficiency. Treatment of patients with advanced renal disease from amyloid or light-chain deposition disease is often unsatisfactory. However, a multicenter trial including 64 patients with renal impairment from amyloidosis treated with a pulse dose strategy of dexamethasone demonstrated improved renal function in 39% at a median of 4 months.²⁷

In summary, patients with acute renal insufficiency caused by cast nephropathy may have improvement with hydration, plasma exchange, and treatment of the underlying MM. Those with amyloid or light-chain deposition disease may benefit from dexamethasone treatment. All patients with MM should be encouraged to drink liberal amounts of water and avoid the use of non-steroidal anti-inflammatory drugs (NSAIDs). Clinicians should use intravenous contrast judiciously in patients with MM, especially in those with volume depletion and heavy urine light-chain excretion, as the risk of precipitating acute renal insufficiency is increased in these patients.²⁸ Hypercalcemia should be corrected promptly in these patients, as they may be especially prone to exacerbations of underlying chronic renal insufficiency.

INFECTIOUS COMPLICATIONS

Infectious complications are frequent in patients with MM and an important cause of mortality in this disease.²⁹ Data suggest that approximately 25% of newly diagnosed patients initially seek care because of recurrent infections, especially of the respiratory and urinary tracts.^{30,31} The underlying mechanisms leading to compromised immune function in patients with MM

are incompletely understood, but are likely related to defects in both primary and secondary immune responses. Low serum levels of normal Ig in patients with MM have long been recognized, and an imbalance in the proportion of Th1 to Th2 cells has recently been described.^{32,33} Patients receiving cytotoxic chemotherapy and corticosteroids may be further immunocompromised due to myelosuppression.

Hypogammaglobulinemia may account for the increased susceptibility to polysaccharide encapsulated organisms, particularly at the time of diagnosis and following initial treatment (see next).^{34,35} However, infections with gram negative bacilli and *Staphylococcus aureus* appear to be more common causes of serious and lethal infections in those patients undergoing chemotherapy within the first 2 months after diagnosis.³⁶⁻³⁸ In addition, such infections frequently necessitate delaying chemotherapy. Efforts to reduce the occurrence of infection in those patients undergoing initial treatment are warranted.

Trimethoprim-sulfamethoxazole (TMP-SMX) has been investigated as a prophylactic agent in a small, randomized, multicenter trial of newly diagnosed patients undergoing chemotherapy for MM.³⁵ This antibiotic was chosen based on low expense, tolerability, and previous experience in other patients with other causes of immunocompromise.³⁵ Fifty-seven patients with MM were randomized to receive prophylaxis consisting of two TMP-SMX 80/400 mg tablets every 12 hours for 2 months, or to a control group that received no prophylaxis. Chemotherapy was administered to all patients; 50% received melphalan plus prednisone, while all others received more intensive combination chemotherapy. The two groups were well balanced with respect to age, gender, and stage of disease. Data collection continued for 3 months after the start of chemotherapy for patients in both groups. Fifty-four patients of the 57 entered were evaluable. Overall, 12 (46%) of the patients assigned to the control group and five (18%) of the patients who received TMP-SMX experienced any infection during the 3 month observation period ($P = 0.04$).³⁵ Bacterial infections were significantly more frequent during the first 2 months in the control group compared to the prophylactic group (35% vs 4%; $P = 0.004$).³⁵ Although not statistically significant, four deaths occurred in the control group while only one occurred in the prophylactic group.³⁵ TMP-SMX caused skin rash requiring cessation of treatment in six (21%) patients. One patient developed exfoliative dermatitis.³⁵

Although reactions to TMP-SMX were observed, this study demonstrated that prophylactic administration of antibiotics is feasible and may confer clinical benefit. The practice of administering a prophylactic antibiotic is not routinely followed, but some centers do recommend prophylaxis for all patients undergoing initial chemotherapy.³⁹ The choice of agent is not settled, and an National Cancer Institute

(NCI)-sponsored trial is currently ongoing comparing TMP-SMX, a fluoroquinolone, or placebo in a similar patient population.

Hypogammaglobulinemia has been suggested to be the cause of susceptibility to infections with polysaccharide encapsulated organisms in patients with MM, similar to infections in patients with primary Ig deficiency.³⁴ Moreover, myeloma patients appear to be more prone to pathogens such as *Streptococcus pneumoniae* or *Haemophilus influenzae* in the time period following initial chemotherapy. Efforts to enhance secondary immune function with passive immunization by administration of intravenous immunoglobulin (IVIG) have been evaluated.

Results from a phase I trial demonstrated that IVIG could be safely given to patients with MM.⁴⁰ Seventeen patients were given doses of IVIG ranging from 150 mg/kg to 500 mg/kg. The infusions were well tolerated, with no significant toxicities. The investigators measured functional antibody to hepatitis B surface antigen and found a range in the half-life from 7 to 20 days for the entire group.⁴⁰ The kinetics of the antibody did not appear to be related to the M-protein subtype or baseline native immunoglobulin G (IgG) levels.⁴⁰

To assess the prophylactic role of IVIG in preventing serious infections, a prospective, randomized, double-blinded, placebo-controlled, multicenter trial including patients with stable phase MM was conducted.⁴¹ Patients were not eligible if they had early, progressive, or terminal MM or received any prophylactic antibiotics within the 2 weeks preceding study entry.⁴¹ Eighty-three patients were enrolled and randomized to receive IVIG 0.4 g/kg or placebo (0.4% albumin) every 4 weeks for 1 year. Patients were stratified by baseline Ig levels. Severity of infection was prospectively defined; major infections included culture positive sepsis or clinical sepsis syndrome without documented organism, meningitis, and pneumonia requiring hospitalization. Moderate infections consisted of acute bronchitis, upper respiratory or urinary tract infections, skin cellulitis or abscess, and localized zoster. Serious infections included all those considered major or moderate, whereas infections were considered minor if antibiotics were not clinically indicated. Patients were well balanced with respect to age, stage, and performance status. Thirty-two of the 42 (76%) patients randomized to IVIG and 26 of the 41 (63%) patients in the placebo group had baseline Ig levels below normal.⁴¹ No episodes of sepsis or pneumonia occurred in the IVIG treatment group, whereas 10 episodes occurred in the placebo group ($P = 0.002$).⁴¹ Respiratory infections other than pneumonia were also significantly less frequent in the IVIG group (6 episodes vs 18; $P = 0.0097$).⁴¹ Three patients withdrew from the IVIG group because of infusion reactions. No comment was made as to how baseline Ig levels affected outcome. However, analysis of 54 patients who had received Pneumovax 1 month prior to study entry

showed that those with poor response to the vaccine (i.e., less than twofold increase or final specific IgG < 40 U/mL) who also received IVIG had six episodes of infection compared with 16 episodes in poor responders in the placebo arm during 128 patient-month follow ups ($P = 0.033$).⁴¹ The short follow-up did not allow for survival analysis.⁴¹ The implication is that those patients who are unable to mount an immune response may benefit from IVIG during stable phase MM. Until further studies exploring risk of infusion reactions, overall survival, quality of life (QOL), and cost effectiveness are available, the routine use IVIG in stable phase MM patients is not routinely recommended. Similarly, there are no prospective data to suggest benefit from IVIG in MM patients with acute bacterial infections.

Patients with hematologic malignancies often inquire about yearly influenza vaccination, and physicians differ on their recommendations. Data is available to guide decision making. Thirty-four consecutive patients with either a chronic lymphoproliferative disorder ($n = 28$) or MM ($n = 6$) were given a virosomal influenza vaccine preparation.⁴² The MM patients had a mean time from diagnosis to study entry of 3 years (range 1–11). A hemagglutinin inhibition assay (HAI) to assess antibody response to three strains of influenza was performed on all patients at baseline and 1 month after vaccination. Seroconversion (HAI titre $\geq 1:20$ in previously seronegative subjects, or a fourfold or greater increase of the titre in previously positive subjects) to all three strains occurred in three of the six (50%) MM patients; seroconversion to at least two of the three strains was documented in two (33%) MM patients, and no response occurred in one patient.⁴² Two mild injection site reactions were reported for the entire 34 patient study population, and none of the MM patients in this study developed influenza in the ensuing 3-month follow-up.

A separate study evaluated the response of MM patients to immunization with pneumococcal (Pneumovax II) and *H. influenzae* type b (Hib) vaccination. Fifty-two MM patients, of whom seven patients had undergone high-dose therapy with autologous stem cell transplantation within the preceding 6 months, were offered vaccination.⁴³ At baseline, 94% of the patients had *S. pneumoniae* antibody titers below the protective level. Postvaccination, 39% achieved protective levels. Similarly, 54% of patients had nonprotective titers of *H. influenzae* antibodies, whereas 75% developed protective titers following vaccination.⁴³ High-dose therapy followed by autologous transplant predicted for poor response to Hib vaccine ($P = 0.04$).⁴³ These results suggest that routine measurement of antibodies in patients with MM to both *S. pneumoniae* and *H. influenzae* should be performed and, if found to be low, vaccination should be offered.

SKELETAL COMPLICATIONS

The skeletal complications of MM are the most distressing of all the end-organ complications encountered in this disease. Osteopenia and lytic bone lesions are a cause of disabling pain and pathologic fractures. Spinal cord compression may result as well. Thirty percent of patients will present with nonvertebral fractures and more than 50% will present with back pain or vertebral fractures.^{44,45} Approximately 80% of patients will have radiographic evidence of osteoporosis, lytic lesions, or fractures at the time of diagnosis.²

Osteoporosis, focal lysis, and hypercalcemia all result from increased osteoclastic activity. The molecular mechanism causing this enhanced activity is incompletely understood, but continues to be an area of intense investigation. The current paradigm proposes that an imbalance in osteoprotegerin (OPG) and osteoprotegerin ligand (OPGL) are central to bone resorption.⁴⁶ OPGL is known to activate osteoclastic cells via the receptor activator of NF- κ B (RANK).⁴⁶ Ex vivo coculture studies suggest that plasma cells derived from patients with MM modulate osteoblast and bone marrow stromal cell production of OPGL and its decoy receptor OPG in such a way that OPG is downregulated while OPGL itself is upregulated.⁴⁶ Recombinant OPG is currently in clinical development and the results of a phase I trial have been published.⁴⁷

BISPHOSPHONATES

Bisphosphonates are a class of drugs that are structural analogs of endogenous pyrophosphate.¹⁵ Carbon substitution for the central oxygen atom makes the molecule resistant to hydrolysis and allows for the addition of two side chains necessary for calcium crystal and bone mineral affinity.¹⁵ Bisphosphonates are selectively deposited to sites of increased bone turnover and are ingested by osteoclasts, causing inhibition their resorptive capacity.^{48,49} Currently, two bisphosphonates, pamidronate (Aredia; Novartis Pharmaceuticals, East Hanover, NJ) and zoledronate (Zometa; Novartis Pharmaceuticals, East Hanover, NJ), are Food and Drug Administration (FDA) approved in the United States for use in MM patients with lytic bone disease.

Bisphosphonates have been extensively studied in patients with MM (see Table 91.2). In general, no overall survival benefit has been observed with their use; rather, significant reductions in clinically measurable skeletal related events (SREs) can be achieved.¹⁵ In larger trials, an SRE is defined as pathologic fracture, spinal cord compression, or need for radiation or surgical intervention.^{50,51} In addition to these clinical endpoints, some studies have included hypercalcemia as an SRE.^{52,53}

When given to MM patients undergoing chemotherapy, pamidronate 90 mg IV over 4 hours monthly can significantly reduce serum and urinary markers of bone

Table 91.2 Randomized trials of bisphosphonate therapy in multiple myeloma

	Pamidronate 90 mg IV over 4 hours every 4 weeks	Zoledronate 4 or 8 mg IV every 3–4 weeks for 12 months
References	48,53	51
Study design	Randomized double-blind, placebo-controlled trial	Randomized, double-blind, comparative trial
Efficacy evaluation	Pamidronate vs placebo	Noninferiority study zoledronate vs pamidronate
Primary endpoint	Combined SREs at 9 months	Combined SREs
Sample size, <i>n</i>	392 (all MM)	1,648 (513 MM, 1,130 breast cancer)
Treatment course	First vs second or greater chemotherapy	First treatment
Percent patients with osteolytic bone lesions at entry	100	100
Results		
Pain score decline	Yes	Yes, equal to pamidronate
Time to first SRE	~12 vs 21 months	Median 12.3 months zoledronate vs 12.0 months pamidronate ($P = NS$)
SREs per year	28% vs 44% at 12 months; 38% vs 51% at 21 months	47–49% zoledronate vs 49% pamidronate
Nonvertebral fractures	15% vs 10%	NR
Vertebral fractures	NR	NR
Radiotherapy needed	25% vs 34%	0.47 vs 0.71 per year ($P = 0.018$)
NNT to a avoid one event	6.2 at 12 months; 7.7 at 21 months	N/A

NNT, Number needed to treat; NR, Not reported; N/A, Non applicable; NS, Not significant.

resorption (cross-linked N-telopeptides of type-I collagen), IL-6, CRP, and β 2-microglobulin, which may lead to a significant reduction of pain.⁵⁴

A large randomized international multicenter placebo-controlled trial led to the FDA approval of pamidronate in MM patients with lytic bone lesions.⁵⁰ Patients with stage III MM and at least one lytic skeletal lesion undergoing chemotherapy were randomly assigned to receive placebo or pamidronate 90 mg IV over 4 hours monthly for a planned 21 months. Patients were stratified into those receiving first-line chemotherapy or second-line and beyond. The primary endpoint was number of SREs after nine doses, in which an SRE was defined as pathologic fracture, need for radiation or surgery, and spinal cord compression.⁵⁰ Three hundred ninety-two patients were included in the safety and survival analysis, while only eligible patients were included in the efficacy analysis ($n = 196$ in pamidronate group vs $n = 181$ in placebo group). The time to first skeletal event was significantly less in the pamidronate group ($P = 0.001$ by the log-rank test).⁵⁰ The mean number of SREs per year was observed to be reduced from 2.1 in the placebo group to 1.1 in the pamidronate group at the planned primary time endpoint ($P = 0.0006$).⁵⁰ Two patients were withdrawn from the pamidronate treatment secondary to an allergic reaction and hypocalcemia. Renal insufficiency was not reported in any patients. Follow-up analysis at 21 months continued to show effect as the proportion of patients treated with

pamidronate developing any skeletal event was less than the placebo group ($P = 0.015$).⁵⁵ Subset analysis identified longer survival in the patients treated with pamidronate who were also receiving second-line or beyond chemotherapy when compared to patients in the placebo arm (21 months vs 14 months; $P = 0.041$).⁵⁵ Objective measures of QOL showed declines in the placebo-treated patients.¹⁵

Zoledronate at doses of 4 mg and 8 mg IV over 5 minutes were shown to be superior to pamidronate 90 mg IV over 2 hours in the treatment of hypercalcemia of malignancy.¹⁶ Additionally, a trial comparing two doses of zoledronate (2 mg and 4 mg) to pamidronate 90 mg in patients with MM or bone metastases from breast cancer suggested equivalent efficacy in reduction of SREs.⁵² These studies provided a rationale for a direct efficacy comparison of pamidronate and zoledronate in a multicenter, double-blind trial.⁵³ The trial included 1648 eligible patients with either stage III MM ($n = 510$) or metastatic breast cancer ($n = 1138$). Patients were randomly assigned to receive pamidronate at 90 mg or zoledronate at either 4 or 8 mg. Doses in all arms were given every 3–4 weeks. Patients in the 8 mg treatment arm were later re-assigned to receive 4 mg because of renal safety concerns with high-dose zoledronate. The primary endpoint was an analysis of the proportion of patients experiencing at least one SRE over a 13 month period.⁵³ Median time to first SRE and the proportion of patients with any SRE calculated on an intent-to-treat basis

were similar among all patient groups, with no statistically significant differences noted.⁵³ Percentages of adverse renal events were similar in patients receiving pamidronate and zoledronate at 4 mg (0.2% and 0.5%, respectively).⁵³ This study led to the FDA approval of zoledronate 4 mg IV infused over at least 15 minutes monthly for the treatment of osteolytic bone lesions in patients with MM.¹⁵

Clodronate (Bonefos; Roche Pharmaceuticals, Nutley, NJ) is available in oral and parenteral formulations and was the first bisphosphonate to demonstrate efficacy for MM patients in earlier European trials. Three hundred fifty patients undergoing their first systemic treatment for MM with oral melphalan and prednisolone were randomly assigned to receive clodronate 2.4 g orally daily or placebo for up to 2 years.⁴⁵ Significantly fewer patients in the treatment group had progression of osteolytic lesions by 24 months (12% vs 24%; $P = 0.026$).⁴⁵ However, clodronate has less potency than pamidronate or zoledronate and must be taken daily.¹⁵ Additionally, clodronate is not yet FDA approved in the United States; clinical trials are in progress.

Ibandronate (Bondronat; Rhone-Poulenc Rorer, Collegeville, PA) is a newer bisphosphonate with an approximate 2-log greater potency than pamidronate.^{15,56} A recent phase III, placebo-controlled trial of 198 evaluable MM patients demonstrated that a monthly 2 mg IV bolus of ibandronate did not lead to a significant improvement in the number of SREs per patient-year (2.13 for ibandronate vs 2.05 for placebo).⁵⁷ Post hoc analysis suggested that ibandronate-treated patients with reductions in bone formation markers (alkaline phosphatase, osteocalcin, and urinary C-terminal telopeptide of type-I collagen) did have fewer SREs compared to placebo patients.⁵⁷ However, a recently published comparison trial showed pamidronate 90 mg monthly caused greater reductions in markers of bone resorption and disease activity (paraprotein, CRP, and β 2-microglobulin) than ibandronate 4 mg monthly.⁵⁸

Osteonecrosis of the mandible is a recently described potential complication of long-term bisphosphonate therapy.⁵⁹ A retrospective review describes 56 patients who received IV bisphosphonate therapy for more or equal to 1 year presenting with lesions typical of non-healing tooth extraction sockets or exposed mandibular bone not amenable to conservative debridement or antibiotic therapy.⁵⁹ Other risk factors in the development of osteonecrosis in these patients included chemotherapy, corticosteroids, and poor oral hygiene.⁵⁹ Based on these findings, the pharmaceutical manufacturer has issued a warning recommending dental examinations along with any indicated preventative dentistry prior to placing patients with risk factors (those receiving chemotherapy, corticosteroids, or who have poor oral hygiene) on chronic bisphosphonate therapy. Furthermore, invasive dental procedures should be avoided during treatment.

A consensus panel of the American Society of Clinical Oncology (ASCO) has developed evidence-based guidelines for the use of bisphosphonates in patients with MM.¹⁵ As previously summarized, level II evidence (i.e., evidence from at least one well-designed experimental study) supports the use of pamidronate 90 mg IV infused over at least 2 hours or zoledronate 4 mg IV infused over at least 15 minutes every 3–4 weeks for MM patients who have plain film radiograph evidence of a lytic bone lesion(s).¹⁵ Bisphosphonate therapy is not routinely recommended for patients with monoclonal gammopathy of undetermined significance, smoldering myeloma, solitary plasmacytomas without evidence of other lytic lesions, or MM patients with osteopenia on bone mineral density measurements and no other evidence of lytic lesions.¹⁵ The duration of bisphosphonate therapy has not been studied, and no clear recommendations on stopping treatment exist.¹⁵ The consensus panel recommends discontinuing treatment if the benefit is no longer exceeding the inconvenience of monthly infusions or significant side effects develop.¹⁵ Additionally, judicious use of longer term therapy is prudent in light of the newly described complication of mandibular osteonecrosis.

PATHOLOGIC FRACTURES

Once pathologic fractures occur, they can cause severe pain and structural instability, leading to postural deformities and possibly spinal cord compression. Clinically useful adjuncts include radiation, analgesia, and surgical intervention.

RADIATION

External beam radiation therapy is used in the majority of patients with fractures and isolated plasmacytomas. It can be useful for urgent pain control and relief of neurologic compromise. The typical dose is 30 Gy delivered in 10 fractions; however no standard dose is defined.

SURGICAL INTERVENTIONS

Vertebroplasty

Vertebroplasty has been used to relieve pain in patients with pathologic vertebral or osteoporotic compression fractures.⁶⁰ It is accomplished by the injection of low-viscosity bone cement into a damaged vertebral body.⁶¹ Two drawbacks to the procedure have been suggested: the technique is not able to restore normal structure of the spine, and cement leakage may occur.⁶⁰

Kyphoplasty

Kyphoplasty is another surgical technique designed to restore height to collapsed vertebral bodies in order to decrease pain and improve function and mobility. The method involves the insertion of a deflated balloon

into the potential space between the upper and lower end-plates of the collapsed vertebrae and inflating the balloon to push the vertebral end-plates apart, thus restoring height. The expanded cavity is then filled with a viscous, partially cured cement, thus supporting the expanded endplates and minimizing the potential for leak.⁶⁰ A prospective cohort study of 55 kyphoplasty procedures in 18 MM patients with osteolytic vertebral compression fractures demonstrated an average gain of 34% of lost height with no major procedure-related complications.⁶⁰ Patients also experienced a significant improvement in objective scores of bodily pain, physical function, vitality, and social function.⁶⁰ Importantly, patients in this study had a mean duration of symptoms prior to procedure of 11 months (range 0.5–24 months), suggesting that patients with “old” fractures should be evaluated by an orthopedic surgeon skilled in this technique to assess potential benefit.

THROMBOEMBOLIC EVENTS

Patients with MM have a higher risk of developing a deep venous thrombosis (DVT) when compared to the general population.^{62,63} A retrospective study using univariate analysis has identified a personal or family history of DVT, immobility, a low serum albumin level, and a high leukocyte count to be associated with risk of DVT in patients with MM or other plasma cell dyscrasias.⁶³ Newly diagnosed MM patients or those with a chromosome 11 abnormality appear to have an increased risk as well.⁶⁴ Currently, however, there is no role for the routine prophylaxis of DVT in such patients.

Thalidomide has been identified as an active drug in both newly diagnosed and relapsed or refractory MM patients.⁶⁵ The incidence of DVT in patients receiving single-agent thalidomide appears to be low.⁶³ In a large phase II trial of 169 patients with advanced and refractory MM given single-agent thalidomide, DVT was observed in 2% of the patients.⁶⁶ However, thalidomide is thrombogenic when given in combination with either dexamethasone or chemotherapy; results of published and unpublished studies report an incidence of 11–28%.^{67–70} The thrombogenic potential of thalidomide is particularly high when combined with doxorubicin-containing regimens.^{68,70,71} Although the full mechanisms of thrombosis is unclear, data from a small cohort of patients treated with thalidomide and dexamethasone for relapsed or refractory MM demonstrated a significant decrease in thrombomodulin within the first month of treatment.⁷² The temporal risk of thalidomide-associated DVT in MM patients appears to be highest during induction regimens early in the course of disease.⁷³ The immunomodulatory thalido-

mid derivative, CC-5013 (lenalidomide; Celgene, Warren, NJ), does not appear to have the same thrombogenic risk as thalidomide.⁷⁴

Prophylactic strategies with both anticoagulants and antiplatelet agents are being explored; no evidence-based guidelines are yet available. A study reporting the results of MM patients who received high-dose chemotherapy with or without thalidomide prior to autologous stem cell transplantation has recently been published.⁷³ Patients randomized to receive chemotherapy with thalidomide were also randomized, in sequential cohorts, to receive either warfarin 1 mg per day or low molecular weight heparin (LMWH; enoxaparin 40 mg s.c. qd). Patients who received chemotherapy alone in this trial had a 14% incidence of DVT. Those who received chemotherapy and thalidomide with or without warfarin had no difference in the incidence of DVT (34% vs 31%), suggesting no efficacy for low-dose warfarin prophylaxis.⁷³ However, patients who received chemotherapy, thalidomide, and LMWH had the same incidence of DVT when compared to matched controls who received chemotherapy alone (15% vs 15%).⁷³ Therefore, LMWH seems to attenuate the added thrombogenic risk conferred by thalidomide in patients receiving thalidomide and high dose chemotherapy.

In a phase II study of pegylated, liposomal doxorubicin, vincristine, reduced frequency dexamethasone, and thalidomide (Dvd-T) for patients with relapsed or refractory MM, a 25% incidence of DVT was observed in the first 20 patients treated.⁷⁰ Low-dose aspirin 81 mg daily was administered to subsequent patients and the incidence of DVT decreased to 13%, a rate comparable to those patients receiving chemotherapy without thalidomide.⁷⁰

SUMMARY

Caring for patients with MM is very challenging. The availability and activity of modern chemotherapy regimens as well as newer classes of drugs with novel mechanisms of action in addition to aggressive transplant regimens has collectively changed the course of MM to that of a chronic disease for a sizeable number of patients. Hence, patients will potentially be receiving several courses of therapy and proper supportive care can enhance QOL and delay or prevent serious complications. Finally, oncology practitioners need to realize that progressive renal insufficiency, anemia, or infection may all herald disease relapse. Therefore, it is reasonable to reassess all parameters of renal and hepatic function in addition to requantification of marrow plasma cell burden and paraproteins in a previously stable patient with new or progressive symptoms.

Chapter 92

PRINCIPLES OF HEMATOPOIETIC STEM CELL TRANSPLANTATION TO TREAT HEMATOLOGIC MALIGNANCIES

Michael R. Bishop

INTRODUCTION

Hematopoietic stem cell transplantation (HSCT) is the process of infusing hematopoietic stem and progenitor cells, which are used primarily to restore normal hematopoiesis or to treat malignancy.¹⁻³ The term HSCT has replaced the relatively archaic term *bone marrow transplantation* for two specific reasons. First, the stem and progenitor cells used in HSCT can be obtained from a variety of sources other than the bone marrow, including the peripheral blood and umbilical cord blood.⁴ It is more important to characterize HSCT according to where the stem cells used for transplantation are derived. The use of hematopoietic stem cells derived from patients themselves is referred to as autologous HSCT.^{1,3} Transplantation of hematopoietic stem cells derived from an identical twin is referred to as syngeneic HSCT, and transplantation of hematopoietic stem cells from stem cells other than the patient or an identical twin is referred to as allogeneic HSCT. The stem cells used for HSCT are of hematopoietic origin, as more primitive stem cells are of interest for regenerative therapy, highlighting their plasticity and unique biologic characteristics.⁵

HISTORY OF HEMATOPOIETIC STEM CELL TRANSPLANTATION

The clinical application of HSCT is less than 50 years old, and its origins are related to identification of the severe myelosuppressive effects of radiation that were observed among nuclear bomb survivors at Hiroshima and Nagasaki.⁶ Intense research began at that time to develop methods to reverse the myelosuppressive effects of radiation, including the infusion of bone marrow.⁷⁻¹⁰ In 1949, Jacobson reported on the effects of shielding the spleen of mice from lethal doses of irradiation.⁷ Shielding of the spleen protected nearly

all mice at a total body irradiation dose of 700 cGy, while unshielded mice all died from marrow aplasia. As the dose of radiation was raised to 1050 cGy, approximately one-third of the shielded mice survived, and a dose of 1200 cGy was lethal to all mice. At autopsy, these latter radiation groups were found to have died from fibrosis of the lungs, liver, and kidneys. The authors erroneously concluded that shielding the spleen was protecting a humoral factor that affected hematopoiesis; however, it would subsequently be determined that early hematopoietic progenitors were actually protected from the effects of radiation. From these early studies, theories evolved that radiation and chemotherapy could be administered at controlled, yet highly myelosuppressive doses, which were capable of eliminating malignant hematopoietic clones, and that normal hematopoiesis could be reestablished by the infusion of normal bone marrow. Early animal studies of HSCT were thwarted by incompatibility between bone marrow recipients and donors leading to a high degree of graft rejection.¹⁰ Among animals that did not reject their marrow grafts, a syndrome of weight loss, alopecia, diarrhea, and eventually death was commonly observed.¹¹ This syndrome was referred to as “runt” disease, which we now refer to clinically as graft-versus-host disease (GVHD), and is discussed in more detail next. The most significant breakthrough for HSCT in particular and for all forms of organ transplantation in general was the recognition that the major histocompatibility complex (MHC) and human leukocyte antigens (HLA) were the major determinants of graft rejection.¹² After the development of clinical methods to determine HLA, which permitted the “matching” of bone marrow donors and recipients, the first successful clinical stem cell transplantation trials among patients with severe combined immunodeficiency disorders and advanced

acute leukemias were reported in the late 1960s and early 1970s.^{1,10} Today, HSCT is a standard treatment for many immunodeficiency states, metabolic disorders (e.g., Hurler's syndrome), defective hematopoietic states (e.g., severe aplastic anemia, thalassemia), and a variety of malignancies. It is currently being investigated in nonmalignant diseases, including autoimmune diseases (e.g., rheumatoid arthritis and multiple sclerosis) and the emerging field of regenerative medicine, which takes advantage of the plasticity of stem cells, to repair defective or damaged tissues (e.g., cardiac muscle after a myocardial infarction).^{13,14} This chapter will focus primarily on the rationale for the application of HSCT in the treatment of hematologic malignancies.

CLINICAL DECISION-MAKING IN HEMATOPOIETIC STEM CELL TRANSPLANTATION

Hematologic malignancies are particularly amenable to the beneficial effects of HSCT due to their relative sensitivity to cytotoxic chemotherapy and radiation, as well as their susceptibility to immunologic effects that are associated with allogeneic HSCT. The intent of HSCT for the treatment of malignancy is to have a significant impact on survival and to potentially cure the disease. The curative intent of HSCT is imperative, as the procedure is associated with a significant degree of morbidity and mortality as compared to other forms of therapy. As such, the decision to employ HSCT is based primarily on the inherent risk of the disease itself versus the potential benefit and inherent risks of the various forms of HSCT being considered. This decision takes into careful consideration many factors, including the specific disease, the available alternative treatment options, the disease state (remission, sensitivity to chemotherapy), patient age and performance status, and availability of a stem cell source. Once it is determined that a patient could potentially benefit from HSCT, the decisions as to what type of transplant (allogeneic vs autologous vs syngeneic), what type of conditioning regimen, and the timing of the transplant (first complete remission vs first relapse) need to be made. These decisions are primarily based upon the aforementioned factors and supplemented by the amount of risk that the patient (and physician) is willing to accept.

TYPES OF HEMATOPOIETIC STEM CELL TRANSPLANTATION

ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION

Histocompatibility

The choice of a syngeneic, autologous, or allogeneic HSCT is relatively predetermined for most patients, as few patients have an identical twin and the availability of an allogeneic donor is limited. In allogeneic HSCT,

stem cells are obtained from someone (i.e., the donor) other than the patient (i.e., the recipient). Donor and recipient are generally identical or "matched" for HLA, which are derived from the MHC located on chromosome 6.¹⁵ A single set of MHC alleles, described as a haplotype, is inherited from each parent, resulting in HLA pairs. The most important HLA include HLA-A, HLA-B, HLA-C, DR, and DQ loci. Among siblings, the genes that encode for HLA-B and C are located so close to each other in the MHC that one is rarely inherited without the other. As a result, an HLA match among siblings is referred to a "6 of 6," as they are matched for HLA-A, B, and DR; however, in actuality they are matched for all of the HLA antigens.³ The other antigens, such as HLA-C, become more important when alternative sources of hematopoietic stem cells are used, such as those from unrelated donors and cord blood, which are described in more detail next and in Chapter 98.¹⁶

Graft-versus-leukemia effect

The distinctive characteristics of allogeneic HSCT are that the stem cell graft is free of contamination by malignant cells and contains T-cells that are capable of mediating an immunologic reaction against foreign antigens. This latter characteristic can be a major advantage if the immunologic response is directed against malignant cells, referred to as the graft-versus-leukemia (GVL) or graft-versus-tumor effect, thus potentially eradicating disease and reducing the chance of disease relapse. However, if the immunologic response is directed against antigens present on normal tissues, it can lead to the destruction of normal organs, described clinically as GVHD. The risk of both graft rejection (host-versus-graft reaction) and GVHD rises with HLA-disparity.

The GVL effect was initially recognized in animal models and subsequently noted among patients undergoing allogeneic HSCT for acute and chronic leukemias.¹⁷⁻²⁰ The clinical importance of the interactions between immunocompetent donor T cells and tumor cells in mediating GVL effect is supported by an increased rate of relapse in allogeneic stem cell grafts from which T cells have been removed (T cell depletion), an inverse correlation between relapse and severity of GVHD, and an increased rate of relapse after syngeneic or autologous HSCT using the same myeloablative conditioning regimen.^{20,21} These data suggested that T cells within the allograft were directly involved in eradicating leukemia. Finally, the most compelling evidence for a T cell-mediated GVL effect originates from the observation that infusion of allogeneic lymphocytes, a donor lymphocyte infusion (DLI), at a time remote from the transplant conditioning regimen, can successfully treat leukemia relapse after allogeneic HSCT.²²⁻²⁵ In an initial report, DLI therapy was given to three patients with chronic myelogenous leukemia (CML) whose disease had recurred

after an allogeneic HSCT.²² The DLI, without any additional cytotoxic therapy, resulted in sustained cytogenetic and molecular remissions. Evidence of a GVL effect similarly has been observed against other hematologic malignancies, including multiple myeloma and lymphomas.^{26,27} Over time, it became increasingly apparent that a significant part of the curative potential of allogeneic HSCT could be directly attributed to the GVL effect. However, there is tremendous variability relative to the clinical effectiveness of the GVL effect against different hematologic malignancies after allogeneic HSCT. Factors that affect the GVL effect after allogeneic HSCT include the presence of mixed T cell chimerism, the development of tolerance between donor and host, the relative susceptibility of the hematologic malignancy to the GVL effect, and suboptimal GVL reactivity.²⁸

The expression of surface or intracellular molecules on malignant cells is essential for recognition or elimination by effector T cells. Malignant cells may directly down-regulate effector cells through secretion of inhibitory factors such as transforming growth factor-beta (TGF- β).²⁹ Malignant cells may also down-regulate HLA class I and class II molecules, may have low- or missing expression of costimulatory molecules, such as CD80, CD83, CD86, CD40, and intercellular adhesion molecule, or alter the presentation antigenic peptide sequences.^{30–33} The cytotoxic effects of effector cells are primarily mediated through the Fas-ligand pathway or tumor necrosis factor (TNF) receptors, or through direct binding of perforin and activation of granzyme B.³⁴ Decreased Fas ligand expression or reduced perforin binding can impair the potency of the GVL effect.^{35–37}

It has long been recognized that an optimal GVL effect requires efficient antigen presentation by antigen presenting cells, such as dendritic cells, and appropriate costimulatory signals to T cells.^{38–40} In HLA-mismatched allogeneic HSCT, natural killer (NK) cells have been found to exert strong alloimmune response that contributes to a potent clinical GVL effect.⁴¹ The interaction of killer-cell immunoglobulin-like receptors (KIR), expressed on NK cells, with MHC inhibits the cytotoxic activity of NK cells.^{42–44} In allogeneic HSCT where donors and recipients are mismatched for HLA (HLA-mismatched or haploidentical HSCT), a lack of appropriate HLA class I ligands in the recipient can inhibit the KIR of donor NK cells, facilitating a strong GVL effect.⁴² Although a beneficial effect of NK cell alloreactivity has been observed in haploidentical HSCT, there has been conflicting data relative to any benefit in the setting allogeneic HSCT from unrelated donors.^{45,46}

The failure to detect clinical evidence of a GVL effect after allogeneic HSCT can be partially attributed to the biologic characteristics of the disease, such as histology and chemotherapy sensitivity.⁴⁷ There are significant differences in the susceptibility of various

hematologic malignancies to the GVL effect, and there can be significant differences in the susceptibility of particular hematologic malignancies relative to their histologies.^{21,48} Evidence of a GVL effect and the efficacy of DLI in non-Hodgkin's lymphoma (NHL) have been primarily limited to follicular or "low-grade" histologies, with only anecdotal cases in patients with diffuse large B-cell or more aggressive NHL histologies.^{48,49} This may reflect the biologic characteristics, such as growth rate or antigen expression, of the respective histologies. In some cases, a clinical GVL effect is not possible, as certain hematologic malignancies can be localized in immunologically "privileged" sites, such as the central nervous system.⁵⁰

An extremely important clinical factor relative to the susceptibility of hematologic malignancies to the GVL effect is chemotherapy sensitivity.^{48,51} In extremely chemotherapy-refractory patients, the GVL effect may be insufficiently potent to be clinically detectable, because the tumor growth rate exceeds the ability of the immune effect to eliminate disease. Patients with chemotherapy-sensitive disease also tend to have less of a disease burden, and the greatest efficacy of the GVL effect has been observed in minimal residual disease states.²⁴ Specifically, relapse is higher among patients who are not in remission at the time of allogeneic HSCT or DLI.⁵² In chronic phase CML, the efficacy of DLI is inversely related to the disease burden; the highest response rates to DLI have been observed among CML patients with disease detectable only by polymerase chain reaction methods, and the lowest efficacy is observed among patients with hematologic relapses.⁵³

Selection of allogeneic stem donor

The choice of donor for an allogeneic HSCT takes into account several factors, including the patient's disease, disease state, and urgency in obtaining a donor. When allogeneic HSCT is being considered for a patient, a fully HLA-matched sibling is the preferred donor, as the risk of graft rejection and GVHD are the least with this source of allogeneic stem cells.³ For patients who lack a fully HLA-matched sibling donor, the preferred alternative sources for allogeneic stem cells include an unrelated fully HLA-matched donor, a partially HLA-matched cord blood unit, or a partially HLA-matched family member.^{54–56} A major disadvantage of an unrelated donor is that the average time required to identify and procure an HLA-matched unrelated donor is approximately 2–4 months, which may be inadequate for patients with rapidly progressive malignancies.⁵⁷ The alternative stem cell source to an unrelated bone marrow donor for allogeneic HSCT is umbilical cord blood.^{55,57,58} The major advantages of umbilical cord stem cells is that they can be obtained in fewer than 4 weeks and cord blood units mismatched for up to 3 of 6 HLA may be used for allogeneic HSCT. This degree of HLA mismatching is acceptable, as the overwhelming

percentage of T cells within the cord blood unit are naive, and the incidence of GVHD is comparable or less than that associated with an HLA-matched unrelated bone marrow donor. The major disadvantage of umbilical cord blood units is that they are associated with a high degree of graft rejection, especially in adults. Engraftment- and treatment-related mortality appears to be directly related to umbilical cord cell dose.^{55,57,58} The other significant disadvantage is that once the cord blood unit is used, there is no way to go back and get additional cells for a DLI or in the event of graft failure.

SYNGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION

Syngeneic HSCT uses stem cells from an identical twin.^{59,60} As the stem cells are genetically identical with the recipient, the major advantages of a syngeneic HSCT are that they are not associated with GVHD or graft rejection. Another significant advantage of syngeneic HSCT, which is shared with allogeneic HSCT, is that there is no risk of contamination by malignant cells. The major disadvantage is that the syngeneic HSCT does not provide a GVL effect that is associated with allogeneic HSCT; conversely, however, syngeneic HSCT is not associated with GVHD or graft rejection. This results in a relatively low risk of treatment-related morbidity and mortality. The greatest disadvantage is that far less than 1% of patients have an identical twin, making this an unavailable option for the overwhelming majority of patients. However, when an identical twin is available, syngeneic HSCT is considered the preferred type of HSCT in almost all clinical situations, due to the aforementioned advantages.

AUTOLOGOUS HEMATOPOIETIC STEM CELL TRANSPLANTATION

Autologous HSCT uses stem cells from patients themselves. The principle behind both syngeneic and autologous HSCT is that certain malignancies, such as leukemias, have a steep dose-response curve to chemotherapy and, to a relative degree, radiation.^{61–63} The major limitation to the administration of higher doses of chemotherapy or radiation, in order to obtain a maximal response, are the myelosuppressive effects of these therapies. Autologous, allogeneic, and syngeneic hematopoietic stem cells are primarily used as a “rescue” product to restore hematopoiesis after patients have received high-dose chemotherapy and/or radiation. The amount of chemotherapy and radiation that can be administered prior to transplant, referred to as the conditioning or preparative regimen, is limited due to associated toxicities to other organs. This limitation in the amount of therapy that can be delivered may permit the survival of resistant tumor cells, which accounts for the relapses that are observed after HSCT.^{64,65} Relapse rates are lower after allogeneic HSCT, as this form of transplant provides a potential

GVL effect at the expense of increased treatment-related morbidity and mortality, primarily through GVHD.^{19–21}

Tumor contamination and “purging”

The major advantages of autologous hematopoietic stem cells are that almost every patient can serve as his/her own donor and there is no graft rejection or GVHD, although attempts have been made to induce autologous GVHD and GVL, as discussed next. Thus, autologous HSCT is also associated with a relatively low treatment-related mortality rate, which varies with disease, disease state, and age. The major disadvantages are that the autologous stem cell graft may be contaminated with tumor cells and, similar to syngeneic HSCT, is not associated with a GVL effect. The contribution of autograft contamination by tumor cells to relapse has varying clinical significance.^{66–68} Attempts have been made to remove or “purge” tumor cells from the autograft using various methods prior to autologous HSCT.^{69–71} However, there is only retrospective and anecdotal evidence that autograft purging results in an improved clinical outcome.^{48,72}

Autologous graft-versus-host disease

Although the high rate of relapse after autologous HSCT has in part been attributed to tumor contamination of the autograft, a similar relapse rate has also been observed with syngeneic HSCT, which is free of tumor contamination.²¹ It is more likely that relapses are due to endogenous tumor cells that survived the cytotoxic effects of the conditioning regimen. It has been hypothesized that these high relapse rates with either syngeneic or autologous HSCT are due to the absence of a GVL effect. Attempts have been made to induce GVHD and an associated GVL effect in the autologous HSCT setting. Murine studies indicated that administration of the immunosuppressive drug cyclosporine after autologous HSCT elicited an autoimmune syndrome with pathology virtually identical to GVHD.⁷³ The GVHD observed after autologous and syngeneic HSCT in murine models was associated with the development of a highly restricted repertoire of CD8+ autoreactive T cells that recognized a peptide from the invariant chain, termed CLIP, presented by MHC class II molecules.⁷⁴ These autoreactive T cells produced type 1 cytokines, including interferon-gamma, interleukin-2 (IL-2), and TNF- α . These studies led to clinical trials in patients with lymphoma and acute leukemia.^{75,76} Although clinical and histologic evidence of GVHD was demonstrated in these trials, there was no clear evidence of a clinical benefit in terms of a reduction in relapse rates.

Sources of hematopoietic stem cells

Hematopoietic stem cells may be obtained from the bone marrow, the peripheral blood, and from umbilical cord blood. Hematopoietic stem cells from bone

marrow are used in both autologous and allogeneic stem cell transplantation, although far less frequently than in the past. Peripheral blood hematopoietic stem cells are used in approximately 90% of autologous HSCT and in approximately 70% of allogeneic HSCT.⁷⁷ The predominance of this stem cell source is related to the relative ease in attainment and moderate improvement in the rate of hematopoietic recovery after infusion, as compared to hematopoietic stem cells derived from bone marrow. Hematopoietic stem cells from cord blood are collected immediately after delivery of a baby. A minimally acceptable cord blood unit dose is 1.7×10^5 CD34⁺ cells per the patient's weight in kilograms, to assure engraftment in the allogeneic HSCT setting.⁷⁸ This criterion is a significant problem for adult patients, where the application of cord blood transplantation has been associated with delayed hematopoietic recovery, especially platelets; graft failure; and a relatively high treatment-related mortality compared to other sources of allogeneic hematopoietic stem cells.

CONDITIONING REGIMENS FOR HEMATOPOIETIC STEM CELL TRANSPLANTATION

As described previously, prior to the infusion of hematopoietic stem cells, patients receive regimens with the intent of "conditioning" or "preparing" the patient for the infusion of hematopoietic stem cells.^{1,3} Most conditioning or preparative regimens consist of chemotherapy alone or combined with radiation, radioimmunoconjugates, and/or monoclonal antibodies that target T cells (e.g., alemtuzumab).^{1,3,79,80} The choice of conditioning regimen is dependent upon the type of transplant (allogeneic vs autologous vs syngeneic) and the specific disease being treated.

MYELOABLATIVE CONDITIONING REGIMENS

The earliest conditioning regimens were designed for the treatment of acute leukemias with syngeneic and allogeneic HSCT.⁸¹ As previously discussed, these early conditioning regimens allowed the administration of maximum doses (i.e., "high-dose") of chemotherapy and/or radiation for the eradication of disease. In the case of an allogeneic HSCT, the conditioning regimen also had to be adequately immunosuppressive to prevent graft rejection, as the recipient's immune system is capable of recognizing the donor hematopoietic stem cells as foreign. The most commonly used chemotherapy agents are alkylating agents (e.g., cyclophosphamide) with or without total lymphoid or total body irradiation at doses varying between 800 and 1440 cGy. The doses of chemotherapy and radiation used in these regimens are referred to as myeloablative, as they result in a degree of myelosuppression and immunosuppression that is nearly universally fatal

without the infusion of hematopoietic stem cells as a rescue product.⁸²

NON-MYELOABLATIVE AND REDUCED-INTENSITY CONDITIONING REGIMENS

The demonstration that an immune-mediated GVL effect plays a central role in the therapeutic efficacy of allogeneic HSCT led to the hypothesis that myeloablative conditioning regimens were not essential for tumor eradication.⁸³ This subsequently led investigators to develop less intense conditioning regimens that were adequately immunosuppressive to permit the engraftment of donor hematopoietic stem cells, and could serve as a platform for the administration of donor T cells as adoptive cellular therapy.⁸⁴ A variety of nonmyeloablative, also referred to as reduced-intensity, conditioning regimens have been reported.⁸⁵⁻⁸⁸ All share the similar goal of providing sufficient immunosuppression to achieve donor engraftment of an allogeneic hematopoietic stem cell graft while attempting to minimize toxicity. The most important clinical question is whether this reduction in toxicity comes at the cost of a loss of antitumor activity within the conditioning regimen.

CLINICAL EFFICACY OF HEMATOPOIETIC STEM CELL TRANSPLANTATION IN HEMATOLOGIC MALIGNANCIES

There is clinical evidence that syngeneic, autologous, and allogeneic HSCT all provide benefit, defined as response, freedom of progression, or overall survival, for the majority of hematologic malignancies.³ However, the beneficial effects of these various forms of HSCT vary greatly with each hematologic malignancy. Myeloablative conditioning regimens with syngeneic, autologous, or allogeneic HSCT result in higher response rates than conventional cytotoxic agents for almost all hematologic malignancies. However, the durability of these responses and their effect on survival varies from disease to disease. Similarly, there is evidence of a clinical GVL effect in almost every hematologic disease; however, the potency and clinical relevance is highly variable. This section will briefly cover the susceptibility of hematologic malignancies to the different forms and effects of HSCT.

CHRONIC MYELOGENOUS LEUKEMIA

Chronic myelogenous leukemia is highly susceptible to the GVL effect, as evidenced by the response of CML to DLI, and that long-term, leukemia-free survival rates exceed 70% for patients who were transplanted in early chronic phase.^{89,90} GVL effect against CML clearly exists, as the greatest efficacy of DLI has been demonstrated in CML. Several studies have implicated peptides associated with the product of *bcr-abl*, but a specific antigen has yet to be identified.⁹¹ However,

studies in CML provide several important insights on the efficacy of DLI in specific, and GVL in general, relative to disease status and lymphocyte dose.^{22,52,53,92} Chronic phase CML is particularly responsive to DLI, with remission rates of 50–80%.^{53,92} In contrast, response rates of accelerated and acute (“blast”) phase CML varies between 10% and 30%; the more advanced states of the CML are inversely correlated to the response to DLI. These variable response rates reflect the biology of disease relative to antigen and MHC presentation, as well as growth rate. In patients with more advanced CML, the GVL effect may be insufficiently potent to be clinically detectable, because the leukemic growth rate exceeds the ability of the immune effect to eliminate disease. There is also considerable variability of response to DLI among CML patients in chronic phase. For CML patients with cytogenetic or molecular relapses, the response rates are approximately 60–70% and 80–90%, respectively.^{53,92} In contrast, the response to DLI among patients with chronic phase CML with morphologic or hematologic relapses is approximately 50–60%. Increased lymphocyte dose appears to improve DLI efficacy against relapse, but it is also associated with increased toxicity in the form of GVHD.⁹² However, lower DLI doses are as effective as higher doses in patients with a low disease burden. These variations in response suggest that tumor bulk plays an important role in the efficacy of DLI in CML. All of these factors, including disease biology, disease state, and tumor bulk, appear to play significant roles relative to the susceptibility of hematologic malignancies to a GVL effect. Autologous HSCT has limited efficacy in CML due to the relative lack of sensitivity of CML cells to cytotoxic therapy, and more importantly due to difficulty in obtaining a relatively tumor-free autograft.⁹³ Due to the tremendous clinical success of imatinib (STI-571, Gleevec), the emerging predominant strategy is to use allogeneic HSCT in patients with more advanced CML, and for patients who have failed or progressed on Gleevec.⁹⁴

ACUTE LEUKEMIAS AND MYELODYSPLASTIC SYNDROMES

Acute myelogenous leukemia (AML), along with acute lymphocytic leukemia (ALL), were some of the first malignancies in which HSCT was demonstrated to have efficacy.^{19,21,81} Initial studies of myeloablative allogeneic HSCT demonstrated that this treatment was capable of resulting in long-term survival for a minority of patients with refractory and relapsed AML.⁸¹ Subsequent studies suggested that a GVL effect contributed to the success of allogeneic HSCT in AML.^{19,21} The evidence for a GVL effect in ALL is less convincing.⁹⁵ In contrast to data in CML, the clinical responses of relapsed AML and ALL to DLI are generally less than 50%, with particularly disappointing results for ALL.^{25,52,95} A number of antigens have been identified as potential targets in AML, explaining the efficacy of

allogeneic HSCT in this disease. These antigens are expressed only on a minority of AML cells, and on normal tissues.^{96–98} Similarly, the response of myelodysplastic syndrome to DLI is relatively poor, although allogeneic HSCT is the only known curative therapy for patients with MDS.⁹⁹

MULTIPLE MYELOMA

The efficacy of high-dose chemotherapy in multiple myeloma has led to inclusion of autologous HSCT as part of its initial therapy.^{100,101} Due to unique biologic characteristics, there are clinical data demonstrating that the inclusion of more than one cycle of high-dose chemotherapy with autologous HSCT may improve upon the results of a single transplant.¹⁰² Although there is clear evidence of a GVL effect against multiple myeloma, a tumor-specific antigen has not been identified. The use of myeloablative allogeneic HSCT is controversial, as they have been associated with a high mortality rate.¹⁰³ Results of allogeneic HSCT in multiple myeloma have been improved with the use of non-myeloablative conditioning regimens.¹⁰⁴

LYMPHOMA

Due its relative sensitivity to chemotherapy, there is substantial evidence that autologous HSCT is efficacious for patients with primary refractory or chemotherapy-sensitive recurrent malignant lymphomas of specific histologies, including “intermediate-grade” (e.g., disease diffuse large B-cell), NHL, and Hodgkin’s lymphomas.^{105–108} The demonstration of a potent GVL effect against lymphomas is less clear, and the efficacy of DLI in lymphoma is anecdotal at best.^{47–49} When specific comparisons were made between syngeneic, autologous, and allogeneic HSCT in different types of lymphoma, a clear GVL effect was not demonstrated.⁴⁸ Thus, the specific role of allogeneic HSCT has not been defined; however, there is evidence that non-myeloablative allogeneic HSCT may provide benefit for patients with recurrent follicular and advanced non-Hodgkin’s lymphoma, as well as for Hodgkin’s lymphoma.^{51,109}

SUMMARY

Hematopoietic stem cell transplantation represents a treatment option that can result in significant improvements, and in many cases cures, for a variety of hematologic malignancies. In the autologous and syngeneic HSCT settings, the efficacy is attributed almost solely to the ability of high-dose chemotherapy and radiotherapy to overcome resistant mechanisms within malignant cells; however, relapse of disease remains the primary reason for treatment failure. Relapse is significantly less in the allogeneic HSCT setting. This reduction in relapse rates is attributed to a T cell-mediated GVL effect, but it comes at the

expense of GVHD, resulting in high treatment-related morbidity and mortality. Advances in the understanding of T cell biology and tumor immunology, which includes identification of immunogenic cancer antigens and an increased ability to identify and expand T cells with tumor reactivity, will lead to the translation of the GVL effect into the syngeneic and autologous HSCT settings. Current studies of adoptive cellular therapy in solid tumors, particularly melanoma, suggest that this is highly possible.¹¹⁰ In the allogeneic HSCT setting, the situation is somewhat reversed, as clinical applications and success at treating malignancy leads the scientific understanding of the biology

of these tumor regressions. To this extent, efforts are underway to elucidate the mechanism(s) of curative allogeneic GVL effects. This understanding is of significant importance, as it may allow one to identify mechanisms of GVL mediation that are distinct from GVHD, resulting in an improved therapeutic ratio. It is apparent that the fields of autologous and allogeneic HSCT therapy conceptually overlap, with each application attempting to achieve a maximal response against cancer cells with relatively reduced toxicity, specifically reduced GVHD in allogeneic HSCT and a reasonable degree of tumor-specific autoimmunity in autologous HSCT.

Chapter 93

PRINCIPLES OF HLA MATCHING AND THE NATIONAL MARROW DONOR PROGRAM

Edward J. Ball

INTRODUCTION

Transplantation of allogeneic hematopoietic stem cells is a potentially curative treatment for a number of hematologic malignancies and other diseases.¹ The best success of this therapy is achieved using HLA-identical sibling donors, but only 30–35% of patients have such donors. Alternate donors that have been used include partially HLA-matched related donors and unrelated donors. The use of alternate donors is generally associated with increased rates of severe complications and mortality. Efforts to reduce complications associated with alternate-donor transplantation include HLA matching and protocols designed to improve engraftment and reduce graft-versus-host disease (GVHD).

The HLA complex is intimately involved in human allogeneic stem cell transplantation, being critically involved in GVHD, graft failure, and graft-versus-leukemia (GVL) effects. Each of these is a reflection of the normal function of HLA molecules in immune responses to pathogenic agents. The principle functions of HLA molecules are to bind peptides and to serve as recognition elements for T lymphocyte and natural killer (NK) cell receptors.^{2,3}

HLA GENETIC ORGANIZATION

The HLA (human leukocyte antigen) complex is the name of the human major histocompatibility complex (MHC). It is located on chromosome 6 (6p21.3), covers about 3600 kilobases of DNA, and contains in excess of 120 expressed genes.^{4,5} Two classes of HLA molecules are central to the control of immune responses: class I (HLA-A, -B, -C) and class II (HLA-DR, -DQ, -DP)^{6,7} (Figure 93.1). Class I molecules are heterodimeric glycoproteins whose alpha chain (~45 kD) is encoded by HLA-complex genes (*HLA-A**, *-B**, *C**) and whose beta chain is β_2 -microglobulin (β_2 -M), encoded on chromosome 15 (15q21–22.2).⁸ Class II

molecules are also heterodimeric glycoproteins, but both alpha and beta chains (~28–32 kD) are encoded within the HLA complex (alpha genes *HLA-DRA1**, *-DQA1**, *-DPA1** and beta genes *HLA-DRB1**, *-DRB3**, *-DRB4**, *-DRB5**, *-DQB1**, *-DPB1**).

VARIATION IN HLA GENETIC ORGANIZATION

Complexity of the HLA region is manifest at several levels. As noted above, each HLA chromosomal segment or haplotype has multiple class I and class II loci. However, there is variation in the number of *HLA-DRB* genes present on commonly occurring haplotypes. There are five different prototypic haplotypes that are very commonly observed^{9–11} (Figure 93.2). Thus, haplotypes expressing DR1, DR8, or DR10 typically have only the *DRB1** gene that can be expressed, while most other haplotypes have *DRB1** and a second gene expressed (*DRB3**, *DRB4**, or *DRB5**, encoding DR52, DR53, and DR51 antigens, respectively). It should be noted that exceptions to these prototypic haplotypes are known.^{12–15} These exceptional haplotypes may be difficult to match in unrelated-donor searches. Further, some reasonably frequent haplotypes do not express a second DR antigen as a result of an inactivating mutation, e.g., *HLA-B57*, *DRB1*0701*, *DRB4*01030102N*, *DQB1*030302*¹⁶; *DRB1*1502*, *DRB5*0108N*, *DQB1*0501*¹⁷; *HLA-B52*, *DRB1*1502*, *DRB5*0110N*, *DQB1*0503*.¹⁸

HLA STRUCTURE AND FUNCTION

The HLA class I^{19,20} and class II^{21,22} molecules were revealed by crystallographic studies to be similar in overall structure. The extracellular portion of both molecules is composed of four domains (Figure 93.3). A peptide binding structure formed by the two domains most distal to the cell membrane ($\alpha 1$, $\alpha 2$ of class I and $\alpha 1$, $\beta 1$ of class II) sits atop two membrane proximal domains ($\alpha 3$ and $\beta 2$ M of class I and $\alpha 2$, $\beta 2$ of class II). The intron/exon arrangement of the class I and class II HLA

Figure 93.1 HLA class I and class II genes of the HLA complex. This figure shows an abbreviated representation of the HLA region of chromosome 6. The relative locations of the genes commonly evaluated in transplant matching are shown. Solid bars represent α -chain genes and slashed bars represent β -chain genes. When present, the DRB3*, DRB4*, or DRB5* genes are located between the DRA1* and DRB1* genes

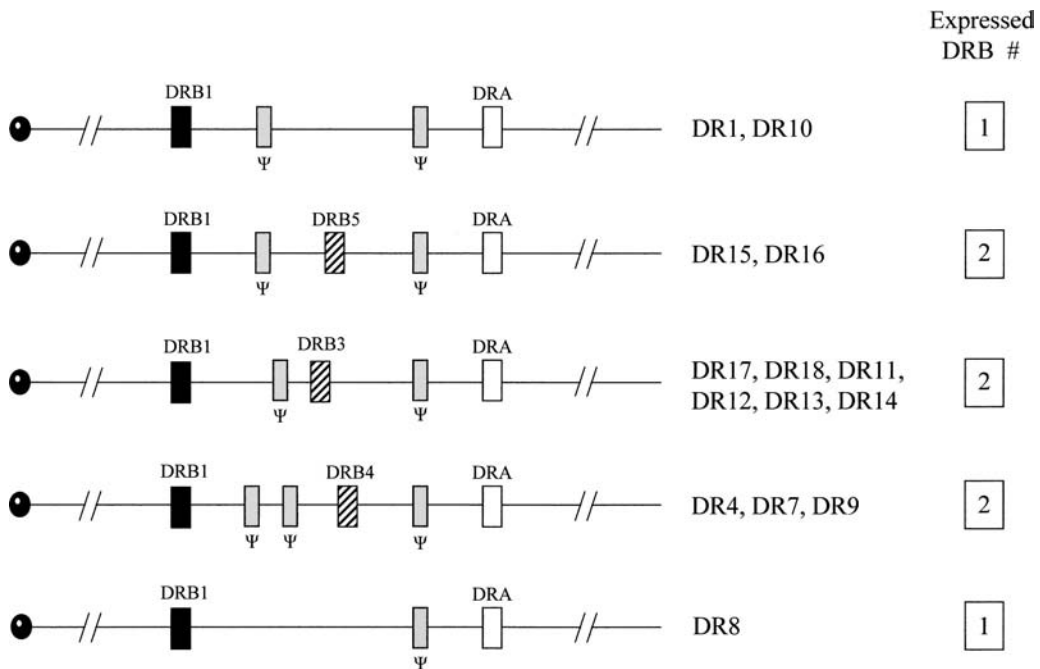

Figure 93.2 Prototypic HLA-DR haplotypes. The number of HLA-DRB genes and expressed DR molecules varies with different haplotypes. In this figure five common or prototypic HLA haplotypes, the normally associated DR types, and number of expressed DR molecules are shown. ψ indicates a nonexpressed DRB pseudogene

Figure 93.3 Domain structure of HLA molecules. HLA class I and class II molecules are heterodimeric glycoproteins composed of four external domains. The two most external domains of each molecule form a peptide binding structure that is recognized by T-cell receptors

(a) Class I

(b) Class II

Figure 93.4 Exon–intron organization of HLA class I and class II genes. Class I and class II genes are segmented into multiple exons separated by noncoding introns. Each external protein domain of the mature molecules is encoded by different exons

genes (Figure 93.4) corresponds in large part to the domain structure of the encoded molecules. Exons 2, 3, 4 of the class I alpha genes primarily encode the alpha 1, 2, 3 domains of the class I protein. In class II molecules, the alpha and beta gene products each contribute one domain to the peptide binding structure of the heterodimer. HLA class I molecules are found on nearly all nucleated cells. Class II molecules have a more restricted distribution, being found on B lymphocytes, activated T lymphocytes, macrophages, and dendritic cells.

T-CELL RECOGNITION OF HLA

As noted previously, the principal function of HLA molecules is to acquire peptide fragments and to interact with effector T cells or NK cells. Peptide fragments bound by HLA molecules are found in a cleft whose walls are formed by more or less parallel alpha helices that sit atop a floor formed by β -pleated sheets (Figure 93.5). In class I molecules, six pockets are formed that accommodate side chains of the bound peptides.^{20,25} Most of the highly polymorphic amino acid positions can be classified according to whether their side chains engage the bound peptide or the T-cell receptor (TCR) (contact residues).²⁶ In a similar fashion, the peptide binding^{21,22} and TCR contact residues of class II mole-

cules have been addressed in crystallographic studies.²⁷ While any HLA molecule can bind numerous different peptides, there is a selective or preferential binding of peptides (peptide binding motif) that is determined by the polymorphic HLA pocket residues. Since the TCR engages both bound peptide and TCR contact residues of the HLA molecule, T-cell specificity is influenced by both types of residues.

In HLA-identical transplants there are no foreign HLA molecules to which the donor can respond. However, cytotoxic T cells against minor histocompatibility antigens arise and can mediate GVHD and GVL.^{28,29} In these cases, peptides from the minor histocompatibility antigens are bound by host HLA molecules and are presented to donor T cells. In essence, such T cells are responding to a foreign peptide in a “self” HLA molecule.

In an allogeneic response to a mismatched HLA antigen, a large portion of T cells are activated.³⁰ While peptide-independent recognition of MHC has been demonstrated in some studies,^{31,32} most alloreactive T cells would appear to recognize foreign MHC in a peptide-dependent or a peptide-specific fashion.^{33–38} Thus, despite most peptide-binding residues being inaccessible to TCRs, they can influence the T-cell response by

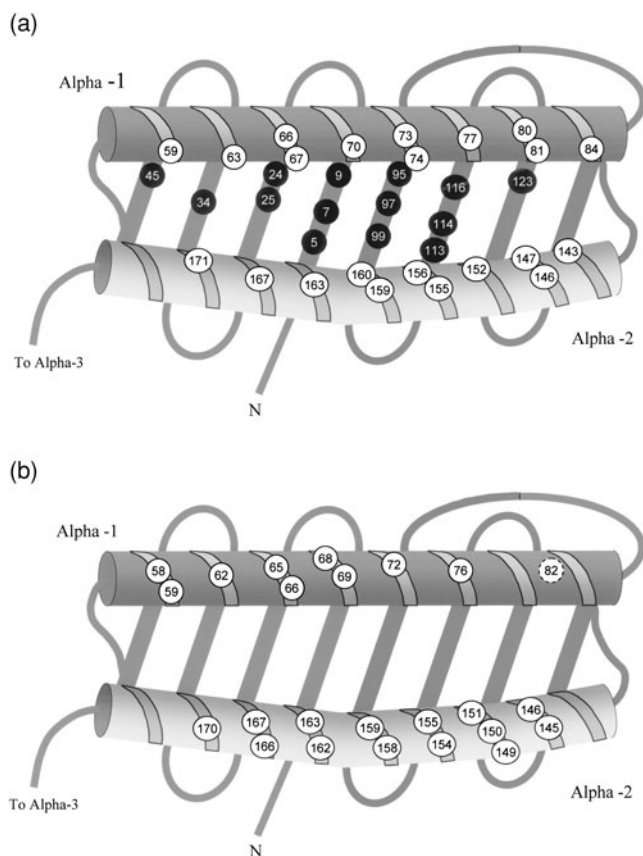

Figure 93.5 Peptide-binding structure of HLA class I molecules. This figure shows a representation of the peptide-binding structure formed by the α -1 and α -2 protein domains of a class I molecule. (a) Amino acid residues involved in peptide binding and (b) amino acid residues that contact the T-cell receptor. Residue positions in white are located in α -helical segments and those in black are located in β -pleated sheet segments of the molecule. The indicated residues are those designated in Ref. 23 and/or 24

dictating which peptides are bound and their orientation by the foreign HLA molecules. Since T cells specific for foreign HLA plus peptides are not negatively selected during thymic selection, alloreactive T cells of this sort can represent a large fraction of the mature T-cell repertoire.

NK CELL RECOGNITION OF HLA

NK cells are lymphocytes of the innate immune system that function early to control infections and have the ability to kill certain tumor cells.^{3,39} Lysis by NK cells is inversely related to target cell expression of class I MHC molecules. Since a number of viruses and tumor cells down regulate expression of class I molecules to avoid killing by cytotoxic T cells, NK cells are able to counter this adaptation. At the same time, the expression of class I molecules by healthy cells prevents their killing by NK cells. The inhibition of lysis is mediated by a set of NK-cell receptors specific for class I molecules. Among these are CD94/NKG2A, which recognize a subset of HLA class I leader peptides bound by the nonclas-

sic HLA-E molecule⁴⁰ and certain killer immunoglobulin-like receptors (KIR) (Table 93.1). Inhibitory receptors KIR2DL1, KIR2DL2, KIR2DL3 recognize an HLA-Cw amino acid motif dimorphism at positions 77 and 80,⁴¹⁻⁴⁴ the latter having been shown to be a receptor contact residue in crystallographic studies.^{43,44} KIR3DL1 is specific for the HLA-Bw4 epitope of a subset of HLA-B molecules.⁴⁵ The Bw4 epitope is determined by amino acids in the region of 77 to 83 of the HLA heavy chain. KIR3DL2 has been indicated to be specific for HLA-A3 and -A11.^{46,47} Studies have indicated that KIR recognition of HLA is dependent on bound peptides, but there is little indication that the peptide contributes to the specificity of the interaction.³

In the normal autologous setting, all NK cells have at least one inhibitory receptor that interacts with an autologous HLA class I molecule, thus preventing attack against normal cells. In an HLA class I mismatched transplant there may be donor NK clones that are able to attack recipient cells because the class I ligands for the inhibitory receptors are not present on these cells. It has been indicated that these cells can mediate an effective GVL effect in HLA-mismatched transplants.⁴⁸⁻⁵⁰

ANTIBODY RECOGNITION OF HLA

Alloantibodies directed against determinants of allogeneic HLA molecules can arise as a result of pregnancy, blood transfusion, and transplantation. Such antibodies are well known to cause rejection of solid organ transplants.⁵¹ The presence of patient antibodies against mismatched donor HLA antigens and a positive lymphocyte crossmatch is strongly associated with engraftment failure or graft rejection.^{52,53} For patients lacking an HLA-matched donor, recognizing the presence of HLA antibodies and defining the specificity(ies) can be very important in finding compatible donors. Antibody reactivity and specificity can be determined by testing against panels of HLA-typed cells or purified HLA antigens.

Table 93.1 HLA ligands for inhibitory KIR

Inhibitory KIR	HLA ligand	HLA ligand	HLA ligand
KIR2DL1	HLA-C Group 2	Lys-80	Cw2, Cw4, Cw5, Cw6, etc.
KIR2DL2, KIR2DL3	HLA-C Group 1	Asn-80	Cw1, Cw3, Cw7, Cw8, etc.
KIR3DL1	HLA-B Bw4 alleles	Residues 77-83	B51, B27, B38, B63, etc.
KIR3DL2	HLA-A3, -A11		

The commonly considered inhibitory killer immunoglobulin-like receptors (KIR) and associated HLA class I ligands are shown. HLA-C group specificity is associated with amino acids at residue position 80; Lysine (Lys, K) or Asparagine (Asn, N). Representative HLA-C group and Bw4 antigens are shown

POLYMORPHISM OF HLA GENES AND PRODUCTS

HLA NOMENCLATURE

Two nomenclature systems exist for the HLA system. The HLA system was originally described using alloantiseria reactive with antigenic determinants of HLA molecules expressed at the cell surface and a nomenclature developed around that typing system. With the advent of DNA-based methods in the mid-1980s a dramatic increase in the level of polymorphism was revealed and required an additional nomenclature system. Alleles identified by DNA typing were grouped according to nucleotide sequence homology, but to the degree possible the allele names retained a relation to the serologic or antigen-level names.

Figure 93.6 outlines the basics of the DNA-based nomenclature. HLA allele names indicate the locus (e.g., *HLA-A**) followed by up to eight digits that refer to a unique nucleotide sequence. With the exception of *HLA-DPBI**, the first two digits of an HLA allele name can be referred to as a family or group designation that signifies a high level of sequence homology. *DPBI** allele names are not grouped into homology-related families in general. This group or family in many, but not all, cases correlates with the serologic or antigen-level typing of the allele product. The third and fourth digits relate to the encoded protein product of the allele. The fifth and sixth digits, when present, indicate nucleotide sequence variant alleles that encode the same protein product due to codon redundancy (synonymous alleles). The seventh and eighth digits refer to allele nucleotide polymorphism outside of

HLA-A*24020102L	Low-expression allele		

Figure 93.6 HLA nomenclature. HLA DNA-based nomenclature consists of the HLA complex name followed by the locus identifier and a multidigit allele identifier with or without a qualifying letter designation. The significance of various positions is indicated in this figure

the coding portions (exons) of the allele. In some cases, these noncoding variations cause important functional characteristics of the allele, such as null or low expression. These expression variants can also be shown with an appended letter suggestive of the expression variation (e.g., N = null, L = low, S = soluble). The most current listing of HLA alleles can be found at <http://www.ebi.ac.uk/imgt/hla/index.html>.⁵⁴

In the laboratory, HLA alleles or molecules can be defined at different levels. Serologic HLA typing defines HLA products based on the pattern of reactivity with selected antibodies. DNA typing systems generally test for particular sequence motifs using sequence-specific oligonucleotide primer amplification (PCR-SSP) and/or oligonucleotide probe hybridization (PCR-SSOP) or direct sequencing (SBT) of amplified gene segments. Low-to-intermediate level resolution DNA test systems identify group or family level types (two digit nomenclature) that correlate in large part to antigen- or serologic-level typing. High-resolution DNA systems indicate specific alleles or a very limited set of allele possibilities. Aside from expression variant alleles, the first four digits of an allele name can be considered to fully define the expressed HLA product (four digit nomenclature).

In many cases, the first two digits of the HLA allele name correspond to the serologic or antigen name of the encoded product. For example, *A*01*, *A*02*, *B*07*, *B*08* alleles serologically type as A1, A2, B7, and B8 for all of the characterized alleles. In other cases, the allele group and serologic antigen name do not have this mnemonic similarity. For example, the B*40 group of alleles encode B60 (e.g., *B*4001*) and B61 (e.g., *B*4002*) antigens by serology. In these cases, the alleles are clearly related based on sequence homology, but are distinct in key residues that are involved in formation of epitopes recognized by antibodies (and T cells). The best source that correlates serologic antigen names with HLA alleles is that of Schreuder and colleagues.⁵⁵ Since many new HLA alleles discovered in DNA-based testing are not serologically characterized, the antigen-level assignment is not formally known. In many cases the probable antigen-level assignment can be surmised by a knowledge of which amino acid sequence motifs are important in antigen definition. A useful resource for this can be found at <http://tpis.upmc.edu/tpis/HLAMatchmaker/>.⁵⁶

HLA ALLELES

The genes of the HLA complex include the most polymorphic human genes with known function. For class I and class II loci that may be considered for matching in transplantation, there are more than 1700 alleles described (Table 93.2) (<http://www.ebi.ac.uk/imgt/hla/index.html>).⁵⁴ Considering the number of loci present per haplotype and the number of alleles at each locus, there is the formal possibility of an incredibly large number of distinct HLA haplotypes ($>9 \times 10^9$ for

Table 93.2 Polymorphism of HLA genes

HLA class I					HLA class II		
Locus	Alleles	Expression variants			Locus	Alleles	Null Variants
		Null	Low	Soluble			
HLA-A	313	20	2	0	HLA-DRB1	377	0
HLA-B	587	15	0	1	HLA-DRB3	41	0
HLA-C	139	2	0	0	HLA-DRB4	13	3
					HLA-DRB5	18	2
					HLA-DQA1	28	1
					HLA-DQB1	56	0
					HLA-DPA1	20	0
					HLA-DPB1	110	2

The number of alleles described for each of the indicated HLA loci is shown in the middle column. The number of expression variant alleles is indicated in adjacent columns. Data represent WHO listed alleles as of July 2004.⁵²

HLA-A, -B, -C, -DRB1) and tissue types. However, the practical numbers encountered are much smaller on two accounts. First, many of the described alleles occur at very low frequency in most or all populations. Thus, the majority of individuals in a population can be accounted for by a relatively limited number of alleles at the commonly typed loci.^{57,58} Second, alleles at different loci appear together more frequently than expected by chance due to linkage disequilibrium.^{6,59,60} As an example, *HLA-A*0101,B*0801,Cw*0701,DRB1*0301,DQB1*0201* may represent ~5% of the haplotypes in Northern European populations despite an expectation of about 0.007% based on the product of the individual gene frequencies. Patients with common or linkage HLA haplotypes more often find well-matched donors in unrelated-donor registries than do those with uncommon associations.⁶¹⁻⁶³

The level of polymorphism of the HLA genes is not equally distributed among the coding exons. For class I HLA genes, exons 2 and 3 are more polymorphic than other exons. For class II genes, exon 2 is the most polymorphic exon. As noted earlier, these exons encode the protein domains that form the peptide binding structure and interface for the T-cell^{22,26,27} and NK-cell receptors.^{43,44,64} Most of the highly polymorphic positions of these domains are involved in peptide-binding or TCR contact²⁶ (Figure 93.5). It may be that matching for these residues is more important than others in reducing adverse transplant outcome, although data supporting this are lacking as of yet.

ETHNIC DIFFERENCES IN HLA ALLELE AND HAPLOTYPE FREQUENCIES

Certain alleles and allele combinations (haplotypes) have very different frequencies in different ethnic or

racial groups.^{58,65-67} Further, a greater complexity due to the variety of alleles and haplotypes is also seen in some groups. The probability of finding an HLA-matched unrelated donor is affected both by this complexity and by the number of individuals of that group represented in the various registries.^{66,68-70} These considerations are the basis for unrelated donor registry recruitment efforts among minority groups.

HLA EXPRESSION VARIANTS (NULL, SOLUBLE, AND LOW-EXPRESSION ALLELES)

A number of HLA class I and class II genes have been described with mutations that prevent cell surface expression ("null" or "soluble") or cause reduced expression ("low")^{54,71} (Table 93.2). The greatest number of these expression variant alleles have been described for *HLA-A** and *-B**, but have been observed for most, if not all, HLA loci. While most of these variants are rare, some are not and may often appear as part of extended haplotypes (e.g., *DRB4*01030102N*,¹⁶ *DRB5*0108N*,¹⁷ *DRB5*0110N*,¹⁸ *A*24020102L*,⁷² *Cw*0409N*⁷³). Known expression variants can be typed by DNA methods, but serologic typing is useful for generic exclusion of such alleles.

The consequences of mismatches for null expression variants have not been reported. However, since the null alleles are generally considered not to produce surface HLA molecules, mismatching between an expressed and nonexpressed allele could result in allostimulation and an adverse transplant outcome.

The *A*24020102L* allele produces surface antigen sufficient to stimulate a T-cell response even though not detected by anti-A24 antibodies in serologic typing.⁷⁴ Severe acute GVHD in an *A*24020102L* patient transplanted with an *A*24*-negative donor was reported by Zanone-Ramseier and colleagues.⁷⁵

HLA MATCHING IN STEM CELL TRANSPLANTATION RELATED DONORS

HLA-IDENTICAL SIBLING DONORS

HLA-identical related donors (typically siblings) are generally considered to produce superior transplant outcome results compared to HLA-matched unrelated donors.^{76,77} It is against this subset of donors that all other alternate donor types are compared with regard to transplant outcome.

Since there is a 50% chance of two siblings inheriting the same HLA haplotype from a parent, there is a 25% chance that they will inherit the same chromosome from each parent. Overall, about 30–35% of patients find an HLA-matched sibling donor for transplantation. Serologic typing and low-resolution DNA typing for HLA-A, -B, -C, -DR may be sufficient to identify an HLA-identical sibling when enough family members have been studied to demonstrate that the same haplotypes were inherited (identity by descent). If not initially typed, HLA-DP typing may also be performed to exclude the possibility of a crossover in the interval between DR/DQ and DP. If two siblings have not been shown to be HLA identical by descent, there is the possibility that they have not inherited the same HLA haplotypes, but rather different haplotypes that are only similar at the tested loci. In such cases, additional study of untested loci and DNA testing at high resolution are warranted. If not initially studied, the inclusion of HLA-C and -DP testing is often useful to identify distinct haplotypes. Although HLA-identical relatives are generally siblings, more distant relatives are sometimes found to be HLA identical. This may be suggested by the architecture of the family and should be addressed when HLA-identical siblings are not identified.

HLA-MATCHED RELATED DONORS

While HLA-identical siblings have inherited the same haplotypes from each parent, other HLA-matched family members may be identified. These may include siblings, parents, and more distantly related individuals. Such individuals have typically inherited one HLA haplotype in common with the patient and a second, matched haplotype of independent origin. Since one haplotype is of independent origin, a higher level of HLA testing is needed to determine the level of similarity of the nonshared haplotype. Both the patient and the prospective donor should be tested for all relevant HLA loci at high resolution. Even when the nonshared haplotype is found to be identical at each tested locus, identity cannot be assumed for untested loci or DNA segments that may be relevant to transplant outcome (e.g., minor histocompatibility antigens, cytokine genes). Thus, donors HLA identical by descent may be preferred to over matched, but haplotype distinct related donors.

An HLA-matched, but haplotype distinct related donor may be favored over a matched unrelated donor on at least three counts. First, the shared haplotype is identical (within the boundaries marked by the tested loci), including any additional genes that may be important to transplant outcome. Second, a related donor is expected to share more minor histocompatibility genes with the patient than an unrelated donor. Third, a related donor is generally more accessible and may result in a more timely transplant.

When an HLA-identical sibling is not identified in the immediate family, the possibility that a more distant relative might be matched should be considered.⁷⁸ This may be particularly relevant when the patient has a rare HLA allele or haplotype paired with a haplotype that is frequent in the general population. The probability of finding a more distant matched relative is a function of the number of relatives available and the frequency of the more common haplotype in the general population or the ethnic group of the family. Allele and haplotype frequencies in various populations are available.^{57,58,65–70} The typical approach is to first determine which branch of the family carries the rare HLA allele or haplotype (e.g., maternal or paternal) and then to trace the rare haplotype by typing additional key relatives.

PARTIAL HLA-MATCHED RELATED DONORS

Partial HLA-matched related donors (PMRD) have been utilized as alternative donors for patients without an HLA-identical or phenotypically matched related donor.^{48–50,79–85} These cases nearly always involve a shared HLA haplotype between the patient and donor. The nature and number of mismatched HLA antigens or alleles can have an important effect on transplant outcome.

With partially matched related donors, the possibility of patient antibodies reactive with the mismatched HLA antigens should be addressed to avoid the associated risk of graft failure. Identification of patient antibodies against mismatched HLA antigens and a positive lymphocyte crossmatch against the donor strongly correlates with increased risk of graft failure.^{52,53,86}

Single-antigen-mismatched related donors

For patients without an HLA-matched related donor, a single-antigen- or allele-mismatched sibling donor is available in less than 5% of cases. Such cases may represent a recombinant HLA haplotype in the patient or donor, which can be demonstrated by family study. Other cases may represent two similar, but entirely unrelated haplotypes being present in the family. For unproven cases and unrelated haplotypes, high-resolution DNA typing and additional locus testing (e.g., Cw, DP) are needed.

Compared to HLA-identical sibling transplants, related single HLA-mismatched transplants have been

reported to have equivalent^{84,85} or reduced^{76,87,88} overall survival. Increased risk of severe acute GVHD has been reported with both class I and class II (*DRB1**) mismatches, although it may be higher with *DRB1** mismatches.^{85,87} Increased risk of graft failure and GVHD is associated with single-antigen PMRD donor transplants, but may be offset in part by lower relapse rates due to GVL effect observed in some studies. The stage of disease when the patient is transplanted is an important variable in transplant outcome. In some^{76,87} but not all^{85,88} reports, the negative overall survival effect of mismatch was observed in low- or standard-risk patients but not or less in high-risk patients where relapse may be a more imminent factor. When compared to unrelated donor transplants, single HLA-mismatched PMRD transplants have been reported to have comparable^{76,85,87,89} overall survival.

Haploidentical HLA-mismatched related donors

Related donors sharing one HLA haplotype, but with a greater level of HLA disparity have also been used.^{48–50,79,81,83,84,90} The greater level of disparity is associated with increased engraftment failure, GVHD, and transplant-related mortality (TRM).^{76,87,91} Drobyski and colleagues⁸³ found that matched, unrelated-donor transplants had better outcomes than related donors, with more than one HLA mismatch for class I (A,B) or class II (*DRB1**,*DQB1**). Improved results may be obtained with more extensive GVHD prophylaxis, rigorous donor T cell depletion, and high stem cell doses.^{48–50,79} Ruggeri and colleagues^{48,49} found that NK cells can have a profound effect in patients receiving rigorously T-cell-depleted stem cells from single haplotype matched donors. In patients who lacked an HLA ligand for an inhibitory KIR present in the stem cell donor (see Table 93.1), donor NK cells capable of killing patient lymphoblasts were found. In patients with myeloid disease, especially AML, KIR epitope mismatched transplants had increased engraftment and lower relapse rates than did KIR epitope matched cases. Leung and colleagues,⁵⁰ in a study of pediatric patients, reported a stronger correlation by testing donor cells for KIR expression and extended the observation to ALL patients. The authors suggest that when inhibitory KIR receptors of donor NK cells are not engaged by recipient ligands they are able to mediate a strong GVL effect and may also promote engraftment. Whether a similar benefit may apply in unrelated stem cell transplants is not established since conflicting studies have been reported.^{92–95}

UNRELATED DONORS

Since only about 30–35% of patients needing a stem cell transplant have a suitably HLA-matched relative able to donate, the majority of patients need alternate

donors. As indicated earlier, some additional patients can be transplanted with partially matched related donors with acceptable outcomes. Nevertheless, many patients do not have suitable related donors and seek unrelated donors. Over the years, a number of national and international donor registries have been set up to facilitate unrelated-donor transplants. There are currently more than 9 million prospective donors registered along with a significant number of stored cord blood units (CBU).

HLA-MATCHED UNRELATED DONORS

While HLA-identical sibling donors produce the best transplant outcomes,⁸⁴ closely matched unrelated donors (MUD) can also produce acceptable results.^{96,97} Sources of stem cells for unrelated donor transplants include bone marrow⁹⁷ peripheral blood stem cells (PBSC),⁹⁸ and umbilical cord blood cells.^{99–103}

In sibling donor transplants, serologic or low resolution HLA testing sufficient to prove haplotype identity is adequate, but this is not the case when unrelated donors are being considered. With the advent of DNA-based HLA testing, it was quickly apparent that serologically defined HLA antigens represent multiple distinct alleles in most cases.⁵⁵ The available literature on the role of HLA matching in stem cell transplant outcome varies both with regard to the number of HLA loci tested and the resolution level of the testing performed.

Which HLA loci should be matched?

As shown in Table 93.3, matching for many of the HLA loci has been reported to be important in affecting transplant outcome, and there has been general consensus that mismatches for HLA-A, -B, and -DR loci are important. Studies using DNA typing methods have demonstrated the importance of matching for HLA-C in MUD transplants.^{104–106,108,109,123} Thus, matching for HLA-A, -B, -Cw, and *DRB1** is supported by numerous studies. Conflicting results have been reported regarding the importance of matching for HLA-DQ and -DP (Table 93.3). In some cases, the effect of mismatch was observed when coupled with mismatches at other loci but not in isolation. The effect of mismatches at *DRB3**, *DRB4**, and *DRB5** (secondary DRB) has not been evaluated. It can be argued that all of these loci should be matched between patient and donor if possible since products of all of these alleles can elicit T-cell responses.^{124,125} Because of strong linkage disequilibrium between *DRB1** and DQ and the secondary DRB loci, matching can generally be accomplished. However, since linkage disequilibrium between *DRB1** and DP is much lower, otherwise very well matched donors are frequently mismatched at DP. If included in a matching algorithm, some centers may use HLA-DP matching to distinguish among otherwise matched donors.

Table 93.3 Effect of HLA matching on unrelated donor transplant outcome

HLA Locus	Matching benefit	Literature citation	
		Match benefit	Lack of benefit
A	Yes	104–107	
B	Yes	104–107	
C	Yes	104–111	
DRB1	Yes	105, 106, 112, 113, 114	104
DRA	No		
DRB3, DRB4, DRB5	Unknown		
DQA1	No	106	
DQB1	Variable reports	110, 115, 116	106, 113
DPA1	Variable reports	117	106, 118
DPB1	Variable reports	118–121	104, 106, 113, 128

What level of matching is appropriate?

Initially, the importance of matching for HLA-A, -B, and -DR was established by serologic or antigen-level assignment.^{126,127} With DNA-based typing it was subsequently shown that allele- or high-resolution-level matching for DRB1* was associated with lower GVHD and TRM,^{112–114,128,129} being most evident when donors were otherwise matched for class I antigens. Since the mid-1990s most centers have matched unrelated donors for DRB1* at the allele- or high-resolution-typing level whenever possible, and often with preference over matching for class I.

Until the later 1990s, most studies of HLA matching involved antigen- or low-resolution-level HLA class I typing and may not have considered HLA-C.

A number of recent large studies have investigated the role of class I matching using allele-level DNA typing. Petersdorf and colleagues^{23,107} found that single-antigen-level or multiple-allele-level class I (A, B, C), but not class II, mismatches in the HVG (host *versus* graft) vector were associated with graft failure in CML patients. The risk of graft failure was particularly high when the mismatch was only in the HVG direction (donor is mismatched at a locus for which the patient is homozygous). In a subsequent study,¹¹⁰ allele- or antigen-level HLA-A, -B, -C mismatches were associated with increased mortality in low risk, but not higher risk CML patients. Two large registry studies of transplants performed at multiple centers and in multiple disease types have also been reported. Morishima and colleagues^{104,105} found that single

HLA-A, -B, -C, and -DRB1* antigen- or allele-level mismatches were associated with increased acute GVHD, and class I mismatches were risk factors for failed engraftment. Flomenberg and colleagues¹⁰⁶ found that antigen or low-resolution mismatching at HLA-A, -B, or -Cw was significantly associated with increased mortality. No significant mortality risk was found for single locus mismatches found only at the allele level (i.e., antigen level matched), although a trend was shown for HLA-A allele mismatches. For severe acute GVHD, only HLA-A antigen-level mismatches were significantly associated although trends for association for HLA-B and -C were present. In sum, these studies show that HLA-A, -B, -C antigen or low-resolution mismatches are clearly associated with reduced overall survival. The effect is at least similar to mismatches for HLA-DRB1* and has called into question the common practice of giving matching preference to DRB1* when choosing partially mismatched unrelated donors. With regard to allele-level versus antigen-level class I mismatches, it would appear that single-antigen-level mismatches are more strongly associated with severe consequences than are allele-level mismatches. However, trends toward allele mismatch effect and indications of cumulative or synergistic effects of multiple allele mismatches suggest that allele-level matching for at least HLA-A, -B, -C, and -DRB1* should be utilized when possible. Similar high-resolution matching for HLA-DQ and -DP is also supported by reports by individual centers.

WHAT IF HLA-MATCHED DONORS ARE NOT AVAILABLE?

If related donors and matched unrelated donors are not available, one may choose to consider partially matched unrelated donors. As discussed earlier, mismatched unrelated donors have increased risk of severe complications and increased mortality. However, despite the increased risk, successful outcomes are observed. Transplantation in these cases may benefit from alternate donor sources, protocols designed to minimize the risk of increased complication rates, or selection of donors whose mismatches may elicit less severe immune responses.

ALTERNATE DONOR SOURCES

Unrelated cord blood stem cells

Unrelated cord blood (UCB) cell transplantation has been used successfully to treat pediatric and smaller adult patients.^{99,101–103} Patients receiving HLA mismatched related and UCB transplants have a lower rate of severe acute GVHD and mortality than is observed in marrow transplants with a similar level of HLA mismatch.¹⁰¹ Stem cell or nucleated cell dose is critical to successful engraftment and is the most important factor affecting patient survival in cord transplants.^{99,101–103} However, minimizing HLA mismatches is still important in cord transplants. Rubinstein and

Stevens¹⁰³ reported that risk of severe acute GVHD correlated with HLA mismatch. Considering HLA-A, -B (antigen level) and *-DRB1** matching, severe GVHD was seen in 8, 19, and 28% for 6/6, 5/6, and $\leq 4/6$ HLA mismatches, respectively.

T-cell depleted stem cell products

T-cell depletion of stem cell products can effectively reduce GVHD, but was found to be associated with an increased relapse rate due to the loss of a GVL effect.^{79,80} However, as noted previously, rigorous T-cell depletion/CD34⁺ enrichment has been successful in related, haplotype mismatched donor transplants, particularly when the HLA mismatch prevents KIR inhibition of donor NK cells.^{48,49,50} This might also apply to unrelated donors, but conflicting indications have so far been reported.⁹²⁻⁹⁵ Another approach may be to transplant T-depleted donor stem cells and then at a later date infuse reserved donor T cells when the patient hematopoietic system has been replaced.¹³⁰ The intent being to avoid the massive initial stimulation of donor T cells by patient hematopoietic cells ("cytokine storm") that may promote GVHD, but recovering a GVL effect at a later point.

CAN ACCEPTABLE HLA MISMATCHES BE PREDICTED?

Even with the large number of prospective donors listed by the various registries around the world, many patients do not find a matched donor even for HLA-A, -B, -C, *-DRB1**. Despite the increased risk associated with HLA-mismatched transplants, acceptable results are achieved for many patients despite an imperfectly matched donor. The question raised is whether certain HLA mismatches are better tolerated than others and if so, whether this can be applied to donor selection to improve outcome.

Comparing different prospective allele mismatches simply on the basis of the number of mismatched amino acids is unlikely to be helpful. More likely to be useful would be a qualitative analysis of the mismatched residues. As discussed previously, most alloreactive T cells recognize foreign MHC in a peptide-dependent or a peptide-specific fashion,³³⁻³⁸ leading to the speculation that HLA amino acids involved in peptide binding and TCR interaction may be more important to matching than other positions (see Figure 93.5). Antigen-level class I mismatches pose a greater risk than allele-level mismatches for graft failure¹¹² and increased mortality.¹⁰⁶ Petersdorf and colleagues²³ observed that there were a greater number of differences in peptide binding and especially TCR contact residues in the antigen-mismatched donor/recipient pairs rather than in allele-level mismatched donor/recipient pairs. Ferrara and colleagues¹³¹ found that transplanted patients whose donors were mismatched at residue 116 of HLA class I molecules (A, B, or Cw) were at higher risk of severe GVHD and increased

mortality than those with mismatches at other residues.¹³¹ This residue is in the floor of the cleft and is expected to contribute to peptide-binding specificity.¹⁹ In addition to the molecular position of the mismatched residue, the nature of the mismatched amino acid may relate to the impact of the change. Substitution with amino acids of similar character may have less effect than that with dissimilar amino acids.

The ability to associate particular HLA allele mismatches with different levels of complication risk would be useful to distinguish among mismatched prospective donors. Elsner and colleagues^{24,132} have developed an online tool that compares HLA alleles based on quantitative, positional, and qualitative evaluation of the mismatched amino acids and produces a dissimilarity score (<http://histocheck.de/>). Shaw and colleagues¹³³ studied 26 HLA-A allele level mismatched transplants but did not find a correlation of the dissimilarity scores and transplant outcome. That HLA allele pairs can be compared with regard to probability of T-cell stimulation is a logical premise. However, further large studies of HLA allele level typed transplant pairs will be needed to determine clinical validity of this approach.

UNRELATED DONOR REGISTRIES

For patients without a suitable related donor, searching unrelated donor registries may provide a suitable donor.¹³⁴ The National Marrow Donor Program (NMDP) is the largest of the registries with over 5 million prospective marrow/PBSC donors and 31,000 CBU¹³⁵⁻¹³⁷ (<http://www.nmdpresearch.org/index.html>). NMDP searches include donors from Bone Marrow Donors Worldwide, representing registries from 39 countries and bringing the total number of prospective donors to over 9 million (<http://www.bmdw.org/database/donors.htm>). As discussed previously, the prospect of finding a match for a patient with uncommon or rare HLA alleles may be different in various populations. Thus, a search of different registries may be more likely to provide a matched donor. In the NMDP registry, five major groups are represented: Caucasian (67.4%), Hispanic (10.6%), African American (9.9%), Asian/Pacific Islander (7.8%), American Indian/Alaska Native (1.6%).¹³⁶ The CBU Registry has about 30% minority representation. Of the registrants, approximately two-thirds have at least serologic or antigen-level typing for HLA-A, -B, -DR.

When a search is requested a list of potentially matched registrants or CBU is generated. NMDP search reports indicate prospective marrow/PBSC donors with potential for 5/6 and 6/6 (A, B, DR) matches and 4/6, 5/6, and 6/6 for CBU. From among those likely to be matched, a sample for confirmatory and additional HLA testing can be requested. This typing can be performed

by the transplant center laboratory or an NMDP reference laboratory. The NMDP requires that both patient and donor be HLA typed at high resolution or allele level for HLA-A*, -B*, and -C* (minimal exons 2 and 3) and DRB1* before donation can occur. This does not indicate that patient and donor must be matched at high resolution for these loci. The intent is to allow analysis of the effect of allele-level matching on transplant outcome.

The prospect of finding a preliminary HLA-A, -B, -DR matched registry donor (i.e. serologic level typing) is 87% for Caucasians, 75% for Asian/Pacific Islander, 85% for Hispanic and 60% for African Americans according to NMDP statistics.¹³⁵ However, when allele-level matching and other loci are considered, the probability of a full match drops markedly. Tiercy and colleagues^{138,139} indicated that half or less of their patients with preliminary matches (A, B, DR antigen level) were able to find allele-level matched donors for HLA-A, -B, -Cw, -DRB1, -DRB3, -DRB5, -DQB1. Finding highly matched donors for patients of ethnic minorities is especially difficult.^{62,70}

STRATEGIES FOR UNRELATED DONOR SEARCHES

Identification of a prospective unrelated stem cell donor is based principally on HLA matching. The patient should be initially typed for all relevant loci at allele/high resolution even though registry-matching algorithms are currently based on A, B, DR. This information can be used to indicate the probability that a matched donor will be found and may suggest the number of donors from a preliminary search that should be recruited for confirmatory or higher resolution testing. Since an increasing proportion of registry donors have been typed at high resolution and for more loci, the preliminary search results may already indicate well-matched donors that can be requested for confirmatory typing. Patients that have common HLA alleles and haplotypes more often find matched unrelated donors⁶¹⁻⁶³ and one can expect that only a few donors need to be typed to find a well-matched donor over the HLA-A through DQ interval. In contrast, rare alleles or haplotypes may indicate that a greater number of donors need to be considered.

In some searches, a large number of donors are possible matches by low resolution typing, and the problem becomes identifying those that may be more likely to match the patient. These can sometimes be prioritized on the basis of additional loci that have been tested. As mentioned previously, the HLA complex displays a high level of linkage disequilibrium between loci. Thus, one may selectively perform confirmatory testing on donors who are listed as *DRB1*13*, *DQB1*0604* or *DRB1*13*, *DRB3*0301* for a patient who is *DRB1*1302*, since these are the most common associations for this allele. Another example would be typing B44, Cw5 prospective donors to enrich for the

*B*4402* subtype as opposed to the other common B44 subtype of *B*4403*.

Some HLA alleles or haplotypes may be rare in the general population but more common in particular ethnic or racial groups. This information can be used to focus a donor search in those groups' registries that are more likely to have individuals that match the patient. Thus, for a patient who is *DRB1*1503* one may focus confirmatory testing mainly on African American donors listed as *DRB1*15* rather than *DRB1*15* Caucasians since the frequency of this allele differs markedly in the two groups (>80% vs <5%, respectively). A number of references regarding HLA antigen or allele frequencies in different populations are available.^{57,58,140} In some cases, donors may be matched for a patient but have been incorrectly typed or listed on the registry. This problem is most apparent for donors who only have serologic-based typing as is more often seen for antigens that are difficult to assign by serologic typing.¹⁴¹ If no matches are indicated for a patient with one of these difficult antigens, one should consider repeating the registry search using a surrogate antigen that the proper antigen may have been mistyped as (e.g., A26 to replace A66). Some problem antigens may have been missed entirely in serologic typing and running a second registry search without that antigen may pick up a matched donor (e.g., A74, particularly when paired with another A19 group antigen).

Patients with null or expression variant alleles may be difficult to match in registry searches, although the indications that the more common variants may appear as part of extended haplotypes may be somewhat encouraging.^{16-18,72,73} Donors with expression variants mismatched to patients can be excluded on the basis of serologic- or DNA-based typing.

SEARCHES FOR HLA-MISMATCHED UNRELATED DONORS

For a significant fraction of patients a fully matched donor may not be obtained. Tiercy and colleagues¹³⁸ indicated that their patients for whom full HLA-matched donors were not found fell into four categories (1) a rare allele in the patient, (2) an unusual B-DR or DR-DQ haplotype in the patient, (3) an antigen that is split into more than two alleles with greater than 10% frequency (e.g., *DRB1*04*), (4) a B antigen that has multiple Cw associations (e.g., *B*51*). Since some patients can do well with mismatched donors, the issue may become finding prospective donors that represent minimal mismatches to the patient, as discussed previously. Given the high level of linkage disequilibrium, especially between HLA-B and -Cw and between DR and DQ, mismatches at B or DR are very often also found to be mismatched at Cw or DQ, respectively. This may affect the choice of prospective donors on whom to perform additional testing to avoid multilocus mismatches.

SUMMARY

HLA matching between patient and donor is a critical component in determining the success of allogeneic stem cell transplantation. High-level matching is associated with improved engraftment, reduced severe GVHD, and improved patient survival. Mismatching at most HLA loci has been correlated with adverse outcome in at least some reports, and there is essential consensus that matching for HLA-A, -B, -Cw, and *-DRB1** is important for improved outcome.

It is important to develop consensus on the effect of mismatching for other HLA loci that have not been well studied or for which there are conflicting indications. Since a significant fraction of patients do not have fully matched donors (related or unrelated), it is important to determine if certain HLA mismatches may be better tolerated than others and produce less risk of adverse outcome. This will require the study of large numbers of patient/donor pairs that have been HLA typed at allele level for each of the polymorphic loci.

Chapter 94

STEM CELL MOBILIZATION

Auayporn Nademanee

Hematopoietic progenitors cells (HPC) were first demonstrated in human peripheral blood (PB) in 1971.¹ In normal individuals small amounts of peripheral blood stem cells (PBSC) are present in the PB during steady state hematopoiesis and many aphereses are required to obtain adequate PBSC for transplant. In the mid 1980s, autologous PBSC transplantations (PBST) were performed successfully as an alternative to bone marrow transplantation (BMT) in patients with malignant lymphoma, breast cancer, and acute leukemia.²⁻⁴ These studies showed that hematopoietic engraftment can be achieved with stem cells collected from the circulating blood rather than from the bone marrow (BM) and hematopoietic reconstitution using stem cells collected during steady-state was similar to BM. However, while most patients experienced a complete and stable hematopoietic reconstitution, some patients had slow platelet recovery or experienced a subsequent fall in PB count with nonmobilized PBST. This raises some concerns about the ability of circulating stem cells collected during steady state to sustain life-long hematopoiesis. Some investigators added PBSC to autologous BM grafts in an attempt to shorten the duration of neutropenia and enhance hematopoietic recovery. However, only the addition of PBSC collected after prior myelosuppressive therapy,⁵ not during the steady state,⁶ were found to accelerate hematopoietic recovery and prompt engraftment.

Blood progenitor cell mobilization in humans was initially noted during recovery from myelosuppressive chemotherapy.⁷ The advances in knowledge in stem cell biology, the availability of hematopoietic growth factors, the availability of large-scale, continuous-flow leukopheresis, and an improved technique for progenitor cells assay, have increased the use of mobilized PBSC for transplantation. PBSC have several advantages when compared to BM grafts, including the fact that it is an outpatient procedure and no general anesthesia is required. In addition, results from randomized studies have shown that the hematopoietic recovery following myeloablative therapy was much more rapid with mobilized PBSC autografts than with BM autografts followed by growth factor.⁸ This has lead to the widespread use of mobilized PBSC in all

autologous transplant settings and in many allogeneic transplant settings.

MECHANISM OF STEM CELL MOBILIZATION

Despite the success of PBST, the exact mechanism involved in PBSC mobilization and homing is not well understood. There is evidence that cytotoxic agents disrupt normal marrow endothelial cell barriers and thus facilitate homing and release of hematopoietic stem cells (HSC). A number of different cytokines are also known to up- or downregulate specific adhesion molecules on both progenitor cells and endothelium and may mediate both the binding and release of HSC and progenitor cells.

A significant number of studies in the past few years have revealed insights into regulation of HSC release, migration, and homing as well as the mechanism of different mobilization pathways. Under steady-state conditions, most of the stem cells are maintained in the G₀ phase of the cell cycle by interaction with stromal cells in the BM, while there is only a small proportion of stem cells in the S or G₂/M phase of the cell cycle. Adhesive interaction between the CD34⁺ hematopoietic stem cell with cellular and matrix components of the BM environment are involved in stem cell mobilization.⁹ Primitive HSC express a wide range of cell adhesion molecules (CAM), including members of the integrin, selectin, immunoglobulin superfamily, and CD 44 families of adhesion molecules. The mobilization process is initiated by stress-induced activation of neutrophils and osteoclasts by chemotherapy and repeated stimulation with cytokines, resulting in shedding and release of membrane-bound stem cell factor (SCF), proliferation of progenitor cells, as well as activation and/or degradation of adhesion molecules such as very late antigen (VLA-4) and L-selectin. Recent studies suggest the interaction between CXCR4 and its ligand stromal-derived factor-1 (SDF-1) plays a key role in stem cell mobilization.¹⁰ Active signaling through SDF-1/CXCR4 and upregulation of adhesion molecules are required for homing, whereas downregulation of adhesion molecules and

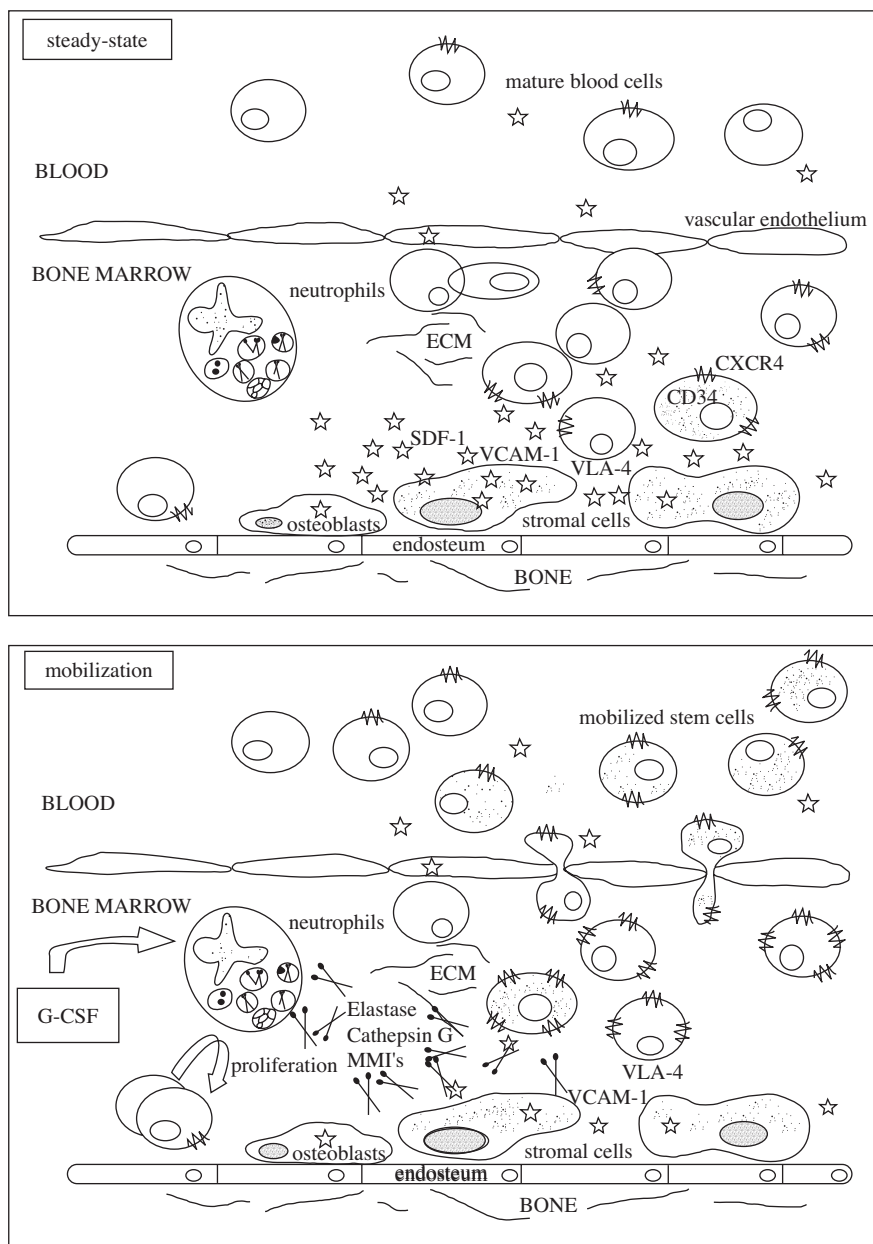

Figure 94.1 A model for stem cell mobilization by G-CSF. In steady state (upper panel), stem cells are localized in close proximity to stromal cells. Retention is mediated by adhesion molecules such as VCAM-1/VLA-4 and through SDF-1/CXCR4 interactions. During mobilization (lower panel), G-CSF induces both cell proliferation and release of neutrophil proteases (elastase, cathepsin G, and MMPs), which participate in cell egress by degrading retention signals (VCAM-1 and SDF-1) and by remodeling the extracellular matrix. Upregulation of CXCR-4 on BM cells during G-CSF-induced mobilization suggests active participation of SDF-1/CXCR4 interactions in the migration of cells toward the blood. (From Lapidot and Petit¹⁰, used with Permission.)

disruption of SDF-1/CXCR4 signaling are required for mobilization of HSC. Lapidot and Petit have recently suggested a model wherein granulocyte colony-stimulating factor (G-CSF) stimulation induces proteases such as neutrophil elastase and other matrix metalloproteases that markedly reduce local BM of SDF-1, resulting in the egress of HSC and progenitor cells from BM into PB.¹⁰ Mobilized CD34⁺ cells have lower levels of VLA-4, c-kit expression, and CXCR4 expression compared with steady-state BM and PB. The release of CD34⁺ cells from the marrow is contingent upon an extensive decrease in L-selectin and moderate decrease in VLA-4 expression on CD34⁺ cells, and therefore, VLA-4 might have a role in facilitation of extravasation and release of CD34⁺ cells from the marrow into blood stream. The reduced c-kit expression before the egress of HSC in the circulation is inversely correlated with stem cell yield. The activation

of the metalloproteinase (MMP)-9 leading to the release of c-kit-L is a decisive checkpoint for the mobilization of HSC as it promotes the recruitment of stem cells into PB. The proposed mechanism of stem cell mobilization is shown in Figure 94.1.

PARAMETERS USED FOR MEASUREMENT OF PBSC

HSC are clonogenic cells capable of self-renewal and multilineage differentiation. Progenitor cells are oligolineage cells that are already more restricted in their differentiation potential and are not able to self-renew. The expression of the antigen CD34 and lineage negativity are often used as surrogate markers for HSC and progenitor cells. The percentage of CD34⁺ cells in PB

under steady-state conditions is about 0.06% and about 1.1% in BM.¹¹

Other parameters used to measure the quantity of PBSC include nucleated and mononuclear cell number (MNC) and colony-forming unit granulocyte-macrophage (CFU-GM). Several studies have shown that the number of MNC count correlates poorly with engraftment kinetics, thus it is no longer used for PBSC enumeration. Both the CFU-GM and CD34⁺ assays are the two most commonly used indicators which have been shown to predict the time to engraftment. Numerous studies have shown a relationship between the dose of CD34⁺ cells, the concentration of CFU-GM, and the time to engraftment.^{12,13} However, CFU-GM assays require significant laboratory skill, and methodology in different laboratories varies greatly. Therefore, quantifying CD34⁺ cells by flow cytometry is now the method of choice for determining graft adequacy. Moreover, the CD34⁺ cell count has been shown to be a good predictor for engraftment kinetics, especially for platelets.

METHODS OF STEM CELL MOBILIZATION

MYELOSUPPRESSIVE CHEMOTHERAPY

Several methods to mobilize PBSC from an extra vascular location into circulation have been described. Myelosuppressive chemotherapy was the first method described for stem cell mobilization.¹⁴ During the recovery phase after myelosuppressive chemotherapy, there was a 14- to 100-fold increase in peripheral blood CFU-GM above the baseline. The extent of this increase is proportional to the severity and duration of the cytopenia. High-dose cyclophosphamide (CY) is the most commonly used regimen since it is active against most tumors. However, there are several disadvantages to chemotherapy mobilization, including the length of time required, toxicity, neutropenic fever and/or sepsis, bleeding diathesis, and the unpredictable timing of apheresis. In addition, little or no increase in peripheral blood CFU-GM was observed in some patients who had received extensive prior therapy and patients with marrow involvement with tumor.¹⁵ With the introduction of hematopoietic growth factors, it is no longer acceptable to use myelosuppressive chemotherapy alone for stem cell mobilization.

HEMATOPOIETIC GROWTH FACTORS ALONE

Several hematopoietic growth factors have been used to mobilize PBSC including G-CSF, granulocyte macrophage colony-stimulating factor (GM-CSF), interleukin-3 (IL-3), and SCF. Currently, G-CSF is the most commonly used agent to mobilize PBSC because of its potency and lack of serious toxicity. There are several common features observed during mobilization with hematopoietic growth factors.¹⁶ First, mobilization kinetics are similar, with peak levels of circulating HPCs generally achieved after 5–10 days of growth factor.

Second, a broad spectrum of HPCs is mobilized, including pluripotential, and committed myeloid, megakaryocytic, and erythroid progenitors. Third, the increase in circulating HPCs is associated with decreased numbers of HPCs in BM. And finally, mobilized HPCs have characteristic phenotypic features distinct from those of HPCs that reside in the BM under steady-state conditions. Relative to BM, a higher percentage of mobilized PBSC are in the G₀ or G₁ phase of cell cycle, and the expression of VLA-4 and c-kit on their surfaces is reduced. A recent study showed that HPCs are selectively mobilized after the M phase of cell cycle thus providing a potential explanation for preponderance of HPCs in the G₀ or G₁ phase of the cell cycle in blood.

The mechanism by which growth factors mobilize PBSC is not clearly understood. Recent animal studies have provided some insight into stem cell trafficking in the BM and the role of adhesion molecules in HPC mobilization.^{16–18} The model of HPC mobilization by G-CSF is shown in Figure 94.2.

G-CSF

G-CSF stimulates neutrophil granulopoiesis in a dose-dependent manner. The level of PB progenitor cells

Figure 94.2 Model of hematopoietic progenitor cell mobilization by granulocyte colony-stimulating factor. In this model, G-CSF-induced HPC mobilization occurs in two steps. In the first step, G-CSF activates a target cell population (as yet undefined). The second step is the generation of secondary signals by these activated cells, leading in turn to HPC mobilization. Potential secondary signals include protease release by activated cells and the modulation of stromal-derived factor-1 (SDF-1) expression in the BM. (From Thomas et al.¹⁶, used with permission.)

increase from 40- to 80-fold after 4–5 days of G-CSF and returns to baseline value within 4–6 days after cessation of G-CSF. Sheridan et al.¹⁹ were the first to report that hematopoietic reconstitution can be accomplished after G-CSF-mobilized PBSC following high-dose chemotherapy. The time to platelet and RBC transfusion independence was shorter with G-CSF-mobilized PBSC. Chao et al.²⁰ reported the results of hematopoietic recovery in 85 patients with Hodgkin's disease who received autologous PBSC using PBSC collected during steady-state or G-CSF-mobilized PBSC, with or without BM. The use of G-CSF-mobilized PBSC resulted in a significantly accelerated time to recovery of granulocytes (10 days vs 12 days; $P < 0.01$) and platelet engraftment (13 days vs 30 days; $P < 0.001$).

Two randomized studies have also shown the benefits of G-CSF-mobilized PBSC compared to autologous BM after high-dose therapy. Fifty-eight patients with heavily pretreated Hodgkin's and non-Hodgkin's lymphoma (NHL) were randomized to receive either G-CSF-mobilized PBSC or autologous BM.²¹ All patients received G-CSF after transplant. Patients who received G-CSF-mobilized PBSC had faster engraftment of both absolute neutrophil count (ANC) $> 0.5 \times 10^9/L$ (11 days vs 14 days; $P = 0.005$) and platelet recovery more or equal to $20 \times 10^9/L$ (16 days vs 23 days; $P = 0.02$). Similar results were reported by Hartman et al.⁸ in a larger randomized study of 129 patients with solid tumor and lymphomas. In addition, a cost analysis showed that the total cost was decreased by 17% in adults and 29% in children receiving PBSC transplantation.

The doses of G-CSF used for mobilization are also important and several studies have shown that using higher doses of G-CSF results in a higher number of CD34⁺, or CFU-GM yield and a lesser number of collections. Nademanee et al.²² showed a dose-response effect for G-CSF, with a sevenfold increase in the number of CD34⁺ cells in the PB over the baseline value for 5 $\mu\text{g}/\text{kg}$ per day and 28 times for 10 $\mu\text{g}/\text{kg}$ per day. Similarly, there were 10- and 17-fold increases in CFU-GM over baseline for 5 $\mu\text{g}/\text{kg}$ per day and 10 $\mu\text{g}/\text{kg}$ per day of G-CSF, respectively. Weaver et al.²³ conducted randomized studies to evaluate different doses of G-CSF, 10, 20, 30, or 40 $\mu\text{g}/\text{kg}$ per day on yields of CD 34⁺ cells in patients with breast cancer. The median number of CD34⁺ cells collected after 10 $\mu\text{g}/\text{kg}$ per day was $0.7 \times 10^6/\text{kg}$ per apheresis (range 0.1–4.4) as compared to 1.2 (range 0.1–6.8) after 30 $\mu\text{g}/\text{kg}$ per day ($P = 0.04$). Patients receiving 10 $\mu\text{g}/\text{kg}$ had lower yields of CD34⁺ cells and had a 3.3-fold increase in the probability of not achieving more or equal to 5.0×10^6 CD34⁺ cells per kg as compared to patients receiving 20–40 $\mu\text{g}/\text{kg}$. These data suggest that doses of G-CSF > 10 $\mu\text{g}/\text{kg}$ per day mobilize more CD34⁺ cells and may be useful when high numbers of CD34⁺ cells are desired.

GM-CSF

GM-CSF is a multilineage CSF because it stimulates the proliferation and differentiation of HPCs into neu-

trophil, eosinophil, and monocyte colonies. GM-CSF functions in conjunction with other cytokines, erythropoietin and IL-3, to promote the proliferation and differentiation of erythroid and megakaryocytic progenitors, respectively. Administration of GM-CSF not only increases the number of monocytes but also increases the function of monocytes and macrophages including oxidative metabolism, cytotoxicity, and Fc-dependent phagocytosis. GM-CSF enhances dendritic cell maturation, proliferation, and migration.²⁴ The ability of GM-CSF to mobilize PBSC was first reported by Socinski et al.²⁵ in 13 patients with sarcoma. After 4–7 days of GM-CSF at doses of 4–64 $\mu\text{g}/\text{kg}$ per day by continuous infusion, they found an 18-fold increase in peripheral blood CFU-GM and an eightfold increase in erythroid burst-colony forming units (BFU-E). Haas et al.²⁶ observed an 8.5-fold increase in the number of circulating CFU-GM using a continuous infusion of GM-CSF at 250 $\mu\text{g}/\text{m}^2$ per day. A total of six aphereses were performed and the median number of MNC and CFU-GM collected was 36×10^9 and 209×10^4 , respectively.

The efficacy of GM-CSF for stem cell mobilization has been compared with G-CSF in both normal donors and in cancer patients. Peters et al.²⁷ suggested that GM-CSF is less efficacious than G-CSF in mobilization and found that the total numbers of CD 34⁺, CD 33⁺, and CD7⁺ cells collected per kg were higher in G-CSF mobilization than with GM-CSF. Weisdorf et al.²⁸ found no significant advantage for either drug as mobilizing agents for PBSC used for autologous transplant in lymphoma patients. Lane et al.²⁹ evaluated the PBSC mobilization efficacy of G-CSF at 10 $\mu\text{g}/\text{kg}$ per day ($n = 8$), GM-CSF 10 $\mu\text{g}/\text{kg}$ per day ($n = 5$), or GM plus G-CSF each at 5 $\mu\text{g}/\text{kg}$ per day ($n = 5$) in normal donors. The median CD34⁺ cell yield with the combination regimen and with G-CSF was significantly higher than with GM-CSF alone. It is widely accepted that as a single agent, G-CSF mobilizes more CD34⁺ cells than does GM-CSF.

G-CSF/GM-CSF

Since the two growth factors mobilize different cells, concurrent or sequential administration of these growth factors may be synergistic. Spitzer et al.³⁰ conducted a randomized study comparing G-CSF plus GM-CSF each at 5 $\mu\text{g}/\text{kg}$ per day with G-CSF 10 $\mu\text{g}/\text{kg}$ per day for stem cell mobilization in 50 patients with lymphoma and solid tumors. There were no statistically significant differences in either the CD34⁺ cell yield or the rate of hematopoietic recovery between the two groups. Winter et al.³¹ conducted a phase I/II study of combined G-CSF and GM-CSF either sequential, G-CSF followed by GM-CSF or GM-CSF followed by G-CSF, or concurrent G-CSF/GM-CSF for mobilization of PBSC. The administration of G-CSF to patients already receiving GM-CSF results in 80-fold increase in HPC over the baseline; however, the addition of GM-CSF to G-CSF was less effective.

G-CSF/SCF

SCF is an early acting hematopoietic factor that displays pronounced synergies with other hematopoietic growth factors such as GM-CSF, G-CSF, erythropoietin, IL-3, and IL-6 to stimulate proliferation of erythroid, megakaryocytic, granulocytic, and mast and basophil progenitor cells. The SCF receptor (*c-kit*) is present on many tissues of neuroectodermal, epithelial, and hematopoietic origin.

In patients with stage II/III breast cancer with no previous chemotherapy, Glaspy et al.³² showed that the leukapheresis yield was 70% higher for those receiving SCF 10 µg/kg per day concomitantly with G-CSF than those receiving G-CSF alone. The combination of SCF+G-CSF has also been shown to be effective in patients with breast cancer with previous chemotherapy and those with heavily pretreated lymphoma. Moskowitz et al.³³ conducted a phase I/II randomized trial of SCF (5, 10, 15, or 20 µg/kg per day) plus G-CSF 10 µg/kg per day, or G-CSF 10 µg/kg per day alone to mobilize PBSC in NHL patients. The combination of SCF+G-CSF was better than G-CSF alone for patients who had received extensive prior therapy. Similar results were reported by Stiff et al.³⁴ in another randomized study using SCF 20 µg/kg per day plus G-CSF 10 µg/kg per day versus G-CSF 10 µg/kg per day in 102 heavily pretreated patients with Hodgkin's disease and NHL. Compared with the G-CSF alone group, the SCF+G-CSF group showed an increase in the proportion of patients reaching the target yield within five leukaphereses (44% vs 17%; $P = 0.002$); reduction in the number of leukaphereses required to reach the target yield, increase in the median yield of CD34⁺ cells per leukapheresis ($0.73 \times 10^6/\text{kg}$ vs $0.48 \times 10^6/\text{kg}$; $P = 0.04$), and an increase in the median total CD34⁺ cells collected within five leukaphereses ($3.6 \times 10^6/\text{kg}$ vs $2.4 \times 10^6/\text{kg}$; $P = 0.05$). These results suggest that SCF plus G-CSF was more effective than G-CSF alone for mobilizing PBSC in heavily pretreated patients. However, SCF administration can be associated with anaphylactic reactions due to mast cell-mediated reactions. Therefore, premedication with ranitidine, albuterol, and either diphenhydramine or cetirizine are required. Due to the high incidence of allergic reactions and the need for observation after administration SCF is difficult to use in standard clinical practice. SCF is not commercially available in the United States.

G-CSF/recombinant human thrombopoietin

Thrombopoietin (TPO) is a naturally occurring glycosylated peptide growth factor and the primary regulator of megakaryocytopoiesis. In preclinical models, TPO has been shown to accelerate the reconstitution of BM CD34⁺ cells and to increase the number of circulating PB progenitor cells after a mid-lethal dose of total body irradiation. TPO has also been shown to enhance proliferation of early progenitor cells committed to the erythroid and myelomonocytic lineage. Results from phase I studies of recombinant human

TPO (rhTPO) in the myelosuppressive and myeloablative settings indicate that rhTPO, alone and combined with chemotherapy and G-CSF, increases the number of progenitor and CD34⁺ cells in the PB.³⁵ Linker et al.³⁶ conducted a randomized, double-blind, multicenter trial in 134 patients to evaluate the efficacy of rhTPO for mobilization and reconstitution after high-dose chemotherapy and PBSCT. For the mobilization phase, patients received study drug at a dose of 0.5 µg/kg, or 15 µg/kg, or placebo given intravenously on days 1, 3, and 5 before initiation of G-CSF 10 µg/kg per day on day 5 and leukapheresis starting on day 9. After high-dose chemotherapy and PBSCT, patients were randomly assigned to receive rhTPO 1.5 µg/kg on day 0, +2, +4, and +6 with either G-CSF 5 µg/kg per day or GM-CSF 250 µg/m² per day, or placebo plus G-CSF 5 µg/kg per day. Administration of rhTPO followed by G-CSF produced a nearly twofold increase in median CD34⁺ cell dose per leukapheresis with a higher CD34⁺ cell yield when rhTPO started before day 5. Comparing rhTPO to placebo, a higher percentage of patients achieved the minimum yield of CD34⁺ cell more or equal to $2 \times 10^6/\text{kg}$ (92% vs 75%; $P = 0.050$) as well as the target yield of more or equal to 5×10^6 CD34⁺ /kg (79% vs 46%; $P = 0.011$). rhTPO also significantly reduced the median number of aphereses required to achieve both a minimum graft (one rhTPO vs two placebo) and a target graft (two rhTPO vs four placebo). However, rhTPO given after transplantation did not enhance platelet recovery. None of the patients developed neutralizing antibodies that cross-react with endogenous TPO. These results suggest that rhTPO is safe and effective in enhancing mobilization and increasing leukapheresis efficiency.

CHEMOTHERAPY PLUS GROWTH FACTORS FOR STEM CELL MOBILIZATION

Although chemotherapy alone can produce increases in progenitors in PB, multiple phase II studies have shown that the addition of growth factors such as G-CSF and GM-CSF to myelosuppressive chemotherapy enhances mobilization and allows for more progenitors to be collected with fewer apheresis procedures while reducing myelotoxicity. Siena et al.³⁷ reported that after high-dose CY, an approximately 30-fold expansion of CFU-GM numbers was observed. This increase was further magnified, to over 100 times control values, when GM-CSF was given to accelerate post-CY hematopoietic recovery. These precursors were both increased in number and enriched in the more immature forms. In addition, there was an increase of the most immature CD34⁺ /CD33⁻ progenitors to multipotent and unipotent colony-forming cells (CD34⁺ /CD33⁺) in PB. In a randomized cross-over trial reported by Koc et al.,³⁸ high-dose CY plus G-CSF results in mobilization of more progenitors than GM-CSF plus G-CSF when tested in the same patient regardless of whether CY+G-CSF was given as the first or second mobilizing strategy.

The magnitude of the increase in circulating stem cells is related to the intensity of myelosuppressive chemotherapy used. Cyclophosphamide at doses of 1.5, 4, or 7 g/m² and G-CSF or GM-CSF are effective in mobilizing PBSC; however higher stem-cell yields were obtained with higher doses of CY (7 g/m²).³⁹ When G-CSF was administered from the day after CY, white blood cell (WBC) decreased reaching a nadir around day 7 or 8 followed by an abrupt increase in WBC and PB CD34⁺ cell counts. Peak circulating CD34⁺ cells and progenitors were seen on approximately day 9 or 10. PBSC collection usually begins on day 10 or when WBC > 1 × 10⁹/L.

While high-dose CY followed by GM-CSF or G-CSF is the most frequently chemotherapy/growth factor mobilization regimen, it has several limitations, including potential cardiotoxicity, hemorrhagic cystitis, nausea, and vomiting. Several investigators have reported the effectiveness of high-dose etoposide (2 g/m²) with GM-CSF or G-CSF as a mobilizing strategy.⁴⁰ It is associated with minimal nonhematologic toxicity and has antitumor activity. Several other combination chemotherapy regimens are also effective for stem cell mobilization. Studies suggest that the combination of CY + etoposide, or CY + Taxol or CY + etoposide + cisplatin are more effective than CY alone.

The dose and type of growth factor utilized with chemotherapy may also be important. Although GM-CSF was the first cytokine to enhance PBSC mobilization by chemotherapy, it is now less commonly used than G-CSF, probably because of side effects such as fever and hypoxemia. The dose of G-CSF used with chemotherapy is lower than when used alone for stem cell mobilization (10–24 µg/kg per day). A higher dose of G-CSF 16 µg/kg per day rather than a lower dose of 8 µg/kg per day was more effective in patients with a variety of malignancies. In a randomized trial reported by Weaver et al.,⁴¹ G-CSF or GM-CSF followed by G-CSF after mobilizing chemotherapy was more effective in patients with solid tumors and hematologic malignancies than GM-CSF. In contrast, for patients with NHL, GM-CSF followed by G-CSF permitted more efficient collection of a target number of CD34⁺ cells than did GM-CSF, while G-CSF was the least efficient of the three cytokine strategies.

It is difficult to conclude which combination of chemotherapy and growth factor is the optimal regimen given the heterogeneity of patient population, the different mobilizing chemotherapy regimens, and the different cytokines used. Moreover, there is no difference in time to recovery of neutrophils and platelets among patients transplanted with PBSC mobilized by different techniques as long as a minimum number of CD34⁺ cells/kg is given. In general, chemotherapeutic agents that are effective for underlying malignancies should be used for pretransplant cytoreduction as well as PBSC mobilization.⁴² Agents that are known to damage stem cells such as melphalan should be avoided.

NEW STRATEGY FOR PBSC MOBILIZATION

AMD 3100

AMD 3100 is a selective antagonist of the chemokine receptor CXCR4, which is present on WBCs. AMD 3100 also reversibly blocks the binding of CXCR4 with SDF-1. In a phase I study, it was noted that AMD 3100 induced leucocytosis. Broxmeyer et al. demonstrated a 40-fold increase in the mobilization of hematopoietic progenitors within 1 h of AMD 3100 injection in mice.⁴³ Results from a phase-I study in 10 healthy volunteers⁴⁴ and 13 patients with multiple myeloma or NHL⁴⁵ demonstrated that AMD 3100 rapidly mobilized PBSC. The absolute CD34⁺ cell count increased from 2.6/µL to 15.6/µL, and 16.2/µL at 4 h and 6 h, respectively, after AMD 3100 administration. Recent studies confirm that AMD 3100 and G-CSF are synergistic. Injection of AMD 3100 given on the fifth day of G-CSF resulted in a striking 50-fold increase in the number of circulating CD34⁺ cells. In addition, PBSC mobilized by AMD 3100 have a higher repopulation potential in human-mouse xenografts than G-CSF-mobilized PBSC. Liles et al.⁴⁶ recently demonstrated that a 240 µg/kg injection of AMD 3100 followed the same day of a single large volume leukapheresis yielded a mean of 3.1 × 10⁶ CD34⁺ cells/kg. Based on these results, AMD 3100 may not only be effective for the rapid mobilization of CD34⁺ cells in patients who have received chemotherapy, but also for mobilization of normal volunteer donors.

OPTIMAL TIME FOR PBSC COLLECTION

The timing of PBSC collection is important in order to maximize the number of progenitors harvested. Using growth factor alone for mobilization, apheresis is usually performed on days 5, 6, and 7 of G-CSF administration. Progenitor cell levels start to decrease after day 8 even with continuation of G-CSF. Following chemotherapy mobilization, it is recommended to start PBSC collection at 12–14 days after chemotherapy when WBC > 1 × 10⁹/L.⁴⁷ For chemotherapy + growth factor mobilization, apheresis usually starts when the WBC reaches 2–5 × 10⁹/L. However, some studies suggest that a delay in PBSC collection until WBC > 10 × 10⁹/L may be more optimal. A strong linear relationship between the number of CFU-GM and CD34⁺ cells in both the leukapheresis product and PB on the day of collection has been well established. Several studies have shown that the number of circulating CD34⁺ cells predicts the extent of PBSC collection and may be used to anticipate or delay leukapheresis, as well as to shorten or extend the duration of procedure. At present CD34⁺ cells measurement is preferable since it is a more direct measurement of progenitor cells, and it should be used to guide stem cell collection.⁴⁸

TARGET AND THRESHOLD

In most studies, 20×10^4 CFU-GM/kg or 2×10^6 CD34⁺ cells/kg is generally accepted as the minimum threshold below which rapid hematopoietic reconstitution may not occur. In a study reported by Bensinger et al.,⁴⁹ patients receiving more than 2.5×10^6 CD34⁺ cells/kg had more rapid neutrophil and platelet recovery than patients who received less than that. However, comparing patients who received more than 5×10^6 CD34⁺ cells/kg to those receiving $2.5\text{--}5 \times 10^6$ CD34⁺ cells/kg, there was no difference in neutrophil engraftment but there was more rapid recovery of platelets. They also found that very high level of CD34⁺ cells ($>10 \times 10^6$ CD34⁺ cells/kg) did not result in a significant faster recovery of either neutrophils or platelets. Kiss et al.⁵⁰ showed that patients who received more or equal to 5×10^6 CD34⁺ cells/kg were found to have statistically significantly faster neutrophil recovery (median 10 days vs 11 days; $P = 0.002$) and platelet recovery (median 9 days vs 21 days; $P = 0.004$) than those receiving less than that. Based on these studies, a minimum cell dose of 2.5×10^6 CD34⁺ cells/kg may be sufficient to ensure rapid recovery of neutrophils and platelet; the optimal transplant cell dose of 5×10^6 CD34⁺ cells/kg is recommended.

Previous chemotherapy is also an important factor in determining a threshold of CD34⁺ cells for rapid engraftment. Tricot et al.⁵¹ analyzed 225 patients receiving autologous PBSC transplants for multiple myeloma and found that the minimum CD34⁺ cell threshold was more or equal to 2×10^6 cells/kg for patients receiving less than 6 months of melphalan, but more than 5×10^6 CD34⁺ cells/kg were required for patients who received more than 12 months of melphalan.

FACTORS AFFECTING PBSC COLLECTION

Several factors have been shown to be significant determinants of progenitor cell yield including the amount of previous chemotherapy, the number of cycles, the degree of BM involvement, previous wide-field radiation, the interval between previous chemotherapy and mobilization, and exposure to stem cell toxic drugs.^{52,53} These factors are indicators of hematopoietic reserve. Haas et al.⁵⁴ found that previous cytotoxic chemotherapy and radiotherapy adversely affected the yield of CD34⁺ cells with each cycle of chemotherapy associated with an average decrease of 0.2×10^6 CD34⁺ cells/kg per apheresis in nonirradiated patients, and large field radiotherapy reduced the collection yields by an average of 1.8×10^6 CD34⁺ cells/kg. Glaspy et al.³² reported that frequency of previous chemotherapy, even with regimens that are not considered stem cell toxin, can decrease the number of CD34⁺ cells harvested in patients with breast cancer. Tricot et al.⁵¹

found a correlation between duration of exposure to previous chemotherapy, especially alkylating agents, and mobilization yield in patients with multiple myeloma. They reported that 91% of patients with exposure of less than 6 months reach more than 5×10^6 CD34⁺ cells/kg as compared to only 28% of patients with exposure more than 24 months. Dreger et al.⁵⁵ reported that prior exposure to stem cell toxic agents such as Carmustine (BCNU) and melphalan was associated with poor stem cell yield. Fludarabine treatment was proven to be associated with poor PBSC mobilization⁵⁶ as well as other stem cell toxic agents such as nitrogen mustard, procarbazine, or more than 7.5 g of cytarabine chemotherapy.⁵⁷

Some investigators found that measurement of BM CFU-GM and CD34⁺ cells during steady-state can be used to predict for PBSC mobilization. Kotasek et al.¹⁵ reported a higher premobilization BM CFU-GM level immediately before CY mobilization predicts for successful collection of CFU-GM. Other investigators have shown that a lower CD34⁺ cell percentage ($<2.5\%$) of the BM products before PBSC mobilization predicts for suboptimal PBSC collection.⁵⁸ Low platelet counts on the first day of stem cell collection⁵⁹ and low numbers of circulating natural killer (CD3⁻16⁺56⁺) cells⁶⁰ prior to administration of mobilization therapy have predicted for poor mobilization. Gazitt et al.⁶¹ evaluated expression of adhesion molecules on CD34⁺ cell in PB of NHL patients and found that good mobilizers had a relatively higher percentage of CD34⁺ cells expressing the VLA-4 antigen.

MOBILIZATION OF TUMOR CELLS AND ITS CLINICAL SIGNIFICANCE

Several studies have shown that tumor cells could be mobilized in PB after chemotherapy and G-CSF.⁶² Circulating tumor cells may be present in patients with certain malignancies regardless of marrow involvement. The presence of these cells in circulation appears to correlate with disease activity and stage. The possibility of infusing cancer cells into patients at the time of PBSC transplant is known to occur in breast cancer, lymphoma, multiple myeloma (MM), and leukemia. However, the biologic significance of infusing PBSC contaminated with tumor cells remains uncertain. Gene-marking studies and retrospective clinical trials have demonstrated that contaminating tumor cells can contribute to disease recurrence after high-dose therapy and autologous PBSC.⁶³ However, other investigators found no increase in the incidence of relapse following high-dose therapy and infusing of tumor contaminated PBSCs.⁶⁴ A 3 to 5-log reduction in malignant contamination in the PBSC can be achieved by CD34⁺ cell selection.⁶⁵ However, phase III randomized study showed no improvement in disease-free and overall survival with CD34⁺ cell selection.⁶⁶ In addition, delay at engraftment and an increase

in the incidence of infectious complications have been reported following CD34⁺ enriched transplant.

MOBILIZATION OF ALLOGENEIC STEM CELLS

Despite the rapid engraftment and the reduction in transplant-related mortality with mobilized PBSC, there are some concerns about the increased risk of acute and chronic graft-versus-host-disease (GVHD) due to the higher numbers of T cells in mobilized PBSC products. Korblyng et al.⁶⁷ compared the allograft content of G-CSF mobilized PBSC to cellular contents of BM harvest and showed that there was a three- to fourfold increase in CD34⁺ cells and a 10- to 20-fold increase in the number of CD3⁺ T cells in PBSC products compared to BM harvest. There have been several randomized trials comparing BM and PBSC in the allogeneic transplant setting, but the results were inconclusive.^{68,69} However, most studies demonstrated a significant enhancement of neutrophil and platelet recovery with allogeneic PBSC, but a survival benefit was observed only in patients with advanced hematologic malignancies. The risk of acute GVHD was not significantly increased with allogeneic PBSC. However, a modest increase in chronic GVHD has been reported in several studies. A meta-analysis of 15 phase II and phase III trials assessing the risk of GVHD in allogeneic PBSC and BM demonstrated a modest increased relative risk of acute GVHD (relative risk 1.2) and a significant increased risk of chronic GVHD (relative risk 1.8) in recipients of allo-

geneic PBSC.⁷⁰ In addition, there was a significant reduction in risk of relapse after PBSC allografts.

Similar to autologous PBSC studies, the numbers of mobilized CD34⁺ cells correlate well with engraftment. Allogeneic PBSC recipients who received more than 5×10^6 CD34⁺ cells/kg had a 95% chance of both neutrophil and platelet recovery by day +15.⁷¹ However, infusion of allogeneic PBSC $> 8 \times 10^6$ CD34⁺ cells/kg has been shown to result in poor survival presumably due to increased rates of chronic GVHD and its complications.

CONCLUSIONS

Currently, mobilized PBSCs are the preferable and major source of stem cells harvested for autologous, and possibly, allogeneic transplantation because of the higher cell yield, faster hematopoietic and immune reconstitution, and decreased procedural risks compared with harvested BM cells. Measurement of PB CD34⁺ cells before collection is necessary for efficient and cost-effective stem cell collection. PBSC collection should be performed early in the course of disease to avoid chemotherapy-induced stem cell damage and to reduce the risk of therapy-induced myelodysplasia. Different mobilization strategies are needed for patients who are at high risk for poor mobilization. Over the last decade, significant progress has been made in understanding the mechanisms of PBSC mobilization and stem cell homing. This has led to the development of new agents that are being tested in clinical trials, which will eventually lead to development of improved mobilization protocols especially for poor mobilizers.

Chapter 95

STEM CELL TRANSPLANTATION FOR SOLID TUMORS AND NONMALIGNANT CONDITIONS

E. Randolph Broun

INTRODUCTION

The use of high-dose chemotherapy (HDC) with stem cell rescue has found utility in a number of settings. Clearly for some diseases (i.e., relapsed intermediate-grade non-Hodgkin's lymphoma) this represents the best available therapy and is the standard of care. This determination was made as a result of carefully designed clinical trials showing a clear advantage to this approach over conventional-dose chemotherapy in a randomized fashion. In other diseases (such as germ cell cancer), the incidence of the disease is such that large randomized trials are not easily performed; yet well-designed trials have demonstrated the superiority of this approach in comparison to conventional-dose chemotherapy. There are other diseases (such as breast cancer and ovarian cancer) in which early enthusiasm has been tempered by the results of randomized trials failing to show any advantage for high-dose chemotherapy. Finally, there are a number of diseases (amyloidosis, renal cell cancer, melanoma, and others) in which the value of high-dose therapy with either autologous or allogeneic stem cell transplant is undetermined. This chapter will review the state of the art in high-dose therapy with stem cell rescue for solid tumors and a variety of other disorders.

BREAST CANCER

The prognosis of patients with advanced breast cancer, either high-risk or metastatic disease, remains poor. The majority of patients with high-risk primary breast cancer, defined by extensive axillary nodal involvement or inflammatory carcinoma, experience relapse after multimodality therapy including surgery, adjuvant chemotherapy, and radiotherapy (RT). Metastatic breast cancer (MBC) remains incurable.

Given this situation, the early enthusiasm for the use of high-dose therapy with stem cell or bone marrow (BM) rescue was not surprising.¹ Phase II studies in both high-risk and MBC yielded results that seemed superior to those obtained with standard-dose chemotherapy.

HDC FOR MBC

Phase II studies

Initial trials of high-dose therapy in MBC targeted patients with refractory,^{2,3} untreated,⁴ and responding disease.⁵⁻⁸ It soon became clear that high-dose therapy produced high complete remission (CR) rates and a consistent long-term event-free survival (EFS) rate of 10–25% in patients transplanted after response to first-line chemotherapy.⁹ Outcome after tandem cycles of the same HDC regimen appears comparable to a single HDC cycle.¹⁰⁻¹⁴

Retrospective analyses identified attainment of a CR to pretransplant induction chemotherapy and low tumor burden as the two most important independent prognostic factors of favorable outcome after HDC, whereas liver involvement and extensive prior chemotherapy exerted an adverse effect.¹⁵ This information was utilized to design a trial to test whether patients with low tumor burden might benefit from high-dose therapy. Sixty patients who were rendered disease free by local treatment, either by pretransplant surgery or posttransplant RT, were enrolled in a study of high-dose cyclophosphamide/cisplatin/BCNU (carmustine) with stem cell rescue. At a median follow-up of 5 years, the EFS and overall survival (OS) rates were 52 and 62%, respectively.¹⁶ In conclusion, these early phase II trials demonstrated impressive results in patients for whom the outlook was otherwise quite poor.

Randomized trials in MBC

Eight randomized trials of HDC in MBC have been reported to date. Of these, six have compared high-dose

therapy to conventional-dose chemotherapy, and two have evaluated the timing of high-dose therapy: early versus late.

Stadtmauer et al.¹⁷ compared a single cycle of high-dose therapy to maintenance conventional-dose chemotherapy in 184 patients responding to a long course of conventional-dose chemotherapy. At a median follow-up of 67 months, an intent-to-treat analysis showed no differences between the two arms in EFS (4% vs 3%) or OS (14% vs 13%). Surprisingly, the partial remission (PR) to CR conversion rate, while small, was higher in the maintenance conventional-dose chemotherapy arm than in the HDC arm (9% vs 6%). This trial has been widely criticized because of its 45% dropout rate.

Using a similar approach, a group of Canadian investigators randomized 224 patients with chemorecursive MBC to receive either additional conventional-dose chemotherapy or a single cycle of high-dose therapy with conventional-dose chemotherapy. In its first intent-to-treat analysis at a median follow-up of 19 months, significant differences in favor of HDC were observed in EFS (38% vs 24%, $P = 0.01$), but not OS (median 2 vs 2.3 years, $P = 0.9$). This trial suffered high attrition (21%) and transplant-related mortality (TRM) (7.7%) rates in the transplant arm.¹⁸

In the French National PEGASE-03 study, Biron et al.¹⁹ randomized 180 responding patients to one cycle of high-dose therapy with conventional-dose chemotherapy or observation. High-dose therapy was well tolerated, with a TRM of 1% and an increase in the CR rate from 11 to 24% ($P = 0.0002$). Interestingly, in this study with a median follow-up of 48 months, there was a significant improvement in EFS in favor of high-dose therapy (27% vs 10%, $P = 0.0005$).

Crown et al.²⁰ looked at initial therapy with tandem high-dose therapy compared with conventional-dose doxorubicin/docetaxel followed by maintenance chemotherapy in 110 patients with MBC. The response rate on the high-dose arm was significantly better, with overall response (71% vs 29%) and CR rates (44% vs 6%) better than the control arm. Using EFS as the primary endpoint, the high-dose arm was superior (16% vs 9%, $P = 0.01$) at a median follow-up of 42 months.

Following a similar design, Schmid et al.²¹ compared two sequential cycles of high-dose therapy to six to nine cycles of another modern conventional-dose chemotherapy regimen of doxorubicin and paclitaxel in 92 untreated patients. The CR rate and EFS were significantly superior in the transplant arm, without significant differences in OS at a follow-up of 14 months.

In the other French trial, Lotz et al.²² randomized 61 responding MBC patients to additional conventional-dose chemotherapy or one HDC cycle. The apparently large differences seen in favor of the transplant arm in EFS (median 35 months vs 20 months) and OS (median 43 months vs 20 months, with 5-year OS rates

30% vs 18%) did not reach statistical significance in this study.

Finally, investigators at Duke University conducted two small trials with a crossover design, comparing early versus late use of HDC in MBC patients in CR,²³ and with bone-only disease,²⁴ respectively. In those studies, patients were randomized to immediate HDC with one cycle of cyclophosphamide/cisplatin/BCNU or observation, with the same HDC offered to patients in the control arm upon relapse or progression. In both trials the immediate transplant arm had significantly superior EFS (25% vs 10%, and 17% vs 9%, respectively) with no significant benefit in OS, compared to late transplant (33% vs 38%, and 28% vs 22%, respectively).

In summary, eight randomized trials in MBC, enrolling 1020 patients, have been reported. None are particularly large with half enrolling 100 or fewer patients. EFS differences in favor of high-dose therapy were seen in seven of those eight trials,¹⁸⁻²⁴ with the only exception being the Philadelphia study.¹⁷ Longer follow-up is needed to see if the EFS advantage translates into an OS benefit.

HIGH-DOSE THERAPY FOR HIGH-RISK BREAST CANCER Phase II studies

The use of high-dose therapy with, initially, BM and, later, Peripheral blood progenitor cell(s) (PBPC) rescue was first explored and reported by Peters et al.²⁵ at Duke University and by Gianni et al.²⁶ at Milan. Each reported results that appeared superior to outcomes after conventional-dose chemotherapy using similar patient selection criteria. Specifically, Peters et al. reported a 72% 5-year EFS in a prospective phase II trial of high-dose cyclophosphamide/cisplatin/BCNU in patients with 10 or more positive axillary nodes. These results have stood the scrutiny of time, with 61% EFS rate at 11-year follow-up.²⁷ Gianni et al.²⁶ used a sequential high-dose single-agent regimen in this patient population. At a median follow-up of 4 years, the observed EFS rate was 57%.

Randomized trials in high-risk breast cancer

Rodenhuis et al.²⁸ randomized 885 patients with four or more involved lymph nodes to receive four cycles of conventional-dose chemotherapy followed by one more cycle of conventional-dose chemotherapy or one cycle of HDC. At a median follow-up of 57 months, there was a trend for an EFS advantage in favor of high-dose therapy (65% vs 59%, $P = 0.09$), with no significant OS differences. The EFS of those patients randomized to high-dose therapy who were actually transplanted appeared superior to those in the control arm ($P = 0.03$). Prospectively planned subset analysis showed that high-dose therapy improved EFS among patients with 10 or more involved nodes (68% vs 49%, $P = 0.05$).

In the Cancer and Leukemia Group B (CALGB) 9082 trial, Peters et al.²⁹ randomized 785 patients with

10 or more positive nodes to receive four conventional-dose chemotherapy cycles followed by one cycle of cyclophosphamide/cisplatin/BCNU or by one additional cycle of those drugs at intermediate doses with granulocyte colony-stimulating factor support. Twenty-five patients who relapsed on the intermediate-dose arm (15%) received subsequent salvage high-dose therapy. At a median follow-up of 5 years, the intent-to-treat EFS (61% vs 60%, $P = 0.5$) and OS rates (70% vs 72%, $P = 0.2$) were similar in the high- and intermediate-dose arms. There were fewer relapses in the transplant arm (32% vs 43%), which represented a 31% relative reduction in the incidence of relapses. Unfortunately, the high 10% treatment-related mortality rate observed in the high-dose arm of this trial (versus 0% in the other arm) offset the decrease in recurrences.

The Eastern Cooperative Oncology Group (ECOG) randomized 540 patients with 10 or more involved nodes to receive six cycles of conventional-dose chemotherapy with or without consolidation with one cycle of high-dose cyclophosphamide/thiotepa with BM support and, towards the end of the study, with PBPC support. With a median follow-up of 6.1 years, there was no significant difference between the high-dose and conventional-dose chemotherapy arms in EFS (55% vs 48%, $P = 0.1$) or OS (58% vs 62%, $P = 0.3$).³⁰

In the Anglo-Celtic trial, Crown et al.³¹ randomized 605 patients with four or more positive nodes to receive conventional-dose chemotherapy followed by one high-dose therapy cycle or maintenance conventional-dose chemotherapy. At a median follow-up of 4 years, the first planned analysis did not reveal differences in EFS (51% vs 54%, $P = 0.6$) or OS (63% vs 62%, $P = 0.8$).

Nitz et al.³² enrolled 403 patients with 10 or more positive nodes to receive a modern dose-dense regimen or two sequential cycles of high-dose therapy with PBPC support. At a median follow-up of 39 months, there was superiority of the transplant arm in EFS (62% vs 48%, $P = 0.001$) and OS (75.6% vs 66%, $P = 0.05$).

In a French trial, Roch et al.³³ randomized 314 patients to receive conventional-dose chemotherapy followed by one cycle of high-dose therapy or observation. At a median follow-up of 33 months, there was an EFS benefit in favor of high-dose therapy in EFS (71% vs 55%, $P = 0.002$), but not OS (84% vs 85%, $P = 0.3$).

In summary, review of these randomized studies presents a conflicting picture. A common theme is relatively short follow-up. While there are several negative trials after fairly long follow-up,^{29,30,34,35} other studies have already shown superiority of transplant in their first analyses,^{32,33} or suggested a nonsignificant trend in favor of transplant.^{28,36} Unfortunately the situation in high-risk breast cancer is similar to that in metastatic disease, with further follow-up needed to

see if the consistent advantage in EFS translates into an improvement in OS.

OVARIAN CARCINOMA

Major improvements are needed in the treatment of advanced ovarian cancer. While the introduction of, initially, cisplatin and, later, taxanes has improved the outcome of these patients, less than 25% of stage III patients achieve long-term disease-free survival (DFS) with current multimodal management, including debulking surgery and conventional-dose chemotherapy. For patients with relapsed disease, salvage conventional-dose chemotherapy is not curative. Stage IV patients have a 5-year survival of less than 5%.

HDC FOR RECURRENT DISEASE

The largest single-center experience is that reported by Stiff et al. from Loyola University.³⁷ This group reported on 100 patients, most with heavily pretreated, platinum-refractory, bulky disease. Patients were treated with a carboplatin- or melphalan-based high-dose regimen with BM or PBPC rescue. Median EFS and OS times were 7 and 13 months, respectively. Tumor bulk and platinum sensitivity were significant prognostic factors with an important finding being that the few patients with low bulk, platinum-sensitive disease had a respectable outcome.

These results were confirmed to a retrospective analysis of 421 patients from the Autologous Blood and Marrow Transplant Registry (ABMTR), receiving high-dose therapy between 1989 and 1996, in most cases for relapsed disease. Most patients had extensive prior chemotherapy, 41% of them had platinum-resistant tumors, 38% had bulky disease, and only 8% received transplants as part of the initial therapy. In this poor-prognosis population, 2-year EFS and OS rates were 12 and 35%, respectively. Younger age, good performance status, nonclear cell histology, remission status at transplantation, and platinum sensitivity were associated with better outcomes.

A retrospective analysis of 254 patients from the European Group for Blood and Marrow Transplant (EBMT) Registry evaluated the front-line use of HDC.³⁸ Half of them were transplanted while having residual disease, and 40% in first CR or near CR.

Outcome was improved for those patients transplanted in remission compared to those with resistant tumors, with a median EFS of 18 months versus 9 months, and median OS of 33 months versus 14 months.

The only completed randomized trial addressing the efficacy of HDC enrolled patients with low-burden, chemosensitive disease receiving first-line therapy. One hundred and ten patients with tumors of less than 2 cm were randomized to second-look laparotomy after four to six cycles of platinum-based chemotherapy,

to receive consolidation with high-dose carboplatin/cyclophosphamide with PBPC support, or three maintenance cycles of conventional carboplatin/cyclophosphamide. An intent-to-treat preliminary analysis of this study showed a significant improvement of EFS in the transplant arm (median 22 months vs 11 months, $P = 0.03$). Unfortunately, a similar trial addressing this crucial question, the US National Cancer Institute sponsored Intergroup trial, was closed prematurely due to poor accrual.

In summary, available data from phase II trials suggest that high-dose therapy offers a potential benefit for patients with platinum-sensitive disease at the time of remission. The only randomized trial comparing HDC to conventional-dose chemotherapy has shown fairly large EFS differences in favor of transplant as consolidation therapy for high-risk patients. In contrast, patients with residual disease at second-look surgery, or who have relapsed, have a much worse outcome.

SMALL-CELL LUNG CANCER

Most patients with small-cell lung cancer (SCLC) respond to chemotherapy, but such responses are usually of relatively short duration, and survival has not significantly increased over the past two decades, either in limited or in extensive disease. These discouraging results prompted the investigation of high-dose chemotherapy with autologous stem cell transplant (ASCT) in the early 1980s. Initial studies testing one or two high-dose chemotherapy cycles as front-line therapy showed no improvement in outcome compared to historical controls.³⁹⁻⁴² Subsequently, delayed high-dose chemotherapy with ASCT was tested as consolidation therapy for a response obtained with conventional-dose chemotherapy. Spitzer et al.⁴³ reported 4-year OS of 19% among 32 such patients with limited disease (LD). There is only one reported randomized trial of HDC in SCLC.⁴⁴ Patients responding to induction chemotherapy were randomized to one additional cycle or to high-dose cyclophosphamide/BCNU/etoposide with ASCT. Although patients received cranial irradiation, no chest RT was delivered. The transplant arm showed improved responses and EFS, but OS was not significantly different between both groups, in part due to a 17% TRM rate on the high-dose arm. All patients with extensive disease (ED) relapsed in both arms of the study.

Subsequent studies incorporated thoracic and cranial RT after transplant. Elias et al.⁴⁵ treated 36 LD patients with a sequence of induction therapy, high-dose chemotherapy with cyclophosphamide/cisplatin/BCNU, and chest and cranial RT after hematologic recovery. Median EFS was 21 months, with a 5-year OS of 41%. All seven patients transplanted in partial response to induction therapy relapsed. However, the 5-year progression-free survival (PFS) was 53% for the

29 patients transplanted in CR. Leyvraz et al.⁴⁶ from the EBMT treated 69 patients (30 with LD and 39 with ED) with three sequential courses of high-dose chemotherapy (ifosfamide, carboplatin, and etoposide) with ASCT as initial therapy. RT, not required but recommended for responders, was administered to 37 patients to the chest, and prophylactically to the brain to 24 patients. Predictably, patients with LD had better outcome than those with ED, with a median OS of 18 months vs 11 months, and 2-year OS rates of 32% vs 5%.

MELANOMA

The prognosis of metastatic melanoma is dismal. Research of HDC for this disease dates back more than 40 years.⁴⁷ Early trials with high-dose single agents with BCNU,⁴⁸ melphalan,⁴⁹ or thiotepa⁵⁰ achieved higher response rates than those expected with conventional-dose chemotherapy, but of brief duration. Disease confined to skin or lymph nodes was more likely to respond. High-dose combinations of melphalan/BCNU,⁵¹ cyclophosphamide/cisplatin/BCNU,⁵² or DTIC (dacarbazine)/melphalan/ifosfamide⁵³ showed higher activity than did single-agent therapy, but no improvement in outcome.

In summary, the use of HDC in melanoma remains experimental. While HDC may provide a favorable setting for testing of immunotherapy against minimal residual melanoma,⁵⁴ it is unlikely that HDC and ASCT will play a meaningful role in the management of this disease in the foreseeable future.

BRAIN TUMORS

Most patients with malignant brain gliomas relapse after surgery and RT, and die within 2 years of diagnosis. The addition of chemotherapy offers a modest survival advantage, especially for younger patients with anaplastic astrocytoma (AA), but virtually none to those with high-grade glioblastoma multiforme (GM). Standard salvage therapy is not curative. The poor outcome of adult patients with malignant gliomas prompted many trials in the 1980s of high-dose single-agent BCNU, a drug with good central nervous system (CNS) penetration.⁵⁵⁻⁵⁷ Initial trials in patients with refractory tumors showed high response rates, although of brief duration. High-dose BCNU was subsequently moved up to first-line therapy, combined with surgery and RT. Johnson et al. reported their experience in 25 patients with unresectable grade III or IV gliomas. These patients were treated with BCNU 1050 mg/m² followed by autologous stem cell transplant and cranial radiotherapy. They reported a median survival of 26 months, significantly better than a group of historical controls albeit with short follow-up.⁵⁸ The largest series was reported by

Durando et al.⁵⁹ in 114 newly diagnosed patients, who were treated with surgery, high-dose BCNU, and RT. At a median follow-up of more than 7 years, the EFS and OS rates were 14 and 24%, respectively. Extent of prior surgery, histology (median OS of 12 months for GM vs 81 months for AA), and young age were predictive of outcome. These observations are consistent with those from nonconcurrent matched-pair comparisons, which did not suggest benefit from high-dose BCNU in patients with high-grade GM.⁶⁰

In summary, available results of HDC in adult patients with high-grade GM, largely employing high-dose single-agent BCNU, do not appear to improve outcome compared to conventional therapy. Further research may identify a role of HDC, in the setting of multimodal treatment, for young patients with AA.

ADULT SOFT-TISSUE SARCOMA

Small series of metastatic soft-tissue sarcoma patients treated with high-dose chemotherapy have been reported. When used as initial⁶¹ or salvage therapy for refractory disease,⁶² high-dose chemotherapy has not produced a clear survival benefit. However, results appeared improved when used as consolidation after induction conventional-dose chemotherapy, particularly for patients transplanted in CR. Blay et al.⁶³ treated 30 patients with responsive metastatic disease with high-dose ifosfamide, etoposide, and cisplatin. At a median follow-up of 94 months, the EFS and OS rates were 21 and 23%, respectively. Those patients in CR before high-dose chemotherapy had a better outcome than those in PR (5-year OS 75% vs 5%).

ADULT SMALL ROUND-CELL TUMORS

The family of small round-cell tumors includes Ewing's sarcomas, primitive neuroectodermal tumors (PNET), rhabdomyosarcomas (RMS), and desmoplastic small round-cell tumors (DSRCT). The results reported to date from high-dose chemotherapy are generally disappointing in RMS, and uniformly dismal in DSRCT.^{61,64} In contrast, results appear encouraging (25–50% long-term EFS rates) in chemotherapy-sensitive high-risk or advanced PNET/Ewing's sarcomas.^{65,66} The benefit of total body irradiation in this setting, employed in most early studies, has been seriously questioned in recent years.⁶⁷ In contrast, melphalan appears to be an important agent in HDC for this disease, and there is debate as to the merits of inclusion of busulfan.⁶⁸

GERM CELL CANCER

Germ cell cancer (GCT) is an uncommon malignancy that occurs most often in young men, and accounts for

about 1% of malignancies in men. There are groups of patients who do poorly despite the best therapeutic efforts: some of these have poor prognostic factors at diagnosis, such as far-advanced disease, choriocarcinoma, or markedly elevated serum markers; others do not achieve remission, or relapse following primary or salvage therapy; and, finally, a few patients demonstrate refractoriness to cisplatin. In each of these settings, high-dose therapy with hematopoietic stem cell rescue (HSCR) has been attempted, with varying degrees of success.

The initial study was a phase I dose-escalation study, done in collaboration with Vanderbilt University,⁶⁹ which examined the use of two courses of high-dose carboplatin and VP-16 with ABMT, in patients with GCTs that were either cisplatin refractory (defined as progression of disease within 4 weeks of previous cisplatin-based therapy) or recurrent after a minimum of two prior courses of cisplatin-based therapy. Thirty-three patients were entered on this trial: The initial 13 patients were treated with escalating doses of carboplatin, to establish a maximum-tolerated dose in combination with 1200 mg/m² VP-16; the subsequent 20 patients were treated with VP-16 1200 mg/m² and the phase II dose of carboplatin, 1500 mg/m², given in three divided doses on days -7, -5, and -3. Toxicities seen in the protocol were the expected severe myelosuppression, moderate enterocolitis, and stomatitis. Grade III hepatic toxicity (more than fivefold increase in liver enzymes), usually in association with massive infection, was observed in 8/33 patients. Significant ototoxicity, neurotoxicity, and nephrotoxicity were not seen, despite the heavy previous exposure to cisplatin in this group of patients. Treatment-related mortality was 7/33 (21%), and causes of death included infection⁷⁰ and veno-occlusive disease of the liver.⁷¹ This was a very heavily pretreated patient population, with over one-half having received three or more prior chemotherapy (CT) regimens, and 67% were cisplatin refractory. Eight patients achieved a CR, and six a PR, for an overall response rate of 44% (95% confidence interval, 27–63%). Of these, 8/14 patients remained alive and disease free with 18 months of follow-up. CR could be achieved despite advanced disease or cisplatin refractoriness. The use of high-dose carboplatin and VP-16 can provide long-term DFS as third- or fourth-line salvage therapy in a small percentage of patients, and overt cisplatin resistance can occasionally be overcome with this approach.

A larger phase II trial was carried out through the ECOG, utilizing the same dose and schedule of agents as in the phase II portion of the initial study.⁷² The same eligibility criteria were used for this study. Forty patients were entered on this multi-institution cooperative group effort between July 1988 and September 1989: 22/38 (58%) evaluable patients proceeded to the second course of high-dose therapy. Toxicity was similar to that seen in the phase I trial, with 5/38 (13%)

patients dying of treatment-related causes. Nine patients (24%) achieved a CR, including two who were rendered disease free with post-SCT surgical resection, and eight achieved a PR, for an overall response rate of 45%. Achievement of a CR was associated with testicular, rather than extragonadal, primary ($P = .12$), absence of liver metastases ($P = .08$), and embryonal cell type ($P = .11$).

A striking finding in this study was the poor outcome in patients with nonseminomatous primary mediastinal germ cell tumors. Unfortunately, this report mirrors the experience at other institutions.

A phase I trial, with further dose escalation of the combination of carboplatin and VP-16, was subsequently carried out. Thirty-two patients were enrolled on a careful dose-escalation schema of each of these agents. The maximum-tolerated dose level was carboplatin 700 mg/m² and VP-16 750 mg/m², given daily on days -6, -5, and -4. Dose-limiting toxicity for this regimen was mucositis. There were five treatment deaths: four caused by sepsis and multiorgan failure, and one by CNS hemorrhage. Significant ototoxicity was also seen. These higher doses are used in the treatment of patients in first relapse, or with limited prior therapy.⁷³

The overall cure rate for patients with recurrent testis cancer, treated with ifosfamide (IFX) and cisplatin-based salvage CT, is in the range of 20–25%.⁷⁴ A logical step to improve the outcome of these patients was the use of high-dose therapy at time of first relapse. The initial trial at Indiana University used two rounds of conventional-dose IFX and cisplatin, with either vinblastine or VP-16 (depending on prior treatment), followed by a single round of high-dose therapy with ABMT, using carboplatin and VP-16 in the dose and schedule used in the ECOG phase II trial. Twenty-five patients were enrolled in this study between July 1989 and January 1992. There was one early death due to sepsis during conventional-dose induction therapy, and no transplant-related deaths on this study. Eighteen of 25 patients completed the planned treatment, including high-dose therapy and ABMT. With a median follow-up of 19 months (range 4–30 months), 9/25 (36%) were alive and free of disease; three had relapsed, and were alive with disease; and six had died of progressive disease.⁷⁵ A follow-up trial examined the use of two cycles of high-dose therapy with HSCR in 25 patients in first relapse of cisplatin-sensitive testicular GCT. At a median follow-up of 26 months, 13/25 (52%) were alive and free of disease, and only one had died of treatment-related causes.⁷⁶

A number of conclusions can be drawn from this series of studies. It is clear that a fraction (15–20%) of patients with GCT, which is either multiply relapsed or overtly cisplatin-refractory, can be cured with high-dose carboplatin and VP-16 with ABMT.^{69,73,77,78} For this population of patients, ABMT is clearly not an investigational therapy, and, in fact, represents the therapy with the greatest curative potential. It is

important to note that cisplatin-refractory patients are rarely cured, and new and innovative approaches are needed. Finally, the use of high-dose therapy with ABMT in patients with gonadal GCT in first relapse, who are platinum-sensitive, is quite successful, with high response rates and low toxicity.

A number of institutions in Europe have reported their experience in the treatment of GCT with high-dose therapy and HSCR.

Droz et al.⁷⁹ reported on 17 patients treated with cisplatin (200 mg/m²), VP-16 (1750 mg/m²), and cyclophosphamide (6400 mg/m²) with BM rescue. This was a heavily pretreated group of patients, and they observed CRs in 9/17 (53%), with 4/17 patients in long-term DFS. Among the refractory patients treated on this protocol, there were no long-term survivors. This group went on to carry out a randomized trial of conventional-dose therapy [cisplatin (200 mg/m²), vinblastine, and bleomycin given every 3 weeks for three to four cycles] versus high-dose therapy with BM rescue, in patients with poor-risk characteristics. One hundred fifteen patients were enrolled, of whom 114 were evaluable. The 2-year survival was 82% in the conventional-dose arm, and 60% in the high-dose arm, a statistically insignificant difference. Unfortunately, this trial suffered from some deficiencies: the dose intensity and total dose of cisplatin was actually higher on the conventional-dose arm than the transplant arm, and small number of patients precluded definite conclusions. Nonetheless, this study did not show an advantage for the use of high-dose therapy with BM rescue for the initial treatment of poor-risk GCT patients.⁸⁰

Rosti et al.⁸¹ published the Italian multicenter experience with high-dose carboplatin, IFX, and etoposide with BM rescue in the treatment of 28 patients. They observed that the five long-term disease-free survivors in this group were all cisplatin sensitive at the time of transplant, and concluded that cisplatin refractoriness predicted for a universally poor outcome. Two other groups have reported a significant experience with the addition of IFX to the combination of carboplatin and VP-16. The German Testicular Cancer Cooperative Study Group published their initial phase I/II experience with this regimen in 1994.⁸² They reported 74 patients, 20 of whom were treated with the phase II doses of carboplatin (1500 mg/m²), VP-16 (2400 mg/m²), and IFX (10 g/m²). IFX was again administered by prolonged infusion. Renal toxicity in this group was mild, with a median maximum serum creatinine level of 1.4 mg/dL; however, with escalating doses of carboplatin, much more severe renal toxicity was observed. Of 23 patients with cisplatin-refractory disease, only 1 was alive, free of disease, with a 7-month follow-up. This group updated their results in 1997,⁸³ revealing an OS of 38%, with a failure-free survival of 31% at 5 years. There were no long-term survivors among cisplatin-refractory patients. Late toxicities of renal insufficiency, paresthesias, and ototoxicity were seen in 20–30% of survivors.

Lotz et al.⁸⁴ carried out a phase I/II trial of this regimen, using a tandem transplant schema in 39 patients, including five with metastatic trophoblastic disease. Overall, there were 13 CRs and four PRs, for an overall response rate of 46%. Thirty-three patients treated on this trial had cisplatin-refractory disease (defined as failure to respond/progression on cisplatin-based CT or relapse within 4 weeks of cisplatin-based CT). In this group there were 21 patients with gonadal GCT, nine of whom achieved a CR with a median duration of 29 months (range 2–84+ months), and no patient with refractory extragonadal GCT was a long-term survivor. The investigators concluded that cisplatin refractoriness could be overcome with dose-intense therapy. The use of high-dose therapy with HSCR has been successful and life-saving for some patients, but many questions remain. In particular, those with primary mediastinal nonseminomatous GCT in relapse, and those with cisplatin-refractory disease, are helped either rarely or not at all. The cumulative information on relapsed mediastinal GCT indicates that this group of patients should be spared the rigors of high-dose therapy and autologous stem cell transplantation. New and innovative approaches are needed for these patients. For those who have cisplatin-refractory disease, the question is more difficult. There appears to be a fraction of such patients who are long-term disease-free survivors in most large series. This is a small fraction, probably no more than 5%, and yet, it is not zero. Ideally, however, such patients should be enrolled in clinical trials to develop more effective approaches. The use of allotransplantation in these two groups has yet to be explored, and may be worthy of evaluation.

ALLOGENEIC STEM CELL TRANSPLANTATION FOR SOLID TUMORS

Allogeneic stem cell transplantation is an effective therapy for a variety of hematologic malignancies. Early clinical observations indicate that a graft-versus-malignancy effect may be present after allogeneic transplant in advanced solid tumors.

The toxicity and TRM associated with conventional, fully ablative allografting was prohibitive in typical patients with solid tumors who might benefit from such an approach. In recent years, many transplant groups have explored the activity of reduced-intensity conditioning regimens with the aim to reduce regimen-related toxicity and TRM.⁸⁵ Different groups have used a variety of approaches to achieve the necessary immunosuppression including fludarabine-based regimens,^{86–88} low-dose fractionated total-body irradiation,⁸⁹ thymic irradiation, and T-cell-depleting antibodies⁹⁰ or cytotoxic drugs in combination with monoclonal antibodies.⁹¹

The occurrence of a graft-versus-malignancy effect that can be exploited for the treatment of solid tumors

may be inferred from early reports of a few cases that used allogeneic, fully ablative transplantation. A graft-versus-malignancy effect was first described after allografting for breast cancer.⁹² Subsequently, Ueno et al.⁹³ reported a small series of breast cancer patients treated with a high-dose alkylating agent regimen. In two of these cases, a disease response occurred during acute graft-versus-host disease (GvHD). More recently, Bay et al.⁹⁴ described responses attributable to a graft-versus-malignancy effect in four patients with refractory ovarian cancer. An anecdotal report identified a complete response in a patient with non-SCLC who had acute GvHD following a myeloablative allogeneic transplant for acute leukemia.⁹⁵ Thus, several tumors have been demonstrated to be susceptible to an immune-mediated graft-versus-malignancy effect after allogeneic SCT. The toxicities of fully ablative conditioning, however, precluded clinical trials to explore this more fully. The improved safety profile of nonmyeloablative allogeneic SCT allowed a number of investigators to initiate pilot studies in chemotherapy-refractory diseases. Advanced renal cell cancer (RCC) and metastatic melanoma were chosen as candidates for these studies because of their poor prognosis and susceptibility to immune therapy. In 2000, Childs et al.⁹⁶ from the National Institutes of Health (NIH) reported a clear graft-versus-malignancy effect in metastatic, cytokine-refractory renal carcinoma: in their report, disease regression occurred in 53% of 19 patients, and was associated with GvHD and full donor T-cell engraftment. Three of four patients who achieved a complete response survived without evidence of disease, including the first patient who remains in remission 4.5 years after the transplant. Disease response occurred primarily in the lungs, but other sites responded as well. The NIH results have been recently updated by Igarashi et al.⁹⁷ demonstrating that 23 of the first 55 patients had regression of metastatic disease compatible with a graft-versus-malignancy effect. Five patients died from transplant-related causes, acute GvHD being the major toxicity associated with the procedure. Other investigators have since confirmed these first observations. Rini et al.⁹⁸ demonstrated 4 partial responses in 15 patients who had undergone allogeneic SCT. Nine of these patients had sustained donor engraftment, with four treatment-related deaths. Blaise et al.⁹⁹ reported their experience of reduced-intensity allografting in a variety of solid tumors; notably, their approach resulted in a rapid engraftment and a low overall TRM (9%). Renal cell cancer patients, most of whom had a progressive disease at time of treatment, had a response rate of 8%.

AMYLOIDOSIS

The use of high-dose therapy and stem cell transplant for primary amyloidosis has gained in popularity recently.

Given the dismal outcome of patients with a diagnosis of AL amyloidosis, with or without conventional-dose therapy, a number of groups have carried out trials exploring the use of high-dose therapy in this setting. It is clear that the selection of patients with amyloidosis for high-dose therapy is of the utmost importance. The extent of organ involvement prior to high-dose therapy accounts for most of the transplant-related morbidity and mortality.^{100,101} In one trial, 43 patients were transplanted; those with two or more involved organs had a 100-day survival of 33% as compared with 81% for those with more than two organs involved. The Mayo Clinic treated 66 patients with a treatment-related mortality of 14%. Multivariate analysis revealed that serum creatinine and number of organs involved were the key predictors of survival. The 30-month survival was 72% overall, but was <20% for patients with more than two organs involved. They have therefore pub-

lished a risk-adapted model for the selection of these patients.¹⁰²

There is one randomized trial reported in which patients received either high-dose therapy as initial therapy or two cycles of oral melphalan and prednisone followed by high-dose therapy. One hundred patients were enrolled and randomized (52 to arm 1 and 48 to arm 2). Nine patients in arm 1 and 16 in arm 2 did not proceed to high-dose therapy. Survival of patients on arm 1 at 1 year was 70% compared with 58% for arm 2 ($P = 0.04$), and 35% of patients in both arms who underwent high-dose therapy achieved a CR.¹⁰³

In summary, the best treatment for AL amyloidosis has yet to be identified. The use of a risk-adapted model as proposed by the Mayo Clinic group makes high-dose therapy feasible for a larger proportion of these patients; yet-well designed clinical trials are needed to define more effective, safer, therapy for patients with this otherwise devastating diagnosis.

Chapter 96

NONMYELOABLATIVE CONDITIONING REGIMEN FOR ALLOGENEIC HEMATOPOIETIC CELL TRANSPLANTATION

Frédéric Baron, Marie-Térèse Little, and Rainer Storb

INTRODUCTION

Due to regimen-related toxicities, the use of conventional allogeneic hematopoietic cell transplantation (HCT) has been restricted to younger and medically fit patients. This is unfortunate, as the median ages at diagnosis of patients with most hematologic malignancies, such as acute and chronic leukemias, lymphomas, multiple myeloma, or myelodysplastic syndromes, range from 65 to 70 years (Table 96.1).¹ The curative potential of allogeneic HCT is the result of eradication of malignant cells by high-dose chemotherapy and total body irradiation (TBI), and of immune-mediated graft-versus-tumor (GvT) effects.^{2,3} The power of the GvT effects, which are mediated by lymphocytes, has led several groups of investigators to infuse donor lymphocytes (donor lymphocyte infusion, DLI) in patients who have relapsed with hematologic malignancies after allogeneic HCT.^{4,5} The induction of durable remissions by DLI demonstrated that the GvT effects were capable of eradicating some hematologic malignancies by themselves, even in the absence of chemotherapy. This prompted the introduction of reduced-intensity conditioning regimens⁶⁻⁸ or truly nonmyeloablative regimens for allogeneic HCT⁹⁻¹¹ that are mainly based on GvT effects. The lower degrees of regimen-related toxicities associated with these procedures have allowed the extension of allogeneic HCT to patients previously deemed ineligible for high-dose conventional approaches due to age or comorbidities.⁹

AIMS OF CONDITIONING REGIMENS

MAKING SPACE FOR DONOR CELLS

Immature progenitor cells occupy defined niches within the marrow stroma to obtain the necessary

support for proliferation and differentiation.¹² To allow access for donor cells to these niches, it was commonly believed that at least some host stem cells must be eradicated by the conditioning regimen. However, there is now evidence that allogeneic grafts can create their own marrow space via subclinical graft-versus-host reactions. First, dogs conditioned only with 4.5 Gy irradiation targeted to the cervical, thoracic, and upper abdominal lymph node chains, and administered postgrafting immunosuppression with mycophenolate mofetil (MMF, a purine synthesis inhibitor) and cyclosporine (CSP) achieved long-term mixed hematopoietic chimerism, as well as in the lymph nodes and bone marrow spaces that were shielded from irradiation.¹³ Secondly, HLA-identical bone marrow can stably engraft without any conditioning regimen or postgrafting immunosuppression in infants with severe combined immunodeficiency disease (SCID).¹⁴ Thirdly, allografts have been successfully carried out with postgrafting immunosuppression with MMF and CSP, but without conditioning in some human patients with T-cell deficiencies other than SCID.¹⁵ Finally, sustained engraftment has been accomplished in dogs after selective T-cell ablation with bismuth-213-labeled anti-TCR $\alpha\beta$ monoclonal antibody and postgrafting MMF/CSP.¹⁶

TUMOR ERADICATION

Radiation or chemotherapy dose-effect curves for tumor eradication are usually straight on a log scale: each radiation or chemotherapy dose increment kills the same fraction of malignant cells. Thus, allogeneic HCT was first used as a means to deliver otherwise supralethal doses of TBI.^{17,18} The major demonstration of the antitumor efficacy of supralethal chemoradiotherapy was evidenced by the superiority of autologous HCT over conventional chemotherapy in various hematologic

Table 96.1 Age of patients at diagnoses and at HCT¹

Disease	Median ages patient (years)		
	Recent allogeneic HCT recipients (FHCRC)		At diagnoses (SEERS)
	Related donor	Unrelated donor

malignancies.¹⁹ However, high-dose pretransplant therapy does not completely eradicate the malignancy in all patients. Attempts to improve disease-free survival by increasing the intensity of the conditioning regimens were usually accompanied by increases in transplant-related mortality (TRM), and overall as well as disease-free survivals remained unchanged or worsened.^{20,21}

PREVENTION OF HEMATOPOIETIC STEM CELL REJECTION

It is necessary to abolish host defenses prior to transplantation to avoid immune-mediated graft rejection caused by alloreactive cytotoxic host T lymphocytes in the major histocompatibility complex (MHC)-identical setting^{16,22} and by alloreactive cytotoxic host T lymphocytes, host natural killer (NK) cells, and HLA-specific antibodies in the MHC-mismatched setting.^{23,24} The risks of graft rejection increase in cases of HLA disparities or host sensitization to major and minor histocompatibility antigens via administration of multiple blood products.^{25,26} Both the conditioning regimen and the donor T lymphocytes are instrumental in the destruction of the host immune system. The latter implies that T-cell depletion of the graft as a method to prevent graft-versus-host disease (GvHD) may also have deleterious effects on engraftment.²⁷

TBI DOSE DE-ESCALATION IN THE DLA-IDENTICAL DOG MODEL

In the preclinical canine dog leukocyte antigen (DLA)-identical transplant model, a dose-response relationship with respect to TBI and allogeneic marrow engraftment has been demonstrated (Table 96.2). A

Table 96.2 Effect of TBI dose and postgrafting immunosuppression on engraftment of DLA-identical marrow grafts

TBI dose (Gy)	Postgrafting immunosuppression	No. of dogs with stable engraftment (%) ^a /no. of dogs transplanted
9.2	None ²⁸	20/21 (95%)
4.5	None ²⁹	6/17 (35%)
4.5	Cyclosporine ²⁹	7/7 (100%)
2.0	Cyclosporine ³⁰	0/4 (0%)
2.0	Methotrexate + cyclosporine ³⁰	2/5 (40%)
2.0	Mycophenolate mofetil + cyclosporine ³⁰	11/12 (92%)
2.0	Sirolimus + cyclosporine ³¹	6/7 (86%)
1.0	Mycophenolate mofetil + cyclosporine ³⁰	0/6 (0%)
1.0	Cyclosporine + G-PBMC ^{b32}	5/8 (63%)

^aMixed or full chimerism.

^bGranulocyte colony-stimulating factor mobilized peripheral blood mononuclear cells.

single TBI dose of 9.2 Gy was sufficiently immunosuppressive to allow engraftment of DLA-identical littermate marrow in 95% of dogs not given postgrafting immunosuppression.²⁸ When the dose was decreased to 4.5 Gy, only 41% of dogs had stable engraftment.²⁹ When dogs were given 4.5 Gy TBI and posttransplant prednisone, none engrafted.²⁹ However, the addition of postgrafting CSP for 5 weeks led to engraftment in all animals studied.²⁹ When the TBI dose was further decreased to 2 Gy, postgrafting immunosuppression, either with CSP alone or with a combination of CSP and methotrexate (MTX), resulted in graft rejection with autologous recovery in the majority of the dogs.³⁰ On the other hand, a postgrafting immunosuppressive regimen combining CSP and MMF lead to the development of stable mixed chimerism in 11 of 12 dogs studied.³⁰ However, when the TBI dose was further decreased to 1 Gy, stable long-term engraftment did not occur, demonstrating a delicate balance between host and donor cells.³⁰ More recently, the combination of rapamycin (sirolimus) and CSP was found to be as effective as MMF/CSP in dogs given DLA-identical marrow followed by 2 Gy TBI (Figure 96.1).³¹ However, here again, stable long-term engraftment did not occur when the TBI dose was further decreased to 1 Gy.³¹

There is some evidence that the rejections observed after 1 Gy TBI are due to immune-mediated host antigraft reactions. First, stable mixed chimerism could be achieved after only 1 Gy TBI by reducing the intensity of host immune responsiveness before HCT with the help of the fusion peptide, CTLA4-Ig, which blocks T-cell costimulation through the B7-CD28 signal pathway.³³ Second,

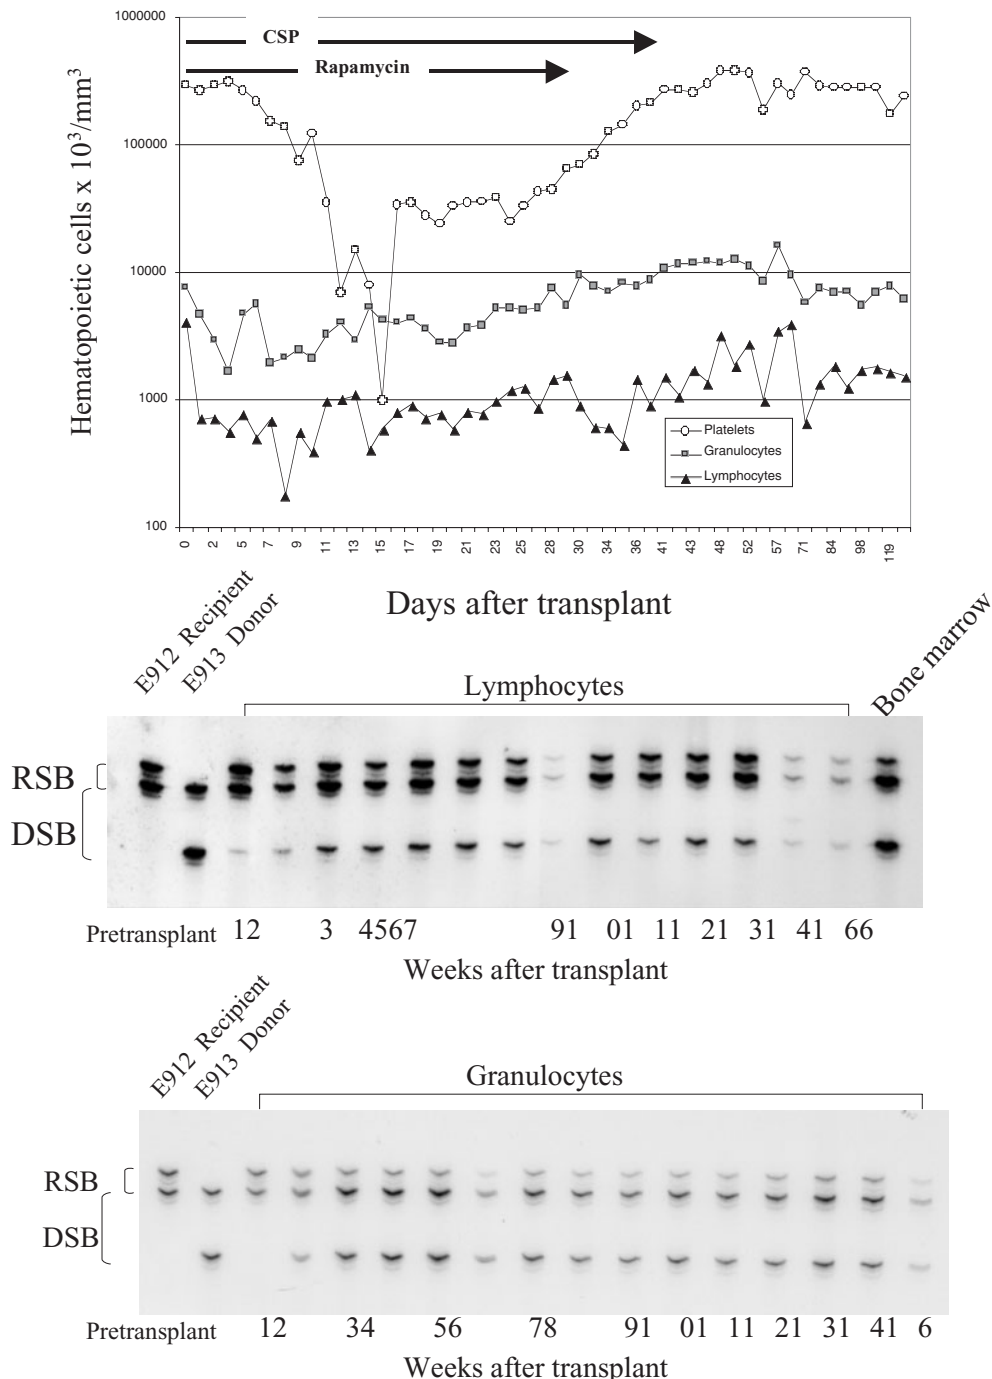

Figure 96.1 Hematologic changes (top panel) and results of chimerism analyses (bottom panel) in a dog conditioned with 2 Gy TBI before a DLA-identical littermate marrow graft and given a combination of rapamycin and CSP for postgrafting immunosuppression. (Reprinted from Baron F, et al.: Hematopoietic cell transplantation: five decades of progress. Arch Med Res 34:528–524, 2003; with permission from IMSS.)

Zauchna et al. demonstrated that the addition of granulocyte colony-stimulating factor mobilized peripheral blood mononuclear cells (G-PBMC) to marrow grafts allowed for a reduction in the pretransplant TBI to 1 Gy and omission of MMF.³² This effect was due to donor CD3 cells contained in G-PBMC, because the addition of the CD3-depleted fraction of G-PBMC resulted in graft rejection in six of seven recipients.³²

REDUCED-INTENSITY OR NONMYELOABLATIVE CONDITIONING REGIMENS

A number of reduced-intensity or truly nonmyeloablative conditioning regimens have been developed for clinical use (Table 96.3). Most of the reduced-intensity conditioning regimens do not meet criteria

Table 96.3 Example of RIC or NMCR currently under investigation

Center	Preparative regimen	Postgraft immuno-suppression	No. of patients (median age in years)	Diseases	GvHD		NRM (time after transplant)	Outcome
					Acute (grade II–IV)	Chronic		
MD Anderson ³⁴	Fludarabine 25 mg/m ² /day (or 2-CDA 12 mg/m ²) × 5 days Melphalan 140–180 mg/m ²	FK506 + MTX	86 (52)	Hematologic malignancies	49%	68%	37% (at 100 days)	2-year OS 28% 2-year DFS 23%
United Kingdom ³⁵	Fludarabine 30 mg/m ² /day × 5 days Melphalan 140 mg/m ² Campath-1H 20 mg/day × 5 days	CSP +/- MTX	44 (41)	Hematologic malignancies. 19 patients had a previous failed transplant	3/44. 1 after DLI	NR	11% (at 12 months)	1-year OS 73% 1-year PFS 71%
Jerusalem ³⁶	Fludarabine 30 mg/m ² /day × 6 days Busulfan (p.o.) 4 mg/kg/day × 2 days ATG 5–10 mg/kg/day × 4 days	CSP +/- MTX	24 (35)	CML in first chronic phase	75% ^a	55%	3 patients (days 116, 499, and 726)	5-year DFS 85%
MD Anderson ³⁷	Fludarabine 25 mg/m ² /day × 5 days or Fludarabine 30 mg/m ² /day × 3 days Cyclophosphamide 1g/m ² /day × 2 days or 750 mg/m ² /day × 3 days +/- Rituximab	FK506 + MTX	20 (51)	Lymphomas	20%	64%	2 (at day 45 and before 10 months)	2-year DFS 84%
National Institutes of Health ³⁸	Fludarabine 25 mg/m ² /day × 5 days Cyclophosphamide 60 mg/kg/day × 2 days	CSP	15 (50)	Hematologic + solid malignancies	10/15 patients. 1 after DLI	NR	2 patients (days 59 and 205)	8/15 patients survived between 121 and 409 (median 200) days
Boston ¹⁰	Cyclophosphamide 50 mg/kg/day × 3–4 days ATG 30 mg/kg/day × 3 days or 15 mg/kg/day × 4 days Thymic irradiation 700 cGy in patients who have not received previous mediastinal irradiation	CSP	21	Hematologic malignancies	12 patients 6 after DLI	NR	2 patients (days 77 and 180)	At a median follow-up of 445 days: 11 patients were surviving 7 patients were surviving free of progression

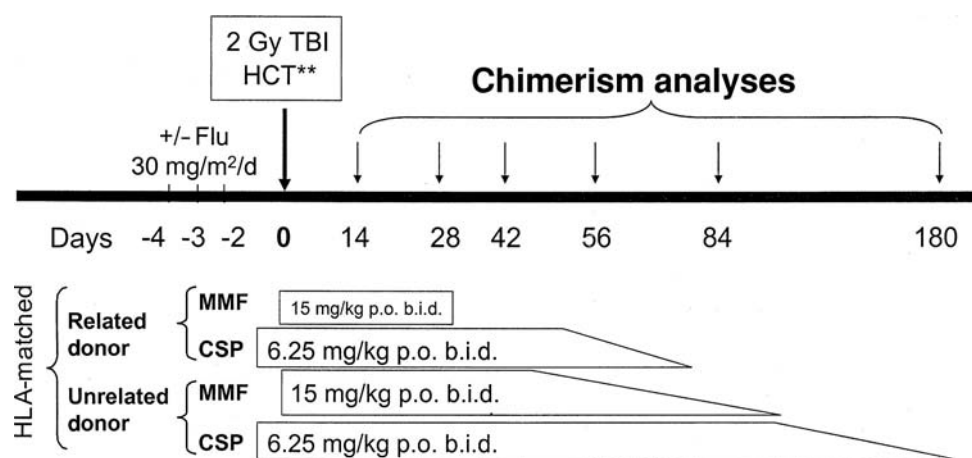

Figure 96.2 Nonmyeloablative HCT regimens for patients with malignancies given grafts from HLA-matched related and unrelated donors. (Reprinted from Baron F, Storb R, Little MT: Hematopoietic cell transplantation: five decades of progress. *Arch Med Res* 34:528–524, 2003; with permission from IMSS.)

of nonmyeloablative conditioning. These include (1) no eradication of host hematopoiesis; (2) prompt hematologic recovery (<4 weeks) without transplant; and (3) presence of mixed chimerism upon engraftment. Reduced-intensity conditioning regimens are aimed at eliminating host-versus-graft reactions and producing major antitumor effects. Conversely, nonmyeloablative conditioning regimens rely on optimization of pre- and posttransplant immunosuppression to overcome host-versus-graft reactions to allow engraftment, and eradication of tumors depend nearly exclusively on the GvT effect. In patients with slowly progressing diseases [i.e., chronic lymphocytic leukemia (CLL), low-grade non-Hodgkin's lymphoma (NHL), and chronic myeloid leukemia (CML) in first chronic phase] or with more aggressive diseases in complete remission, a nonmyeloablative conditioning regimen might be sufficient to achieve engraftment and cure the malignant disease. However, cytoreduction might be required in patients with aggressive diseases (acute leukemia, multiple myeloma, high-grade lymphoma, Hodgkin's disease), who are not in complete remission at the time of the transplant.

REDUCED-INTENSITY CONDITIONING REGIMENS

Most reduced-intensity conditioning regimens have combined purine analogs (fludarabine, cladribine, or pentostatin) and alkylating agents, usually cyclophosphamide, busulfan, or melphalan. In 1997, Giralt et al. reported engraftment of HLA-identical related transplants after a reduced-intensity conditioning regimen combining fludarabine 30 mg/m²/day × 4 days, cytarabine 2 g/m²/day × 4 days, and idarubicin 12 mg/m²/day × 3 days.⁶ Initial engraftment was greater than 90% with TRM around 20%. Giralt et al. subsequently reported a more intense regimen combining fludarabine (120–125 mg/m²) and melphalan (140–180 mg/m²) for patients with advanced leukemia,

multiple myeloma, or renal cell carcinoma.³⁴ Nonrelapse mortalities at 100 days and 1 year after the transplant were around 20 and 40%, respectively.³⁴ The Jerusalem group developed another protocol combining fludarabine, antithymocyte globulin (ATG), and low-dose oral busulfan.⁷ This regimen allowed the achievement of full donor chimerism in the majority of the patients with a low TRM. However, most patients included in this study were younger and would be considered eligible for conventional allogeneic HCT. Kottaridis et al. used another regimen combining Campath-1H (100 mg/m²), melphalan (140 mg/m²), and fludarabine (150 mg/m²).^{35,40} This regimen allowed engraftment with low incidences of GvHD and TRM in HLA-matched related and unrelated recipients.

NONMYELOABLATIVE CONDITIONING REGIMENS

Childs et al. developed a regimen combining cyclophosphamide (120 mg/kg) and fludarabine (125 mg/m²).^{11,38} TRM was 12% at 1 year in metastatic renal cell carcinoma patients. Spitzer et al. showed that mixed chimerism could be achieved with a regimen combining cyclophosphamide, thymic irradiation (in patients who had not previously received mediastinal radiation therapy), and ATG.¹⁰ However, around 30% of the patients subsequently rejected their transplant.

Based on the canine allogeneic transplant model, we studied the induction of mixed chimerism jointly with other centers, using low-dose (2 Gy) pretransplant TBI combined with postgrafting immunosuppression consisting of MMF and CSP, initially in HLA-matched related recipients (Figure 96.2).⁹ Typically, patients did not become severely pancytopenic, and more than 50% of eligible patients were treated entirely in the outpatient setting.⁹ Two-year nonrelapse mortality was 7%.⁹ Nonfatal graft rejection was observed in 16% of

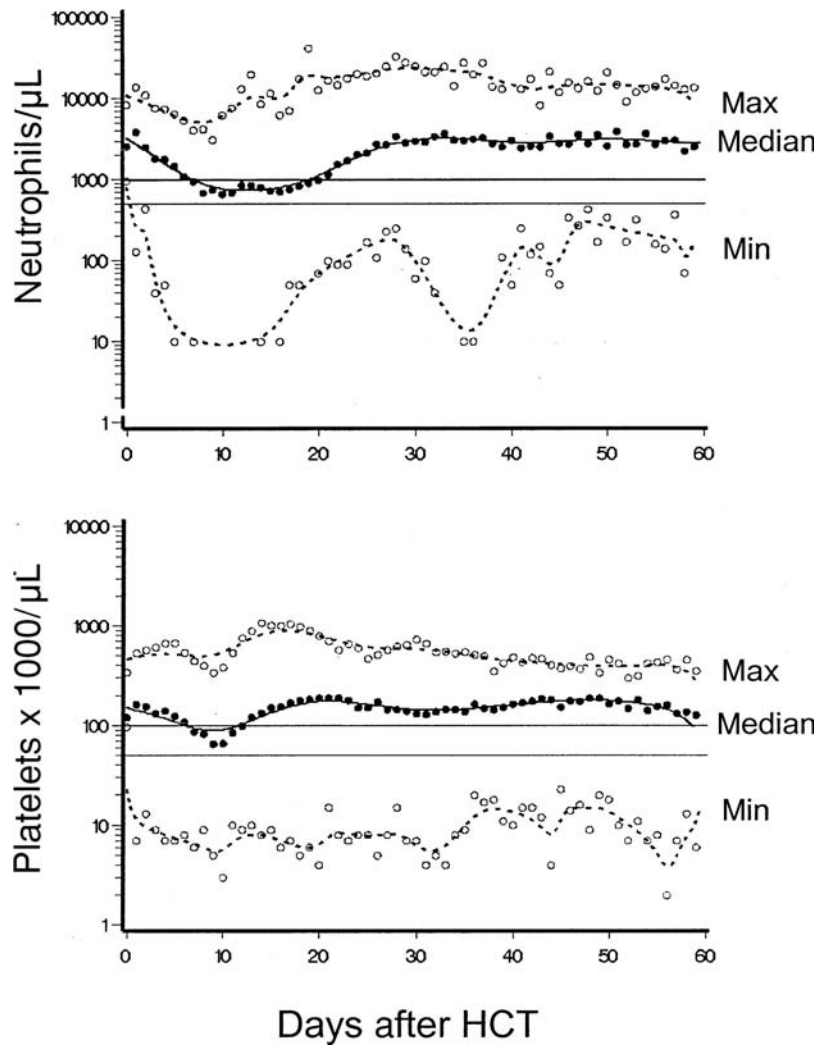

Figure 96.3 Neutrophil and platelet changes in 212 patients with malignancies conditioned with 2 Gy TBI +/- fludarabine (30 mg/m²/day × 3 days) and given HLA-matched related G-PBMC grafts. (Reprinted from Storb R: ASCO Educational Book 77-83, 2002; with permission from the American Society of Clinical Hematology.)

patients.⁹ Therefore, in subsequent patients, three doses of fludarabine (30 mg/m²/day) were added, and rejections decreased to 3%.¹⁸ We studied a similar protocol that extended the duration of postgrafting immunosuppression with MMF and CSP to 96 and 180 days, respectively, to condition patients for HLA-matched unrelated donor grafts (Figure 96.2).^{39,41}

CHIMERISM EVALUATION AND ENGRAFTMENT KINETICS

ASSESSMENT OF HEMATOPOIETIC CHIMERISM

The assessment of hematopoietic chimerism required more sensitive techniques than conventional cytogenetic analyses because of the availability of only small numbers of dividing cells. The most widely used techniques have been fluorescent in situ hybridization (FISH), with X- and Y-specific probes in case of sex-

mismatched transplant, and polymerase-chain-reaction-based assays of polymorphic mini- (variable number tandem repeats) or micro-satellite markers in case of sex-matched transplant. Other techniques based on restriction fragment length polymorphism have also been used.

ENGRAFTMENT KINETICS

The engraftment kinetics after a nonmyeloablative conditioning regimen were first analyzed by Childs et al.³⁸ The authors studied chimerism evolution in 15 patients conditioned with cyclophosphamide and fludarabine. Postgrafting immunosuppression was carried out with CSP alone. The patterns of engraftment varied considerably among their patients, but most often full donor chimerism was achieved earlier in T cells than in granulocytes, and the achievement of full donor T-cell chimerism preceded GvHD and antitumor responses. The kinetics of B-cell recovery were distinct from those

of myeloid and T-cell lineages, while NK-cell chimerism was closely correlated with T-cell chimerism.

Ueno et al. studied chimerism evolution in 23 patients, with metastatic tumors transplanted after a reduced-intensity conditioning regimen combining fludarabine and melphalan.⁴² Postgrafting immunosuppression consisted of tacrolimus and short MTX. All patients showed 100% T-cell and granulocyte chimerisms on days 30 and 100 after the transplant.

Keil et al. analyzed the impact of day 28 chimerism on outcome after nonmyeloablative HCT in 38 patients conditioned with fludarabine followed by low-dose (2 Gy) TBI.⁴³ Postgrafting immunosuppression was carried out with MMF and CSP. Generally, donor T-cell chimerism lagged behind myeloid chimerism. In addition, patients with <90% donor T cells on day 28 after the transplant had significantly higher risks of graft rejection and relapse and significantly worse progression-free survival than patients with ≥90% donor T cells.

Baron et al. analyzed T-cell chimerism in 35 patients conditioned with TBI (2 Gy) alone ($n = 15$), TBI (2 Gy) and fludarabine ($n = 13$), or fludarabine and cyclophosphamide ($n = 7$). Patients received either unmanipulated ($n = 18$), CD8-depleted ($n = 11$), or CD34-selected G-PBMC ($n = 6$). Median donor T-cell contributions on days 28, 60, 100, 180, and 365 in recipients of unmanipulated G-PBMC were 75, 85, 87, 90, and 100%, respectively. Evolution of donor T-cell chimerism did not differ significantly between recipients of unmanipulated and CD8-depleted G-PBMC, while CD34 selection resulted in significantly decreased donor T-cell chimerism.⁴⁴

We analyzed the kinetics of donor engraftment in peripheral blood hematopoietic subpopulations from 120 patients conditioned with 2 Gy TBI +/- fludarabine and postgrafting immunosuppression with MMF and CSP.⁴⁵ On day 14 posttransplant, the highest degree of donor chimerism was noted in the NK-cell fraction, followed by lymphocytes, monocytes, and granulocytes. By day 28, donor granulocyte chimerism had surpassed those in the remaining cell populations. Most patients remained mixed chimeras for at least 180 days posttransplant, with greater than 60% donor chimerism in each subpopulation except in patients with CML or MDS, who had lower percentages of donor T-cell chimerisms. Patients receiving G-PBMC had higher degrees of donor T-cell chimerism than recipients of marrow. Greater intensity of therapy before HCT was also associated with higher degrees of donor chimerisms. Low donor T-cell chimerism on day 14 (<50% CD3⁺ T cells) was strongly associated with a higher risk of graft rejection.

Taken altogether, these results suggest that the engraftment kinetics after nonmyeloablative or reduced-intensity conditioning HCT depend on the intensity of pretransplant chemotherapy, the intensity of the preparative regimens, and whether the grafts

have been depleted of T-cells or not. Moreover, monitoring mixed chimerism early after transplant may predict transplantation outcomes and/or allow early intervention to prevent graft rejection or disease progression.

TOXICITY

There are important differences in toxicities among the various studies, in part related to the intensities of the regimens used, the ages of the patients studied, and the nature of the grafts used (sibling vs unrelated and HLA-matched vs mismatched). The 100-day TRM ranged from <5% in HLA-matched nonmyeloablative HCT recipients conditioned with low-dose TBI +/- fludarabine¹⁸ to 37% in patients given melphalan and purine-analog-containing preparative regimens.³⁴ In a multicenter European Bone Marrow Transplant (EBMT) study reporting on 188 transplants for lymphoma with various reduced-intensity or nonmyeloablative conditioning regimens, the 100-day and 1-year probabilities of TRM were 13 and 26%, respectively, and those were significantly higher in older patients.⁴⁶

Analysis of data from the first 45 patients receiving 2 Gy TBI as a conditioning regimen showed that no patients experienced regimen-related painful mucositis, pulmonary toxicity, cardiac toxicity, veno-occlusive disease of the liver, hemorrhagic cystitis, or new onset alopecia.⁹ Fifty-three percent of eligible patients were treated entirely in the outpatient department, with others having relatively short hospitalizations (median 8 days). The hematologic changes were much milder than those observed after conventional HCT (Figure 96.3). Platelet and red blood cell transfusion requirements were significantly reduced in these patients compared to a concurrent group of myeloablative recipients, with 77% of patients not requiring platelet and 37% not requiring red blood cell transfusions.⁴⁷ Liver and lung toxicities were also significantly reduced after nonmyeloablative HCT. The frequency of a bilirubin >4 mg/dL was 26% at 200 days in 193 consecutive nonmyeloablative HCT recipients versus 48% at 100 days in 1419 consecutive allogeneic HCT recipients conditioned with cyclophosphamide-based myeloablative regimens.⁴⁸ The 120-day cumulative incidence of idiopathic pneumonia syndrome was 2.2% in 183 nonmyeloablative HCT recipients versus 8.4% in 917 recipients of myeloablative conditioning regimens.⁴⁹

GRAFT-VERSUS-HOST DISEASE

Most reports show that GvHD is a major cause of morbidity and mortality after reduced-intensity or nonmyeloablative conditioning regimens.^{7,9,34,39,41} In

the EBMT lymphoma study, grade II–IV acute GvHD was seen in 29% of in vivo T-cell-depleted HCT recipients, versus 58% of T-cell-replete HCT recipients ($P = 0.03$).⁴⁶ In multivariate analysis, both T-cell depletion of grafts and grafts from sibling donors were associated with lower GvHD incidences.⁴⁶ In a French study that used a conditioning regimen of fludarabine, busulfan, and ATG, the cumulative incidence of grade II–IV acute GvHD was 36%, and the 2-year cumulative incidence of chronic GvHD was 43%.⁵⁰ In multivariate analysis, a lower incidence of acute GvHD was significantly associated with higher ATG doses infused during conditioning ($P = 0.0005$), whereas the use of G-PBMC instead of marrow as the stem cell source was the only risk factor for the development of chronic GvHD ($P = 0.0007$). Not surprisingly, the relapse rates were much lower in patients who experienced GvHD than in those without it, suggesting potent GvT effects.

We recently compared GvHD in 44 nonmyeloablative and 52 age-matched conventional HCT recipients (ablative group).⁵¹ HCT included grafts from both related and unrelated donors who were at least serologically matched for HLA-A, -B, and -C, and allele-level matched for HLA-DRB1 and -DQB1. The median patient age was 56 years in the nonmyeloablative group versus 54 years in the ablative group. Postgrafting immunosuppression was MMF and CSP in the nonmyeloablative group, and MTX plus CSP ($n = 48$) or MMF plus CSP ($n = 4$) in the ablative group. Grades II–IV and III–IV acute GvHD to day 100 were lower among unrelated recipients in the nonmyeloablative group than among those in the ablative group ($P = 0.01$ and 0.01 , respectively). Peaks of skin and gastrointestinal morbidities occurred between 6 and 12 months in the nonmyeloablative group and during the first month in the ablative group. Interestingly, 7 of 10 nonmyeloablative HCT recipients who required steroid treatment for cutaneous GvHD after day +80 had acute inflammatory changes similar to those seen in acute GvHD (“late onset acute GvHD”). These observations emphasized that a new GvHD classification that is based on criteria emphasizing the quality of target organ involvement rather than temporal presentation would be required to assess GvHD after nonmyeloablative HCT. The median time to initiation of corticosteroids was 3.0 months in the nonmyeloablative group versus 0.9 months ($P < 0.001$) in the ablative group. Significantly smaller proportions of nonmyeloablative compared to ablative recipients required steroids during each of the first 3 months after HCT (month 1, $P < 0.001$; month 2, $P < 0.001$; month 3, $P = 0.02$). However, differences in steroid requirements between the nonmyeloablative and the ablative groups were no longer significant beyond the first 3 months after HCT. The 15-month cumulative incidence of death with manifestations of GvHD under treatment was 24% in the nonmyeloablative

group versus 35% not significant (NS) in the ablative group. One-year overall survival was 68% in the nonablative group versus 50% ($P = 0.04$) in the ablative group.

IMMUNE RECONSTITUTION AND INFECTIONS

To date, few reports have analyzed immune reconstitution after nonmyeloablative HCT. Mohty et al. showed that early CD8⁺ T lymphocyte and NK-cell recoveries after HCT with a reduced-intensity conditioning regimen take place, whereas naive CD4⁺CD45RA⁺ T lymphocytes remained below normal values during the first months after the transplant.⁵² Similar results were reported by Baron et al.⁴⁴ We recently compared immune reconstitution after conventional and nonmyeloablative transplantation.⁵³ During the first 6 months, absolute lymphocyte subset counts were similar, but counts of cytomegalovirus (CMV)-specific T-helper lymphocytes were higher at days 30 and 90 in the nonmyeloablative patient group. Conventional transplant recipients had higher naive CD4 and CD8 counts 1 year after the HCT, probably reflecting lower counts of recent thymic emigrants in nonmyeloablative recipients; this finding might be related to the older age of nonmyeloablative recipients.

Mohty et al. analyzed infectious complications occurring during the first 6 months after HLA-identical sibling transplantation with an ATG-based reduced-intensity conditioning regimen.⁵⁴ The 6 month cumulative incidences of bacteremia, positive CMV antigenemia, and fungal infection were 25, 42, and 8%, respectively.

Junghans et al. compared the incidence of post-transplant CMV infections in 56 nonmyeloablative recipients with that in 112 matched controls who were treated by conventional HCT during the same time period.⁵⁵ CMV disease occurred in neither low- and intermediate-risk CMV nonmyeloablative or control patients. The 100-day incidence of CMV disease for high-risk CMV patients (defined as recipients serologically positive for CMV) was 9% in the nonmyeloablative group versus 19% ($P = 0.08$) in the control group. However, the 1-year probability of CMV disease for high-risk CMV patients was similar in the two groups ($P = 0.87$). The onset of CMV disease was significantly delayed in the nonmyeloablative group compared to the control group (medians of 130 days vs 52 days, $P = 0.02$). These results agreed with the evolution of CMV-specific immunity after nonmyeloablative or conventional HCT, and emphasized that nonmyeloablative HCT recipients should receive CMV surveillance beyond day 100 and preemptive ganciclovir treatment similar to that routinely given to recipients of myeloablative regimens.

The same authors analyzed the incidence of bacterial infections during the first 100 days and of fungal infections during the first year posttransplantation.⁵⁶

The 30- and 100-day incidences of bacteremia were 9 and 27% in the nonmyeloablative group versus 27% ($P = 0.01$) and 41% ($P = 0.07$) in the control group, respectively. Invasive aspergillosis occurred at a similar rate (15% in the nonmyeloablative group vs 9% in the control group, $P = \text{NS}$). Fukuda et al. analyzed risks and outcomes of invasive fungal infections in 163 nonmyeloablative HCT recipients. The 1-year cumulative incidence of proven or probable invasive fungal infections, invasive mold infections, invasive aspergillosis, and invasive candidiasis were 19, 15, 14, and 5%, respectively. Invasive mold infections occurred late (median 107 days) after nonmyeloablative HCT. Risks factors were GvHD and CMV disease. Nonrelapse mortality in nonmyeloablative recipients' was 22%, of which 39% were mold infection related.

PRELIMINARY RESULTS WITH NONMYELOABLATIVE CONDITIONING

HLA-MATCHED RELATED GRAFTS

We recently reviewed results of the first 212 patients treated by our group of collaborators.¹⁸ Conditioning regimens consisted of 2 Gy TBI alone ($n = 102$), or 90 mg/m² fludarabine plus 2 Gy TBI ($n = 110$). Patient diagnoses included multiple myeloma ($n = 66$), acute leukemias or myelodysplastic syndromes ($n = 58$), chronic leukemias ($n = 43$), lymphomas ($n = 41$), and other hematologic malignancies ($n = 4$). Median patient age was 55 (range 18–73) years. The declines in blood counts after HCT were generally modest. The incidences of grade II, III, and IV acute GvHD were 29, 10, and 5%, respectively. Chronic GvHD was seen in 65% of patients. With a median follow-up of 11.5 (3–42) months, overall survival and progression-free survival were 63 and 52%, respectively. Typically, remissions occurred over extended periods of time, and some patients achieved complete remissions beyond 1 year posttransplant.

HLA-MATCHED UNRELATED GRAFTS

Maris et al. reported the results in 89 patients given grafts from unrelated donors matched for HLA-A, -B, and -C antigens and HLA-DRB1 and -DQBI alleles.³⁹ The median patient age was 53 (range 5–69) years. Diagnoses included acute leukemias ($n = 17$), myelodysplastic syndromes ($n = 21$), chronic leukemias ($n = 19$), multiple myeloma ($n = 7$), lymphomas ($n = 17$), or other hematologic malignancies ($n = 8$). Stem cell sources were marrow ($n = 18$) or G-PBMC ($n = 71$). Durable engraftment was observed in 85% of G-PBMC and 56% of marrow recipients ($P = 0.007$). Factors associated with increased risks of graft rejection were marrow instead of G-PBMC as stem cell source and the absence of chemotherapy preceding HCT. Cumulative probabilities of grades II, III, and IV acute GvHD were 42, 8, and 2%, respectively. Chronic

extensive GvHD was seen in 37% of patients. Grades II–IV acute GvHD ($P = 0.02$) and chronic GvHD ($P = 0.04$) were associated with decreased risks of relapse. Nonrelapse mortality at day 100 and 1 year were 11 and 16%, respectively. One-year overall and progression-free survivals were 57 and 44% for G-PBMC recipients, and 33 ($P = 0.13$) and 17% ($P = 0.02$), respectively, for marrow recipients. Risk factors favorably associated with improved overall survival in a multivariate analysis included <5% blasts in the marrow before HCT, low relapse risk disease category, transplantation from female donors, and CD3⁺ cell doses $\geq 2.33 \times 10^8$ cells/kg.

HCT WITH NONMYELOABLATIVE CONDITIONING AFTER FAILURE OF PREVIOUS HCT

Given that TRM after a second myeloablative allogeneic HCT in adults ranges from 50 to 80%,⁵⁷ several authors have investigated the use of nonmyeloablative or reduced-intensity conditioning regimens in this setting. Nagler et al. described 12 high-risk, heavily treated patients with a median age of 33 (range 8–63) years who received HLA-identical sibling ($n = 9$) or unrelated ($n = 3$) HCT⁵⁸ for acute leukemias or lymphomas. Patients were conditioned with a reduced-intensity regimen consisting of fludarabine (180 mg/m²), busulfan (8 mg/kg/day), and ATG (40 mg/kg). Three-year TRM and progression-free survival rates were 10 and 50%, respectively. Branson et al. reported on 38 patients with refractory, progressive, or relapsed lymphoproliferative diseases after autologous HCT.⁵⁹ The median age was 44 (range 25–64) years. The conditioning regimen consisted of Campath-1H (100 mg), fludarabine (150 mg/m²), and melphalan (140 mg/m²). Fourteen-month TRM and progression-free survival rates were 20 and 50%, respectively. Feinstein et al. studied 55 patients with a median age of 43 (range 18–69) years who failed previous myeloablative autologous ($n = 49$), allogeneic ($n = 4$), or syngeneic ($n = 2$) HCT.⁶⁰ All patients were considered ineligible for conventional allografts because of age (older than 30 years), medical infirmity, or high-risk of TRM (prior high-dose TBI or dose-limiting organ irradiation). Twelve patients had disease that remained untreated after they failed conventional HCT, and 13 others had treatment-refractory disease at the time of the nonmyeloablative HCT. The nonmyeloablative conditioning regimen consisted of 2 Gy TBI alone ($n = 7$), or 2 Gy TBI and 90 mg/m² fludarabine ($n = 48$). Donors were HLA-identical siblings ($n = 31$) or HLA-matched unrelated donors ($n = 24$). Thirty-three patients died a median of 127 days (range 7–834 days) after HCT: 21 of relapse, 11 of TRM, and 1 of suicide. The TRM rate on day 100 was 11%, with an estimated 1-year TRM rate of 20%. One-year progression-free survival was 28%, and untreated disease at the time of the nonmyeloablative HCT increased the risk of death.

RESULTS IN DIFFERENT DISEASE SETTINGS

Myeloid malignancies

Or et al. reported results of a reduced-intensity conditioning regimen HCT in 24 CML patients in first chronic phase. Patients had a median age of 35 (range 3–63) years.³⁶ Nineteen received their HCT from HLA-matched family members (18 siblings and one father), and five patients received their HCT from HLA-matched unrelated donors. The 5-year probability of progression-free survival was 85% [95% confidence interval (CI) 70–100%], suggesting that results after a reduced-intensity conditioning regimen may be as good as after myeloablative conditioning in chronic-phase CML. Feinstein et al.⁶¹ reported outcomes in 18 patients with de novo ($n = 13$) or secondary ($n = 5$) AML in first complete remission who received a nonmyeloablative HCT from HLA-identical sibling donors. Median age was 59 (range 36–73) years. Conditioning consisted of 2 Gy TBI alone ($n = 10$) or combined with fludarabine ($n = 8$). Two rejections were observed in patients not given fludarabine, and one of the two died with relapse. At a median follow-up of 766 days, seven patients have remained in complete remission. The 1-year estimates of TRM, overall survival, and progression-free survival were 17 (95% CI 0–35%), 54 (95% CI 31–78%), and 42% (95% CI 19–66%), respectively. For the 13 patients older than 55 years, the figures were 8 (95% CI 0–22%), 68 (95% CI 43–94%), and 59% (95% CI 31–87%), respectively. These results are promising, as the 1-year progression-free survival for AML patients older than 55 years is around 45% with conventional chemotherapy.

Chronic lymphocytic leukemia

Dreger et al. reported results of 77 patients who received reduced-intensity conditioning regimen HCT ($n = 34$) or nonmyeloablative HCT ($n = 43$) for CLL in EBMT-affiliated centers.⁶² The median age was 54 (range 30–66) years, and the median number of previous chemotherapy regimens was 3 (range 0–8). Eight patients were in complete remission, 42 in partial remission, and 27 had refractory disease at transplant. The 1-year probability of TRM was 18% (95% CI 9–37%), and the 2-year probabilities of overall survival and progression-free survival were 72 (95% CI 61–83%) and 56% (95% CI 43–69), respectively.

Sorror et al. recently reported outcomes in 14 chemotherapy-refractory CLL patients who received a nonmyeloablative HCT from HLA-matched unrelated donors.⁶³ The median patient age was 58 (range 48–67) years. Two patients rejected their transplants. With a median follow-up of 19 months, seven patients were in complete remission, two in partial remission, and two had stable disease. Estimated 2-year progression-free survival was 62%.

Lymphoma

Robinson et al. reported results in 188 patients with lymphoma [low-grade NHL $n = 52$, high-grade NHL

($n = 62$), Hodgkin's disease ($n = 52$), and mantle cell lymphoma ($n = 22$)] who received various reduced-intensity conditioning regimens or nonmyeloablative HCT in EBMT-affiliated centers.⁴⁶ The median age was 40 (range 2–61) years, and the median number of prior treatment courses was 3 (range 0–6). Forty-eight percent of patients had undergone prior autologous transplantation. The 1-year probability of TRM was 25.5%. The 1-year probability of progression-free survival was 46%, and was significantly better in patients with chemosensitive disease, Hodgkin's disease, and low-grade NHL.

Multiple myeloma

We recently reported results in 54 multiple myeloma patients who first received a cytoreductive autologous HCT followed by a planned nonmyeloablative HCT.⁶⁴ Patients were 29–71 (median 52) years old and had previously treated stage II or III multiple myeloma. Forty-eight percent had refractory (35%) or relapsed (13%) disease. Conditioning regimens for autologous and nonmyeloablative transplants were melphalan 200 mg/m² and 2 Gy TBI, respectively. Nonmyeloablative HCT was performed 40–229 (median 62) days after the autologous transplant. The 100-day mortalities after autologous and allogeneic HCT were 2 and 2%, respectively. With a median follow-up of 552 days after allografting, 57% of patients achieved complete remissions and 26% partial remissions. Of the 28 patients with responsive disease entering the trial (complete/partial remissions), 3 have died and 2 have had disease progression. In contrast, of the 26 patients with relapsed or refractory disease at study entry, 9 have died. Causes of death in both groups were complications related to GvHD ($n = 4$), progression ($n = 3$), pulmonary failure ($n = 2$), lung cancer ($n = 1$), CMV infection ($n = 1$), and encephalopathy ($n = 1$). The estimated 2-year overall and progression-free survivals were 78 and 55%, respectively.

SUMMARY

Reduced-intensity conditioning and nonmyeloablative regimens allowed engraftment of allogeneic hematopoietic cells and the development of GvT effects. Remarkably, a minimally toxic regimen of 2 Gy TBI with or without fludarabine followed by post-grafting immunosuppression with MMF and CSP assured engraftment rates similar to those following myeloablative conditioning. Antitumor responses occurred after the achievement of full donor T-cell chimerism, though complete remissions required extended periods of time, with some patients achieving complete remissions more than 1 year after transplant. In patients with slowly progressing diseases such as CLL, low-grade NHL, chronic-phase CML, or with more aggressive diseases in complete remission,

nonmyeloablative conditioning may be sufficient to achieve engraftment and cure. In patients with aggressive diseases such as acute leukemias, multiple myeloma, high-grade lymphomas, and Hodgkin's disease not in complete remission, cytoreduction by preceding chemotherapy or autologous HCT may be required. Remaining challenges include prevention

of both severe GvHD and infections, in particular invasive fungal infections. Further progress in adoptive transfer of T-cell populations with relative tumor specificity is likely to make HCT after reduced-intensity or nonmyeloablative regimens more effective, and might even extend the use of allogeneic HCT to the therapy of nonhematopoietic malignancies.

Chapter 97

UMBILICAL CORD BLOOD TRANSPLANTATION

Ian Horkheimer and Nelson Chao

INTRODUCTION

Transplantation of hematopoietic stem cells (HSCs) collected from bone marrow (BM) or peripheral blood (PB) of related and unrelated donors has become a successful treatment option for several malignant and nonmalignant disorders (Table 97.1). Further success has been hampered by the limited number of suitable HLA-matched donors, the prolonged length of donor unit procurement, and significant transplant-related morbidity. Over the past 15 years, in efforts to overcome these obstacles, allogeneic transplantation using umbilical cord blood (UCB) as an alternative source of HSCs has been investigated.

The use of UCB as a source of HSCs was proposed in the early 1980s. UCB cells have been shown in vitro to demonstrate both self-renewal and hematopoietic differentiation capabilities.¹⁻⁴ Umbilical cord blood transplantation (UCBT) entered the clinical arena in 1988 when a child with severe Fanconi anemia was successfully transplanted using UCB harvested from an HLA-matched sibling.⁵ The Placental Blood Project was launched in 1993 to evaluate the clinical utility of expanding UCB as a source of HSCs. Shortly thereafter, mismatched related and unrelated UCBTs in children with high-risk leukemia were performed.⁶ Since 1998, more than 2500 UCBTs have been completed—75% performed in children and the remaining 25% in adults.⁷ Potential advantages of UCB as an alternative source of HSCs include (1) negligible risk to donor, (2) absence of donor attrition, (3) ease of procurement and rapid allocation, (4) reduced risk of graft-versus-host disease (GVHD), and (5) less stringent HLA-matching restrictions.

UCB BANKING

Given today's population dynamics, the estimated probability of any patient obtaining an HLA-matched related-donor HSC unit is approximately 30–40%.⁸ The likelihood of securing a matched unrelated donor

unit varies according to ancestry and is less likely in patients of certain racial and ethnic backgrounds. As such, approximately 50% of all patients requiring allogeneic transplantation are unable to secure an unrelated HLA-matched donor unit.⁹ As an alternative source of HSC, UCB has the potential to alleviate this donor shortage. UCB banks have been developed to optimize the chances of finding a suitable donor for allogeneic transplantation. Netcord, a cooperative network of large experienced UCB banks in the United States, Europe, Japan, and Australia was founded in 1998 to establish minimum UCBT standards, reach an international agreement on aspects that protect the infant donor and mother, and facilitate the matching process. As of March 2004, over 150,000 UCB units have been banked in 36 UCB registries throughout 21 countries.¹⁰

ETHICAL CONSIDERATIONS

UCB as an alternative source for allogeneic transplantation has generated several ethical concerns.¹¹ In 1997, a working group composed of experts in medicine, blood banking, law, ethics, anthropology, and the social sciences convened to examine these issues.¹² A consensus statement to inform public policy and raise awareness regarding UCB banking procedures was generated. This statement addressed the following dilemmas: (1) the potential promise of UCB as an investigational agent, (2) maintaining linkage of the donors and stored UCB units, (3) the uncertainty of autologous UCB banking, (4) monitoring of private-sector marketing practices, (5) assuring equitable UCB banking recruitment and use, and (6) the process of obtaining informed consent.

INFORMED CONSENT

Informed consent is routinely a prerequisite for the procedures of UCB banking. Prenatal efforts are often directed at recruiting potential donors. Information regarding the risks and benefits of the collection, storage, and potential uses of UCB are explained to parents of prospective donors. By convention, the mother must consent by proxy as UCB is technically of fetal

Table 97.1 Diseases treated by UCBT

Malignant	Nonmalignant
Acute lymphocytic leukemia	Fanconi's anemia
Acute myeloid leukemia	Severe combined immunodeficiency
Chronic myelogenous leukemia	Severe aplastic anemia
Juvenile chronic myelogenous leukemia	Osteopetrosis
Chronic lymphocytic leukemia	Thalassemia
Hodgkin's lymphoma	Myelofibrosis
Non-Hodgkin's lymphoma	Sickle cell anemia
Neuroblastoma	Hurler's syndrome Myelodysplastic syndrome Wiskott–Aldrich syndrome Adrenoleukody-strophy Blackfan–Diamond Syndrome Hunter syndrome Amegakaryocytic thrombocytopenia Lesch–Nyhan Syndrome Gunther's disease Kostman syndrome X-linked lymphoproliferative disorder

origin. At least four models of obtaining informed consent exist: before labor, during labor, after collection, and phased.¹³ Before-labor consent allows the donor parent(s) to review and examine the consent documents weeks to months prior to childbirth. Donors not exposed to recruitment efforts, often as a result of inadequate prenatal care, may be excluded; potential restriction in the diversity of the global UCB bank may result. During-labor consent occurs during the early phase of labor. Consent for testing and donation may also be obtained at this time. The after-collection model does not require consent for UCB collection. Once collected, an informed consent process for testing and donation is engaged. This may be troublesome given various personal, cultural, and religious beliefs toward UCB. In light of the potential advantages and disadvantages of these consent models, a phased consent policy has been adopted by some authorities. The premise upon which this policy is based is that the decision to collect UCB is not necessarily closely linked to the decision to test or donate the unit. In the first phase, information regarding UCB is dispersed during prenatal visits. Consent for the second and third phase may be completed at this time. Omission of the first phase does not preclude progression to the second or third phases. The second phase begins during labor

when a consent form is delivered and reviewed explaining the process of UCB collection. The final phase is completed after delivery when the mother may agree to the processing, storage, and potential transplantation of the collected UCB.

Policies and recommendations vary based on patient demographics and the practices of health care providers. Nearly all centers employing *in vitro* UCB collection methods require prelabor consent. The largest UCB bank in the world, the New York Blood Center, uses the after-collection model. The phased-consent policy has been adopted by the American Red Cross, North Central Blood Services Cord Blood Bank. The American Medical Association Working Group on Ethical Issues of Umbilical Cord Blood Banking states “In general, when UCB collection is anticipated, the norm should be to obtain written informed consent before labor and delivery, followed by an affirmation of this consent after delivery.”¹²

COLLECTION

Optimal yield of mononuclear cells remains a critical factor in UCB collection. A suitable UCB unit has been defined as a volume of at least 40 ml (excluding anticoagulant) and a total nucleated cell (TNC) count of 6×10^8 .^{8,14} Factors associated with improved UCB harvest include fewer previous births, larger infant size, greater gestational age, longer umbilical cord, and larger placenta.^{15,16} Two methods of UCB collection exist *in utero* and *ex utero*. *In utero* collection is initiated within seconds of delivery of the baby but prior to expulsion of the placenta. The umbilical cord is clamped, transected, and disinfected. The umbilical vein is then punctured with a 16-gauge needle connected to a standard closed blood donor collection system (450 ml) containing approximately 20–30 ml of CPDA (citrate, phosphate, dextrose, adenine) anticoagulant, and drained by gravity. *Ex utero* UCB collection takes place immediately following placental delivery. The delivered placenta is placed in a plastic-lined absorbent cotton pad suspended from a support frame. Within minutes, the disinfected umbilical cord vein is punctured and drained into a blood donor set containing CPDA anticoagulant. The method of collection varies between UCB banks and among collection sites within UCB banks. A small, randomized single-institution trial detected a statistically significant increase in mean volume (83.26 ml vs. 48.42 ml) and mononuclear cell numbers (3.12×10^8 vs. 1.806×10^8) with *in utero* collection.¹⁷ This was supported by a retrospective single-institution analysis.¹⁸ A large, retrospective multicenter analysis of five programs established by the American Red Cross Cord Program argued equivalency between *in utero* and *ex utero* methods.¹⁹

PROCESSING, STORAGE, AND PREPARATION FOR USE

In 1995, the National Heart, Lung, and Blood Institute funded three UCB banks and six transplant centers to

assist in establishing standard operation procedures for the collection, processing, and investigation of UCB use.¹⁴ Several modifications of the standard procedure of UCB processing and storage have been developed to reduce unit size (and thus storage costs) and enhance red blood cell (RBC) depletion while maintaining sterility and HSC composition and activity.²⁰⁻²⁶ Three to five milliliters of UCB is removed for HLA-typing, disease testing, microbiological cultures, progenitor cell assays, and assessment of total nucleated and CD34⁺ cell counts. RBC depletion and volume reduction begin with the addition of 6% hydroxyethyl starch to enhance RBC sedimentation. The mixture is centrifuged at 50g for 5 minutes. The leukocyte-containing supernatant is then centrifuged at 400g for 10 min yielding a sediment of white cells. The leukocyte pellet is resuspended in plasma and diluted to a final volume of 20 ml.

UCB is cryopreserved with chilled dimethyl sulfoxide to a final concentration of 10% and a total volume of 25 ml. The sample is placed in aluminum containers and frozen to -50°C in a -80°C freezer. The UCB unit is then transferred to a liquid nitrogen storage device where it may be housed for several years.²⁷

Preparation of a frozen UCB unit for infusion is similar to the procedure used for PB stem cell units. The unit is placed in a sterile, sealable plastic bag, submerged, and gently agitated in a 37°C water bath. When thawed, equal volumes of 10% dextran and 5% albumin are added to a volume double of that was originally collected. The suspension is then centrifuged at 250g for 10 min. The pellet is resuspended with equal volumes (50 ml) of 10% dextran and 5% albumin. Samples of the final unit are sent for bacterial and fungal cultures.

HLA TYPING AND UCB TESTING

UCB is HLA typed and subjected to a standard battery of laboratory tests prior to storage. More specific testing for genetic diseases is guided by the donor's history. As a result of the prospective HLA typing and testing, the time required to find a UCB donor and proceed to transplantation is significantly reduced compared to that required for BM sources²⁸ (Table 97.2). HLA typing in preparation for allogeneic transplantation has largely focused on class I (HLA-A and HLA-B) and class II (DRB) antigens. Class I antigens are typed by serologic methods (microlymphocytotoxicity assay), while class II antigens are identified with molecular biology techniques (low- and high-resolution polymerase chain reaction (PCR)). HLA typing of UCB poses certain obstacles, particularly for the serologic assays. Available tissue is often limited due to efforts to maximize the volume of cells available for infusion. The sample size may be inadequate for either initial or repeat typing efforts. In addition, interference with serologic reagents, a high background of dead cells, and contamination of the sample with immature erythroblasts and early myeloid cells may make the results uninterpretable. Given this, recent interest in

molecular typing of class I antigens has been generated. A review of 1644 UCB units deemed 14.5% of the serologically HLA-typed class I antigens unsatisfactory due to cross-reactions, false positives, unclear split assessments, or an inability to perform the assay due to poor cell viability.²⁹ Of these unreliable samples 100 were analyzed using molecular biology (PCR) methods, which found that the initial serologic HLA type was incorrectly determined in 56.7% of the units. Nearly 20% could not be typed due to high cell mortality. Similar results were reported in a separate review of over 200 consecutively HLA-typed UCB units.³⁰

UCB BIOLOGIC CHARACTERIZATION AND IMMUNE RECONSTITUTION

Successful allogeneic transplantation relies on hematopoietic recovery and immune reconstitution and maturation, processes that depend in part on the cellular components of the graft. HSCs can be identified by *in vitro* colony assays and can be further characterized phenotypically using flow cytometric techniques. Human HSCs have been defined as either pluripotent or lineage committed. Pluripotent HSCs have the capacity for both self-renewal and sustained differentiation, whereas lineage-committed human HSCs have the potential for self-renewal but are destined to differentiate along a specific hematopoietic lineage. Pluripotent HSCs are CD34⁺CD38⁻CD90⁺HLA-DR⁻. Lineage-committed HSCs are CD34⁺38⁺, with coexpression of either CD33 (myeloid), CD15 (late myeloid), CD64 (granulomonocytic), CD71 (erythroid), CD61 (megakaryocytic), CD7 (T cell), or CD19 (B cell) antigens. UCB contains a disproportionately higher number of phenotypically immature HSCs. UCB immune function is also thought to be immature. *In vitro*, UCB T cells demonstrate decreased allogeneic responses following primary antigen stimulation.^{31,32}

Table 97.2 Tests commonly performed on UCB

ABO and Rh blood group antigens
Blood group antibody screen
HLA class I and II typing
Hemoglobin electrophoresis
G-6PD activity
Osmotic fragility and spectrin/ankrin analysis
VDRL/RPR
Bacterial and fungal cultures
Cytomegalovirus (CMV) IgM antibody
Hepatitis B virus core antibody and surface antigen
Hepatitis C virus antibody and PCR
Human immunodeficiency virus (HIV) ELISA/Western Blot, p24 antigen, and PCR
Human T-lymphocyte virus (HTLV) I, II ELISA/Western Blot

Following allogeneic stem cell transplant, engraftment is dependent on pluripotent and myeloid lineage-committed HSCs. B-cell reconstitution begins with differentiation of donor-derived HSCs and CD34⁺CD38⁺CD19⁺CD20⁺ B-lineage committed HSCs in the PB and BM. T-cell reconstitution is believed to occur initially by a thymic-independent pathway. Antigen stimulation drives the conversion of naïve CD45RA⁺CD45RO⁻ T cells present in the allograft to memory CD45RA⁻CD45RO⁺ T cells with resultant limited T-cell receptor (TCR) diversity.³³⁻³⁵ Following this, a thymic-dependent pathway is responsible for further immune reconstitution. CD34⁺CD38⁺CD7⁺CD3⁻ T-lineage-specific HSCs repopulate in the BM and migrate to the thymus. These HSCs down-regulate CD34 antigen and eventually become CD4⁺CD8⁺ T-cell precursors. TCRs are up-regulated as is CD3 antigen. CD4 or CD8 antigen is then selectively lost, resulting in a more durable and diverse naïve CD45RA⁺CD45RO⁻ CD4⁺ or CD8⁺ T-cell repertoire.^{33,36,37}

BIOLOGIC CHARACTERIZATION

Comparative flow cytometry analyses of the cellular content of UCB, BM, and PB units have been performed.^{38,39} The absolute number of pluripotent HSCs was significantly reduced in UCB units as compared to BM and PB units. A mean of 0.21×10^6 cells/UCB unit was approximately 1/10 that of the other sources, but these HSCs were present at a higher frequency (UCB 3.39%, BM 1.47%, PB 1.82%). UCB units also possessed a significantly lower absolute number of myeloid-committed HSCs (26–65 fold) and fewer total lymphocytes (0.59×10^9 cells/unit) as compared to BM and PB sources. Of these lymphocytes, the frequency of B cells in UCB samples (18.5%) was similar to BM units and approximately twice that of PB units. The percentage of B-lineage-specific HSCs was greater in UCB units (3.79%) as compared to PB units, although no difference was detected in the frequency of immature CD19⁺CD20⁻ B cells and mature CD19⁺CD20⁺ B cells. The proportion of T cells in UCB samples (58%) was similar to that of BM, both of which were decreased as compared to PB samples (71.2%). T-lineage-specific HSCs were present at a three- to fourfold higher frequency in UCB units (12.1%) as compared to BM and PB units. UCB units also had a higher frequency of naïve CD45RA⁺CD45RO⁻ CD4⁺ and CD8⁺ cells. The percentage of NK cells (CD3⁻CD16/56⁺) was highest in UCB units as compared to that in BM and PB sources (24.8%, 15.0%, and 8.5%, respectively).

IMMUNE RECONSTITUTION

Following UCBT, B-cell recovery is commonly regained within weeks, while T-cell competence is often not complete for 12–36 or more months. Quantitative assessment of immune reconstitution

may be performed by determining lymphocyte subset counts. Qualitative determination may be undertaken by evaluation of T-cell-receptor excision circles (TRECs)—stable, nonreplicating episomal DNA by-products of the TCR rearrangement process. TRECs provide an estimate of the thymus's ability to produce new T cells.⁴⁰ Analysis of TCR V β -chain complementary determining region 3 (CDR3) is a measure of TCR diversity.⁴¹

Quantitative immune reconstitution in children the first 100 days post-UCBT has been evaluated.⁴² B-cell counts increased to normal levels 30–90 days post-transplant as did serum immunoglobulin levels. NK cell counts remained within the normal range during the first 100 days. CD4⁺ and CD8⁺ T-cell counts did not recover during this period. Additional pediatric patients were followed several months post-UCBT.⁴³ CD4⁺ and CD8⁺ cells recovered at medians of 12 and 9 months. Multivariate analysis of factors affecting lymphocyte subsets revealed that GVHD had an adverse affect on CD4⁺ recovery. Recipients of unrelated-donor grafts had worse CD8⁺ recovery. A separate analysis in children found that naïve and memory T-cell counts reached normal levels between 6 and 12 months post-UCBT in children. In adults, CD4⁺ and CD8⁺ T cells did not reach normal levels until 2 years post-UCBT, while naïve and memory T-cell recovery were delayed until 3 years post-UCBT.⁴⁴ TREC determination and V β -chain TCR CDR3 analysis following UCBT has been assessed in both children and adults.^{44,45} TREC levels and V β -chain TCR diversity were limited in both populations in the first 2–6 months post-UCBT. In children, TCR diversity broadened as early as 9 months; TREC levels were detectable 1 year post-UCBT. In adults, development of TCR diversity was delayed until nearly 3 years post-UCBT. TREC levels were first detected at 18 months. Increasing TREC levels in both children and adults coincided with the appearance of naïve CD4⁺ T cells. These data suggest that the antigen-driven peripheral expansion of T cells following pediatric UCBT is more short lived as a result of earlier thymic-dependent immune reconstitution. Following adult UCBT, thymic-dependent immune reconstitution is more delayed.

CLINICAL DATA

The promising results of UCB as an alternative source of HSCs in pediatric related- and unrelated-donor transplantation generated worldwide interest. In 1992, in an attempt to more quickly learn the true risks and benefits of UCBT, the International Cord Blood Transplant Registry (ICBTR), now a part of the International Bone Marrow Transplant Registry (IBMTR), was established as a repository of clinical data on the outcomes of patients who received UCB. EuroCord, a registry and forum for the development of cooperative studies

within the European community, was formed in 1995. Success in the pediatric population eventually led to UCBT for adult diseases. Analyses of UCBT clinical data have shown that the most important factor in predicting the rate and likelihood of engraftment is the number of nucleated cells infused (cell dose = TNC/kg). On the basis of the increased body mass of adults, the reduced cell dose limits the utility of UCB in this population. GVHD appears to occur less frequently following UCBT as compared to transplantation from BM and PB sources. This is thought to be a consequence of the immature immune characteristics of UCB. As a result of the reduced rates of GVHD, a greater degree of HLA disparity is allowed, further enlarging the potential-donor pool. Given the immature immune function of UCB grafts, a diminished graft-versus-leukemia (GVL) effect has been postulated but not observed. GVL effect following UCBT is believed to be the result of early CD3⁻CD16/56⁺ NK-cell recovery eventually followed by T-cell reconstitution. Transplant-related mortality (TRM) following UCBT remains a significant limitation, particularly in the adult population, and is most often a result of the conditioning regimen, failed or delayed engraftment (infection and/or hemorrhage), or GVHD.

PEDIATRIC RELATED-DONOR UCBT

The clinical data reported on pediatric related-donor UCBT are largely based on the experiences of the ICBTR^{46,47} and the EuroCord Registry^{48–50} (Table 97.3). The ICBTR reported on 74 children with a median age of 4.9 years. Both malignant and nonmalignant diseases were treated. The conditioning regimen was total body irradiation (TBI) based in half of the patients. GVHD prophylaxis consisted of cyclosporine and either prednisone or methotrexate. HLA type was identical or disparate at one locus in 75% of the patients. The EuroCord Registry reported on 138 patients with a median age of 5 years, 63% of whom had a malignant disease. The conditioning regimen varied according to disease and age, but again was TBI based in approximately half of the patients. GVHD prophylaxis consisted mainly of cyclosporine. The majority of the grafts were HLA identical.

The ICBTR reported a 91% engraftment rate at day 60 with median neutrophil recovery at 22 days in closely HLA-matched patients. Platelet recovery occurred at a median of 51 days. There was no statistical correlation between engraftment and cell dose. The EuroCord Registry noted an 83% probability of engraftment with neutrophil recovery occurring at a median of 26 days. This was associated with a cell dose of $\geq 3.7 \times 10^7$ /kg.

The ICBTR recorded a 3% rate of acute GVHD in patients with 0–1 HLA mismatch, followed by three cases of chronic GVHD. The EuroCord Registry reported acute grade II–IV GVHD in 20% of patients and chronic GVHD in 6%. Fifty percent of patients

Table 97.3 Pediatric related donor UCBT

	ICBTR ^{46,47}	EuroCord ^{48–50}
Cell Dose (TNC/kg)	4.7×10^7	4.0×10^7
Engraftment %: median days to neutrophil recovery	91% ^a 22	83% 26
Acute GVHD	3%	20%
TRM	NA	NA

^aObserved at 60 days.

^bObserved in patients with malignant diseases.

^cObserved in patients with nonmalignant diseases.

^dObserved at 1.6 years.

^eObserved at 1 year.

with any HLA disparity developed grade II–IV GVHD, while only 9% did so in HLA-identical transplants.

Initial reports from the ICBTR and EuroCord Registry noted relapse in 49 and 22% of patients with malignancies. The ICBTR reported a 46% event-free survival (EFS) for patients with a malignant disease compared to 78% for patients with a nonmalignant condition. The overall survival (OS) for all patients was 62%, with a median follow-up of 1.6 years. Those who were HLA matched or disparate at one loci had a higher OS of 72%. The EuroCord Registry reported an OS of 63% at 1 year. The 2-year OS varied with disease—46% in patients with malignancies, 76% with aplastic anemia, 79% with inborn errors of metabolism, and 100% with hemoglobinopathies. OS correlated with infusion of $\geq 3.7 (10^7$ TNC/kg, HLA identity (73% if HLA-identical and 33% with any HLA-disparity), age <6, weight <20 kg, and negative cytomegalovirus (CMV) serology.

In a multivariate analysis of data from the EuroCord Registry after related-donor HLA-matched UCBTs and SCTs, it was found that neutrophil and platelet recovery following UCBT were delayed as compared to that in SCT. Rates of acute and chronic GVHD were reduced following UCBT (RR 0.40 and 0.35, respectively). Survival was similar.⁵¹

PEDIATRIC UNRELATED-DONOR UCBT

Data regarding pediatric unrelated-donor UCBT, of which nearly two-thirds were in patients with malignant diseases, have been reported by at least four sources: Minnesota/Duke,^{46,52,53} New York Blood

Center (NYBC) (IBMTR)⁵⁴ EuroCord Registry,^{49,50,55} and Minnesota⁵⁶ (Table 97.4). The Minnesota/Duke group reported on 85 children with a median age of 5.6 years. The conditioning regimen varied, as did GVHD prophylaxis. Eleven percent were HLA identical, 35% were disparate at one locus, and the remaining grafts were mismatched at ≥ 2 loci. The NYBC registry (IBMTR) reported on 562 patients (460 of which were pediatric). Seven percent of the grafts were HLA identical, 39% were disparate at one locus, and 54% were mismatched at ≥ 2 loci. The EuroCord Registry reported on 291 patients with a median age of 5 years. The conditioning regimen varied according to disease. Seventeen percent were HLA identical with the remaining disparate at ≥ 1 loci. The Minnesota group reported on 102 patients (80 of which were pediatric). The median age was 7.4 years and the median weight was 25.9 kg. The conditioning regimen was mainly TBI/Cyclophosphamide(Cy). All patients received antithymocyte globulin (ATG). GVHD prophylaxis was largely cyclosporine and methylprednisolone. Fourteen percent were HLA identical, 43% were disparate at one locus, and the remaining grafts were mismatched at ≥ 2 loci.

The Minnesota/Duke group reported engraftment in 94% of the patients at a median of 24 days. Engraftment

correlated with a cell dose $\geq 3 \times 10^7$ /kg. The early use of granulocyte colony-stimulating factor and a conditioning regimen other than TBI also improved hematopoietic recovery. The IBMTR noted a median time to neutrophil recovery of 28 days. Ninety-one percent of the patients recovered their neutrophil counts by day 60. More rapid engraftment was associated with a greater number of UCB unit precryopreservation leukocytes and greater HLA identity. Platelet engraftment occurred in 58% of the patients by day 100 and 85% by day 180, with more rapid recovery in younger patients and those without infection or GVHD. The EuroCord Registry observed neutrophil recovery in 82% of the patients by day 60. The median time to recovery was 29 days. In a subgroup analysis, 79% of the patients with acute leukemia recovered neutrophil counts by 60 days. This correlated with a cell dose $\geq 3.7 \times 10^7$ /kg. The Minnesota group recorded an engraftment rate of 88% by day 42. The median time to neutrophil recovery was 23 days and correlated with a CD34⁺ cell dose $\geq 1.7 \times 10^5$ /kg. Platelet recovery occurred in 65% of the patients by six months, with a median time to recovery of 86 days. Platelet recovery was associated with younger age, higher CD34⁺ cell dose, and the lack of acute grade III–IV GVHD.

The Minnesota/Duke group noted acute grade II–IV GVHD in 40% of the patients and grade III–IV GVHD in 10%. No association between HLA disparity and acute GVHD was observed. The IBMTR, EuroCord Registry, and Minnesota group reported similar rates of acute grade II–IV GVHD. The IBMTR reported a trend ($p = 0.06$) toward significance of an association between acute GVHD and HLA disparity. The observed rates of chronic GVHD from these sources ranged from 9 to 25%.

The EuroCord Registry's subgroup analysis of patients with acute leukemia noted a 1-year TRM of 34% in those with good risk disease as compared to 65% in those with advanced disease. The Minnesota group reported 1- and 2-year TRM rates of 30 and 35%. By univariate analysis, a reduction in 1-year TRM to 20% was demonstrated if the CD34⁺ cell dose was $\geq 1.7 \times 10^5/\text{kg}$. Reduced TRM was also predicted by younger age, higher cell dose, and the absence of severe GVHD. By Cox regression analysis, CD34⁺ cell dose, development of severe GVHD, and age were the only factors predictive of TRM. The IBMTR noted relapse in 14% of the patients with leukemia. Higher rates were seen in patients with advanced disease and acute myeloid leukemia (AML). The EuroCord Registry reported relapse in 31% of the patients with good risk leukemia as compared to 77% in patients with poor risk disease. The Minnesota group observed a 37% cumulative incidence of relapse at 2 years. By Cox regression analysis, this was associated with age and malignancy risk group, but not cell dose, HLA match, or prior acute/chronic GVHD.

The IBMTR reported a 54% EFS at 100 days. By multivariate analysis, correlation was noted between EFS and cell dose, HLA identity, diagnosis (CML > Fanconi anemia > severe aplastic anemia), younger age, and the location of the transplantation center. The EuroCord Registry reported a 2-year EFS of 21% in patients with aplastic anemia, 36% with malignant diseases, and 51% with inborn errors of metabolism. Of the patients with acute leukemia, the 2-year EFS was 49% in good risk patients as compared to 8% in those with advanced disease. The Minnesota/Duke group reported a 40% OS at 2 years. The Minnesota group observed an OS of 58% at 1 year and 47% at 2 years. The OS increased to 70% at 1 year in patients receiving $\geq 1.7 \times 10^5$ CD34⁺ cells/kg. By univariate analysis, OS was associated with younger age, nonmalignant disease, higher cell dose, and the absence of severe GVHD. By Cox regression analysis, HLA match, CD34⁺ cell dose, and absence of severe GVHD predicted OS.

The EuroCord Registry completed a comparative analysis of pediatric unrelated UCBTs and unmanipulated or T-cell depleted SCTs in patients with acute leukemia.⁵⁷ The majority of UCBTs were HLA mismatched. The median cell dose for those undergoing

UCBT was $3.8 \times 10^7/\text{kg}$. Disease characteristics, conditioning regimens, and GVHD prophylaxis varied. A delay in neutrophil engraftment was noted in those undergoing UCBT (32 days as compared to 18 and 16 days in unmanipulated and T-cell depleted SCT, respectively). The rate of acute grade II–IV GVHD was reduced in UCBTs (35% as compared to 58 and 20%). A greater early TRM was observed in UCBTs (39%). Two-year EFS was improved in unmanipulated SCTs (43%), but was similar in T-cell depleted SCTs and UCBTs (37%, and 31%, respectively).

PEDIATRIC UNRELATED-DONOR UCBT FOR MALIGNANT DISEASES

The EuroCord Registry reported unrelated-donor UCBT data from 95 children (median age 4.8 years) with AML.⁵⁸ Eight percent were HLA identical, 46% were disparate at one locus, and 43% were mismatched at ≥ 2 loci. The median cell dose was $4.4 \times 10^7/\text{kg}$. The median time to neutrophil recovery was 26 days. By multivariate analysis, neutrophil recovery correlated with the status of disease at transplantation and the use of hematopoietic growth factor immediately post-UCBT. Acute GVHD was seen in 35% of patients and was not predicted by HLA disparity. Chronic GVHD was noted in 5 of 53 patients. The 100-day TRM was 20%. Relapse occurred in 26% of the patients and was associated with weight ≥ 21 kg and active disease at the time of transplantation. The 2-year EFS was 42% with an OS of 49%. Disease status and major ABO incompatibility predicted EFS and OS.

PEDIATRIC UCBT FOR NONMALIGNANT DISEASES

Data regarding pediatric UCBT for nonmalignant diseases are limited to abstract reports^{59–62} and publications by Locatelli et al.⁶³ and Staba et al.⁶⁴ Locatelli et al. reported on 44 patients, three-quarters of whom had a hemoglobinopathy/thalassemia and one-quarter had sickle cell disease (SCD). The UCB donor was related in all transplants. Ninety-three percent of the grafts were HLA identical. Neutrophil recovery at 60 days occurred in 89% of the patients. The median time to neutrophil recovery was 23 days. Platelet recovery was reported in 90% of the patients at a median of 39 days. Acute GVHD developed in 11% of the patients. The 2-year Kaplan-Meier estimate of EFS was 79% for patients with thalassemia and 90% for those with SCD. OS was 100%.

Staba et al. reported on 20 consecutive patients with Hurler's syndrome. All UCB donors were unrelated. The median age was 11 months. One patient was HLA identical, 11 were disparate at one locus, and the remaining grafts were mismatched at ≥ 2 loci. The conditioning regimen was Busulfan(Bu)/Cy/ATG. GVHD prophylaxis consisted of cyclosporine and methylprednisolone. The mean cell dose was $8.34 \times 10^7/\text{kg}$

and the mean number of CD34⁺ cells infused was 2.51×10^5 /kg. The median time to neutrophil recovery was 24 days. Twenty-five percent of patients developed acute grade II–IV GVHD. Two patients developed chronic GVHD. The EFS at a median of 905 days was 85%.

ADULT UNRELATED-DONOR UCBT

Adult unrelated-donor UCBT has been performed predominantly in relapsed hematological malignancies, with the exception of a small series of patients with de novo AML.⁶⁵ The adult UCBT data are less mature than those of the pediatric population, yet reasonable rates of engraftment have been observed. Unfortunately, high TRM rates and marginal survival limit this treatment option to a select group of adult patients. The data have been reported in abstract form^{66–68} and from the following sources: EuroCord,^{50,69} Laughlin et al.,⁷⁰ Sanz et al.,⁷¹ and Duke^{72,73} (Table 97.5). The EuroCord Registry reported on 108 patients with a median age of 26 years and a median weight of 60 kg. GVHD prophylaxis was predominantly cyclosporine and corticosteroids. 6% of the grafts were HLA identical, 35% were disparate at one locus, and 59% were mismatched at ≥ 2 loci. Laughlin et al. reported on 68 patients with a median age of 31.4 years and a median weight of 69.2 kg. The conditioning regimen was largely TBI

based/ATG. GVHD prophylaxis was cyclosporine alone or cyclosporine and methylprednisolone. Two grafts were HLA identical, 26% were disparate at one locus, and 71% were mismatched at ≥ 2 loci. Sanz et al. reported on 22 patients with a median age of 29 years and a median weight of 69.5 kg. The conditioning regimen consisted of Bu/Cy/ATG/thiotepa. GVHD prophylaxis was cyclosporine and prednisone. One graft was HLA identical, 13 were disparate at one locus, and 8 were mismatched at ≥ 2 loci. The Duke group reported on 57 patients with a median age of 31 years and a median weight of 70 kg. The conditioning regimen was TBI or Bu based plus ATG. GVHD prophylaxis was cyclosporine and methylprednisolone. Two grafts were HLA identical, eight were disparate at one locus, and the remaining grafts were mismatched at ≥ 2 loci.

The EuroCord Registry reported engraftment in 81% of the patients at 60 days. The median time to neutrophil recovery was 32 days and was associated with a cell dose $\geq 1.7 \times 10^7$ /kg. Laughlin et al. reported a 90% engraftment rate at 42 days. The median time to neutrophil recovery was 27 days, while the median times to platelet and RBC recovery were 58 and 60 days, respectively. The neutrophil recovery rate was more rapid if the TNC count before freezing was $\geq 1.87 \times 10^7$ /kg. Sanz et al. observed engraftment in all 20 patients who survived longer than 30 days. The

median time to neutrophil recovery was 22 days. The Duke group recorded a median time to neutrophil recovery of 26 days. No association was noted with cell dose. The median time to platelet recovery was 84 days and was predicted by a CD34⁺ cell dose $\geq 1.37 \times 10^5/\text{kg}$.

The EuroCord Registry documented acute GVHD in 38% of the patients and chronic GVHD in 26%. Laughlin et al. noted acute grade II–IV GVHD in 60% of the patients and grade III–IV GVHD in 20%. Sanz et al. reported similar rates. Long et al. noted grade II–IV GVHD in 30% of the patients and grade III–IV GVHD in 16%. Eight of 25 evaluable patients developed chronic GVHD.

The EuroCord Registry experienced a TRM of 56% at 180 days. This was improved with a cell dose $\geq 2.0 \times 10^7/\text{kg}$, greater HLA identity, inactive disease, and transplantation after 1998. Laughlin et al. noted a 100-day TRM of 50%, similar to that reported by Sanz et al. and Long et al. The EuroCord Registry noted a “low” rate of relapse, as did Laughlin et al. (4 of 54 patients with a malignancy). Sanz et al. did not report any relapses. The Duke group observed relapse in 7 of 25 patients who engrafted and survived longer than 100 days.

The EFS reported by the EuroCord Registry was 21% at 1 year. Laughlin et al. noted a 26% EFS at 22 months. This correlated with a CD34⁺ dose $\geq 1.2 \times 10^5/\text{kg}$. Long et al. recorded a 3-year EFS of 15%, improved with age ≤ 32 years. The EuroCord Registry reported an OS of 27% at 1 year. This was improved in patients with CML in chronic phase or acute leukemia in CR1/CR2. The cell dose was also important since

those patients who received $\leq 1 \times 10^7/\text{kg}$ had a 75% probability of death as compared to 30% if the dose was $\geq 3 \times 10^7/\text{kg}$. Laughlin et al. noted an OS of 28% at 22 months. Sanz et al. observed an 8-month OS of 55% (five patients had CML). Long et al. reported a 3-year OS of 19%.

CURRENT AND FUTURE DIRECTIONS

Delayed engraftment with prolonged neutropenia following UCBT may lead to life-threatening infections. Cell dose has been shown to be critical in predicting the rate of engraftment. Investigators have developed techniques to increase the number of UCB stem cells available for transplantation by ex vivo expansion, with the goal of shortening the period of neutropenia.^{74–77} These preclinical advances are yet to be translated into improved clinical outcomes. Preliminary results of multidonor, pooled UCB units have been reported in a small series of adult patients.⁷⁸ TRM is a major complication of allogeneic SCT. Toxicities of the conditioning regimens often limit allogeneic transplantation to younger patients with relatively few comorbidities. In efforts to expand this therapy to older and more frail patients, nonmyeloablative conditioning regimens have been developed. These regimens have been applied in small series of adult UCBTs.^{79–85} High rates of engraftment (cumulative incidence of 94% with median neutrophil recovery in 9.5 days), severe GVHD (9%), TRM (28%), and survival (EFS 31% and OS 39%) have been reported.⁷⁹

Chapter 98

GRAFT-VERSUS-HOST DISEASE: NEW PERSPECTIVES ON PATHOBIOLOGY AND THERAPY

Thomas R. Spitzer and Robert Sackstein

INTRODUCTION

The transplantation of healthy hematopoietic stem cells into a patient with aplastic anemia or leukemia is potentially curative therapy, but the development of graft-versus-host disease (GVHD)—which often occurs even when the donor and recipient are siblings fully matched at the HLA loci—significantly limits survival. The first descriptions of GVHD following allogeneic bone marrow transplant in humans were made in the 1960s. Significant strides in prophylaxis of GVHD have been made over the past four decades by the use of pharmacologic agents such as methotrexate and cyclosporine and by manipulation of the donor cell inoculum to limit the infusion of effector donor lymphocytes. However, given the extensive clinical observations and investigations on the nature of this complication, it is remarkable that the diagnosis of GVHD is still clinically challenging and that this complication continues to pose a formidable obstacle to successful allogeneic hematopoietic stem cell transplantation (HSCT). On the other hand, patients with GVHD have improved leukemia-free survival (the graft-versus-leukemia (GVL) effect) and this graft-versus-malignancy (GVM) effect, a beneficial by-product of the alloreactivity of the donor cells, may extend to lymphomas, myeloma, and even solid tumors.¹⁻⁴ Thus, a major question in HSCT biology is how to preserve a GVM effect while eliminating GVHD. This chapter will review some of the critical issues in the clinical manifestations and pathobiology of GVHD, including the results of recent investigations using an *in vitro* lymphocyte-skin adhesion assay to better define the mechanisms of GVHD. Advances during the past decade in the prevention and treatment of GVHD including recent evidence for a role of cellular modulation of GVHD will also be reviewed.

CLINICAL PRESENTATION AND PATHOBIOLOGY OF ACUTE GVHD

GVHD occurs in two forms, “acute” and “chronic,” defined separately by the timing of onset posttransplant and by differences in the clinical presentation and pathology of affected target organs. Acute GVHD, by classical definition, is GVHD that occurs within 100 days of HSCT, usually around the time of leukocyte engraftment or shortly thereafter. Though this operational term is useful in delineating GVHD occurring immediately posttransplant from the more indolent and progressive changes of chronic GVHD, it is important to note that acute GVHD can occur beyond 100 days posttransplant, particularly in the setting of donor lymphocyte infusions (DLI) used in the prevention or treatment of disease relapse. There are three principal target tissues affected in acute GVHD—the skin, liver, and gut. Although the clinical staging and the overall grading of acute GVHD is based on the relative level of involvement of these three tissues (Table 98.1), other organs, especially the lymphoid tissues and the bone marrow, are targets of the GVHD reaction.

The most common tissue affected in acute GVHD is the skin, with over 80% of patients with GVHD manifesting skin eruptions.⁵ The typical skin presentation consists of a maculopapular rash that can resemble a sunburn, initially involving the ears, neck, shoulders, upper chest and back, and the palms and soles of the extremities. The extent of skin surface involved and the presence of bullae or desquamation define the different stages of skin involvement. The clinical findings of cutaneous GVHD are corroborated by histologic analysis of skin biopsy material, and, therefore, discrete pathologic criteria contribute to the diagnosis of cutaneous GVHD (Table 98.1).⁶ However, the characteristic pathologic changes of acute cutaneous GVHD are not

Table 98.1 Histologic grading for acute cutaneous GVHD

Grade 0	Grade 1	Grade 2	Grade 3	Grade 4
Normal skin	Perivascular mononuclear cell infiltrates	Perivascular mononuclear cell infiltrates	Grade 2 changes plus epidermolysis and bulla formation (from fusion of basilar vacuoles)	Denudation of epidermis (separation of epidermis from dermis)
	Vacuolar degradation of epidermal–dermal junction	Vacuolar degradation		
		Dyskeratotic cells or eosinophilic bodies in the epidermis		

specific for GVHD alone and can occur in a variety of other cutaneous diseases and reactions. Many skin eruptions occur posttransplant in response to the preparative regimen, hypersensitivity to drugs (e.g., antibiotics), infections, and even the recovery of leukocytes, and, therefore, there is no “gold standard” for accurate pathologic diagnosis of GVHD.⁷ Moreover, there is no correlation between the numbers of infiltrating mononuclear cells or of dyskeratotic cells in skin specimens and the clinical outcome.⁷ The diagnosis of cutaneous GVHD is based on exclusion of other confounding contributors such as drugs and viral exanthems, and depends upon *clinicopathologic correlation*, i.e., clinical history and manifestations supported by characteristic pathologic changes. Indeed, the timing of the clinical manifestations is an important component of the diagnosis, as some pathologists will consider GVHD in the differential only if characteristic histopathologic changes occur during or after engraftment.

Involvement of the gut and liver in GVHD is usually accompanied by skin changes, but, rarely, these tissues can be involved separately or together without skin manifestations. The primary clinical manifestation of gut GVHD is diarrhea and abdominal pain. The diarrhea is initially watery in nature but, commonly, becomes bloody requiring transfusion support with platelets and red cells. The volume of diarrhea defines the different stages of gut involvement. Rectal biopsy is helpful in the diagnosis of gut GVHD, particularly when diarrhea occurs in the absence of cutaneous eruptions. The early finding of lymphocytic infiltrates at the crypts—accompanied by necrosis and dropout of crypt cells—is characteristic of the diagnosis, but, again, is not pathognomonic for GVHD. Like the skin, different pathologic stages are recognized culminating in mucosal denudation (grade 4), and the differential includes drug reactions and infection (particularly cytomegalovirus infection). Hepatic GVHD is manifested by a rise in the conjugated bilirubin, and the level of total bilirubin elevation defines the clinical stages of liver disease. Lymphocytic infiltrates in the interlobular and marginal bile ducts are characteristic

histopathologic findings, which lead to the clinically identifiable cholestatic picture.

As mentioned above, the timing of skin, gut, and liver changes is a critical component of the diagnosis of GVHD. Although a “hyperacute” form of GVHD can occur typically in HLA-mismatched donor—recipient pairs, manifested by fever and markedly accelerating skin changes with diarrhea and hyperbilirubinemia before engraftment, most acute GVHD will initially present about the time of engraftment or thereafter. Within the past several years, characteristic clinical findings of an “engraftment syndrome” have been described in recipients of both autologous and allogeneic stem cell transplants.^{8–10} This syndrome typically consists of noninfectious fever, a maculopapular skin eruption resembling GVHD, capillary leak with resultant weight gain and pulmonary infiltrates/effusions, and, not uncommonly, hyperbilirubinemia and diarrhea. The fact that these changes occur in autologous transplant recipients indicates that the pathophysiology of this entity does not depend on alloreactivity per se. Interestingly, the skin biopsy findings are consistent with GVHD.⁸ Treatment of this syndrome requires prompt administration of corticosteroids to prevent complications of capillary leak, including renal dysfunction and pulmonary failure.

The pathophysiology of the engraftment syndrome may overlap with that of acute GVHD. The common feature in these entities may be primary endothelial damage as a consequence of inflammatory mediators such as IL-2, TNF- α and IFN- γ , released locally by infiltrating perivascular lymphocytes.^{8,11–13} In GVHD, however, there is also evidence of direct cell-mediated immunologic reactivity resulting in microvascular injury.¹⁴ One effect of combining cyclosporin A and rapamycin is to modify the migration capabilities of lymphocytes, by altering lymphocyte and/or endothelial adhesive structures mediating lymphocyte recruitment from the vasculature and into the tissue. In this regard, corticosteroids, the first-line pharmacologic agents in the treatment of acute GVHD, also profoundly affect lymphocyte migration to lymphoid and

extra-lymphoid tissues,^{15,16} and decreased lymphocyte infiltrates in affected tissues are a prognostic sign for steroid-responsiveness in GVHD therapy.¹⁷

In Billingham's classic description of the elements required for the development of GVHD,¹⁸ three requirements were emphasized: (1) The host must be incapable of rejecting the graft; (2) The graft must contain immunocompetent cells; and (3) There must be incompatibilities in transplantation antigens between donor and host. Despite the fact that this description needs to be modified somewhat in light of evidence of GVHD occurring in the setting of blood transfusions, solid organ transplants, and in the case of cyclosporin-induced autologous GVHD (due to induction of autoreactive T cells¹⁹), Billingham's tenets reflect important basic principles in the biology of GVHD. However, given the data reviewed above and the pathologic evidence of lymphocytic infiltrates consistently accompanying GVHD-induced tissue injury, a fourth requirement to Billingham's criteria must be proposed: effector lymphocytes must migrate to the target tissues in GVHD.

The pathologic hallmark of acute GVHD is mononuclear cell infiltrates in the involved tissues.^{20,21} The pathogenesis of acute GVHD involves the migration of both alloreactive lymphocytes and of NK cells into target tissues.^{22–25} A central role for alloreactive T cells in the development of GVHD is indicated by the fact that T-cell depletion of donor marrow significantly abrogates the incidence of GVHD.²⁶ Indeed, the lymphocytic infiltrates of dermal GVHD are composed of donor-derived cells.²⁷ Infiltrating NK cells may contribute to tissue damage in GVHD by their local release of inflammatory cytokines such as TNF- α and IFN- γ .^{28,29} The NK cell infiltrates are also donor-derived,³⁰ indicating that their localization in tissues is likewise due to recruitment from the circulation.

PREVENTION OF GVHD

The central dilemma regarding the prevention of GVHD is how to preserve a potent GVM effect of the transplant while avoiding the deleterious aspects of clinical GVHD. Conventional strategies that have been attempted for the prevention of GVHD have focused on either pharmacologic intervention or ex vivo T-cell (or T-cell subset) depletion. More recently, manipulation of the host—donor cellular environment has been attempted in an effort to dissociate GVM from GVHD.

PHARMACOLOGIC STRATEGIES

The availability of cyclosporine-based pharmacoprophylaxis in the early to mid 1980s represented a major advance in the field of clinical HSCT. Prospective randomized trials evaluating the combination of cyclosporine and methotrexate compared with cyclosporine or methotrexate alone for leukemia

or severe aplastic anemia were conducted.^{31,32} Significant reductions in the incidence of acute GVHD were seen in both studies. In the case of transplantation for hematologic malignancy (acute myelogenous leukemia in first complete remission or chronic phase chronic myelogenous leukemia) an overall survival benefit was realized. However, for severe aplastic anemia a survival difference did not reach statistical significance. Pharmacologic GVHD prophylaxis alone has been shown to be considerably less effective in the prevention of GVHD following HLA-mismatched donor HSCT.^{33,34} For recipients of HLA-2 or -3 antigen mismatched non-T-cell-depleted transplants, acute GVHD incidence exceeds 70–80% and transplant-related mortality is very high.³³ Despite these limitations, cyclosporine-based pharmacoprophylactic strategies have had a major impact on the practice of clinical HSCT. The reduction in acute GVHD-related morbidity and mortality has allowed for the transplantation of considerably older patients and of patients without HLA genotypically identical sibling donors.

More recently, there have been several reported pharmacologic advances in the prevention of GVHD (Table 98.2). Triple drug immunoprophylaxis (cyclosporine, methotrexate, and corticosteroids) has been shown to be superior to cyclosporine and corticosteroids alone for the prevention of GVHD following HLA-matched donor HSCT for hematologic malignancies.³⁵ The lack of an overall survival benefit (perhaps due to an impairment of the GVM effect) and an increased infection risk associated with more intensive immunosuppressive regimens have underscored the limitations of this approach.

The introduction of tacrolimus has represented an advance in the management of GVHD. Two multicenter prospective randomized trials comparing tacrolimus and methotrexate with cyclosporine and methotrexate for GVHD prophylaxis following HSCT for hematologic malignancies have been conducted.^{36,37} In the first trial involving HLA genotypically identical sibling donors, a significant reduction in the incidence of GVHD in the tacrolimus-treated patients was observed.³⁶ The second trial involved patients receiving transplants from HLA-matched unrelated donors. Once again, GVHD incidence was reduced in the tacrolimus-treated group.³⁷ In both trials, however, no significant difference in overall survival between two treatment groups was observed. The toxicity profile of tacrolimus was somewhat different than that of cyclosporine. More neurotoxicity was observed with tacrolimus. However, there was less renal impairment and hypertension in tacrolimus-treated patients.

Newer agents are presently being evaluated for GVHD prophylaxis. Rapamycin, an mTOR inhibitor that has been shown to cause G1 cell cycle arrest, has been evaluated in several GVHD prophylaxis strategies.

Table 98.2 GVHD prophylaxis strategies

Pharmacologic	Result
Methotrexate	Limited GVHD protection
Methotrexate + CYA or corticosteroids	Improved prophylaxis compared with single-agent methotrexate; survival advantage in aplastic anemia
Methotrexate + tacrolimus	Superior prophylaxis compared with CYA/methotrexate but no survival advantage
Methotrexate + CYA + corticosteroids	Superior prophylaxis compared with CYA/methotrexate but no survival advantage
Tacrolimus + sirolimus +/- methotrexate	Promising GVHD protection in HLA-matched related and unrelated donor settings
CYA 1 MMF	Promising GVHD protection with less morbidity than with methotrexate combinations (mucositis, myelosuppression)
Ex vivo T-cell depletion	
Pan T-cell depletion	
Negative selection	Decreased GVHD but increased relapse rate, engraftment failure
Positive (CD34 ⁺ cell) selection	Decreased GVHD but increased relapse rate, engraftment failure. Possible protection from PTLD by B-cell depletion
Selective T-cell depletion	
CD8 ⁺ cell depletion (bone marrow)	Decreased GVHD, apparent preservation of GVL effect but increased engraftment failure

GVHD, graft-versus-host disease; CYA, cyclosporine; MMF, mycophenolate mofetil; GVL, graft-versus-leukemia.

In combination with tacrolimus and methotrexate, or tacrolimus alone, a very low incidence of acute GVHD has been reported following HLA-matched unrelated donor transplantation and HLA-matched related donor transplantation, respectively.^{38,39}

Mycophenolate mofetil (MMF) is a purine antagonist which in combination with cyclosporine has been effective in the prevention of GVHD in preclinical (canine) models⁴⁰ and in clinical trials following HLA-matched nonmyeloablative transplantation.⁴¹ Recently, the combination of MMF and tacrolimus was shown to have similar GVHD protective effects as cyclosporine and methotrexate following HLA-matched myeloablative stem cell transplantation.⁴² Mucositis was reportedly less frequent than with methotrexate-containing regimens and delayed engraftment was obviated.

EX VIVO T-CELL DEPLETION

A series of experimental and clinical observations have shown that GVHD can be effectively prevented by infusing less than $1-5 \times 10^5$ T cells/kg of recipient body weight.^{43,44} Early enthusiasm for the ex vivo removal of immunocompetent T cells from the marrow graft, however, was tempered by an increased risk of engraftment failure and relapse of the underlying malignancy.⁴⁵⁻⁴⁷ This increased relapse risk was somewhat disease-specific. In chronic myelogenous leukemia (CML), for example, an increase in relapse risk from approximately 10-20% following HLA-matched donor non-T-cell-depleted transplantation to 60-80% following T-cell-depleted transplantation was observed.⁴⁷ In acute myelogenous leukemia (AML) in first remission, on

the other hand, an effect of T-cell depletion on probability of relapse was not apparent.⁴⁸

Given the limitations of ex vivo T-cell depletion, this strategy has not reached widespread acceptance for the prevention of GVHD following HLA genotypically identical donor HSCT for hematologic malignancies, particularly CML. However, given the more profound impact of GVHD on mortality risk following HLA nongenotypically identical donor transplants, T-cell-depletion strategies are being reevaluated.

In an effort to diminish the problems of engraftment failure and relapse following ex vivo T-cell depletion, recent investigations have focused on the depletion of selective T-cell subsets. Ex vivo depletion of CD8⁺ T cells has been shown to result in an apparent reduction of GVHD with no increase in relapse probability following HLA-matched sibling donor HSCT for CML.⁴⁹ An increased risk of engraftment failure, however, has further demonstrated the importance of T cells in overcoming host alloresistance to engraftment.

Recently, adoptive cellular immunotherapy via DLI has been increasingly utilized for its capacity to enhance GVH alloreactivity and to impart a potent GVM effect.^{50,51} In CML, for example, a cytogenetic and molecular remission is achieved with DLI for the treatment of relapse following allogeneic HSCT in the majority of cases, demonstrating that a potent antitumor effect, with at least a several log tumor cell cytoreduction, is achievable.⁵⁰⁻⁵³ In a nonrandomized comparison of non-T-cell-depleted transplants and CD6⁺ T-cell-depleted transplants for CML (followed by DLI at time of relapse), similar survival probabilities were realized.⁵⁴ Not surprisingly an increased probability of

relapse occurred in the T-cell-depleted transplant recipients, but the majority of these patients achieved a second remission with DLI, which in most cases appeared to be durable. This suggests that for at least selected patients who are at high risk for transplant-related morbidity or mortality an *ex vivo* T-cell-depleted HSCT followed by DLI for posttransplant relapse may be a rational treatment strategy.

Given the potent antitumor potential of DLI and experimental evidence suggesting that delayed DLI may be associated with a substantially lower risk of GVHD than with early T-cell infusion(s), clinical trials evaluating *ex vivo* T-cell-depleted bone marrow or peripheral blood progenitor cell (PBPC) transplants followed by delayed T-cell infusions have been conducted.^{55–57} Preliminary results suggest that this strategy is feasible and that delayed DLI can be performed without a prohibitive risk of GVHD.⁵⁶ The optimal dosing and timing of delayed T-cell infusion(s) remain to be determined.

CELLULAR MODULATION OF GVHD AND THE SEPARATION OF GVHD FROM GVM

Experimental and clinical experience have suggested that host cells surviving the transplant conditioning regimen may be instrumental in the regulation of GVHD.^{58–61} The availability of sensitive methods for detecting the presence of residual host cells (e.g., microsatellite analyses evaluating variable number of tandem repeat sequences) has demonstrated that at least a transient presence of host cells in many patients can be seen following HSCT.^{62,63} An increased incidence of acute GVHD with increasing intensity of the preparative regimen, possibly because of the increased cytokine release and damage to host elements following these aggressive preparative regimens, has been observed.⁶⁴ A relationship between the presence of mixed lymphohematopoietic chimerism and a reduced incidence of acute GVHD has also been seen in some series.^{65–67}

In several animal models the intentional induction of mixed lymphohematopoietic chimerism has been associated with a reduction in the incidence of GVHD.^{40,60,68,69} These mixed chimeric states are achievable following either myeloablative preparative regimens in which a combination of mixed T-cell-depleted syngeneic and T-cell-depleted allogeneic marrow is transplanted (“mixed” marrow transplantation) or following nonablative preparative regimens with peri-transplant *in vivo* anti-T-cell therapy.^{58,68,70,71}

Clinical trials at the Massachusetts General Hospital have been conducted utilizing similar nonmyeloablative preparative regimens for the induction of mixed chimerism followed by DLI in patients with advanced hematologic malignancies.^{72–74} Mixed chimerism has been reliably achieved with regimens consisting of

cyclophosphamide, anti-T-cell antibody therapy, and thymic irradiation. Sustained remissions of chemorefractory lymphoproliferative malignancies have been observed in a number of patients who achieved mixed chimerism followed by either spontaneous conversion to full donor hematopoiesis or DLI, which resulted in chimerism conversion. In several cases this chimerism conversion following DLI was not accompanied by significant clinical GVHD, providing proof of principal that GVHD is separable from GVM in mixed chimeras given delayed DLI. Sustained mixed lymphohematopoietic chimerism was also shown to be achievable following haploidentical stem cell transplantation.⁷² An increased risk of GVHD in recipients of haploidentical transplants has, however, prompted a revision of the strategy in an effort to induce a GVH free state of mixed chimerism as a platform for DLI. A combination of vigorous *in vivo* T-cell depletion with an anti-CD2 monoclonal antibody and *ex vivo* T-cell depletion (using a CD34⁺ cell selection device) has resulted in the uniform induction of mixed chimerism following haploidentical stem cell transplantation with minimal or no GVHD. The conversion of chimerism, in some cases following delayed DLI, and in some cases with minimal or no GVHD, has provided further evidence that GVHD and GVM are separable, even in the haploidentical transplant setting.

Other cellular modulatory approaches to separate clinical GVHD from GVM have included the administration of exogenous cytokines posttransplant to dissociate T-cell subset effector function^{75–77} (Table 98.3). Early clinical trials have not substantiated a benefit of high-dose IL-2 posthaploidentical stem cell transplantation.⁷⁸ However, the optimal timing and dosing of IL-2 may not have been achievable clinically.

Table 98.3 Separation of GVHD from GVT

Method	Mechanism
Induction of mixed lymphohematopoietic chimerism, delayed DLI	<ul style="list-style-type: none"> ■ Initial bidirectional tolerance ■ Resolution of pro-inflammatory cytokine milieu prior to DLI ■ Confinement of the GVL alloresponse to the lymphohematopoietic space
<i>Ex vivo</i> T-cell subset (CD8 ⁺ cell) depletion	GVHD protection from CD8 ⁺ cell removal, preservation of GVT effect from CD4 ⁺ cells, other effector cell populations
Enrichment for CD4 ⁺ , CD25 ⁺ cells	Inhibition of GVHD by T-regulatory cells
ATG/TLI conditioning	Increase of regulatory natural killer T cells
Depletion of L-selectin ⁺ T cells	Inhibition of The capacity of T cells to home to lymph nodes

DLI, donor lymphocyte infusion; GVL, graft-versus-leukemia; GVHD, graft-versus-host disease.

Manipulation of the cellular environment of the graft may also contribute to a separation of GVHD and GVM. As discussed above, CD8⁺ T-cell-depleted marrow grafts may be associated with less GVHD and preservation of potent GVL effect,⁴⁹ and CD8⁺ T-cell-depleted DLI have been shown to induce remissions in patients with hematologic malignancies in relapse after allogeneic stem cell transplantation, with less GVHD than occurs with unmanipulated DLI (with comparable numbers of CD4⁺ cells).⁷⁹

On the basis of preclinical murine models showing that NK1.1⁺ TCR αβ⁺ cells have non-major histocompatibility complex (MHC)-restricted natural suppressor activity and the percentage of these cells can be increased by the administration of total lymphoid irradiation (TLI) and antithymocyte globulin (ATG), clinical trials utilizing TLI/ATG have been initiated by Strober and colleagues in an effort to suppress GVHD and preserve a GVL effect.⁸⁰ A comparable human CD8⁺ NK⁺ cell population of natural suppressor cells has been shown to be increased in percentage following TLI/ATG conditioning. Impressive GVHD protection and disease-free survival probabilities have been demonstrated in early clinical trials of reduced-intensity of transplantation for advanced hematologic malignancies.⁸¹

Given the complexity of the cellular and cytokine interactions that affect the incidence and severity of GVHD, an only preliminary understanding of how the host—donor cellular environment might be manipulated to prevent GVHD exists. Which host or donor regulatory cells are important in the suppression of GVHD, for example, remain to be determined. Several cell populations including the NK1.1⁺ murine cell population and the CD4⁺ CD25⁺ cell subset and lymphokine-activated killer cells exhibiting both veto and natural suppressor activity have been postulated as having a regulatory role in the suppression of the GVH reaction.^{82,83} Given the compelling experimental and clinical evidence for a protective effect of cytokines and regulatory cell populations, future efforts should be made to define the mechanism of these effects and hopefully optimize their clinical benefits.

TREATMENT OF GVHD

ACUTE GVHD

The treatment of acute GVHD, particularly severe (grade III–IV) GVHD, remains inadequate. Corticosteroids are the mainstay of therapy for acute GVHD, particularly if they are not utilized as prophylaxis.^{84,85} Several studies have established the response rates for treatment of GVHD with corticosteroids.^{86,87} The highest response rates have been demonstrated in cutaneous GVHD (>60%). Sustained response rates of only 20–40% have been seen for visceral (gut and liver) GVHD. Long-term survival has been correlated with the grade of GVHD and response to medical therapy. Patients with grade

III or IV GVHD who do not achieve a complete remission of their GVHD with medical therapy have a less than 50% probability of long-term survival; mortality rates in excess of 90% have been reported for grade IV GVHD.⁵ Most patients who receive corticosteroids for grades II–IV GVHD require long-term corticosteroid administration. Substantial morbidity which usually accompanies long-term corticosteroid administration includes heightened infection risk, hypertension, diabetes mellitus, osteoporosis and aseptic necrosis of the hip and other bones, and proximal myopathy.⁸⁵

Given the substantial morbidity with intensive corticosteroid therapy of acute GVHD, attempts have been made to both improve the response rate of treatment and to provide a steroid sparing effect by adding additional immunosuppressive therapy (Table 98.4). In a randomized trial comparing prednisone with equine antithymocyte globulin and prednisone for the initial treatment for acute grades II–IV GVHD, response rates were the same.⁸⁸ There were more infectious complications in the combined therapy group. No difference in survival was observed between the two groups at day 100 and after 6 months and 2 years. In a comparison of upfront methylprednisolone versus methylprednisolone/daclizumab (an anti-IL-2 receptor monoclonal antibody) for acute GVHD, response rates were also similar.⁸⁹ Significantly worse 100-day and 1-year survival for the combined therapy group led to early closure of the trial. The increased mortality in the

Table 98.4 Treatment strategies for GVHD

Acute GVHD	Chronic GVHD
Pharmacologic immunosuppression	Pharmacologic immunosuppression
Corticosteroids	Corticosteroids
Cyclosporine	Cyclosporine
Tacrolimus	Tacrolimus
Sirolimus	Sirolimus
Mycophenolate mofetil	Azathioprine
	Mycophenolate mofetil
Antibody Therapy	Thalidomide
Polyclonal	Clofazimine
Antithymocyte globulin (equine, rabbit)	
Monoclonal	T-cell modulation
Anti-T-cell (anti-CD3, CD2, ect)	Extracorporeal photophoresis
Daclizumab (anti-IL-2 receptor)	
Infliximab (anti-TNF- α)	
Alemtuzumab (anti-CD52 ⁺)	
Other biologic therapy	
Denileukin diftitox	
Gene therapy	
Thymidine kinase suicide gene transduction/ganciclovir	

GVHD, graft-versus-host disease.

combination group was attributed to both relapse and GVHD-related mortality, possibly as a result of a negative impact on regulatory (CD4⁺CD25⁺) cells due to daclizumab.

Thus, corticosteroids alone (or in combination with a calcineurin inhibitor which is often still being administered at the onset of GVHD) remain the initial treatment of choice for grades II–IV GVHD. For patients who do not respond to methylprednisolone (or an equivalent corticosteroid) at a dose of 2 mg/kg/day, several possible strategies exist. Increasing the steroid dose to 5 mg/kg or higher has been evaluated in previous noncontrolled situations.⁹⁰ While a dose—response relationship may exist for corticosteroids, higher doses (particularly those of 10 mg/kg/day or greater) are associated with increased steroid-related complications and transplant-related mortality. Equine or rabbit antithymocyte globulin has been used most frequently as second-line therapy. While transient responses are common, particularly in cutaneous GVHD, the mortality rate in patients requiring ATG for steroid refractory acute GVHD is very high (approximately 90%) owing primarily to opportunistic infections.^{87,91} Several other therapies, on the basis of their targeting of cytokines and/or effector cell populations, have been evaluated in steroid refractory GVHD. Favorable response rates have been seen with monoclonal antibodies targeting tumor necrosis factor- α (infliximab)⁹² and the IL-2 receptor (daclizumab and basiliximab).^{93,94} A fusion protein consisting of IL-2 and diphtheria toxin has shown promising activity in steroid refractory GVHD.⁹⁵ The transient nature of the responses is not surprising given the complex, multifactorial mechanisms of GVHD. The cumulative immunosuppressive effect of corticosteroids and other immunosuppressive agents to which these potent highly specific immunosuppressive agents are added is also not surprisingly notable for a very high risk of infectious complications. In an experience from the MD Anderson Cancer Center with infliximab for steroid refractory GVHD an overall response rate of 65% was seen, with most of the patients (62%) achieving a complete remission. Fungal, bacterial, and viral infections were seen in 46, 69, and 57% of the patients, respectively. Estimated overall survival probability from the time of the transplant was only 31%.⁹¹

In an effort to more specifically target effector T cells while avoiding the more broad immunosuppressive effects of pharmacologic immunosuppressive therapy, gene therapy approaches have been evaluated for the treatment of acute GVHD. T cells transduced with a herpes viral thymidine kinase gene have been evaluated in preclinical transplant models and in preliminary clinical trials with ganciclovir administered in the event of GVHD, resulting in death of the effector T cells and in some instances, reversal of the GVHD.⁹⁶ Improving the efficiency of gene transduction and

preservation of the cells that mediate a GVM effect remain important future goals of this strategy.

CHRONIC GVHD

The treatment of chronic GVHD has also been problematic with long-term immunosuppressive therapy required for many patients with symptomatic disease. With the routine use of PBPC, and the transplantation of older patients, the problem of extensive chronic GVHD has increased.^{97,98} Treatment strategies must weigh the need to ameliorate the clinical manifestations of chronic GVHD against the risks of long-term (often lifetime) administration of immunosuppressive medications (including but not limited to infection, osteonecrosis, and secondary malignancy). Some recent series have focused on local control of chronic GVHD manifestations, such as oral cyclosporine rinses or ophthalmic cyclosporine solution for xerostomia and xerophthalmia, respectively.^{99,100} Extracorporeal photopheresis has been shown to be an effective salvage strategy for patients with steroid refractory GVHD.¹⁰¹ The cumulative morbidity of immunosuppressive therapy can hopefully be lessened with this approach. Long-term venous access issues can be problematic given the heightened infection risk of patients with chronic GVHD.

The optimal therapy for extensive chronic GVHD remains uncertain. An alternate-day corticosteroid and cyclosporine regimen has been shown to be effective in the management of chronic GVHD with an acceptable toxicity profile.¹⁰² Corticosteroids as a single agent have been shown to be superior to combined corticosteroids and azathioprine for chronic GVHD.¹⁰³ For their steroid sparing effect, however, combination regimens are often employed in the treatment of chronic GVHD. Newer agents with substantial activity in chronic GVHD include MMF¹⁰⁴ and sirolimus¹⁰⁵ (Table 98.4). Thalidomide has demonstrated some activity in steroid refractory chronic GVHD.¹⁰⁶ Clofazimine has been shown to have efficacy in the treatment of the connective tissue variant of chronic GVHD.¹⁰⁷ Ursodiol may ameliorate the clinical manifestations of hepatic GVHD.¹⁰⁸ Other vitally important supportive care aspects of the management of chronic GVHD include immunoglobulin repletion for patients with severe hypogammaglobulinemia, antimicrobial prophylaxis (e.g., penicillin for *Streptococcus pneumoniae*, co-trimoxazole for pneumocystis carinii pneumonia (PCP) prophylaxis), physical therapy to prevent joint contractures, and frequent dental and ophthalmological evaluations to address dental hygiene and to evaluate for and treat corneal ulceration, and ocular infections, respectively.

SUMMARY

Though significant strides in the prevention and therapy of GVHD have been made over the last two decades,

a greater understanding of the molecular immunology of this complication is still needed in order to develop more effective therapies to eliminate GVH while maintaining beneficial alloreactivity against malignancy. Though there may not be a single therapeutic approach that will achieve this aim, the considerable experimental and clinical evidence indicates that modulation of

tissue-specific homing, in combination with lower toxicity preparative regimens and selective enrichment or depletion of effector T cells, will yield novel and effective alternatives to minimize the risk of GVHD. These approaches, combined with judicious application(s) of immunopharmacologic agents, may prove sufficient to achieve the full curative promise of allogeneic HSCT.

Chapter 99

INFECTIOUS COMPLICATIONS FOLLOWING STEM CELL TRANSPLANTATION

David L. Longworth

INTRODUCTION

Hematopoietic stem cell transplantation (HSCT) has been increasingly used in the treatment of malignant and nonmalignant hematologic disorders, autoimmune diseases, and genetic and metabolic diseases. More than 50,000 HSCTs are performed annually worldwide.¹ Despite significant advances in defining optimal immunosuppressive regimens, in shortening the duration of neutropenia through the availability of hematopoietic growth factors, and in preventing and managing infectious and noninfectious complications, HSCTs continue to be associated with significant morbidity and mortality. Infectious and noninfectious complications such as graft-versus-host-disease (GVHD), adult respiratory distress syndrome (ARDS), and venoocclusive disease (VOD) are the major contributors to adverse outcome.

This chapter focuses on the recognition, management, and prevention of infectious complications following autologous and allogeneic HSCT. Guidelines focusing on infection prevention were recently published by the Centers for Disease Control and Prevention,² and include general and infection-specific strategies, as well as recommendations regarding infection control. The latter is beyond the scope of this discussion and the reader is referred to the guidelines as well as to a recent excellent review regarding infection control management in HSCT.³

A thorough pretransplant infectious disease evaluation is essential in HSCT candidates. Specific infectious complications following HSCT are predictable and can be anticipated based upon the sequential suppression of the various components of host defense associated with the conditioning regimen and subsequent HSCT.⁴ The clinical syndromes that most commonly occur and the pathogens involved vary over time. For purposes of differential diagnosis in the HSCT recipient with suspected infection, three distinct periods of

infection risk exist, each with unique deficiencies in host immune function.⁵ These include the preengraftment period (from the initiation of the conditioning regimen to engraftment), the early engraftment period (from engraftment to day 100), and the late engraftment period in allogeneic HSCT recipients (from day 100 until cessation of immunosuppressive medications). This chapter reviews the appropriate pretransplant infectious disease evaluation; the immune defects and associated infectious complications during the preengraftment, early engraftment, and late engraftment periods; and the prevention, diagnosis, and management of selected syndromes and pathogens encountered in HSCT recipients.

PRETRANSPLANT EVALUATION

A careful pretransplant infectious disease history should be obtained in all HSCT candidates (Table 99.1). This should include a history of prior bacterial, mycobacterial, and opportunistic infections, especially invasive fungal infections produced by *Aspergillus* or *Candida* species. In those with prior invasive fungal disease, a careful clinical and radiographic evaluation should be performed to exclude residual active disease, which would require aggressive treatment prior to HSCT. Antimicrobial susceptibility profiles of recent bacterial pathogens should be noted, as patients may remain colonized with these organisms. Patients with a prior history of tuberculosis, exposure to tuberculosis, or positive skin test for tuberculosis should be evaluated clinically and with chest radiograph for evidence of active disease. A travel history should be obtained to identify potential exposure, even in the remote past, to *Strongyloides stercoralis*, which may reactivate in the face of immunosuppression. Patients with potential exposure or unexplained peripheral eosinophilia should be screened pretransplant for

Table 99.1 Components of a pre-HSCT infectious diseases evaluation

- Complete infectious disease history, including prior infections, antimicrobial susceptibility profiles, and their management
- In those with prior invasive fungal infection or nocardiosis, clinical evaluation and imaging studies to assess disease activity
- Travel and immunization history
Selected screening for *Strongyloides stercoralis* and *Trypanosoma cruzi* in those at risk
- Evaluation for TB exposure, clinical, and radiographic evaluation in those at-risk
- Dental evaluation
- Serologic testing for CMV, HSV, VZV, EBV, hepatitis A,B,C, HIV 1 and 2, *Toxoplasma gondii*, *Treponema pallidum*

S. stercoralis with an enzyme-linked immunosorbent assay, which has a sensitivity exceeding 90% in detecting latent asymptomatic infection. Seropositive individuals should receive ivermectin prior to HSCT. Individuals who were born or have resided in areas of South America, Central America, or Mexico where Chagas disease is endemic, or who have received a blood transfusion while visiting those areas, should be screened for *Trypanosoma cruzi* IgG using at least two serologic tests.² Serologic testing should also be performed to identify prior exposure to cytomegalovirus (CMV), varicella zoster virus (VZV), herpes simplex virus (HSV), human immunodeficiency virus 1 and 2 (HIV), hepatitis A, B and C, Epstein—Barr Virus (EBV), *Toxoplasma gondii*, and *Treponema pallidum*. CMV-seronegative HSCT recipients are at-risk for acquiring CMV from seropositive donors or blood products. CMV-seronegative candidates for allogeneic HSCT with a CMV-seronegative donor should receive only CMV-seronegative or leukocyte-reduced red cells and platelets.²

A formal dental evaluation should be performed in all HSCT candidates and, if necessary, restorative work completed prior to transplant so as to minimize the occurrence of infection from oral mucositis associated with the conditioning regimen. This is especially important given the emergence of viridans streptococci as important pathogens in the early transplant period.⁶

THE PREENGRAFTMENT PERIOD

The preengraftment period commences with the initiation of the preparative regimen and ends at the time of engraftment. This usually occurs by about day 20 in autologous HSCT recipients and by day 30 in allogeneic HSCT recipients, but may vary depending upon the conditioning regimen and the underlying disease. The presence of indwelling intravascular devices,

mucositis of the mouth and gastrointestinal tract, neutropenia, and lymphopenia are the major defects in host defense that occur during the preengraftment period. These are present in both autologous and allogeneic HSCT recipients, and thus the types of infectious complications seen in these respective groups are similar; however, the shorter duration of neutropenia in autologous HSCT recipients is responsible for a lower incidence of infectious complications in these individuals.

MICROBIOLOGY

Table 99.2 summarizes the common pathogens encountered during the preengraftment period. The most common portals of entry for bacterial infection during this period include central venous catheters and mucositis of the mouth and gut arising from the preparative regimen. Thus, not surprisingly, bacterial pathogens such as viridans streptococci and Gram-negative bacilli from the mouth and gastrointestinal tract, respectively, and skin organisms such as coagulase negative staphylococci are the most common bacterial pathogens encountered in the preengraftment period. Up to 12% of infections occur prior to transplant.⁴ Although Gram-negative infections were common during the 1980s, the use of prophylactic oral antibiotics such as fluoroquinolones and trimethoprim-sulfamethoxazole at the onset of neutropenia has led to a shift in the spectrum of bacterial pathogens seen in the preengraftment period. Gram-positive organisms now account for a majority of bacterial infections and for 50% of bacteremias.^{7,8} Coagulase negative staphylococci

Table 99.2 Common pathogens encountered during the preengraftment period

Pathogen	Site of origin/involvement
Bacteria	
<i>Staphylococci</i>	Skin, intravascular devices
<i>Streptococci</i>	Mouth, GI tract
Gram-negative bacilli	GI tract
<i>Clostridium difficile</i>	Colon
Viruses	
Herpes simplex 1	Mouth, esophagus
Herpes simplex 2	Genitals, anus, skin
Community respiratory viruses	Upper respiratory tract, pneumonia
Fungi	
<i>Candida</i> species	Originate from gut May involve bloodstream, mouth, esophagus, skin, intravascular devices; rarely viscera or bone marrow
<i>Aspergillus</i> species	Pneumonia, sinusitis; rarely CNS and skin

and viridans streptococci have emerged as dominant pathogens, and the latter have been associated with a shock syndrome.⁹ Penicillin resistance is an emerging problem in viridans streptococci.¹⁰ Gram-negative infections are the second most common cause of bacterial infections in the preengraftment period, and now include less common and more often multiresistant organisms such as *Enterobacter*, *Acinetobacter*, *Klebsiella*, *Citrobacter* and *Stenotrophomonas* species. Vancomycin-resistant enterococci and *Clostridium difficile* are important emerging pathogens, although diarrhea following HSCT is infectious in fewer than 15% of cases.^{11,12}

HSV and community-acquired respiratory viruses (CRV) are the most common viral pathogens encountered in the preengraftment period. Autologous and allogeneic HSCT recipients appear to be at similar risk for these viral infections. HSV infections are almost always attributable to reactivation of latent asymptomatic infection in seropositive individuals. In the absence of prophylaxis, 70–80% of seropositive individuals will reactivate HSV in the preengraftment period, with a peak incidence at 2–3 weeks posttransplant. HSV type 1 (HSV 1) accounts for 85% of episodes and produces gingivostomatitis⁴; infection in the mouth may spread to the trachea, esophagus or lungs. In the initial posttransplant period, up to half of mouth lesions may be attributable to HSV 1.⁴ The remaining 15% of HSV reactivation episodes are due to HSV type 2 involving the genitals or other cutaneous sites.

Reactivation of other human herpes viruses (HHV) in the early posttransplant period, including HHV-6 and HHV-8, has been associated with the development of clinical symptoms. HHV-6 may reactivate in seropositive recipients of both autologous and allogeneic HSCTs, on average at 2–4 weeks posttransplant.^{13,14} An anti-CD3 monoclonal antibody for prophylaxis against acute GVHD in allogeneic HSCT recipients appears to increase the risk of HHV-6 reactivation, which has been associated with the development of fever, rash, interstitial pneumonia, encephalitis, delayed white cell engraftment, and an increase in the severity of GVHD.^{14,15} HHV-8 reactivation was recently reported to cause fever, rash, and hepatitis 2–3 weeks following autologous HSCT.¹⁶ The pathogenetic significance of HHV-7 reactivation has been debated; HHV-7 may serve as a cofactor for the development of CMV disease following organ transplantation.¹⁷

CRV infections may develop in both autologous and allogeneic HSCT recipients and tend to mirror the seasonal occurrence of influenza, parainfluenza, respiratory syncytial virus (RSV), and rhinovirus infections in the community. Outbreaks of RSV and influenza have been described on stem cell transplant units.^{18,19} Prevention of infection and containment of outbreaks require meticulous attention to infection control practices, cohorting of infected individuals, immunization

against influenza of health care workers and at-risk HSCT candidates pretransplant, and influenza prophylaxis on HSCT units during outbreaks.^{2,19} Influenza, parainfluenza, and RSV may produce lower respiratory tract infection in the early posttransplant period with significant morbidity and mortality^{20,21}; tracheobronchitis and pneumonia are usually heralded by the onset of upper respiratory tract symptoms, such as rhinorrhea, sinus congestion, and sore throat. Lymphopenia appears to be a risk factor for progression to lower respiratory tract infection in HSCT recipients with influenza.²¹ Other pathogens, such as *Aspergillus* species, are frequently isolated in patients with influenza involving the lower respiratory tract. Antiviral therapy in HSCT recipients with influenza with a neuraminidase inhibitor is preferred to amantadine or rimantidine, as neuraminidase inhibitors appear to shorten the duration of viral shedding.²¹ Inhaled ribavirin and intravenous immunoglobulin have been advocated for those with RSV. The optimal therapy for a parainfluenza lower respiratory tract infection has not been defined; in a recent study involving allogeneic and autologous HSCT recipients with parainfluenza pneumonia, inhaled ribavirin with or without immunoglobulin did not improve survival.²² Adenovirus infections occur in up to 6% of pediatric HSCT recipients, often following engraftment, but occasionally in the preengraftment period.²³ Hemorrhagic cystitis, hemorrhagic colitis, pneumonia, nephritis, and hepatic failure are the most common presentations; disseminated disease has been reported.

Invasive fungal infections due to molds and *Candida* species are important clinical problems in the preengraftment period. Autologous HSCT recipients have a lower incidence of these infections compared with those receiving allogeneic transplants. Prior to 1990, *Candida albicans*, *C. tropicalis*, and *C. parapsilosis* were the most common causes of invasive fungal infections in this setting. However, the demonstration in the early 1990s of the utility of fluconazole prophylaxis in reducing the incidence of superficial and invasive fungal infections in HSCT recipients and its subsequent widespread use^{24,25} has led to a decline in the incidence of infections from these organisms. Fluconazole prophylaxis in HSCT recipients has also led to the emergence of the fluconazole-resistant yeasts *C. krusei* and *C. glabrata* as important pathogens in the preengraftment period, and to the emergence of aspergillosis as the most common invasive fungal infection following HSCT.

Candidal infections can present in the preengraftment period as superficial cutaneous infection, thrush, esophagitis, urinary tract infections, fungemia, or as disseminated infection involving the skin, viscera, and bone marrow. Although infection most often arises from organisms that colonize mucosal surfaces, infection of intravascular devices or contamination of infusates such as total parenteral nutrition (TPN) fluid

are occasional causes of candidal bloodstream infections. Risk factors for invasive candidal infections include prolonged and severe neutropenia, breakdown of mucosal barriers, and the use of broad spectrum antibiotics, corticosteroids, and TPN.²⁶

Invasive molds are a growing cause of morbidity and mortality in the preengraftment period, especially in allogeneic HSCT recipients.²⁷ Invasive aspergillosis following HSCT occurs in a bimodal distribution, with peak onsets at 16 days and 96 days following HSCT.²⁷ While the overall incidence of invasive aspergillosis is higher in allogeneic HSCT recipients, early onset disease is more common in autologous HSCT recipients.²⁷ Risk factors for early onset disease occurring within 40 days of HSCT include transplantation for hematologic malignancy without first remission, HLA-mismatched related donor, HSCT outside a laminar airflow room, and HSCT during summer months.²⁷ Pneumonia, often with cavitation, is the most common clinical syndrome; invasive aspergillosis can also involve the sinuses, brain, and skin. Other emerging fungal pathogens include *Fusarium* species and the *Zygomycetes*. Fusariosis typically presents as fungemia with hematogenous spread to the skin, and occurs in a trimodal distribution following allogeneic HSCT, with peak incidences prior to engraftment, at 62 days, and beyond 1 year following HSCT.²⁸ Survival is poor, especially in those with neutropenia. *Zygomycetes*, which present with sinopulmonary disease and for which iron overload and decompensated diabetes mellitus represent risk factors, have been increasingly seen in HSCT recipients receiving antifungal prophylaxis with voriconazole.^{26,29,30}

EVALUATION AND MANAGEMENT OF THE FEBRILE PATIENT

The differential diagnosis of fever in the HSCT recipient in the preengraftment period includes infectious and noninfectious causes, as summarized in Table 99.3. The differential diagnosis is guided by the presence or absence of localizing symptoms and physical findings and by the prior infectious disease history. Routine cultures of blood should be obtained, including through respective lumens of intravascular devices. In multilumen central venous catheters, infection may be confined to the inner surface of a single lumen. Cultures of urine, stool assays for *C. difficile* toxin, nasopharyngeal specimens for direct fluorescent antibody testing for CRVs, and mouth cultures for HSV should be obtained as clinically indicated. Plain films of the chest may disclose an infiltrate even in the absence of respiratory symptoms and should be obtained. In patients with sinus symptoms, computed tomography of the sinuses is preferred to sinus plain films. In persistently febrile individuals and those at high risk for invasive aspergillosis, computed tomography of the chest should be performed in search of an occult infiltrate, even if the chest radiograph is normal. In those with a halo sign or cavitory infiltrate, both

Table 99.3 Common causes of fever in the HSCT recipient in the preengraftment period

Syndrome	Common pathogens
Bacteremia	<i>Staphylococci</i>
Intravascular devices	<i>Viridans streptococci</i>
Bowel	Gram-negative bacilli
Other	
Oral Mucositis, Esophagitis	Noninfectious Herpes simplex virus
Diarrhea	Noninfectious <i>Clostridium difficile</i>
Pneumonia	Mouth flora (aspiration) Gram-negative bacilli <i>Staphylococci</i> Community respiratory viruses <i>Aspergillus</i> species
Intravascular device	<i>Staphylococci</i> Gram-negative bacilli <i>Candida</i> species
Noninfectious causes	
Drug fever	
Chemical aspiration	
Engraftment syndrome	

suggestive of invasive pulmonary aspergillosis, bronchoscopy is indicated to establish a microbiologic diagnosis.

The selection of an empiric antimicrobial regimen should be guided by the suspected anatomic origin of the fever, by the pathogens suspected, and by local susceptibility profiles of institutional isolates. It is imperative to prospectively monitor and report to clinicians the antimicrobial susceptibility profiles of bacterial pathogens encountered within the institution and on the stem cell transplant unit, as this may impact on the selection of empiric antibacterial regimens and identify potential outbreaks.² The recent change by the National Committee on Clinical Laboratory Standards in the breakpoint defining susceptibility of coagulase negative staphylococci to methicillin has led to the reclassification of >95% of coagulase negative staphylococci as methicillin-resistant. As these organisms are the most common cause of intravascular device-related bacteremia in HSCT recipients, this has resulted in increasing pressure to include vancomycin in empiric antibacterial regimens in febrile HSCT recipients. The emergence of vancomycin-resistant enterococci and vancomycin-intermediate and vancomycin-resistant *Staphylococcus aureus*³¹ has led, on the other hand, to recommendations to minimize indiscriminate vancomycin use.² However, a recent single center study suggested that early empiric vancomycin administration with as little as two doses between days -7 and +7 dramatically reduced the

incidence of viridans streptococcal bacteremia in HSCT recipients.³² Therefore, vancomycin may be included in the initial coverage of febrile HSCT recipients pending cultures, but its long-term empiric use in the absence of a microbiologic diagnosis or strong clinical indication is discouraged. Persistent fever despite antifungal prophylaxis with fluconazole or low-dose amphotericin should heighten concern about invasive fungal infection and prompt consideration of empiric antifungal therapy with higher dose amphotericin B or voriconazole.

PROPHYLAXIS AND THERAPY

Routine decontamination of the gut is not recommended for HSCT candidates.² The use of oral fluoroquinolones and an agent active against Gram-positive cocci in asymptomatic neutropenic patients reduces the occurrence of Gram-positive and Gram-negative bacteremias, but has no impact on fever-related morbidity or infection-related mortality.³³ A novel strategy to reduce the occurrence of oral mucositis after intensive chemotherapy using palifermin (recombinant human keratinocyte growth factor) has demonstrated promise. In a double-blind, placebo-controlled trial involving patients with hematologic malignancies, palifermin recipients had less severe mucositis, a shorter duration of mucositis, and a lower incidence of fever during neutropenia and bacteremia compared with placebo recipients.³⁴

Acyclovir prophylaxis is indicated for all HSV-seropositive HSCT candidates and has been shown to reduce the occurrence of viral reactivation.³⁵ Prophylaxis should commence at the initiation of the preparative regimen and continue to engraftment or to the resolution of mucositis.² Valacyclovir has not been FDA-approved for this indication.

Antifungal prophylaxis is indicated during neutropenia in all allogeneic and most autologous HSCT recipients. Fluconazole has been recommended by the Centers for Disease Control and Prevention, the Infectious Disease Society of America, and the American Society of Blood and Marrow Transplantation,² but is not effective in the prevention of infections due to *Aspergillus* species, *C. krusei*, and *C. glabrata*. This has led some centers to use other agents for antifungal prophylaxis, including low or moderate dose amphotericin B, liposomal amphotericin B, inhaled or nasal amphotericin B, and voriconazole. Unfortunately, the efficacy of these various prophylactic strategies has not been demonstrated in well designed clinical trials. Moreover, the zygomycetes have emerged as important pathogens in patients receiving voriconazole prophylaxis or therapy.^{29,30} Oral itraconazole should not be used because of its variable absorption; its interactions with other agents such as cyclosporine, methylprednisolone, rifampin, antiepileptics, and warfarin; and the prolonged time required to achieve steady state concentrations in the blood.² New antifungals

are in development and may have a future role in prophylaxis against fungal infections in HSCT recipients. A recent large, randomized, double-blind, multicenter, prospective phase 3 clinical trial compared fluconazole with micafungin, a new echinocandin, for prophylaxis against invasive fungal infections in neutropenic patients undergoing autologous and allogeneic HSCT.³⁶ Micafungin was superior to fluconazole across treatment groups and was associated with a lower incidence of aspergillosis and colonization with *C. glabrata*.

Empiric antibacterial therapy in febrile HSCT recipients should be guided by the suspected site of infection and by knowledge of antimicrobial susceptibility profiles of institutional isolates as well as by organisms previously infecting or colonizing the patient. Catheter-related infections can often be cured without device removal, except in those with tunnel, fungal, or mycobacterial infections and in those who are hemodynamically unstable. Empiric antifungal therapy in persistently febrile neutropenic patients has traditionally been amphotericin B. A recent randomized, double-blind, multicenter study compared the echinocandin caspofungin with liposomal amphotericin B for empiric therapy in 1095 persistently febrile neutropenic patients, of whom 75 were HSCT recipients.³⁷ Caspofungin was as effective and better tolerated than amphotericin B, with lower incidences of nephrotoxicity and infusion-related side effects.

For decades amphotericin B has been the treatment of choice for invasive aspergillosis and other filamentous fungi; however, response rates have been disappointing, and as low as 10–15% in allogeneic HSCT recipients.³⁸ Several alternative agents have recently become available with superior efficacy. Voriconazole is a broad-spectrum triazole with activity against most *Candida* and *Aspergillus* species. In a randomized, unblinded trial comparing high-dose amphotericin B with voriconazole for primary therapy in 277 patients with suspected or proven invasive aspergillosis, many of whom were HSCT recipients, voriconazole had superior efficacy and fewer serious side effects compared with amphotericin B. After 12 weeks, 52.8% of voriconazole recipients versus 31.6% in the amphotericin B group had responded to therapy, though transient visual disturbances occurred in nearly half of voriconazole recipients.³⁹

While superior to amphotericin B, voriconazole is not uniformly effective and many patients require salvage therapy. Several recent studies have examined alternative strategies. The utility of the echinocandin caspofungin was examined in 83 patients with invasive aspergillosis who were refractory to or intolerant of conventional therapy; 79.5% had failed conventional therapy with formulations of amphotericin B and 25% were HSCT recipients.⁴⁰ Forty-five percent responded to caspofungin, including 50% with pulmonary aspergillosis and 23% with disseminated

disease; however, HSCT recipients had a poorer response compared with those with hematologic malignancies. In a small, single center observational study, HSCT recipients with refractory invasive aspergillosis were treated with a combination of voriconazole and caspofungin, and compared with an earlier group treated with voriconazole alone.⁴¹ In this nonrandomized study, patients who received combination therapy had improved survival at 3 months compared with historical controls who received voriconazole monotherapy.

THE EARLY ENGRAFTMENT PERIOD

The early engraftment period begins with the resolution of neutropenia and continues to approximately day 100. The risk of infection in this period is substantially lower in autologous compared with allogeneic HSCT recipients. With the resolution of neutropenia, most patients quickly heal their mucositis. However, GVHD in allogeneic HSCT recipients can lead to recurrent breakdown of mucosal barriers in the gastrointestinal tract, predisposing to recurrent bacterial or fungal bloodstream infections. Nearly all allogeneic HSCT recipients require indwelling vascular devices through this period, which pose an ongoing risk for bacterial infection. Impaired cell-mediated immunity is the major risk factor for infection in this period, especially in allogeneic HSCT recipients, which may be further compromised by the immunosuppressive therapy required to prevent rejection or treat GVHD. Additional immune defects in this period include hyposplenism, diminished neutrophil opsonic and phagocytic function, and the deleterious effects of immunomodulating viruses such as CMV and HHV6.

MICROBIOLOGY

The pathogens requiring consideration in the early postengraftment period are summarized in Table 99.4. Bacterial infections arising from indwelling intravascular devices and mucositis in the setting of GVHD continue to occur in the early postengraftment period. The microbiology of these infections is similar to that encountered in the preengraftment period. Invasive fungal infections due to resistant yeasts, *Aspergillus* species, *Fusaria* species, and zygomycetes also occur during this period. GVHD, graft failure, and corticosteroid therapy are major risk factors for invasive aspergillosis, whose peak incidence in allogeneic HSCT recipients occurs at this time.²⁷ Patients remain at-risk for CRV infections. Unlike children, in whom adenovirus infection is more often seen in the preengraftment period, adult patients tend to develop adenovirus infection beyond 90 days.⁴² As in children, pneumonia, hemorrhagic cystitis, hemorrhagic colitis, and nephritis are the major clinical syndromes.

Table 99.4 Pathogens encountered in the early postengraftment period

Pathogens	Common sites of involvement, origin
Common	
Bacteria	
<i>Staphylococci</i>	Intravascular devices
<i>Streptococci</i>	Mouth and bowel with GVHD
<i>Enterococci</i>	Mouth and bowel with GVHD
Gram-negative bacilli	Intravascular devices, GI tract with GVHD
Viruses	
CMV	Viremia, pneumonia, enterocolitis; reactivation of latent infection, primary infection
Fungi	
<i>Aspergillus</i> species	Pneumonia, CNS
Less Common	
Bacteria	
<i>Legionella</i> species	Pneumonia, exclude nosocomial water source
<i>Listeria monocytogenes</i>	Meningoencephalitis, bacteremia
Viruses	
Adenovirus	Pneumonia, nephritis, hemorrhagic cystitis, hemorrhagic colitis, hepatitis
HHV6	Fever, rash, interstitial pneumonia, encephalitis
Community-acquired respiratory	Upper respiratory tract infections, pneumonia viruses
Fungi	
Zygomycetes	Pneumonia, sinusitis
<i>Candida</i> species	Fungemia, hepatosplenic candidiasis, disseminated infection; intravascular devices and gut with GVHD
<i>Fusaria</i> species	Fungemia, cutaneous disease, pneumonia
<i>Pseudallescheria boydii</i>	Pneumonia
Parasites	
<i>Pneumocystis carinii</i>	Pneumonia
<i>Toxoplasma gondii</i>	CNS, pneumonia, disseminated disease; reactivation of latent infection
<i>Strongyloides stercoralis</i>	Enterocolitis, pneumonia, bowel perforation, Gram-negative bacteremia; accelerated autoinfection cycle

Several pathogens require special comment. Legionellosis is uncommon but has been reported in the setting of HSCT.⁴³ The disease may occur in the pretransplant or preengraftment periods, but is most common in the early engraftment period.⁴³ A sentinel

case occurring beyond day 10 of hospitalization should raise the possibility of nosocomial transmission, and an appropriate epidemiologic and environmental investigation is mandatory.² Unrecognized nosocomial transmission of legionellosis for over a decade in the transplant setting has been described.⁴⁴ HSCT patients with legionellosis present with fever and lobar, patchy, or nodular pulmonary infiltrates. In those with nodular infiltrates, the disease may mimic invasive pulmonary aspergillosis, the most common cause of such infiltrates in this setting. HSCT recipients with legionellosis are at increased risk for mortality and may require more prolonged courses of therapy than immunocompetent individuals.⁴⁴ *Legionella pneumophila* infections are more often fatal than those due to non-*pneumophila* *Legionella* strains.

Listeriosis in HSCT recipients is rare, but occurs most often in the early postengraftment period.⁴⁵ Meningoencephalitis and bacteremia are the most common clinical presentations. A history of high-risk food ingestion associated with listeriosis is typically absent.

Parasitic infections are uncommon following HSCT, but are most likely to occur in the early postengraftment period. The incidence of *Pneumocystis carinii* pneumonia has declined dramatically with the widespread use of chemoprophylaxis. The median time to onset is 9 weeks following HSCT. Patients typically present with fever, worsening dyspnea, dry cough, and interstitial pulmonary infiltrates.⁴⁶ One hundred and ten cases of toxoplasmosis have been described following HSCT⁴⁷; 64% have occurred between days 31 and 100, likely representing reactivation of latent infection in the face of immunosuppression. Forty-eight percent of cases have been confined to the brain. Disseminated infection occurred in 48%. Fever was the most common sign, but was only present in 43%. Focal neurologic symptoms, headache, altered mentation, and respiratory complaints were present in a minority of patients. Meningitis occasionally accompanies cerebral toxoplasmosis, and the organism can be identified on cytologic examination of cerebrospinal fluid. Hyperinfection strongyloidiasis is rare following HSCT and has not been reported in autologous recipients.² Immunosuppression in allogeneic recipients leads to acceleration of the autoinfection cycle of *S. stercoralis* in those with unrecognized asymptomatic infection. Patients typically develop symptoms 4–6 weeks from the initiation of immunosuppressive therapy consisting of fever, diarrhea, respiratory symptoms, and occasionally intestinal perforation owing to widespread migration of larval parasites through the bowel wall and the lungs.⁴⁸ Specimens of stool, sputum, and bronchoalveolar lavage fluid typically demonstrate larvae of *S. stercoralis* on parasitologic examination.

CMV is the most important and common viral pathogen encountered in the early postengraftment period. In the era prior to prophylactic or preemptive

therapy, morbidity and mortality from CMV were substantial. Among seropositive allogeneic HSCT recipients, the group at greatest risk, the incidence of CMV infection varied from 42% to 69%; symptomatic disease developed in 16–25%, with pneumonia in up to 5%.⁴⁹ The incidence in autologous HSCT recipients was lower but still substantial. Prior to the availability of antiviral therapy, mortality from CMV pneumonia following HSCT approached 50%.⁵⁰ The widespread use of targeted prophylaxis or preemptive therapy from engraftment to day 100 in allogeneic HSCT recipients has led to a significant decline in the incidence of symptomatic disease during the early engraftment period, but late disease beyond day 100 is increasingly recognized.^{5,51} Risk factors for symptomatic CMV disease include advanced age, conditioning with total body irradiation, seropositive recipient status, HSCT from a matched unrelated donor, CD34+ allogeneic HSCT, acute GVHD, and high titers of circulating CMV. Symptomatic disease is uncommon in autologous HSCT recipients; patients at higher risk include seropositive recipients with underlying hematologic malignancies, those receiving intensive conditioning regimens, and recent recipients of fludarabine or 2-chlorodeoxyadenosine.² CMV appears to be immunomodulatory and seronegative allogeneic HSCT recipients with seropositive donors have a higher risk of death from bacterial and fungal infections.⁴⁹

The common clinical syndromes produced by CMV include fever without localizing findings, interstitial pneumonia, enterocolitis, and bone marrow suppression. Hepatitis, retinitis, and CNS disease are less common.

EVALUATION AND MANAGEMENT OF THE FEBRILE PATIENT

The differential diagnosis of fever in the early engraftment period is broad. Essential considerations include the patient's prior infectious disease history in the preengraftment and pretransplant periods; timing of onset of fever; the presence or absence of localizing signs and symptoms; the presence or absence of GVHD or symptoms suggestive of GVHD; risk of CMV; and current medications. The differential diagnosis for common clinical syndromes is summarized in Table 99.5 and includes both infectious and noninfectious causes.

Fever at the time of engraftment raises several special considerations, including engraftment syndrome, which is often accompanied by a diffuse maculopapular rash; acute GVHD; or flare of occult infection as leucocytes return and migrate to a site of inflammation.

Fever in the absence of localizing symptoms during the early postengraftment period has many causes. Bacteremia or fungemia from intravascular devices or from the bowel in patients with GVHD may present without localizing symptoms. Patients with pulmonary

Table 99.5 Common causes of fever in the early engraftment period

<i>Syndrome</i>	<i>Common sources, pathogens</i>
Fever at engraftment	Engraftment syndrome Acute GVHD Occult focal infection
Fever without localizing findings	
■ Bacteremia	Intravascular devices <i>Staphylococci</i> Gram-negative bacilli Gut GVHD Gram-negative bacilli <i>Enterococci</i>
■ Fungemia	Intravascular devices <i>Candida</i> species Gut GVHD <i>Candida</i> species
■ Occult pneumonia	Aspergillosis Fusariosis Zygomycosis
■ Sinusitis	GVHD, bacterial infection
■ Viral infections	CMV, HHV6
■ Drug fever	Penicillins, cephalosporins, trimethoprim-sulfamethoxazole, vancomycin, phenytoin
Fever and a pulmonary infiltrate	
■ Fungal pneumonia	Aspergillosis, Fusariosis, Zygomycosis
■ Bacterial pneumonia	<i>Staphylococci</i> , Gram-negative bacilli, Legionellosis
■ Viral pneumonia	CMV, community respiratory viruses
■ Noninfectious causes	Aspiration, idiopathic interstitial pneumonia, diffuse alveolar hemorrhage
Fever with diarrhea	
■ GVHD	
■ <i>C. difficile</i>	
■ CMV	
■ Community viruses	

fungal infections such as aspergillosis, fusariosis, or zygomycosis may lack cough, dyspnea, and hemoptysis at the outset. Sinusitis from infection or GVHD may be asymptomatic except for fever. CMV infection may present only with fever and must be strongly considered in CMV seropositive allogeneic HSCT recipients and seronegative recipients with a CMV seropositive donor. HSCT recipients who are CMV D-/R- have a small risk of CMV in this period. The concern for reactivation CMV is heightened in at-risk and high-risk individuals who are being followed and monitored prospectively for viremia, rather than receiving prophylaxis from the time of engraftment. Fever without

localizing signs or symptoms may also occur as an initial manifestation of adenovirus infection or reactivation of HHV6. Noninfectious causes of fever include early GVHD and new medications. Medications which are most likely to cause drug fever include trimethoprim-sulfamethoxazole, penicillins, cephalosporins, vancomycin, and phenytoin.

The differential diagnosis of fever and a pulmonary infiltrate includes infectious and noninfectious causes. Infectious causes include bacterial pneumonia (including legionellosis), pulmonary fungal infections, and CRV infections during seasonal outbreaks. Noninfectious causes include diffuse alveolar hemorrhage (though fever may be absent), aspiration pneumonia, and idiopathic interstitial pneumonia.

In patients with fever and diarrhea, concerns include GVHD, CMV or adenovirus enterocolitis, *C. difficile*-associated diarrhea, and community-acquired viral gastroenteritis caused by rotavirus, Norwalk virus, or coxsackievirus during seasonal outbreaks. Diarrhea is infectious in origin in a minority of HSCT patients during this period.

The differential diagnosis of fever and rash depends upon the appearance of the rash. If maculopapular, concerns include engraftment syndrome, acute GVHD (especially if the rash involves the palms and soles), drug reaction, and reactivation of HHV6. A papulopustular rash consisting of only a few scattered lesions should suggest disseminated candidiasis. Nodular skin lesions may occur with disseminated aspergillosis or fusariosis, disseminated cryptococcosis, and nocardiosis. The latter two infections are rare following HSCT, especially in the early postengraftment period, and are generally encountered beyond 100 days. A vesicular rash should suggest HSV or VZV, the latter being uncommon between days 30 and 100.

The diagnostic evaluation should be tailored based upon the presence or absence of localizing signs and symptoms to suggest a source of fever. Blood cultures for bacterial pathogens are indicated in most patients. In those with clinical clues as to the cause of fever, additional cultures and imaging studies may be pursued. In those without localizing findings, blood cultures should be obtained from each lumen of indwelling vascular devices and peripherally. Fungal blood cultures should be collected if unexplained fever persists. Patients at-risk for CMV infection should be tested using the pp65 antigenemia assay, polymerase chain reaction, or hybrid capture for CMV viremia. Computed tomographic scans of the sinuses, chest, and abdomen should be considered in search of occult sinusitis, occult pulmonary infiltrates, and thickening of the bowel wall suggestive of GVHD or infectious enterocolitis. Biopsy for histopathologic examination and culture may establish a diagnosis in patients with rash; vesicular lesions should be unroofed and scraped for viral culture. In patients with fever and pulmonary infiltrates, bronchoscopy should be strongly considered.

PROPHYLAXIS AND THERAPY

Antibacterial prophylaxis is recommended in allogeneic HSCT recipients who develop chronic GVHD and should be targeted at encapsulated organisms, including *Streptococcus pneumoniae*, *Hemophilus influenzae*, and *Neisseria meningitidis*.² Selection of a regimen should be guided by local pneumococcal susceptibility profiles. Prophylaxis against *Pneumocystis carinii* is indicated in allogeneic HSCT recipients and should commence with engraftment and extend through all periods of immunodeficiency and for at least 6 months.² High-risk autologous HSCT recipients are candidates for PCP prophylaxis, including those with underlying hematologic malignancies, recipients of intensive preparative regimens or graft manipulation, and recent recipients of fludarabine or 2-chlorodeoxyadenosine. Trimethoprim-sulfamethoxazole is the preferred agent. In allergic individuals, desensitization should be attempted. In those unable to tolerate trimethoprim-sulfamethoxazole, alternative agents include dapsone, atovaquone, and aerosolized pentamidine. The latter is least effective and should only be used in patients unable to tolerate other regimens.

Prophylaxis against *I. gondii* is recommended in allogeneic HSCT patients with active GVHD or with a prior history of *Toxoplasma* chorioretinitis.² Trimethoprim-sulfamethoxazole is preferred, though rare break-through cases have occurred.⁵² In sulfatolerant patients, clindamycin, pyrimethamine, and leucovorin may be substituted.

Prophylaxis against yeast infections is not routinely recommended following engraftment. The utility of and optimal regimen for prophylaxis against aspergillosis in the early postengraftment period is unclear; many centers nevertheless choose to continue *Aspergillus* prophylaxis though this period, especially in high-risk individuals with GVHD.

All allogeneic HSCT recipients at-risk for CMV, including CMV seropositive recipients and seronegative recipients with seropositive donors, should either receive prophylaxis commencing at engraftment or should be monitored at least weekly for evidence of CMV viremia.² Several tests may be used to detect CMV viremia, including the pp65 antigenemia assay, CMV-DNA PCR, or hybrid capture DNA detection. Routine and rapid shell vial cultures are less sensitive and more time-consuming. CMV-DNA PCR is extremely sensitive, but has a low positive predictive value.⁵³ Patients with detectable antigenemia on 2 or more consecutive tests positive for CMV DNA should commence preemptive therapy. Ganciclovir given intravenously has been the agent of choice for prophylaxis and preemptive treatment. However, one recent multicenter, randomized study compared oral valganciclovir with intravenous ganciclovir from engraftment to day 100 in CMV seropositive allogeneic HSCT recipients and found oral valganciclovir comparably effective.⁵³ Once commenced, ganciclovir should be continued through

day 100 or at least for 3 weeks in those receiving preemptive therapy, whichever is longer. If tests are available to detect viremia, a negative test result should be confirmed prior to discontinuing ganciclovir. A prophylactic strategy is preferred in centers unable to perform CMV antigen detection or CMV DNA detection by PCR or hybrid capture. Some centers with these capabilities nevertheless prefer a prophylactic strategy, while others advocate preemptive therapy so as to limit unnecessary ganciclovir exposure, as ganciclovir prophylaxis has been associated with more neutropenia, delayed recovery of CMV-specific immune responses, and a higher incidence of invasive fungal and bacterial infections.^{2,49,54} Neutropenia arising on ganciclovir may be managed with G-CSF, or by holding the drug for several days. In those unable to tolerate ganciclovir, foscarnet may be used. The strategies of CMV prophylaxis and preventive therapy have reduced the incidence of CMV disease in the early postengraftment period. There is increasing evidence, however, of late CMV disease beyond day 100 in high-risk patients.⁵¹ Risk factors for late disease include the presence of chronic GVHD, corticosteroid use, delayed development of high avidity anti-CMV antibody, low CD4 count, and receipt of a matched unrelated or T-cell-depleted HSCT.² The utility of extended prophylaxis in high-risk patients has not been proven; these individuals should be monitored for evidence of CMV viremia beyond day 100, especially during intensification of immunosuppression. If detected, 3 weeks of preemptive therapy is recommended.

Because CMV disease is rare following autologous HSCT, screening for viremia is not routinely recommended, except in high-risk patients with underlying hematologic malignancies, in those who have recently received fludarabine or 2-chlorodeoxyadenosine, or in recipients of particularly intensive preparative regimens.² In such individuals, monitoring to day 60 has been suggested; viremic patients should receive 3 weeks of preemptive therapy.

Patients with tissue invasive CMV disease, such as pneumonia and enterocolitis, should receive 3 weeks of therapy.⁵ Ganciclovir-resistant CMV is rare and usually occurs in immunodeficient patients who have previously received multiple courses of ganciclovir. Sustained viremia through ganciclovir should suggest the presence of UL97 genotypic resistance mutations and prompt a switch to foscarnet.

THE LATE ENGRAFTMENT PERIOD

The late engraftment period commences at day 100 and continues until the discontinuation of all immunosuppressive therapy and the absence of GVHD. Beyond day 100, autologous HSCT recipients have a more rapid return of immune function compared with allogeneic recipients, and their risk of opportunistic infection is

low. Defects in humoral, cellular, and reticuloendothelial immune function persist beyond day 100 in allogeneic HSCT recipients for up to 18–36 months, especially in those with GVHD and in those who have received matched unrelated, mismatched family-related, or umbilical cord blood HSCTs. In general, the risk of opportunistic infection correlates with the severity of chronic GVHD during this period.

MICROBIOLOGY

Allogeneic HSCT recipients who continue to require indwelling intravascular devices and who have disrupted mucosal barriers from chronic GVHD remain at-risk for bacterial infections from these sites. In addition, because of humoral immunodeficiency, these patients are at higher risk of infection with encapsulated organisms such as *S. pneumoniae* and *H. influenzae*. These typically present as bacteremia, pneumonia, or sinusitis.

Allogeneic HSCT recipients are at-risk beyond day 100 for a number of viral infections. As many will be out of hospital, CRV infections continue to pose a threat. Late-onset CMV disease is increasingly common, and in a recent study developed in 17.8% of allogeneic HSCT recipients a median of 169 days after transplantation.⁵⁵ Mortality was 46%, and 38% of survivors had a second episode a median of 79 days following the first episode. Risk factors at 3 months for late CMV disease and death included GVHD, absolute lymphopenia <100 lymphocytes/cc, CD4 T-lymphocyte count <50 cells/cc, prior CMV antigenemia, and absent CMV-specific T-cell responses. Beyond 3 months, continued antigenemia or CMV DNA detection in peripheral leucocytes or plasma predicted late disease and death.

VZV is common following HSCT and occurs in both autologous and allogeneic HSCT recipients.⁵⁶ Eighty-six percent of cases occur within the first 18 months, with a median onset at 5 months.^{5,56} Risk factors include age >10, radiation as part of the conditioning regimen, and VZV seropositivity.⁵⁶ Patients with dermatomal disease are at-risk for cutaneous or visceral dissemination, especially in the setting of GVHD. Atypical presentations of VZV with few vesicles or pain in the abdomen or back can occur. Atypical generalized zoster presents with multiple vesicular lesions without a dermatomal distribution. In those with dermatomal disease, the presence of more than 10 lesions outside the dermatome defines cutaneous dissemination. Visceral dissemination may involve the lungs, liver, or CNS.

EBV infection is common following HSCT, especially in EBV seronegative patients with a seropositive donor. Symptomatic disease is less common and may include fever with a mononucleosis-like illness, aplastic anemia, meningoencephalitis, or posttransplant lymphoproliferative disorder (PTLD). PTLD is the most feared manifestation of EBV infection and arises due to

polyclonal or monoclonal B-cell activation in the setting of inadequate EBV-specific T cell immune surveillance. PTLD may present as a mono-like illness, as focal mass lesions in various sites, such as the lung or brain, as intestinal bleeding or perforation, or as widespread disease involving multiple organs, mimicking lymphoma. Onset typically occurs 3–5 months following HSCT. The incidence varies from <1% in matched related allogeneic HSCT recipients to up to 18% in certain high-risk groups, including recipients of matched unrelated, mismatched or T-cell depleted allografts, and those who receive GVHD prophylaxis with T-cell specific monoclonal antibodies or antithymocyte globulin.^{57,58}

Mycobacterial infections due to *M. tuberculosis* and nontuberculous mycobacteria are rare but reported following HSCT and typically present with a median onset at 4–5 months following transplantation.^{59,60} Nontuberculous mycobacterial infections present as catheter-related infections, or as pulmonary, cutaneous, or disseminated disease. *M. tuberculosis* most often produces reactivation pulmonary disease, but rarely presents with pleural, nodal, cutaneous, marrow, or CNS involvement.

EVALUATION AND MANAGEMENT OF THE FEBRILE PATIENT

The differential diagnosis of fever in the late post engraftment period is broad, as many patients will be out of hospital and at-risk for community-acquired infectious diseases. The risk of opportunistic infection is proportionate to the extent of GVHD present and the degree of residual immunodeficiency. Autologous HSCT recipients are much less likely to have an opportunistic infection compared with allogeneic patients. The diagnostic evaluation and management should be guided by the history, by the presence or absence of localizing complaints, by the presence or absence of GVHD and the degree of immunodeficiency, and by the prior infectious disease history.

The differential diagnosis of fever without localizing symptoms or signs should include bacteremia, late-onset CMV disease, and PTLD. Although patients with chronic GVHD or indwelling intravascular devices remain at-risk for bloodstream infections with staphylococci and Gram-negative bacilli, encapsulated organisms should be suspected. All patients should have blood cultures obtained. High-risk patients for late-onset CMV disease should be screened for CMV viremia. PTLD is rare, but circulating EBV may be sought by PCR and high titers correlate with a greater likelihood of PTLD. If suspected, CT scans to identify adenopathy or masses in the chest, abdomen or pelvis should be performed.

In febrile patients without an obvious source of infection, empiric antibiotic therapy should be strongly considered pending blood cultures and should include coverage of *S. pneumoniae*, *H. influenzae*, and

N. meningitidis. Knowledge regarding the local incidence of penicillin-resistant pneumococci is essential in selecting a regimen. Patients with proven bacteremia with an encapsulated organism should be screened for hypogammaglobulinemia. Patients with late CMV viremia or invasive disease should be treated as outlined previously; clearance of viremia should be documented at the conclusion of 3 weeks of antiviral therapy.

The differential diagnosis in patients with a pneumonia syndrome depends upon the history, the likelihood of opportunistic infection, and the radiographic pattern of the infiltrate. In patients with acute onset of fever, a productive cough and a focal infiltrate, pneumococcal or *H. influenzae* pneumonia should be suspected. The presence of a nodular or cavitory infiltrate should suggest aspergillosis, tuberculosis, nocardiosis, zygomycosis, or PTLD. Interstitial infiltrates should suggest CMV, PCP, CRV, or noninfectious causes, which may account for up to 50% of cases in this setting. Diagnostic evaluation should include blood cultures and examination of expectorated sputum for pathogens suspected from the history and radiographic findings. Bronchoscopy may be necessary to establish a diagnosis in those with nodular, cavitory or interstitial infiltrates.

Sinusitis and otitis media from encapsulated organisms occur with higher frequency in the late engraftment period; symptoms to suggest these diagnoses should be carefully sought in allogeneic HSCT recipients with fever. Patients with VZV may present with

dermatomal or atypical pain that heralds the onset of rash by up to 72 h.

PROPHYLAXIS AND THERAPY

Patients with chronic GVHD should receive prophylactic antibiotic therapy directed against encapsulated organisms as long as immunosuppressive treatment is being administered; the regimen should be selected based upon local resistance patterns of *S. pneumoniae* and *H. influenzae*.² The 23-valent pneumococcal polysaccharide vaccine should be administered 12–24 months after HSCT and HiB conjugate vaccine should be given at 12, 14, and 24 months as well.² Patients with hypogammaglobulinemia may require replacement therapy if they experience recurrent infections with encapsulated organisms, or at the time of a serious first episode.

CMV prophylaxis is not recommended beyond day 100, but high-risk patients should receive biweekly screening. Ganciclovir should be administered for at least 3 weeks if viremia is detected. EBV and VZV prophylaxis are not recommended.² Anecdotal reports have suggested efficacy of acyclovir and ganciclovir in patients with PTLD, but no large trials have been performed and antiviral therapy is not recommended.² If possible, immunosuppression should be reduced if PTLD is identified. The administration of donor-derived, EBV-specific cytotoxic T cells has demonstrated promise in the prevention of PTLD in high-risk patients.⁶¹ Influenza immunization is indicated on an annual basis beginning 6 months after HSCT.²

Chapter 100

NONINFECTIOUS COMPLICATIONS OF STEM CELL TRANSPLANTATION

Scott I. Bearman

INTRODUCTION

Blood or marrow transplantation is the standard of care for many hematologic malignancies and selected nonmalignant diseases. Whether transplantation succeeds or fails depends, in part, on the ability of the patient to tolerate the preparative treatment. This chapter will focus on the major toxicities of *myeloablative* preparative regimens. Reduced-intensity regimens are usually described as being *nonmyeloablative*. Some of these regimens are, in fact, quite toxic. Although this is a generalization, it is safe to say that reduced-intensity regimens are associated with fewer early treatment-related deaths. Where these regimens are most appropriately used remains the subject of intense investigation. A more detailed discussion of this approach can be found elsewhere in this text.

REGIMEN-RELATED TOXICITY

Toxicities that can be directly attributed to the preparative regimen are referred to as regimen-related toxicities (RRTs). Excluded are infection, hemorrhage, and graft-versus-host disease (GVHD). Less clear are the toxicities that are the result of GVHD prophylaxis. Although flawed, a set of criteria developed in Seattle in the late 1980s remains one of the few designed to evaluate toxicity from myeloablative therapy.¹ This system was devised in patients who were prepared for transplantation using cyclophosphamide and total body irradiation (TBI). Life-threatening or fatal RRT was more common in patients who received higher TBI doses, who were transplanted with relapsed disease, and who received allogeneic versus autologous grafts. It also demonstrated that RRT was cumulative. Patients who developed grade 2 RRT in three or more organs were more likely to die by day 100 than those who developed grade 2 RRT in fewer organs.

Preparative regimens, particularly those that are myeloablative, usually employ noncross resistant drugs with nonoverlapping, nonhematopoietic toxicities. Dose-limiting toxicities are to nonhematopoietic organs and are similar among the different regimens (Table 100.1). The spectrum of such toxicities may change as newer immunosuppressive regimens that do not include methotrexate are studied.²⁻⁵

CARDIAC TOXICITY

Cardiac toxicity is the dose-limiting toxicity of the oxazophosphorine chemotherapeutic agents cyclophosphamide and ifosfamide. Pathologically, cardiac toxicity is characterized by hemorrhagic pancarditis. Patients with severe cardiac toxicity can develop severe congestive heart failure and pericardial effusions with tamponade within 24–48 h of receiving high-dose cyclophosphamide or ifosfamide.^{6,7} Risk factors reported for severe cardiac toxicity include previous treatment with anthracyclines^{8,9} and reduced left-ventricular function prior to transplant.¹⁰

Murdych and Weisdorf evaluated the incidence of serious cardiac complications over a 20-year period in more than 2800 patients transplanted at the University of Minnesota.¹¹ Twenty-six of 2921 (<1%) patients developed life-threatening cardiac toxicity, half of whom died. Severe cardiac toxicity remains an uncommon complication of high-dose cytoreduction. However, subclinical cardiac toxicity, manifested by asymptomatic pericardial effusions and echocardiographic evidence of left-ventricular dysfunction, is not uncommon.^{8,12,13}

The pathogenesis of cardiac toxicity is unclear. Several groups have measured troponin 1 (Tn1) levels in patients receiving high-dose chemotherapy. Morandi and colleagues measured Tn1 levels in 16 breast cancer patients who received 7 g/m² of cyclophosphamide as part of a high-dose chemotherapy regimen.¹⁴ Cyclophosphamide was given in five divided doses every 3 h

Table 100.1 Dose-limiting toxicities of drugs commonly used in myeloablative preparative regimens

Drug	Organ at risk
Cyclophosphamide	Heart, bladder, liver
Busulfan	Lungs, liver
Etoposide	Mucosa
BCNU	Lungs
Melphalan	Mucosa

over a 13-h period. Tn1 was measured at baseline and at 6, 12, 24, and 48 h after the first dose of cyclophosphamide. Levels never exceeded normal values in any of the patients studied and were not measurable in 12 of the 16 patients.

However, this may not be the case with anthracycline-containing high-dose regimens. Cardinale and colleagues measured Tn1 levels shortly after transplant and 1 month later. Patients were segregated into three groups: those whose levels remained normal (Tn1 -/- group), those with only an early rise in troponin (Tn1 +/- group), and those whose troponin levels were elevated at both time points (Tn1 +++ group). Echocardiograms were performed in all patients prior to and at various times following transplant. They reported that left ventricular ejection fractions did not change in the Tn1 -/- patient group and less than 1% of patients had cardiac events. Cardiac events were much more common in patients whose Tn1 levels increased, even transiently. Patients in the Tn1 +++ group had a significantly greater number of cardiac events (84%) than patients in the Tn1 +/- group (37%).¹⁵ These results suggest that cardiac toxicity after high-dose anthracyclines occurs by disruption of myocardial membranes while cardiac toxicity after high-dose cyclophosphamide occurs by another mechanism, possibly affecting endothelium or interstitium.¹⁶

Cardiac toxicity following autologous transplantation for AL amyloidosis is common and often severe. Cardiac involvement is common in patients with AL amyloidosis and is associated with an increased risk of cardiac toxicity following transplant. Investigators at Boston University reported that 20 of 28 patients who died within 3 months of transplant had evidence of amyloid cardiomyopathy prior to transplant.¹⁷ The Mayo Clinic group reported that five out of six patients with interventricular septal wall thickness greater than 15 mm died after transplant, none of whom had congestive heart failure or reduced left ventricular function.¹⁸

Life-threatening arrhythmias are common in patients transplanted for AL amyloid. Moreau et al. reported that three of nine patients who died within 1 month of transplant had fatal cardiac arrhythmias.¹⁹ Cardiac complications may be more common among AL amyloid patients even after less intense preparative therapy. Comenzo and colleagues reported that 5 of 30

patients who received 100 mg/m² of melphalan rather than the standard 200 mg/m² died of transplant-related complications by day 100. Two had cardiac arrests. Their pretransplant ejection fractions were 37% and 40%.²⁰

MUCOSAL AND GASTROINTESTINAL TOXICITY

Most of the drugs or modalities used in myeloablative regimens produce mucosal injury, including etoposide, melphalan, and TBI. About 75% of patients who are prepared using myeloablative regimens develop mucositis.^{1,21,22} It is the most common complaint of transplant patients.^{23,24} Injury to actively dividing cells in the basal cell layer begins with the first cytoreductive treatment and lasts 10–14 days, leading to atrophy, ulceration, and local infection, which is also compounded by neutropenia. Severe mucositis is associated with an increased risk of bacteremia. Utilization of total parenteral nutrition, number of febrile days, and total charges all correlate with increasing severity of mucositis.²⁵

A number of strategies to prevent mucositis have been studied. Glutamine, an essential amino acid that has been reported to protect the mucosa,^{26,27} has been the subject of several randomized trials. One study found no benefit while the other two reported a benefit for patients receiving glutamine supplementation.^{28–30} In the largest of these studies, Anderson randomized 193 patients to receive or not to receive oral glutamine. Autologous stem cell recipients benefited with less pain and narcotic use while allogeneic transplant patients did not. However, day 28 survival was superior for allogeneic patients who received glutamine. The authors suggested that allogeneic transplant patients did not benefit because of the use of methotrexate for GVHD prophylaxis.

Both G-CSF and GM-CSF have been studied to prevent mucositis. Patients who receive conventional dose chemotherapy appear to benefit from hematopoietic growth factors but transplant patients do not.^{31,32} Interleukin-11 (IL-11) has been reported to reduce mucositis in autologous transplant recipients.³³ The benefits of IL-11 appear to be outweighed by the risks among allogeneic transplant recipients. Antin and coworkers studied IL-11 in allotransplant recipients prepared with cyclophosphamide/TBI who received cyclosporine and methotrexate as GVHD prophylaxis. The study was stopped early due to excessive toxicity.³⁴

There have been several recent studies with promising new agents to prevent mucositis. Keratinocyte growth factor (KGF) is a member of the heparin-binding family of fibroblast growth factor 7 and stimulates the proliferation and differentiation of epithelial cells from several tissues, including the gastrointestinal tract.^{35,36} KGF was shown to reduce mucositis in animals receiving chemotherapy and/or radiation.^{37,38} Spielberger and colleagues recently reported the results

of a prospective, randomized placebo-controlled study of KGF in patients prepared for autologous transplant with TBI and high-dose etoposide and cyclophosphamide.³⁹ Patients given KGF before and after high-dose chemoradiotherapy had less WHO grade 3 and 4 oral mucositis and required less narcotics and total parenteral nutrition. The duration of mucositis was reduced, as well.

The synthetic protegrin iseganen has also been studied to prevent mucositis in transplant patients. Protegrins are naturally occurring antibiotic peptides derived from specific granules of neutrophils, with a very broad spectrum of activity. Vesole and colleagues conducted a phase II study of iseganen in 187 transplant patients prepared with mucositis-causing regimens.⁴⁰ Mucositis was reduced by 42% in patients who took this agent for 4 or more days prior to stem cell infusion. Recently, a prospective randomized trial of iseganen was conducted and reported. Giles et al. randomized 501 patients to receive or not to receive iseganen with myeloablative therapy. In this study, the incidence and severity of mucositis was not different in the two groups.⁴¹

There have also been several studies of the cytoprotectant amifostine. Amifostine is an organic thiophosphate that is dephosphorylated by membrane bound alkaline phosphatase to its active metabolite WR-1065. It is a potent free radical scavenger and has been shown to be cytoprotective against radiotherapy and certain chemotherapeutic agents, such as cisplatin and nitrogen mustard.^{42,43} Amifostine has been studied in the transplant setting in patients prepared with high-dose melphalan. Phillips and colleagues have reported a phase I/II study of melphalan dose escalation with amifostine. Mucositis was not greater in patients treated with escalated doses of melphalan (with amifostine) than in patients treated with the standard dose of 200 mg/m² without amifostine.^{44,45}

Other gastrointestinal complaints, such as nausea and vomiting, pain, and diarrhea are common after high-dose chemotherapy and/or TBI. Patients experience nausea and vomiting due to effects on the brain's emesis center or because of direct mucosal toxicity. Treatment of mucosal pain with opiates can also cause or worsen nausea. The type 3 serotonin antagonists ondansetron, granisetron, and tropisetron are effective in about half of patients.^{46,47} Delayed nausea and vomiting remain significant problems in transplant patients.⁴⁸ Newer agents such as palonosetron, another 5-HT₃ antagonist and aprepitant, a neurokinin-1 receptor antagonist, may have a role in transplant patients.⁴⁹

VENOOCCLUSIVE DISEASE OF THE LIVER/SINUSOIDAL OBSTRUCTION SYNDROME

Hepatic toxicity is, arguably, the most problematic RRT after ablative preparative therapy. Patients with hepatic toxicity develop painful hepatomegaly and

retain fluid early in the course of the disease, which is followed by rising bilirubin and, sometimes, transaminases.^{50–52} Clinical signs of portal hypertension precede those of hepatic parenchymal injury (hyperbilirubinemia, elevated transaminases). Furthermore, not all patients have hepatic venular occlusion on biopsy or autopsy material.⁵¹ For this reason, DeLeve and colleagues have suggested that the more appropriate name for this toxicity is *sinusoidal obstruction syndrome* (SOS) rather than venoocclusive disease (VOD).

The sinusoidal endothelial cell (SEC) appears to be the primary target in this syndrome. The endothelial marker plasminogen activator inhibitor-1 increases early and specifically in patients with SOS–VOD.^{53,54} Another endothelial marker, thrombomodulin, also increases after high-dose therapy.⁵⁵ Hyaluronic acid, which is metabolized by SEC, has also been reported to be elevated in patients with SOS–VOD.⁵⁶ Coculture of SEC and hepatocytes and exposure to cyclophosphamide results in greater damage to SEC compared to hepatocytes. It is believed that metabolic activation of cyclophosphamide by hepatocytes generates the toxic metabolite acrolein, which produces the injury. Supporting intracellular levels of glutathione can reverse this injury.⁵⁷ Busulfan affects cyclophosphamide metabolism by reducing glutathione levels in hepatocytes and SEC.^{58,59} This is probably why SOS–VOD occurs less frequently when cyclophosphamide administration precedes busulfan than the other way around.⁶⁰ Fatal VOD can occur after IV busulfan plus cyclophosphamide although busulfan levels are far more reliable after intravenous administration.⁶¹

Fluid retention and painful hepatomegaly are the first signs of SOS–VOD and appear on or around the date of stem cell infusion. Hyperbilirubinemia develops about a week later. Ascites is uncommon in patients with mild or moderate disease while about half of patients with severe disease develop ascites.⁵⁰ The most common cause of death in patients with SOS–VOD is multiorgan failure rather than liver failure.^{50,62} Rapid increases in weight and bilirubin characterize patients with SOS–VOD who are more likely to die.

Active hepatic parenchymal inflammation (elevated transaminases),⁵⁰ second transplants using ablative preparation,⁶³ and preexisting hepatic fibrosis^{64,65} have been reported to be risk factors for SOS–VOD. Elevated levels of soluble thrombomodulin and von Willebrand factor prior to transplant have been reported in patients who went on to develop SOS–VOD, suggesting that endothelial injury prior to the start of preparative therapy is also a risk factor.⁶⁶

Historically, SOS–VOD was a common complication of ablative transplant, with up to 53% of patients developing this problem and up to two thirds of affected patients dying.⁵⁰ More recent reports suggest that the incidence of SOS–VOD is much less.⁶⁷ The decrease in incidence and severity of SOS–VOD may be due to healthier patients with fewer underlying risk

factors (chronic hepatitis C being largely eliminated), and the use of less intensive preparative regimens.

An association between SOS–VOD and treatment with gemtuzumab ozogamicin, a humanized anti-CD33 monoclonal antibody conjugated to the antitumor antibiotic calicheamicin, has been reported.^{68–70} SOS–VOD after gemtuzumab ozogamicin has been reported in both transplant and nontransplant settings. Recently, Wadleigh et al. reported that SOS–VOD was more common in patients who received gemtuzumab ozogamicin prior to transplant than in patients who did not receive gemtuzumab ozogamicin. Furthermore, only patients who received gemtuzumab ozogamicin within 3.5 months of their transplant developed SOS–VOD.⁷¹ Rajvanshi et al. reported on the outcome of patients who received gemtuzumab for relapsed AML *after* a previous stem cell transplant. Eleven of 23 patients developed SOS–VOD.⁶⁹ Histologic material was available from five patients. Extensive sinusoidal collagen deposition was seen, suggesting that gemtuzumab ozogamicin targets CD33⁺ cells within the sinusoids.

Fractionated TBI results in less SOS–VOD than single fraction.⁷² Shielding the liver during TBI may reduce SOS–VOD but may increase the risk of relapse.⁷³ Many institutions use ursodeoxycholic acid^{74,75} but it is unclear whether survival is impacted by this agent. Spontaneous recovery is the usual outcome for patients with SOS–VOD who recover and treatment is supportive.

Richardson and colleagues have studied defibrotide (DF), a single-stranded polydeoxyribonucleotide with anti-ischemic, antithrombotic and thrombolytic activity and no significant anticoagulant effects, in patients with severe SOS–VOD.⁷⁶ A total of 102 patients with severe SOS–VOD, 97% of whom had multiorgan dysfunction, have now been treated.⁷⁷ Fifty-four percent of patients achieved complete responses. Median PAI-1 levels decreased and protein C increased in patients who achieved complete responses. No significant adverse events occurred. There are also anecdotal reports of using *N*-acetylcysteine⁷⁸ and L-glutamine^{79,80} for prevention or treatment of SOS–VOD. Surgical or invasive approaches have been used for patients with severe SOS–VOD, with mixed results. Several patients have even been treated with portosystemic shunts⁸¹ or liver transplantation.^{82–84} Transplantation was successful in several patients.

RENAL DYSFUNCTION

Renal dysfunction occurs commonly after ablative high-dose preparative therapy. The causes include tumor lysis, infusion of cryopreserved marrow or stem cells, certain chemotherapeutic agents, and nephrotoxins. Ifosfamide, melphalan, and cisplatin are the agents used in high-dose regimens most likely to cause

renal dysfunction. Renal dysfunction due to these drugs is usually mild and reversible. Severe renal dysfunction occurs most commonly in association with dysfunction of multiple organs.

The manifestations of early and late renal dysfunction after transplantation are different. About 40% of patients develop early renal dysfunction, which may require dialysis in 25–50% of the affected patients.⁸⁵ Early renal dysfunction is more likely in allotransplant recipients due to GVHD prophylaxis with cyclosporine or tacrolimus. Severe dysfunction is more common in the setting of nephrotoxic antibiotics or sepsis. Treatment of early renal dysfunction is supportive and requires delicate management of intravascular volume, diuretics, hemodialysis, or ultrafiltration. Most patients who need dialysis die.

Late renal dysfunction usually manifests as hemolytic uremic syndrome (HUS). Patients present with microangiopathic hemolytic anemia, hypertension, renal failure, and encephalopathy. Both autologous and allogeneic patients develop late renal dysfunction, which is often attributable to TBI. Partial shielding of the kidneys can reduce the incidence of HUS.^{62,86} Cyclosporine, tacrolimus, and sirolimus can also cause HUS.^{87–89} HUS due to cyclosporine or tacrolimus is usually not improved by switching to the other agent.⁹⁰ Several groups have studied amifostine in the transplant setting to prevent renal toxicity, with mixed results.^{91,92}

The issue of whether preexisting renal dysfunction precludes patients from transplant has also been recently studied. Patients with AL amyloidosis commonly develop nephrotic syndrome and/or renal insufficiency. High-dose melphalan and autologous stem cell transplantation can improve nephrotic syndrome in many patients.^{17,18,93,94} In the immediate peritransplant period renal function usually worsens and then improves.⁹⁵ Unfortunately, most patients with AL amyloidosis have progressive renal dysfunction over time. Those patients who achieve complete hematologic responses after autologous transplant preserve their renal function better than patients who have persistent disease after transplant. Renal failure does not preclude transplantation for patients with AL amyloidosis provided cardiac and pulmonary function are satisfactory. AL amyloid patients with renal failure who undergo transplant develop more toxicity than other patients but their complete remission rates and 1-year survival are comparable to patients without end-stage renal disease.¹⁷

San Miguel and colleagues⁹⁶ reviewed the outcomes of 566 patients with multiple myeloma in the Spanish Autologous Stem Cell Transplantation registry. Patients were categorized according to renal function (abnormal function at diagnosis but normal at transplant; abnormal at both diagnosis and transplant; normal at both diagnosis and transplant). Treatment-related mortality was significantly greater

in patients who had abnormal renal function at both diagnosis and transplant. They reported that poor performance status, hemoglobin ≤ 9.5 mg/dL, and creatinine ≥ 5 mg/dL were independent risk factors for TRM. Renal function did not affect response to transplant.

Badros et al. transplanted 81 multiple myeloma patients with renal failure, including 38 on dialysis.⁹⁷ Sixty patients (including 27 on dialysis) received 200 mg/m² of melphalan while 21 received 140 mg/m². Patients on dialysis developed significantly more pulmonary complications and encephalopathy. Early treatment-related mortality was not influenced by the dose of melphalan. Only 31 of the 81 patients received a second planned cycle of high-dose melphalan. The patients in this study who received two transplants did not do any better than those who were transplanted once.

NEUROTOXICITY

Some agents used in transplant regimens can cause central nervous system (CNS) toxicity and peripheral neuropathy. Antiseizure medications providing therapeutic levels can prevent seizures that can occur after high-dose busulfan.^{98,99} CNS toxicity occurring after high-dose cytarabine can be reduced by careful attention to renal function and dose adjustment when indicated.^{100,101}

Leukoencephalopathy is a progressive and often fatal form of CNS toxicity that presents with seizure, confusion, dysarthria, weakness, and coma, usually several months posttransplant.^{102,103} Most patients who develop leukoencephalopathy have received radiation and/or intrathecal therapy after transplant. Cyclosporine or tacrolimus can also cause leukoencephalopathy that tends to occur earlier than leukoencephalopathy due to CNS therapy and usually improves after discontinuation of treatment.¹⁰⁴ Neurotoxicity as a result of cyclosporine resolves or improves in most patients after switching to tacrolimus.⁹⁰

Some patients develop cognitive dysfunction after stem cell transplantation. Phipps and colleagues conducted a prospective study of neurocognitive function in children who underwent transplant and found that age at the time of transplant was the single predictor of late neurocognitive sequelae. Patients who were 6 years of age or older had a minimal risk of cognitive sequelae while younger patients, particularly those younger than 3 years of age, had a greater risk.¹⁰⁵ Some adults also experience neuropsychological impairment after transplant, characterized by slowed reaction time, difficulty with attention and concentration, and troubles with reasoning and problem solving,¹⁰⁶ which was correlated with TBI dose. The incorporation of taxanes in high-dose regimens has increased the incidence of peripheral neuropathy in transplant patients.¹⁰⁷⁻¹¹³ Whether taxane drug levels correlate with neurotoxicity is unclear.^{107,113}

HEMORRHAGIC CYSTITIS

Hemorrhagic cystitis after transplant may be caused by cyclophosphamide or ifosfamide. The nonenzymatic metabolite of these agents, acrolein, causes hyperemia and ulceration of the bladder mucosa, resulting in hemorrhage and focal necrosis. Previously treatment with busulfan appears to increase the risk of hemorrhagic cystitis.¹¹⁴ Prophylaxis includes hyperhydration with forced diuresis, bladder irrigation, or mesna. There is no clear preferred strategy. Randomized studies comparing one prophylactic strategy to another have had mixed results.¹¹⁵⁻¹¹⁹

BK polyoma virus is another cause of hemorrhagic cystitis.^{117,120-123} Several investigators have demonstrated the presence of BK viruria in patients undergoing transplant, not all of whom had hemorrhagic cystitis. Neither background viral reactivation nor urothelial damage explain the increase in BK viruria in patients with hemorrhagic cystitis. This data was corroborated by Bogdanovic and colleagues, who also found that the risk of hemorrhagic cystitis from BK virus was the viral load.¹²⁴

Late hemorrhagic cystitis can also be caused by adenovirus. In both culture and PCR analyses, 60% and 57% of patients were positive for adenovirus, respectively. PCR was not quantitative in this study and therefore no information is available regarding the number of viral copies and extent of disease.¹²⁵

Early microscopic hematuria usually resolves spontaneously. Late hemorrhagic cystitis can result in significant bleeding and pain and treatment can be problematic. A number of therapies have been reported, including bladder instillation with formalin,¹²⁶ prostaglandin E₁¹²⁷ or alum,¹²⁸ electrode fulguration,¹²⁹ suprapubic cystostomy,¹³⁰ and embolization of vesicle arteries.¹³¹ Several patients have been treated with intravesical antibiotics.¹³² Most of these reports are anecdotal, making it difficult to determine whether one is superior to another. Hemorrhagic cystitis may be more common in recipients of unrelated donor stem cells.¹³³

PULMONARY TOXICITY

Idiopathic pneumonia syndrome occurs in 10% or less of patients who undergo transplantation using myeloablative preparative regimens. It occurs in similar frequency among allogeneic and autologous transplant recipients and has a high case-fatality rate, about 75%.^{134,135} IPS occurs a median of 21 days posttransplant and appears to be more common in allogeneic transplant recipients with severe acute GVHD and in patients transplanted for diagnoses other than leukemia.¹³⁴ Almost 70% of patients with IPS require mechanical ventilation a median of 2 days after the onset of radiographic changes. Ventilated patients rarely survive to be discharged from the hospital.^{136,137} Patients with IPS who die usually do so as a result of respiratory failure. Steroids are usually ineffective.

The precise mechanism of IPS is unclear, although the data suggest that a number of proinflammatory events in the peritransplant period are responsible. BAL fluid of patients with lung injury contains increased amounts of TNF- α .^{138,139} Schots et al. reported that serum levels of TNF- α and the inflammatory cytokines IL-6 and IL-8 are increased in patients who develop major treatment-related complications, including IPS.¹⁴⁰ In a small series of patients, neutralization of TNF- α with Etanercept, a soluble, dimeric TNF- α binding protein, resulted in significant improvement in pulmonary function in patients with IPS.¹⁴¹

Other investigators have studied potential markers for IPS, in the hope that they might identify patients at risk and intervene before development of clinical disease. DiNubile and colleagues measured plasma gelsolin levels in 24 patients undergoing allogeneic stem cell transplantation.¹⁴² Gelsolin is one of several proteins found in plasma that bind actin. There was a significant association between the last measured gelsolin

level and survival time posttransplant. Lower gelsolin levels were associated with a higher chance of dying. The authors postulate that the conditioning regimen produces tissue injury that depletes circulating gelsolin.¹⁴³

CONCLUSION

The reduction in toxicity due to ablative regimens is not likely to diminish by the development of new ablative programs. In fact, there are few examples of truly new ablative regimens. Rather, better understanding of the pathophysiology of RRTs will lead to new approaches for their prevention and treatment. Development of newer immunosuppressive regimens, such as the combination of tacrolimus or cyclosporine with mycophenolate mofetil, is likely to make a much greater impact on toxicity than changes in the ablative program itself.

Chapter **101****PHARMACOLOGY OF
TRADITIONAL AGENTS USED
TO TREAT HEMATOLOGIC
MALIGNANCIES***Jennifer L. Shamp***THE HISTORY OF CANCER CHEMOTHERAPY**

The term *chemotherapy* refers to the treatment of cancer or other malignant diseases by using specific drugs that selectively destroy growing cells. Prior to the advent of chemotherapy, two main modalities were used in the treatment of cancer: surgery and radiation. Both options, although effective for many types of cancer, are localized forms of therapy. Chemotherapy provided the first systemic form of treatment, using the bloodstream as a means of disseminating drug to both the tumor site as well as areas of metastasis. Additionally, this provided a major breakthrough in the treatment of hematologic malignancies, such as leukemia and lymphoma, which had previously been virtually untreatable with surgery or radiation.

The advent of modern chemotherapy originated during World War I, with the observation that soldiers who had been exposed to mustard gas, or sulfur mustard, experienced significant decreases in their white blood cell counts, specifically their lymphocytes. Krumbaar first described these findings in 1919, as he noted atrophy of lymphoid and testicular tissue, as well as bone marrow depression, in soldiers who had been subject to poisonings.¹ This observation led investigators to take a closer look at nitrogen mustard, a compound closely related to sulfur mustard, as an antitumor agent. Various animal studies took place throughout the 1920s and 1930s, and advances in the use of nitrogen mustard as a topical anticancer agent were made.¹ With the start of World War II, initiatives in chemical warfare again intensified. Further study of nitrogen mustard and related compounds suggested that the basic effects on cellular mechanisms could be compared to that of X-rays. A true breakthrough occurred at Yale University in 1942, when Goodman, Gilman, Philips, and Allen discovered the systemic

antitumor activity of nitrogen mustard.² Because of wartime secrecy, these findings were not published until 1946. Their observations in animals led to the first human study, in 1942, of a man with “x-ray resistant lymphosarcoma.” After 10 days of therapy with this compound, the result was striking, as the patient’s tumors had virtually melted away.³ Although the patient relapsed one month later, a new era in the treatment of cancer had begun.

**CHEMOTHERAPEUTIC AGENTS USED
IN THE TREATMENT OF HEMATOLOGIC
MALIGNANCIES****ALKYLATING AGENTS**

Thousands of variants of the basic chemical structure of nitrogen mustard have been developed over the years, but few have matched the success and utility of the original compound. These variants include some of the oldest, yet most valuable of all antineoplastic drugs. Five basic types of alkylating agents are currently in use.

- Nitrogen mustard derivatives (mechlorethamine, cyclophosphamide, ifosfamide, melphalan, chlorambucil)
- Ethylenimines (triethylenemelamine, thiotepa, altretamine)
- Alkyl sulfonates (busulfan)
- Nitrosoureas (carmustine, streptozocin)
- Triazines (dacarbazine)

The chemotherapeutic effect of alkylating agents is attributed to their highly reactive alkyl groups, which form covalent bonds with nucleophilic groups found on proteins and nucleic acids.⁴ The alkylating agents by nature are strong electrophiles (electron acceptors), which react quickly with nucleophiles (electron donors)

found on DNA bases, such as phosphate, amino, sulfhydryl, hydroxyl, carboxyl, and imidazole groups. Ultimately, these bonds result in cross-linking of DNA base pairs, either between two strands of DNA or within the same strand. This cross-linking prevents the DNA strand from unwinding properly for replication, ultimately leading to inhibition of DNA synthesis and cell death.^{4,5} It is thought that apoptosis is stimulated by p53 pathways in response to this DNA damage. Alkylating agents can affect cells at any point in the cell cycle (cell-cycle nonspecific), but rapidly dividing cells experience the strongest insult.

Toxicity

As Krumbhaar noted in 1919, poisoning caused by sulfur mustard is characterized by aplasia of bone marrow, dissolution of lymphoid tissue, and ulceration of the gastrointestinal tract.¹ While the alkylating agents differ somewhat in spectrum of activity and severity of adverse effects, most exhibit toxicities similar to those observed with the original agent. These compounds are typically dose-limited by suppressive effects on the bone marrow. Myelosuppression often manifests acutely, with an onset of 6–10 days and recovery within 14–21 days.⁵ Some compounds, such as busulfan and carmustine, exhibit a prolonged suppression of granulocytes and platelets, and for this reason are commonly used in stem cell transplant preparative regimens. Suppression of both cellular and humoral immunity occurs frequently. The rapidly dividing cells of the intestinal mucosa are particularly sensitive to the effects of alkylating agents, evidenced by mucositis and stomatitis. Specific organ toxicities, such as pulmonary fibrosis, have been reported with all alkylating agents. In addition, this entire class of compounds is associated with a high incidence of secondary malignancies, affecting up to 5% of exposed patients⁶ (Table 101.1).

Selected alkylating agents

Cyclophosphamide Cyclophosphamide is a nitrogen-mustard derivative that possesses a broad spectrum of activity. Its clinical usefulness is widespread, and it remains a key component of treatment regimens for a variety of malignancies, including non-Hodgkin's lymphoma and acute lymphocytic leukemia.⁵ Additionally, the immunosuppressive properties of cyclophosphamide have been found to be effective in the treatment of various nonmalignant conditions, such as Wegener's granulomatosis, rheumatoid arthritis, nephrotic syndrome, and control of organ rejection after transplantation.⁵

Cyclophosphamide is a prodrug and requires activation by hepatic cytochrome P450 2B enzymes for its therapeutic effect. It is converted to 5-hydroxyphosphamide, which exists in equilibrium with its tautomer, aldophosphamide. Further conversion to phosphoramidate mustard in susceptible cells results in liberation

of the active alkylating compound and subsequent cell toxicity.¹⁷

Pharmacokinetics/metabolism: Cyclophosphamide is well absorbed from the gastrointestinal tract and is available for both oral and intravenous administration. It distributes widely to tissues, and penetrates the CNS to a small extent.¹⁸ Hepatic metabolism is required for conversion of cyclophosphamide to its active form as well as inactive metabolites. These inactive metabolites undergo renal excretion along with unchanged drug (<15%).¹⁸

Toxicity: The dose-limiting toxicity of cyclophosphamide is myelosuppression, mainly leukopenia. While white blood cells are sensitive to cyclophosphamide, platelets are less affected. Alopecia, dose-dependent nausea and vomiting, mucositis, and stomatitis are common. Cardiac dysfunction, manifesting as congestive heart failure, has occurred rarely. Cyclophosphamide may potentiate the cardiac toxicity of anthracyclines.⁵ The classic toxicity associated with cyclophosphamide (as well as the structurally related ifosfamide) is hemorrhagic cystitis, which has been reported in up to 15% patients.⁹ Acrolein, a toxic metabolite of both cyclophosphamide and ifosfamide, is thought to bind to crucial thiols in the bladder wall, causing mucosal damage. This creates a syndrome of hematuria, urinary frequency, and irritation.¹⁹ In severe cases, massive hemorrhage and bladder carcinoma can occur. Aggressive hydration and therapy with the detoxifying agent mesna, which binds acrolein in the bladder and prevents mucosal attachment, can minimize the risk of this effect.¹⁹

Busulfan Busulfan is an alkyl sulfonate derivative that reacts with the N7 position of guanosine, leading to cross-linking of DNA strands and subsequent inhibition of DNA synthesis. Busulfan is unique in that it affects the cells of myeloid origin to a greater extent than those of lymphoid origin.⁵ In addition, busulfan is toxic to hematopoietic stem cells and is thus frequently used in stem cell transplant preparative regimens.

Pharmacokinetics/metabolism: Busulfan is rapidly and completely absorbed from the gastrointestinal tract and is available for oral and intravenous administration. It distributes widely throughout the body and achieves CSF levels similar to concurrent plasma levels.^{12,19} The compound undergoes extensive metabolism in the liver and is a substrate for cytochrome P450 3A3/4. Approximately 10–50% metabolites are excreted in the urine. Half-life ranges from 2 to 3 h.¹⁹

Toxicity: The most notable toxicity of busulfan is the profound suppression of the bone marrow; severe pancytopenia is also common and often indication of the compound. This is a delayed effect, with the onset of myelosuppression occurring 7–10 days after the therapy is initiated. Other common toxicities include urticaria, skin hyperpigmentation, and alopecia. At

Table 101.1 Alkylating agents in the treatment of hematologic malignancies

Agent	Clinical uses	Mechanism of action	Common toxicities
Nitrogen mustard derivatives Mechlorethamine	HD, NHL	Bifunctional alkylating agent with two reactive groups ⁵	Acute <ul style="list-style-type: none"> ■ DLT^a = Myelosuppression (onset 4–7 days) ■ Severe nausea/vomiting (onset 30 min to 2 h⁷) ■ Extravasation (vesicant) Chronic <ul style="list-style-type: none"> ■ Secondary malignancies ■ Sterility

^aDLT = dose-limiting toxicity.

higher doses, such as those used in stem cell transplant regimens, adverse effects become more severe. Mild nausea and vomiting may occur. In addition, because of its ability to readily penetrate the CNS, busulfan can lower the seizure threshold, causing generalized tonic-clonic seizures.¹² For this reason, prophylactic antiepileptic medications are commonly administered. Venous occlusive disease, or VOD, is thought to be associated with high doses of busulfan.¹² Finally, pulmonary toxicity can occur. “Busulfan lung” is characterized by pulmonary fibrosis and presenting symptoms include nonproductive cough, shortness of breath, and weight loss.^{5,12,19} This complication may correlate with duration of busulfan therapy, with a higher incidence occurring in those who have received

greater than 3 years of treatment. It is often fatal, with average survival of 5 months after diagnosis.¹⁹

ANTIMETABOLITES

As a class, antimetabolites exhibit S-phase specific cytotoxicity. These agents chemically resemble the purine and pyrimidine nucleoside bases involved in normal cellular DNA replication (adenine, guanine, cytosine, and thymine) or impair enzymes involved in protein or DNA synthesis. These nucleoside analogs essentially “trick” cells into incorporating the toxic drug into newly synthesized DNA strands in place of normal nucleotide bases.^{5,20} This leads to synthesis inhibition and chain termination. Multiple antimetabolites are currently in use (Table 101.2).

Table 101.2 Antimetabolite compounds and selected toxicities

Agent	Mechanism of action	Clinical uses	Common toxicities
Purine analogs Fludarabine, Fludara	Adenosine analog; incorporated into DNA resulting in chain termination; also inhibits ribonucleotide reductase, which depletes cells of deoxyribonucleotide triphosphate pools	CLL, NHL	<ul style="list-style-type: none"> ■ DLT^a = Myelo-suppression (onset 10–14 days²¹) ■ Neurotoxicity ■ Immunosuppression (can last up to 2 years²²) ■ Mild nausea/vomiting ■ Interstitial pneumonitis (onset ranges from 3 days after first cycle to 6 days after seventh cycle²³)
Cladribine, 2-CDA, Leustatin	Adeosine analog; incorporated into DNA resulting in chain termination; also inhibits ribonucleotide reductase, which depletes cells of deoxyribonucleotide triphosphate pools	Hairy cell leukemia, NHL	<ul style="list-style-type: none"> ■ DLT = Myelo-suppression (onset 7–14 days²⁴) ■ Immunosuppression (onset 4–6 months; typically lasts 1 year, may last up to 40 months²⁴) ■ Fever
6-Mercaptopurine, 6-MP	Hypoxanthine analog; interferes with purine biosynthesis; also incorporated into DNA resulting in chain termination ²⁵	ALL	<ul style="list-style-type: none"> ■ Mucositis ■ Diarrhea ■ Mild myelosuppression (onset 7–10 days²⁴) ■ Hepatotoxicity, jaundice (onset typically 2–3 months²⁴)
6-Thioguanine, 6-TG	Guanine analog; incorporated into DNA resulting in chain termination ²⁵	AML, ALL	<ul style="list-style-type: none"> ■ DLT = Myelo-suppression (onset 7–10 days²⁶) ■ Mild nausea/vomiting ■ Immunosuppression²⁶ ■ Mucositis ■ Diarrhea
Pyrimidine analogs Cytarabine, Cytosine arabinoside, Ara-C, Cytosar-U	Cytidine analog; incorporated into DNA resulting in chain termination; also inhibits DNA polymerase resulting in decreased DNA synthesis/repair	AML, ALL, CNS leukemia, NHL	Moderate dose <ul style="list-style-type: none"> ■ DLT = Myelo-suppression (onset 4–7 days²⁷) ■ Alopecia ■ Mild nausea/vomiting High dose (>1 g/m ²) <ul style="list-style-type: none"> ■ Cerebellar toxicity (onset typically 5 days²⁸) ■ Myelosuppression ■ Severe nausea/vomiting (onset 1–3 h, typically lasts 3–8 h²⁷) ■ Conjunctivitis ■ Transient hepatic dysfunction (elevation of serum transaminases) ■ Pulmonary complications ■ “Ara-C syndrome”: allergic reaction characterized by fever, myalgias, rash, conjunctivitis (onset 12 h after infusion²⁸)

table continues

Table 101.2 continued

Agent	Mechanism of action	Clinical uses	Common toxicities
Gemcitabine, Gemzar	Cytidine analog; incorporated into DNA resulting in chain termination; ^{29,30} Also inhibits ribonucleotide reductase, depleting cells of deoxyribonucleotides required for DNA synthesis	Investigational use in Hodgkin's disease, cutaneous T-cell lymphoma, mantle cell lymphoma, CLL	<ul style="list-style-type: none"> ■ DLT = Myelo-suppression (onset 7–10 days³¹) ■ Hepatic transaminase elevations (transient) ■ Proteinuria, hematuria ■ Generalized rash ■ Flu-like symptoms, fever (onset 6–12 hours³¹)
Decitabine, 2'-deoxy-5-azacytidine, Aza dC, DAC, dezocitidine	Cytidine analog; incorporated into DNA resulting in chain termination; once incorporated into DNA, inhibits DNA methyltransferase enzymes (DNMTs), preventing the transfer of a methyl group to DNA strands ³² . Formerly silenced genes are subsequently activated, altering cell differentiation and apoptosis pathways.	Investigational studies in refractory AML, CLL, Small lymphocytic lymphoma, MDS	<ul style="list-style-type: none"> ■ Myelosuppression (onset 14 days, may last up to 30 days) ■ Nausea/vomiting ■ Fatigue, lethargy ■ Hepatic transaminase elevations
5-azacytidine	Cytidine analog; incorporated into DNA resulting in chain termination; once incorporated into DNA, inhibits DNA methyltransferase enzymes (DNMTs), preventing the transfer of a methyl group to DNA strands ³² . Formerly silenced genes are subsequently activated, altering cell differentiation and apoptosis pathways. Also incorporated into RNA, altering tRNA methylation and inhibiting protein synthesis ³² .	CML, AML, myelodysplasia	<ul style="list-style-type: none"> ■ Myelosuppression ■ Nausea/vomiting ■ Diarrhea ■ Mutagenic potential
Pentostatin, 2-Deoxycoformycin, Nipent	Inhibits adenosine deaminase, which metabolizes adenosine and deoxyadenosine; leads to accumulation of deoxyadenosine triphosphate (dATP), which inhibits ribonucleotide reductase and causes cell death	Hairy cell leukemia	<ul style="list-style-type: none"> ■ DLT = Myelo-suppression (onset 7–10 days³³) ■ Immunosuppression ■ Severe nausea/vomiting (onset 12–24 h after infusion¹¹) ■ Transient hepatic transaminase elevations ■ Nephrotoxicity and neurotoxicity (rare at current doses) ■ Transient lethargy, confusion
Folic acid analog Methotrexate	Folic acid analog; binds DHFR and inhibits conversion of folic acid to active "tetrahydro" form, which deprives cells of necessary precursor for thymidylate and purine synthesis ⁹	ALL, CNS leukemia, NHL, BMT	<ul style="list-style-type: none"> ■ DLT = Myelo-suppression (onset 4–7 days) ■ Mucositis, stomatitis (onset 3–7 days¹¹) ■ Hepatic transaminase elevations (onset 12–24 h, usually lasts 10 days¹¹) ■ Pulmonary toxicity ■ Nephrotoxicity

^aDLT= dose-limiting toxicity.

Antimetabolites: Selected nucleoside analogs

Cytarabine Cytarabine is an antimetabolite that is currently considered the foundation of treatment for AML. It is one of the most active agents available against this disease and has been considered an integral component of induction and postremission therapy for the past two decades. In addition, cytarabine exhibits significant activity against lymphomas, meningeal leukemia, and meningeal lymphoma. It has little use in the treatment of solid tumors. Cytarabine is administered in a wide range of doses, and evidence supports a significant dose-response effect.³⁴

Chemically, cytarabine is the arabinose analog of the nucleotide base cytosine. Arabinose analogs differ from human analogs by the placement of a hydroxyl group on the sugar moiety of the nucleoside. Cytarabine penetrates cells via a carrier-mediated transport process, where it must be phosphorylated by the enzyme deoxycytidine kinase (dCK) to its active form, ara-CTP. Because of its structural similarity to cytosine, ara-CTP is directly incorporated into DNA in place of cytosine, where it terminates strand elongation by inhibiting DNA replication. This antimetabolite effect is thought to be the main mechanism of cytarabine activity at moderate doses (100–200 mg/m²). In addition, cytarabine further affects DNA synthesis by direct inhibition of the enzyme DNA polymerase, which is responsible for strand elongation as well as DNA repair. The degree of activity correlates linearly with the degree of incorporation into DNA. This is heavily influenced by the plasma cytarabine concentration.³⁵

Pharmacokinetics/metabolism: Cytarabine is degraded within the cell by cytidine deaminase to the inactive compound uracil arabinoside, or ara-U. Cytarabine is widely distributed in the body, with a volume of distribution approximating total plasma volume. It penetrates the CNS and achieves concentrations approximately 20–40% of simultaneous plasma levels.¹⁹ Cytarabine is metabolized extensively in the liver and excreted as metabolites within 36 h; approximately 80% is excreted in the urine as ara-U. The plasma half-life is 2–6 h, while the CSF half-life is longer, ranging from 2 to 11 h.^{5,19}

Toxicity: Toxicity of cytarabine is dose-dependent; at higher doses (>1 g/m²), cytarabine is dose-limited by cerebellar toxicity. This often manifests as a syndrome of dysarthria, nystagmus, and ataxia, and may progress to generalized encephalopathy and seizures. Some degree of CNS toxicity has been documented in up to 40% of patients receiving high-dose cytarabine.¹⁹ This is typically reversible upon discontinuation of drug, but may be permanent. It is highly correlated with older age, renal dysfunction, and elevated alkaline phosphatase levels, and dose adjustments are strongly recommended for both groups of patients.^{5,19,36,37} In addition, high-dose cytarabine can cause severe conjunctivitis, maculopapular skin rash, palmar-plantar erythema, and hepatic toxicity characterized by

cholestatic jaundice. At lower doses, cytarabine can cause significant myelosuppression. Alopecia and dose-related nausea and vomiting are common as well.⁵

Gemcitabine Gemcitabine is a pyrimidine analog, structurally similar to cytarabine, and was initially developed as an attempt to expand upon the cytotoxic effects of the latter agent. Chemically, it differs from cytarabine by the substitution of geminal fluorines for the hydroxyl group at the 2' position.^{20,38} This chemical alteration allows for greater cellular permeability and increased affinity for the enzyme dCK, which phosphorylates gemcitabine to its active gemcitabine-5'-triphosphate form.³⁸ This compound, upon incorporation into DNA, results in chain termination. Increased cellular transport and increased affinity for dCK allow for greater intracellular retention and accumulation of gemcitabine as compared to cytarabine. This may account for the extended spectrum of activity seen with the newer compound.²⁵ In addition, there is evidence that gemcitabine inhibits ribonucleotide reductase, leading to the depletion of cellular deoxyribonucleotide triphosphate pools. This not only depletes cells of active nucleotides essential for DNA synthesis, but also propagates the toxicity of gemcitabine. Cells are forced to further incorporate gemcitabine into DNA strands because of the lack of competition with normal nucleotides. Additionally, as a result of the structural conformation of gemcitabine, a normal base pair is routinely added to DNA strands just after incorporation of the toxic compound. This effectively protects gemcitabine from being excised by DNA repair enzymes from the newly formed strand, and ensures cell death. This mechanism has been termed "masked chain termination." Gemcitabine has demonstrated activity in a variety of solid as well as hematologic malignancies, including Hodgkin's disease, mantle cell lymphoma, and chronic lymphocytic leukemia.³⁸

Pharmacokinetics/metabolism: Extensive deamination of gemcitabine occurs in the gastrointestinal tract; therefore, the compound is not active orally and is available only as a solution for injection. Deamination by cytidine deaminase is the primary metabolic route, which occurs in liver, plasma, and peripheral tissues. More than 90% of drug is recovered in the urine as the difluorouridine metabolite.^{5,19} Because of the dependence of half-life on infusion duration, many infusion schedules have been evaluated. A longer infusion duration (>70 min) is associated with a longer half-life (4–10 h) and increased clinical activity.^{29,30}

Toxicity: The dose-limiting toxicity associated with gemcitabine is myelosuppression, mainly consisting of neutropenia. Nausea and vomiting are mild. Acutely (within 6–12 h of drug administration), fever and flu-like symptoms, such as headache, chills, malaise, and myalgias, are common. Elevations in hepatic transaminases may occur and caution should be used when

treating patients with underlying hepatic dysfunction.³⁹ Mild proteinuria and hematuria have been reported frequently.^{5,19} A generalized, macropapular rash occurs in approximately 25% of patients; this is typically reversible and does not usually require discontinuation of drug.¹⁹

Fludarabine Fludarabine monophosphate is a structural analog of the purine adenine. Initially, the arabinose analog of adenine, ara-A, was developed. However, because of the rapid inactivation by adenosine deaminase enzymes, the drug exhibited less than optimal antitumor activity. The addition of a fluorine atom resulted in a compound that retained antitumor activity, while resisting inactivation by deaminase enzymes.⁵ Thus, F-ara-A or fludarabine was developed. This compound is highly effective in the treatment of chronic lymphocytic leukemia; in addition, it has activity in acute leukemia and non-Hodgkin's lymphoma.¹⁹

Similar to cytarabine and other nucleoside analogs, fludarabine requires transport into tumor cells and activation to its triphosphate form for cytotoxic activity. The first step in this phosphorylation is performed by the enzyme dCK, which results in the active compound F-ara-ATP. This compound is active in both dividing and resting cells.⁴⁰ DNA synthesis inhibition results from competitive uptake of F-ara-ATP, rather than adenine, by dividing cells for incorporation into DNA strands. Once incorporated, chain elongation is halted, inhibiting DNA synthesis. F-ara-ATP exhibits additional activity through inhibition of specific enzymes, such as DNA polymerase α , DNA ligase, and topoisomerase II.⁴¹ These actions are S-phase specific, and incorporation of fludarabine into DNA at this point in cell division is required for apoptosis. Unlike cytarabine, fludarabine is also incorporated into RNA, where it inhibits the RNA polymerase II enzyme. Subsequently, RNA transcription is terminated, and protein synthesis cannot be achieved. This may account for the activity of fludarabine in resting cells.⁴¹ Finally, evidence indicates that fludarabine may activate apoptotic pathways as well, by stimulating APAF-1, which subsequently leads to activation of caspase-9 and caspase-3 pathways.⁴⁰

Pharmacokinetics/metabolism: Fludarabine is inactivated by deaminase enzymes, particularly adenine deaminase. Its terminal elimination half-life is approximately 10 h and renal excretion is the primary route of elimination.⁴² As excess toxicity results from accumulation of drug in renal dysfunction, dosage adjustments are recommended for patients with moderate renal dysfunction (creatinine clearance 30–70 ml/min). Fludarabine should be avoided for patients with severe renal dysfunction (creatinine clearance <30 ml/min).⁴³

Toxicity: When fludarabine was first developed, doses were limited by neurologic toxicity. At these

higher doses, a syndrome of delayed CNS toxicity was seen, characterized by paralysis and coma. It was eventually found that fludarabine could be used in lower doses, maintaining activity at less risk to the patient. For the doses used currently, severe CNS toxicity is rare.¹⁹ A small portion of patients experience some degree of neurotoxicity, which can manifest as somnolence, paresthesias, and peripheral neuropathies. The dose-limiting toxicity of fludarabine is now considered to be myelosuppression.^{5,19,42} Immunosuppression is common as well, and suppression of CD4 and CD8 cells can last up to a year before returning to normal levels. Slowly reversible, dose-dependent pulmonary toxicity consistent with interstitial pneumonitis has been reported rarely.

Antimetabolites: Folic acid analog

Methotrexate Methotrexate is a unique antimetabolite that is used in a multitude of malignancies, including solid tumors, lymphomas, and lymphocytic leukemias as well as a variety of autoimmune and inflammatory disorders. This agent is the most well characterized and widely used of all the antimetabolites.

Methotrexate differs structurally from folic acid by replacement of a hydroxyl group with an amino group on the pteridine ring, as well as an additional methyl group.¹⁹ Access to the target site of action is achieved through specific intracellular transport systems, which are mediated by the reduced folate carrier and folate receptor protein. Methotrexate exerts its cytotoxic effect through inhibition of the enzyme dihydrofolate reductase (DHFR). This enzyme is responsible for converting dietary folates to their reduced or active "tetrahydro" form for use by cells in thymidylate and purine synthesis. Through binding of DHFR to methotrexate, intracellular pools of reduced folates are depleted and synthesis of DNA is prevented.⁵ This action can be overcome by supplying the active tetrahydro form of folate to cells exogenously; this compound is known as leucovorin or folinic acid.

Pharmacokinetics/metabolism: Oral bioavailability is variable and incomplete. Methotrexate distributes widely to tissues, including the CNS. In moderate doses, CNS levels are low; however, at high methotrexate doses (>1 gm/m²) therapeutic CNS levels are achieved. Methotrexate can accumulate in fluid collections, such as pleural fluid and ascites. These fluid accumulations can act as reservoirs, slowly releasing methotrexate into the bloodstream over a prolonged time course.¹⁹ Methotrexate undergoes hepatic metabolism and enterohepatic cycling to various metabolites, which are eliminated renally (filtration and active secretion). Methotrexate solubility is pH-dependent, and methotrexate can crystallize in the renal tubules at high doses.⁵ Alkalinization of the urine increases the solubility of methotrexate, minimizing the risk of this complication. Terminal half-life is approximately 8–10 h, but can be prolonged to

over 20 h in patients with renal insufficiency, impaired enterohepatic cycling, or significant third-space fluids.¹⁹

Toxicity: The dose-limiting toxicity of methotrexate is myelosuppression. Granulocytes and platelets are the cell lines most affected. Mucositis, stomatitis, and mucosal ulceration can be severe. At higher doses, nephrotoxicity and acute renal failure can result from intratubular precipitation of drug. Hepatic toxicity is characterized by elevations in serum transaminases and bilirubin, portal fibrosis, and occasionally cirrhosis. Pulmonary toxicity is rare but potentially fatal. CNS toxicity can result from intravenous administration as well as direct intrathecal administration.¹⁹

ANTITUMOR ANTIBIOTICS

Antitumor antibiotics: Anthracyclines, anthracene derivatives

Daunorubicin, doxorubicin, idarubicin Anthracyclines are among the most effective antineoplastic agents

ever developed; the various compounds have been in use for more than 20 years (Table 101.3). They possess a wide spectrum of activity against a variety of solid tumors and hematologic malignancies and are an essential component of current therapies in AML, ALL, and Hodgkin's disease, to name a few. These compounds share an aglycone or sugar moiety attached to a four-membered anthracene ring complex, known as a chromophore. It is this chromophore that gives these drugs their intense coloring. The original anthracyclines, doxorubicin and daunorubicin, were derived from the pigment-producing bacteria *Streptomyces peucetius* in the early 1960s.⁵⁸

The anthracene derivatives are cell-cycle nonspecific; however, they exert the greatest activity against rapidly dividing cells. The mechanism of action of these agents is still being elucidated and remains somewhat controversial. There is evidence supporting a variety of mechanisms.^{58,59} Traditionally, anthracyclines have been considered intercalating agents. Because of

Table 101.3 Common properties of anthracene and anthracenedione derivatives

Agent	Dosing information	Clinical uses	Dose adjustments
Anthracene derivatives			
Doxorubicin	Dose range, 40–75 mg/m ² Maximum cumulative dose, ⁴⁴ 550 mg/m ² * <i>If prior RT</i> , 450 mg/m ²	All, Hodgkin's disease, NHL, sarcomas, germ cell tumors, many solid tumors (breast, stomach, head/neck, liver, bladder)	Renal impairment ⁴⁵ ■ CrCl < 10 ml/min: give 75% dose Hepatic impairment ⁴⁶ ■ Bilirubin 1.2–3 mg/dl: give 50% dose ■ Bilirubin 3.1–5 mg/dl: give 25% dose ■ Bilirubin > 5 mg/dl: avoid use
Daunorubicin	Dose range, 45–90 mg/m ² Maximum cumulative dose, ⁴⁷ 550 mg/m ² * <i>If prior RT</i> , 400 mg/m ²	ALL, AML	Renal impairment ⁴⁸ ■ CrCl < 10 ml/min: give 75% dose Hepatic impairment ⁴⁸ ■ Bilirubin 1.2–3 mg/dl: give 75% dose ■ Bilirubin 3.1–5 mg/dl: give 50% dose ■ Bilirubin > 5 mg/dl: Avoid use
Idarubicin	Dose range, 10–12 mg/m ² Maximum cumulative dose: doses of 150–290 mg/m ² have resulted in 5% chance of cardio-myopathy ⁴⁹	AML, ALL	Renal impairment ⁵⁰ ■ Serum creatinine ≥ 2 mg/dl: give 75% dose Hepatic impairment ^{50,51} ■ Bilirubin 1.5–5 mg/dl: give 50% dose ■ Bilirubin > 5 mg/dl: avoid use
Anthracene-dione derivatives			
Mitoxantrone	Dose range, 10–15 mg/m ² Maximum cumulative dose: doses exceeding 80–120 mg/m ² have been associated with a higher incidence of cardio-myopathy ^{52–56}	AML	Renal impairment ⁵⁷ : not necessary Hepatic impairment: dose reduction advised; no guidelines available

their planar structure and positively charged sugar moieties, anthracyclines are thought to “intercalate” or insert between negatively charged phosphate bridges of DNA base pairs, binding tightly and creating covalent bonds. Two types of bonds are formed: more stable drug–DNA cross-links and less stable drug–DNA adducts.⁵⁸ These bonds create torsional strain and lead to DNA deformation and uncoiling. Additionally, this intercalation interferes with several enzymes involved in DNA replication and transcription, including helicase, DNA polymerase, and RNA polymerase.⁵⁹

Anthracyclines are also considered potent topoisomerase II poisons. Topoisomerase is an enzyme that temporarily relieves torsional strain during DNA synthesis. The topoisomerase enzymes accomplish this task by causing temporary single-strand (topoisomerase I) or double-strand (topoisomerase II) DNA breaks, and subsequently resealing these breaks after twisting of the double helix is modified. A structurally dependent function of the anthracene derivatives is to stabilize a reaction intermediate in which DNA strands are cleaved and covalently linked to topoisomerase II, impeding DNA resealing. This DNA damage is followed by growth arrest in G1 and G2 phases and programmed cell death.⁵⁸

Generation of free radicals and subsequent lipid peroxidation occurs with anthracyclines as well, and this mechanism is thought to contribute to the efficacy as well as the cardiotoxicity of these compounds. Electron transfer and reduction of anthracyclines takes place quickly, leading to the formation of superoxide anions and hydrogen peroxide. These highly reactive compounds bind iron, generating the most toxic of the hydroxyl radicals, which can cleave DNA. The ability of various tissues to diffuse these free radicals is thought to account for the characteristic distribution of anthracycline toxicity.^{5,58}

Pharmacokinetics/metabolism: Anthracyclines as a class distribute rapidly and widely to all body tissues except the CNS, accounting for a large distribution volume. Metabolism occurs mainly in the liver, followed by biliary excretion. Elimination is biphasic, with estimated half-lives of approximately 30 h for doxorubicin, 15–20 h for daunorubicin, and 15–20 h for idarubicin. Renal elimination accounts for <10% of total clearance with each of these compounds; however, enough drug escapes to color the urine bright red or orange.¹⁹

Toxicity: The most common short-term toxicity associated with these compounds is myelosuppression, characterized mainly by leukopenia. Other common effects include alopecia, moderately severe nausea and vomiting, and mucositis. The most notorious adverse effect associated with the anthracyclines is cardiotoxicity. This typically manifests as chronic congestive cardiomyopathy, which is cumulative and dose-dependent.⁵⁸ It is thought to result from numerous factors related to anthracycline treatment, including

free-radical accumulation in the cardiac myocytes, increased membrane lipid peroxidation, changes in adrenergic function and adenylate cyclase, irreversible decrease in mitochondrial calcium loading and ATP content, and induction of nitric oxide synthase, leading to nitric oxide activation of metalloproteinases. These effects depend on peak drug concentrations as well as cumulative dose.⁵⁸ Continuous infusion may decrease the risk of cardiotoxicity by decreasing the peak concentration; however, this results in much greater stomatitis.¹⁹ Patients are also at risk for late onset cardiotoxicity, characterized by left ventricular dysfunction and arrhythmias.

Antitumor antibiotics: Anthracenedione derivatives

Mitoxantrone Mitoxantrone, developed in an attempt to create an anthracene derivative with an improved toxicity profile, is actually an anthracenedione. Structurally, it is composed of a three-membered anthracene complex and lacks a sugar moiety.¹⁹ Mitoxantrone intercalates between DNA base pairs, resulting in inhibition of DNA synthesis and function, as well as inhibiting topoisomerase II. However, it is thought to have a decreased tendency for free radical formation and thus there is a lower chance of cardiotoxicity. Recent reports have challenged this assumption, however, and it is generally thought to exhibit a similar cardiotoxicity profile to the structurally similar anthracyclines.⁶⁰

Antitumor antibiotics: Miscellaneous compounds

Bleomycin Bleomycin is a small peptide compound that is isolated from the fungus *Streptomyces verticillus*. While the drug contains 13 identifiable peptide fractions, the primary component (approximately 70% of commercial product) is bleomycin A2. Bleomycin requires the presence of iron for activity; bleomycin–iron complexes can bind directly to DNA, and upon oxidation, form free radical intermediates that lead to single and double strand breaks.⁶¹ The DNA lesions introduced by bleomycin are similar to those seen with ionizing radiation.⁶² This agent has activity in a variety of malignancies, including testicular cancer and Hodgkin’s lymphoma, and is an integral component in the treatment of these diseases.

Pharmacokinetics/metabolism: Bleomycin is poorly absorbed orally, and is available only as a solution for injection. It distributes to intracellular and extracellular fluid, and achieves its highest concentrations in skin, kidney, lung, and heart tissues. It does not penetrate the CNS.⁶¹ Bleomycin is degraded by the enzyme bleomycin hydrolase, which is present in tissues throughout the body. Lowest levels of this enzyme are found in the skin and lungs, which may account for the toxicity profile associated with this agent. Renal excretion is the primary route of bleomycin elimination, with 45–70% of drug excreted unchanged in the urine.¹⁹ Dose adjustments are recommended in patients with renal dysfunction, as elimination half-

life is extended from 2 to 4 h to more than 20 h in these patients.¹⁹

Toxicity: The skin and lungs are the organs most sensitive to the toxic effects of bleomycin. Mucocutaneous toxicity is common, and typically occurs 14–21 days after treatment.⁵ This can present as erythema, hyperpigmentation, ulceration, skin peeling, and thickening of the nail beds. Stomatitis and alopecia are common as well. Pulmonary toxicity is dose-limiting and can occur months after completion of therapy. It has been associated with cumulative dose (>400 units) as well as advanced age, renal dysfunction, preexisting pulmonary disease, and previous chest irradiation.¹⁹ Interstitial pneumonitis is characteristic, presenting as cough and dyspnea with nonspecific radiograph findings. This complication can be fatal or reversible. Hypersensitivity reactions, such as fever and chills, occur in up to 25% of patients treated with bleomycin. These reactions are thought to be due to direct release of pyrogens rather than histamine, and can often be managed with antipyretics.¹⁹ Nausea and vomiting are mild, as is myelosuppression.

VINCA ALKALOIDS

Vincristine, vinblastine, vindesine, vinorelbine

The vincas are natural compounds originally derived from the periwinkle plant. Two of these compounds, vincristine and vinblastine, are used in the treatment of a variety of hematological malignancies, including lymphocytic leukemia, lymphoma, Hodgkin's disease, and myeloma.

Vinca alkaloids are known as “spindle poisons,” because of their ability to inhibit the assembly of microtubules. This targeting of microtubules is thought to be one of the most important sites of anti-tumor activity discovered to date.⁶³ These compounds act by directly binding to the “vinca domain” on tubulin, blocking its ability to polymerize into microtubules.⁶⁴ Microtubules are cytoskeletal fibers, comprising tubulin subunits, which are responsible for a variety of cellular functions crucial to mitosis, including chromosomal segregation and maintenance of cellular shape. Disruption of microtubule dynamics by vinca alkaloids results in absence of a mitotic spindle, which leads to irregular dispersion of chromosomes throughout the cytoplasm. Ultimately, cells are arrested during mitosis in the metaphase/anaphase transition, and apoptosis occurs. Microtubules are responsible for a variety of other cellular functions as well, including cellular transport and motility, phagocytosis, neurotransmission, and axonal transport.⁶⁵ Inhibition of these nonmitotic cellular functions may account for some of the adverse effects common to the vinca alkaloids.

Pharmacokinetics/metabolism: Vinca alkaloids, as a class, are poorly absorbed from gastrointestinal tract. They are only available for intravenous administration. Distribution occurs mainly within the blood, and

the compounds bind tightly to blood components. Penetration of the CNS is poor. All four compounds are metabolized extensively by the liver and excreted in the bile. Small amounts of unchanged drug are recovered in the urine. Dosage adjustments are recommended for patients with hepatic dysfunction to avoid excessive toxicity.¹⁹

Toxicity: Although vincas are structurally similar, their spectra of activity and adverse effects differ significantly. The dose-limiting toxicity of vincristine is neurotoxicity, likely due to inhibition of microtubule effects related to neuronal transmission.⁶⁵ This can manifest as sensory and/or motor neuropathy and is characterized by paresthesias, palsies, and pain. Autonomic complications, such as abdominal pain, orthostatic hypotension, constipation, and paralytic ileus, may also occur. For this reason, vincristine doses have traditionally been limited to 2 mg, although recent protocols are challenging this maximum dose. Other adverse effects associated with vincristine include SIADH and alopecia. Fatal cases of intrathecal administration have been reported.⁶⁶ While the potential for myelosuppression exists with vincristine, it is uncommon at standard doses. Conversely, the dose-limiting toxicity for vinblastine and vinorelbine is myelosuppression. Anemia and thrombocytopenia can occur, but leukopenia is most significant.⁵ Although neurotoxicity may occur, it is much less common than with vincristine. This primarily manifests as myalgias and arthralgias and occurs more commonly with vinorelbine than vinblastine.⁵

PODOPHYLLOTOXIN DERIVATIVES

Etoposide, teniposide

Podophyllotoxin is an extract from the mandrake plant (mayberry or podophyllum). This compound is a well-known spindle poison that binds to microtubule proteins and inhibits assembly of microtubules. The podophyllotoxin derivatives, etoposide and teniposide, while originally developed in an effort to retain the activity of podophyllotoxin, both exert their anti-tumor activity through a different mechanism.^{5,67} Teniposide differs from etoposide by the addition of a sulfur-containing group in place of a methyl group on the sugar ring and is approximately 10-fold more potent than etoposide in vitro.¹⁹ These agents are active against a variety of malignancies, including small cell lung cancer, testicular cancer, leukemia, and lymphoma.

Etoposide and teniposide are thought to exert their activity by binding to topoisomerase II, forming stable ternary complexes with DNA and topoisomerase II. As a result, topoisomerase II remains bound between the free end of the cleaved DNA strand and the drug, unable to reseal the broken DNA. This ultimately results in accumulation of strand breaks and subsequent cell death.^{5,68} Because these compounds target the enzyme topoisomerase II, drug administration

schedule is important as this enzyme is expressed only in certain phases of mitosis. Thus, continuous administration is advantageous because it maximizes the likelihood of exposing a dividing tumor cell to the drug. Indeed, one study showed this dramatic effect by comparing 1-day administration of etoposide (500 mg/m²) to 5-day administration (100 mg/m²/day) in SCLC patients. Although the same total dose of drug was administered, the response rate of the group receiving single-day infusion was 10%, while the consecutive treatment group had a response rate of 89%.⁶⁹ Thus, exposing cells to lower concentrations of drug for prolonged times is thought to maximize the therapeutic effect of the topoisomerase II inhibitors.

Pharmacokinetics/metabolism: Both drugs bind significantly to plasma proteins. Etoposide is approximately 50% absorbed from the gastrointestinal tract and is available orally. Considerable pharmacokinetic interpatient variability exists with both intravenous and oral dosing.⁷⁰ Etoposide and teniposide undergo extensive metabolism in the liver. It is estimated that 30–70% of etoposide is excreted renally, while this accounts for only 5–20% of teniposide elimination. Dose adjustments are recommended for patients with moderate renal dysfunction (estimated creatinine clearance <50 ml/min) in order to avoid excessive toxicity.^{71,72} Various metabolites have been identified for both compounds, but their significance has been disputed.

Toxicity: Toxicities of the two agents are similar. The dose-limiting toxicity for both is myelosuppression, which mainly manifests as leukopenia. Thrombocytopenia occurs less often and is usually not as severe.⁵ Reversible alopecia, mild nausea and vomiting, and stomatitis are common. Allergic reactions including anaphylaxis have been observed. These are more common with teniposide, which is less-water soluble than etoposide. Hepatotoxicity has been reported in up to 3% of patients receiving etoposide, consisting of hyperbilirubinemia, ascites, and transaminase elevations. Secondary leukemias, including AML and APL, have been reported. Toxicity in general is enhanced in patients with low serum albumin levels because of the decreased binding of the drug and increased free levels.¹⁹

MISCELLANEOUS AGENTS

L-Asparaginase

Erwinia asparaginase, pegaspargase, Escherichia coli L-asparaginase L-Asparaginase is a compound that is actually an enzyme, L-asparagine aminohydrolase. The original, most commonly used agent is derived from *Escherichia coli*. Other available forms include a derivative produced by *Erwinia chrysanthemi* and the longer-acting pegylated asparaginase (pegaspargase). L-asparaginase possesses activity against malignancies of lymphocytic origin and is mainly used in the treatment of ALL. L-Asparaginase acts by breaking down

L-Asparagine, a nonessential amino acid required by cells for protein and nucleic acid synthesis. Most cells are able to synthesize adequate supplies of asparagine on their own; however, certain malignant cells, particularly those of lymphocytic origin, lack the synthetase enzyme required for asparagine formation. These cells are particularly sensitive to the effects of L-asparaginase. By converting existing cellular supplies of asparagine to aspartic acid and ammonia, L-asparaginase quickly depletes cells of this amino acid, thus inhibiting protein synthesis.⁷³

Pharmacokinetics/metabolism: L-Asparaginase is not absorbed orally and is available only for parenteral administration. Distribution volume approximates plasma volume, and L-asparaginase does not penetrate CNS significantly.⁵ Metabolism of L-asparaginase occurs through systemic degradation,⁷⁴ and the drug is cleared by the reticuloendothelial system.

Toxicity: While toxicity to the bone marrow is minimal, L-asparaginase and related compounds are associated with a variety of adverse effects. Hypersensitivity reactions, including anaphylaxis, can occur immediately and have been reported in up to 43% of patients treated with the *E. coli*-derived compound. Because allergic reactions are more likely to occur with intravenous administration,⁷⁵ asparaginase is typically given by intramuscular or subcutaneous injection. Patients who do react to *E. coli*-derived asparaginase may be switched to another source of drug, either pegaspargase or *Erwinia asparaginase*. This is associated with a high success rate and may enable the patient to complete a prescribed course of therapy. L-Asparaginase is also associated with coagulation abnormalities. It is thought that asparaginase depletes plasma proteins involved in both coagulation and fibrinolysis, including fibrinogen, factor IX, factor XI, antithrombin III, protein C, and protein S.^{76,77} Both bleeding and thrombosis have been reported.^{76–78} Pancreatitis is another complication associated with asparaginase and routine monitoring of amylase or lipase is recommended.^{5,79}

Hydroxyurea

While hydroxyurea is not a nucleoside analog, it is generally considered to be an antimetabolite due to its similar mechanism of action to this class of drugs. Structurally, it is an analog of urea and inhibits the enzyme ribonucleotide reductase. As a result of this inhibition, ribonucleotides are prevented from being converted to the active deoxyribonucleotide forms necessary for DNA synthesis and repair. Subsequently, DNA synthesis cannot occur and cells are stranded in the S phase or the G1–S interface.¹⁹

Pharmacokinetics/metabolism: Hydroxyurea is well absorbed from the gastrointestinal tract and is available for oral administration. Bioavailability is approximately 80–100%. It is widely distributed throughout

Table 101.4 Mechanisms of resistance to traditional antineoplastic agents

Chemotherapeutic class	Mechanisms of resistance
Alkylating agents	<ul style="list-style-type: none"> ■ Mutations of p53 tumor suppressor gene ■ Decreased transport of drug by active transport mechanisms ■ Increased production of nucleophilic substances (electron donors) that bind and detoxify reactive alkyl groups ■ Increased activity of DNA repair enzymes ■ Increased metabolism of drug to inactive form⁸¹
Antimetabolites: nucleoside analogs	<ul style="list-style-type: none"> ■ Inefficient cellular uptake and insufficient intracellular concentration of drug due to deficient transport mechanisms ■ Increased degradation of active compound by enzymes (cytidine deaminase or 5'-nucleotidase) ■ Loss of deoxycytidine kinase (<i>dCK</i>) gene, which converts drug to active form^{35,82}
Antimetabolites: folic acid analog (Methotrexate)	<ul style="list-style-type: none"> ■ Saturated active transport mechanisms ■ Increased production of DHFR (dihydrofolate reductase) ■ Slower rates of thymidylate synthesis ■ Alterations in binding affinity of DHFR and methotrexate⁵
L-Asparaginase	<ul style="list-style-type: none"> ■ Increased levels of enzyme asparagine synthetase within tumor cells^{5,19}
Anthracene derivatives	<ul style="list-style-type: none"> ■ Increased drug efflux mechanisms, such as P-glycoprotein or MDR-1 ■ Decreased expression of topoisomerase II enzyme ■ Mutation of topoisomerase II enzyme^{81,83}
Vinca alkaloids	<ul style="list-style-type: none"> ■ Increased levels of P-glycoprotein membrane efflux pump ■ Altered expression of tubulin isotypes ■ Tubulin mutations ■ Altered expression of microtubule-regulatory proteins^{64,84}
Podophyllotoxin derivatives	<ul style="list-style-type: none"> ■ Amplification of <i>MDR-1</i> gene mutation ■ Decreased expression of topoisomerase II enzyme ■ Mutation of topoisomerase II enzyme ■ Mutation of <i>p53</i> tumor suppressor gene^{5,81}
Hydroxyurea	<ul style="list-style-type: none"> ■ Increased expression of ribonucleotide reductase^{5,19}

the body, with levels detected in the CNS, fluid accumulations, and breast milk. While significant interpatient variability exists, approximately 50% of hydroxyurea is hepatically metabolized, with 50% of drug eliminated as urea and unchanged drug in urine.^{5,19}

Toxicity: The dose-limiting toxicity of hydroxyurea is myelosuppression. This is often the desired therapeutic effect as well. Mild nausea and vomiting is common, which is more severe with higher doses. Finally, skin pigmentation and macropapular rash may occur⁸⁰ (Table 101.4).

TREATMENT OF HEMATOLOGIC MALIGNANCIES: SUMMARY

Many valuable agents have been developed for the treatment of hematologic malignancies since the first patient with lymphoma was treated with nitrogen mustard in 1942. While these traditional agents have broad therapeutic potential and are currently

considered integral components of treatment regimens for leukemias and lymphomas, they are associated with a variety of toxicities as well. Nausea and vomiting, myelosuppression, alopecia, mucositis, infertility, and carcinogenesis are just some of the adverse effects commonly associated with these compounds. This has a dramatic impact on patients' quality of life. More recently, great advances have been made in understanding the molecular biology of cancer. New therapies are being developed to specifically target only those cells exhibiting genetic mutations, thus protecting healthy cells from unnecessary toxicity. In addition, research has been done evaluating mechanisms of resistance of tumor cells to chemotherapeutic agents and compounds are being engineered to specifically block these pathways. The ultimate goal is the development of a compound that specifically targets a chromosomal abnormality, leaving healthy cells free of toxic effects and dramatically improving the quality of life of cancer patients.

Chapter 102

BIOLOGICAL RESPONSE MODIFYING AGENTS IN THE TREATMENT OF HEMATOLOGIC MALIGNANCIES

Christopher J. Lowe and Jennifer Fisher Lowe

Drugs can only repress symptoms: they cannot eradicate disease. The true remedy for all disease is nature's remedy . . . There is at bottom only one genuine scientific treatment for all diseases, and that is to stimulate the phagocytes. Stimulate the phagocytes. Drugs are a delusion

*Sir Bloomfield Bonington (George Bernard Shaw—
The Doctor's Dilemma, 1906)*

Sir Bloomfield Bonington's views on medicine are not completely fictitious, as numerous investigators have attempted to harness and employ nature's remedy in the treatment of various diseases. In the early 1900s, an orthopedic surgeon by the name of William Coley investigated the association of febrile illnesses with spontaneous tumor regression.¹ This unusual therapeutic relationship prompted him to attempt treating sarcomas by infecting patients with bacterial infections with the hope of inducing high fevers. Obvious problems ensued with this approach and so he modified the therapy to be less pathologic. In place of inducing a true infection, he attempted to elicit the febrile state with a vaccine containing two killed bacteria: *Streptococcus pyogenes* and *Serratia marcescens*. Coley's vaccine became widely used and was eventually endorsed by the American Medical Association in 1936.¹

This is an early example of modifying the human body's defenses to serve as a therapeutic intervention. This chapter describes current therapeutic modalities, which like Dr. Coley's vaccine manipulate the function of the human body with the intent of curing disease.

TYROSINE KINASE INHIBITORS

The analysis of the human genome has revealed 518 putative protein kinase genes.^{2,3} Of these genes, a subset

of approximately 90 are responsible for protein tyrosine kinases.^{2,3} Various protein tyrosine kinases have been implicated in the pathophysiology of malignant conditions. Increased activity or deregulation of these kinases results in alterations in normal downstream cellular signaling. Examples of such processes include the bcr-abl fusion protein in chronic myeloid leukemia and HER-2 overexpression in breast cancer.

Recently, numerous targeting methodologies have been employed to inhibit specific tyrosine kinases in various malignancies. The most promising binding site for such inhibitors has been the adenosine triphosphate (ATP) complex binding site. Although a consistent structure within various tyrosine kinases, minor nuances in this catalytic domain configuration has allowed the development of highly selective inhibitors.⁴

IMATINIB (STI-571, GLEEVEC)

Historically, chronic myelogenous leukemia (CML) was treated with agents that had little effect on overall survival (hydroxyurea and busulfan) or induced such toxicity that effective doses were rarely maintained (interferon). Imatinib, a phenylaminopyrimidine derivative, is a selective tyrosine kinase inhibitor used in the treatment of Philadelphia chromosome positive leukemia. This orally administered agent represented a breakthrough in the therapy of CML, and more recently has been integrated into Philadelphia chromosome positive acute lymphoblastic leukemia (ALL) treatment regimens.

Imatinib's ability to competitively inhibit the ATP binding site of the bcr-abl tyrosine kinase prevents phosphorylation of proteins involved in signal transduction.⁵ By inhibiting the aberrant tyrosine kinase, imatinib halts cellular proliferation and tumor formation by bcr-abl expressing cells and decreases CML

colony growth without inhibiting normal colony growth.^{6,7} This inhibition is accomplished not only by the parent compound, but also by the active *N*-demethylated piperazine metabolite.

In addition to the pharmacological activity described above, the drug has exhibited the ability to inhibit the tyrosine kinase activity of c-kit, platelet-derived growth factor (PDGF), and stem cell factor (SCF). The former has led to its utility in gastrointestinal stromal tumor therapy.⁸ Imatinib also inhibits tyrosine kinase activity of *abl* in normal cells, although this is not considered clinically relevant.⁵

While a large number of patients have experienced clinical benefit from receiving imatinib, success has not been uniform. Some patients have exhibited *de novo* resistance, while others have developed resistant disease after an initial favorable response. This resistance may be multifactorial, with possible variables including gene and protein amplification, mutations in the protein kinase, binding of imatinib to proteins in the plasma, and additional oncogenic mutations that may bestow an additional growth advantage on the cells.⁹⁻¹¹

Pharmacokinetics/metabolism

Oral imatinib is well absorbed, with a bioavailability of nearly 100%.¹² Peak plasma concentration occurs within 4 h of administration, regardless of whether or not the dose is taken with food.¹³ Following oral administration, the elimination half-lives of imatinib and its major active metabolite are approximately 18 and 40 h, respectively.¹³ Repeat dosing does not have a significant impact on the drug’s pharmacokinetics and accumulation is 1.5 to 2.5-fold with daily administration.^{12,13} In-vitro models have established that at clinically relevant concentrations, imatinib is approximately 95% protein bound, primarily to albumin and α_1 -acid glycoprotein.¹² Hepatic enzymes, predominantly the cytochrome P450-3A4 isoenzyme, are responsible for the drug’s metabolism.¹³ Other cytochrome enzymes, such as CYP1A2, CYP2D6, CYP2C9, and CYP2C19, also contribute to imatinib’s degradation.¹³ Because many other medications can affect this metabolic system, imatinib is susceptible to alterations in kinetics/dynamics via cytochrome-based drug–drug interactions (Table 102.1) Most of the oral dose is eliminated via the feces and only 5% is excreted unchanged through the urine.¹³

Table 102.1 Imatinib CYP450 mediated drug–drug interactions¹³

Interacting medication	Result
Alfuzosin	Imatinib’s enzyme inhibition results in increased alfuzosin exposure
Aprepitant	Enzyme inhibition by aprepitant may result in elevated plasma concentrations of imatinib
Carbamazepine	Significant decrease in exposure to imatinib may occur when coadministered with the enzyme inducer carbamazepine
Clarithromycin	Clarithromycin may decrease the metabolism and increase concentrations of imatinib
Cyclosporine	Plasma concentrations of cyclosporine may be altered when coadministered with imatinib
Dexamethasone	Significant decrease in exposure to imatinib may occur when coadministered with dexamethasone
Eletriptan	Increased exposure to eletriptan may be expected when eletriptan is used concomitantly with imatinib
Erythromycin	Erythromycin may decrease the metabolism and increase concentrations of imatinib
Itraconazole, ketoconazole, voriconazole	Azole antifungals may decrease the metabolism and increase concentrations of imatinib
Phenobarbital	Significant decrease in exposure to imatinib may occur when coadministered with the enzyme inducer phenobarbital
Phenytoin	Significant decrease in exposure to imatinib may occur when coadministered with the enzyme inducer phenytoin
Rifabutin, rifampin	Imatinib is susceptible to significantly increased clearance when coadministered with enzyme inducers such as rifampin and rifabutin
Simvastatin	Plasma concentrations of simvastatin may be increased when coadministered with imatinib
St. John’s Wort	Concomitant use of imatinib and St. John’s Wort resulted in significantly increased clearance of imatinib
Warfarin	Concurrent treatment with imatinib and warfarin may increase the bioavailability of warfarin, thereby increasing the risk of bleeding

Toxicity

The majority of patients who received imatinib in clinical studies did experience side effects, but most of these effects were mild or moderate in severity.¹² Approximately 4% of patients discontinue therapy due to toxicity.¹³ The most common side effects are nausea, vomiting, edema, muscle cramps/pain, diarrhea, and rash. Nausea can be minimized if the dose is taken with food and/or a large glass of water.¹³ Edema most commonly manifests in the periorbital area or in the lower extremities and is usually ameliorated with diuretics or other supportive care measures.^{13,14} A small percent of patients experience more severe forms of fluid retention (pleural/pericardial effusions, pulmonary edema, ascites, and cerebral edema) and may require interruptions in therapy.¹⁴ This is usually dose-related and more common in the elderly and those in blast crisis and accelerated phase CML.¹³ Skin rashes, which vary greatly in appearance and severity, are commonly controlled with antihistamines or steroids. These topical reactions can be quite severe and are actually the most common reason for termination of imatinib therapy.¹⁴

Two additional adverse effects, which occur with lower frequencies but have noteworthy clinical significance, are hepatic and hematological toxicity. Significant liver dysfunction occurs in fewer than 5% of patients and is managed with dose reductions or temporary interruptions in therapy.¹³ Therefore, liver function tests should be monitored routinely throughout the duration of imatinib therapy.¹⁴ Myelosuppression is the most common Grade 3 or 4 adverse event observed in patients being treated with imatinib.¹⁵ Marrow suppression may represent a beneficial therapeutic effect, but may also be due to toxicity to normal progenitor cells.¹⁴ Neutropenia and thrombocytopenia, the most common manifestations of the marrow suppression, are more common in patients with advanced disease. Colony stimulating factors (filgrastim) have been successfully employed to assist neutrophil recovery and facilitate more sustained administration of imatinib.¹⁵

INTERFERONS

Discovered in 1957 and named after their ability to *interfere* with viral replication, interferons are cellular

glycoproteins with numerous biologic activities.¹⁶ In 1981, the first recombinant DNA-derived interferon was successfully expressed in bacteria and purified in large quantities for clinical study.^{16,17} The naturally occurring proteins have since been found to possess antiviral, antiproliferative, and immunomodulating properties.¹⁸

There are five major species of interferon: alpha, beta, gamma, omega, and tau.¹⁹ Three of these (alpha, beta, and gamma) have been approved by the U.S. Food and Drug Administration (FDA) for a total of 11 disease states (Table 102.2).

INTERFERON ALPHA

Interferon- α -2a is produced by recombinant DNA technology—combining an *Escherichia coli* start codon with the DNA sequence for human interferon- α -2a. The resulting molecule is nearly identical to naturally occurring interferon- α , with the exceptions being the addition of an N-terminal methionine residue and the lack of carbohydrate side chains.¹⁸

This class of drugs, because of its antiproliferative and immunomodulatory capabilities, has found its place in the treatment of various malignancies. Specifically, interferon- α has exhibited clinical activity in multiple tumor types. Drug effect has been observed in acute and chronic leukemia, lymphomas, and multiple myeloma.^{20–23}

The precise mechanism of action of interferons is not fully understood. Unlike traditional antineoplastic agents that exert their activity directly from their cytotoxic interactions on cancer cells, interferon's benefits result from a complex cascade of biologic modulation and drug-induced antiproliferation. The binding of interferon to the cell surface elicits alterations in gene transcription and translation.²⁴ Influences such as these on the activities of natural killer cells and macrophages appear to be the most noteworthy.²⁵

Interferon's ability to inhibit cellular proliferation affects both normal and malignant cells. Although the mechanism is not completely understood, interferon-induced prolongation of the cell cycle is principally responsible for the antiproliferative effects.²⁴ This activity appears to be concentration-dependent and occur primarily while the tumor cells are in phases G₀ and G₁.^{26,27} Additionally, these effects appear to be reversible since normal cellular growth resumes upon cessation of interferon exposure.²⁴

Table 102.2 Therapeutic indications²⁵

Drug	FDA approved indication
Interferon- α	Chronic myelogenous leukemia, condyloma acuminata, follicular lymphoma, hairy cell leukemia, chronic hepatitis B (adult and pediatric), chronic hepatitis C, Kaposi's sarcoma, malignant melanoma
Interferon- β	Multiple sclerosis
Interferon- γ	Chronic granulomatous disease

Pharmacokinetics/metabolism

Interferon α is supplied as a clear liquid for injection. Bioavailability is greater than 80% upon subcutaneous or intramuscular injection.²⁸ Interferon α , both recombinant and naturally occurring, is widely distributed in the body (excluding the central nervous system), with highest concentrations occurring in the spleen, kidney, liver, and lung.^{24,28} The metabolism of recombinant interferon- α -2a is consistent with that of alpha interferons in general.²⁴ Alpha-interferons undergo renal filtration and extensive proteolytic degradation at the brush border or in the lysosomes of the tubular epithelium during reabsorption, resulting in a half life of approximately 5 h.²⁸ Because of the unique mechanism of metabolism, it has been suggested that interferon- α may accumulate in patients with impaired renal function, but this is controversial.²⁴ Interferon- α may not be removed by hemodialysis.²⁹

Toxicity

The side effect profile of interferon- α is well documented in the literature. Uniformly, with the first dose of interferon, patients experience a flu-like syndrome consisting of fever, chills/rigors, tachycardia, nausea, vomiting, malaise, and headaches.^{17,24,25,28} Although the presence of these side effects is relatively consistent, the severity can be affected by variables such as dose, route of administration, and treatment schedule.¹⁷ As a result of the cytokines released (IL-2, IL-6, TNF- α) in response to interferon administration, the patient's body attempts to generate heat via shivering and vasoconstriction. The onset of this fever, which often reaches 38–40°C, usually occurs within 4 h of drug administration and may persist for up to 8 h.^{17,24} This reaction is frequently followed by a period of diaphoresis.²⁵ As a preventative measure to attenuate this constellation of symptoms, patients may be premedicated with acetaminophen or nonsteroidal anti-inflammatory drugs. These symptoms will likely diminish over time and may resolve with continued therapy; however, tolerance may be lost if therapy is delayed for more than one day.^{17,24}

On the other hand, fatigue continues and often worsens throughout therapy. Considered the most common dose-limiting toxicity, fatigue is often described as a feeling of lassitude, weakness, tiredness, or lack of motivation. This may manifest itself as job absenteeism, social withdrawal, increased sleeping, and potentially a decrease in performance status.^{17,24,25} Intermittent and/or evening dosing schedules may diminish the impact of this significant side effect.^{24,25}

Laboratory abnormalities described with the use of interferon- α include neutropenia and elevated liver enzymes that require dose modifications to maintain safety. Other side effects include depression, myalgias/arthralgias, gastrointestinal toxicity, and CNS depression.²⁸

RETINOIDS

The therapeutic potential of vitamins has been evaluated in cancer trials for many years. A correlation between retinol (vitamin A) and cancer was first noted in the 1920s, when experimentally induced vitamin-A deficiency led to preneoplastic lesions and ultimately neoplasms.³⁰ Retinoids, naturally occurring and synthetic analogues of retinol, modulate differentiation, inhibit growth, and induce apoptosis in a wide variety of cancer cell lines. This is accomplished through interaction with two types of nuclear receptors, retinoic acid receptors (RARs) and retinoic X receptors (RXRs).^{31,32} Dysregulation of retinoid metabolism has been implicated in carcinogenesis, and the therapeutic administration of retinoids is beneficial in certain cases.³³ The ability of retinoids to function as differentiating agents has led to unique opportunities in the treatment of acute promyelocytic leukemia (APL).

TRETINOIN (VESANOID, ALL-TRANS-RETINOIC ACID, ATRA)

APL is characterized by the specific chromosomal translocation t(15;17). This translocation fuses the promyelocytic leukemia (*PML*) gene located on chromosome 15 to the retinoic acid receptor α (*RAR- α*) gene positioned on chromosome 17, resulting in the formation of a chimeric protein, *PML/RAR- α* .³⁴ The *PML/RAR- α* fusion protein, which is leukemogenic, occurs in more than 99.9% of cases of APL. This protein causes an arrest of maturation at the promyelocyte stage of myeloid-cell development and accumulation of abnormal promyelocytes in the bone marrow.³⁵ Tretinoin binds to *RAR- α* on the surface of malignant promyelocytes. This leads to degradation of the *PML/RAR- α* fusion protein, resulting in the differentiation of malignant cells into mature myeloid cells that are then incapable of further proliferation.³⁶ The use of tretinoin has significantly improved the outcome of APL patients.^{37–41}

Pharmacokinetics/metabolism

Tretinoin, as an oral preparation, is well absorbed into systemic circulation, with a peak plasma concentration between 1 and 2 hours after oral administration.⁴² Food increases the bioavailability of tretinoin; however, the clinical significance of this is unknown. The activity of intravenous liposomal tretinoin has been evaluated, but demonstrated no clear advantage when compared with standard oral tretinoin.⁴³ The drug undergoes hepatic metabolism via the cytochrome P450 system. The degradation of the parent compound results in the formation of four identified metabolites: 13-*cis* retinoic acid, 4-*oxo trans* retinoic acid, 4-*oxo cis* retinoic acid, and 4-*oxo trans* retinoic acid glucuronide.⁴² Tretinoin acts as both an inhibitor and a substrate of the cytochrome P450 enzyme and therefore the product is susceptible to potential drug interactions. Tretinoin is greater than 95% protein-bound, predominantly to albumin. The

drug is eliminated via both the urine and the feces, although no dosage adjustments are required for any organ dysfunction. The terminal half-life is approximately 0.5–2 h following initial dosing in patients with APL.⁴²

Toxicity

Tretinoin does not elicit the usual toxicities associated with cytotoxic chemotherapy administration. It is neither immunosuppressive nor myelosuppressive. There are, however, two serious and specific complications that can result from tretinoin treatment of APL: hyperleukocytosis (40%) and retinoic acid syndrome (25%).⁴² Hyperleukocytosis is thought to be due to the increased amount of circulating mature cells that have undergone differentiation, and more commonly occurs in patients who present with an initial high white blood cell count ($>5 \times 10^9/L$) at diagnosis. Hyperleukocytosis may precede the development of the second complication, retinoic acid syndrome. This syndrome is characterized

by fever, dyspnea, weight gain, diffuse pulmonary infiltrates on chest X-ray, and pleural or pericardial effusions.⁴⁴ The syndrome generally occurs during the first month of treatment and may commence following the initial dose of tretinoin. The management of the syndrome includes the administration of high-dose steroids and appropriate supportive care measures. Treatment with dexamethasone (10 mg intravenously administered every 12 h for 3 days or until resolution of symptoms) should be initiated without delay at the first suspicion of symptoms. Tretinoin can be restarted in most cases once the syndrome has resolved.⁴⁵

Virtually all patients experience some degree of vitamin A toxicity, including headache, fever, weakness, and fatigue.⁴² These adverse effects are seldom permanent or irreversible, nor do they usually require interruption of therapy. Other common adverse drug reactions include flushing, hypotension, increase in serum cholesterol and triglycerides, and gastrointestinal toxicity such as abdominal pain, constipation, and diarrhea.⁴²

Table 102.3 Biological response modifying agents^{13,28,42,48,52,61,64}

Drug	Dosing	Dosage form	Common side effects
Imatinib (Gleevec [®])	CML: 400–600 mg PO QD ALL: 400–800 mg PO QD	100 and 400 mg capsules	Fluid retention, muscle cramps, nausea/vomiting, myelosuppression
Interferon- α 2a (Roferon [®] A)	CML: 9 million IU SQ/IM QD Hairy cell leukemia: 3 million IU SQ/IM QD	Prefilled syringes: 3 million IU/0.5 ml, 6 million IU/0.5 ml, 9 million IU/0.5 ml	Flu-like symptoms, fatigue, injection site reaction, depression, nausea, vomiting
Interferon- α -2b (Intron [®] A)	Hairy cell leukemia: 2 million IU/m ² SQ/IM, three times/week Follicular lymphoma: 5 million IU SQ, three times/week	Multidose prefilled pens: 18 million IU pen, six 3 million IU doses/pen 30 million IU pen, six 5 million IU doses/pen 60 million IU pen, six 10 million IU doses/pen Vials (powder): 10 million IU/vial 18 million IU/vial 50 million IU/vial Vials (solution): 10 million IU/vial 18 million IU/vial 25 million IU/vial	Flu-like symptoms, fatigue, injection site reaction, depression, nausea, vomiting, sarcoidosis
Tretinoin (Vesanoid [®])	45 mg/m ² /day PO (divided twice daily)	10 mg capsules	Headache, elevated liver function tests, leukocytosis, APL syndrome
Bexarotene (Targretin [®])	Oral: 300 mg/m ² PO QD Topical: apply 1% gel every other day for 1 week then at weekly intervals increase to once daily, then twice daily, then three times daily, and finally four times daily (as tolerated)	75 mg capsules 1% gel (60g tube)	Oral: rash, hypercholesterolemia, hyperlipidemia, Topical: pruritus, rash
Arsenic Trioxide (Trisenox [™])	0.15 mg/kg IV QD for a maximum of 60 days (administer over 1 hour)	1 mg/10 ml ampule	Headache, nausea, fatigue, leukocytosis, APL syndrome, cardiac abnormalities

BEXAROTENE (TARGRETIN)

In 1994, a new family of intracellular receptors, the retinoid X receptors (RXRs) was described.⁴⁶ RXRs can form heterodimers with various receptor partners, such a retinoic acid receptor, vitamin D receptor, thyroid receptor, and peroxisome proliferator activator receptors. Bexarotene, available for both topical and oral use, is an RXR ligand that selectively binds and activates RXR subtypes (RXR α , RXR β , RXR γ). Once activated, these receptors function as transcription factors regulating the expression of genes that control apoptosis, cellular differentiation, and proliferation.⁴⁷⁻⁴⁹ The capsules are indicated for the treatment of topical manifestations of cutaneous T-cell lymphoma in patients who are refractory to at least one prior systemic therapy, while the 1% gel is indicated for the topical treatment of cutaneous lesions (Stage IA and IB) who have refractory or persistent disease after other therapies or who have not tolerated other therapies.⁵⁰⁻⁵⁴ Oral bexarotene is also under investigation for use in AIDS-related Kaposi's sarcoma, diabetes mellitus, lymphomatoid papulosis, psoriasis, and solid tumors such as breast, non-small cell lung cancer, and renal cell carcinoma.

Pharmacokinetics/metabolism

Bexarotene is well absorbed by the gastrointestinal tract, with peak plasma levels occurring 2-4 h after oral administration and an initial response expected between 8 and 26 weeks.⁴⁸ Absorption is significantly increased after a fat-containing meal. Bexarotene is highly protein bound (>99%). Extensive metabolism occurs hepatically via the CYP3A4 isoenzyme, and the drug is primarily eliminated through the hepatobiliary system and in the feces, with less than 1% of the drug is excreted in urine. The elimination half-life is approximately 7 h.⁴⁸

Toxicity

Bexarotene's use is commonly associated with reversible hypertriglyceridemia (80%) and hypercholesterolemia (32%).⁴⁸ The antihyperlipidemic medications that are most effective for reversing this hypertriglyceridemia are atorvastatin and fenofibrate.⁵⁰ The incidence of hypothyroidism is 30% with thyroid

function tests returning to baseline as early as eight days after discontinuation.^{48,55} Dose-related leukopenia has also been reported. The most common symptomatic side effects reported are fatigue/lethargy, headache, asthenia, rash, nausea, abdominal pain, infection, peripheral edema, dry skin, cataracts, and sensitivity to sunlight. Bexarotene is contraindicated in pregnancy, being classified as category X.⁴⁸

MISCELLANEOUS

ARSENIC TRIOXIDE (TRISENOX, ATO)

Although arsenic's accolades primarily revolve around its reputation as an almond-flavored poison, as it was depicted in Frank Capra's 1944 film *Arsenic and Old Lace*, it has an older and more admirable history as a medicinal agent. In the eighteenth century, Thomas Fowler compounded a potassium-bicarbonate-based solution of arsenic trioxide (As₂O₃) that was used empirically to treat a variety of diseases.⁵⁶ In 1910, Nobel prize winner Paul Ehrlich created the organic arsenical compound salvarsan that was best known as the "magic bullet" for syphilis, but also found use in treating hypertension, ulcers, heartburn, and chronic rheumatism.⁵⁷ With evolutions in medicine and the concerns for toxicity, arsenic's use declined over time. In the late 1970s, observational studies preformed in China reported the effectiveness of arsenic trioxide as part of a treatment regimen for APL.⁵⁸ These results have since been confirmed in trials in the United States, leading to FDA approval in September 2000.⁵⁹⁻⁶¹

Similar to tretinoin, arsenic has been shown to cause degradation of PML-RAR- α , promoting cellular differentiation.⁶² However, arsenic acts primary on the PML gene and restores the cell's apoptotic ability, while tretinoin targets the RAR- α gene and reverses the differentiation arrest. Yet, the degradation of PML-RAR- α may not be the sole mechanism of action.⁶² Arsenic is thought to also act through the intracellular environment to influence apoptosis, differentiation, growth arrest, and angiogenesis.

The multiple mechanisms of actions suggest that arsenic may have antitumor activity in other hematological malignancies, such as multiple myeloma, the

Drug	Necessary dosing adjustment
Imatinib (Gleevec®)	Discontinue if liver transaminases are >5 times upper limit of normal or bilirubin is >3 times upper limit of normal. May resume at a reduced dose once transaminase level is <2.5 times upper limit of normal and/or bilirubin is <1.5 times upper limit of normal. Neutropenia may also necessitate dose reductions.
Interferon- α -2a (Roferon®-A)	Dose reductions of 50% or withholding individual doses may be needed when severe adverse events occur.
Interferon- α -2b (Intron®-A)	Dose reductions of 50% or withholding individual doses may be needed when severe adverse events occur. Administration should be withheld for a neutrophil count <1000/mm ³ , or a platelet count <50,000/mm ³ .

myelodysplastic syndromes, and a variety of solid tumors.⁶³ Most of the available data is preliminary and published in abstract form, and therefore must be interpreted with caution. Arsenic's use continues to be explored, and novel combination strategies are being studied to expand its potential use.

Pharmacokinetics/metabolism

Arsenic is administered solely by the intravenous route. Oral formulations are no longer used due to the high occurrence of severe gastrointestinal toxicity.⁵⁸ After intravenous injection, peak levels are achieved 4 h from the end of the infusion. Arsenic is metabolized by methylation in the liver and excreted primarily in the bile. Arsenic is preferentially distributed in tissues containing significant amounts of sulfhydryl group-containing proteins; mainly in the liver, kidneys, heart, lung, hair, and nails.⁶¹ The drug is rapidly eliminated with a half-life of 12 h.⁶¹

Toxicity

There are several adverse events associated with arsenic trioxide that warrant careful monitoring and

management. The most common non-life-threatening adverse events are nausea, rash, fatigue, neuropathy, fever, headache, vomiting, diarrhea, tachycardia, and hypokalemia. More serious complications include the APL differentiation syndrome, and QT prolongation.^{60,61} Most of the toxicities are manageable, reversible, more common during induction therapy and do not require discontinuation.

APL differentiation syndrome, characterized by fever, dyspnea, weight gain, pulmonary infiltrates, and pleural or pericardial effusions, with or without leukocytosis, occurred in 23% of APL patients.⁶⁰ This syndrome can be fatal and is treated immediately with intravenous dexamethasone (10 mg twice daily for 3 days or until signs have abated).⁶¹

Arsenic can cause QT prolongation (potentially leading to a torsade de pointes ventricular arrhythmia) and complete atrioventricular block. Prior to patients receiving arsenic, a 12-lead electrocardiogram should be performed and serum electrolytes (potassium and magnesium) should be assessed and replaced aggressively if indicated. If the absolute QT interval is greater than 500 msec, the drug should be discontinued.⁶¹

Chapter **103**

PHARMACOLOGY OF MONOCLONAL ANTIBODIES

Jennifer L. Shamp

HISTORY

Currently, dynamic changes are taking place in the field of oncology. Remarkable advances have been made in elucidating the complex mechanisms of cellular signaling and malignant transformation, providing unique targets for therapy. Monoclonal antibodies (MoAbs) represent a subset of these newer, targeted therapies. MoAbs are designed to target specific surface proteins found on tumor cells, thus selecting malignant cellular clones for destruction while sparing healthy cells. This streamlined approach offers significant advantages over traditional chemotherapy, where healthy cells are often sacrificed in order to eradicate malignant cells. Recent improvements in technology and laboratory methods have enhanced the effectiveness of MoAbs, making them more amenable to clinical use.

Interestingly, while most of the currently available MoAbs have entered the marketplace in the past decade, the notion of antibody therapy has been around for years. Conceptually dating back to the nineteenth century, the initial idea of “serotherapy” was developed by Behring through his work with tetanus toxin. He discovered that immunizing toxin-naïve animals with serum from animals exposed to tetanus toxin provided a protective effect against lethal doses of tetanus. Thus, he concluded that some form of antitoxin develops upon exposure to lower doses of toxin, providing future protection against the disease.¹ Rapidly building on this concept of a “magic bullet,” Hericourt and Richet prepared an “antiserum” to extracts of osteogenic sarcoma, which they used to treat patients with the disease. In 1953, Pressman and Korngold showed that antibodies could specifically target tumor cells, thus renewing interest in using immunotherapy for the treatment of cancer.² Another breakthrough occurred in 1968, when Porter and Edelman identified the “antitoxin,” or Y-shaped immunoglobulin structure well-known today.³ Finally, in 1975, the Nobel prize-winning publication by Kohler and Milstein described a realistic methodology

for the creation of compounds that specifically select and bind to cancer cells. Their “hybridoma” cell lines were created from animals repeatedly immunized with target antigen. Subsequently, the B lymphocytes of these animals were isolated and immortalized, and the ability to produce specifically targeted antibodies was retained.⁴ Thus began the serious evaluation of MoAbs as potential therapeutic agents in the treatment of cancer.

Three types of MoAbs have emerged, representing three distinct therapeutic strategies: unconjugated MoAbs, immunotoxin-conjugated MoAbs, and radionuclide-conjugated MoAbs.¹ The unconjugated MoAbs represent the simplest form of therapy, where the antibody itself achieves cell death through stimulation of host immune effector mechanisms. The conjugated MoAbs, on the other hand, are covalently linked to either a toxin or a radioisotope. The release of the toxin/radioisotope upon direct delivery to the targeted cell accounts for the cytotoxicity of these compounds.⁵

UNCONJUGATED MOABS

PHARMACOLOGY

The unconjugated MoAb is a structurally complex macromolecule comprising an immunoglobulin with a constant region (Fc) and a variable region (Fab) that is engineered to target a specific cell surface marker. Ideally, cell surface markers would be found solely on malignant clones; unfortunately, a cell surface marker of this type has not yet been discovered. Thus, these cell surface proteins are found not only on malignant cells, but on healthy lymphoid or myeloid cell lines as well. These agents bind to the targeted cell surface protein and form an antigen–MoAb complex, which then allows the exposed Fc fragment of the drug to activate host effector mechanisms.⁵ Cellular destruction can occur via two pathways: (1) complement-mediated cytotoxicity (CMC), which involves activation of complement C1q on the Fc region, leading to the formation

of a membrane-attack complex that lyses the target cell and (2) antibody-dependent cellular cytotoxicity (ADCC), which occurs through binding of Fc region receptors to natural killer cells, monocytes, and macrophages, leading to opsonization of the target. Because host effector mechanisms require activation by Fc region receptors located on cell surfaces, these molecules cannot be internalized, but must remain on the cell surface in order to function.^{1,5} The immunoglobulin isotypes vary in their ability to activate these cellular functions. The IgG1 subclass is thought to be the most effective in stimulating ADCC and CMC functions in humans.⁶

THERAPEUTIC CHALLENGES

Between 1975 and the early 1990s, researchers in MoAb therapy suffered a variety of setbacks and challenges. Patients treated with the agents in clinical settings did not show dramatic responses. The initial murine products were hindered by the development of HAMA (human anti-mouse antibodies); host antibodies identified murine protein fragments as foreign, subsequently inactivating the compounds after repeated administration.¹ This was further complicated by allergic-type reactions and even anaphylaxis. Other potential reasons for the limited success of these compounds included short drug half-lives, inadequate recruitment of the patients’ immune effector cells, lack of specificity of tumor antigens, internalization of the target antigen by tumor cells, and inadequate quantities of antibody administered.¹ With the advancement of technology and laboratory techniques involved in the production of antibodies, as well as clinical research in genomics and cellular-signaling pathways, the development of therapeutic MoAbs has improved significantly in the past 15 years. Production of humanized and human chimeric antibodies, as well as clinical advances in identification of antigenic receptors, has resulted in the FDA approval of 17 MoAbs since 1986. Eight of these compounds received approval for cancer indications (Table 103.1).

APPROVED COMPOUNDS

Rituximab (Rituxan)

Rituximab, the most extensively studied MoAb to date, is a chimeric human/mouse IgG1-κ MoAb designed to target cell surface protein CD20. Rituximab consists of murine variable regions from the parent 2B8 MoAb grafted onto a human IgG1 constant-region backbone.⁵ The cell surface protein CD20 offers an ideal target, as it is expressed on >95% normal B lymphocytes and B-cell lymphomas, but not stem cells or plasma cells. Additionally, CD20 is not shed or internalized upon antibody binding; thus, the antibody-CD20 complex remains on the surface of the cell, available to bind and stimulate ADCC and CMC.⁸ In addition to ADCC and CMC, rituximab achieves therapeutic activity by direct induction of calcium influx

Table 103.1 Monoclonal antibodies currently approved for the treatment of hematologic and oncologic malignancies⁷

Monoclonal antibody	Target antigen	Clinical uses	FDA approval
Rituximab (Rituxan [®])	CD20	B-cell lymphomas, CLL	1997
Trastuzumab (Herceptin [®])	HER2/neu	Breast cancer	1998
Gemtuzumab (Mylotarg [®])	CD33	AML,APL	2000
Alemtuzumab (Campath [®])	CD52	B-cell CLL	2001
⁹⁰ Y-ibritumomab (Zevalin [®])	CD20	B-cell lymphoma	2002
¹³¹ I-tositumomab (Bexxar [®])	CD20	B-cell lymphoma	2003
Bevacizumab (Avastin [®])	VEGFR	Colorectal cancer	2004
Cetuximab (Erbix [®])	EGFR	Colorectal cancer	2004

and apoptosis.^{5,8} Rapid depletion of CD20+ B lymphocytes from blood, bone marrow, and lymph nodes lasting 3–6 months is observed following administration of rituximab.¹ Full recovery is typically achieved after 9–12 months.⁹ However, during this time, T lymphocyte and IgG levels remain constant, even though B lymphocyte and IgM levels drop. In essence, humoral immunity remains intact and patients do not experience an increased risk of infection during this time.^{1,5}

Clinical trials Original phase I studies of rituximab used single doses escalating up to 375 mg/m². The trials were actually stopped before any dose-limiting toxicity was reached, illustrating the favorable side effect profile of the drug. While some patients received more than 1000 mg of rituximab, adverse effects were mild and typically reversible. These consisted mainly of infusion-related effects such as fever, asthenia, chills, nausea, vomiting, rash, and urticaria.¹⁰ Adverse effects were most common with initial doses and typically subsided with subsequent drug exposure. Further studies evaluated rituximab for a variety of indications, beginning with relapsed low-grade and follicular non-Hodgkin’s lymphoma.¹¹ A pivotal trial evaluated weekly rituximab 375 mg/m² for 4 weeks in a population of patients with a median of two prior relapses. Response rates were impressive, with 48% of patients achieving partial responses and 6% achieving complete responses.¹² Rituximab has been studied in combination with traditional chemotherapy as well. A second pivotal trial compared CHOP alone to CHOP plus rituximab in patients between 60 and 80 years of age

with previously untreated diffuse large B-cell lymphoma. The rituximab arm had no significant increase in adverse events compared to the control arm, but showed significantly higher rates of event-free and overall survival.¹³ Use of rituximab has now expanded to other B-cell malignancies, including chronic lymphocytic leukemia and small lymphocytic lymphoma.⁸ Dose intensification protocols have been evaluated with the goal of improving response rates in these disease states; however, the exact role of rituximab in these malignancies remains to be defined.¹⁴

Pharmacokinetics The pharmacokinetic profile of rituximab exhibits significant interpatient variability. Serum concentrations can fluctuate up to fivefold between patients; in addition, with each successive dose of drug, an individual's serum concentration increases significantly. In one pharmacokinetic study, median values for peak serum levels essentially doubled from the first to the fourth dose.¹⁵ Rituximab serum half-life follows the same pattern, increasing 2.7-fold between the first and fourth doses (ranging from 3.2 to 8.6 days). This increase in half-life supports the theory that rituximab undergoes lymphocyte-mediated clearance. Fluctuating plasma concentration values may correspond to circulating CD20+ lymphocyte numbers, as well as CD20+ receptor saturation, suggesting that clearance is dependent on the amount of CD20+ cells present.^{9,14}

Adverse effects Rituximab is fairly well tolerated, with the majority of adverse effects being infusion-related. In one pivotal trial, adverse events were reported in 84% patients; however, <5% of these were considered severe (grade 3 or 4 based on NCI-CTC criteria). Additionally, these adverse reactions were typically limited to the first dose; 55% of patients reported no adverse effects with subsequent doses.¹² These reactions appear to correspond to clearance of CD20+ lymphocytes, and are most severe upon initial exposure to the drug.⁹ Patients at highest risk include those with circulating malignant lymphocyte counts >25,000/mm³ as well as patients with bulky disease (lesions ≥10 cm). Premedication with acetaminophen and antihistamines reduces the commonly experienced fever, chills, and malaise; in the rare cases where bronchospasm, angioedema, or hypotension occurs, stopping the infusion and providing supportive care usually resolves the reaction.⁹

Alemtuzumab (Campath-1H)

Alemtuzumab, the end result of two decades' worth of research and development, is a humanized rat IgG-1 antibody directed against cell surface marker CD52.¹ Initially, alemtuzumab was developed as a rat IgM antibody and used for in vitro T-cell depletion prior to stem cell transplantation. While in vitro Campath-1M was successful, trials evaluating systemic use in lym-

phoma patients demonstrated disappointing results. This was thought to be due to the IgM component of the compound ineffectively stimulating ADCC. Thus, Campath-1G was developed, an IgG2b antibody. Initially more successful against lymphoma and bone marrow cells, Campath-1G encountered problems when patients quickly developed HAMA as a result of the murine nature of the drug.¹⁶ Finally, a humanized rat IgG-1 antibody was developed, known as Campath-1H or alemtuzumab. The CD52 surface protein is expressed on most lymphocytes (both B and T cells), monocytes, macrophages and eosinophils, as well as cells lining the distal epididymis, vas deferens, and seminal vesicles in the male reproductive tract; however, it is not found on erythrocytes, platelets, or stem cells.⁸ In addition, while CD52 is highly expressed in some forms of CLL, NHL, and ALL, it is not shed or internalized, making it an excellent MoAb target.⁸ Once alemtuzumab binds to the CD52 receptor, cellular cytotoxicity is achieved through ADCC, CMC, and direct apoptosis.¹⁷

Clinical trials Alemtuzumab is currently indicated for the treatment of fludarabine-refractory B-cell CLL. Three major studies have assessed alemtuzumab in this population.^{18–20} The largest of these studies was an international collaboration between centers in the United States and Europe; this study evaluated 12 weeks of intravenous alemtuzumab in 92 fludarabine-resistant patients, of which 76% had Rai stage II or IV disease.²⁰ The overall response rate was 33%, with 2% CR. Median survival was 16 months. Patients with bulky lymphadenopathy were less likely to respond, possibly indicating poor tumor penetration of alemtuzumab.^{8,20} Toxicity was moderate and consisted mainly of infectious problems (55% patients) as well as infusion-related reactions. Rai et al. supported these findings with a study evaluating 24 poor-prognosis, fludarabine-treated chronic lymphocytic leukemia patients.¹⁹ After up to 16 weeks of treatment with alemtuzumab (target dose 30 mg three times weekly), the overall response rate was 33%. Median time to progression was 19.6 months. Because of the high incidence of infusion-related reactions encountered during intravenous infusion of alemtuzumab, subcutaneous use has emerged as a potential alternative route of administration. Another trial evaluated subcutaneous alemtuzumab in 41 patients with advanced, previously untreated CLL.²¹ An overall response rate of 87% was achieved, with 19% CR. While injection site reactions were seen in 90% patients, these were grades 1–2 in severity. The infusion reactions generally encountered with intravenous dosing were absent, aside from some patients experiencing rigors.^{21,22}

Alemtuzumab has demonstrated some activity in other hematologic malignancies as well, including T-cell PLL and low-grade lymphomas.^{23–25} An encouraging study by Pawson et al. evaluated 15 patients

with refractory T-cell prolymphocytic leukemia, most of whom had failed prior treatment with pentostatin. The response rate was 73%, with 60% patients achieving CR.²³ These results were subsequently verified in other studies with T-cell lymphoma patients; response rates have consistently remained above 50% even in heavily pretreated populations.^{24,25}

Combination therapy with alemtuzumab has recently been explored; one study evaluated six patients with refractory disease who were treated with fludarabine and alemtuzumab concurrently.²⁶ Five patients responded, with one patient achieving a complete response. Additionally, sequential therapy with fludarabine followed by alemtuzumab has been studied; this combination, while associated with significant rates of infectious complications (12 of 57 patients developed grade 3 or 4 infections during or after alemtuzumab treatment), patients who completed therapy showed significant response rates. Thirty-six of 57 patients enrolled finished both the fludarabine and alemtuzumab phases of treatment; this group achieved an overall response rate of 92%, with 42% CR.²⁷ Longer follow up and additional studies will help to fully elucidate the role of combination therapy with alemtuzumab.

Administration and pharmacokinetics Alemtuzumab is typically administered in a gradual dose-escalation fashion, which helps reduce the severity of infusion-related reactions that occur upon first exposure to the compound. The initial recommended dose of alemtuzumab is 3 mg infused over 2 h on day 1, followed by 10 mg on day 2, and if tolerated, 30 mg thrice weekly. Treatment is generally continued for 4–12 weeks as tolerated. With maintenance dosing, peak levels of alemtuzumab reach steady state after approximately 6 weeks, at which point the drug half-life is 12 days.²⁸

Adverse effects Adverse effects associated with alemtuzumab consist mainly of infusion-related reactions, infectious complications, and hematologic toxicity. Acute infusion toxicities are quite common, seen in 90% of patients in a large trial by Keating et al.²⁰ Rigors, fever, nausea, vomiting, and rash are often seen with initial infusions; however, these typically decrease with subsequent drug exposure.²² Rarely, hypotension and dyspnea are encountered.⁸ Premedication with acetaminophen and antihistamines is recommended to reduce this possibility. Infectious complications have been problematic as well; opportunistic infections, CMV reactivation, HSV infection, PCP, candidiasis, and septicemia have all been reported.²⁰ Currently, antibacterial and antiviral prophylaxis is recommended in order to prevent these complications. Lymphocyte counts drop rapidly after alemtuzumab treatment, resulting in a severe and prolonged lymphopenia. Myelosuppression, on the other

hand, consisting of anemia, neutropenia, and thrombocytopenia, is typically moderate and transient.^{8,20}

IMMUNOTOXINS

PHARMACOLOGY

The immunotoxin-conjugated MoAbs, or ITs, are fusion proteins that consist of MoAbs covalently linked to protein toxins. These highly potent toxins are typically derived from plant, bacterial, or fungal sources and possess the ability to disrupt protein synthesis through a series of catalytic enzymatic reactions at very small concentrations.¹ The most technically challenging of all MoAbs to design and deliver, immunotoxins are genetically engineered to retain their cytotoxic potency, while their tissue-binding domains are truncated in order to allow for MoAb-directed targeting of specific cell surface proteins. This minimizes binding of the toxin to healthy cells, while selectively targeting malignant clones.²⁹ In order for the toxin to exert its effect, it must undergo internalization by the cell, rather than remaining on the cell surface as with unconjugated MoAbs. This allows the toxin to gain access to critical intracellular functions located within the cytosol. Receptor-mediated endocytosis occurs once the compound binds to the cell surface. Upon entering a cell, the toxin is carried by clathrin-coated vesicles to either acidic endosomes (bacterial toxins) or neutral *trans*-Golgi (plant toxins), where interruption of protein synthesis occurs. Both plant and bacterial toxins disrupt the elongation step of protein synthesis, through enzymatic alteration of either elongation factor 2 or its binding site.³⁰ Toxins that have been used in this manner include ricin, abrin, diphtheriatoxin, and pseudomonas toxin. A variety of compounds are currently in clinical development (Table 103.2).

THERAPEUTIC CHALLENGES

The majority of literature evaluating immunotoxins consists of data from phase I trials. While these studies have collectively shown that therapeutic serum levels of toxin can be achieved with acceptable toxicity, much research remains to be done. The compounds have been plagued with high toxicity profiles and low response rates.³⁰ Many different MoAb-toxin combinations have been studied and the adverse effect profile has remained surprisingly consistent. Most of the phase I dose-escalation trials have been limited by the development of a vascular leak syndrome; peripheral edema, pulmonary edema, weight gain, hypoalbuminemia, hypotension, and pericardial effusions are thought to be due to toxin-mediated endothelial damage.^{5,30} Hypersensitivity reactions are common as well, along with fever, malaise, and nausea. Further complicating these hypersensitivity responses is the fact that patients can react to one or both components of the

Table 103.2 Immunotoxins currently under investigation for hematologic malignancies^{31,32}

Compound	Target	Toxin	Clinical use
DAB389-IL2 (Ontak)	Interleukin 2 receptor	Diphtheria toxin	Cutaneous T-cell lymphoma
Anti-TAC (Fv)-PE38 (LMB-2)	CD25	Pseudomonas toxin	B-cell lymphomas, T-cell lymphomas, and Hodgkin's disease
RFT5-dgA	CD25	Ricin	Hodgkin's disease
RFB4-dgA	CD22	Ricin	Non-Hodgkin's lymphoma, B-CLL
HD37-dgA	CD19	Ricin	Relapsed B-cell non-Hodgkin's lymphoma
RFB4(dsFv)-PE38 (BL22)	CD22	Pseudomonas toxin	B-cell lymphomas, B-CLL, hairy cell leukemia
Anti-CD7-dgA	CD7	Ricin	T-cell non-Hodgkin's lymphoma
DT-Anti-Tac(Fv)	CD25	Diphtheria toxin	Leukemias, lymphomas
B3-Lys-PE38	Lewis Y	Pseudomonas	Carcinoma
B3(Fv)-PE38		toxin	
B3(dsFv)-PE38			
BR96(sFv)-PE40			
e23(Fv)-PE38	ErbB2/HER2	Pseudomonas toxin	Breast cancer
FRP5(scFv)-ETA			
MR1(Fv)-PE38	Mutant EGF-R	Pseudomonas toxin	Liver, brain tumors
SS1(Fv)-PE38	Mesothelin	Pseudomonas toxin	Ovarian cancer

Fv, antigen recognition site on the monoclonal antibody; IL2, interleukin 2; toxins include PE38 (truncated pseudomonas exotoxin), DAB₃₈₉ (truncated diphtheria toxin), and dgA (deglycosylated ricin A chain).

compound. HAMA and antitoxin responses have been documented, which limits the ability to retreat patients because of neutralizing antibodies that render the compounds ineffective.⁵ Other factors contributing to the limited activity of immunotoxins include minimal penetration of bulky tumor sites, particularly in non-Hodgkin's lymphoma and Hodgkin's disease.^{30,33}

APPROVED COMPOUNDS

Gemtuzumab ozogamicin (Mylotarg)

Gemtuzumab ozogamicin (GO) is one of the first clinically available immunoconjugates, approved in 2000 for the treatment of relapsed AML in patients ≥ 60 years of age with CD33-positive disease. The compound consists of a humanized MoAb to CD33 linked to two molecules of the enediyne antitumor antibiotic *n*-acetyl- γ -calicheamicin.²⁸ Calicheamicin is a cytotoxic natural product isolated from *Micromonospora echinospora* that is at least 1000 times more potent than conventional chemotherapy agents such as doxorubicin.³⁴ The cell surface protein CD33 is expressed by most hematopoietic cells; in fact, this protein is not found outside of the hematopoietic system. As such, it is an excellent target for new therapies in hematologic malignancies. Immature and mature myeloid cells as well as erythroid, megakaryocytic, and multipotent progenitor cells express CD33. More importantly,

leukemic blasts in approximately 90% of patients with AML express this marker.²⁸ Once GO binds to CD33 receptors, it forms an antibody-calicheamicin complex on the cell. This complex rapidly undergoes endocytosis, where lysosomal enzymes then cleave the covalent bond between the MoAb and calicheamicin, liberating the calicheamicin toxin inside the cell. The enediyne component of calicheamicin is responsible for much of its toxicity; this reactive portion of the molecule produces cytotoxic biradicals upon aromatization, which leads to phosphodiester DNA strand breaks. After calicheamicin binds to the DNA duplex minor groove, double-strand breaks in the oligopyrimidine and oligopurine tracts occur; this positions the enediyne ring to abstract hydrogen atoms from neighboring strands.³⁴

Clinical trials Results of phase I studies evaluating GO in patients with relapsed AML showed that two doses of 9 mg/m² resulted in >75% saturation of CD33 antigen on peripheral blood mononuclear cells.³⁵ This subsequently became the recommended dose for phase II trials. A series of three phase II trials enrolled a total of 142 patients with untreated, relapsed AML. The data was compiled and published in one report.³⁶ The median age was 61, and the median length of first CR was 11.1 months; 109 patients (77%) received two doses of drug and 5 (3%) received 3 doses; the overall

response rate was 28% in patients whose initial responses lasted < 1 year and 32% in patients whose original responses lasted > 1 year. There were 23 complete responses (16%) and 19 CR_ps (complete response without full platelet recovery, >100,000/l). No significant difference in response rates or overall survival was seen based on age or cytogenetic profiles. Toxicities consisting of fever, rigors, hypotension, and other infusion-related events were common (grade 3 or 4 infusion reactions occurred in 34% patients during the first dose, but only 12% during the second dose). Other significant grade 3/4 adverse effects included thrombocytopenia (99%), neutropenia (97%), hyperbilirubinemia (23%), and infections (28%). Based on these studies, the FDA granted GO conditional approval as single-agent therapy for CD33-positive, relapsed AML in patients >60 years of age who are not candidates for other chemotherapy. This approval was contingent upon ongoing studies evaluating the role of GO in recurrent AML as well as the comparison of GO with chemotherapy versus chemotherapy alone.²⁸

A variety of studies further evaluating GO have been conducted^{37,38}; Nabhan et al. published a trial evaluating GO as initial AML treatment in 12 patients who were >65 years old. The overall response rate was 27%. Treatment was fairly well tolerated; however 100% patients experienced grade 3 or 4 neutropenia and/or thrombocytopenia.³⁷ Five patients experienced elevations in LFTs, notably bilirubin, although none of these were considered grade 3 or 4. No evidence of hepatic venoocclusive disease (VOD) was reported.

Additionally, GO has been evaluated in combination with other chemotherapeutic agents.³⁹ Piccaluga et al. evaluated nine patients with a median age of 63 years (five with untreated AML and four with relapsed AML). Patients received GO 6 mg/m² on day 1 and 4 mg/m² on day 8 concurrently with cytarabine 100 mg/m²/day continuous infusion days 1–7. Three of five patients with untreated disease achieved CR, along with two of four patients with relapsed AML. Median overall survival was 6 months. The most common adverse effect was myelosuppression; again, 100% patients experienced grade 3 or 4 neutropenia and/or thrombocytopenia. Infusion-related reactions were documented in two patients; transaminase elevations were encountered as well, with ALT/AST elevations occurring in seven patients (grade 3 in two cases), hyperbilirubinemia in three patients, and alkaline phosphatase elevation in seven cases.³⁹ The most concerning adverse event was grade 3/4 bleeding, which occurred in four patients.

Other combination regimens with different agents, including cytarabine, daunorubicin, topotecan, idarubicin, cyclosporine, fludarabine, troxacitabine, and anti BCL-2 antisense are currently under investigation or being published. A trial with topotecan, Go, and cytarabine was moderately effective but associated with significant toxicity.⁴⁰ Additionally, 2 of 14 patients

included in this study developed hepatic VOD. This seems to be a major toxicity of concern with GO combination regimens. More data is needed before GO can be recommended in conjunction with other chemotherapy agents.

Administration/pharmacokinetics Gemtuzumab is administered as an intravenous infusion over 2 h. A full course of treatment consists of two doses of 9 mg/m², given 14 days apart.²⁸ Pretreatment with antihistamines and/or corticosteroids is recommended in order to reduce infusion-related reactions. Elimination half-life of the drug is fairly long; median half-life of the antibody component is 72.4 h, while median half-life of the calicheamicin component is 45.1 h.²⁸ Increased median plasma concentrations are observed following a second dose; this indicates reduced tumor burden and lesser clearance by CD33+ blast cells as compared to the first dose.⁴¹

Adverse effects GO is associated with a variety of adverse effects, mainly consisting of infusion-related reactions, hepatotoxicity, and myelosuppression.³⁴ The infusion-related events are similar to those associated with other MoAbs and include fever, rigors, hypotension, dyspnea, nausea, emesis, and headache. Premedication with corticosteroids may reduce this complication. Myelosuppression is profound and prolonged; counts typically nadir at 7–14 days and recover at 28–35 days.³⁶ In some cases, recovery may take even longer; in fact, some patients never achieve full recovery of platelet counts; thus, the development of the response denoted CR_p (<100,000/mm³). Hepatotoxicity associated with GO therapy is another recognized adverse effect. Typically, this consists of transient hyperbilirubinemia and/or transaminitis that is of little clinical significance. The average onset is within 8 days, and duration is 20 days.³⁶ A more concerning manifestation of hepatotoxicity is hepatic veno-occlusive disease (VOD). This seems to be more common when GO is used in combination with other chemotherapy or after stem cell transplant.³⁴ When GO is used in the approved single-agent manner, VOD incidence is approximately 1–5%. However, when GO is used in combination therapy, VOD risk increases to 5–12%.³⁴ This adverse effect is unpredictable and does not correlate to age, gender, underlying disease (MDS versus AML), baseline renal or hepatic function, alcoholism, or hepatitis history.³⁴ It has been postulated that premedication with acetaminophen may increase the risk of VOD by interfering with glutathione oxidation-reduction reactions, leaving sinusoidal endothelial cells susceptible to attack by calicheamicin-generated free radicals. Until the exact mechanism of VOD development is discovered, it is recommended to avoid premedication with acetaminophen prior to GO treatment.^{28,42} VOD remains a significant concern

with GO therapy and more data is needed to determine the risks and benefits of treatment with this agent.

RADIOIMMUNOCONJUGATES

PHARMACOLOGY

The radiolabeled MoAbs consist of a MoAb coupled with a radionuclide. This therapeutic modality was developed to act as a “guided missile”; the MoAb delivers ionizing radiation solely to cells that express the antigenic determinant to which the antibody was originally developed. Thus, healthy cells are spared from the toxic effects of the radiation. Hematologic malignancies are ideal candidates for this type of treatment because they are known to be exquisitely radiosensitive.^{5,43} Radiolabeled MoAbs offer certain advantages over other MoAbs: They do not depend on host effector mechanisms or cellular internalization transport mechanisms to exert their toxic effects; rather, they emit continuous, decreasing, low-dose-rate irradiation in the form of electrons, or β^- particles, that are discharged over 1–5 mm.⁴³ These particles induce lethal DNA damage to antigen-positive cells as well as neighboring cells in close proximity to target cells.^{5,44} This can be advantageous when treating physically inaccessible, bulky tumors. Two major radionuclides are currently used in radioimmunoconjugate synthesis: ¹³¹I and ⁹⁰Y. These two radionuclides differ slightly in terms of radiation and half-life. ¹³¹I emits not only β^- particles, but also a high degree of γ radiation. The half-life of ¹³¹I is 193 h. In contrast, ⁹⁰Y emits only β^- particles and has a much shorter half-life of 64 h.⁵ However, ⁹⁰Y emits higher energy particles that actually penetrate deeper into tissue. Theoretically, this may be advantageous when treating larger, more bulky tumors. On the other hand, ⁹⁰Y is less readily available and more expensive than ¹³¹I. In addition to the DNA damage induced by the radionuclide, there is some evidence to suggest that the antibody itself stimulates host immune effector mechanisms, which may account for some of the activity of these radioimmunoconjugates in non-Hodgkin’s lymphoma.⁴⁴

THERAPEUTIC CHALLENGES

Some challenges have been encountered with radioimmunoconjugates as well. Tumor bulk, location, and burden vary greatly among patients and can significantly affect the distribution of the drug. Complex and meticulous dosimetry studies using trace-labeled radioimmunoconjugates must be conducted with each patient prior to initiating therapy. This determines where the highest concentration of radiation will be delivered; ideally, tumor sites receive the largest dose, while healthy organ and tissue sites are exposed to smaller doses.⁵ If dosimetry studies show unfavorable distribution of radiation, patients do not receive adequate therapy. Other issues hindering the success of

these compounds include large tumor burden, which prevents access of the radionuclide to the site; shedding of the antigen and circulating tumor cells, both of which deplete drug from the circulation; and nonspecific binding of the compound by normal host tissues, subsequently enhancing the toxicity.⁵ Some adverse effects encountered with these agents are similar to those experienced with other MoAbs, such as fever, chills, rash, nausea, and other infusion reactions as well as potential development of HAMA. Of particular concern is the myelosuppression, especially thrombocytopenia, seen with these compounds.^{45,46} While considerable patient variability exists, peripheral blood counts typically nadir at 3–4 weeks and stay low for up to 16 weeks after treatment. Bone marrow involvement, prior radiation, and chemotherapy exposure can enhance this effect.⁴³

APPROVED COMPOUNDS

⁹⁰Y-Ibritumomab tiuxetan (Zevalin)

⁹⁰Y-Ibritumomab tiuxetan is a radioimmunoconjugate comprising a murine-derived MoAb, targeting cell surface protein CD20, bound to the radionuclide ⁹⁰Y. The cell surface protein CD20 is expressed on >95% normal B lymphocytes and B-cell lymphomas, yet not stem cells. Additionally, CD20 is not internalized upon antibody binding; thus, the antibody-CD20 complex remains on the surface of the cell, available to bind and stimulate antibody-dependent and complement-mediated cytotoxicity.⁴⁷ The bridge between the Fc portion of the MoAb and the ⁹⁰Y isotopes is achieved through the linking compound tiuxetan. Isotopes are electrostatically chelated to tiuxetan, which is then attached to exposed amino acids in the antibody by very stable thiourea covalent bonds. Upon selective binding of the compound to CD20 receptors, ⁹⁰Y emits β^- radiation that is discharged over 1–5 mm, damaging the DNA of B lymphocytes and immediately surrounding cells.⁴³ In addition, it is thought that some contributory activity of the drug is derived from CMC and effector cell mechanisms induced by the MoAb component. Because the half-life of this compound is relatively short (64 h) and ⁹⁰Y does not emit γ -rays, ibritumomab tiuxetan is considered the safer of the approved radioimmunoconjugates.^{28,43}

Administration and pharmacokinetics Treatment with ibritumomab tiuxetan can be divided into two phases 1-week apart: a “cold” phase and a “hot” phase. The cold phase consists of delivery of an imaging agent, ¹¹¹In, which lacks therapeutic β^- emissions but does emit γ -radiation for imaging. This serves to map the distribution and uptake of the drug. In addition, rituximab is administered with the goal of clearing circulating CD20+ B lymphocytes from the circulation. This dose of rituximab is repeated in 1–2 weeks, again clearing the bloodstream of circulating CD20+ lymphocytes in order to better facilitate uptake of radiolabeled

drug into the tumor mass.⁴³ Administering therapeutic radiolabeled drug without first priming the system with cold anti-CD20 antibody merely results in uptake of drug by circulating B lymphocytes and the reticuloendothelial system.²⁸ By initially binding up circulating B lymphocytes, as well as tumor cells on the periphery of the mass, drug penetration of the tumor is enhanced. Additionally, the unlabeled anti-CD20 antibody also stimulates immune effector cells and leads to more effective tumor kill.⁴³

Adverse effects The major adverse effect associated with ibritumomab tiuxetan is myelosuppression, consisting mainly of neutropenia and thrombocytopenia.^{45,46} Because of this, several parameters must be met before patients can be treated with this agent. Qualifications for therapy include <25% lymphoma involvement of bone marrow, platelet count >100,000 cells/mm³, and no history of hypocellular marrow or failed stem cell collection.²⁸ The average time to neutrophil nadir is 62 days, while platelets typically nadir around day 53. Cells recover after approximately 22–35 days.⁴³ Additional adverse effects include those seen with other anti-CD20 agents, such as fever, hypotension, chills, skin rash, and rarely nausea and vomiting.⁴⁵

¹³¹I Tositumomab (Bexxar)

¹³¹I tositumomab is a radioimmunoconjugate comprising a murine anti-CD20 MoAb covalently linked through tyrosine amino acids in the immunoglobulin protein to iodine-131. Tositumomab does not require a linker due to direct covalent bonding between the MoAb and the radionuclide. ¹³¹I is more readily available than ⁹⁰Y and is relatively inexpensive. However, ¹³¹I emits both β- and γ-irradiation, necessitating special radiation precautions for patients receiving this compound. Dehalogenation (cleaving of the radionuclide from the compound) can occur as well; this results in potential uptake of free iodine by the thyroid and stomach. Oral thyroid blockade is recommended beginning 24 h before therapy and continuing for 14 days in order to prevent iodine uptake and subsequent hypothyroidism.⁴⁷ The rate of dehalogenation varies significantly among patients, resulting in fluctuating rates of urinary clearance. Thus, dosimetry calculations incorporating total-body distribution and tissue uptake must be completed for each patient. Doing this enables maximal tumor targeting while minimizing toxic effects to normal tissues.⁴³ Because ¹³¹I emits γ-radiation as well, it can be used as the tracer agent for the cold phase of treatment. Thus, the imaging agent is the same ¹³¹I tositumomab, used at a lower dose. Unlabeled tositumomab is also used as the cold antibody to deplete the CD20+ B-lymphocyte “sinks,” resulting in a higher dose of drug delivered to the tumor.⁴⁷

Pharmacokinetics The half-life of ¹³¹I tositumomab is approximately 8 days, but varies somewhat among

individuals because of fluctuating clearance rates of the compound.¹ The major dose-limiting toxicity of ¹³¹I tositumomab is myelosuppression, similar to that seen with ⁹⁰Y ibritumomab. Therefore, patients must have <25% lymphoma involvement of bone marrow, platelet count >100,000 cells/mm³, and no history of hypocellular marrow or failed stem-cell collection in order to receive drug.²⁸ Other acute toxicities include infusion-related effects such as nausea, vomiting, skin rash, hypotension, fever, and chills.⁴⁵ It is thought that these effects are related to the clearance of CD20+ cells.

INVESTIGATIONAL AGENTS

Numerous conjugated and unconjugated MoAbs are currently under development for the treatment of hematologic malignancies (Table 103.3). This area of research is expanding, with technological advancements rapidly increasing the spectrum of use beyond the current scope. The lymphomas and leukemias are subjects of many clinical trials, from identification of cellular surface proteins and genetic mutations to targeting specific antibodies, cell signaling pathways, and cytokines. Combination MoAb therapy is another avenue that is being explored.⁵⁸

Epratuzumab (LL2)

Epratuzumab is a humanized IgG1-κ MoAb targeted to cell surface protein CD22. This compound was initially developed in murine form and later genetically engineered to a humanized form. CD22 is mainly expressed on B lymphocytes and has been found in 60–80% of B-cell malignancies.⁵⁹ Because of its specificity for B lymphocytes, and relative lack of toxicity toward other cell lines, epratuzumab is considered an attractive agent for use in heavily pretreated lymphoma populations. Both human and murine forms are currently being investigated. Additionally, cold antibody, as well as radiolabeled (¹³¹I and ⁹⁰Yttrium) compounds, are being evaluated. Epratuzumab is rapidly internalized upon binding to CD22-expressing cells, and the main mechanism of toxicity is thought to be ADCC; CMC and direct apoptosis have not been observed in *in vitro* studies.⁶⁰

Epratuzumab has been studied in relapsed and refractory B-cell malignancies. The compound was administered intravenously, with doses ranging from 120 to 1000 mg/m²/week in phase I studies.⁶¹ Premedication with acetaminophen and diphenhydramine was included to minimize infusion reactions. Patients tolerated treatment well, as most infusion reactions were considered grade 1 and no dose-limiting toxicity was reached. In this initial treatment-refractory group of 40 patients, 3 CRs and 6 PRs were observed.⁶¹ Combination therapy with epratuzumab has also been evaluated.⁵⁸ In fact, the first trial of combination MoAb therapy included this agent. Epratuzumab and rituximab target two distinct cell

Table 103.3 Monoclonal antibodies under investigation for hematologic malignancies

Compound	Target	Cellular expression	Investigational hematologic uses	Approved clinical uses
Infliximab (Remicade®)	TNF- α	Numerous cell lines, including macrophages, are activated by TNF- α ⁴⁸	Steroid-refractory GVHD ⁴⁹	Rheumatoid arthritis, Crohn's disease ⁴⁸

surface proteins and therefore may act synergistically. Preliminary results show that combination therapy has been well-tolerated, with most patients demonstrating objective responses.⁵⁸ It remains to be seen whether initial results will be confirmed upon further evaluation. However, combination therapy is an exciting therapeutic avenue to explore, potentially offering improved efficacy by targeting two different cell surface proteins.

Apolizumab(HU1D10)

Apolizumab is another humanized IgG1MoAb currently under investigation. This compound is designed to target the antigenic determinant 1D10, which binds to the β chain variant of human leukocyte antigen-DR (HLA-DR). This 1D10 antigenic determinant is expressed primarily by lymphocytes, macrophages, and mesenchymal dendritic cells.⁶² While it is found on normal B lymphocytes, monocytes, and dendritic cells, it is also expressed on a proportion of NHL and CLL cells.⁶³ A recent study evaluated flow cytometry immunophenotyping of lymphoid malignancies in 105 patients <21 years of age. Results showed that 87/87 (100%) patients with pre-B cell ALL expressed HLA-DR and 3/3 (100%) patients with Burkitt lymphoma expressed this

antigen. However, only 2 out of 11 (18%) patients with T-cell malignancies exhibited a positive result for HLA-DR.⁶⁴ Thus, HU1D10 targets an important cell surface protein expressed in leukemias and lymphomas of B-cell origin. HU1D10 stimulates CMC, ADCC, and caspase-independent, direct apoptosis of cells expressing 1D10 antigen.^{62,63} A few phase I studies are currently evaluating patients with relapsed B-cell lymphomas; preliminary results indicate manageable toxicity, consisting mainly of grade 1–2 adverse effects.^{65–67} In one study, three of six patients with follicular lymphoma treated with 4 weekly infusions exhibited partial responses. These responses were delayed in nature, occurring at a median of 106 days and improving up to 400 days after treatment.⁶⁶ Authors suggest a unique mechanism of action due to this pattern of response, and further studies may help clarify the activity of HU1D10, including a potential role in combination therapy.

CONCLUSIONS

After many long and arduous years of research and development, MoAbs are finally beginning to play a pivotal role not only in cancer therapeutics, but in

other disease states as well. Laboratory techniques enabling the chimerization or humanization of antibodies has resulted in significant improvement in the tolerability of these compounds. Additionally, advancements in bioreactor capabilities have enabled companies to meet commercial demands for these products. Developments in recombinant technology involving linkers, toxins, and radiolabeled isotopes will lead to the availability of more MoAbs for routine

clinical use. Future studies will center on genomics, and genetic mutations found within cells that affect cellular signaling pathways. Detailed knowledge of these pathways will allow for combination regimens that concurrently target multiple areas in the malignant transformation of a cell. This opens the door for highly explicit treatment regimens that minimize toxicity to healthy cells, while maximizing toxicity to malignant clones.

Chapter 104

BLOOD PRODUCT TRANSFUSIONS IN THE HEMATOLOGIC MALIGNANCIES

Ronald E. Domen

INTRODUCTION

Blood transfusion support is critical for patients with hematologic malignancies undergoing aggressive treatment regimens. Stem cell transplantation, as well as other chemotherapy treatment protocols for the hematologic malignancies, is associated with periods of prolonged pancytopenia, i.e., "iatrogenic aplastic anemia," that require the ready availability of specialized blood transfusion support. Such blood banking and transfusion medicine expertise is typically available only in facilities that support the highly specialized treatment of these complicated patients. Although the primary treatment of patients with hematologic malignancies may be performed at specialized or academic medical centers located away from the patient's home, it is often the patient's local or community hospital that is called upon to transfuse blood products in specific or emergent situations after the patient has been discharged home. Although convenient for the patient, the local hospital may not be prepared to address complicated transfusion issues. The need for specialized transfusion support in the hematologic malignancies often continues well beyond the patient's immediate hospitalization and treatment, and not occasionally for the life of the patient.

Transfusion of any blood product involves the risk of an adverse reaction, including disease transmission. Therefore, it is important that a patient who requires a transfusion be transfused only when necessary and only with the specific, indicated blood component. This chapter will consider important topics related to blood product transfusion that have relevancy to any physician who may be called upon to treat patients with hematologic malignancies. In addition, the issue of transfusion in palliative care and the hospice setting will be briefly examined.

RED BLOOD CELL TRANSFUSION

Anemia is a common complication in patients with hematologic malignancies. The symptoms of anemia in any given patient can be variable, depending on several, often independent factors: the hemoglobin level, the rapidity of the development of the anemia, the patient's age, and the presence of underlying disease.¹ In general, red blood cell transfusion is indicated to relieve or prevent the signs and symptoms of hypoxemia. Ideally, the decision to transfuse should be individualized and appropriate for each patient and his or her disease process.¹⁻³ Anemia is usually not associated with significant symptoms until the hemoglobin concentration is less than 7 or 8 g/dL. Symptoms are also related to the rapidity of the fall in hemoglobin concentration and the patient's ability to maintain a normal blood volume. In general, red cell transfusion is usually not indicated when the hemoglobin concentration is >10 g/dL, but it is usually indicated when the hemoglobin concentration is <7 g/dL.¹⁻³

Guidelines for the appropriate use of red cell transfusions have been developed and published by several physician groups.⁴⁻⁶ Common general principles include the following: (1) the cause of anemia should be determined prior to transfusion, if possible, and appropriate specific or alternative therapy instituted (e.g., iron for anemia secondary to iron deficiency, vitamin B₁₂ for anemia secondary to vitamin B₁₂ deficiency, etc.); (2) clinical judgment for the need for transfusion should be used rather than a universal or automatic "trigger" hemoglobin level for transfusion; (3) a determination and assessment of those symptoms that are to be alleviated should be made; (4) an assessment of the patient's intravascular blood volume should be done and any volume deficiency restored with crystalloid or colloid solutions; (5) patients with

underlying cardiovascular or respiratory diseases may need to maintain a hemoglobin concentration >10 g/dL; and (6) the risks and benefits of the transfusion should be discussed with the patient (i.e., informed consent).

Providing compatible red blood cells for transfusion to patients with cancer who have not undergone stem cell transplantation is usually not significantly different than transfusion for any other patient with anemia. The usual principles of specimen collection, serum antibody screening, and crossmatching apply. In general, approximately 3% of all patients transfused with red cells will form an alloantibody to one or more of the foreign red cell antigens.⁷ However, approximately 25% of alloantibodies will decrease in titer over time and may no longer be detectable in routine serological tests.⁸ If the patient should again be challenged by the specific foreign antigen, an anamnestic response and subsequent hemolytic transfusion reaction may result. Although patients with hematologic malignancies may be immunosuppressed, they may still form red cell alloantibodies following transfusion.

The patient who has undergone an ABO incompatible hematopoietic stem cell transplantation presents unique challenges in providing compatible transfusion support. Approximately 30–40% of patients undergoing an allogeneic hematopoietic stem cell transplantation will receive an ABO incompatible graft from their donors.^{9–11} A major ABO mismatch between the donor and recipient is present when a foreign ABO antigen is introduced into the patient. A typical example would be, a group O recipient receiving a transplant from a group A, B, or AB donor.^{9,10} In a major ABO mismatch, the recipient has preformed circulating anti-A and/or anti-B isohemagglutinin that could potentially react with newly introduced ABO antigen on the stem cells or on contaminating donor red blood cells. The production of anti-A and/or anti-B may continue for several months following the transplant.^{9,10,12–14} Red cells used for transfusion must, therefore, be compatible with both the donor and the recipient. Group O red cells can be given to all major ABO-incompatible recipients in order to avoid confusion.

A minor ABO mismatch involves the introduction of foreign anti-A and/or anti-B isohemagglutinins or lymphocytes capable of producing anti-A or anti-B after engraftment.^{9–11} An example is a group A recipient who receives group O or B stem cells (or a group B recipient who receives group O or A stem cells, or a group AB recipient who receives group O, A, or B donor stem cells).

Combined major and minor ABO mismatch occurs when a group A recipient receives group B cells, or when a group B recipient receives group A stem cells.^{9,10} In addition, other antigen mismatches (e.g., in the Rh system) may be important in certain clinical situations.^{15,16} Passenger lymphocytes from the donor graft may also produce non-ABO antibodies, with resulting immune hemolysis.^{15–17}

Major, minor, and combined major and minor ABO mismatched stem cell transplantation can be associated with acute or delayed hemolysis following transfusion of donor cells.^{9,10} Acute hemolysis following a major ABO mismatched transplantation can generally be avoided by removing the incompatible red cells prior to transfusion of the graft. Immune hemolysis complicates approximately 10–15% of minor ABO incompatible stem cell transplants.¹¹ Delayed immune hemolysis can be seen following minor ABO incompatibility, when the transplanted passenger lymphocytes recognize the recipient's A or B antigen as foreign and actively produce anti-A or anti-B. This scenario is more likely to occur when the donor is group O and the recipient is group A or B and is characterized by the onset of immune hemolysis approximately 7–10 days after transplantation. The risk of immune hemolysis following minor ABO incompatibility appears to increase when the donor is unrelated or when cyclosporin is the sole agent used to prevent graft-versus-host disease (GVHD). While the majority of cases of immune hemolysis following minor ABO incompatibility are self-limited and last for 2 weeks or less, rare cases of severe hemolysis following minor ABO incompatibility have been fatal.¹¹ As noted above, non-ABO antibodies may also be produced by passenger lymphocytes and result in clinically significant immune hemolysis. Guidelines for blood product selection in the stem cell transplant setting are shown in Table 104.1.

Stem cell transplant patients can also suffer acute or delayed hemolytic transfusion reactions secondary to the usual causes for this adverse reaction (e.g., misidentification of blood crossmatching specimens, patient identification errors, laboratory testing errors, etc.) and it should not be assumed that hemolysis is simply secondary to the engraftment of an ABO mismatched bone marrow.¹⁰ Other causes for hemolysis, such as thrombotic thrombocytopenic purpura (TTP), can also complicate the clinical course of patients with hematologic malignancy or stem cell transplantation.

PLATELET TRANSFUSION

As early as 1910, platelet transfusions were shown to have a beneficial effect in bleeding patients.¹⁸ In the 1960s, the development of plastic blood collection and storage bags allowed the ready concentration and storage of platelets. In 1964, investigators at the National Cancer Institute reported the efficacy of platelet transfusions in patients undergoing therapy for leukemia.¹⁸

Thrombocytopenia or decreased platelet function are common complications in patients with hematologic malignancies. Patients with decreased platelet number or function are at increased risk for hemorrhage. The normal lifespan of a platelet is approximately 9.5–10.5 days and approximately 4–5 days for the transfused platelet.^{10,19,20} The splenic pool accounts

Table 104.1 Transfusion support for patients undergoing ABO-mismatched allogeneic HPC transplantation¹⁰

^aPlatelet concentrates should be selected in the order presented.¹⁰

HPC = hematopoietic progenitor (stem) cell; Phase I = from the time when the patient/recipient is prepared for HPC transplantation; Phase II = from the initiation of myeloablative therapy until (1) for RBC – DAT is negative and antidonor isohemagglutinins are no longer detectable (i.e., the reverse typing is donor type) and (2) for FFPs – recipients erythrocytes are no longer detectable (i.e., the forward typing is consistent with donor's ABO group); Phase III = after the forward and reverse type of the patient are consistent with donor's ABO group. Beginning from Phase I all cellular components should be irradiated and leukocyte reduced. (From Ref 10, used with permission.)

for approximately 30–35% of the total body platelet mass.^{19,20} However, platelet lifespan decreases with increasing thrombocytopenia.²¹ A number of conditions in the patient with hematologic malignancy can potentially alter platelet numbers or function and can be associated with hemorrhage (Table 104.2). Platelets are generally indicated in bleeding patients with thrombocytopenia and/or platelet dysfunction. Platelet transfusion is generally not indicated in platelet-consumptive states (e.g., ITP or TTP) unless life-threatening bleeding is present.^{19,21–23}

Assuming a steady-state condition, there is a fairly direct linear relationship between the platelet count and the bleeding time as the platelet count decreases below 100,000/ μ L.²¹ Serious spontaneous hemorrhage usually does not occur until the platelet count falls below 10,000/ μ L, and this threshold is used by many physicians for the prophylactic administration of platelets.^{24,25} Indeed, otherwise stable thrombocytopenic patients can probably tolerate platelet counts in the 5000–10,000/ μ L range.^{22,23} A higher platelet transfusion “trigger” may be considered in those patients with underlying complications of fever or infection, other coagulation defects (e.g., hypofibrinogenemia), intracranial pathology, or other conditions that affect platelet function or number.^{19,22,23} Higher platelet counts are also warranted in those thrombocytopenic patients undergoing invasive procedures or

surgery. A platelet count of 50,000/ μ L is generally felt to be adequate for many surgeries, and a count in the 30,000–40,000/ μ L range is probably adequate for needle biopsies.^{19–23,26} However, only minimal evidence-based data is available as to what constitutes an optimal platelet count for various invasive procedures.

Platelet components for transfusion are prepared by two primary methods: platelet concentrates (random platelets) or plateletspheres (apheresis platelets).^{10,27} A single platelet concentrate is the unit of platelets obtained from an individual unit of randomly donated whole blood. A platelet concentrate contains at least 5.5×10^{10} platelets suspended in 40–70 mL of plasma. The approximate dose for platelet concentrates is 1 unit/10 kg of patient body weight. Thus, in the adult patient, the usual transfusable dose would be 4–6 units pooled as a single unit. As each platelet concentrate in a pooled product comes from an individual donor, each pooled transfusion exposes the recipient to that number of donors. Although the risk of transfusion-transmitted infection bears some relationship to the number of donor exposures, the increasing efficacy of donor screening and testing has decreased concerns in this area. Apheresis platelets are collected using cell separator technology, and 1 unit of apheresis platelets contains $\geq 3.0 \times 10^{11}$ platelets suspended in 100–500 mL of plasma. Thus, in the adult patient, a unit of apheresis platelets contains one transfusable dose of platelets.

Paraproteinemia (e.g., macroglobulinemia, multiple myeloma)	
Hepatic and/or renal failure	
Drugs	
<i>Disordered platelet distribution</i>	
Splenomegaly	
Massive transfusion	

Both preparations of platelets are stored at room temperature (20–24°C) for up to 5 days after collection. Room temperature storage has been shown to be conducive to the potential growth of contaminating bacteria and this complication has prompted blood banks to recently institute bacterial surveillance systems for platelets.²⁸ Transfusion-transmitted bacterial infection should be considered in any patient who develops fever during a platelet transfusion, and appropriate cultures from the platelet product and the patient should be obtained.²⁹ Novel platelet products, such as frozen platelets, cold-stored liquid platelets, and lyophilized platelets are in various stages of research and development.³⁰

The response to platelet transfusion will depend on the patient's clinical status and can be assessed by (1) whether or not bleeding stops following transfusion and/or (2) measuring the posttransfusion platelet increment 10–60 min after transfusion. The corrected count increment (CCI) is one accurate measure of patient response to platelet transfusion.^{10,20,26} The CCI is calculated as follows:

$$\text{CCI} = (\text{posttransfusion count } [\mu\text{L}] - \text{pretransfusion count } [\mu\text{L}]) \times \text{BSA}(\text{m}^2) / (\text{platelets transfused } (\times 10^{11})),$$

where BSA is the patient's body surface area (m²). The CCI is generally >7500 at 10–60 min after transfusion and >4500 at 24 h. The predicted platelet count increment (PPCI) and the percent platelet recovery (PPR) are also measures that have been used to evaluate the expected response to platelet transfusion.^{10,20,21,26} Others have more simply defined a poor response to prophylactic platelet transfusion as a failure to increase the platelet count above the "trigger" count prior to the transfusion.^{22,23}

Platelet refractoriness is defined as the repeated failure (two or more times) to achieve a satisfactory response to platelet transfusions.^{22,23} Some authors have used two consecutive failures to achieve a satisfactory response as indicative of refractoriness, while others have used two to three failures (not necessarily consecutive) over a 2-week period. A number of immune and nonimmune factors can contribute to decreased platelet increments following transfusions (Table 104.2).^{19,22,23,31} The primary immune cause of platelet refractoriness is HLA alloimmunization, but its incidence has declined in recent years primarily due to the recognition that leukocyte reduction of blood components helps to prevent HLA alloimmunization. Nonimmune causes of platelet refractoriness, such as infection and splenomegaly, are important reasons associated with decreased platelet survival following transfusion. The Trial to Reduce Alloimmunization to Platelets (TRAP) Study Group found that for patients with AML, the incidence of HLA alloimmunization was 33% in those who had never been pregnant and 62% in those who had been pregnant.³² In patients who received leukocyte-reduced blood components, the incidence of HLA alloimmunization was 9% and 32%, respectively.³²

The management of patients refractory to platelet transfusion can present many challenges.²⁶ Platelets expressing HLA class I antigens and antibodies to these antigens is one of the primary causes of immune-mediated platelet refractoriness. While HLA matching between the donor and the recipient has been the traditional approach to selecting platelets for alloimmunized patients, other methods, such as platelet crossmatching, have shown efficacy.²⁶ Blood centers or blood banks that have established standardized platelet crossmatch techniques and procedures can often supply compatible apheresis platelets from their inventory in relatively

short periods of time. As blood group A and B antigens are also expressed on platelets, ABO matching of platelets should also be considered in the patient who is refractory.^{26,33–35} In addition, anecdotal experience supports a trial of random, pooled platelet concentrates for the patient who has been receiving only apheresis platelets. A random mix of HLA types in a pooled platelet concentrate might “bypass” the patient’s HLA antibodies. Other approaches to platelet refractoriness, such as the use of intravenous immunoglobulin (IVIg), intravenous Rh-immune globulin, or continuous platelet drips have not been supported by controlled studies.²⁶ While there is no definitive or standardized approach

to managing platelet refractoriness, our approach is presented in Figure 104.1.

SPECIALIZED BLOOD COMPONENTS

LEUKOCYTE-REDUCED BLOOD COMPONENTS

There are three main indications for using red blood cell and platelet components that are leukocyte-reduced: (1) to decrease or prevent the occurrence of febrile, nonhemolytic transfusion reactions, (2) to reduce the incidence of HLA alloimmunization, and (3) to prevent or reduce the risk of transfusion-transmitted

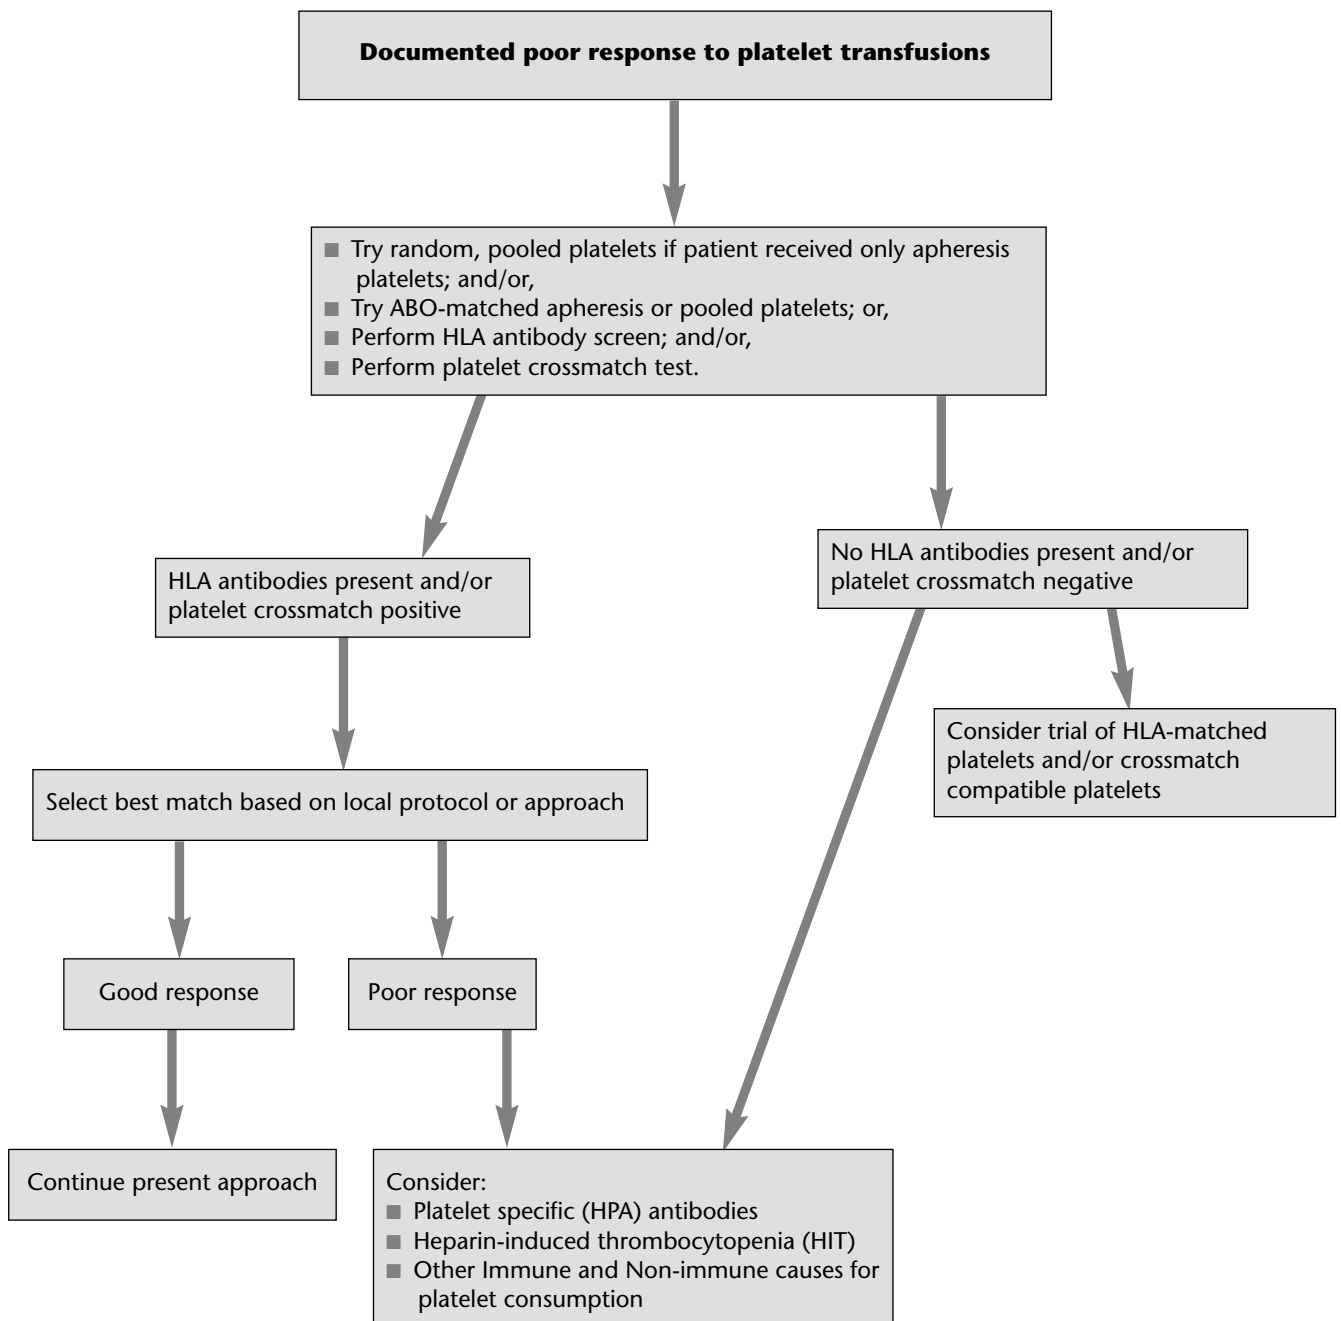

Figure 104.1 Algorithm for evaluation of platelet refractoriness

cytomegalovirus (TT-CMV) infection.^{22,23} Other clinical uses of leukocyte-reduced blood components, such as reducing transfusion-related immunomodulation, or reducing other transfusion-transmitted infections (e.g., EBV, HHV-8, HTLV-I/II, etc.), should be considered experimental until additional studies are performed. Leukocyte reduction has not been shown to prevent transfusion-associated GVHD (TA-GVHD; see below).^{36,37}

A unit of whole blood contains approximately $\geq 1-10 \times 10^9$ white blood cells.¹⁰ Leukocyte reduction can be performed during or shortly after collection (prestorage leukocyte reduction), in the laboratory prior to issuing of the blood component (poststorage leukocyte reduction), or at the bedside. The first two methods are preferable, as bedside leukocyte reduction lacks proper quality control measures to achieve uniform leukocyte reduction.³⁸ Red blood cells and platelets (pooled platelets and apheresis platelets) are considered to be leukocyte-reduced if the residual leukocyte count is $< 5 \times 10^6$. In addition to the use of specialized filters to achieve leukocyte reduction, apheresis platelets can also be considered leukocyte-reduced if the residual leukocyte count is $< 5 \times 10^6$ at the time of collection.

Some blood centers in the United States, as well as a number of countries, have promoted and instituted universal leukocyte reduction of all blood components for all patients.

Leukocyte reduction for febrile, nonhemolytic transfusion reactions

Febrile, nonhemolytic (FNH) transfusion reaction is one of the most frequent adverse reactions related to transfusion.³⁹ In addition to a rise in temperature ($\geq 1^\circ\text{C}$), FNH transfusion reactions can be associated with chills, rigors, headaches, nausea, and/or vomiting.³⁹ Symptoms typically appear during the transfusion, but may not manifest until 1–2 h later. Usually, FNH transfusion reactions are not life-threatening, but can be associated with increased patient discomfort requiring the administration of additional medications. In addition, fever can also be a manifestation of more severe transfusion reactions (e.g., hemolytic transfusion reactions or bacterial contamination).

Leukocyte reduction for the prevention of FNH reactions is more effective in the case of red blood cell transfusions and less effective for platelet transfusions.^{39–42} FNH transfusion reactions can have multiple causes related to both recipient and donor factors, but in the case of platelets, the release of inflammatory cytokines by leukocytes during storage probably accounts for the majority of reactions. Prestorage leukocyte reduction helps to further decrease the incidence of platelet-related FNH reactions by decreasing the passive accumulation of cytokines released by white cells. IL-1 α is one of the primary cytokines felt to be responsible for FNH reactions following platelet transfusion. TNF α , IL-6, and IL-8 have also been shown to accumulate in

plasma during platelet storage, but the role played by these cytokines in contributing to FNH reactions is unclear.^{39,43}

There is suggestive evidence that some severe hypotensive reactions following the transfusion of leukocyte-reduced blood components may be related to the infusion of bradykinin.^{39,43} It is speculated that bradykinin is generated during the filtration process when certain leukocyte-depletion filters are used. These hypotensive reactions may be enhanced if the recipient, or the donor, is taking angiotensin converting enzyme (ACE) inhibitor medications.^{39,43}

HLA alloimmunization and leukocyte reduction

A number of studies have been performed that demonstrate the efficacy of leukocyte reduction to prevent HLA alloimmunization.^{32,44–48} As platelets have HLA class I antigens, leukocyte reduction has been shown to decrease the incidence of refractoriness to platelet transfusion (see above). There does not appear to be any significant effect of leukocyte reduction on the incidence of platelet refractoriness secondary to platelet-specific antibody. All patients who are potential candidates for stem cell transplantation should receive leukocyte-reduced blood transfusions to minimize the formation of HLA antibodies. In our institution, as in many others, all patients with hematologic and solid tumor malignancies routinely receive leukocyte-reduced blood products from the time of initial diagnosis.

CMV “safe” blood components and leukocyte reduction

Transfusion-transmitted CMV (TT-CMV) infection was first described in 1966. The incidence of CMV seropositivity in the blood donor population ranges from 60% to 80% or higher, depending on the geographic area. Prior to the advent of current leukocyte-reduction filters, providing CMV “safe” blood products required the collection of blood from CMV-seronegative blood donors. However, despite seronegativity, some donors may still be able to transmit CMV (approximately 4% of seronegative blood products are associated with a risk of TT-CMV), and maintaining a separate inventory of CMV-seronegative blood is problematical.^{49,50} Some blood centers no longer routinely test blood donors for CMV.

Following primary infection, CMV remains latent in various white blood cell populations, but periodic viral shedding and/or reactivation of infection may occur. Sites of latency include CD34+ hematopoietic progenitor (stem) cells, CD33+ progenitor cells, monocytes (macrophages), and probably granulocytes. Monocytes appear to be one of the primary sites of CMV latency.^{50–53} In healthy, CMV-seropositive blood donors, approximately 0.004–0.12% of peripheral blood mononuclear cells are latently infected.⁵² Over the years, a growing number of studies have demonstrated the efficacy of leukocyte reduction in making blood components CMV “safe” for the prevention of

TT-CMV in hematologic and stem cell transplant patients.^{51–60} However, some studies question the efficacy of leukocyte reduction in preventing TT-CMV.⁶¹ Improved methods to monitor and detect CMV antigenemia and infection in the immunosuppressed patient have led to early detection and treatment of infection.^{62,63} In addition, emerging data indicates that other factors, such as the seropositive stem cell transplant recipient, the degree of immunosuppression, and the stage of acute GVHD put the recipient at greater risk for CMV infection/disease because of reactivation of latent virus, rather than through the acquisition of new infection through blood transfusion.^{64–66}

While specific data is lacking, a number of institutions have used leukocyte reduction as the sole method for providing CMV-safe blood components. The only cellular blood component that cannot be leukocyte-reduced is granulocytes. If CMV status of the donor is important in those rare instances when granulocyte transfusions are considered for the infected patient with a hematologic malignancy, consideration should be given to test the donor for CMV (see below).

IRRADIATION OF BLOOD COMPONENTS

TA-GVHD is a rare, potentially lethal disorder caused by the engraftment and proliferation of donor lymphocytes in the transfusion recipient.^{36,67} Viable donor lymphocytes in the transfused blood component recognize the HLA antigens of the recipient and mount an immune response. TA-GVHD was first reported almost four decades ago and, to date, over 200 cases of TA-GVHD have been reported. The true incidence is unknown, as it is thought that many patients with TA-GVHD go unrecognized and additional cases are underreported, but it is estimated that TA-GVHD occurs in 0.1–1.0% of patients with hematologic malignancies.^{67,68} While TA-GVHD occurs more commonly in immunocompromised patients, numerous cases have occurred in immunocompetent patients.

TA-GVHD can be prevented by gamma irradiation of blood components prior to transfusion. The standard dose of irradiation is 2500 cGy (25 Gy or 2500 rad) targeted to the central portion of the container, and a minimum of 1500 cGy targeted to all other areas of the component. The maximum dose should not exceed 5000 cGy.^{67,68} The only indication for the irradiation of blood is to prevent TA-GVHD. Those at risk for TA-GVHD are still being defined, but most authorities would agree that the patient groups listed in Table 104.3 should receive irradiated blood components.^{67–70} Some hospitals have opted to simply irradiate their entire blood supply in order to avoid this complication of transfusion.

All cellular blood products have been implicated in causing TA-GVHD. The clinical presentation of TA-GVHD generally includes fever, rash, diarrhea, and evidence of liver dysfunction.^{67,68} Fever is often the presenting sign and may occur as early as 4 days

Table 104.3 Patients at risk for TA-GVHD who should receive irradiated blood products^{67–70}

Significant risk
Patients undergoing hematopoietic stem cell transplantation (allogeneic or autologous)
Recipients of a stem cell transplant (allogeneic or autologous)
Congenital immunodeficiency syndromes
Intrauterine transfusions
Exchange transfusions in neonates
Patients receiving HLA-matched platelet transfusions or donors known to be haplotype-homozygous
Patients with Hodgkin's lymphoma
Transfusions from biologic (blood) relatives
Chronic lymphocytic leukemia treated with highly immunosuppressive purine analogues (e.g., fludarabine)
Possible/probable risk
Other hematologic malignancies (e.g., acute leukemia, non-Hodgkin's lymphoma)
Immunosuppressed patients with solid tumors receiving immunosuppressive and myeloblastic therapy (e.g., neuroblastoma, rhabdomyosarcoma, glioblastoma, immunoblastic sarcoma)
Immunosuppressed solid organ transplant recipients
Premature neonates
Recipient-donor pairs from genetically homogeneous populations (e.g., Japan)
No defined risk
Patients with acquired immunodeficiency syndrome (AIDS)
Full-term, healthy neonates
Patients receiving immunosuppressive medications

posttransfusion. Pancytopenia (particularly leukopenia and thrombocytopenia) develops late in the course (median 16 days).^{67,68} Infection or hemorrhage are the most common causes of death, occurring within 3 weeks of onset.^{67,68} Treatment is rarely effective, and the mortality rate is >90%.^{67,68} In our institution, as in many others, patients with hematologic malignancies, as well as those who have undergone stem cell transplantation, routinely receive irradiated blood products from the time of initial diagnosis.

WASHED AND VOLUME-REDUCED BLOOD COMPONENTS

The typical unit of red blood cells for transfusion is already volume-reduced (i.e., low volume or “packed”). Platelets can also be volume-reduced prior to transfusion if there is a clinical need to limit the patient's intake of fluids.¹⁰

The washing of red cells and platelets is typically performed with 0.9% sodium chloride (normal saline). Washing effectively removes most of the plasma in the unit of red cells or platelets. Limiting a patient's exposure to donor plasma may be indicated for the recipient who is IgA-deficient and in whom there is concern about exposure to IgA-containing plasma, or if the plasma contains a specific protein or antibody that

might be detrimental to the recipient.^{71,72} A patient known to have anaphylactic/anaphylactoid reactions to allogeneic plasma may also be a candidate for washed blood components.^{71,72} In the case of red blood cells, if there are clinical concerns about the recipient receiving potassium, washing may also be indicated to remove potassium that has accumulated in the plasma during storage or following irradiation. Both red cells and platelets are typically lost during the washing process. Washing is not effective in removing infectious agents, and thus does not decrease the potential for transfusion-transmitted infection. Washing is also not effective in removing significant numbers of white blood cells (i.e., for rendering a component leukocyte-reduced).¹⁰

GRANULOCYTE TRANSFUSION

Infection remains one of the leading causes of death in the hematologic malignancies, and the transfusion of granulocytes to the neutropenic, infected patient has been attempted with varying levels of success as a therapeutic adjunct.⁷³⁻⁷⁷ Typically, granulocytes are collected from normal donors by apheresis techniques using hydroxyethyl starch (HES) following corticosteroid administration.^{10,73,74} Corticosteroid administration to the normal donor enhances the number of granulocytes collected, and HES is a red cell sedimenting agent that promotes separation of the granulocytes from contaminating red cells during collection. The final product should contain at least 1×10^{10} granulocytes.¹⁰ Granulocytes should be maintained at 20–24°C without agitation, and must be transfused within 24 h of collection. Once initiated, a course of granulocyte transfusion therapy should be continued at least daily for 4–5 days. Granulocytes should be administered through a standard blood infusion set, but leukocyte-reduction filters are contraindicated. If a CMV-safe granulocyte product is desired then the donor's CMV status must be determined, although the importance of testing the donor for CMV has been questioned by some.^{78,79} Granulocytes contain significant amounts of contaminating red blood cells and should thus be ABO and Rh compatible with the recipient. If the recipient also has red cell alloantibodies, then the donor's red cells should be negative for the corresponding antigen(s). If necessary, granulocytes can be irradiated prior to administration.

The indications for granulocyte transfusion typically include patients who have (1) a polymorphonuclear leukocyte (PMN) count $<500/\mu\text{L}$, (2) a documented infection, and (3) are unresponsive to antibiotic therapy (generally for at least 48 h).^{73,74,77} It is also expected that the patient, and his or her bone marrow, will recover once the infection is controlled. Most patients will experience FNH transfusion reactions during or following granulocyte transfusion. In addition, a significant percentage of recipients will develop

antileukocyte antibodies following repeated granulocyte transfusions. Pulmonary reactions (e.g., infiltrates, hypoxia, or dyspnea) are also commonly seen after granulocyte transfusions.^{73,74,77} These reactions can often be treated symptomatically, but more severe adverse reactions, such as transfusion-related acute lung injury (TRALI), can also be seen.⁸⁰ Although not commonly reported following granulocyte transfusion, TRALI can cause significant morbidity and mortality. The administration of amphotericin B in close proximity to granulocyte transfusions has been reported to cause pulmonary reactions.^{73,77} This has been disputed but, when feasible, separating the administration of both by several hours seems prudent.

The prophylactic use of granulocytes has not been supported by most randomized studies in the literature.⁷³⁻⁷⁷ In addition, not all types of infection respond equally to a course of granulocyte transfusion therapy. For example, fungal infections appear to be less responsive than bacterial infections.⁷³⁻⁷⁷ Because of the conflicting data on efficacy, the use of granulocytes has decreased over the years. More recent studies have focused on the number of granulocytes collected from donors. With the ready availability of granulocyte colony-stimulating factor (G-CSF), increased interest has been directed towards using G-CSF, with or without concurrent dexamethasone administration, to stimulate the formation and collection of larger numbers of PMNs in donors.⁸¹⁻⁸³ Several studies have demonstrated the feasibility of collecting large numbers of PMN's from normal donors, but the efficacy of granulocytes collected in this manner remains to be proven.⁸⁴ In addition, the side effects associated with G-CSF administration has raised ethical concerns of its usage in otherwise healthy donors.⁸⁵ The use of G-CSF in normal donors should only be performed as part of formal research protocols, and a national donor registry should be established to collect safety and efficacy data.⁸⁵

TRANSFUSION IN PALLIATIVE CARE

There are relatively few studies related to transfusion therapy in the palliative care and hospice settings, although anemia and its associated symptoms may be evident in these patients. Although bleeding may be an indication for transfusion, the relief of symptoms related to anemia, such as weakness or shortness of breath, are probably more common in this setting.⁸⁶ Fatigue and mood disturbances are common in patients with advanced cancer.⁸⁷ Anemia, and related nutritional deficiencies (e.g., iron deficiency), have been shown to be contributory factors to causing fatigue, impaired cognitive function, poor concentration, memory problems, and other related symptoms.⁸⁷⁻⁹¹ Transfusion, with or without erythropoietin, can be considered for these quality of life issues for patients in the terminal stages of cancer, rather than for any possible prolongation of life

when, quality may not be significantly altered.⁹²⁻⁹⁴ Transfusions can be administered in the patient's home as well as in conventional care settings; however, home transfusion therapy requires greater commitment and communication between care givers in order to provide safe and efficient transfusion therapy.⁹⁵⁻⁹⁸ Home transfusion therapy, and transfusion in the hospice setting, has been well-received by those patients unable or unwilling to travel to the hospital or infusion unit.⁹⁹⁻¹⁰¹ If palliative care initiatives for adult and pediatric patients are to be performed in the home, then transfusion therapy should be given consideration in this setting. Adverse reactions to transfusions should be handled with the same due diligence as in any other conventional care setting in order to guard against and prevent any increased morbidity and mortality.⁹⁷⁻¹⁰¹

SUMMARY

The use of specialized blood products in patients with hematologic malignancies is an important part of the therapeutic and supportive care of these patients. While the indications for red cell transfusion are essentially the same for any patient who has anemia, platelets and other specialized components have unique requirements in this group of patients. The ready availability of leukocyte-reduced and/or irradiated blood components are essential elements for optimal patient care. Close cooperation and consultation between the treating physicians and the transfusion service are critical, as these patients can present many transfusion-related challenges. Transfusion medicine specialists should be readily available for consultation.

Chapter 105

GROWTH FACTOR SUPPORT IN HEMATOLOGIC MALIGNANCIES

George Somlo

HEMATOPOIETIC GROWTH FACTORS

Over the preceding decades, a variety of hematopoietic growth factors—glycoproteins by their chemical structure—have been identified. Following purification, cloning, and manufacturing of recombinant forms of these glycoproteins, their potential use in clinical practice has been tested extensively. Native growth factors and their recombinant derivatives target cytokine type receptors and facilitate growth and differentiation of multilineage and late-stage cell types.

Two groups of myeloid growth factors currently available for clinical use are recombinant human granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF). These factors differ in their specific roles as well as in their hematopoietic targets. G-CSF stimulates cells of multilineage potential and enhances late-stage differentiation of neutrophils. GM-CSF also effects multilineage proliferation and acts synergistically with G-CSF in its effect on neutrophils. In addition, it supports development of mixed neutrophil, eosinophil, and macrophage colonies.^{1,2} Two recombinant G-CSF products are currently in the market: lenograstim—expressed in yeast—is available outside the United States, while filgrastim—expressed in *Escherichia coli*—is in use within the United States. Recently, a pegylated version of filgrastim, characterized by a much-prolonged half-life, has been successfully tested and approved as a potential alternative to filgrastim. Out of the two GM-CSF preparations in use, sargramostim is expressed in yeast, while molgramostim is bacteria-derived. Sargramostim is in clinical use in the United States.

Recombinant human erythropoietin is the primary regulatory growth factor of erythropoiesis. Erythropoietin is responsible for the differentiating and maturation process in later phases of red cell development. Epoetin alpha and its glycosylated modified form darbepoetin alpha (with a resulting longer half-life) are clinically used in the United States, while epoetin beta is used elsewhere.³⁻⁵

The primary regulator of thrombopoiesis is thrombopoietin. While this glycoprotein does have an effect on multilineage progenitors, there is substantial homology between this growth factor and erythropoietin, e.g., it is unique by its functional ability in stimulating megakaryocyte progenitor colony growth and differentiation. Lack of expression of the receptor for this growth factor will result in substantially reduced thrombocyte counts, but, albeit in reduced number, functional platelets will still be present, suggesting that other factors might play a role in the growth, differentiation, and maturation of the megakaryocyte lineage. Recombinant thrombopoietin will lead to an increase in megakaryocyte and platelet counts, but, due to its relatively late onset of effects (10–14 days), and pending further evaluation of safety of specific recombinant thrombopoietin products following administration, identification of its potential clinical benefits await validation in future clinical trials.^{6,7}

Platelet release is also facilitated by interleukin-11 (IL-11), possibly through a synergistic effect with other cytokines, including thrombopoietin. IL-11 is associated with a number of side effects, and its role as well as the appropriate dosing in hematologic malignancies has yet to be established adequately.^{8,9}

GENERAL INDICATIONS FOR PRESCRIBING GROWTH FACTORS

NEUTROPENIA

The most significant risk from severe and/or prolonged myelosuppression is febrile neutropenia. Majority of patients with leukemias, myelodysplasias, and advanced stages of lymphomas and myeloma are already immunocompromised; hence, they are at high risk for developing febrile neutropenias.

PRIMARY PROPHYLAXIS

This term describes the application of growth factors for the purpose of preventing febrile neutropenia in untreated patients. According to guidelines developed

by the American Society of Clinical Oncology (ASCO),¹⁰ such prophylaxis is warranted in the setting of treating high-risk patients with chemotherapy regimens associated with at least a 20% likelihood of febrile neutropenia. Most patients in need of intense combination of chemotherapy for newly diagnosed or relapsed leukemia or lymphoma are at high risk for febrile neutropenic complications, either because of disease-related cytopenia, age, poor performance-status, immune-deficiency, or due to myelosuppression caused by therapy. Most patients suffering from hematologic malignancies should be considered candidates for growth factor support even under the current guidelines, based on conclusions from randomized or well-conducted controlled studies in virtually every disease category and with differing treatment modalities. Debate, however, exists about the use of primary prophylaxis growth factor support in patients with acute myeloid leukemia or advanced myelodysplastic syndrome.

SECONDARY PROPHYLAXIS

In patients who have experienced febrile neutropenia following chemotherapy, chances of a repeat incidence can be avoided by either dose reduction, delay in treatment, or by administration of growth factors. While not all patients who have developed febrile neutropenia with the first cycle of chemotherapy will develop it during subsequent cycles, appropriate actions are needed to avoid potentially fatal future episodes. Recent data with dose-dense, growth factor-supported regimens in patients with malignant lymphomas suggest that prescribing the full planned dose without delay translates into clinical benefits. While dose-dense/intense chemotherapy mandates the use of growth factors, considering that timely administration of chemotherapy is of therapeutic importance, administration of growth factors in general is an important ancillary tool and should be preferred to the strategy of dose adjustment or delay of therapy.¹¹

ANEMIA

Patients with hematologic malignancies frequently present with anemia and are likely to face worsening of this condition while undergoing induction therapy, as well as repetitive consolidation, or maintenance therapy. While acute reversal of anemias still requires blood transfusions, epoetin alpha and beta are now available to treat both disease and treatment-related anemias. Current guidelines developed by ASCO recommend use of erythropoietin for patients with a hemoglobin of less than 10 g/dL in the setting of treated or untreated myelodysplasia. Either treatment-related or disease-associated anemia can also be alleviated by the judicious use of erythropoietin.⁴

THROMBOCYTOPENIA

Hematologic malignancies frequently present with symptoms due to absolute and/or functional thrombocytopenia. Currently, platelet transfusion remains the only proven method leading to rapid rise in platelet counts. The exact role and optimal dosing of the only approved platelet-lineage specific agent, IL-11, either in the prevention of the need for platelet transfusion or as a facilitator of platelet recovery, is unclear.^{8,9} Advanced clinical studies of thrombopoietin-like agents in patients with autoimmune thrombocytopenia are in progress .

GROWTH FACTORS IN SPECIFIC HEMATOLOGIC DISEASES

ACUTE MYELOID LEUKEMIA

The majority of patients undergoing remission induction and subsequent postremission therapy for acute myeloid leukemias will suffer from neutropenic fever. Given that their general health is frequently compromised by the time the diagnosis is made, whenever such patients develop this complication, prolonged hospitalization and antibiotic therapy are the likely consequences. Bacterial and fungal infections are significant causes for morbidity and mortality following administration of intensive induction or consolidation chemotherapy. Concerns over the routine use of growth factors have been based on the theoretical possibility that such factors may stimulate growth of clonogenic leukemia cells. Additionally, by enhancing proliferation and rendering the nonclonal, healthy hematopoietic progenitors prime targets to cytotoxic agents, prolonged cytopenia could become an unintended result.

Over the past decade, several randomized, placebo-controlled trials of growth factor administration after induction chemotherapy, generally in older patients with newly diagnosed acute myeloid leukemia, demonstrated a significant reduction, by 2–6 days, in the time period required to reach an absolute neutrophil count more than $0.5 \times 10^9/L$. Similarly, duration of antibiotic use and hospitalization were significantly reduced in many studies. When growth factors were prescribed within 1–3 days from completion of remission induction therapy, neither the time of initiating them, nor the degree of marrow suppression seemed to have an effect on outcome.^{12–23} The concept of priming leukemia cells is based on the assumption that changes in the cell cycle may increase sensitivity to specific agents used for remission induction, specifically to Ara C. Several trials prescribed CSF prior to therapy, but none of them suggested any benefit associated with this approach.^{24,25} One study evaluating the addition of G-CSF, both with or without all-trans retinoic acid (ATRA), to chemotherapy revealed an increased complete response rate but no improvement

in survival.²¹ Only two trials demonstrated either improved disease-free or overall survival.^{13,19} Similarly, following consolidation therapy, two studies demonstrated a significant decrease in the duration of absolute neutropenia and use of antibiotic therapy, without any effect on survival.^{15,20}

In general, these trials did not reveal evidence suggesting stimulation of either leukemic growth or drug resistance, and majority of studies did not reveal therapeutic benefits in terms of complete response rate or overall survival. There were no studies comparing the effect of G-CSF to GM-CSF in the setting of postinduction or postconsolidation support.

CHRONIC MYELOID LEUKEMIA

Grade 3 or 4 neutropenia had been observed in 13% patients with chronic myelogenous leukemia (CML), treated on a phase III randomized trial with imatinib. Imatinib does not affect the Philadelphia chromosome negative normal hematopoietic progenitors, and while G-CSF and GM-CSF have been tested without adverse consequences in a phase II trial of this agent, the standard recommendation is to withhold and subsequently restart the therapy, rather than prescribing growth factors.²⁶

MYELODYSPLASTIC SYNDROME

GM-CSF and G-CSF increase the neutrophil count in patients with severe neutropenia secondary to myelodysplasia. Both neutrophil and eosinophil counts increase following administration of GM-CSF.²⁷ Randomized studies demonstrated a decrease in the duration of neutropenia and improved treatment response associated with the use of G-CSF in patients receiving chemotherapy, or subsequent chemotherapeutic intervention.^{21,28,29} There was no evidence of any effect on duration of response or survival, although in one study higher remission rates and reduced infection rates allowed consideration of allogeneic transplantation in a greater number of patients.²⁹ There was no evidence of transformation to leukemia in either in these studies, in spite of theoretical risk to the contrary. However, prolonged administration of G-CSF in patients having more than 5% myeloblast counts is not recommended due to the potential risk of facilitating disease progression.

The use of erythropoietin is based on a relatively small, randomized placebo-controlled trial in low risk (refractory anemia without ring sideroblasts) myelodysplasia. A fixed erythropoietin dose of 1050 U/kg per week led to an increase of hemoglobin by 1–2 g/dL of hemoglobin in 50% of low-risk patients, versus 6% in the control group.³⁰ The addition of G-CSF or GM-CSF to erythropoietin may also have a synergistic effect on erythropoietic differentiation and response. In at least one study, administration of both G-CSF and erythropoietin was required in order to generate and maintain an erythrocyte response.³¹ A predictive model based on

serum epo level and prior transfusion requirements has been developed to guide the use of combination of G-CSF and erythropoietin in patients with myelodysplasia.³²

ACUTE LYMPHOCYTIC LEUKEMIA

The effect of G-CSF both in the setting of remission induction and consolidation therapy has been tested in prospective trials, most of which were randomized. These trials were carried out in adults and children, both during remission induction and consolidation therapy. In the larger studies, duration of neutropenia was shortened by 5–8 days.^{33–39} At least in one acute lymphocytic leukemia trial conducted in adults, a trend toward increased complete response rate was also observed, but without improvement in survival.³³ In general, there was no improvement in relapse-free or overall survival in any of the randomized trials using posttreatment G-CSF.

All of these studies demonstrated a decrease in the duration of neutropenia following the use of growth factors. The majority of studies also revealed decreased hospitalization, antibiotic use, and decrease in documented infections.³⁹

Administration of G-CSF allowed for timely delivery and intensification of the planned chemotherapy cycles. Hence, G-CSF is recommended both following remission induction therapy, and consolidation, with an expectation to reduce the duration of absolute neutropenia by approximately 1 week, and in order to allow maintenance of dose intensity.

CHRONIC LYMPHOCYTIC LEUKEMIA

Single-agent therapy does not usually mandate the use of growth factors in patients treated for chronic lymphocytic leukemias. More intense attempts of induction with combination regimens are likely to generate a higher incidence of grade 3 or 4 neutropenias. While randomized trials are unavailable, in a recent study administration of FAND (Fludarabine, Ara C, mitoxantrone, and dexamethasone) resulted in an incidence of more than 60% grade 3 or 4 absolute neutropenia. This study suggested that the incidence of severe neutropenia-associated pneumonias might have been reduced in patients supported by G-CSF prophylaxis, in contrast to an earlier cohort of patients treated on the same study but without administration of G-CSF.⁴⁰ One randomized trial that included patients with chronic lymphocytic leukemia suggested a benefit in terms of reduced need of red cell transfusion in patients who were given erythropoietin. General recommendations of erythropoietin use for the treatment of postchemotherapy anemias, according to ASCO guidelines, do apply to this category of malignancies. Erythropoietin may be beneficial for patients who are receiving supportive care only, though these guidelines do not address this specific clinical scenario.⁴¹

LYMPHOMA AND MULTIPLE MYELOMA

Both G-CSF and GM-CSF have been tested in prospective, randomized trials in patients with lymphomas, in an effort to reduce morbidity and mortality associated with infectious complications, and to potentially improve response rates and therapeutic outcome. Results of an updated meta-analysis of 12 prospective, randomized, controlled (placebo or no prophylaxis) trials have recently been published. The findings support the use of G-CSF/GM-CSF, especially in older patients who are receiving treatment for non-Hodgkin's lymphoma. In the meta-analysis, the relative risk of febrile neutropenia (RR 0.74) and infection (0.74) were both reduced. Other potential study endpoints, such as antibiotic use, infection-related mortality, and overall outcome, were not affected.⁴²

Recently, a pegylated, longer-acting version of G-CSF had been tested in a phase II randomized trial of patients receiving salvage chemotherapy for refractory non-Hodgkin's or Hodgkin's lymphomas. Chemotherapy consisting of ESHAP (etoposide, cisplatin, ARA-C and methylprednisolone) was followed by administration of filgrastim daily single dose of 5 µg/kg versus pegfilgrastim given once 100 µg/kg. The incidence and duration of grade 4 neutropenias were similar between the two groups, revealing equivalent effects of single administration of the pegylated compound versus a median of 11 injections of filgrastim.⁴³

The concept of dose-dense chemotherapy is based on the assumption that, although rapid reduction of tumor mass promotes faster tumor regrowth, sensitivity to the effects of chemotherapy agents may also increase during such periods.⁴⁴ Hence, the goal of this therapeutic strategy is to deliver chemotherapy in the shortest possible interval. To test this theory, the German High-Grade Lymphoma Study Group compared six cycles of CHOP (cyclophosphamide, doxorubicin, Vincristine, and prednisone) given either every 21 days, or every 14 days (this latter schedule was supported with G-CSF). These investigators also attempted to answer whether the addition of etoposide to CHOP would result in improved outcome. Based on this 2 × 2 factorial design, two parallel studies (in patients aged 60 or less vs patients aged over 60 years) were carried out. Patients receiving CHOP every 2 weeks were prescribed G-CSF for 10 days, starting on day 4, based on the expected high incidence of significant neutropenia. In patients aged over 60 years, complete response rates were higher (76.1% vs 60.1%) and relative risk reduction for event-free and overall survival was significantly greater (0.66, $p = 0.003$; 0.58, $p < 0.001$) in those treated on the dose-dense, every 2-week schedule. The addition of etoposide was associated with increased toxicity and no obvious benefit. Hence, further trials to expand and confirm the role of dose-dense delivery of CHOP are ongoing, and these studies are also incorporating rituximab into the treatment arms.¹¹ The ASCO growth factor guidelines regarding

both primary and secondary prophylaxis of neutropenia and, similarly, guidelines regarding chemotherapy-associated anemia, apply to patients with multiple myeloma.^{4,10} Evaluation of epoetin beta in a randomized, double-blind, controlled study in transfusion-dependent patients with multiple myeloma (the study also included patients with chronic lymphocytic leukemia and low-grade malignant lymphoma) revealed that transfusion-free and severe anemia-free survival were significantly better, with a risk reduction of 43% and 51%, respectively, in patients receiving epoetin beta at a dose of 150 IU/kg three times a week for a period of 16 weeks, versus control. Approximately 2/3 of patients receiving epoetin beta responded, versus 27% in the placebo group. Quality of life was also significantly improved and correlated with a rise of ≥ 2 g/dL of hemoglobin.⁴¹

AUTOLOGOUS AND ALLOGENEIC STEM CELL TRANSPLANTATION

AUTOLOGOUS STEM CELL TRANSPLANTATION AND SUBSEQUENT GROWTH FACTOR SUPPORT

Randomized trials of G-CSF versus control following autologous peripheral blood and stem cell transplantation have documented a benefit from prescribing G-CSF, in terms of decreased duration of neutropenia and hospitalization. In general, patients treated with autologous transplantation do experience shortened periods of neutropenia and reduced duration of hospitalization after receiving filgrastim ranging from 5 to 30 µg/kg per day, or two different dose schedules of lenograstim.⁴⁵⁻⁴⁸ As illustrated by the wide range of prescribed doses of G-CSF and lenograstim, the optimal dose and timing/duration of administration is still unclear in the postautologous recovery phase.⁴⁷ A non-randomized study suggested a benefit in terms of decreased duration of hospitalization, neutrophil recovery, and cost savings, when G-CSF was initiated on the day immediately after peripheral blood progenitor cell reinfusion, in comparison to starting this therapy 4 days later.⁴⁹ These findings have not been supported in other randomized studies regardless of whether administration of G-CSF began on day 1 versus 7, or 3 versus 5 days after reinfusion of stem cells.^{50,51}

Not all growth factors are created equal: GM-CSF support following reinfusion of primed peripheral blood progenitor cells did not result in any benefit in one placebo-controlled trial.⁵²

Myeloablative therapy will induce severe anemia necessitating transfusion of virtually all patients undergoing autologous transplantation. Earlier data suggested that administration of erythropoietin, when given both prior to ablative therapy and when resumed subsequently on day 1, failed to decrease the number of red blood cell transfusions in comparison to placebo.⁵³ Recently, the effects of erythropoietin,

administered at a dose of 500 units/kg per week starting from day 30 after transplantation, to a cohort of patients treated for malignant lymphoma or myeloma were assessed. In a retrospective analysis, mean hemoglobin levels were substantially better: only 2 of 41 patients in the treatment group versus 12 of 45 patients in a previously treated “control” group without erythropoietin support experienced hemoglobin levels less than 9 g/dL.⁵⁴ The potential benefit of such delayed administration, as well as pilot data demonstrating a protective effect in multiple myeloma patients in whom erythropoietin is provided prior to the second phase of a tandem transplant, needs to be confirmed in a prospective randomized fashion.⁵⁵ The effect of erythropoietin has also been evaluated in patients with lymphomas undergoing intense salvage therapy followed by consolidation. When epoetin beta was prescribed at a dose of 10,000 IE thrice a week during the entire course of two cycles of DHAP (dexamethasone, ARA-C, and cisplatin), followed by further intensification and peripheral blood progenitor cell collection and BEAM (carmustine, etoposide, melphalan, and ARA-C) therapy, the number of red cell transfusion required (4.5 vs 8.3) and mean hemoglobin levels during the course of therapy were all favorably affected by growth factor therapy.⁵

ALLOGENEIC STEM CELL AND STEM CELL TRANSPLANTATION FOLLOWED BY GROWTH FACTORS

In the early posttransplant phase, neutropenia-associated infectious complications are one of the most significant treatment-related toxicities. Infusions of primed peripheral blood progenitor cell and stem cell transplantations from HLA-matched siblings have shortened the duration of neutropenia. A benefit in terms of accelerated neutrophil recovery has been described in trials involving patients who were recipients of allogeneic peripheral blood progenitor cells and growth-factor support (G-CSF).⁵⁶ In a subsequent randomized trial in T-cell depleted allogeneic blood progenitor recipients treated with or without posttransplantation growth factor support, there was no difference in the degree of immune reconstitution and no statistically significant difference in treatment outcome as measured by relapse, infections, or incidence of chronic graft versus host disease.⁵⁷

Use of growth factors following allogeneic stem cell transplantation is not without side effects. There is a potential for delay in platelet recovery after using GM-CSF in the posttransplantation setting.⁵⁸ A recent retrospective analysis suggested that recipients of stem cell transplantations should not receive G-CSF support in the immediate posttransplantation period. In the study, patients with acute myelogenous leukemia (1789 patients transplanted with HLA-matched sibling bone marrow and 434 patients transplanted with peripheral blood progenitor cells) were analyzed. Twenty-eight percent of bone marrow recipients and 40% of peripheral

blood progenitor cell recipients received G-CSF during the first 2 weeks following transplantation.

While neutrophil recovery was faster, platelet engraftment did take longer, and the incidence of acute grades II–IV graft versus host disease was also higher (50% vs 39%, $p = 0.007$) in recipients of bone marrow who also received G-CSF support. The incidence of chronic graft versus host disease, as well as transplant-related mortality and leukemia-free and overall survival were also adversely affected. No such adverse effects were noted in recipients of peripheral blood progenitor cells regardless of whether they received growth factor support.⁵⁹

CONCLUSIONS

Granulocyte growth factors can be given safely both as primary and secondary prophylaxis to the majority of patients with hematologic malignancies.

G-CSF administration in acute myeloid and lymphoid leukemias, chronic lymphocytic leukemia, myelodysplasia, lymphomas, and in the postperipheral blood progenitor phase in all of these disease categories, and in myeloma, has led to shortened duration of myelosuppression and subsequent decrease in morbidity due to reduction in the incidence of febrile neutropenias and other infectious complications. Survival, however, has not been reliably affected.

G-CSF is also indicated and should be prescribed in the specific situation when dose-dense/intense therapy is of potential benefit to the patient; e.g., when treating older lymphoma patients on a biweekly schedule with CHOP. While the optimal timing, dose, and duration are still not well established in most clinical situations, administration of 5 $\mu\text{g}/\text{kg}$ of G-CSF and, if chosen, 250 $\mu\text{g}/\text{kg}$ of GM-CSF are recommended, starting within 1–5 days after completion of therapy.¹⁰ Pegylated G-CSF has been found to be equally efficacious and safe as G-CSF in the setting of treating lymphomas with a standard regimen. However, further evaluation of pegfilgrastim is required to confirm safety and efficacy during induction and dose/dense consolidation therapy for leukemias, and in combination with dose/dense treatment regimens. Further evaluation is also needed in the pre- and post-transplantation settings.

Administration of erythropoietin is justified in early phases of myelodysplasias and during repetitive administration of chemotherapy cycles for patients with lymphomas in order to increase hemoglobin values, avoid transfusions, and ameliorate anemia-associated fatigue and improve quality of life. The optimal dose and frequency are still unknown, but the effects of erythropoietin prescribed to lymphoma patients at doses of 10,000 U thrice a week were equivalent to a dose of 30,000 U, given every 3 weeks, in one randomized trial. Darbepoetin alpha had been tested

in patients with lymphoproliferative diseases and was found to be effective at ranges 1–4.5 g/kg per week in comparison to placebo. Patients with multiple myeloma, chronic lymphocytic leukemia, and lymphomas may benefit from administration of erythropoietin when they are experiencing symptoms related

to low hemoglobin, and/or are transfusion dependent. Further studies are required to establish the role of erythropoietin and darbepoetin alpha in acute leukemias and, while preliminary data are encouraging, additional trials are needed in the peri- and posttransplantation settings.

Chapter 106

TREATMENT APPROACH TO PREGNANT WOMEN

Revathi Suppiah, Joanna Brell, and Matt E. Kalaycio

The hematologic malignancies are uncommon disorders in reproductive-age women. Cancer complicates 1 in 1000 pregnancies.¹ The most frequently occurring tumor in pregnancy is cervical cancer, followed by breast cancer, melanoma, ovarian cancer, thyroid cancer, leukemia, and lymphoma.² The incidence of leukemia during pregnancy is estimated to be 1 per 75,000 pregnancies.³ Pregnancy per se does not increase the risk of malignancy.

Cancer is the leading cause of death among women aged 35–54 years,⁴ and as childbearing increases among older females, the incidence of pregnancies complicated by malignancy is likely to increase. Depending on the type of malignancy and stage of diagnosis, postponing chemotherapy until after delivery may not be feasible. This is often the case in acute leukemia.⁵ The use of chemotherapy during the second and third trimester has been reported with good outcomes. Despite the emotionally and physically demanding therapy, pregnant patients with leukemia have successfully delivered healthy term infants either before, during, or after chemotherapy.

MATERNAL PHYSIOLOGIC CHANGES WITH PREGNANCY

Several normal adaptive changes occur in the hematologic environment during pregnancy. Plasma volume increases by about 50% with only a 20–50% rise in red cell mass, resulting in a normocytic anemia.⁶ Inadequate hematopoiesis can result if iron and folate stores are not supplemented in advance. The normocytic anemia often becomes microcytic if iron metabolism cannot keep pace with fetal demand despite supplementation.

Leukocytosis occurs during pregnancy, most likely due to increased levels of endogenous steroids. By the third trimester, white blood cell (WBC) may reach as high as 12,000/ μ L and up to 20,000–30,000/ μ L during labor.⁷ Platelet counts in the low normal range may be seen during gestation (gestational thrombocytopenia).⁶ Immune thrombocytopenic purpura occurs more often

in young women; any platelet count that acutely drops or is less than 50,000/ μ L must be investigated.

The physiologic changes occurring with pregnancy can directly affect the dosing and toxicity of chemotherapeutic agents. The increase in renal blood flow, glomerular filtration rate, and creatinine clearance may increase the clearance of drugs excreted by the kidneys. Amniotic fluid may act as a physiologic third space, and thereby may enhance the toxicity of agents by delaying elimination. The physiologic increase in body water with the increase in plasma volume may change the volume of drug distribution.

INTERACTIONS BETWEEN PREGNANCY, LEUKEMIA, AND MATERNAL/FETAL OUTCOME

IMPACT OF PREGNANCY ON LEUKEMIA

Pregnancy has not been shown to have any consequence on the development, response to treatment, duration of response, or overall survival of acute leukemia.^{1,8} The complete response rates of 76–77% reported by Reynoso et al. in both pregnant acute myelogenous leukemia (AML) and acute lymphoblastic leukemia (ALL) patients are consistent with those of nonpregnant patients.⁸ Acute leukemia is fatal if untreated. In all patients, untreated acute leukemia has an overall survival from 2 weeks to 3 months, with deaths most commonly resulting from infection or hemorrhage. Patients not receiving leukemia therapy prior to labor and delivery had approximately 60% perinatal mortality rate in the 1960s–1970s.⁹ Many of the maternal deaths in leukemic patients during labor and delivery appear to occur in women with either untreated acute leukemia or with disease unresponsive to therapy.⁸

In the early stages of chronic leukemias, treatment is not essential. If adequate hematologic parameters are maintained without significant bleeding or infection, uncomplicated gestation and delivery can take place with sufficient prenatal care. Leukapheresis may be performed if cytoreduction is necessary.

Acute leukemias, however, are more aggressive and patients require therapy for disease control almost immediately upon diagnosis. There are a few reports of pregnant patients not receiving chemotherapy for acute leukemia. Some patients were diagnosed at delivery or in the last few weeks of gestation and had labor induced before beginning the treatment.¹⁰ Catanzarite and Ferguson reviewed fetal outcomes in untreated acute leukemic patients.¹¹

- Four patients diagnosed close to delivery (induced or spontaneous deliveries), between 37 and 42 weeks of gestation—all healthy infants
- One patient diagnosed at 14 weeks—elective abortion with retained placenta and maternal death from hemorrhage
- One patient diagnosed at 28 weeks—intrauterine death, maternal demise from intracerebral hemorrhage at 30 weeks
- One patient diagnosed 1 month prior to conception—disseminated intravascular coagulation (DIC) at 34 weeks with fetal demise within 24 hours

Five of the seven patients died 33 days or less after diagnosis, primarily from hemorrhage and/or infection.¹¹ These examples emphasize the need for early intervention in acute leukemia; pregnant patients require the same aggressive approach as nonpregnant leukemics to attain a goal of complete remission.

PLACENTAL FUNCTION

The placenta separates maternal and fetal circulatory systems and regulates transport between the two systems. Transport occurs via the placental membrane, which is composed of fetal tissue.¹² Maternal arterial blood is driven by the blood pressure into the intervillous spaces. Fetal blood is confined to the villous vascular system. Substances cross by simple diffusion, facilitated diffusion, active transport, or pinocytosis. Placental membrane interruptions can occur, especially toward the end of gestation, due to thinning of the membrane with time. The fetal capillary system

also becomes progressively more exposed to the intervillous spaces.

Several substances can easily transfer across this membrane, including most nutrients, waste products, proteins such as immunoglobulin G antibodies, certain hormones, viruses, and water-soluble vitamins.⁹ Substances that are lipid-soluble, less plasma protein-bound, nonionized, or of low molecular weight are capable of crossing the placenta; most chemotherapeutic agents have similar qualities.⁹

In a retrospective review by Germann et al.,¹³ 160 patient pregnancies exposed to anthracyclines were analyzed. Fetal outcome was normal in 73% cases. After intravenous injection of anthracyclines, only barely detectable concentrations were detected in the fetus. Table 106.1 illustrates the results of two studies of anthracycline concentrations in fetal tissues, amniotic fluid, and placenta.^{13,14}

Transplacental studies have resulted in conflicting data. Roboz et al.¹⁵ reported that doxorubicin was undetectable in amniotic fluid at 4 and 16 hours post-maternal intravenous administration; this nonexistence in the amniotic fluid cannot exclude transplacental passage. D’Incalci et al.¹⁶ detected doxorubicin in fetal liver, kidney, and lung after elective termination; no levels were found in the amniotic fluid, fetal brain, or gastrointestinal tract 15 hours after administration. The fetal heart was not assessed.

Using liquid chromatography, Karp et al.¹⁷ illustrated that doxorubicin concentrations were greatest in placental tissue, with none in cord tissue or blood in a healthy infant born 48 hours after therapy. A doxorubicin metabolite was detected in the cord, placental tissue, and neonatal spleen in a stillborn baby delivered 36 hours after maternal intravenous therapy.

At the time of delivery in a woman with acute promyelocytic leukemia (APL) undergoing therapy with all-trans retinoic acid (ATRA), its levels were measured in her venous blood and in the neonate’s umbilical artery, vein, and peripheral blood.¹⁸ Maternal ATRA levels were detectable at 2 and 4 hours after

Table 106.1 Transplacental passage of anthracyclines in vivo

Ref.	Maternal cancer	Time of therapy (weeks)	Treatment	Dose	Fetal outcome	Time interval between infusion and measurements (hours)	Measurements in fetal tissues	Results
13	AML-FAB 3	29–30	Daunorubicin	45 mgm ² daily for 3 days	Fetal death	48	Liver Kidney Lung Skin Heart	0.015 ng/mL 0.02 ng/mL 0.02 ng/mL ND; LD 1.5 ng/100 mg ND
14	Breast cancer	32–35	Doxorubicin	20 mg/m ²	Normal child	96	Amniotic fluid only	ND; LD 0.2 ng/mL

FAB, French American British classification; ND, not detectable; LD, limit of quantification.

the last dose; no neonatal levels were found at 2 or 4 hours.

Although there are inconsistent data regarding the passage of chemotherapeutic agents across the placenta, it is assumed that virtually all chemotherapeutic agents do cross and other factors, such as fetal metabolism, may be the major determinant of teratogenicity.

PASSAGE OF LEUKEMIC CELLS TO THE FETUS

Maternal cancer cells can metastasize to the placenta, and occasionally to the fetus. Read and Platzner¹⁹ reported on 44 pregnant patients with various malignancies. They found six cases of acute leukemia involving the placenta or fetus, three patients with AML with only placental involvement (fetus not assessed in one instance), one ALL patient with placental involvement but not fetal, and two ALL patients with the placenta not examined, but ALL diagnosed in those fetuses.

Dildy et al.²⁰ published a review on maternal malignancies metastatic to the products of conception. Out of 53 patients, there were 8 cases of either leukemia or lymphoma detected in the placental tissue. Four of these included fetal involvement.

Another case involved a patient diagnosed with acute monocytic leukemia one day after delivery of a healthy male infant; subsequently at 20 months of age, the child was diagnosed with acute monocytic leukemia.²¹ The histochemical staining and immunophenotyping of the mother and child's leukemic cells were identical. The child's bone marrow cytogenetic karyotype was 40% 46 XY, but the remaining 60% was 46 XX and most likely originated from his mother. The child had no other cytogenetic anomalies and both mother and child were in complete remission when last assessed.²¹

DIAGNOSIS IN PREGNANCY

PRENATAL CARE

Prenatal care provides a thorough medical monitoring system for young women. This includes a complete blood count (CBC) at the patient's first presentation; any abnormalities other than the expected hematopoietic changes should be further investigated, including bone marrow aspirate and biopsy. A repeat hemoglobin/hematocrit should be performed between 26 and 28 weeks of gestation and again at 32–36 weeks, with further testing according to abnormal results.¹⁰

The symptoms of leukemia in general are nonspecific: fatigue, dyspnea, fever, chills, and generalized malaise. Signs may include bleeding, bruising, petechiae, or infections that point to hematologic dysfunction. Pregnant patients should seek medical attention with any of these problems, as the symptoms of acute leukemia will only worsen with time. The diagnosis of any type of malignancy during pregnancy can be challenging as constitutional symptoms are often attributed to a normal pregnancy.

DIAGNOSTIC WORK-UP

If there is any suspicion of marrow dysfunction based on the blood counts, peripheral blood smear, or presence of circulating leukemic blasts, then a bone marrow biopsy and aspirate should be performed. Bone marrow evaluation at any gestational age is safe; only local anesthesia is used and the patients can maintain a lateral decubitus position for an estimated 20-minute procedure. If a pregnant woman is diagnosed with acute leukemia, a multilumen central venous catheter is often required due to frequent blood draws, transfusions, chemotherapy infusions, and antibiotic use. Catheter placement can be safely performed by a general surgeon or interventional radiologist. Fluoroscopy is often used for guidance during placement, but can be avoided or used sparingly with pelvic shielding. Measurement of left ventricular ejection fraction is recommended prior to initiation of therapy, as anthracyclines are cardiotoxic. Multigated acquisition scans are often used, but in pregnant patients an echocardiogram can be performed to avoid radiation exposure. Computed tomography (CT) scans of the abdomen and pelvis are not critical for treatment or prognosis, and therefore are not required in the work-up of a pregnant leukemic patient. In summary, there is minimal fetal risk in the maternal diagnostic work-up for acute leukemias and in preparation for therapy.

PHARMACOKINETICS WITH PREGNANCY

Maternal changes occur during pregnancy that can affect the metabolism of drugs.⁹ These include:

- Increased plasma volume, which in turn can increase the volume for drug dilution
- Decreased albumin and increased plasma proteins due to estrogen, which can affect ratios of free and bound drugs
- Increased renal blood flow and glomerular filtration rate, with subsequent influence on excretion of drugs
- Increased activity of hepatic mixed function oxidases, thereby directly altering drug metabolism
- Decreased gastric emptying, leading to interference with drug absorption

Fetal pharmacokinetics are not well established. The length of exposure to possible teratogens is an important factor; metabolites of maternal medications can be eliminated by the fetus into the amniotic fluid with subsequent fetal ingestion, gastrointestinal absorption, and elimination, thereby continuing the cycle.⁹ Depending on the efficacy of these various processes and the types of drugs and their metabolites, there may be enhanced or diminished fetal exposure to medications. There is no data to conclude that amniotic fluid functions as a third-space compartment or if this could affect the dosing of medications during pregnancy. There is also no evidence to suggest that

doses of chemotherapeutic agents should be altered to account for the new metabolic function in the mother.

TERATOGENICITY OF CHEMOTHERAPEUTIC AGENTS

All chemotherapeutic agents are theoretically teratogenic and mutagenic. Fetal malformation, intrauterine growth retardation (IUGR), spontaneous abortion, and fetal death may occur. The teratogenicity of any particular drug depends on the timing of exposure, the total dose, and the drug characteristics on placental transfer. Drugs with high lipid solubility, low molecular weight, and decreased plasma protein binding have greater tendency for placental transfer from mother to fetus.

Chemotherapeutic agents cause cell death through several different mechanisms. They act on rapidly proliferating cells and thereby are potentially harmful to fetal tissues. Normal fetal cells undergo rapid growth with multiple cell divisions during the first trimester, especially during organogenesis (2–11 weeks of gestation). With the exception of brain and gonadal tissues, organogenesis is accomplished by 12 weeks of gestation. Therefore, if chemotherapy is administered during the first trimester, there is a high risk of fetal death due to immaturity of all fetal tissues.^{9,22} During organogenesis, drug-induced teratogenesis can also manifest with major or minor abnormalities of organ systems without fetal death.

If chemotherapy causes severe damage early in gestation, spontaneous abortion often occurs. If sublethal damage occurs during organogenesis, malformation can result. Once organ development is complete, the rate of cell division decreases and the rate of cell injury and congenital malformations due to chemotherapy equals the risk in the general population (3%).^{23,24} Although the available data suggests that chemotherapy administration after organogenesis does not appear to cause significant teratogenicity, one needs to take into account that central nervous system development is not complete and fetal growth and development may still be affected.

Doll et al.⁹ reported on 139 cancer patients treated with various chemotherapeutic agents during the first trimester; the rate of fetal malformations was 17%. In 45 of these patients exposed to two or more agents concurrently, 16% had infants with malformations. If patients who received folate antagonists and radiation therapy were excluded, the malformation rate dropped to 6%.

The Toronto Leukemia Study Group reported that one-third of all infants exposed to chemotherapy in utero had pancytopenia at birth.²⁵ Aviles and Niz²⁶ reported on 17 infants delivered to mothers with acute leukemia treated during pregnancy. They concluded that chemotherapy did not have a major impact on later development. Garber²⁷ also reported on 43 children

born to mothers with hematologic malignancies who underwent chemotherapy during pregnancy. Nineteen of the mothers received treatment during the first trimester. No physical, neurologic, psychological, hematologic, or cytogenetic defects were detected.

Cytarabine is a significant chemotherapeutic agent in leukemia. Wagner et al.²⁸ treated a patient for ALL, with relapse of disease on maintenance therapy, who acquired a second complete remission. The patient was on maintenance therapy with cytarabine when she conceived. Her three cytarabine cycles may have coincided with normal limb bud development, as her infant had a malformed right hand and bilateral femur, tibiofibular and foot defects, as well as bilateral external ear abnormalities.²⁸

Another woman with AML conceived while undergoing treatment with cytarabine and oral thioguanine.²⁹ She continued this treatment until her term delivery. The neonate had upper and lower distal limb abnormalities, especially of his hands. The patient was continued on the same medications and again conceived 2–4 weeks after her last dose of chemotherapy. This infant was born without any abnormalities.²⁹

Caligiuri and Mayer²³ reported on leukemic pregnant patients treated with cytarabine as either a single agent or in combination. Eighteen of these women gave birth to normal offspring, and five pregnancies ended in elective abortions. Another AML patient was 20 weeks pregnant when treated with cytarabine and daunorubicin; she received reinduction with mitoxantrone and cytarabine. She subsequently underwent consolidation therapy with one cycle of cytarabine and idarubicin between weeks 29 and 30. Two days later she delivered a stillborn but phenotypically normal infant.³⁰

The use of anthracyclines with combination chemotherapy has been reported by Turchi and Villasis in 20 pregnant patients.³¹ Among the 20 patients treated, no fetal malformations resulted, but there was one maternal-fetal death, one therapeutic abortion, one spontaneous abortion, and four neonatal problems (marrow hypoplasia, pneumothorax, sepsis, and polycythemia) that all resolved.³¹ In the infant who developed polycythemia, the maternal course was complicated by relapsed null-cell ALL on maintenance folate antimetabolites, requiring reinduction chemotherapy, pulmonary infiltrates requiring mechanical ventilation, and prolonged bone marrow aplasia. The infant was born at 36 weeks' gestation, weighed 2400 g, and polycythemia resolved with normal marrow function.³²

APL has been reported in approximately 10% of cases of leukemia in pregnancy, similar to the percentage in nonpregnant leukemic patients. In 1995, Hoffman et al.³³ published a case report and a review of the English literature that compiled 24 cases of APL occurring in pregnant patients. Ten of these patients received an anthracycline with or without cytarabine or another agent for induction therapy. Three fetuses were exposed in the first trimester, with one spontaneous abortion, and five

were exposed in the second trimester; the seven live neonates were normal. Two patients were treated in the third trimester, with one intrauterine death at 29 weeks' gestation.³³

Requena et al.³⁴ described two patients with APL treated with cytarabine, thioguanine, daunorubicin, and mitoxantrone during the second trimester. Both women delivered normal neonates, though one infant was intubated for a total of 7 minutes. Takatsuki et al.³⁵ evaluated two APL patients who were both given a non-ATRA chemotherapy regimen. One patient received combination chemotherapy with daunorubicin at 14 weeks, when she presented with APL and DIC; intrauterine fetal death occurred (IUFD) at 19 weeks. The other patient was diagnosed with APL and DIC at 29 weeks of gestation. Combination chemotherapy including daunorubicin produced a complete remission, and the patient successfully delivered a normal infant.³⁵

The advent of ATRA brought unknown risks to pregnant patients with APL. Another vitamin A derivative, 13-*cis*-retinoic acid, causes a specific retinoic embryopathy when taken in the first trimester.³ Therefore, ATRA would be suspected of causing a similar set of deformities. Three of the patients described by Hoffman et al.³³ received ATRA between gestational weeks 30 and 32; they delivered a total of four normal, but premature, neonates. One patient was diagnosed with relapsed APL in the first trimester and treated with ATRA. Her infant was premature, but healthy at 15 months of age.³³ Giagounidis et al.³⁶ reviewed 13 cases of APL in pregnancy treated with ATRA and did not find any fetal malformations attributed to ATRA. Several reports of fetal outcomes of pregnant patients who received ATRA are illustrated in Table 106.2.^{37–47}

With the exception of the folate antimetabolites, teratogenicity cannot be completely attributed to one single

Table 106.2 Pregnancy outcomes of 11 patients with APL who received ATRA during gestation

Ref.	Week treated	Response	Other agents administered	DIC	Week delivered; outcome
37	At 23 weeks, for 35 days	CR	None	Yes; clinically mild, but excess perinatal hemorrhage	32 weeks; normal twins
38	At 26 weeks, for 30 days	CR	None	Yes	30 weeks; normal, but cardiac arrest (recovered)
39	At 28 weeks, for 30 days	CR	None	Yes	32 weeks; normal
40	At 6 weeks, for 4 weeks	CR, then relapsed at 30 weeks	Prednisone	Yes	32 weeks; normal, RDS (resolved)
41	At 14 weeks, for 60 days	CR	rhG-CSF, rhEPO	No; Jehovah's Witness	40 weeks; normal
42	At 34 weeks, for 4 weeks	CR	None	Yes; received blood products	38 weeks; normal
43	At 29 weeks, for 1 day; labor began 24–36 hours later	NR	None	No; no bleeding complications	Postnatal death; bilateral renal agenesis before APL diagnosed
44	At 30 weeks, for 2 weeks	CR	Daunorubicin, steroids day of delivery	Yes	32 weeks; fetal distress, normal
45	At 30 weeks, for 38 days	CR	None	No	33 weeks; atrial arrhythmia 2 days before delivery up to 1 day after birth; otherwise normal
46	At 24 weeks, until delivery	CR	daunorubicin, IV heparin	yes; received multiple blood products	33 weeks; small intracranial hemorrhages by imaging
47	At 28 weeks, for 4 weeks	CR	none	no	29 weeks; normal

CR, complete remission; NR, no response; RDS, respiratory distress syndrome; rhG-CSF, recombinant human granulocyte colony-stimulating factor; rhEPO, recombinant human erythropoietin; IV, intravenous.

chemotherapeutic agent when combination chemotherapy is administered with various other agents such as antiemetics, antibiotics, antifungals, antivirals, premedications, and blood products. The majority of leukemic patients and neonates survive gestation, labor, and delivery without major complications. Conventional chemotherapy to treat leukemia during pregnancy is not associated with a marked increase in the rate of malformation or long-term sequelae.^{23,26}

TREATMENT OF SPECIFIC HEMATOLOGIC MALIGNANCIES

OVERVIEW

The diagnosis of a life-threatening disorder during pregnancy is a formidable challenge for both the patient and the physician. All risks, benefits, and alternatives for the patient and fetus must be discussed in detail. The patient should understand that no outcome can be guaranteed, but the available data should be presented to her in a comprehensive manner. Conclusions regarding the complexity of the decision to treat and continue the pregnancy should be reached by the consensus of the patient, patient's family, and physician. Unfortunately, there are no large prospective studies that address chemotherapy administration during pregnancy, and subsequently physicians are forced to formulate treatment regimens based on small retrospective studies and case reports.

ACUTE LEUKEMIAS

Leukemia itself can adversely affect perinatal outcome. Spontaneous abortion, prematurity, IUGR, and death have been associated with maternal leukemia. The earlier the diagnosis of leukemia during pregnancy, the higher the perinatal mortality. Adverse factors include maternal anemia, DIC, or leukemic cells affecting blood flow, nutrient exchange, and oxygen delivery in the intervillous spaces of the placenta. Acute leukemia is a hematologic urgency and requires treatment without delay. Chemotherapy at full doses can be safely administered, even during the first trimester, if cure of the hematologic malignancy is considered reasonable.⁴⁸⁻⁵⁰ However, great concerns remain about the teratogenic and mutagenic effects on the fetus during organogenesis.

Management of acute leukemias is based on the stage of pregnancy at the time of diagnosis of the malignancy. In the first trimester, the patient should be offered the option of termination due to concerns of the 10–20% risk of teratogenicity with chemotherapy during organogenesis^{51,52}; if abortion is declined, then the patient should be treated. Patients diagnosed with leukemia after the first trimester should undergo prompt chemotherapy.

Caligiuri and Mayer compiled 72 cases of new-onset leukemia diagnosed with or during pregnancy.²³ AML

was diagnosed in 44 patients, ALL in 20, chronic myelogenous leukemia (CML) accounted for five cases (four in chronic phase), hairy-cell leukemia (HCL) in one instance, and two cases were not specified. They reported on 58 patients who were administered chemotherapy while pregnant; only eight cases were not given cytarabine, or an anthracycline, or both. As the time of the first exposure to chemotherapy advanced from first to third trimester, the number of spontaneous abortions and stillbirths decreased, with most neonates born normal regardless of premature or term birth. There were no congenital defects reported in patients undergoing chemotherapy during the first trimester. There were no perinatal deaths; overall fetal survival was 84% (49 of 58 fetuses).²³

Catanzarite and Ferguson¹¹ reviewed records on pregnancy and acute leukemia. They collected outcomes on 39 fetuses first exposed to chemotherapy during gestation, ranging from conception to the third trimester. A total of 31 patients received induction chemotherapy for AML (24 patients) or ALL (seven patients) during their pregnancy. Eight patients conceived while on maintenance therapy. Twenty infants were delivered at term and 12 were premature. There were a total of three therapeutic abortions, two perinatal deaths (at 21 days and 3 months of life, both from infection with no evidence of leukemia), and two intrauterine deaths (at 24 and 30 weeks), for a fetal survival of 32/39 or 82%. There were no malformations recorded.¹¹

In a recent review by Ali et al.,⁵³ 10 pregnancies in 8 patients with acute leukemia were discussed. Six of the patients had AML and two had ALL. Three of the pregnancies were diagnosed when the leukemia was in remission, six at the time of leukemia diagnosis, and one at the time of relapse. In this case series, five of the eight pregnant women died from their malignancy. Only 1 child survived from the 10 pregnancies, and this child was not exposed to any chemotherapeutic agents.⁵³ Table 106.3 illustrates the maternal and fetal data of the eight cases.

Hansen et al. published a case of a 24-year-old patient diagnosed with ALL at 24 weeks of gestation.⁵⁴ The patient began course one of induction chemotherapy at 26 weeks with cyclophosphamide, daunorubicin, vincristine, prednisone, and L-asparaginase. At 30 weeks gestation, she was started on intensification therapy with methotrexate, cyclophosphamide, 6-mercaptopurine, vincristine, and L-asparaginase. This course of chemotherapy was repeated at 34 weeks. Two days later, she had a normal spontaneous vaginal delivery with a normal infant, but with mild meconium aspiration. Serial abdominal ultrasounds throughout pregnancy revealed gradual decline in the rate of fetal growth, with recurrent, transient oligohydramnios, yet uterine artery doppler and fetal heart rate testing remained normal.⁵⁴

Children and adults who undergo treatment with anthracyclines are at risk for dose-related cardiotoxicity.⁵⁵

Table 106.3 Summary of eight patients with acute leukemia during pregnancy

Case	Age (year)	Pregnancy	AML subtype	Leukemia status	Period of pregnancy, status of fetus	Treatment during pregnancy	Outcome of pregnancy	Condition of patient
1	23	1	AML-M ₄	Active disease	8 weeks, alive	—	Spontaneous abortion	Died during CT
2	25	2 3	ALL-L ₁ , B cell ALL-L ₁ , B cell	Active disease 4th year of CR	24 weeks, dead fetus 8 weeks, alive	—	Therapeutic abortion Alive baby, normal	CR CR, still alive
3	21	4 5	ALL-L ₂ , B cell ALL-L ₂ , B cell	12th mon. of CR. Relapse, active disease (31st month of CR)	12 weeks, alive 8 weeks, alive	— —	Spontaneous abortion Therapeutic abortion	CR Died during CT
4	37	6	AML-M ₃	Active disease	26 weeks, alive	Daunorubicin, cytarabine	Spontaneous abortion in 1st wk of CT	Died during CT
5	29	7	AML-M ₄	Active disease	24 weeks, alive	Daunorubicin, cytarabine	IUD during CT, therapeutic abortion	Died during CT
6	24	8	AML-M ₁	6th month of CR, relapse at 12th week of gestation	8 weeks, alive	—	Therapeutic abortion	Died during CT
7	20	9	AML-M ₃	Active disease	19 weeks, dead fetus	—	Therapeutic abortion	Still in 1st CR
8	21	10	AML-M ₄	Active disease	12 weeks, alive	—	Therapeutic abortion	Still in 1st CR

CR, complete remission; IUD, intrauterine death; CT, chemotherapy.

This toxicity is related to free-radical damage to myocardial fibers.⁵⁶ Whether anthracycline exposure to the developing fetus in utero is cardiotoxic is unknown. Meyer-Wittkopf et al.⁵⁷ performed fetal echocardiograms every 2 weeks from week 24 in a patient undergoing treatment for breast cancer with doxorubicin and cyclophosphamide. No differences in systolic function were discovered between exposed and unexposed fetuses. Echocardiograms of up to 2 years of age revealed no myocardial damage.⁵⁷ Three cases of neonatal cardiac effects after in utero exposure to anthracyclines have been reported.^{56,58,59} One had been exposed to both doxorubicin and pelvic irradiation and subsequently developed only one coronary artery.⁵⁸ Two developed right-sided cardiomyopathy after second trimester exposure to idarubicin with tretinoin or with vincristine, daunorubicin, and cyclophosphamide.^{56,59}

Idarubicin is more lipophilic and therefore has increased propensity for placental transfer. It may also have a higher affinity for DNA. An IUFD has been

reported 2 days after idarubicin was given for consolidation therapy for AML.³⁰ Epirubicin, another anthracycline, was used to treat 13 women in two studies. Twenty-three percent of fetuses exposed to epirubicin died either as fetuses or as neonates.^{60,61}

MYELOYDYSPLASTIC SYNDROMES

Siddiqui et al.⁶² described five women diagnosed with myelodysplastic syndromes (MDS) during pregnancy from 1982 to 1987 (see Table 106.4). Steensma et al.⁶³ identified all patients at the Mayo Clinic with MDS and pregnancy seen between 1976 and 2000. A total of seven pregnancies were discovered, occurring in four patients with MDS between 1983 and 2000. In three of the four patients, MDS was suspected after an initial CBC for routine prenatal care. Patients were between 21 and 42 years of age. After bone marrow evaluation, all patients had refractory anemia except one with refractory anemia with excess blasts (RAEB). Three patients, including the RAEB patient, delivered normal term

Table 106.4 Myelodysplasia associated with pregnancy

Maternal age (year)	Gestational week	Subclass; course or therapy	Pregnancy outcome	Maternal outcome
22	16	RAEB; septic endometritis	Therapeutic abortion	AML by 4th month; expired after 2 years
31	12	RA; no CBC changes after abortion	Therapeutic abortion	Expired 1 month after MRD-BMT
32	20	RA; transfusional support	Healthy, term infant	AML in 5th month, increased platelets postpartum; expired
31	30	RAEB; no treatment	Down syndrome infant at 36 week	AML after 2 years; expired
31	Unknown	Unknown	Low birth weight infant	Postpartum AML; expired

Reprinted with permission from Siddiqui T. et al.

CR, complete response; MRD-BMT, matched related donor-bone marrow transplant; RA, refractory anemia.

infants. The other patient developed spontaneous abortion. Only one patient required therapy for MDS due to rapid progression into acute leukemia; she was treated with idarubicin and cytarabine at 30 weeks gestation without remission, and treated again with same agents successfully prior to delivery. She delivered a healthy infant and subsequently underwent a matched unrelated allogeneic stem cell transplantation 2 months postpartum and remained in remission.⁶³

Although only a handful of cases of MDS with pregnancy have been reported, the relative indolence of MDS suggests that termination of pregnancy should only be a consideration seldom. In most patients, disease-specific therapy can be postponed until after delivery, but patients in the high-risk International Prognostic Scoring System (IPSS) may require cytotoxic therapy during pregnancy.⁶³

CHRONIC MYELOGENOUS LEUKEMIA

Unlike acute leukemias, chronic leukemias often do not require urgent therapy. With observation and supportive care alone, many pregnancies can be completed successfully without complications. Cytotoxic chemotherapy can often be delayed until after delivery if a patient remains in the chronic phase.

Cytotoxic agents (interferon, hydroxyurea, imatinib mesylate) and leukapheresis have been used in pregnant CML patients. Interferon (IFN) is not teratogenic and has no known adverse effects on pregnancy.^{9,64,65} The use of imatinib has recently been reported in one pregnant patient.⁶⁶

There have been a few cases of use of hydroxyurea in pregnant patients⁶⁷⁻⁷¹; the majority of these patients conceived while on therapy, and the fetuses were exposed to the drug throughout the gestational period. Both maternal and fetal outcomes were uncomplicated in these cases.

The first report of a patient conceiving while on IFN for CML was published in 1991. IFN, 4 million units subcutaneously administered every other day,

controlled blood counts, and the patient delivered a healthy infant at term.⁶⁴ Another patient on IFN therapy for approximately 2 years for chronic phase CML became pregnant. Therapy was continued and she delivered a normal term infant.⁷² No adverse fetal effects from IFN have been reported.

Imatinib has an excellent safety profile, but in toxicology studies it has been shown to induce abortions and can be teratogenic at high concentrations in animals.⁷³ Therefore, pregnancy is considered a contraindication for the use of imatinib and contraception is recommended while on this therapy. The first case of pregnancy conceived while on imatinib was reported by Heartin et al.⁶⁶ A 34-year-old woman with Philadelphia positive chronic phase CML was started on leukapheresis and hydroxyurea. She achieved complete hematologic remission within 4 weeks. After two negative pregnancy tests, she was treated with imatinib 400 mg daily. Despite appropriate contraception counseling, the patient became pregnant after 25 days of treatment and ultrasound confirmed a viable fetus of 7 weeks. Imatinib was discontinued immediately, but the fetus had been exposed to imatinib during the crucial period of embryogenesis between approximately days 8 and 33 of gestation. The patient required hydroxyurea at 29 weeks of gestation due to a WBC of 82,000/ μ L and platelets of 529,000/ μ L. Labor was induced at 38 weeks of pregnancy, and a healthy baby girl was delivered. At 6 weeks postpartum, hydroxyurea was stopped and imatinib was resumed. Six months after imatinib therapy, she attained a major complete cytogenetic response and maintained the response for at least 24 months. This was the first reported case of a pregnant woman exposed to imatinib. Although the pregnancy was uneventful for both mother and child, there is not yet enough data to support the use of imatinib in pregnant patients. The recommendation of barrier contraceptive use in women of child-bearing age while undergoing treatment with imatinib is still enforced. However, this case report suggests that if and when

patients inadvertently conceive while on imatinib, the pregnancy can evolve uneventfully and successfully with adequate care and monitoring.

CHRONIC LYMPHOCYTIC LEUKEMIA

The incidence of chronic lymphocytic leukemia (CLL) during pregnancy is rare, as this malignancy affects mainly the older population, with a median age of approximately 70 years, and it affects men twice as often as women. Only 10–15% of patients are under the age of 50 years.⁷⁴ The management of CLL in the pregnant patient is challenging due to lack of data. Information regarding the effects of various chemotherapeutic agents on the developing fetus is derived solely from reports describing teratogenic and mutagenic effects in animal experiments, and case reports on pregnancy outcomes complicated by various other malignancies. Only four cases of pregnancy and CLL have been described.^{75–78}

The natural course of CLL can be highly variable, and chemotherapy is often not indicated if the disease is in an early and stable stage, as there is no data to support improvement in survival with early intervention.⁷⁹ Therefore, CLL may not require treatment immediately because it has a relatively indolent course, but it can carry a risk of leukostasis, as well as risk of placental insufficiency, IUGR, increased fetal prematurity, and increased mortality.⁸⁰ Leukapheresis has been successfully used in both acute and chronic leukemias for rapid reduction of high WBC counts in patients with symptoms of increased viscosity. This form of treatment provides a temporary alternative to chemotherapy for the pregnant patient with signs/symptoms of leukostasis.^{81–83}

In a case reported by Chrisomalis et al.,⁷⁵ a 30-year-old woman with CLL experienced repeated infections during pregnancy that were treated successfully with antibiotics. She was not treated for the CLL, as she was asymptomatic. In addition to her bone marrow, the intervillous spaces of the placenta were filled with mature-appearing lymphocytes consistent with CLL. The patient delivered a healthy newborn, and the patient and baby remained in good health 1 year after delivery.⁷⁵ Welsh et al.⁷⁶ reported a 22-year-old patient with CLL diagnosed at 35 weeks gestation with a WBC count of 45,400/ μL . She delivered a healthy infant at term. Four months following delivery, her WBC count decreased to 10,300/ μL without therapy. She continued to have a high percentage of monoclonal lymphocytes, but the absolute number decreased. The authors concluded that this represents an apparent spontaneous “clinical” but not “clonal” regression.⁷⁶

Ali et al. published a case of a 30-year-old woman who presented with anemia and cervical lymphadenopathy in the 17th week of gestation.⁷⁸ Based on clinical findings, and microscopic analysis of her peripheral blood and bone marrow, she was diagnosed

as having stage IV B-cell CLL. The patient underwent three courses of leukapheresis at the 25th, 30th, and 38th weeks of gestation to maintain the WBC count below 100,000/ μL . Therapeutic pheresis was well tolerated by the mother and fetus, and no complications were identified. A healthy baby was born at term without anatomical or hematologic abnormalities.

There have been no reports on the use of purine analogues in pregnancy.

Targeted therapy with an anti-CD52 or anti-CD20 monoclonal antibody has been used in untreated CLL patients and in those with progressive disease after fludarabine treatment.^{84,85} Rituximab is one such anti-CD20 monoclonal antibody, and there exists little evidence for its safety during pregnancy. One report on rituximab and pregnancy has been published in a non-Hodgkin’s lymphoma patient. A 29-year-old female with stage IIA bulky CD20+ diffuse large B-cell lymphoma was treated with rituximab during 21 weeks of gestation. She received four cycles of therapy along with doxorubicin, vincristine, and oral prednisolone. The patient developed a very good partial remission and subsequently delivered a healthy term infant by Cesarean section. The child developed normally, and a normal peripheral B-cell population was detected at 4 months.⁸⁶

HAIRY-CELL LEUKEMIA

HCL is a rare hematologic malignancy of older men, with a median age of 50–55 years. It has a generally favorable prognosis, with excellent treatment response to nucleoside analogs. HCL has been reported in a few pregnant women.^{64,87–89} Two pregnant patients diagnosed with HCL received IFN during second and third trimesters of pregnancy. No side effects were reported, and both delivered healthy infants at term.⁶⁴ In another patient, treatment was deferred until after delivery, although the patient required a splenectomy at 16 weeks. She subsequently delivered at term without complications.⁸⁸ Another report described a woman found to have HCL and massive splenomegaly late in the second trimester. Due to pancytopenia (WBC 4000/ μL , platelet count 65,000/ μL , hematocrit 28.6%), she underwent splenectomy with resolution of thrombocytopenia and normal progression of pregnancy successfully.⁸⁹

ADULT T-CELL LEUKEMIA-LYMPHOMA

Human T-cell lymphotropic virus type I (HTLV-I), the causative agent in adult T-cell leukemia-lymphoma, is uncommon in the United States. A case report of adult T-cell leukemia-lymphoma during pregnancy has been published.⁹⁰ A 23-year-old female was admitted with a 1-week history of sore throat, fever, and fatigue during the 26th week of gestation. The WBC was 55,900/ μL with 74% unclassified cells. Flow cytometry revealed

increased numbers of CD3+, CD4+, and CD3-CD25+ T cells in her blood, and her bone marrow demonstrated 34% atypical, intermediate-size lymphocytes. IgG anti-HTLV-I or HTLV-II antibodies were present and HTLV-I was detected by a polymerase chain reaction assay. The patient was treated with hydroxyurea and CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) with a subsequent drop in her WBC to 12,700/ μ L. On the eighth day of admission, a healthy infant was delivered by cesarean section.⁹⁰

SUMMARY

Despite the retrospective and often anecdotal nature of the available data on pregnancy and leukemia, several principles of management can be inferred:

1. If possible, chemotherapy should be avoided during the first trimester; use of chemotherapy after the first trimester appears to be safe.
2. Patients with acute leukemia require chemotherapy as soon as feasible regardless of trimester to avoid poor maternal outcomes.
3. Once a decision to treat has been made, chemotherapy should be given at full doses and on schedule to maximize efficacy.
4. A multidisciplinary team including specialists in oncology, obstetrics, perinatology, and neonatology is necessary to coordinate care, improve the chance of cure in the mother, and minimize neonatal harm.

Beyond these basic tenets, treatment should be individualized with other proper obstetric care and monitoring to maximize the potential for favorable outcomes.

Chapter 107

TUMOR LYSIS SYNDROME, DISSEMINATED INTRAVASCULAR COAGULOPATHY, AND OTHER NON-INFECTIOUS COMPLICATIONS OF LEUKEMIA AND LYMPHOMA

Rajesh Kukunoor and Mikkael A. Sekeres

INTRODUCTION

A multitude of complications are known to occur during the treatment of leukemia and lymphoma. This chapter will summarize some of the more common, yet unique syndromes that carry serious implications of morbidity and mortality if not recognized and treated early.

TUMOR LYSIS SYNDROME

A constellation of metabolic abnormalities seen in tumors with rapid cell turnover, often as a consequence of treatment, is termed tumor lysis syndrome (TLS). It results from the lysis of predominantly malignant cells, releasing their contents into the systemic circulation at a rate that exceeds the elimination capacity of the kidneys. Hyperuricemia is central to the pathogenesis and diagnosis of this disorder.

PURINE METABOLISM

Leukemic cell lysis results in releasing purines into the extracellular space. Through a process of deamination, these purines are converted to xanthine and hypoxanthine. The oxidation of xanthine and hypoxanthine by xanthine oxidase leads to the formation of uric acid, which is eventually converted to allantoin by urate oxidase. Inhibition of these enzymatic pathways forms the basis for the treatment of hyperuricemia in TLS.

RISK FACTORS FOR THE DEVELOPMENT OF TLS

A large tumor burden with rapid cell turnover, elevated LDH, preexisting hyperuricemia, sensitivity of tumors to chemotherapy, and abnormal baseline renal function, predispose to an increased risk of TLS.¹ Tumor cell type is also an important determinant in assessing risk. TLS is most frequently encountered in aggressive lymphomas, especially the Burkitt's type.²⁻⁷ Among the other hematological malignancies, T-cell ALL has the highest risk of TLS,⁸ followed by chronic leukemias⁹⁻¹¹ and other indolent lymphomas.^{12,13} Most often, TLS is observed in the setting of systemic chemotherapy, but spontaneous occurrences are reported.^{2,13} In addition, TLS can occur in response to a variety of other therapies, such as corticosteroids,^{3,4,12,14} intrathecal methotrexate,¹⁵⁻¹⁷ tamoxifen, total body radiation,¹⁸ imatinib mesylate,¹⁹ and monoclonal antibodies such as rituximab^{6,20} and gemtuzumab ozogamicin.²¹

DIAGNOSIS AND CLINICAL FEATURES

The diagnosis of TLS is based on the demonstration of characteristic metabolic abnormalities, including hyperuricemia, hyperkalemia (or, rarely, hypokalemia), hyperphosphatemia, and hypocalcemia.

Hyperuricemia

Increased uric acid levels predispose to uric acid crystal deposition in renal tubules leading to oliguric renal failure.²² Nausea, vomiting, hematuria, oliguria, and anuria requiring dialysis can be encountered. Occasionally, hyperuricemia results in crystal deposition in joints

(gouty arthritis) and can present as arthralgias or monoarthritis.

Hyperphosphatemia and hypocalcemia

Leukemic cells may contain four times the amount of inorganic and organic phosphorous as noncancerous cells.²³ Cell lysis causes extracellular release of this phosphorous, which in turn binds to calcium, with subsequent hypocalcemia. Precipitation of calcium phosphate crystals in renal tubules may further contribute to renal failure. Severe hypocalcemia can be associated with hypotension, QT prolongation, and arrhythmias. Neurologic manifestations can include tetany, carpopedal spasm, paraesthesias, and laryngospasm.²⁴

Hyperkalemia

Leukemic cells lysed by induction chemotherapy also release potassium into the extracellular space. This becomes a concern especially in the setting of inadequate renal clearance, when serum potassium concentration can rise to dangerous levels and result in cardiac arrest.²⁵ Hypokalemia may occur in the setting of acute monoclonal leukemia in which lysozyme release acts at the level of kidneys to cause potassium depletion.

MANAGEMENT

Identification of patients at risk and institution of appropriate prophylactic measures are essential for the management of TLS. The cornerstones of therapy include aggressive hydration, maintenance of adequate urinary output (with gentle diuresis, if necessary), urinary alkalization, frequent monitoring of electrolytes, and specific treatment of individual metabolic abnormalities.

Hyperkalemia

Several approaches for the treatment of hyperkalemia are available. Methods that reduce serum potassium level through excretion, rather than via intracellular shifts, are preferred. Elimination of potassium in infusions, use of cation exchange resins such as sodium polystyrene sulfonate, loop diuretics (especially in the fluid overloaded patient), and hemodialysis (in severe cases)²⁶ are reasonable strategies.

Hyperphosphatemia and hypocalcemia

Reduction of serum phosphate levels with oral phosphate binders, such as aluminum hydroxide, is usually effective. Spontaneous correction of serum calcium levels is noted when hyperphosphatemia is adequately managed. In cases of severe symptomatic hypocalcemia, cautious repletion with calcium chloride or gluconate can be undertaken. Overzealous intravenous calcium replacement should be avoided, as this can promote metastatic calcifications.^{27,28}

Hyperuricemia

Treatment of hyperuricemia should focus on measures that prevent uric acid formation and precipitation,

and augment uric acid metabolism to allantoin. Allopurinol 300 mg/day is used prophylactically to prevent uric acid synthesis from purines released as a result of leukemic cell lysis, through inhibition of xanthine oxidase. Alkalinization of urine with sodium bicarbonate infusions to a target urinary pH of 7.0 is effective in preventing uric acid deposition in the renal tubules. However, overaggressive alkalinization could foster calcium phosphate precipitation, and therefore should be done with care.²⁷

Urate oxidase metabolizes uric acid to allantoin, which is 5- to 10-fold more soluble than uric acid²⁹ and is readily excreted by the kidneys.³⁰ Recombinant urate oxidase (rasburicase) has been recently approved for the treatment of hyperuricemia in pediatric patients with acute leukemia. It is extremely effective in reducing serum uric acid to low levels within a few hours of administration,³¹ but is used in severe cases that have failed traditional prophylactic methods, and in whom the probability of acute renal failure is very high. This therapy is initiated only when a patient's uric acid rises to ≥ 14 .

DISSEMINATED INTRAVASCULAR COAGULOPATHY

Among the thrombo-hemorrhagic complications of hematologic neoplasia, disseminated intravascular coagulation (DIC) remains one of the most common and life-threatening disorders. DIC is not a disease in itself, but represents a syndrome characterized by excess thrombin generation, usually triggered by an underlying condition.

PATHOGENESIS

Though it is well known that DIC can accompany any kind of leukemia, it is most commonly observed in patients with acute promyelocytic leukemia (APL). The development of DIC in leukemia is related to several mechanisms, including release of procoagulant factors, fibrinolytic substances, and inflammatory cytokines, and the interaction of the leukemia cells with the vascular endothelium, macrophages, and platelets.

Tissue factor (TF)^{32,33} and cancer procoagulant (CP)³⁴ are expressed in all leukemic cell types, with greatest expression seen in APL. Differentiation of leukemic blasts to more mature forms by all-*trans* retinoic acid (ATRA) is associated both with loss of expression of CP,³⁵ and with decreased expression of TF,³⁶ regardless of the degree of cellular differentiation.³⁷ Fibrinolytics, such as u-PA and t-PA,^{38,39} and the proteases elastase and chymotrypsin have been identified in leukemic blasts. These enzymes may be responsible for the proteolytic cleavage of clotting factors,⁴⁰ $\alpha 2$ antiplasmin and fibrinogen.⁴¹ In addition, the overexpression of annexin II, a fibrinolytic receptor protein on the surface of APL cells, correlates with both the clinical manifestation of

bleeding and the *in vitro* ability of the promyelocytic cell lines to generate plasmid.⁴²

There is some evidence that induction chemotherapy itself transiently worsens the coagulopathy of APL. Postulated mechanisms for this phenomenon include release of procoagulants from lysis of tumor cells, vascular endothelial damage by chemotherapy, induction of leukemic blast and monocyte tissue factor, and decrease in naturally occurring anticoagulants, such as antithrombin, and protein C and S.⁴³

MANAGEMENT OF DIC

Supportive care and treatment of the underlying cause are the cornerstones of therapy of DIC. Platelet transfusions represent an important aspect of managing patients with DIC in the setting of APL. The risk of bleeding is significantly decreased by prophylactic platelet transfusions coupled with the urgent institution of chemotherapy to counteract the coagulopathy.^{44,45} In one study, giving prophylactic platelet transfusions to keep platelet count $>30 \times 10^9/L$ and no heparin was associated with a higher response rate to induction chemotherapy.⁴⁶ The role of heparin therapy in the treatment of DIC associated with APL is uncertain. The rationale for the use of heparin is to decrease the consumption of clotting factors and platelets and to reduce intravascular fibrin formation and thrombus deposition in the microvasculature. Several small retrospective uncontrolled studies support the use of heparin in this setting.⁴⁷ However, another large retrospective study showed no benefit with respect to early hemorrhagic deaths, CR rate, or overall survival in patients treated with heparin compared with supportive care only.⁴⁸

Differentiation therapy with ATRA is also known to alter the clinical course of the coagulopathy of APL. Falanga et al.⁴⁹ noted a steep decline in all markers of fibrin degradation and clotting activation after therapy with ATRA. ATRA is also thought to exert this effect by inhibiting secretion of TNF- α and IL1- β ; inhibiting TF expression on monocytes, and by stimulating t-PA production.⁵⁰ Randomized clinical trials have not only demonstrated an increase in CR rate and a reduction in the rate of early hemorrhagic deaths in patients treated with concurrent ATRA plus chemotherapy.⁵¹

HYPERLEUKOCYTOSIS AND LEUKOSTASIS

The majority of patients with acute leukemia present with non-specific symptoms such as fatigue, weight loss, and fevers. Approximately 5–30% of adult patients with acute leukemia will have a more dramatic presentation related to an extraordinarily high leukocyte count, usually greater than $100,000/mm^3$. About 5–18% patients with adult AML^{52,53} present with hyperleukocytosis, with a majority of them having symptoms referable to leukostasis.⁵⁴ Even though hyperleukocytosis is

generally considered to have a negative impact on prognosis,^{53,55} its independent prognostic value in AML is controversial due to its close association with other established markers of unfavorable disease such as age, karyotype, CNS involvement, and antecedent hematological disorders.

The incidence of hyperleukocytosis in ALL is 10–30%. Hyperleukocytosis is a well-established negative prognostic factor for pediatric and adult ALL. Interestingly, in ALL, hyperleukocytosis rarely results in leukostasis. T-cell ALL, male sex, 11q23 rearrangements, and Ph+ ALL are all associated with a higher incidence of hyperleukocytosis. The major consequence of an increased WBC count is leukostasis, which is sludging of the microcirculation with leukemic blasts. Leukemic blasts can also form microaggregates and white, bland thrombi in these small vessels, leading to further impairment in flow. Direct endothelial damage and bleeding can occur as a result of local hypoxemia that is exacerbated by the high metabolic activity of the dividing blasts. Pathological examination frequently reveals end-organ infiltration with leukemic blasts. This is a consequence of direct endothelial damage mediated by soluble cytokines released during the interaction between leukemic blasts and the endothelium, with subsequent migration of these blasts into the perivascular space. There is emerging evidence that the differential expression of certain adhesion molecules on the vascular endothelium of AML patients may facilitate interaction of the leukemic blast with the vascular endothelium, with subsequent migration.⁵⁶ The pulmonary and cerebral vascular beds are the most clinically relevant targets of leukostasis. Cerebral involvement can range from subtle confusion and somnolence to frank intracerebral bleeding and coma. Early pulmonary involvement is signaled by mild dyspnea and respiratory alkalosis. Without treatment, this can progress to respiratory failure requiring mechanical ventilation. Typical chest X-ray findings include diffuse interstitial or alveolar infiltrates, but can be normal in the early stages.

Pulmonary leukostasis was found to be the single worst prognostic factor in patients with AML.⁵⁷ Fever is almost always present at presentation, and usually is not related to infection. Spurious hypoxemia can be related to increased consumption of oxygen by the blasts in the blood collection tube, and can be avoided by immediate transportation of an arterial blood gas sample on ice.

The short-term prognosis for patients with AML with hyperleukocytosis remains poor. As predictive factors for leukostasis lack a high degree of specificity, aggressive supportive care and prompt cytoreduction are essential. At our center, we use hydroxyurea,^{58,59} 1–3 grams orally every 6 hours in combination with emergent leukapheresis for patients presenting with WBC counts $>100,000/mm^3$ or signs or symptoms indicative of leukostasis in AML. In ALL, the threshold to initiate leukapheresis is higher; usually $>200,000/mm^3$ in many

centers. In addition to clearing circulating blasts, leukapheresis is thought to improve the coagulopathy that may be present in these patients by replacement with fresh frozen plasma, thereby reducing the risk of hemorrhage. However, leukapheresis has never been shown convincingly to reduce the risk of developing clinically significant leukostasis or reducing early mortality.⁶⁰ Though there are scanty reports in the literature regarding the use of cranial irradiation,⁶¹ it has been largely abandoned as a therapeutic modality due to toxicity, inconvenience, and lack of efficacy data.

DIFFERENTIATION SYNDROME

The incorporation of ATRA into the treatment paradigm of acute promyelocytic leukemia has significantly improved the cure rate of this disorder. ATRA causes differentiation of the malignant phenotype into a more mature myeloid cell.^{62,63} Treatment with ATRA is generally well tolerated, but a distinct clinical syndrome has been described in treated patients. Termed variably as differentiation syndrome or the retinoic acid syndrome (RAS), it was first formally described by Frankel et al. in 1992.⁶⁴ The differentiation syndrome can also occur in the setting of therapy with arsenic trioxide.

The differentiation syndrome occurs with an incidence of 6–26% in most large series.^{65,66} The incidence seems to be somewhat increased (26%)⁶⁶ in patients treated with ATRA monotherapy, compared to 10% when combined with cytotoxic chemotherapy.⁶⁷ Concurrent versus sequential administration of ATRA does not appear to alter the incidence of this syndrome. Median time to onset of symptoms is 10–12 days, but can range from 2 to 47 days.⁶⁶ Typical findings include leukocytosis, fever, weight gain, dyspnea, and alveolar infiltrates on radiological examination of the chest.

PATHOPHYSIOLOGY

Several mechanisms have been postulated to explain the pathogenesis of the differentiation syndrome. Molecules such as cathepsin G that are known to increase capillary permeability, and cell surface adhesion molecules such as CD15s and the integrins (CD 11a and CD11b) are implicated in the pathogenesis of this syndrome.⁶⁸ Increased expression of IL-1 on the APL cell induces ICAM-1 and VCAM-1 expression on the vascular endothelium, which in turn enhances leukemic cell binding to the endothelium.⁶⁹ Cytokines, including TNF- α , IL-6, and IL-1 β , may contribute by promoting leukocyte activation.^{70,71}

PROPHYLAXIS AND TREATMENT

Prophylactic administration of prednisolone in APL patients with WBC counts rising above 10,000/ml on treatment with ATRA prevented pulmonary toxicity

despite WBC counts as high as 100,000/ml.⁷² This is a promising strategy, but needs to be evaluated in a larger prospective trial.

In an attempt to decrease the incidence of the differentiation syndrome, several dose modifications of ATRA have been tried. ATRA at a dose of 25 mg/m²/d did not decrease the incidence of the syndrome, but appeared to have similar efficacy as the standard dosage of 45 mg/m²/d.⁷³ In another small study, an even lower dose of ATRA at 15–20 mg/m²/d had a lower incidence of the differentiation syndrome without compromising efficacy.⁷⁴ These strategies, however, need confirmation in larger trials.

Recognition of the clinical syndrome and prompt initiation of therapy with intravenous dexamethasone 10 mg every 12 hours for three days at the first sign of fever, dyspnea, unexplained weight gain, or pulmonary infiltrates is of utmost importance. Treatment with ATRA can be continued in mild cases of the differentiation syndrome with good outcomes.⁶⁶ However, ATRA should be discontinued in moderate to severe cases and may be resumed once symptoms resolve. If ATRA is resumed, close monitoring is required, as the syndrome can recur despite prophylaxis with steroids. ATRA does not appear to cause the syndrome when used in the maintenance phase. With early and aggressive treatment, the mortality of RAS in most large series is about 1%.⁶⁶

NEUTROPENIC ENTEROCOLITIS

Neutropenic enterocolitis (NE), or typhlitis, is a relatively frequent gastrointestinal complication encountered in patients with prolonged neutropenia, usually in the setting of post-induction therapy for acute leukemia. Its incidence ranges between 2.6 and 12%,^{75,76} depending on clinical diagnoses versus autopsy findings. It can also occur after prolonged neutropenia, as occurs with bone marrow transplantation.⁷⁷ It is encountered after induction therapy for acute leukemias in approximately 3–7%^{78,79} of patients, and only rarely with chronic leukemias.⁸⁰ Occasionally, NE is reported in non-neoplastic conditions, such as HIV infections.⁸¹ Although typhlitis is predominantly seen in patients with prolonged neutropenia after aggressive chemotherapy for leukemia, it can occasionally be the presenting feature of the disease.^{82,83}

PATHOGENESIS

The parts of the gastrointestinal tract that are most commonly affected by NE include the cecum, ascending colon, and terminal ileum. Macroscopic changes include bowel wall edema, mucosal ulcerations, serosal ecchymoses, and fibrinous plaques. Histopathological examination reveals transmural necrotizing inflammation, mucosal leukemic cell infiltration, ischemic and hemorrhagic necrosis, microvascular thrombosis, bacterial

infiltrates with absence of an inflammatory response, and mucosal pseudomembranes.⁸⁰

The factors implicated in the pathogenesis of NE are: prolonged neutropenia and an immunocompromised state; bowel ischemia worsened by anemia; leukemic infiltration of bowel wall; bacterial translocation to pockets of necrosis caused by rapid regression of the bowel wall; intramural hemorrhage secondary to thrombocytopenia; shift in bacterial flora due to antibiotic usage; nosocomial colonization by hospital flora; drug induced paralytic ileus (vincristine); and cytarabine induced mucosal damage.

The most common bacterial pathogens involved are gram negative gut flora such as *E. coli*, *Enterococcus*, *Enterobacter* and the *Clostridium* species. Septic shock can ensue and is associated with a high mortality.

The symptom complex of fever, abdominal pain or tenderness, and diarrhea in a patient with prolonged neutropenia after aggressive chemotherapy may suffice for a clinical diagnosis of NE.⁸⁴ Surgical consultation is frequently obtained, although surgical intervention is required less often. The most common finding on plain X-ray of the abdomen is ileus, and is present in 85% of cases. Ultrasound of the RLQ is sensitive, and may show bowel wall thickening.^{85,86} CT scan may reveal a RLQ infiltrative mass, pericecal fluid, and pericecal fat standing suggestive of inflammation.⁸⁷ Histological confirmation of the diagnosis is not required.

Management of the patient with NE should be individualized. Aggressive supportive care measures including broad gram negative and anaerobic coverage, adequate fluid and electrolyte balance, and adherence to strict neutropenic precautions are imperative. Surgical intervention is required in cases of perforation or peritonitis, persistent GI bleeding despite resolution of neutropenia and thrombocytopenia, or clinical deterioration suggesting septic shock.⁸⁸ Barring a few reports,⁸⁹ there is no convincing data to support the routine use of growth factors in the treatment of this disorder. Complications arising as a consequence of NE include: fistula formation, bowel perforation, bowel stenosis, prolonged ileus, massive GI bleeding, bacteremia with metastatic abscesses (hepatosplenic), acute colonic pseudoobstruction (Ogilvie's syndrome), and frank septic shock.⁹⁰

PARANEOPLASTIC SYNDROMES

Several paraneoplastic manifestations are associated with the hematological malignancies, particularly the lymphomas. In several instances, autoimmune disorders such as Sjogren's disease, rheumatoid arthritis, SLE, and autoimmune thyroiditis precede the development of the lymphoma by several years. While tests supporting a diagnosis of autoimmune phenomena such as platelet antibodies, direct antiglobulin tests, antineutrophil and

antiphospholipid antibodies are positive in approximately 40% patients with NHL, clinically relevant problems are seen in a minority of patients (<10%).⁹¹

HEMATOLOGIC SYNDROMES

Warm autoimmune hemolytic anemia (AIHA) and occasionally cold antibody-mediated hemolysis is seen most commonly in association with CLL,⁹² but 3–5% patients with NHL⁹³ and 1–2% with HD also develop this complication.⁹⁴ Fludarabine associated hemolytic anemia is also observed in patients with CLL and occasionally in NHL. In a study of patients with NHL, AIHA was associated with female sex, poorer response rate to treatment, a higher incidence of monoclonal gammopathy, and inferior overall survival when compared to patients without AIHA.⁹³ AIHA associated with lymphoma usually parallels the disease course and sometimes heralds the onset of relapsing disease. In contrast, autoimmune thrombocytopenia is seen more commonly with HD than with NHL. Unlike AIHA, when ITP recurs, it is seldom associated with a relapse. Treatment is the same as for de novo cases, and accompanies therapy for the underlying malignancy.

Several paraneoplastic coagulopathies resulting in bleeding diatheses, mediated by the secreted paraprotein, are well described in the lymphoproliferative disorders. Acquired factor VIII^{95,96} and factor X inhibitors, acquired von Willebrand's disease,^{97,98} and rarely acquired Glanzmann's thrombasthenia⁹⁹ have all been reported. Conversely, thrombosis as a result of anticardiolipin and anti-beta 2 glycoprotein-I antibodies is also reported in patients with NHL.¹⁰⁰

Eosinophilic syndrome with organ infiltration has been observed with HD and T-cell lymphoma. IL-5 is the principle cytokine that is believed to mediate this process.^{101,102} Other rarer paraneoplastic hematologic syndromes associated with the lymphomas include hemophagocytic syndrome,¹⁰³ autoimmune neutropenia,¹⁰⁴ pure red cell aplasia,¹⁰⁵ and amegakaryocytic thrombocytopenic purpura.¹⁰⁶

RENAL SYNDROMES

A variety of renal syndromes have been observed in association with hematological neoplasms. Notably, nephrotic range proteinuria precedes the diagnosis of HD in many cases. A renal biopsy most commonly reveals minimal change disease.¹⁰⁷ Unlike other paraneoplastic manifestations, this condition responds well to the treatment of the underlying malignancy; recurrence of proteinuria is an ominous sign and usually indicates relapsing disease. Renal amyloidosis is well described in the advanced stages of HD.¹⁰⁸ In contrast, renal disease in NHL is more heterogeneous

and often presents with renal dysfunction along with proteinuria. Membranoproliferative glomerulonephritis and crescentic glomerulonephritis are somewhat more common, though a variety of other histopathologies have been reported.^{109,110} Treatment of the lymphoma usually results in improvement of renal function.

DERMATOLOGIC SYNDROMES

Paraneoplastic pemphigus is a severe dermatologic syndrome that is most commonly associated with NHL,¹¹¹ but can also be seen in the course of CLL, multiple myeloma, Waldenstrom's macroglobulinemia, HD, and other solid tumors. It presents as painful mucocutaneous erosions of the lips, oropharynx, and skin. In paraneoplastic pemphigus, the antibodies target the plakin proteins of desmosomes that are found in all epithelial tissues, including the respiratory tract.^{112,113} As a consequence, bronchiolitis obliterans with respiratory failure may develop in about 30% of these patients. Immunosuppressive therapy with cyclosporine and rituximab,^{114,115} in some cases, has been associated with good responses to the skin and mucosal lesions, but does not seem to alter the eventual outcome, even when good control of the underlying neoplasm is achieved. Noursari et al.¹¹³ noted a mortality rate of greater than 90% in 84 patients with paraneoplastic pemphigus, the leading cause of death in the absence of respiratory failure being infection.¹¹⁴ Sweet's syndrome is a prototype of the neutrophilic dermatoses and is found more often with AML, but is also reported in NHL, HD, and a variety of other hematological malignancies.^{116,117} It manifests with an acute onset of fever, leukocytosis, and cutaneous plaques which show dermal infiltration with neutrophils.

T-cell lymphoma and HD can rarely be associated with eosinophilic fasciitis, which presents with painful sclerotic lesions on the extremities and trunk.¹¹⁸⁻¹²⁰ Treatment with corticosteroids has modest results, but as with any other paraneoplastic manifestation, control of the underlying malignancy is crucial. Other conditions that have been rarely associated with lymphoma are pyoderma gangrenosum,¹²¹ Bazex syndrome,¹²² granuloma annulare,¹²³ and molluscum contagiosum.¹²⁴

NEUROLOGIC SYNDROMES

Paraneoplastic manifestations of the central nervous system, while being quite rare, tend to occur more commonly in the course of HD than with any other hematological neoplasm. Paraneoplastic cerebellar degeneration (PCD) and paraneoplastic limbic encephalitis (PLE) are two distinct syndromes that deserve mention. HD is the most common hematologic malignancy associated

with PCD,¹²⁵ which occurs in about 0.5% of patients with HD.¹²⁶ It has been reported in all phases of the disease and is characterized by the symptom complex of dysarthria, nystagmus, ataxia, and intention tremor. The pathogenesis involves Purkinje cell destruction in the cerebellum by antineuronal antibodies such as anti-Tr antibodies^{127,128} and anti-mGluR1 antibodies¹²⁹ in HD. PLE is more infrequent than PCD, and HD accounts for 4-7% of this rare disorder.¹³⁰ While anti-Hu and anti-Ta antibodies have been described in patients with PLE in the context of other solid tumors, no specific antibodies have been identified in patients with PLE in the setting of HD. Personality changes, depression, memory loss, cognitive impairment, and occasionally psychosis are the predominant clinical manifestations. Prognosis is poor, and neurological improvement is rare.

As a group, peripheral neuropathy is probably the most common paraneoplastic manifestation of hematological malignancies, most often occurring in patients with lymphoma. In the majority of cases, these neuropathies tend to be a direct consequence of the cancer (nerve compression by tumor, immunoglobulin deposition, or treatment toxicity) rather than paraneoplastic. However, when it occurs, paraneoplastic neuropathy can manifest either as an indolent process, as in chronic inflammatory demyelinating polyneuropathy, or in a more acute fashion as Guillain-Barre syndrome.¹³¹⁻¹³³ In patients who have high monoclonal paraprotein IgM in the setting of either Waldenstrom's macroglobulinemia, multiple myeloma, or occasionally NHL, a debilitating peripheral neuropathy can develop as a consequence of anti-myelin associated glycoprotein antibodies (anti-MAG antibodies).¹³⁴ A variety of therapies have been used with limited success in the treatment of these neuropathies and include IVIg, plasmapheresis, corticosteroids, cyclophosphamide, fludarabine, interferon, and rituximab.

MISCELLANEOUS

Nonbacterial or marantic endocarditis was noted in 19% of asymptomatic patients with HD or NHL.¹³⁵ The thrombotic rate was also increased in these patients, suggesting a hypercoagulable state.

Hypercalcemia occurs in 0.3-0.4% of patients with lymphoma.¹³⁶ While it is more common with adult T-cell leukemia/lymphoma, it can also be seen with HD and B-cell NHL. A variety of mechanisms, including parathyroid hormone-related peptide, Il-6, TNF,¹³⁷ prostaglandins, and elevated levels of vitamin D₃,¹³⁸ have been postulated as being etiologic. Therapy is similar to that used for other forms of hypercalcemia.

Another rare disorder is recurrent angioedema of the face, larynx, extremities, and occasionally scrotum due to acquired C1 esterase-inhibitor deficiency.¹³⁹ It is

usually associated with indolent B-cell lymphoproliferative disorders, commonly with lymphoplasmacytoid differentiation and paraprotein secretion, and can precede the diagnosis of lymphoma by several years.¹⁴⁰ Laboratory testing reveals low C1 esterase-inhibitor activity, low C4 and C3, and low C1q levels.

Rare cases of cholestatic jaundice without evidence of intrahepatic disease may occur in NHL and HD.^{141,142} The so-called “vanishing duct” syndrome, characterized by extrahepatic obstruction without intrahepatic ductal dilatation, eventually culminates in hepatic failure and carries a poor prognosis.^{143,144} There are several case reports of vasculitis associated with lymphoproliferative disease, including Wegener’s granulomatosis and Churg-Strauss disease, temporal arteritis, and cryoglobulinemia.

THROMBOCYTOPENIA

A low platelet count often is present in a person with acute leukemia, either from bone marrow replacement or from the bone marrow suppressive effects of the leukemia itself; from platelet consumption as a sequela of the disease or infection; or from the myelosuppressive effects of antileukemic chemotherapy. The incidence of serious spontaneous hemorrhage increases when the platelet count falls below 10,000/mm³, and this should be the threshold for platelet transfusions in the absence of bleeding. Using a platelet count of 10,000/mm³, as opposed to a count of 20,000/mm³, results in a similar incidence of bleeding complications and a 21.5% reduction in platelet use.¹⁴⁵

Chapter 108

FERTILITY ISSUES IN THE HEMATOLOGIC MALIGNANCIES

Ashok Agarwal and Tamer M. Said

INTRODUCTION

Young adults diagnosed with cancer are living longer than ever due to improved treatment regimens. The 5-year survival rate for certain subtypes of leukemia and Hodgkin's and non-Hodgkin's diseases, for example, has dramatically increased to 75%–90%.¹ However, the neoplastic disease per se and/or its treatment commonly impair fertility, leaving many patients unable to bear healthy, biological children.

Hematologic malignancies, in particular, can adversely affect fertility in a number of ways. Since these diseases generally involve the hypothalamus and pituitary, they can directly affect gonadotropin secretion, resulting in secondary hypogonadism and, hence, defective sperm formation and infertility. In addition, chemotherapy and radiation therapy—both being used to treat hematologic malignancies—are toxic to the male and female gonads. Even if fertility does not decline as a result of therapy or returns naturally, patients can still be rendered sterile by cytotoxic therapy, as these drugs can cause genetic mutations in germ cells.² Similarly, any cytotoxic therapy administered to pregnant women has the potential for serious teratogenic consequences on the fetus (see Chapter 106).

IMPACT OF MALIGNANCY ON THE REPRODUCTIVE SYSTEM

In the past, infertility associated with malignant disease was considered a side effect of the drugs and radiation used during the course of treatment. However, this view is changing due to strong evidence that decreased fertility sometimes exists before the treatment starts. In a study conducted on 158 male patients with Hodgkin lymphoma,³ severe damage to fertility was observed in 21% cases before treatment. The decrease in fertility was most prominent in patients with an elevated erythrocyte sedimentation rate (ESR) and in those with advanced disease. In another study, semen analysis

showed that 70% of male patients with Hodgkin lymphoma had reduced fertility before therapy.⁴

The effect of Hodgkin lymphoma on testicular function does not involve local tumor or metastasis. Instead, the disease may lead to structural abnormalities in the testicular parenchyma, such as tubular hyalinization.⁵ These changes may be caused by an immune-mediated disorder that alters the balance between distinct subpopulations of lymphocytes, which normally inhibit or stimulate the production of spermatozoa. However, this hypothesis requires further testing.⁶ In addition, cytokines (e.g., interleukins and tumor necrosis factor) that are secreted by tumor tissue may be partly responsible for the impaired testicular function seen in patients with Hodgkin's disease.⁷

In general, malignancy is associated with an increased catabolic state and malnutrition. Therefore, most patients experience weight loss and decreased reproductive capacity. In addition, hypothalamic dysfunction can occur and pituitary gonadotropin levels can fall, thus affecting the fertility.⁸ Stress hormones may further reduce fertility by leading to a rise in prolactin and endogenous opiate secretion, which in turn suppress gonadotropins.⁹

GONADAL TOXICITY FOLLOWING MALIGNANCY TREATMENT

In addition to Hodgkin and non-Hodgkin's lymphoma, acute lymphocytic leukemia and acute myeloid leukemia are among the most common neoplastic disorders during the reproductive years.¹⁰ As the mortality rate decreases and the survival rate increases, the consequences of cancer treatment vis-a-vis impaired fertility are more frequently encountered.

SUSCEPTIBILITY OF THE MALE GONAD TO CANCER TREATMENT

Testicular architecture

Chemotherapeutic agents enter testis via blood vessel plexus in the interstitial region. Although the Sertoli

cells usually maintain a protective barrier between the blood and the testicular germ cells, many chemotherapeutic drugs can severely interrupt the integrity of this barrier.

Germ cells that do actively differentiate are more susceptible to cytotoxic injury, resulting in necrosis, whereas testicular somatic cells are affected only in function. As a result, cytotoxic therapy can deplete germ cells to the point where the seminiferous tubules contain only Sertoli cells. The depletion occurs in a time-dependant manner because late-stage germ cells (spermatocytes onward) are relatively more resistant. However, studies in rodents revealed that these late-stage cells are susceptible to mutagenesis, and any mutations in their DNA can be passed on to the next generation.¹¹ Surviving stem cells can remain in the testis, but will fail to differentiate into mature spermatozoa for several years after cytotoxic abuse. The eventual recovery of sperm production depends on the survival of the spermatogonial stem cells, as well as on their ability to differentiate.¹²

The effects of cancer therapy on testicular architecture vary with the patient's age and pubertal status. It was initially thought that the testicles of pre- and peripubertal males were less vulnerable to toxic effects induced by treatment. However, it is now clear that these patients experience as much testicular structure damage following chemo/radiotherapy as adults.¹³

Hormonal imbalances

The loss of germ cells exerts secondary effects on the hypothalamic-pituitary-gonadal axis. Germinal aplasia reduces the size of the testes. Consequently, testicular blood flow decreases, thus reducing the testosterone levels in the circulation.¹⁴ Because testosterone is a negative regulator of luteinizing hormone (LH), which is secreted by the pituitary, and LH is the primary stimulator of testosterone synthesis by the Leydig cells, LH increases to maintain constant serum testosterone levels. In addition, inhibin secretion by the Sertoli cells declines and, as inhibin limits follicle-stimulating hormone (FSH) secretion by the pituitary, serum FSH levels tend to rise.

SUSCEPTIBILITY OF THE FEMALE GONAD TO CANCER TREATMENT

Ovarian architecture

Histological sections of ovaries exposed to cytotoxic drugs show a spectrum of changes, ranging from reduced number of follicles to no follicles and fibrosis.¹⁵ The exact incidence of premature ovarian failure (POF) after chemotherapy is difficult to establish because there are many contributing factors. Depending on the type of chemotherapy regimen used, the incidence of amenorrhea ranges from 0% to 100%.¹⁶ Cytotoxic drugs may impair follicular maturation and/or deplete primordial follicles.^{15,17} Temporary amenorrhea occurs when cytotoxic drugs destroy maturing follicles,

whereas permanent amenorrhea or POF occurs when all primordial follicles are destroyed. The close structural and functional relationship between the oocyte and the hormone secreting-granulosa cells makes it difficult to identify an exact target for cytotoxic drugs. The destruction of one leads to the demise of the other.

Hormonal imbalances

Unlike male germ cells, female germ cells proliferate only during prenatal life; after birth, these progressively decrease in number due to apoptosis, and ovulation. Germ cells inside the female gonad do not proliferate, whereas the somatic cells do. Radiation and chemotherapy induce oocytes to undergo apoptosis, which reduces the number of germ cells,¹⁸ resulting in estrogen insufficiency. Therefore, when follicles are destroyed by cytotoxic therapy, the frequency of menses decreases and amenorrhea commonly occurs. Irreversible ovarian failure and menopause occur if the number of follicles falls below that is required for menstrual cyclicity.

EFFECT OF MALIGNANCY TREATMENT ON FERTILITY

Post-treatment of Hodgkin's lymphoma in men with chemotherapy results in testicular germ cell aplasia and decreased libido.⁵ The seminiferous epithelium inside the testes is most sensitive to the detrimental effects of chemotherapy. Therefore, after treatment with gonadotoxic agents, patients may be rendered oligozoospermic or azoospermic. Because testosterone production by the Leydig cells remains unaffected, patients still develop normal secondary sexual characteristics.¹⁹ However, treatment with high, cumulative doses of gonadotoxic chemotherapy can lead to Leydig cell dysfunction.

Doses as low as 0.1 Gy to 1.2 Gy can have detectable effects on spermatogenesis in adult males, with doses over 4 Gy causing more permanent effects.²⁰ Somatic cells are more resistant to chemotherapy and radiation-induced damage than are germ cells. Indeed, Leydig cell dysfunction is not observed until doses of 20 Gy are administered to the prepubertal boy and up to 30 Gy in sexually mature males.²¹ Testosterone production is therefore relatively preserved below these doses. Thus, many patients develop normal secondary sexual characteristics despite a severe impairment of spermatogenesis.

Young patients with a hematological malignancy are often treated with bone marrow transplantation (BMT).²² During BMT, patients may be given alkylating agents and receive total body irradiation for conditioning, both of which result in POF, hormonal disturbances, and eventually, infertility.²³ Long-term female survivors treated with total body irradiation and BMT are at risk for ovarian follicular depletion and impaired uterine growth and blood flow, in addition to early pregnancy loss and premature labor if pregnancy is

achieved.²⁴ Because women aged above 30 years face a higher incidence of POF following chemotherapy, their treatment regimens should contain fewer alkylating agents.²⁵

A study that documented the late effects associated with treatment of early Hodgkin's lymphoma revealed that 43/191 men and 16/149 women had sought medical advice for infertility, while 57/191 men and 54/149 women were able to parent children. In addition, sexual activity was disrupted in 25.8% of cases.²⁶

TRANSMISSION OF GENETIC MATERIAL

Radiation and several alkylating agents can produce single-gene mutations and chromosomal translocations in spermatogonia.²⁷ The persistence of a mutation depends mainly on its location. Mutations that occur early in stem spermatogonia will produce mutation-carrying sperm for the lifetime of the male, whereas those occurring in later stages of spermatogenesis will only lead to a mutation-carrying sperm for a few months.¹¹ Meiotic and post-meiotic germ cells are more susceptible to mutations than are stem spermatogonia. Therefore, the mutational risks are highest when a pregnancy occurs within one spermatogenic cycle after the male is exposed to the damaging agent.¹¹ In females, most alkylating agents and a variety of other chemotherapeutic drugs induce chromosome aberrations or other mutations in developing oocytes that result in embryonic death.²⁷

Although sperm DNA integrity can vary greatly among cancer patients, patients with Hodgkin's and non-Hodgkin's diseases generally have a significantly higher prevalence of DNA damage than healthy men.²⁸ Sperm DNA damage can be assessed with a variety of techniques,²⁹ but none can definitively determine whether the mutations will be passed onto any offspring.

POTENTIAL FOR FERTILITY FOLLOWING MALIGNANCY TREATMENT

RESTORATION OF FERTILITY

Sperm quality may naturally improve after cancer treatment. However, some defects may persist. The incidence of infertility in men who have recovered sperm production following cytotoxic therapy is generally not higher than that of the general population. An interesting case report³⁰ has documented paternity following bone marrow conditioning and transplantation in a patient with acute myeloid leukemia. For the first time, the preservation of fertile sperm was seen despite the use of chemotherapy. Cancer patients with sperm counts below normal (oligozoospermic) are still capable of having children.³¹ Similarly, infertile women who have menstrual dysfunction following cytotoxic therapy may be treated for menstrual dysfunction and infertility in a manner similar to that of

the general population. However, the risk of an adverse pregnancy outcome is higher in these women, and they may require closer observation.³²

ASSISTED REPRODUCTIVE TECHNIQUES

The reproductive capacity of individuals undergoing malignancy treatment can be preserved by cryopreserving the gametes and using assisted reproductive techniques (ART) when pregnancy is desired.³³ When non-cryopreserved spermatozoa are used in combination with intrauterine insemination (IUI), in vitro fertilization (IVF), and intracytoplasmic sperm injection (ICSI), clinical pregnancy rates of 30–40% per cycle and delivery rates of 30% can be expected at most reproductive clinics. On the other hand, cryopreserved sperm from cancer patients results in complete pregnancies in only 18% of cycles.³⁴ Similarly, autologous cryopreserved embryos from in vitro-fertilized oocytes can be successfully implanted after cytotoxic therapy if the patient can undergo ovarian hyperstimulation before therapy.³⁵

Men who remain azoospermic long after chemotherapy may benefit from testicular sperm extraction (TESE) combined with intracytoplasmic sperm injection (ICSI). The potential for sperm retrieval is not clearly affected by the chemotherapy regimen or by the disease treated.³⁶ Therefore, men should not be considered sterile despite prolonged non-obstructive azoospermia after undergoing chemotherapy.

OPTIONS FOR FERTILITY PRESERVATION

SEMEN CRYOPRESERVATION

With the advancement of ART, all men diagnosed with cancer should be offered the option of semen cryobanking, a procedure that provides the only reasonable chance of establishing pregnancy after therapy.³⁷ Semen cryopreservation is a widely available and inexpensive option (< \$1000) that yields good results.

Patients diagnosed with cancer used to be considered poor candidates for sperm cryopreservation because they present with disease-induced suboptimal semen quality and cryosensitivity. Men with Hodgkin's lymphoma have pre-freeze and post-thaw sperm quality that is below normal.^{38,39} However, as a general rule, there is no cancer group for which sperm cannot be retrieved and stored.⁴⁰ Even the absence of spermatozoa in semen should not prevent physicians from attempting to preserve a patient's fertility. In many cancer patients who suffer from azoospermia before treatment, testicular sperm extraction "Onco-tese" may be successfully attempted (unilateral or bilateral), and the retrieved sperms may be cryopreserved for future use.⁴¹

Almost 40% of patients who cryopreserve their semen may have a healthy live birth using ART.³³ Based on the experience at the Cleveland Clinic in the

last two decades, the percentage decline in semen quality (from pre-freeze to post-thaw) in patients with cancer shows a similar trend that of normal donors. This suggests that the effect of cryodamage on spermatozoa from patients with cancer is similar to that of normal donors.^{42,43} Cryopreserving semen after the start of therapy can adversely affect their chromosomal structure, causing de novo mutations, but should still be attempted if the imperativeness of starting therapy outweighs the chance for cryopreservation, as viable sperm may still be recovered. Therefore, it is crucial to cryopreserve sperm before chemotherapy or radiotherapy and also to advocate the use of contraception during therapy and for 6 months after.

Only a small percentage of patients (< 10%) who bank their spermatozoa before chemotherapy or radiotherapy return for assisted reproduction.⁴⁴⁻⁴⁶ This finding may be explained by several reasons: recovery or waiting for possible resumption of spermatogenesis, short period from original illness, anxiety regarding potential risks for the children, and uncertainty about long-term health and, therefore, suitability to be parents.⁴² However, trends have started to change, and awareness of sperm banking has increased over the past 4 to 5 years, coinciding with the advent of ICSI.

In males with cancer, the extent of sperm DNA damage plays an important role in determining how semen should be cryopreserved before therapy begins. Specimens with high sperm concentration and motility and low levels of DNA damage can be preserved in relatively large aliquots suitable for IUI. If a single specimen of good quality is available, then it should be preserved in multiple small aliquots suitable for IVF or ICSI.²⁸

TESTICULAR TISSUE HARVESTING

Although spermatogenesis does not occur in prepubertal testes, and prepubertal testes do not produce mature spermatozoa, these do contain the diploid stem germ cells from which haploid spermatozoa can be derived. Therefore, testicular tissue can be harvested from a biopsy and stored either as a tissue section or as isolated germ cells, before cancer therapy. Following cure and on entering adulthood, this tissue can be thawed and used to produce offspring in either of the two ways: the stored germ cells can be re-implanted into the patient's own testes to restore natural fertility, a procedure known as germ cell transplantation, or the stored stem cells can be matured in vitro until they are able to achieve fertilization via ICSI.⁴⁷ Although these two measures have been the subject of intensive research in the last decade, further refinements in the protocols may still be needed before they can be used routinely in clinical practice.

Germ cell transplantation

Germ cells isolated from the testes of donor male mice can repopulate immunologically compatible testes

when injected into the seminiferous tubules of recipient animals; the recipients show normal morphological features characteristic of the donor species.⁴⁸ Similarly, mouse germ cells transplanted into the testes of infertile mice colonize the recipient seminiferous tubules and initiate donor spermatogenesis in more than 70% of recipients.⁴⁹ The most striking result of these experiments was that healthy offspring (by mating) were produced from spermatozoa generated within the recipient testes by donor germ cells.

Establishing a successful method for testicular stem cell transplantation of frozen, thawed testicular cells would be of immense benefit to boys with childhood cancer undergoing sterilizing treatment. It is possible to reinitiate spermatogenesis after cryopreservation of testicular germ cell suspensions. Although cell survival is acceptable, current protocols need further improvement.⁵⁰ Male germ cells obtained before chemotherapy can be frozen and, after thawing, can be transplanted into animals to maintain the entire genetic information of the donor for a limited period.

Before stem cell transplantation can be considered for preserving the fertility of pre-pubertal boys, two issues must be carefully examined.⁵¹ First, the testis biopsy taken from the cancer patient may contain malignant cells. These cells must be removed from the cell suspension because studies in rats have shown that one single malignant cell can reintroduce the disease. Second, the cell suspension consists of all testicular cells, and the proportion of spermatogonial stem cells is low (estimated at 1/5000).⁵²

In vitro maturation

In vitro germ cell maturation would be particularly useful in patients who have received extremely gonadotoxic therapy and in whom the supporting Sertoli cells would be unable to support spermatogenesis. Mouse spermatogonial stem cells can survive up to 4 months in culture and retain their ability to commence spermatogenesis following transplantation into a recipient.⁵³ However, it appears that current methods for in vitro maturation of diploid stem cells into haploid spermatozoa are not well developed. Ongoing research may improve their feasibility.

OOCYTE CRYOPRESERVATION

Although successful fertilization and embryonic cleavage have been reported after injection of cryopreserved thawed oocytes, the pregnancy rate is not high enough to justify its routine use in clinical practice.⁵⁴ The main reason for poor outcomes after oocyte cryopreservation is related to the oocyte's structural complexity. Oocyte subcellular organelles are far more complex and perhaps more sensitive to thermal injury than preimplantation embryos. Oocyte donation may be considered in cases characterized by complete ovarian follicular depletion. However, the presence of other factors, such as uterine impairment, would be of

major concern. In addition, complications during pregnancy and pre-term deliveries would be expected in these cases.⁵⁵

OVARIAN TISSUE CRYOPRESERVATION

Ovarian tissue banking in humans is being considered to restore fertility in patients who lose ovarian function because of chemotherapy or radiotherapy.⁵⁶ Ovarian tissue cryopreservation and transplantation was first examined in rodent studies and then in sheep and human ovarian xenograft studies.⁵⁷ However, no pregnancies have been reported in humans from the use of cryopreserved ovarian tissue. Although promising, there is a theoretical risk that malignant stem cells will be reimplanted along with the thawed cryopreserved ovary.^{58,59} With the publication of promising data from humans, ovarian tissue cryopreservation from selected patients before cancer treatment and in those requiring oophorectomy may be advocated. However, this option is currently under experimental evaluation, and few centers offer this to patients.

EMBRYO CRYOPRESERVATION

Embryo cryopreservation was introduced to maximize the chances of conception during a single menstrual cycle. Cryopreservation of preimplantation embryos is currently an integral part of patient care in clinical practice. This option may not be socially acceptable in prepubertal females and adolescents. However, acceptable, long-term data are available about the outcome of children born from these procedures.⁶⁰

CHOICE OF CYTOTOXIC REGIMENS

Currently, treatment regimens for hematologic malignancy include a variety of chemotherapeutic agents, all of which affect reproductive functions differently. For young patients, agents with minimal toxicity but maximal therapeutic effect are selected. For example, NOVP (Novantrone (mitoxantrone), Oncovin (vincristine), Vinblastine, Prednisone) may be preferred over MOPP (nitrogen mustard, vincristine, procarbazine, and prednisone) for the treatment of Hodgkin's lymphoma. Although NOVP markedly affects spermatogenesis, sperm production recovers rapidly after treatment, usually within 3 to 4 months. This rapid recovery is due to the fact that NOVP chemotherapy damages spermatogenic germ cells rather than inhibiting stem cells.⁶¹

Similarly, ABVD (adriamycin, bleomycin, vinblastine, and dacarbazine) is used to treat Hodgkin's disease instead of MOPP because the former dramatically reduces gonadal toxicity.⁶² VAPEC-B (adriamycin, cyclophosphamide, etoposide, vincristine, bleomycin, and prednisolone), which is used in the treatment of non-Hodgkin's lymphoma, minimizes the dose of cyclophosphamide and therefore results in less gonadal failure than CHOP-Bleo (cyclophosphamide, adriamycin, Oncovin (vincristine), prednisone, bleomycin).⁶³

GONADAL SHIELDING

The gonads must be outside the field of radiation or shielded from the direct radiation beam unless they are being irradiated directly as a result of actual or potential neoplastic involvement. Although gonadal shields can reduce the amount of radiation two- to fivefold, some radiation may still reach the gonads. For example, the gonads typically receive 2 to 3 Gy with an inverted Y-field, which is used for Hodgkin's disease.⁶⁴ To minimize ovarian exposure, oophoropexy may be performed to relocate the ovaries away from the direct beam.^{65,66} Laparoscopic oophoropexy may be of benefit in cases of Hodgkin's disease, if performed before pelvic irradiation.⁶⁷

MEDICAL TREATMENT

Hormones

When testosterone suppressors such as gonadal steroids, GnRH analogs, and antiandrogens were used before and during cytotoxic therapy in male rats, they enhanced the recovery of spermatogenesis and fertility.⁶⁸ These suppressors may work by enhancing the potential of the somatic cells in the testis to support the recovery of spermatogenesis.⁶⁹ For a while, it was assumed that recovery of stem spermatogonia cells could possibly be stimulated after prolonged periods of iatrogenic azoospermia, but research does not support this theory. Hormone treatment given before and during cytotoxic therapy was found to protect spermatogenesis in only one of eight clinical trials.⁴⁰

Gonadotropin-releasing hormone (GnRH) agonists may protect ovarian function from the effects of cyclophosphamide⁷¹ by decreasing the recruitment of primordial follicles. Strong evidence supports the use of GnRH agonistic analogues to minimize the gonadotoxic effect of chemotherapy because they induce a pre-pubertal milieu.^{59,72} However, the feasibility of using oral contraceptives or GnRH agonists to protect women against ovarian damage has not been established.⁷³ Another hormone, medroxyprogesterone, helps protect primordial follicles from the acute toxic effects of chemotherapy. Nevertheless, the quality of the follicles will be impaired, and many will undergo atresia, resulting in a shortened fertility period.⁷⁴

Hormone replacement therapy (HRT) should be considered in young pre-menopausal women who have developed ovarian failure due to malignancy or cancer treatment.⁷⁵ Even with the use of HRT, though, uterine size can decrease by 40%.²⁴ Importantly, any residual ovarian function remaining after chemotherapy is considered a good prognostic sign because the ovaries may be stimulated with steroid hormones and/or gonadotropins.⁷⁶

Anti-apoptotic drugs

Oocytes exposed to chemotherapeutic agents in vitro undergo various changes leading to apoptosis.⁷⁷ Because a series of specific signaling events are

activated in the cell that is bound for apoptosis, inhibiting these signaling events could potentially stop the apoptotic process and protect the patient from POF. Sphingosine-1-phosphate is an example of an apoptotic inhibitor. The oocytes of mice that had been treated with sphingosine-1-phosphate therapy resisted apoptosis that was induced by doxorubicin.⁷⁸ This concept offers a promising experimental alternative to guard against apoptosis. With the eventual identification of the molecular and genetic framework of chemotherapy-induced germ cell death, apoptotic inhibitors may some day play a role in preventing oocyte loss.

ETHICAL AND LEGAL ISSUES

Options for future fertility following cancer treatment must be considered in the patient's best interests. Thus, the advantages of any intervention or of an active decision not to intervene must outweigh any disadvantages, both in the short and long term. Any intervention intended to preserve fertility must have a sound evidence base as well as moral provenance. It should neither raise unrealistic expectations, nor have long term adverse effects on the patient or his or her offspring.⁷⁹

Informed consent should be given voluntarily by a competent person. However, in view of the complexity of the issues surrounding fertility preservation, the anxieties of both patients and their families at the time of diagnosis, and the limited time for discussion due to

the urgency of commencing treatment, the validity of such consent may be impaired. The first stage of consent is for the collection and storage of the germinal tissue or gametes. The second stage is for use of the collected material for fertilization. In addition, it is important to consider what will happen to stored cells in the event of divorce or the patient's death. While some would advocate destruction of the tissue in the latter situation, others have suggested allowing the parents to donate the tissue for research purposes.⁸⁰

SUMMARY

Patients with hematologic malignancies have impaired fertility indirectly as a result of necessary cytotoxic treatment regimens. The deterioration in fertility potential may be temporary or permanent. However, the decreasing mortality rate and the increasing survival rate as a result of effective treatment have made fertility issues more frequently encountered.

A variety of measures may be used to minimize the deleterious effects of malignancy and its treatment on the human fertility potential. Moreover, assisted reproductive techniques in combination with our rapidly evolving understanding of cryobiology offer encouraging measures to preserve productiveness following malignancy treatment. These measures should be considered in young adults, and patients should be counseled regarding the pros and cons of each of the available options for fertility preservation.

Chapter 109

PALLIATION OF SYMPTOMS ASSOCIATED WITH HEMATOLOGIC MALIGNANCIES

Mellar P. Davis

INTRODUCTION

Patients presenting with hematologic malignancies experience multiple symptoms while also confronting the emotional distress of a newly diagnosed life-threatening illness. Most will notice reduced physical functioning prior to admission. Many will also note a change in their role within the family structure as they become more dependent because of the symptoms. Overall quality of life is significantly impaired compared to the age-matched normal population.¹ Pain and fatigue will improve with successful treatment and approximate the normal population at 3 months. However, physical and role (social) functioning within the family remains substantially below premorbid levels despite successful therapy.¹ Other symptoms at diagnoses include fever from infections, bleeding, and weight loss.² Weight loss is particularly evident in patients with myeloma and amyloid or in individuals who have primary amyloidosis.³ Little is written about the presenting symptoms associated with acute leukemia. Some of the reported symptoms include fatigue, fever, bleeding, and pain. The pain from acute leukemia is more generalized than the pain that occurs with myeloma, and more frequently centered in the chest.⁴

Symptoms near the end of life for hematologic malignancies in general are protean. Dyspnea occurs due to cardiac insufficiency (perhaps from comorbidities, anthracycline toxicity, or radiation), fevers from infections, and hyperleukocytosis, which can cause neurologic deficits and hypoxemia. Lymphangitic tumor infiltration with pain and shortness of breath, pulmonary fibrosis, mediastinal adenopathy with atelectasis, pleural effusion, and growing tumor masses add to dyspnea, pain, and debility.⁵ Fevers occur in 40% of acute leukemia patients near the end of life. Severe pain is present in 27%. Abdominal pain is present in 60%, bone pain in 30%, and thoracic pain in 10%.⁵ Clinical evidence of bleeding occurs in 20%, excluding ecchymosis

and petechiae. Delirium will be present in at least 25%, with the incidence steadily rising as death approaches. Mucositis will be a major problem in 9%.⁵

Chemotherapy will be given to 46% as palliation in the terminal phase, either for hyperleukocytosis or painful compressive lymphadenopathy. Many will receive short courses of radiation for the same reason. Antibiotics will be prescribed in nearly half. Blood transfusions, particularly red blood cells, will be given to 40% in the terminal phase of their illness.⁵ Patients will be on opioids (27% of patients), steroids (40%), and benzodiazepines (90%), all of which will be necessary to palliate symptoms but will also increase the risk of delirium. A Do Not Resuscitate (DNR) order will be written in only 38% despite the fact that deaths are anticipated in nearly 80%.⁵

Many patients with acute leukemia in the terminal phase will have clinically evident (wet) bleeding (44%), fever with infections (71%), and bone pain (76%).⁴ One quarter will have oral pain and dysphagia and over one-third of patients will have problems with nausea and vomiting.⁴ Such symptoms will preclude oral opioids for pain control. Many patients will have central lines for parenteral infusion, while a minority without venous access will be given subcutaneous opioids.⁴ Rectal administration of medications, commonly used in hospice, is avoided because of the risk of infections and bleeding. As a result, the versatility of palliative medications is limited by the disease process.

Unadjusted survival for leukemia and lymphoma patients entering hospice programs is much shorter than that for the patients with solid tumors. In 1996, the median survival for patients with hematologic malignancies after hospice enrollment was 23 days, and 20% died within 7 days.⁶

Patients with hematologic malignancies have a greater chance of dying within the hospital compared to patients with solid tumors⁷. In South Australia, all leukemia patients died in the hospital and few received

palliative consults for managing symptoms at the end of life.⁷ On average, the risk of dying within a hospital is four times that of solid tumor patients. Patients with hematologic malignancies have the lowest enrollment in hospice programs per disease category.⁸ This may in part be because of the reluctance of hospice programs to administer blood transfusions, a treatment considered palliative by most physicians specializing in the hematologic malignancies.

SYMPTOMS AND MANAGEMENT

LOCAL SYMPTOMS

Pain

Pain will be experienced by most patients with advanced cancers, and hematologic malignancies are no exceptions.⁹ Myeloma pain is well localized, whereas acute leukemia often is associated with more generalized pain, as previously discussed. Neuropathic pain will occur in myeloma because of the development of amyloid, spinal cord compression, leptomeningeal metastases, or due to myelin-associated monoclonal proteins.¹⁰ As a general rule, two-thirds of the pain syndromes in cancer patients are directly related to cancer and one-third are related to treatment. However, many of the chemotherapy agents used to treat hematologic malignancies produce neuropathic pain (e.g., thalidomide, now popular in the treatment of myeloma). Mucositis is treatment related, and is a major cause of pain during induction chemotherapy and periods of myelosuppression. This is particularly true for high-dose antimetabolites such as methotrexate or cytosine arabinoside, and high-dose melphalan used as preparation for stem cell transplantation (SCT) in myeloma. Graft-versus-host disease will produce a mucositis and oral pain, which can persist.

Pain intensity is easily “quantified” by using unidimensional pain scales such as the visual analogue scale, the numerical scale, and the category scale.^{9,11} Older patients are usually able to complete a category scale by rating pain as none, mild, moderate, or severe. Either the category scale or even a pictorial face scale can be used by those with moderate cognitive impairment.⁹ Pain intensity is influenced by mood, perceived meaning of pain, and psychological state (depression, delirium, or anxiety), and is not the same as nociception. Pain syndromes that are resistant to opioids include neuropathic pain, cutaneous pain, incident flares of pain, and colic.^{9,12}

The evaluation of pain by most physicians is suboptimal.^{13–15} Assessment requires a good pain history, which requires evaluating pain intensity, location, radiation, palliative factors, and referral, as well as response to prior treatments. In addition, the physician should understand the influence of pain on daily activities (pain interference). Multidimensional pain tools such as the Brief Pain Inventory are available for this purpose.¹⁶

As pain is a multidimensional experience, treatment should include both nonpharmacologic and pharmacologic therapies.⁹ The reduction of anxiety, depression, and delirium with supportive psychotherapy, cognitive behavioral therapy, and medications will increase pain thresholds and reduce pain intensity. Surgery and orthodontics, as well as radiation therapy, should be considered as complementary to pharmacologic therapy.

Most patients with cancer actually have several pains. Most have chronic pain with transient flares of acute pain.¹⁷ In approximately one-third, neuropathic pain will be prominent, though many will have a mixed pattern of neuropathic and nociceptive pain.¹⁸ Both the type of pain, pain intensity, and the temporal nature of pain govern the analgesic dosing strategy. Therapy needs to be individualized.^{19,20} Opioids should be used for moderate to severe pain.^{19,20} Eighty percent of patients with severe pain will have pain controlled by morphine or other potent opioids. Opioid titration to response is a cardinal principle of treatment. An effective drug will be ineffective if underdosed; potent opioids do not have a ceiling dose. Twenty percent of patients will require a complex approach to pain management of opioid (route) conversion, opioid rotation to an alternative opioid, opioid sparing (by adding an adjuvant analgesic), or maintenance of opioid dosing with simultaneous treatment of opioid side effects (particularly in those who are actively dying).^{9,21,22} Most mistakes in dosing occur with (1) failure to give around-the-clock doses; (2) failure to provide breakthrough doses for transient flares of pain; (3) failure to titrate to response; (4) combining different opioids at less than optimal levels; (5) failure to use adjuvant analgesics effectively; and (6) failure to recognize and treat opioid side effects and proactively prevent constipation with laxatives.²³

Several factors play a role in opioid choices: efficacy, versatility, drug interaction, therapeutic index, availability, cost, and organ function. Opioid agonist/antagonists, nalbuphine, butorphanol, and meperidine should not be used.^{9,21} The most common potent opioids in the first-line treatment of cancer pain are morphine and methadone, fentanyl, hydromorphone, and oxycodone if limiting side effects occur with morphine.^{24–28} Low doses of a potent opioid can be substituted for “weak” opioids (by World Health Organization classification). Choices will depend upon the patient’s previous opioid experience, comorbidities (renal and hepatic function), and comedications. The type of pain does not play a particularly strong role in the choice of opioids.

Principles to opioid dosing include titration to response, around-the-clock dosing, provision for rescue doses for transient flares of pain, use of sustained release formulations to improve compliance, proactive treatment of constipation with stool softeners and laxatives, and individualized dosing to pain pattern.

Dose titration is based upon the percentage of baseline dose. Baseline dose should be increased 100% for pain levels that persist between 7 and 10 on a numerical scale (in which 0 indicates no pain and 10 represents the worst pain imaginable) and 50% for pain levels of 5–6.²¹

Rescue doses are either 100% of the four-hourly dose, 25–50% of the four-hourly dose, or 5–15% of the total opioid daily dose.^{19,21} Both breakthrough pain and “end of dose failure” pain are a result of suboptimal around-the-clock dosing, and the around-the-clock dose should be increased in order to improve pain and reduce the number of pain flares during the day. Incident pain should be titrated separately and not added to the around-the-clock dose of opioids.

Opioid rotation will successfully manage pain in those who are experiencing dose-limiting side effects with opioids (cognitive failure, visual hallucinations, myoclonus, or intractable nausea and vomiting) and poorly controlled pain.²² Non-cross-tolerance between potent opioids is a clinical feature that allows for opioid rotation. Non-cross-tolerance is related to genetic differences in opioid receptors and differences in receptor conformations induced by the opioid binding to the receptor. Differences in multiple opioid subtypes and G-protein interactions also contribute to non-cross-tolerance.^{9,22,29} In order to rotate or switch an opioid it is necessary to understand opioid equivalents (Table 109.1).

Rotations for reasons of uncontrolled pain should be at equivalent doses and rotations for reasons of side effects should be at 50–75% of equivalent doses.²¹ Converting from oral to rectal route should be done at equivalent doses. Converting the same opioid from oral to parenteral should be 3:1 for morphine, 2:1 for oxycodone (if parenteral oxycodone is available), 2:1 for methadone, and 5:1 for hydromorphone (though some use 2:1 for hydromorphone).

Adjuvant analgesics improve the opioid therapeutic index either by blocking opioid tolerance (which occurs

with *N*-methyl-D-aspartate receptor antagonists) or by facilitating opioid analgesia, as occurs through tricyclic antidepressants (and enhanced monoamine release). Adjuvants are used for three reasons (1) a pain pathophysiology that is less responsive to opioids, such as neuropathic pain; (2) when opioid side effects occur and adjuvants allow for reduced opioid doses; and (3) to diagnose a complex pain syndrome.²¹ (Table 109.2).

As mentioned previously, supportive psychotherapy, surgery, radiation therapy, and orthotics are an important part of pain management in cancer patients. Kyphoplasty, as an example, has been found to effectively reduce the mechanical back pain associated with myeloma and osteolytic vertebral compression fractures.³⁰

Nausea and vomiting

Nausea is common with uncontrolled infections, elevated intracranial pressure, certain medications, abdominal radiation, chemotherapy, and advanced cancer independent of treatment.^{31,32}

Table 109.1 Opioid equivalents

Opioid	Potency ratio compared to morphine	Available routes
Fentanyl	70–100:1 (oral morphine to parenteral fentanyl)	IV/SC/ED/IT
Methadone	4–12:1	PO/PR/SC/IV
Oxycodone	1–1.5:1	PO/PR
Hydromorphone	4–6:1	PO/PR/SC/IV/ED/IT
Morphine	1:1	PO/PR/SC/IV/ED/IT

PO, by mouth; PR, by rectum; SC, subcutaneous; IV, intravenous; ED, epidural; IT – Intrathecal.

Table 109.2 Adjuvant analgesics

Drug	Dose
Anti-seizure medications	Gabapentin 100 mg TID up to 3600 mg/day Valproic acid 250–500 mg at night up to 150 mg/day Carbamazepine 100 mg BID up to 1200 mg/day
Tricyclic antidepressants	Amitriptyline 10–25 mg at night up to 150 mg/day Desipramine 10–25 mg at night up to 150 mg/day Nortriptyline 10–25 mg at night up to 150 mg/night
Nonsteroidal anti-inflammatory drugs	Ibuprofen 200 mg BID up to 800 mg 3 times daily Naprogen 250 mg twice daily up to 500 mg 3 times daily
Corticosteroids	Dexamethasone 2–4 mg daily up to 16 mg daily Prednisone 10 mg daily up to 60 mg per day
Miscellaneous	
Mexiletine	150 mg twice daily up to 450 mg twice daily
Clonazepam	0.5 mg twice daily up to 20 mg/day
Lidocaine Transdermal Patch 5%	1–3 daily over 12 h
Pamidionate	90 mg IV monthly
Zoledronate	4 mg monthly

The frequency and severity of chemotherapy-induced nausea and vomiting (CINV) depends upon the type of chemotherapy, the dose, patient risk factors (for example, females and nonusers of alcohol are at higher risk), and the type of antiemetic regimen. CINV and nausea in general are major concerns that patients have with chemotherapy, and a major factor contributing to noncompliance.³³

In the 1980s, high-dose metoclopramide was found to be effective in preventing CINV from highly emetogenic chemotherapy (principally cisplatin). In the 1990s, serotonin receptor antagonists were found to dramatically reduce acute CINV and were better tolerated than high-dose metoclopramide.³³ As a result of their increased use, along with the use of corticosteroids, delayed (after 24 h) CINV became more prevalent. Delayed nausea and vomiting is experienced by 60% of the patients, whereas acute nausea and vomiting is experienced by 26% despite the use of 5-HT₃ receptor antagonists and corticosteroids.³⁴ Though corticosteroids and 5-HT₃ receptor antagonists are more effective in reducing vomiting than nausea, patients actually fear nausea more than vomiting.

Physicians are generally compliant with guidelines for prophylaxis of acute CINV based upon the emetogenic potential of individual chemotherapy protocols, but poorly follow the recommendations for preventing delayed CINV.³⁴ Such recommendations include dexamethasone and either metoclopramide or a 5-HT₃ receptor antagonist for 4 days postchemotherapy in highly emetogenic or moderately emetogenic chemotherapy.

Serotonin receptor antagonists reduce nausea and vomiting associated with radiation, total body radiation, and high-dose chemotherapy as preparation for SCT, but do not particularly prevent delayed nausea and vomiting from total body radiation or with SCT. Serotonin plays a minor role in delayed nausea and vomiting associated with highly emetogenic chemotherapy, total body radiation, and transplant. Substance P may actually be the more important neurotransmitter.^{35,36}

Responses among the various 5-HT₃ receptor antagonists tend to be equivalent. Palonosetron, however, has been found to reduce delayed CINV compared to first generation 5-HT₃ antagonists, probably due to its long half-life.³⁷⁻³⁹

The addition of aprepitant, a neurokinin 1 receptor antagonist, to dexamethasone plus a 5-HT₃ receptor antagonist improves both acute and delayed CINV relative to dexamethasone and a first generation 5-HT₃ antagonist.^{40,41} However, the three-drug regimen has been reported to be effective only in cisplatin or highly emetogenic regimens, whereas palonosetron is approved for moderately emetogenic chemotherapy.³⁹ Initial trials of palonosetron- and aprepitant-containing regimens were not compared to regimens that included dexamethasone for delayed CINV. Combinations of palonosetron, dexamethasone, and

aprepitant have been recommended for moderate to highly emetogenic chemotherapy, including protocols containing cyclophosphamide, doxorubicin, and carboplatin in high doses, though this prophylactic regimen needs to be tested clinically.³⁹ Finally, at least in a small group of patients receiving moderate to highly emetogenic chemotherapy, the atypical neuroleptic, olanzapine, plus dexamethasone was found to prevent delayed nausea and vomiting, and this may be a reasonable regimen for those who have extrapyramidal reactions to metoclopramide or standard neuroleptics.³⁷

Mucositis

Mucositis can be dose limiting to chemotherapy or radiation. This can be the worst experience a patient has during high-dose chemotherapy or SCT.⁴² Mucositis can be quite painful, and it can accelerate nutritional depletion, prolong hospital stays, and increase medical expenditures associated with treatment. Pain severity follows the degree of observable mucositis. The peak pain severity and observable mucositis also correlate with dysphagia. Pain severity and objective mucositis are used in the National Cancer Institute Common Toxicity Criteria (Table 109.3).⁴³ Mucositis is also a common portal of entry for bacteria, particularly in myelosuppressed patients, and can lead to bacterial infections.⁴² It is the major factor associated with sepsis in SCT patients.

Factors that predispose to mucositis are the duration of chemotherapy (more than dose), diurnal variation in chemotherapy exposure, drug type (greatest with antimetabolites), and combinations of chemotherapy with radiation.⁴² Patient factors include poor oral hygiene, preexisting xerostomia, hepatic and renal dysfunction, impaired DNA repair capability, poor nutritional status, and pleural or peritoneal effusions (which act as reservoirs for antimetabolites).^{42,44,45}

Treatment of mucositis Treatment regimens can be categorized into those which minimize chemotherapy contact with oral mucosa, modify mucosal epithelium proliferation, reduce the inflammatory or infectious complications, and reduce pain⁴² (Table 109.4).

Table 109.3 National Cancer Institute common toxicity criteria for myeloablative chemotherapy ⁴³	
0	No mucositis
1	Painless ulcer, erythema, or mild soreness in the absence of lesions
2	Painful erythema, edema, or ulcers but the pain is such that patients can swallow
3	Painful erythema, edema, or ulcers that prevent swallowing or necessitate hydrate or parenteral nutrition
4	Severe ulceration which requires prophylactic intubation or results in aspiration pneumonia

Table 109.4 Therapies for oral mucositis

Treatment therapies that alter drug contact with mucosal surface

Glucocorticocoids
Providone Iodine
5-Aminosalicylate
Antibacterial agents
Antifungal agents
Antiviral agents
Therapies to reduce the pain of mucositis
Topical diphenhydramine
Viscous lidocaine
Dyclonine HCL
Low energy helium neon laser
Opioids

Preventive measures are generally unproven or marginally helpful.^{46–49} No particular agent is uniformly efficacious and accepted as a standard of care. There are a large number of management practices but little evidence to base recommendations.⁴⁵

Mucosal and dental health should be evaluated before treatment. Periodontal evaluation, and if necessary radiographic examinations (panorex), should be done prior to considering high-dose chemotherapy, SCT, or radiation therapy. Dental prosthetics should be checked for proper fitting. Restoration procedures should be done 3 weeks before mucotoxic therapy.⁴² Cultures for herpes simplex may be helpful if prolonged neutropenia is anticipated or if mucositis is prolonged. Xerostomia should be treated to avoid prolonged chemotherapy contact with oral mucosal surfaces. Drugs associated with xerostomia, such as tricyclic antidepressants, should be avoided during chemotherapy or SCT. Saliva substitutes, sodium bicarbonate, milk, or sugarless gum may act as a saliva

“wash” to reduce or dilute oral chemotherapy concentrations. Fluoride (stannous fluoride) will reduce dental caries and calcium phosphate oral rinses maintain enamel.⁴² Brushing with a soft brush and flossing should be encouraged except during radiation or myeloablative chemotherapy. Foam brushes should be used during myelosuppression. Removable prosthetics should not be worn except at meal times.⁴² Hot, spicy, coarse foods, fruits, and beverages with high-acid content or alcohol should be avoided. Smoking should be discouraged.⁴²

GENERALIZED SYMPTOMS

Fatigue

Fatigue is the most prevalent and one of the most important untreated cancer symptoms.^{50–54} (Table 109.5). Fatigue is of primary importance to quality of life. There is a large discrepancy between the known importance of fatigue to quality of life and discussions and treatment of fatigue by physicians. Most oncologists believe that pain affects their patients to a greater extent than fatigue, whereas most patients feel that fatigue affects their lives to a greater extent than pain.⁵⁵ Even though nearly 80% of physicians believe that fatigue is both overlooked and undertreated, 74% of patients believe that fatigue must simply be endured without any recourse to treatment.⁵⁵ Half or more of patients do not discuss fatigue with their hematologist/oncologist and only 27% receive any recommendations about treatment.⁵⁵ Unfortunately, the most common information physicians impart to patients regarding fatigue are (1) nothing can be done (told to patients 40% of the time) or (2) increase time spent resting (37% of the time), both of which are poor advice.^{50,51} Other advice includes taking multivitamins or modifying diet, which again is a poor advice,⁵³ particularly when considering that fatigue can persist for years in cancer survivors.^{53,56}

Fatigue has a multifaceted character similar to pain. This includes a physical, affective, and cognitive dimension. Patients with fatigue will complain of a lack of energy, weakness, somnolence, and inability to concentrate.^{57,59} Cancer fatigue does not usually improve with rest and is unlike fatigue in individuals without cancer.⁵³ Fatigue is frequently accompanied by loss of emotional control (90%), a feeling of isolation (74%), and dejection (72%).⁵³

Table 109.5 Fatigue prevalence

Normal population, 13–23%
At diagnosis of cancer, 50%
With bone metastasis, 75%
During chemotherapy or radiation, 60–96%

Assessment for fatigue can be done using following three questions:

1. Do you feel or have you felt unusually tired?
2. If you are fatigued can you indicate how tired you are using a numerical scale of 0 (no fatigue) to 10 (the greatest degree of fatigue imaginable)?
3. How much does your fatigue impact your daily life?⁵⁷

The National Cancer Comprehensive Cancer Network has established that the patients who rate the severity of fatigue >4 require detailed assessment and treatment.^{52,57,60}

The NCCN recommends focusing on following five factors that may influence fatigue: pain, emotional distress, insomnia and sleep hygiene, anemia, and hypothyroidism. In addition, comorbidities such as infection, poor nutritional status, and metabolic abnormalities should be considered.^{53,60}

The treatment of fatigue requires an understanding of associative causes, and intervention when possible. These include elimination of nonessential central-acting (sedative) medications, treatment of insomnia, transfusion of blood for anemia, correction of electrolyte and endocrine abnormalities, treatment of pain, treatment of depression, prevention of deconditioning with moderate exercise, and treatment of hypothyroidism.^{57,61}

The nonpharmacologic management of fatigue includes education centered on energy conserving techniques and stress reduction. Tasks should be spread out over a longer period of time during the day.⁶² A diary of activities may help patients cope with their fatigue and adjust activities to their fatigue level.⁶² Low-intensity, short-interval exercises should be encouraged.^{60,62} Rhythmic or repetitive movements, as with walking, cycling, or swimming, will gradually increase stamina.⁵⁷ There is an added psychological benefit to exercise.^{63,64} Restorative activities such as gardening, quiet times (spiritual or meditation), volunteer activities, and walking in a natural environment can reduce cancer fatigue.⁶² Stress can be reduced by massage, visual imagery, biofeedback, and laughter.^{53,59,60,62} Education about sleep hygiene and a concerted effort to improve nutrition are considerations. Both pharmacologic and nonpharmacologic therapies should be used together (Table 109.6).

Depression

Approximately 80% and certainly more than 50% of psychologic and psychiatric morbidity associated with advanced malignancies goes unnoticed by physicians.⁶⁵⁻⁶⁷ Antidepressants account for only 1-5% of the psychotropic medications prescribed by physicians to cancer patients, even though one-third of patients have significant depression. The reasons for under recognition include the absence of biological markers for depression, a lack of training on the part of physi-

Table 109.6 Pharmacologic management of fatigue

Anemia (goal is ≥12 gm %)
Erythropoietin 40,000 iu weekly
Darbepoetin 200 µg every other week
Depression
Methylphenidate 5 mg at 8 am and 5 mg at noon, titrate to 1 mg/kg
Sertraline 50 mg/day up to 200 mg/day
Paroxetine 10 mg/day up to 50 mg/day
Mirtazapine 15 mg at night titrate to 45 mg
Bupropion 100 mg/day up to 450 mg kkg
Miscellaneous agents
Modafinil 100 mg at 8 am and noon up to 400 mg/day
Prednisone 20-40 mg daily

cians to recognize depression (and delirium), a sense that both depression and cognitive changes are “appropriate” and normal for advanced cancer, the inappropriateness of screening instruments developed in non-cancer populations for cancer patients, overlapping neurovegetative signs associated with cancer and depression (i.e., anorexia, cachexia, insomnia), and time constraints or lack of interest.^{65,67}

Physicians should screen patients for depression as depression will make it difficult to treat other symptoms and other symptoms may improve with resolution of depression. The depressed patient may not be compliant with medications. Depression is a major cause of symptom distress in advanced malignancies and is a primary reason for the desire for death at the end of life.^{66,68} Depression reduces pleasure, meaning, and social connections. It reduces the ability to do the work of separating and saying goodbye and is a major cause of anguish among family members.⁶⁷

Screening tools aid in detecting depression, especially for physicians who are not psychiatrically astute (Table 109.7). Screening tools that are sensitive to cancer-associated depression are not dependent upon neurovegetative symptoms to diagnose depression. Screening tools that probe for helplessness, hopelessness, worthlessness, and anhedonia are, on the other hand, more discriminating in cancer.⁷⁰ In addition, patient scores on these self-rated depression scales rarely change over time in untreated patients, with little week-to-week variation,⁷⁰ indicating good intrasubject reliability.

The diagnosis of depression is fairly reliable when dysphoria and/or anhedonia are present for at least 2

Advanced cancers

weeks and are accompanied by at least two of the following four symptoms: depressed mood, weight loss or gain, insomnia/hypersomnia, agitation or psychomotor retardation, fatigue or lack of energy, depreciation or guilt of feelings, and difficulty concentrating (DSM-IV criteria).⁷¹ The Endicott modification of the DSM-IV criteria for cancer patients exchanges fearfulness and depressed appearance for appetite/weight loss; social withdrawal and reduced talkativeness for insomnia or hypersomnia; brooding, self-pity, and pessimism for lack of energy and fatigue; and anhedonia for diminished concentration.^{69,72}

A list of factors associated with an increased risk for depression can be found on Table 109.8.

Treatment Treatment is divided into nonpharmacologic and pharmacologic approaches. Nonpharmacologic therapy includes individual psychotherapy, cognitive-behavioral techniques, and supportive psychotherapy. Psychotherapy and pharmacotherapy are complementary and should be used together.⁷² Responses occur in a graded fashion with improvement in sleep first, followed by increased activities and mood.⁷¹

Treatment of the underlying cause should be initiated before beginning antidepressants (Table 109.9).⁷¹ Most antidepressants in cancer are prescribed too late and in too low a dose.^{66,72,73}

The choice of medical therapy is in part determined by survival. Tricyclic antidepressants and selective serotonin reuptake inhibitors can be started if life expectancy is

months and methylphenidate can be started if survival is expected to be short.^{72,74} The patient should be screened for medical causes of depression (Table 109.9).

Delirium

Cancer patients are prone to delirium. They are usually elderly, malnourished, frequently dehydrated, have multisystem impairment, are immobile, and often have sensory deprivation due to hearing loss or vision loss.⁷⁵ Delirium is one of the most frequent neuropsychiatric complications of cancer.^{76,77} Delirium is missed by physicians in 32–67% of patients, and is largely untreated.⁷⁵ The symptoms of delirium are most commonly misconstrued as anxiety, debility, or depression as a normal part of the illness.^{78,79} Because symptom severity changes with time and fluctuates during the day, it can be missed in a single encounter. Physicians are frequently untrained in recognizing and treating delirium.⁷⁷ The frequency of delirium in advanced cancer ranges between 25 and 40% and between 45 and 85% in those who are terminally ill.^{78–80} Delirium, if untreated (or irreversible), leads to self-injury (e.g., through falls, pulling out lines, inadequate self-care, and reduced compliance) as well as secondary medical problems such as decubitus ulcers and aspiration pneumonia.^{78,79} Delirium confers a relative risk for mortality of 6.2 during hospitalization compared to individuals who are not delirious. Risk factors for delirium include a previous brain insult such as a cerebral vascular accident or head injury, brain radiation or intrathecal chemotherapy, central nervous system tumor involvement, bone metastases, a previous confusional state or dementia, alcohol abuse, corticosteroids, cytotoxic therapy within the last month, the use of benzodiazepines and opioids, dehydration, visual and hearing impairment, elevated temperature, abnormal liver function tests, abnormal calcium, phosphorus, or sodium, or a low albumin.⁸¹ Patients with malignancies are almost uniformly exposed to polypharmacy and a significant portion have either brain metastases or leptomeningeal implants (Table 109.10). Comorbidities such as heart failure will further predispose these individuals to the development of delirium.^{77–80} Delirium typically evolves from multiple factors, often a combination of medications, infection, and organ failure.^{80,82} Approximately 25% of the patients will have cranial lesions at the time of their delirium.^{78,79} Patients with advanced cancer frequently have elevated proinflammatory cytokines such as IL-1,

Structural brain lesion	15%
Multiple causes	67%

TNF α , and IL-6, which stimulate microglial IL-1 and TNF α , resulting in insomnia, depression, and delirium.⁸³ Delirium risk increases with the number of risk factors. Unusual causes for delirium in cancer are nonconvulsive status epilepticus most frequently related to brain metastases, a previous stroke, or a metabolic abnormality.⁸⁴⁻⁸⁶

Delirium occurs during transplantation more frequently with older age, female gender, acute leukemia or solid tumors, a history of alcohol abuse, and total body radiation.^{78,79} SCT patients have an incidence of delirium that approximates 50%. High-risk individuals are those with pretransplant hepatic and renal dysfunction, poor performance status, and preexisting cognitive deficits. The median duration of each delirium episode is 8 days. The peak incidence occurs in the second or third week.

The DSM-IV criteria for delirium involves the following four clinical factors: disturbances in consciousness, changes in cognition (memory, language, or perception), acute and fluctuating course, and occurring in conjunction with a serious medical illness.⁷⁸ (Table 109.11). Changes in sleep-wake cycles commonly occur (e.g., the Sundown syndrome). Delirium can be hyperalert, hypoalert, or mixed.⁷⁷ (Table 109.10). The hypoalert subtype is frequently under recognized and often does not prompt a response by physicians, but actually has the worst outlook.⁷⁵ These individuals are usually not “problem” patients compared to individuals with hyperalert delirium. Their delirium can be misinterpreted as fatigue or somnolence.⁷⁸ The differential diagnosis of delirium includes dementia, unipolar or bipolar affective disorders, psychosis (schizophrenia), or substance toxicity or withdrawal.⁷⁸

Multiple screening tools for delirium are available (Table 109.12). The most well-known screening tool is the Mini-Mental State Examination Scale (MMSES), which is not as sensitive to delirium as other screening tools because of its emphasis on short-term memory and concentration. The MMSES requires a minimum of an eighth-grade education.⁷⁸ The Confusion Assessment Method and the Memorial Delirium Assessment Scale may be more apropos in this population.

Preventing delirium involves targeting six factors: (1) minimizing cognitive impairment (limiting polypharmacy, particularly anticholinergics and benzodiazepines); (2) preventing sleep deprivation; (3) minimizing immobility; (4) improving visual impairment; (5) improving hearing impairment; and (6) proactively

Lethargy or coma	61%

treating dehydration.^{87,88} Reversible factors for the treatment of delirium are outlined in Table 109.12. Once delirium has occurred, preventive interventions will have little impact on decreasing the delirium severity or relapse.^{87,88}

The initial treatment for delirium is to reverse the underlying cause. Opioid rotation is usually effective if delirium is due to opioid neurotoxicity. Discontinue psychotropics (tricyclic antidepressants, benzodiazepines) as well as anticholinergics, if possible. Treat hypercalcemia, hyponatremia, hypomagnesemia, and infections. Nonconvulsive status epilepticus requires an EEG for detection, and the treatment of choice is either anti-seizure medication or benzodiazepines, and not neuroleptics.⁸⁴

Neuroleptics are the drug of choice for delirium (Table 109.13). There are only two randomized controlled trials of neuroleptics in advanced cancer. Haloperidol and chlorpromazine, but not lorazepam (as a single agent), were beneficial in the management of delirium. Three nonrandomized trials found olanzapine and mianserin (the parent compound for mirtazapine) efficacious in resolving delirium.⁸⁷ The peak response will occur in 5-7 days after initial therapy.⁸⁹ Patients who have developed extrapyramidal reactions to haloperidol can be safely treated with olanzapine.⁹⁰ High doses of haloperidol (over 5 mg as a single dose) will rapidly reduce agitation and paranoia, but also can induce a prolong QTc interval and predispose patients to a rhythm disturbance.⁹¹ Lorazepam or other benzodiazepines reduce agitation, but will not improve orientation, concentration, or organizational skills. Benzodiazepines are the treatment of choice for delirium associated with alcohol withdrawal.^{80,92} Other agents that are useful in treating delirium are gabapentin and valproic acid.⁷⁷ Neuroleptics can be

Haloperidol	1-2mg IV/SC/PO q 2-4 hours as needed up to 20 mg per day
Resperidol	0.5 mg twice daily to 1mg twice daily up to 4 mg per day
Olanzapine	2.5-5.0 mg twice daily up to 20 mg per day
Quetiapine	25 mg twice daily up to 100 mg twice day

safely discontinued 7–10 days after the return to baseline cognitive function.⁸⁹

Responses (in terms of resolution of delirium) with neuroleptics range between 30 and 50%.^{77,93} Delirium associated with hypoxemia, metabolic abnormalities, and infections tend to be irreversible with medications. Twenty-five percent of delirious patients will die within 30 days of the onset of delirium, and only one-third who sustain a delirium episode recover enough function to be able to be discharged home.⁹³

HOSPICE TRANSITION AND HEMATOLOGIC MALIGNANCIES

Hematologic malignancies are poorly represented in hospice populations. There are several reasons for this. Patients continue to receive palliative therapies including blood transfusion, platelet transfusions, and recombinant erythropoietin which hospices (because of capitated reimbursement) cannot afford and thus do not support. It is hard to not give antibiotics or blood product transfusions while a patient remains hospitalized. Thus, transfusions are usually continued until the patient's performance score is so poor that he or she cannot attend an outpatient clinic and there may not be time to refer to hospice. Radiation for the relief of bone pain in myeloma and soft tissue pain in lymphoma is expensive. Some hospices cannot afford even single-fraction radiation. In addition, a significant number of myeloma patients, as well as patients with amyloid, will be on dialysis, which precludes hospice care due to financial constraints. Newer targeted specific agents, including monoclonal antibodies, proteasome inhibitors, and thalidomide, are palliative but expensive and delay hospice transfers, again for cost reasons.

Prior to each change in treatment and with each relapse, the goals of care (and therapy) should be reviewed with the patient. The understanding by the patient as to the intent of treatment, and what is meant by "treatment," can be widely divergent. Patients may believe they are receiving curative therapy while physicians have palliation and disease maintenance in mind. Discussions about advanced directives are important early in the course of disease, particularly for chronic leukemias, myeloma, and amyloid. This is sometimes difficult for physicians, as they recognize that patients assume by such conversations that they are terminally ill. Advanced directives should be portrayed as an extension of autonomy in the face of an unpredictable disease course ("hoping for the best but planning for the worst," which is a good way of introducing the subject).

Hope can be fostered in those with advanced or incurable hematologic malignancies. Patients should be taught that they can live with their illness rather than die from their disease. Hope can be defined in increments that are achievable: hope to have symptoms

relieved, hope to have a series of better days, hope to live to an important date, hope to have life closure. Inquiry into prognosis is a teachable moment. It is better that patients and families see what is evolving than physicians foretell the date of death. Patients and families value knowledge concerning the symptoms and signs of the dying process. Quantifying life expectancy as an answer to prognosis does not equip the patient or family to understand the dying process, nor discern its presence. Physicians are also usually overly optimistic regarding the time a patient has left. Prognostication by physicians, if taken by families as "the gospel," results in sociologic death as the predicted hour approaches. "Foreseeing" the dying process rather than foretelling life expectancy is the better way of handling questions about prognosis. On the other hand, a relative timetable may help patients with closure and estate planning, and so a general answer as "days to weeks" or "weeks to months" or "months to years" may suffice.

It is important to nurture spirituality throughout the course of illness, but even more so near the end of life. Rituals help move the center of hope from this life to the afterlife.⁹⁴ Many religious traditions have sacraments particular to the afterlife. These rituals become a physical sign for preparedness and belief and can help transition family and friends who are reluctant to "give up the fight" at the end of life care.^{95–97}

MANAGING THE ACTIVELY DYING

Dying patients require symptom management, physical expressions of love, the presence of significant others, truth telling, and dignity through meticulous maintenance of personal hygiene.^{98,99} Patients should not be subject to venipuncture and procedures for curiosity sake when the goals of care are "comfort." Family education, frequent visits, and intensive low-technology care are other elements to good end of life care. Symptoms change during the course of illness. At the end, pain, delirium, nausea, vomiting, and secretions are the important symptoms to control.^{99–101} Opioids should be maintained despite changing mentation. Families often mistake the dying process for drug toxicity and need to understand the difference. Terminal agitation or restlessness may arise from a full rectum or bladder, poorly controlled pain, or delirium. Patients should be examined for fecal impaction and a distended bladder, and measures should be taken to relieve either one if present. As patients become more nonverbal, the therapeutic decision regarding terminal agitation is between adjusting the opioid or the neuroleptic. Families may be helpful in deciphering pain behaviors. However, in the end it is a trial of one or the other.^{99–101} We have used chlorpromazine for terminal delirium, while others have used a combination of haloperidol and a benzodiazepine, usually lorazepam or midazolam. Both chlorpromazine and haloperidol treat nausea and

vomiting. Individual doses of chlorpromazine are 12.5–25 mg parenteral or per rectum titrated to response. Doses may range from 25 to 200 mg every 4–6 h. Secretions respond to antimuscarinics. Once secretions are clinically evident, antimuscarinics should be given around the clock, with dosing similar to opioids in pain management. Glycopyrrolate 0.1–0.2 mg intravenous or subcutaneous every 4–6 h is a reasonable choice. Terminal sedation is occasionally necessary for refractory delirium or dyspnea. Phenobarbital 100 mg intravenous or subcutaneous every 8 h up to 1200 mg over 24 h has been our choice for sedation.

SUMMARY

Hematologic malignancies have a cluster of symptoms that differ in degree from solid tumors. Fatigue, depression, delirium, treatment-related mucositis, and treatment-related pain are common symptoms. These symptoms can occur at early stages of disease, can persist through remission, and will require both nonpharmacologic and pharmacologic management. Involvement of palliative therapy early in the course of disease can minimize suffering from multiple symptoms while the patient undergoes disease-modifying antitumor therapy.

 topoisomerase I inhibitors, 489–490
 topoisomerase II inhibitors, 3, 5, 9, 664
 topotecan, 489, 492–493
 t(5;12)(q33;p13) gene, 490
 t(5;10)(q33;q22), 490
 t(15;17)(q22;q12-21), 10
 t(8;21)(q22;q22)/*AML1(RUNX1)- ETO(CBFA2T1)*, 16–17
 t(8;21)(q22;q22) gene, 10–11
 tranexamic acid, 65
 trapoxin, 97
 treatment-related mortality (TRM), 73
 triazenes, 1089
 trichostatin, 97
 tumor lysis syndrome (TLS), 26–27, 42, 1159–1160
 tumor necrosis factor α (TNF- α), 482
 tyrosine kinase inhibitors, 1105–1107

U

umbilical cord blood (UCB) transplantation
 biologic characterization and immune reconstitution, 1041–1042
 clinical data on outcomes of, 1042–1047
 future research, 1047
 UCB banking, 1039–1041

V

VAD, 876
 vincristine, 3

W

Wright–Giesma stain, 28, 32

Z

zalcitabine, 662
 zaragozic acid, 97
 zidovudine, 662
