CLINICAL MALIGNANT
HEMATOLOGY

CLINICAL MALIGNANT HEMATOLOGY

Notice

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the editors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

CLINICAL MALIGNANT HEMATOLOGY

Mikkael A. Sekeres

Matt E. Kalaycio

Brian J. Bolwell

To my children, Gabriel and Samantha, and to Jennifer, for their unwavering support and unremitting love, and for putting my life in perspective. To my parents and teachers, my inspirations. And always to my patients, for what they have taught me.

Mikkael A. Sekeres

To my wife Linda for all her love and support.

Matt E. Kalaycio

To all members of the Cleveland Clinic Bone Marrow Transplant Program, past and present; to our patients and their caregivers; to the Elisabeth Severance Prentiss Foundation for their continued support; and to Nina, Brian, Greg, and Augusta.

Brian J. Bolwell

CONTENTS

THE COLOR INSERT CAN BE FOUND BETWEEN PAGES 554 AND 555

<i>Contributors</i>	<i>xiii</i>
<i>Preface</i>	<i>xxi</i>
<i>Acknowledgments</i>	<i>xxii</i>

PART I LEUKEMIA

SECTION 1 ACUTE MYELOID LEUKEMIA

1. Epidemiology, Risk Factors, and Classification	1
<i>Leonard T. Heffner Jr.</i>	
2. Molecular Biology, Pathology, and Cytogenetics of Acute Myeloid Leukemia	9
<i>Krzysztof Mrózek, Claudia D. Baldus, and Clara D. Bloomfield</i>	
3. Clinical Features and Making the Diagnosis	25
<i>Anjali S. Advani and Karl S. Theil</i>	
4. Treatment for Acute Myeloid Leukemia in Patients Under Age 60	41
<i>Richard M. Stone</i>	
5. Treatment Approach to Acute Myeloid Leukemia in Older Adults	51
<i>Mikkael A. Sekeres</i>	
6. Treatment Approach to Acute Promyelocytic Leukemia	63
<i>James L. Slack</i>	
7. Approaches to Treatment of Secondary Acute Myeloid Leukemia and Advanced Myelodysplasia	73
<i>Elihu Estey</i>	
8. Definition of Remission, Prognosis, and Follow-up	83
<i>Mikkael A. Sekeres and Matt E. Kalaycio</i>	
9. Treatment of Relapsed or Refractory Acute Myeloid Leukemia and New Frontiers in Acute Myeloid Leukemia Therapy	91
<i>Frederick R. Appelbaum</i>	

SECTION 2 ACUTE LYMPHOBLASTIC LEUKEMIA

10. Epidemiology, Risk Factors, and Classification	103
<i>Joseph O. Moore</i>	
11. Molecular Biology, Pathology, and Cytogenetics of Acute Lymphoblastic Leukemia	111
<i>Meir Wetzler, Krzysztof Mrózek, and Clara D. Bloomfield</i>	
12. Clinical Features and Making the Diagnosis	121
<i>Ronald M. Sobecks</i>	
13. Treatment Approach to Adult Acute Lymphoblastic Leukemia	127
<i>Elizabeth S. Rich, Cara A. Rosenbaum, and Wendy Stock</i>	
14. Definition of Remission, Prognosis, and Follow-up	143
<i>Meir Wetzler</i>	
15. Treatment of Relapsed or Refractory Acute Lymphoblastic Leukemia and New Frontiers in Therapy	151
<i>Nicole Lamanna and Mark A. Weiss</i>	

SECTION 3 CHRONIC MYELOGENOUS LEUKEMIA

16. Epidemiology, Risk Factors, and Classification of Chronic Myeloid Leukemia	159
<i>Tariq I. Mughal and John M. Goldman</i>	
17. Molecular Biology, Pathology, and Cytogenetics	163
<i>Michael Deininger</i>	
18. Treatment Approach to Chronic-Phase Chronic Myelogenous Leukemia	177
<i>Jorge E. Cortes</i>	
19. Treatment Approach to Accelerated-Phase or Blast-Crisis Chronic Myelogenous Leukemia	189
<i>Eric J. Feldman</i>	

20. Definition of Remission, Prognosis, and Follow-up <i>Matt E. Kalaycio and Ilka Warshawsky</i>	195	33. Treatment of Relapsed or Refractory Hairy Cell Leukemia and New Frontiers in Hairy Cell Leukemia Therapy <i>Robert J. Kreitman</i>	301
21. New Frontiers in the Treatment of Relapsed or Refractory Chronic Myelogenous Leukemia <i>Seema Gupta, Javier Pinilla-Ibarz, Peter Maslak, and David A. Scheinberg</i>	203	SECTION 6 SPECIAL TOPICS IN LEUKEMIA	
SECTION 4 CHRONIC LYMPHOCYtic LEUKEMIA			
22. Molecular Biology, Pathology, and Cytogenetics of Chronic Lymphocytic Leukemia <i>Martin J.S. Dyer and Randy D. Gascoyne</i>	213	34. Management of Fever and Neutropenia in Leukemia <i>Robin K. Avery</i>	311
23. Clinical Features and Making the Diagnosis <i>William G. Wierda, Joan H. Admirand, and Susan M. O'Brien</i>	225	35. Autologous Stem Cell Transplantation for Leukemia <i>Alexander E. Perl, Selina M. Luger, and Edward A. Stadtmauer</i>	321
24. Indications for Treatment and Treatment Approach for Chronic Lymphocytic Leukemia <i>Kanti R. Rai and Bhoomi Mehrotra</i>	235	36. Allogeneic Hematopoietic Stem Cell Transplantation for the Acute Leukemias in Adults <i>Corey Cutler and Joseph H. Antin</i>	337
25. Response Criteria, Prognosis, and Follow-Up in Chronic Lymphocytic Leukemia <i>Emili Montserrat</i>	239	37. Transplantation in Chronic Leukemia <i>Thomas S. Lin and Edward A. Copelan</i>	355
26. Treatment of Chronic Lymphocytic Leukemia <i>Matt Kalaycio</i>	245	PART II MYELODYSPLASTIC SYNDROMES AND MYELOPROLIFERATIVE DISEASES	
27. Aggressive Transformation and Paraneoplastic Complications of Chronic Lymphocytic Leukemia <i>Terry J. Hamblin</i>	251	SECTION 1 MYELODYSPLASTIC SYNDROMES	
SECTION 5 HAIRY CELL LEUKEMIA			
28. Epidemiology, Risk Factors, and Classification of Hairy Cell Leukemia <i>Diane M. BuchBarker</i>	265	38. Myelodysplastic Syndromes: Molecular Biology, Pathology, and Cytogenetics <i>Rami Komrokji and John M. Bennett</i>	367
29. Molecular Biology, Pathology, and Cytogenetics in Hairy Cell Leukemia <i>Mirko Zuzel and John C. Cawley</i>	269	39. Clinical Features and Making the Diagnosis of Myelodysplastic Syndromes <i>Lewis R. Silverman</i>	377
30. Clinical Features and Making the Diagnosis of HCL <i>Olga Frankfurt, Martin S. Tallman, and LoAnn C. Peterson</i>	277	40. Treatment Approach to Early Myelodysplastic Syndromes <i>Virginia M. Klimek and Stephen D. Nimer</i>	385
31. Indications for Treatment and Initial Treatment Approach to Hairy Cell Leukemia <i>Alan Saven, Andrew P. Hampshire and Lyudmila Bazhenova</i>	285	41. Aplastic Anemia and Stem Cell Failure <i>Jaroslav P. Maciejewski</i>	397
32. Definition of Remission, Prognosis, and Follow-up in Hairy Cell Leukemia <i>Eric H. Kraut</i>	295	42. Allogeneic Stem Cell Transplantation for Myelodysplastic Syndrome and Aplastic Anemia <i>Vikram Mathews and John F. DiPersio</i>	415
		43. Definition of Response, Prognosis, and Follow-up of Myelodysplastic Syndromes <i>Miguel A. Sanz and Guillermo F. Sanz</i>	425
		44. Treatment of Relapsed or Refractory Myelodysplastic Syndromes and New Frontiers in Myelodysplastic Syndrome Therapy <i>Huma Qawi, Naomi Galili, and Azra Raza</i>	435

SECTION 2 CHRONIC MYELOPROLIFERATIVE DISEASES

45. **Epidemiology, Risk Factors, and Classification** 445
Hanspreet Kaur, Deepjot Singh, and Alan Lichtin
46. **Molecular Biology, Pathology, and Cytogenetics** 449
Claire N. Harrison
47. **Clinical Features and Making the Diagnosis** 461
Richard T. Silver
48. **Treatment Approach to Polycythemia Vera and Essential Thrombocythemia** 469
Steven M. Fruchtman and Celia L Grosskreutz
49. **Approach to Chronic Idiopathic Myelofibrosis (with Extramedullary Hematopoiesis)** 475
Ruben A. Mesa and Ayalew Tefferi
50. **Management of Chronic Myelomonocytic Leukemia and Other Rare Myeloproliferative Disorders** 487
Miloslav Beran

PART III LYMPHOMA

SECTION 1 NON-HODGKIN'S LYMPHOMA

51. **The Classification of Non-Hodgkin's Lymphoma** 503
P.G. Isaacson
52. **Pathology and Molecular Genetics of Non-Hodgkin's Lymphoma** 513
James R. Cook and Eric D. Hsi
53. **Treatment Approach to Follicular Lymphomas** 531
Bruce D. Cheson
54. **Treatment Approach to Diffuse Large B-Cell Lymphomas** 543
Sonali M. Smith and Koen van Besien
55. **Treatment Approach to Mantle Cell Lymphoma** 555
Ellie Guardino, Kristen N. Ganjoo, and Ranjana Advani
56. **Treatment Approach to High-Grade Non-Hodgkin's Lymphomas** 565
John W. Sweetenham
57. **Treatment Approach to Marginal Zone and MALT Lymphomas** 577
Emanuele Zucca

58. **Treatment Approach to Primary Central Nervous System Lymphomas** 589
Tamara N. Shenkier and Joseph M. Connors
59. **Treatment Approach to Cutaneous Lymphomas** 601
Christiane Querfeld, Timothy M. Kuzel, Joan Guitart, and Steven T. Rosen
60. **Mature T-Cell Non-Hodgkin's Lymphoma: Diagnosis and Therapy** 613
Nam H. Dang and Fredrick Hagemester
61. **Treatment Approach to HIV-Related Lymphomas** 631
Mark Bower
62. **Posttransplant Lymphoproliferative Disorders** 645
Terrance Comeau and Thomas Shea
63. **Treatment Approach to Adult T-Cell Lymphoma/Leukemia** 657
Karen W.L. Yee and Francis J. Giles
64. **Autologous Hematopoietic Cell Transplantation for Non-Hodgkin's Lymphoma** 671
Ginna G. Laport and Robert S. Negrin
65. **Allogeneic Hematopoietic Stem Cell Transplantation for Non-Hodgkin's Lymphoma** 689
Hillard M. Lazarus
66. **Definition of Remission, Prognosis, and Follow-up in Follicular Lymphoma and Diffuse Large B-Cell Lymphoma** 701
John W. Sweetenham
67. **Treatment of Transformed Non-Hodgkin's Lymphoma** 711
Phillip J. Bierman
68. **New Frontiers in Non-Hodgkin's Lymphoma Therapy** 723
Eric Winer, Sridar Pal, and Francine Foss

SECTION 2 HODGKIN'S LYMPHOMA

69. **Hodgkin's Lymphoma: Epidemiology and Risk Factors** 733
Brian J. Bolwell
70. **Prognostic Factors in Hodgkin's Lymphoma** 739
Michel Henry-Amar
71. **Classification, Pathology, and Molecular Genetics of Hodgkin's Lymphoma** 751
James R. Cook and Eric D. Hsi
72. **Clinical Features and Making the Diagnosis** 759
Kristie A. Blum and Pierluigi Porcu

73. Treatment Approach to Classical Hodgkin's Lymphoma <i>Brian J. Bolwell and Toni K. Choueiri</i>	767	86. Definition of Remission, Prognosis, and Follow-up <i>S. Vincent Rajkumar and Angela Dispenzieri</i>	913
74. Treatment Approach to Nodular Lymphocyte-Predominant Hodgkin's Lymphoma <i>Brad Pohlman</i>	783	87. Treatment of Relapsed or Refractory Multiple Myeloma and New Frontiers in Multiple Myeloma Therapy <i>Manmeet Ahluwalia and Mohamad A. Hussein</i>	927
75. Autologous Stem Cell Transplantation for Hodgkin's Lymphoma <i>Craig Moskowitz and Daniel Persky</i>	793	SECTION 2 SPECIAL TOPICS IN MULTIPLE MYELOMA	
76. Hodgkin's Lymphoma: Follow-up Care <i>Omer N. Koç</i>	801	88. Hyperviscosity Syndrome <i>Marcel N. Menke and Steve P. Treon</i>	937
77. Treatment of Relapsed or Refractory Hodgkin's Lymphoma and New Frontiers in Hodgkin's Lymphoma Therapy <i>Angelo M. Carella, Angela Congiu, Sandro Nati, and Ercole Brusamolino</i>	807	89. Monoclonal Gammopathy of Undetermined Significance <i>Shaji Kumar, Philip R. Greipp</i>	943
SECTION 3 SPECIAL TOPICS IN LYMPHOMA		90. Amyloidosis <i>Madhav V. Dhodapkar</i>	955
78. Epidemiology of Second Malignancies Following Lymphoma Therapy and Screening Recommendations <i>Jonathan W. Friedberg and Andrea K. Ng</i>	815	91. Treatment of Complications in Multiple Myeloma <i>Paul Masci</i>	963
79. The Appropriate Use of PET and Gallium Scans in Lymphoma <i>Rebecca Elstrom</i>	823	PART V STEM CELL TRANSPLANTATION	
PART IV MULTIPLE MYELOMA AND RELATED DISORDERS		92. Principles of Hematopoietic Stem Cell Transplantation to Treat Hematologic Malignancies <i>Michael R. Bishop</i>	975
SECTION 1 MULTIPLE MYELOMA		93. Principles of HLA Matching and the National Marrow Donor Program <i>Edward J. Ball</i>	985
80. Epidemiology and Risk Factors of Multiple Myeloma: Insights Into Incidence and Etiology <i>Ashraf Badros</i>	833	94. Stem Cell Mobilization <i>Auayporn Nademanee</i>	1001
81. Molecular Biology, Pathology, and Cytogenetics <i>Silvia Ling, Lynda Campbell, Phoebe Joy Ho, John Gibson, and Douglas E. Joshua</i>	847	95. Stem Cell Transplantation for Solid Tumors and Nonmalignant Conditions <i>E. Randolph Broun</i>	1013
82. Clinical Features and Making the Diagnosis of Multiple Myeloma <i>Yi-Hsiang Chen</i>	859	96. Nonmyeloablative Conditioning Regimen for Allogeneic Hematopoietic Cell Transplantation <i>Frédéric Baron, Marie-Thérèse Little, and Rainer Storb</i>	1025
83. Initial Treatment Approach to Multiple Myeloma <i>Jeffrey A. Zonder</i>	873	97. Umbilical Cord Blood Transplantation <i>Ian Horkheimer and Nelson Chao</i>	1039
84. Treatment of Multiple Myeloma <i>Robert A. Kyle and S. Vincent Rajkumar</i>	889	98. Graft-Versus-Host Disease: New Perspectives on Pathobiology and Therapy <i>Thomas R. Spitzer and Robert Sackstein</i>	1051
85. Allogeneic Stem Cell Transplantation for Multiple Myeloma <i>Edwin P. Alyea</i>	901	99. Infectious Complications Following Stem Cell Transplantation <i>David L. Longworth</i>	1063

100. Noninfectious Complications of Stem Cell Transplantation <i>Scott I. Bearman</i>	1077	105. Growth Factor Support in the Hematologic Malignancies <i>George Somlo</i>	1139
PART VI SPECIAL TOPICS IN NEOPLASTIC HEMATOLOGY		106. Treatment Approach to Pregnant Women <i>Revathi Suppiah, Joanna Brell, and Matt E. Kalaycio</i>	1147
101. Pharmacology of Traditional Agents Used to Treat Hematologic Malignancies <i>Jennifer L. Shamp</i>	1089	107. Tumor Lysis Syndrome, Disseminated Intravascular Coagulopathy, and Other Non-Infectious Complications of Leukemia and Lymphoma <i>Rajesh Kukunoor and Mikkael A. Sekeres</i>	1159
102. Biological Response Modifying Agents in the Treatment of Hematologic Malignancies <i>Christopher J. Lowe and Jennifer Fisher</i>	1105	108. Fertility Issues in the Hematologic Malignancies <i>Ashok Agarwal and Tamer M. Said</i>	1171
103. Pharmacology of Monoclonal Antibodies <i>Jennifer L. Shamp</i>	1115	109. Palliation of Symptoms Associated with Hematologic Malignancies <i>Mellar P. Davis</i>	1179
104. Blood Product Transfusions in the Hematologic Malignancies <i>Ronald E. Domen</i>	1127	Index	1191

PREFACE

The clinical aspects of hematologic malignancies have changed dramatically over the past decade. The development of targeted therapies, based on years of advanced understanding of basic scientific mechanisms of disease, has led to their widespread use and ultimately to the first decrease in cancer-related mortality not attributable to screening programs. The impact of these advances will be fully felt over the next two decades, when the population of older adults in the United States is expected to double, and continued evolution of intensive therapy and supportive measures will make approaches such as bone marrow transplantation available to more patients than ever before.

Resources available to clinical oncologists or hematologists who treat patients with hematologic malignancies are limited. With this in mind, we planned a textbook devoted solely to this topic. Recognizing, also, that oncologists and hematologists are busier than ever and require accessible information about specific topics, we asked our authors to write focused chapters that address different aspects of a disease, and that would be useful to both general and disease-specific practicing oncologists and hematologists, physicians-in-training, researchers, and nurses. We are proud of the end-product.

Sections of *Clinical Malignant Hematology* are divided by disease, and each disease is further divided

into specialty areas where applicable. These areas include epidemiology, risk factors, and classification; molecular biology, pathology, and cytogenetics; clinical features and making the diagnosis; treatment approach to all disease subtypes; and treatment of relapsed or refractory disease, including new frontiers in therapy. In addition, we have included chapters about specialty topics within hematologic malignancies, both within disease sections and in the last part of the book. These topics range from disease-specific indications for bone marrow transplantation and management of infections to treatment of the pregnant patient with a hematologic malignancy and fertility issues in this patient population.

Chapter authors are world experts in their fields. We asked them to use evidence-based findings in the presentation of their material but not at the expense of offering practical information about managing these complicated and often very sick patients. We are grateful to our authors for rising to this challenge and helping us to produce the first definitive textbook on hematologic malignancies. We welcome your feedback about the content and about any areas you would want to see expanded for future editions, particularly as some material may not keep pace with the rapid change in therapy. We ask you to e-mail comments to our editor at McGraw-Hill, Robert Pancotti: robert_pancotti@mcgraw-hill.com.

ACKNOWLEDGMENTS

A book of this magnitude cannot be accomplished without the help of a number of people at every step of the way. We would like to thank our editors at McGraw-Hill, first Marc Strauss and later Robert Pancotti, whose keen intellect, gentle guidance, sound judgment, and good sense of humor made this project possible. We are

grateful for the administrative assistance we received from Bridget Rini, Victoria Mineff, and Fran Palasek, whose help in coordinating the receipt and editing of over 100 chapters was invaluable. Finally, we are deeply appreciative of our chapter authors, who provided us with outstanding information.

Section 1

ACUTE MYELOID LEUKEMIA

Chapter 1

EPIDEMIOLOGY, RISK FACTORS, AND CLASSIFICATION

Leonard T. Heffner Jr

ACUTE MYELOCYTIC LEUKEMIA

EPIDEMIOLOGY AND RISK FACTORS

Acute myelocytic leukemia (AML) is a clonal expansion of any one of several nonlymphoid hematopoietic progenitors that retain the capacity of self-renewal, but are severely limited in their ability to differentiate into functional mature cells. These various progenitors include cells of granulocytic, monocyte/macrophage, erythroid, and megakaryocytic lineage.

Leukemia is not a common malignancy relative to many other forms of cancer, comprising 3% of all new cancers in males and less than 2% in females. Deaths from leukemia comprised 4.3% of all cancer deaths in males in 2006 and 3.3% in females. In 2006, it was estimated there were 11,930 new cases of AML, representing 34% of all forms of leukemia. An estimated 9040 deaths due to AML occurred in 2006—40.6% of deaths from all leukemias. Both the incidence and the number of deaths are slightly greater in males versus females.¹ Surveillance, epidemiology, and end-results (SEER) data over a 25-year period from 1973 to 1998 show that the incidence rates by age groups have been stable, other than a slight increase in the age group above or equal to 65 years old.² As per the SEER data (1996–2000), 86% of acute leukemia in adults (>20 years old) is AML.

Although there are several well-recognized risk factors for the development of AML, little is known about the etiology of most cases. Like most malignancies, there is no recognized factor common to most cases of AML. While there is little reason to assume that adult

and childhood leukemia do not have a common etiology, differences in tumor biology and outcomes suggest that these disorders are significantly different. Proven or possible risk factors for AML can be categorized as genetic, environmental, and therapy-related. At this time, the proven risk factors include only radiation, benzene exposure, and chemotherapeutic agents.^{3–9}

Studies of leukemia in identical twins have shed considerable light on the pathogenesis of this disease. While concordance rates for monozygotic twin childhood leukemia is less than 25%, concordance in infants (<1-year old) is nearly 100%.^{10–15} This implies that events occurring in utero are sufficient for the rapid development of acute leukemia and that clonal progeny spread from the initially affected fetus to the other fetus via shared placental circulation. Yet, in older twin children the discordance rate is 90%, indicating the prenatal event is insufficient for leukemogenesis and a second postnatal event is required, probably involving genes regulating a proliferation or survival function. In adult twins there is no evidence of concordance.¹⁶

Familial acute leukemia outside of a recognized medical syndrome is rare, but there are documented familial clusters of specific subtypes of AML.^{17,18} There are also a number of medical syndromes in which AML is a component feature, including Down syndrome, Bloom syndrome, Fanconi anemia, neurofibromatosis I, ataxia-telangiectasia, Schwachman syndrome, and dyskeratosis congenita.^{19–25} Many of these disorders have been associated with both AML and acute lymphocytic leukemia (Table 1.1).

Table 1.1 Conditions associated with an increased incidence of AML

Genetic	Environmental
Identical twin with leukemia	Radiation
Familial leukemia	Ionizing
Down syndrome	Nonionizing
Bloom syndrome	Chemicals
Fanconi anemia	Benzene
Neurofibromatosis I	Pesticides
Schwachman syndrome	Smoking
Dyskrytosis congenital	
Ataxia-telangiectasia	
Acquired hematologic diseases	Therapy related
Chronic myelocytic leukemia	Alkylating agents
Myelofibrosis	Topoisomerase II Inhibitors
Essential thrombocythemia	DNA intercalating agents
Polycythemia rubra vera	
Aplastic anemia	
Paroxysmal nocturnal hemoglobinuria	

The effects of acute high-dose exposure from the nuclear explosions at Hiroshima and Nagasaki as well as the nuclear accident at Chernobyl demonstrate the leukemogenic potential of ionizing radiation.^{3,26} Follow-up of the atomic bomb survivors through 1990 identified 249 leukemic deaths, with 53.7% attributable to radiation exposure. In this population, there is an excess relative risk of leukemia (ERR) per sievert of 4.62 compared with an ERR of 0.40 for other cancers.²⁷ The risk appears to be greatest at 5–10 years after exposure.²⁸ Evaluation of the specific types of leukemia in the life span study (LSS) of atomic bomb survivors showed the highest ERR for acute lymphocytic leukemia (Table 1.2), although those exposed to gamma irradiation at Nagasaki more commonly had AML.^{28,29} Leukemogenic risks for lower doses of ionizing radiation are less clear, and are complicated by the need to distinguish acute versus protracted low-dose exposure. Table 1.3 outlines the levels of exposure to

radiation in routine daily activity compared to the episodes of more acute exposure. Among the cohort in the LSS study with exposure of 5–100 mSv (mean for entire study 200 mSv), there is a statistically significant increased incidence of solid organ cancer compared to the population exposed to less than 5 mSv.³⁰ Chronic low-dose exposure studies in workers in nuclear plants have found an increased risk of leukemia, although these studies have some limitations and are not all statistically significant.³¹ A greater than expected risk of AML has been reported in the use of low doses of radiation for benign medical conditions, such as menorrhagia, ankylosing spondylitis, rheumatoid arthritis, tinea capitis, and peptic ulcer disease.^{32–36} Exposure to the chronic low dose α -particles of thorium dioxide in Thorotrast has been associated with an increased incidence of the acute erythroleukemia subtype of AML.³⁷ However, there is no evidence that diagnostic X-rays are causally related to leukemia.^{38,39} The contribution of nonionizing radiation to the development of leukemia is unclear, as there have been conflicting results and criticism of the methodologies in some studies. At this time, there is no evidence of a major contribution of either occupational or residential electromagnetic field exposure resulting in an increased incidence of leukemia.^{40–42} Cosmic radiation exposure has been shown to increase slightly the risk of AML in commercial jet pilots.^{43,44}

Among environmental factors associated with an increased risk of leukemia, benzene has been studied extensively. Occupational benzene exposure in the leather, petrochemical, rubber, and printing industries has been linked to an excess incidence of leukemia.^{8,45,46} Ethylene oxide, butadiene, and styrene are industrial chemicals that have been associated with leukemia, but studies have been somewhat inconsistent or inconclusive in establishing a direct link.^{47–51} Pesticide use has been suggested as a possible explanation for the increased risk of dying from leukemia among farmers and other agricultural workers.⁵² However, other case-control and cohort studies have

Table 1.2 Leukemia incidence by cell type and corresponding model-based risk estimates for LSS cohort or atomic bomb survivors

Leukemia subtype	Number of cases	Excess relative risk per Sv	Attributable risk (%)	Excess absolute risk (cases per 10 ⁴ person years at 1 Sv)
ALL	38	9.1	70	0.62
AML	117	3.3	46	1.1
CML	62	6.2	62	0.9
All leukemias (includes unspecified types, CLL, etc.)	231	3.9	50	2.7

Table 1.3 Approximate mean doses relevant to societal low-dose radiation exposures and to low-dose radiation risk estimation

	Approx. mean individual dose (mSv)
Round trip flight, New York to London	0.1
Single screening mammogram (breast dose)	3
Background dose due to natural radiation exposure	3/year
Dose (over a 70-year period) to 0.5 million individuals in rural Ukraine in the vicinity of the Chernobyl accident	14
Dose range over 20-block radius from hypothetical nuclear terrorism incident (FASEB scenario 1: medical gauge containing cesium)	3–30
Pediatric CT scan (stomach dose from abdominal scan)	25
Radiation worker exposure limit	20/year
Exposure on international space station	170/year
A-bomb survivors (mean dose in LSS cohort)	200
Medical X-rays (breasts dose in scoliosis study)	100
Nuclear workers (mean dose from major studies)	20
Individuals diagnostically exposed in utero	10

Modified from Brenner DJ, et al.: Cancer risks attributable to low doses of ionizing radiation: assessing what we really know. *PNAS* 100:13761–13766, 2003, copyright 2003 National Academy of Sciences, U.S.A.

failed to show an association between pesticide exposure and leukemia.^{53,54} Indeed, there has been no evidence for an increased risk of AML related to pesticide exposure, although studies have implicated an increased risk of childhood leukemia.⁵⁵ Cigarette smoking has been found in several studies to produce a mild increased risk of leukemia, especially AML, possibly related to the presence of benzene in tobacco smoke.^{46,56–58} Indeed, the International Agency for Research on Cancer (IARC) recently reviewed eight cohort studies, with six showing a greater than expected risk of myeloid leukemia.⁵⁹ Interestingly, it appears the smoking-associated risk for AML may be restricted to the t(8;21) subgroup.⁶⁰ Despite these data, a large prospective cohort study of 334,957 construction workers failed to show evidence that smoking bears any major relationship to the occurrence of leukemia.⁶¹ The use of hair dyes known to contain animal carcinogens has been associated with a slight increased risk of acute leukemia of both myeloid and lymphoid type. This risk seems to be greatest for the use of permanent dyes and for longer and more frequent usage, with no increased risk for nonpermanent dyes.⁶² However, two other cohort studies failed to find any consistent association between hair dye use

and hematopoietic cancers.^{63,64} Viruses have long been suspected as a causal agent in leukemia, and the retrovirus HTLV-1 has been linked to adult T-cell leukemia/lymphoma.⁶⁵ However, there has as yet been no convincing evidence of a viral etiology of adult AML.

The development of acute leukemia in long-term survivors of Hodgkin's lymphoma raised the awareness of a relationship of leukemia to prior chemotherapy.^{66,67} An increased incidence of treatment-related AML (tAML) has been found in both benign and malignant diseases for which alkylating agents have been a major part of the therapy, and it is felt that 10–15% of all leukemias are therapy-related.^{6,9,68} Secondary disease following treatment may occur in 0–20% of cases.⁶⁹ All of the commonly used alkylating agents have been associated with an increased risk of AML, including busulfan, chlorambucil, BCNU, CCNU, cyclophosphamide, mechlorethamine, and procarbazine.^{6,9} Typically, in Hodgkin's lymphoma treated with the MOPP (mechlorethamine, vincristine, procarbazine, prednisone), the incidence of AML peaks at 7 years, but may occur even in the first 2 years post-treatment.^{70,71} A common characteristic of these therapy-related leukemias is the loss of all or part of chromosomes 5 and/or 7, occurring in 50–90% of cases, often with a complex karyotype.^{72,73} There is also an increased risk of AML following treatment with the topoisomerase II inhibitors, notably etoposide and tenoposide. In contrast to the other forms of tAML, this group of leukemias typically show translocations involving the *mixed-lineage leukemia (MLL)* gene on chromosome 11 (band 11q23) or the *AML1* gene on chromosome 21 (band q22). Most commonly, there is a shorter interval between drug exposure and diagnosis of AML, without a preceding myelodysplastic syndrome (MDS) phase.^{74,75} Phenotypically, these cases are usually myelomonocytic or monocytic. Additionally, the DNA intercalating agents, such as doxorubicin, are associated with a type of AML similar to that associated with the topoisomerase II inhibitors.⁷⁶ The natural history of some hematologic disorders, such as polycythemia vera, essential thrombocythemia, myelofibrosis, and aplastic anemia, is associated with a slightly increased risk of AML, but that risk increases with the use of chemotherapeutic agents, radiotherapy, or immunosuppressive therapy.^{77–80} High-dose chemotherapy followed by autologous stem cell transplantation (ASCT) for lymphoma can be complicated by the development of tAML/MDS.⁸¹ The actuarial risk in multiple series has varied from 3% to 24%. Median time from ASCT to development of tAML/MDS is 47–50 months, and has been variably influenced by pretransplant therapy, the conditioning regimen, and stem cell mobilization.⁸² As the mechanisms by which leukemia develops as a consequence of these environmental exposures are learned, the burgeoning field of molecular epidemiology will further allow

the determination of the risk of subsequent leukemia in these exposed populations.

AML: CLASSIFICATION

Although acute leukemia has long been recognized as a hematologic malignancy, it has been only in the last 50 years that AML has been looked at as a distinct entity. Indeed, classification of the acute leukemias was primarily based on age and cell morphology, with the adult form being predominately granulocytic with some variants based primarily on the cell type, such as promyelocytic, monocytic (Schilling), myelomonocytic (Naegli), or erythroleukemia of DiGuglielmo. However, there was considerable difficulty at times distinguishing between lymphoid and myeloid acute leukemias other than by age at onset. The development of reliable histochemical staining by Hayhoe and colleagues in the 1960s improved our diagnostic accuracy, but did not produce a clear system of classification.

In 1976, some order was introduced into the classification of the morphologically heterogeneous acute leukemias with the establishment of the French-American-British (FAB) system.⁸³ The FAB classification was based on morphology, cellularity, blast percentage, and cytochemistry, and was modified over the next several years with the recognition of AML of megakaryocytic lineage (AML-M7) and of minimally differentiated leukemia (AML-M0).^{84,85} A limitation of the FAB classification has been the clinical diversity of AML, as well as the emerging genetic diversity of the disease and the lack of correlation to improvement in treatment outcomes. In addition, over the past several decades there has been an increasing recognition of a group of hematologic disorders variously designated as preleukemia or myelodysplasia, which preceded the diagnosis of AML in many, but clearly not all cases. It is important to know and remember the FAB system both for historical purposes and because many important clinical trials still being followed and reported are based on that system.

Beginning in 1995, a project was begun by the World Health Organization (WHO) involving an international group of pathologists, assisted by a clinical advisory committee of expert hematologists, to establish a classification of hematologic malignancies. AMLs are recognized as one of the three main categories of myeloid neoplasms, along with MDSs and myeloproliferative disorders. This classification draws on the combination of morphology, immunophenotype, genetic features, and clinical syndromes. In particular, this system also more formally incorporates the relationship of AML to the MDSs.

The major goal of the WHO classification was to develop a clinically relevant system that could incorporate the genetic and clinical features of AML with the morphology and newer biological information about the disease. An attempt was made to discriminate between distinct disease entities as opposed to

prognostic factors, especially with the increasing information on genetic abnormalities in AML. This has led to recognition of four main groups within the category of AML: (1) AML with recurrent cytogenetic translocations, (2) AML with multilineage dysplasia, (3) AML and MDSs, therapy-related, and (4) AML not otherwise categorized. Within each group are several subcategories, as outlined in Table 1.4.

In addition to placing patients with AML into unique clinical and biological subgroups, the other major departure with the FAB system was the lowering of the threshold for the number of blasts in the blood or bone marrow to 20% rather than 30%. This is based on the data showing similar outcomes and biological features in the patients with 20–29% blasts, who were previously classified as having MDS compared to those patients with traditional AML.

Approximately 30% of patients with newly diagnosed AML will have one of the four well-defined cytogenetic abnormalities listed in Table 1.4. Because patients with these abnormalities have a somewhat distinctive phenotype and a relatively favorable response to treatment, they can be considered distinct clinicopathological entities. While other balanced translocations are considered recurring genetic abnormalities, it is felt that these abnormalities have more prognostic import. Undoubtedly, as we learn more

Table 1.4 WHO classification of AMLs

- | | |
|--|---|
| A. AML with recurrent cytogenetic translocations | |
| ■ | AML with t(8;21)(q22;q22), AML1(CBF α)/ETO |
| ■ | AML with t(15;17)(q22;q11–12) and variants (PML/RAR α) |
| ■ | AML with abnormal bone marrow eosinophils Inv(16)(p13q22) or t(16;16)(p13;q11), (CBF β /MYH11X) |
| ■ | AML with 11q23(MLL) abnormalities |
| B. AML with multilineage dysplasia | |
| ■ | with prior myelodysplastic syndrome |
| ■ | without prior myelodysplastic syndrome |
| C. AML and myelodysplastic syndromes, therapy-related | |
| ■ | alkylating agent-related |
| ■ | epipodophyllotoxin-related (some may be lymphoid) |
| ■ | other types |
| D. AML not otherwise categorized | |
| ■ | AML minimally differentiated |
| ■ | AML without differentiation |
| ■ | AML with maturation |
| ■ | acute myelomonocytic leukemia |
| ■ | acute monocytic leukemia |
| ■ | acute erythroid leukemia |
| ■ | acute megakaryocytic leukemia |
| ■ | acute basophilic leukemia |
| ■ | acute panmyelosis with myelofibrosis |
| E. Acute biphenotypic leukemia | |

Modified from Jaffe ES, et al.: World Health Organization Classification of Tumors: Pathology and Genetics of Tumors of Haematopoietic and Lymphoid Tissues. Lyon, France: IARC Press; 2001:45–107, Copyright 2001 International Agency for Research on Cancer.

about the significance of these and other genetic abnormalities, the WHO classification will need to be modified.

While many cases of AML present with a well-documented history of myelodysplasia, often there are dysplastic changes in the blood and bone marrow at the time of diagnosis of AML without an antecedent history of MDS. The WHO attempts to resolve this dilemma of the relationship between these two entities by establishing the classification of AML with multilineage dysplasia. The recognition of AML in this category without prior MDS requires at least 20% blasts in the blood or bone marrow and dysplastic changes in at least 50% of cells in 2 or more myeloid lineages. It is actually felt by some that AML should be divided into the two large categories of true de novo AML and myelodysplasia-related AML.

Exposure to certain therapies, such as alkylating agents and topoisomerase II inhibitors, has long been known to increase the risk of the subsequent development of AML. The WHO classification places these cases in a separate category, divided into two groups, based on the known agents associated with this risk. While there are common features between these groups, there is sufficient difference to justify each. The topoisomerase II inhibitor-related AML generally has a shorter latency period between exposure to the mutagen and development of AML. This may be as little as 6 months, but can be as long as 6 years, with a median time of 2–3 years compared to 4–7 years for alkylating agent-related AML. In addition, topoisomerase II inhibitor-related AML typically presents without MDS features, often has a monocytic component, and includes balanced translocations as the genetic abnormality.

Unfortunately, no classification system will be entirely inclusive, and the WHO recognizes this with the group of AML, not otherwise categorized. This group corresponds in most cases to the same morphologic entity as is delineated in the FAB schema. Indeed, this is pointed out as a limitation of the system, one which gives the clinician no help in planning therapy for a given case of AML. However, those who developed the WHO classification point out that the system is meant to be of worldwide application, and that there will be places where the diagnostic facilities are not yet sophisticated enough to provide information to make a more specific categorization. This last category of AML does include the entity of acute erythroid leukemia, and recognizes that there are two subtypes. Pure erythroid leukemia has at least 80% immature erythroid precursors with minimal differentiation and no significant myeloblastic component, as distinguished from the second subtype, which has at least 50% immature erythroid precursors and 20% myeloblasts in the nonerythroid population.

Modifications of the WHO classification will continue to be made with advances in our knowledge of the biology and treatment of AML. An International Working Group has recently recommended some definitions of terminology. Thus, de novo AML is defined as “AML in patients with no clinical history of prior MDS, myeloproliferative disorder, or exposure to potentially leukemogenic therapies or agents.” Secondary AML is defined as those patients with AML who do have prior MDS or exposure to leukemogenic therapies and should be categorized as “AML secondary to prior existing MDS, myeloproliferative disorder, or the development of AML secondary to proven leukemogenic exposure.”⁸⁶

MOLECULAR BIOLOGY, PATHOLOGY, AND CYTOGENETICS OF ACUTE MYELOID LEUKEMIA

*Krzysztof Mrózek, Claudia D. Baldus,
and Clara D. Bloomfield*

INTRODUCTION

The term acute myeloid leukemia (AML) is used to describe several neoplastic blood disorders characterized by clonal expansion of immature myeloid cells in the bone marrow (BM), blood, or other tissue,^{1,2} as a result of increased cell proliferation, prolonged survival, and/or disruption of differentiation of hematopoietic progenitor cells. Although the etiology of AML is still unknown, the risk of developing AML is increased by exposure to ionizing radiation and chemical mutagens such as alkylating agents, benzene, and topoisomerase II inhibitors. The risk of AML is also considerably greater in patients suffering from Down syndrome and rare genetic disorders such as Bloom syndrome, neurofibromatosis, Schwachman syndrome, ataxia-telangiectasia, Klinefelter syndrome, Fanconi anemia, and Kostmann granulocytic leukemia.³ The aforementioned associations suggest a role of genetic factors in initiating leukemogenesis. Indeed, advances in basic and clinical research have revealed that malignant transformation in all patients with AML, the vast majority of whom do not suffer from inherited genetic disorders, is associated with acquisition of somatic mutations and/or epigenetic events, such as hypermethylation, that affect and change expression of genes involved in hematopoiesis.

Many AML-associated genetic rearrangements can be detected cytogenetically as nonrandom chromosome abnormalities, while others are submicroscopic and detectable only by molecular genetic techniques [e.g., a reverse transcription polymerase chain reaction (RT-PCR)].⁴⁻⁶ A single genetic abnormality is usually not sufficient to cause overt leukemia, but multiple alterations of different pathways within the same cell are involved in the process of leukemogenesis. It appears that at least two different kinds of mutations

must occur in the hematopoietic progenitor cell to transform it into a malignant cell, initiating development of a clonal AML blast population. These are (1) mutations that activate genes involved in signal transduction of proliferation pathways and thereby confer a survival advantage and increase the rate of cell proliferation (referred to as “class I mutations”), and (2) mutations of genes encoding hematopoietic transcription factors, in the form of either gene fusions generated by reciprocal chromosome translocations or intragenic mutations, which disrupt the process of normal cell differentiation (“class II mutations”).⁷

A number of cytogenetic and molecular genetic rearrangements correlate well with the morphology and/or immunophenotype of leukemic marrow and blood, as well as the patients’ clinical characteristics, and are therefore incorporated into the World Health Organization (WHO) Classification of Tumors of Hematopoietic and Lymphoid Tissues.¹ In other instances, such correlations are less clear, and subtypes of AML are identified primarily on the basis of morphological and cytochemical criteria. In this chapter, we will review major types of AML with an emphasis on cytogenetic and molecular genetic findings.

PATHOLOGY

Diagnosis of AML is primarily made by experienced hematopathologists on the basis of light microscopic examination of blood and BM smears stained with Romanowsky stains, such as May–Grünwald–Giemsa or Wright–Giemsa stains. Myeloid lineage of leukemic blasts can be confirmed using cytochemical reactions, such as a reaction using *o*-toluidine or amino-ethyl carbazole as substrates to detect the presence of myeloperoxidase (MPO), an enzyme present in primary granules

of myeloblasts and some monoblasts; a reaction employing Sudan black B (SBB) to detect intracellular lipids that has reactivity similar to MPO but with less specificity for the myeloid lineage; and reactions detecting nonspecific esterase (NSE) that employ alpha-naphthyl butyrate and alpha-naphthyl acetate (ANA). Moreover, in the case of minimally differentiated leukemia, a distinction between AML and acute lymphoblastic leukemia (ALL) can be made with the help of immunophenotypic analysis by flow cytometry or immunohistochemical reactions on slides. Immunophenotyping is also helpful in the identification of acute megakaryoblastic leukemia (AMKL), and in suggesting or excluding particular subtypes of AML within the WHO classification.¹ This classification divides AML into several entities based on morphological and cytochemical criteria, which predominated in the previous French–American–British (FAB) classification, but also takes into account cytogenetic, molecular genetic, immunophenotypic, and clinical features. The major categories and subcategories of the WHO classification are presented in Table 2.1.

One of the most important changes introduced by the WHO classification is that the blast percentage in the marrow required for the diagnosis of AML has been reduced from 30% in the FAB classification to 20% in the WHO classification. Moreover, in patients positive for *t(8;21)(q22;q22)* and the *AML1(RUNX1)-ETO(CBFA2T1)* fusion gene, *inv(16)(p13q22)/t(16;16)(p13;q22)* and *CBFB-MYH11*, and *t(15;17)(q22;q12-21)* and *PML-RARA*, AML can be diagnosed even if the percent of blasts in the marrow is less than 20%.^{1,2}

CYTOGENETICS

Leukemic blasts of the majority of patients with AML at diagnosis carry at least one clonal chromosome abnormality, i.e., an identical structural aberration or gain of the same, structurally intact chromosome (trisomy) found in at least two metaphase cells or the same chromosome missing (monosomy) from a minimum of three cells. Abnormal karyotypes are more frequent in children with de novo AML, being detected in 70–85% of patients compared with 55–60% of adults.^{8–13} Therapy-related (secondary) AML is usually characterized by a high proportion, 80–90%, of both adult and pediatric patients who carry chromosome abnormalities.¹² Among AML patients with an abnormal karyotype, slightly more than one-half harbor only one chromosome aberration, whereas the remaining patients have two or more aberrations, including 10–15% of patients whose karyotype is complex, i.e., contains three or more aberrations.^{12,13}

From the cytogenetic standpoint, AML is heterogeneous, with more than 200 different structural and numerical aberrations identified as recurring in this disease.⁵ While many of the recurring aberrations are

rare, being thus far detected in a few patients worldwide, others are more common (Table 2.2). Notably, cytogenetic findings at diagnosis constitute one of the most important independent prognostic factors for attainment of complete remission (CR), risk of relapse, and survival.^{8–14} Recent large collaborative studies^{8–10} have proposed cytogenetic risk systems categorizing AML patients into one of three risk groups (favorable, intermediate, or adverse) based upon cytogenetic findings at diagnosis (Table 2.2). Although some differences among the three prioritization schemata exist, pretreatment cytogenetic results are being used to stratify therapy.^{15,16} Moreover, a recent report advocates the use of cytogenetic remission as one of the criteria of CR in AML.¹⁷ This is based on a recent study that demonstrated a significantly worse outcome for patients whose marrow on the first day of morphologically documented CR contained cytogenetically abnormal cells than those whose marrow showed an entirely normal karyotype.¹⁸

Major cytogenetic studies of AML agree that the prognosis of patients with *inv(16)/t(16;16)*, *t(8;21)*, and *t(15;17)* is relatively favorable (these subtypes of AML are discussed below), whereas the clinical outcome of patients with *inv(3)(q21q26)* or *t(3;3)(q21;q26)*, -7 , and a complex karyotype is adverse (Table 2.2). Complex karyotype has been defined as either greater than or equal to five unrelated cytogenetic abnormalities or greater than or equal to three abnormalities. However, Byrd et al.¹⁰ have shown that although patients with three or four abnormalities [other than *t(8;21)*, *inv(16)/t(16;16)*, or *t(9;11)(p22;q23)*] had significantly better survival and a lower probability of relapse than those with greater than or equal to five abnormalities, their probabilities of achieving a CR, or obtaining prolonged CR and survival, were significantly worse than those of patients with a normal karyotype. These data seem to justify combining patients with three or four abnormalities with those with greater than or equal to five abnormalities into one complex karyotype category with greater than or equal to three abnormalities if three clinical prognostic groups are going to be used. Of note, patients with *inv(16)/t(16;16)*, *t(8;21)*, *t(15;17)*, or *t(9;11)* and greater than or equal to three abnormalities are usually not included in this prognostically unfavorable complex karyotype category, because in these patients, the presence of a complex karyotype does not influence prognosis adversely.^{8,10}

Patients with a normal karyotype of marrow cells at diagnosis constitute the largest cytogenetic subset of AML and are classified in the intermediate prognostic category by all major classification schemata.^{8–10} However, despite the absence of microscopically detectable chromosome aberrations, these patients can harbor submicroscopic genetic abnormalities discernible only by molecular genetic techniques, such as RT-PCR or direct sequencing. Among several such

Table 2.1 The WHO classification of AMLs^a

WHO category of AML	Postulated cell origin	Morphology and cytochemistry	Cytogenetics	Immunophenotype
AML with t(8;21)(q22;q22), [AML1(RUNX1)/ETO(CBFA2T1)]	Myeloid stem cell with predominant neutrophil differentiation	<i>AML with recurrent genetic abnormalities</i> BM contains large blasts with abundant basophilic cytoplasm often with azurophilic granulation and/or single Auer rods, smaller blasts, promyelocytes, myelocytes, and mature neutrophils with variable dysplasia and homogeneous pink cytoplasm. There is an increase in eosinophil precursors, which do not have abnormalities seen in AML with inv(16)/t(16;16)	t(8;21), variant translocations, or insertions	CD34+, CD13+, CD33+, MPO+; frequently, CD19 present on a subset of the blasts; often CD56+; some cases are TdT+, with dim expression
AML with abnormal BM eosinophils and inv(16) (p13q22) or t(16;16) (p13;q22), (CBFB/MYH11)	Hematopoietic stem cell with potential to differentiate to granulocytic and monocytic lineages	In addition to myelomonocytic features (see below), marrow contains an increased number of abnormal eosinophils, with immature, large purple-violet eosinophil granules and faint positivity to naphthol ASD chloroacetate esterase reaction. Myeloblasts can have Auer rods. MPO activity is seen in 3% or more of blasts; monoblasts and promonocytes are usually NSE positive	inv(16) or t(16;16)	CD13+, CD33+, MPO+; often positive for some or all of the following: CD14, CD4, CD11b, CD11c, CD64, CD36, and lysozyme; may be CD2+
AML with t(15;17)(q22; q12-21), (PML/RARA) and variants	Myeloid stem cell with potential to differentiate to granulocytic lineage	Hypergranular APL: Abnormal promyelocytes of variable size and irregular shape, often kidney-shaped or bilobed, with cytoplasm packed with pink, red, or purple large granules. Cells containing multiple Auer rods, which are usually larger than in other types of AML, are called Faggot cells. Myeloblasts with single Auer rods may be present. Strongly positive MPO reaction; NSE weakly positive in 25% of cases. Microgranular (hypogranular APL): predominantly bilobed promyelocytes with the apparent absence of or a few large granules. Rare Faggot cells and/or abnormal promyelocytes with visible granules. Higher than in hypergranular APL leukocyte count with numerous abnormal microgranular promyelocytes. Strongly positive MPO reaction	t(15;17), variant translocations, or insertions	CD33+ homogeneously and brightly; CD13+ heterogeneously; CD34 and HLA-DR generally absent, if expressed then only on a subset of cells; CD15– or dimly expressed; frequent coexpression of CD2 and CD9

table continues

Table 2.1 continued				
WHO category of AML	Postulated cell origin	Morphology and cytochemistry	Cytogenetics	Immunophenotype
AML with 11q23 (<i>MLL</i>) abnormalities	Hematopoietic stem cell with multilineage potential	Mostly monocytic and myelomonocytic morphology, although a minority of cases have morphological features of AML with or without maturation	t(9;11)(p22; q23), t(6;11)(q27;q23), t(11;19)(q23; p13.1) and other translocations, inversions, and insertions involving band 11q23	No specific immunophenotypic features; variable expression of CD13 and CD33; cases with monoblastic morphology are CD34 ⁻ and CD14 ⁺ , CD4 ⁺ , CD11b ⁺ , CD11c ⁺ , CD64 ⁺ , CD36 ⁺ , and/or lysozyme ⁺
May develop de novo or following an MDS/ myeloproliferative disease	Hematopoietic stem cell	<i>AML with multilineage dysplasia</i> Dysplasia present in at least 50% of the cells of two or more myeloid lineages	Aberrations similar to those occurring in MDS, mostly unbalanced: -5/del(5q), -7/del(7q), +8, +11, -18, +19, +21, del(11q), del(12p), del(20q). Less often der(1;7)(q10;p10), inv(3)/t(3;3), t(3;5)(q25;q34)	Blasts, which often constitute a subpopulation of cells, are CD34 ⁺ , CD13 ⁺ , and CD33 ⁺ . Frequent aberrant expression of CD56 and/or CD7; increased expression of MDR1 on the blasts
Alkylating agent/radiation-related type	Hematopoietic stem cell	<i>AML and MDS, therapy related</i> Panmyelosis, dysplastic changes, ringed sideroblasts in up to 60% of cases	Often complex karyotypes with -5/del(5q), -7/del(7q), and del(17p)	Blasts, which often constitute a subpopulation of cells, are CD34 ⁺ , CD13 ⁺ , and CD33 ⁺ . Aberrant expression of CD56 and/or CD7 is frequent, and expression of MDR1 on the blasts increased
Topoisomerase II inhibitor-related type (some may be lymphoid)	Hematopoietic stem cell	A significant monocytic component, most cases have acute myelomonocytic or monoblastic leukemia. APL also reported	Balanced translocations involving 11q23 [t(9;11), t(6;11), t(11;19), etc.], t(8;21), t(3;21)(q26;q22), inv(16), t(8;16)(p11;p13), t(6;9)(p23;q34), and, in therapy-related APL, t(15;17)	

AML, minimally differentiated	Hematopoietic stem cell at the earliest stage of myeloid differentiation/maturation	<i>AML not otherwise categorized</i> Medium-size blasts with round or slightly indented nuclei with dispersed chromatin and 1 or 2 nucleoli, and agranular cytoplasm with a varying degree of basophilia. Less often blasts are small and resemble lymphoblasts, with more condensed chromatin, inconspicuous nucleoli, and scanty cytoplasm. MPO, SBB, and naphthol ASD chloroacetate esterase reactions are negative	There is no consistent abnormality; recurrent aberrations include +4, +8, +13, -7, and complex karyotypes	CD13+, CD33+, and/or CD117+; cCD3-, cCD79a-, and cCD22-; often MPO-; most cases are CD34+, CD38+, and HLA-DR+; CD11b-, CD14-, CD15-, CD65-; TdT+ in \geq one-third cases; CD7, CD2, and CD19 may be expressed but with lower intensity than in lymphoid leukemias
AML without maturation	Precursor hematopoietic cell at the earliest stage of myeloid differentiation	In a proportion of cases, myeloblasts with azurophilic granulation and/or Auer rods are present. Other cases have blasts similar to lymphoblasts, without azurophilic granulation. Variable (but always in \geq 3% of blasts) MPO and SBB positivity	There is no consistent abnormality	Expression of at least two of the following: CD13, CD33, CD117, and/or MPO. Often CD34+. CD11b- and CD14-
AML with maturation	Hematopoietic precursor cell at the earliest stage of myeloid development	Myeloblasts with azurophilic granulation and/or Auer rods are present, and myelocytes, promyelocytes, and mature neutrophils constitute \geq 10% of BM cells. There is variable degree of dysplasia. Blasts and maturing neutrophils are lysozyme and MPO positive	Deletions and translocations involving 12p, t(6;9)(p23;q34), t(8;16)(p11;p13)	Expression of one or more of the following: CD13, CD33, and CD15. CD117, CD34, and HLA-DR also may be expressed
Acute myelomonocytic leukemia	Hematopoietic precursor cell with potential to differentiate into neutrophil and monocytic lineages	The BM contains \geq 20% neutrophils and their precursors and \geq 20% monocytes, monoblasts, and promonocytes	The majority of cases are cytogenetically abnormal, but no specific aberration has been identified	Variable expression of CD13 and CD33. CD4, CD14, CD11b, CD11c, CD36, CD64, and/or lysozyme may be expressed. Residual population of less differentiated myeloblasts expresses CD34 and panmyeloid markers
Acute monoblastic and monocytic leukemia	BM stem cell with some commitment to monocytic differentiation	80% or more of the leukemic cells are monoblasts, promonocytes, and monocytes; a neutrophil component is minor (<20%). In acute monoblastic leukemia, monoblasts constitute \geq 80% of monocytic cells, whereas in acute monocytic leukemia, promonocytes predominate. Both monoblasts and promonocytes usually display NSE activity; monoblasts are MPO negative and promonocytes may show scattered MPO positivity	In cases with hemophagocytosis by leukemic cells, t(8;16)(p11;p13) is often detected	Variable expression of CD13, CD33, and CD 117. CD4, CD14, CD11b, CD11c, CD36, CD64, CD68, and/or lysozyme may be expressed. CD34 often negative

table continues

Table 2.1 continued				
WHO category of AML	Postulated cell origin	Morphology and cytochemistry	Cytogenetics	Immunophenotype
Erythroleukemia (erythroid/myeloid)	Multipotent stem cell with wide myeloid potential	<i>Acute erythroid leukemias (erythroid/myeloid and pure erythroleukemia)</i> Dysplastic erythroid precursors at all maturation stages may be present. There may be large multinucleated erythroid cells. The myeloblasts are similar to those in AML with and without maturation	Complex karyotypes with $-5/\text{del}(5q)$ and $-7/\text{del}(7q)$ are frequent	Erythroblasts lack myeloid-associated antigens, are MPO $-$, and react with antibodies to hemoglobin A and glycophorin A. Myeloblasts are usually CD13 $+$, CD33 $+$, CD117 $+$, and MPO $+$. CD34 and class II HLA-DR expression are variable
Pure erythroleukemia	Primitive (BFU-E/CFU-E) stem cell with some degree of commitment to the erythroid lineage	Erythroblasts are medium to large in size and have basophilic cytoplasm. Infrequently, the blasts are smaller and resemble lymphoblasts. Erythroblasts are negative for MPO and SBB, but show reactivity with ANA esterase, acid phosphatase, and periodic acid Schiff	Complex karyotypes with $-5/\text{del}(5q)$ and $-7/\text{del}(7q)$ are frequent	In more differentiated forms, glycophorin A and hemoglobin A are expressed but MPO and other myeloid antigens are not. Glycophorin A is usually not expressed in more immature forms, which are positive for carbonic anhydrase 1, CD36, and Gero antibody against the Gerbich blood group
Acute megakaryoblastic leukemia	Hematopoietic precursor cell committed to the megakaryocytic lineage and possibly erythroid lineage and/or able to differentiate into these lineages	More than 50% of the blasts are of megakaryocyte lineage. Megakaryoblasts are usually medium to large in size but small blasts resembling lymphoblasts may also be present. Marrow fibrosis may occur in some patients	Translocation $t(1;22)(p13;q13)$ is recurrent in children younger than 2 years. In some adults, $\text{inv}(3)$ or $t(3;3)$ is found, but they also occur in other AML types	Megakaryoblasts express CD36 and one or more of the following: CD41, CD61, and/or CD42 (less often). CD13 and CD33 may be positive, and CD34, CD45, and HLA-DR are often negative
Acute basophilic leukemia	Early myeloid cell committed to the basophil lineage	Medium-size blasts with moderately basophilic cytoplasm containing coarse basophilic granules. Characteristically, blasts are positive for cytochemical reaction with toluidine blue, and usually stain diffusely with acid phosphatase, but are negative for SBB, MPO, and NSE by light microscopy	No consistent abnormality	CD13 $+$, CD33 $+$, CD34 $+$, class II HLA-DR $+$; usually, CD9 $+$, some cases TdT $+$; negative for specific lymphoid markers

Acute panmyelosis with myelofibrosis	Myeloid hematopoietic stem cell. The fibroblastic proliferation is an epiphenomenon	Marked pancytopenia in the blood. BM aspirations often unsuccessful. BM biopsy hypercellular with variable hyperplasia of the granulocytes, megakaryocytes, and erythroid precursors. Variable degree of fibrosis, with increase in reticulin fibers	If analysis successful, the karyotype is usually complex, with $-5/\text{del}(5q)$ and/or $-7/\text{del}(7q)$	Phenotypic heterogeneity, with expression of one or more of the following: CD13, CD33, CD117, and MPO
Myeloid sarcoma	Primitive myeloid hematopoietic cell	Granulocytic sarcoma, the most common type, consists of myeloblasts, neutrophils, and neutrophil precursors, and is divided into three types based upon degree of maturation. The blastic type contains mainly myeloblasts, the immature type myeloblasts and promyelocytes, and the differentiated type promyelocytes and more mature neutrophils. Less frequent monoblastic sarcoma is composed of monoblasts	In some cases of myeloid sarcoma, $t(8;21)$ or $\text{inv}(16)/t(16;16)$; in monoblastic sarcoma $11q23$ translocations	Most myeloid sarcomas express CD43. Granulocytic sarcoma myeloblasts are CD13+, CD33+, CD117+, and MPO+. The monoblasts in monoblastic sarcoma are CD14+, CD116+, CD11c+, and react with antibodies to lysozyme and CD68 by immunohistochemistry
Undifferentiated acute leukemia	Multipotent progenitor stem cell	<i>Acute leukemia of ambiguous lineage</i> The leukemic cells lack any differentiating features	Frequently abnormal cytogenetically. Recurrent aberrations include $\text{del}(5q)$ and $+13$, often as a sole abnormality	Often HLA-DR+, CD34+, CD38+, and may be TdT+ and CD7+. Negative for markers specific for a given lineage, such as cCD79a, cCD22, CD3, and MPO. Generally, do not express more than one lineage-associated marker.
Bilineal acute leukemia	Multipotent progenitor stem cell	May present as monoblastic or poorly differentiated myeloid leukemia, or as ALL. In some cases, blasts are morphologically undifferentiated; in others, populations of small blasts resembling lymphoblasts may coexist with larger blasts	Typically abnormal cytogenetically. Cases with B lymphoid component often have $t(9;22)(q34;q11.2)$, $t(4;11)$, or other $11q23$ aberrations; these aberrations are not found in cases with T lymphoid component	Coexistence of two populations of blasts, each of which expresses antigens of a distinct lineage, which is myeloid and lymphoid or B and T
Biphenotypic acute leukemia	Multipotent progenitor stem cell	May present as monoblastic or poorly differentiated myeloid leukemia, or as ALL. In some cases, blasts are morphologically undifferentiated; in others, populations of small blasts resembling lymphoblasts may coexist with larger blasts	Usually abnormal cytogenetically. Cases with B lymphoid component often have $t(9;22)$, $t(4;11)$, or other $11q23$ aberrations; these aberrations are not found in cases with T lymphoid component	Blasts coexpress myeloid and T- or B-lineage-specific markers or, concurrently, T- and B-specific antigens

^a Data from Jaffe et al.¹ and Mitelman et al.³⁶

Table 2.2 Prognostic significance of the more common chromosome aberrations in AML

Chromosome aberration ^a	Cytogenetic risk category
inv(16)(p13;q22)/t(16;16)(p13;q22); t(8;21)(q22;q22); t(15;17)(q22;q12-21)	Favorable
none (normal karyotype); -Y; del(7q)^b; del(9q)^b; del(11q)^c; del(20q)^d; isolated +8^e; +11, +13, +21, t(9;11)(p22;q23)^c	Intermediate
complex karyotype with ≥3 abnormalities; inv(3)(q21;q26)/t(3;3)(q21;q26); -7; del(5q)^f; -5; t(6;9)(p23;q34)^g; t(6;11)(q27;q23)^h; t(11;19)(q23;p13.1)^h	Unfavorable

^a Chromosome aberrations whose prognostic impact is agreed on by major studies⁸⁻¹⁰ are indicated by bold type.

^b Classified in the adverse-risk category by SWOG/ECOG.⁹

^c Would be included in “abn 11q” group and classified in the adverse-risk category by SWOG/ECOG.⁹

^d Would be included in “abn 20q” group and classified in the adverse-risk category by SWOG/ECOG.⁹

^e Classified in the adverse-risk category with regard to overall survival by CALGB.¹⁰

^f Classified in the intermediate-risk category with regard to probability of achievement of CR and survival by CALGB if not part of a complex karyotype.

^g Classified in the intermediate-risk category by virtue of being “other structural” abnormality by MRC⁸ and by CALGB (but intermediate only with regard to probability of achievement of CR).¹⁰

^h Would be included in “abnormal 11q23” group and classified in the intermediate-risk category by MRC⁸ and by CALGB (but only with regard to probability of achievement of CR).¹⁰

mutations associated with AML, internal tandem duplication (ITD) of the *FLT3* gene (*FLT3* ITD), partial tandem duplication (PTD) of the *mixed lineage leukemia* (*MLL*) gene (*MLL* PTD), and point mutations of the *CCAAT/enhancer-binding protein α* (*CEBPA*) gene have been recently found to be of prognostic significance in patients with AML and a normal karyotype (Table 2.3). Likewise, adverse prognosis has been associated with overexpression of the *brain and acute leukemia, cytoplasmic* (*BAALC*) gene.¹⁹⁻²¹

Later in the chapter we will discuss in greater detail the four AML categories delineated primarily because of cytogenetic and molecular genetic findings, followed by data on major molecular genetic rearrangements relevant to AML pathogenesis, some of which are associated with clinical outcome.

CORE-BINDING FACTOR LEUKEMIA

Two categories in the WHO classification of AML, namely AML with t(8;21)(q22;q22)/*AML1*(*RUNX1*)-*ETO*(*CBFA2T1*) and AML with abnormal BM eosinophils and inv(16)(p13;q22) or t(16;16)(p13;q22)/*CBFB*-*MYH11*, are characterized by chromosomal aberrations

that rearrange genes encoding different subunits of core-binding factor (CBF). These AML types are collectively referred to as CBF AML. The CBF complex is a heterodimeric transcription factor, composed of α and β subunits, which regulates transcription of several genes involved in hematopoietic differentiation, including cytokines such as interleukin-3 (*IL-3*), granulocyte-macrophage colony-stimulating factor (*GM-CSF*), and the macrophage colony-stimulating factor receptor (*M-CSFR*). The CBF α subunit, encoded by the *RUNX1* gene (also known as *AML1* and *CBFA2*), harbors a DNA-binding domain, whereas the CBF β subunit does not directly bind DNA, but physically associates with CBF α and stimulates its DNA-binding activity, thereby regulating transcription.²² The intact CBF complex is critical for normal hematopoiesis; disruption of either of its subunits directly contributes to leukemic transformation.

AML with t(8;21)(q22;q22)/*AML1*(*RUNX1*)-*ETO*(*CBFA2T1*)

This type of CBF AML is associated with t(8;21) and its relatively rare variants, such as insertions ins(8;21)(q22;q22q22) or ins(21;8)(q22;q22q22), and complex translocations involving three or four different chromosomes that invariably include chromosomes 8 and 21 with breaks in bands 8q22 and 21q22. The t(8;21) represents one of the most frequent chromosomal aberrations in AML, occurring in approximately 6% of adult and 12% of childhood patients.¹³ Interestingly, most patients, approximately 70%, carry at least one additional (secondary) chromosome abnormality, the most frequent of which are loss of one sex chromosome (-Y in male and -X in female patients), del(9q), and trisomy of chromosome 8 (+8).^{23,24}

Both t(8;21) and its variants lead to fusion of the DNA-binding domain of the *RUNX1* gene, located at 21q22, with the *CBFA2T1* gene at 8q22 and creation of a chimeric gene *RUNX1-CBFA2T1*. The chimeric fusion protein impairs normal hematopoiesis through a dominant-negative inhibition of the wild-type *RUNX1*. In addition, it has been shown that *RUNX1-CBFA2T1* itself recruits nuclear corepressor complexes, which includes the histone deacetylase enzyme HDAC1, and is responsible for transcriptional repression of *RUNX1* target genes, and thus generates novel signals that alter normal transcription. These observations have prompted studies attempting to reverse the block of differentiation using histone deacetylase (HDAC) inhibitors.²⁵

Morphologically, the presence of t(8;21)/*RUNX1*-*CBFA2T1* is strongly (but not exclusively) associated with AML with maturation in the neutrophil lineage. Characteristic pink-colored cytoplasm of neutrophils and an increased number of eosinophil precursors [without abnormalities typical for AML with inv(16)] appear to distinguish patients with t(8;21) from other patients with AML with maturation but without t(8;21)/*RUNX1*-*CBFA2T1*.^{26,27}

Notably, the clinical outcome of patients with t(8;21) is relatively favorable,^{8–10,12–14} especially when regimens containing repetitive cycles of high-dose cytarabine are used as postremission therapy.^{28,29} The favorable outcome does not seem to be influenced by the presence of secondary chromosome aberrations, although one recent study reported loss of the Y chromosome in male patients to be associated with shorter overall survival,²³ but this has not been corroborated by another large study.²⁴

AML with inv(16)(p13q22)/CBFB-MYH11

This type of CBF AML is characterized by the presence of inversion of chromosome 16, inv(16)(p13q22), or, less commonly, a reciprocal translocation between homologous chromosomes 16, t(16;16)(p13;q22), in leukemic blasts. These chromosome aberrations can be detected in about 7% of adult and 6% of pediatric AML patients.^{10,13} Notably, secondary aberrations [e.g., +22, +8, del(7q), or +21] are less common in patients with inv(16)/t(16;16) than in patients with t(8;21), being detected in approximately one-third of patients with inv(16)/t(16;16).^{23,24}

Both the inv(16) and the t(16;16) fuse the myosin, heavy chain 11, smooth muscle gene (*MYH11*) with the C terminus of the *CBFB* gene. The chimeric protein retains the ability to interact with the RUNX1 and has been suggested to block CBF-dependent transcription.²²

The marrow of patients with inv(16)/t(16;16)/*CBFB-MYH11* shows monocytic and granulocytic differentiation and abnormal eosinophils, a hallmark of this disease. These eosinophils are essentially always present, albeit sometimes scarce, constituting as little as 0.2% of marrow cells.

The prognosis of CBF AML patients with inv(16)/t(16;16) is favorable,^{8–14} and can be improved by regimens with multicourse high-dose cytarabine.³⁰ Two large recent studies demonstrated that patients who carry a secondary +22 in addition to inv(16) or t(16;16) have a significantly reduced risk of relapse compared with patients with an isolated inv(16)/t(16;16).^{23,24} The reasons for this difference in outcome and the molecular consequences of trisomy 22 remain to be elucidated.

ACUTE PROMYELOCYTIC LEUKEMIA—A DISEASE WITH RETINOIC ACID RECEPTOR α REARRANGEMENTS

Acute promyelocytic leukemia (APL) is the third category in the WHO classification that is characterized by specific cytogenetic and molecular genetic rearrangements as well as unique marrow morphology, presenting clinical features, and responsiveness to targeted therapy with all-*trans*-retinoic acid (ATRA). APL comprises from 8% (adults) to 10% (children) of AML cases.¹³ Essentially, all patients with APL carry a gene fusion of the *retinoic acid receptor α* (*RARA*) gene, located at 17q12–21, with one of several partner genes, the most common of which is the *promyelocytic leukemia* (*PML*) gene, mapped to 15q22. In the vast majority (>90%) of APL patients, the *PML-RARA* fusion gene is created by a subtle but

detectable microscopically reciprocal translocation t(15;17)(q22;q12–21); in an additional 4%, the *PML-RARA* gene is generated by an insertion of a small segment from 17q, with the *RARA* gene into the locus of the *PML* gene.³¹ Most of these insertions are cryptic, i.e., not detectable by routine cytogenetic study, and associated with a normal karyotype; they can be identified only using RT-PCR or fluorescence in situ hybridization (FISH). Approximately one-third of APL patients with t(15;17) carry at least one secondary aberration, the most common of which is trisomy 8 or 8q. Additionally, in a small proportion of APL cases, other, rather infrequent, chromosomal aberrations are found, including t(11;17)(q23;q12–21), t(11;17)(q13;q12–21), t(5;17)(q35;q12–21), and dup(17)(q21.3q23). Each of these rearrangements results in a fusion of the *RARA* gene with, respectively, the *PLZF* gene at 11q23, *NUMA1* gene at 11q13, *NPM* gene at 5q35, and *STAT5b* gene at 17q21.1–21.2.^{32,33}

The *RARA* gene is a member of the nuclear hormone receptor gene family and contains transactivation, DNA-binding, and ligand-binding domains. As a consequence of the t(15;17) or ins(15;17), the DNA- and ligand-binding domains of *RARA* are fused to the *PML* gene. The chimeric *PML-RARA* fusion protein binds to corepressor/HDAC complexes with higher affinity than does the wild-type *RARA*, leading to aberrant chromatin acetylation and alterations of chromatin conformation that inhibit the normal transcription of genes regulated by *RARA*. This blocks cell differentiation and leads to the accumulation of leukemic blasts at the promyelocytic stage. Importantly, therapeutic doses of ATRA, but not physiological ATRA levels, are capable of changing conformation of the *PML-RARA* protein and releasing corepressor/HDAC complexes that lead to transcriptional activation of downstream target genes. Moreover, both ATRA and arsenic trioxide, another compound used in targeted APL treatment, also induce proteolysis of the *PML-RARA* protein. This leads to granulocytic differentiation of the leukemic blasts.³⁴

A strong correlation exists between t(15;17)/*PML-RARA* and its variants and marrow morphology in which abnormal promyelocytes dominate. There are two major morphologic subtypes of APL, hypergranular (or typical) and microgranular (or hypogranular), and both are associated with the presence of t(15;17)/*PML-RARA* or variants. The microgranular variant, which sometimes can be misdiagnosed morphologically as acute monocytic leukemia, is associated with very high leukocyte counts with abundant abnormal microgranular promyelocytes.¹

It is important to determine which of the APL-associated translocations and gene fusions are present, because patients with t(11;17)(q23;q12–21)/*PLZF-RARA* are resistant to standard ATRA-based therapy. Although it has been reported that t(11;17)(q23;q12–21)/*PLZF-RARA*-positive APL displays distinguishing morphological and immunophenotypic characteristics, such as

prevalence of blasts with regular nuclei, an increased number of Pelger-like cells, and CD56 positivity,³⁵ the diagnosis should always be supported by results of cytogenetic, FISH, and/or RT-PCR analyses.

AML WITH REARRANGEMENTS OF BAND 11Q23 AND THE MLL GENE

This category represents approximately 4% of cases of adult AML, but rearrangements involving band 11q23 and the *MLL* gene (also known as *ALL1*, *HRX*, and *HTRX*) are three to four times more common in children with AML, being especially frequent among infants aged 12 months or less, 43–58% of whom carry an 11q23/*MLL* abnormality.¹³ At both the cytogenetic and molecular genetic level, AML with the 11q23/*MLL* rearrangements is extremely heterogeneous. Well over 30 different balanced chromosome abnormalities, mostly translocations but also inversions, insertions, and interstitial deletions, involving band 11q23 and another chromosome locus have been reported.^{5,36} The most common of these is t(9;11)(p22;q23), resulting in the *AF9-MLL* gene fusion; other more frequent recurrent translocations and fusion genes in AML include t(6;11)(q27;q23)/*AF6-MLL*, t(11;19)(q23;p13.1)/*MLL-ELL*, and t(11;19)(q23;p13.3)/*MLL-MLLT1*.

In some studies, patients with various 11q23/*MLL* rearrangements have been included in the same cytogenetic category and classified as having either adverse⁹ or intermediate⁸ prognosis. However, increasing evidence suggests that prognosis of patients with 11q23/*MLL* rearrangements depends on the partner chromosome/gene involved, with t(9;11)-positive patients having a better prognosis,^{37,38} which places them in the intermediate cytogenetic risk group.¹⁰ The survival of adults with t(6;11) and t(11;19)(q23;p13.1) studied by Cancer and Leukemia Group B (CALGB) was significantly shorter than that of the cytogenetically normal group, and consequently they were assigned to the adverse-risk group for survival.¹⁰

The *MLL* gene is a homeotic regulator that shares homology to sequences of the *Drosophila* trithorax gene. It encodes a nearly 430-kd protein. The C-terminus of *MLL* positively regulates *HOX* gene expression during development of hematopoietic stem cells. The N-terminus contains an AT hook region functioning as a DNA-binding domain and a region similar to the noncatalytic domain of methyltransferases.

Additionally, amplification of the *MLL* gene, without rearrangements of the gene, has been recently recognized as a recurrent aberration in patients with AML and myelodysplastic syndromes (MDS), a complex karyotype, and results in an adverse prognosis.^{39–41} *MLL* amplification was shown to result in overexpression of the gene and *MLL* gain of function because it was associated with increased expression of one of its physiologic downstream targets, *HOXA9*.⁴²

In addition to rearrangements generated by chromosome translocations, the *MLL* gene can also be

Table 2.3 Genetic anomalies that impact prognosis of AML patients with normal cytogenetics

Genetic rearrangement	Prognostic significance
Internal tandem duplication of the <i>FLT3</i> gene	CRD, DFS, and survival significantly shorter for patients with <i>FLT3</i> ITD compared with patients without <i>FLT3</i> ITD; especially, poor outcome for <i>FLT3</i> ITD patients with no expression of an <i>FLT3</i> wild-type allele or a high <i>FLT3</i> mutant/wild-type allele ratio
Loss-of-function mutations of the <i>CEBPA</i> gene	CRD and survival significantly longer for patients with the <i>CEBPA</i> gene mutations compared with patients without mutated <i>CEBPA</i>
Partial tandem duplication of the <i>MLL</i> gene	CRD and EFS significantly shorter for patients with <i>MLL</i> PTD compared with patients without <i>MLL</i> PTD
Overexpression of the <i>BAALC</i> gene	DFS, EFS, and survival significantly shorter for patients with high expression of <i>BAALC</i> compared with low <i>BAALC</i> expression patients
Mutations of the <i>NPM1</i> gene	CR rates, EFS, RFS, DFS, and OS significantly better for patients with <i>NPM1</i> mutations who do not harbor <i>FLT3</i> ITD

CRD, CR duration; DFS, disease-free survival; EFS, event-free survival; RFS, relapse-free survival; OS, overall survival.

rearranged in AML patients without structural chromosome abnormalities involving band 11q23. These *MLL* rearrangements occur in the majority of patients with isolated trisomy 11⁴³ and in 8–11% of karyotypically normal adults with de novo AML,^{44,45} and result from a PTD spanning exons 5 through 11 or, less frequently, exons 5 through 12.^{43–46} Among patients with normal cytogenetics, the *MLL* PTD confers poor prognosis (Table 2.3), and represents an independent adverse prognostic factor for remission duration.⁴⁵

MOLECULAR GENETICS

MUTATIONS IN AML-ASSOCIATED TRANSCRIPTION FACTORS *CEBPA*

The *CEBPA* gene encodes a transcription factor expressed mainly in myelomonocytic cells that is

essential for granulopoiesis, showing cell-type-specific and differentiation-stage-specific expression patterns. Mutations in *CEBPA* have been reported in 7–11% of AML patients.^{47,48} These include N-terminal nonsense mutations resulting in a premature termination of the full-length protein with dominant-negative properties, and C-terminal in-frame mutations resulting in a decrease of DNA-binding potential. Interestingly, *CEBPA* mutations have been found predominantly in AML FAB subtypes M1 or M2, suggesting the induction of a stage-specific block in the differentiation pathway. Clinical studies have revealed that mutations in *CEBPA* confer a favorable prognosis in AML patients with normal cytogenetics,⁴⁹ and among those classified in the intermediate-risk cytogenetic group.^{47,48}

RUNX1

In addition to its involvement in the translocation t(8;21), *RUNX1* is also dysregulated by mutations found in patients with AML and MDS, as well as by amplification in patients with ALL. Germline mutations resulting in *RUNX1* haploinsufficiency have been reported in cases of familial platelet disorder, an autosomal-dominant disease with quantitative and qualitative platelet defects and progressive pancytopenia, with a predisposition to development of AML.⁵⁰ In de novo AML, somatic point mutations occur in up to 10% of cases. Interestingly, *RUNX1* mutations are mainly found in minimally differentiated AML (FAB M0), with a frequency of up to 22%, reflecting the importance of *RUNX1* in the earliest stages of hematopoiesis.

GATA1

The *gata-binding protein 1* (*GATA1*) gene, located at Xp11.23, encodes a lineage-specific zinc-finger transcription factor required for normal development of erythroid and megakaryocytic lineages. Inherited missense mutations within the zinc-finger domain inhibiting the interaction with the essential cofactor, Friend of *GATA1* (*FOG1*), have been found in familial dyserythropoietic anemia and thrombocytopenia. Somatic mutations leading to production of an alternative protein that retains its intact zinc-finger interaction domain have been identified exclusively in patients with Down syndrome suffering from AMKL or transient myeloproliferative disorder.

SIGNAL TRANSDUCTION PATHWAYS

Signal transduction pathways control the transmission of extracellular signals (e.g., growth factors, including G-CSF, GM-CSF, and *FLT3* ligand) via the receptor-tyrosine-kinase-RAS cascade into intracellular response mechanisms (proliferation, differentiation, and apoptosis). In AML, mutations, epigenetic changes and aberrant expression of genes involved in these pathways, result in increased proliferation and/or dysregulated differentiation and apoptosis.

RECEPTOR TYROSINE KINASE AND DOWNSTREAM SIGNALING PATHWAYS

Members of the *RTK-RAS* signaling pathway, including receptor tyrosine kinases (RTKs) such as *FLT3*, *FMS*, *KIT*, and *VEGFR*, and the *NRAS* and *KRAS* genes, are frequently (in more than 50% of patients) mutated in AML; as a result, this pathway appears to play a central role in leukemogenesis. The identification of these specific molecular alterations has not only helped in elucidating the mechanisms involved in leukemogenesis, but also has resulted in targeted therapies, such as *FLT3* inhibitors for AML patients with *FLT3* ITD or *FLT3* overexpression, RTK inhibitors for patients with *KIT* mutations or overexpression, as well as *RAS* inhibitors including farnesyltransferase inhibitors.⁵¹

FLT3

The *FLT3* gene encodes a class III RTK, which plays an important role in cell proliferation, differentiation, and survival. The *FLT3* receptor is preferably expressed on hematopoietic stem cells, and activation by its ligand (*FLT3* ligand) induces oligomerization leading to phosphorylation and activation of downstream pathways (mainly via phosphorylation of intracellular substrates). Mutations of the *FLT3* gene are found in up to 40% of AML patients. These mutations include *FLT3* ITD, affecting exons 14 and 15, in up to 30% of patients, and activating point mutations of D835 within the activation loop in the tyrosine kinase domain (TKD; Asp835 mutation), in about 5–10% of AML cases. The *FLT3* ITD, as well as mutations in the TKD, promote autophosphorylation of *FLT3*, and the constitutively active receptor confers ligand-independent proliferation.⁵²

Clinical studies have demonstrated that both adults and children with AML and *FLT3* ITD have a significantly inferior clinical outcome.^{53–60} In some analyses, the worst outcome has been bestowed by *FLT3* ITD coupled with lack of an *FLT3* wild-type allele or a high *FLT3* mutant/wild-type allele ratio.^{59,60} In one study, relatively infrequent patients with simultaneous presence of both the *FLT3* ITD and the Asp835 mutation had the least favorable outcome.⁶¹ However, although *FLT3* ITD is also common in APL patients with t(15;17), it has thus far not been shown to predict prognosis in these patients.^{55,57,62} Likewise, *FLT3* Asp835 mutations have not hitherto been correlated with inferior prognosis, but because they are relatively infrequent, larger clinical studies are necessary to determine their prognostic importance.

KIT

Asp816 substitution mutations that result in constitutive activation of *KIT* have been found in about 5% of AML patients.⁶³ *KIT* exon 8 mutations have been found in 24% of patients with inv(16) and 2% of t(8;21)-positive patients, whereas *KIT* Asp816 mutations were present in 8% of patients with inv(16) and in 11% of those with t(8;21) AML.⁶⁴ In patients with

inv(16), *KIT* mutations were associated with a significantly higher relapse rate.⁶⁴

RAS

The small membrane-associated G protein RAS and its relatives are signal transduction components connecting various classes of receptors (including RTK) to cytoplasmic pathways. Mutations of the GTPase oncogene *NRAS* occur in about 15% of AML patients, *KRAS* mutations occur in fewer than 5% of cases, and *HRAS* mutations are rare. *NRAS* mutations (primarily point mutations in codons 12, 13, and 61) occur at specific positions that are critical for guanine triphosphate (GTP) hydrolysis, thereby preventing the conversion of the active RAS-GTP to the inactive RAS-GDP.

OVEREXPRESSION OF THE BAALC GENE

The *BAALC* gene, mapped to band 8q22.3, encodes a protein with no homology to any known proteins or functional domains. *BAALC* is expressed mainly in neuroectoderm-derived tissues and hematopoietic precursors, with no expression in mature BM or blood mononuclear cells.⁶⁵ High expression of *BAALC* mRNA in circulating blasts is an independent adverse prognostic factor in uniformly treated adults younger than 60 years with de novo AML and normal cytogenetics.^{19,20} In another, smaller study, high expression of *BAALC* predicted shorter disease-free survival (DFS) and overall survival in patients with a normal karyotype who did not carry *FLT3* ITD or mutations in the *CEBPA* gene.²¹

COOPERATION BETWEEN MUTATIONS

It has been hypothesized that at least two somatic mutations with differing consequences collaborate to induce AML, as each alone is incapable of fully transforming a normal into a leukemic cell. These include mutations in the signal transduction pathways conferring a proliferation stimulus and mutations in genes encoding hematopoietic transcription factors that impair cell differentiation. This concept is consistent with Knudson's two-hit hypothesis, which proposes that at least two events are necessary to promote cancer.⁶⁶ This concept is important for the understanding of the mechanisms involved in leukemogenesis as well as for the development of novel treatment strategies that may have to target several dysregulated molecules in different pathways. Interestingly, simultaneous mutations of two genes cooperating in the same pathway (e.g., *FLT3* and *RAS*) are rare.

CBF AML and additional mutations

Neither *RUNX1-CBFA2T1* nor *CBFB-MYH11* alone are capable of inducing overt AML. These fusion genes dictate the phenotype of the disease, but additional abnormalities are required for the leukemic transformation. Recent studies have demonstrated that 40% of AML patients with inv(16) acquire either *KIT* exon 8, *KIT* Asp816, *FLT3* ITD, or *FLT3* Asp835 mutations.^{63,64}

Mutations of the *KIT* gene were less common in t(8;21) AML, with a frequency of about 13% and were absent in non-CBF AML.⁶⁴ Mutations of the *FLT3* and *KIT* gene were mutually exclusive.

t(15;17)/PML-RARA and FLT3 ITD

PML-RARA contributes to the development of APL. However, incomplete penetrance and long latency observed in *PML-RARA* transgenic mice suggest that additional events are required for complete leukemic transformation. The observation that *FLT3* mutations are found in about one-third of patients with t(15;17) has led to the hypothesis that the primary translocation event might impair differentiation and a second hit, such as the *FLT3* ITD, confers the proliferation stimulus for the leukemic cells.⁶⁷ Indeed, experimental data demonstrate that *PML-RARA* and *FLT3* ITD cooperate and that the two events lead to an ATRA-responsive APL-like disease with a short latency and 100% penetrance.⁶⁸

GENE EXPRESSION PROFILING

Gene expression profiling using DNA microarray technology is a powerful tool allowing analysis of expression of thousands of genes in one experiment. Early studies demonstrated that it is possible to correctly distinguish AML from ALL based on gene expression profiles. This proof of principle underscored the accuracy and power of analyzing mRNA expression levels of thousands of genes simultaneously.⁶⁹ Subsequent studies have shown that several cytogenetically and molecularly defined AML subtypes, such as t(15;17)/*PML-RARA*, t(8;21)/*AML1(RUNX1)-ETO(CBFA2T1)*, and inv(16)/t(16;16)/*CBFB-MYH11*, display characteristic gene expression signatures and that these gene expression signatures, not surprisingly, correlate with clinical outcome.⁷⁰ Moreover, novel gene clusters, apparently not corresponding to cytogenetic aberrations, have also been identified; some have had prognostic significance.⁷⁰ These studies have identified numerous genes selectively over- or underexpressed within particular subtypes of AML, which may provide important insights into the molecular pathways involved.

EPIGENETIC CHANGES—GENE SILENCING THROUGH DNA HYPERMETHYLATION

Expression of genes involved in hematopoiesis may be affected both by gene fusions and point mutations and by epigenetic mechanisms such as DNA methylation. Hypermethylation of cytosine nucleotide residues within CpG-rich regions (CpG islands) in the gene promoters leads to gene inactivation. CpG island hypermethylation has been detected in almost all types of solid tumors and leukemia, but patterns of aberrant DNA methylation appear to differ among particular types of neoplasia, with AML displaying a rela-

tively high number of methylation targets, some of which are not found in solid tumors.⁷¹ There seems to be an overrepresentation of methylated CpG islands on chromosome 11 relative to its size.⁷²

Most studies correlating clinical outcome with methylation of other genes have linked CpG island methylation with poor prognosis. Patients with APL and *CDKN2B* methylation had a significantly shorter 5-year DFS than those without *CDKN2B* methylation.⁷³ In another study,⁷⁴ *CDKN2B* methylation was frequently detected in therapy-related AML and MDS patients with deletion or loss of 7q and was shown to confer a poor prognosis. More recently, *EXT1* hypermethylation, which is more common in APL than in other types of AML, has been reported to increase the likelihood of resistance to treatment with ATRA in a relatively small series of patients.⁷⁵ Importantly, clinical trials of low-dose hypomethylating agents, such as 5-azacytidine and 5-aza-2'-deoxycytidine (decitabine), in AML and MDS have yielded promising results, especially in elderly patients.

CONCLUSIONS AND FUTURE DIRECTIONS

Significant progress in unraveling the genetic basis of AML has been made during the last 30 years. First, cytogenetic analyses have identified a great number of recurrent chromosome abnormalities, many of which have been dissected molecularly, leading to identification of novel genes involved in leukemogenesis. More recently, submicroscopic mutations and epigenetic changes affecting other genes have been described,

and gene expression profiling has uncovered characteristic molecular signatures of some AML subtypes. Both cytogenetic and molecular findings are associated with specific laboratory and clinical characteristics, and are being used as diagnostic and prognostic markers, guiding the clinician in selecting effective therapies. Clinical trials have begun testing the effectiveness of treatments, using compounds targeting specific molecular defects in leukemic blasts. Ongoing research will likely help resolve differences among the major cytogenetic risk-assignment schemata in prognostic categorization of more frequent chromosome aberrations, and will shed light on the currently unknown prognostic significance of less common aberrations. Likewise, novel molecular genetic rearrangements suitable for therapeutic targeting will continue to be discovered. Standardization of microarray assays will likely enable meaningful comparison of results obtained in different laboratories and may eventually lead to application of gene expression profiling in individual patients, with the goal of predicting their response to therapy and tailoring treatment to specific molecular lesions acquired by the leukemic blasts. These advances will hopefully result in improved clinical outcome of patients with AML.

Chapter 3

CLINICAL FEATURES AND MAKING THE DIAGNOSIS

Anjali S. Advani and Karl S. Theil

HISTORY OF ACUTE MYELOGENOUS LEUKEMIA

Acute myelogenous leukemia (AML) is a clonal disorder of the bone marrow that is characterized by abnormal proliferation of immature myeloid cells and arrested stem cell differentiation.¹ The history of AML dates back to the middle of the nineteenth century, when Virchow described the clinical disease as “the direct cause for the increase in the number of colorless particles in the blood.”² In 1868, Neumann related AML to changes in the bone marrow.²

CLINICAL FEATURES IN AML

Patients usually present with symptoms secondary to cytopenias, as the leukemia suppresses normal hematopoiesis. Patients may have pallor, fatigue, and shortness of breath secondary to anemia; bleeding, bruising, and ecchymoses secondary to thrombocytopenia/coagulation defects; and infections secondary to neutropenia.³ Fifteen to twenty percent of patients will present with fevers, which can result from infection or from the leukemia itself.⁴ Fewer than 20% of patients will have bone pain.⁴

EXTRAMEDULLARY INVOLVEMENT

More uncommonly, patients present with symptoms secondary to leukemic infiltration of various tissues, leading to hepatomegaly, splenomegaly, leukemia cutis (2–10% of patients), gingival involvement, tumorous nodules (myeloid sarcoma) (3–5% of patients), lymphadenopathy, bone, or central nervous system (CNS) involvement (1% of patients).^{3,5} Occasionally, patients may present with pericardial effusions.² Pulmonary infiltrates may also represent leukemia. Leukemic infiltrates in the lungs occur more commonly in patients presenting with high white blood counts and a monocytic component to their leukemia. Computed tomographic scan and bron-

choscopy may be needed to make a definitive diagnosis and to rule out other etiologies, such as infection and pulmonary hemorrhage.

Extramedullary involvement is more common with the monocytic or myelomonocytic subtypes of AML, and may be associated with a worse prognosis. The cytogenetic abnormality most commonly associated with extramedullary leukemia is t(8;21)(q22;q22).^{5,6} The incidence of extramedullary leukemia appears to be particularly high in patients who relapse, and may be decreasing with the use of intensive high-dose cytarabine as consolidation.⁵ The most common site of extramedullary leukemia in patients with the t(8;21)(q22;q22) abnormality is paraspinal disease.⁵ The presence of CD56, an adhesion molecule expressed in a variety of tissues including neural tissues, may be an additional risk factor for extramedullary leukemia in patients with t(8;21) or monocytic AML.^{5,7–9}

MYELOID SARCOMAS

Also known as granulocytic sarcomas, chloromas, and extra-medullary myeloid tumors, myeloid sarcomas are tumors of immature myeloid precursors.¹⁰ They may precede or occur concurrently with another hematologic condition, such as chronic myelogenous leukemia (CML), AML, or other myeloproliferative disorders.^{10,11} They also may be a sign of relapsed disease.¹² These patients should be treated with systemic induction therapy, regardless of whether or not the bone marrow is involved. On physical examination, myeloid sarcomas frequently have a purplish hue, and may be associated with itching.¹² When placed in dilute acid, myeloid sarcomas turn green, because of their increased content of myeloperoxidase.⁴ The diagnosis should be suspected if eosinophilic myelocytes are present in a hematoxylin—eosin-stained biopsy.⁴ If Auer rods are present or a myeloid origin detected, the diagnosis is confirmed.^{4,13,14} CD43 positivity in the absence of CD3 is a nonspecific but sensitive marker for myeloid sarcoma.¹⁰ Three types of myeloid sarcomas are described in the World Health Organization (WHO) classification:

(1) blastic granulocytic sarcoma, which is composed almost exclusively of myeloblasts; (2) immature form of granulocytic sarcoma, composed of a mixture of promyelocytes and myeloblasts; and (3) differentiated granulocytic sarcoma, composed of maturing neutrophils and promyelocytes.^{10,11}

Granulocytic sarcomas occur commonly in subcutaneous tissues, but can affect any organ.¹² Patients presenting with an extramedullary chloroma causing spinal cord compression benefit from adequate local spine radiation (in addition to chemotherapy), and have a higher chance of neurologic recovery.⁵

OTHER SKIN MANIFESTATIONS

Leukemia cutis usually presents as itchy papules or nodules that may be single or multiple.² Skin biopsy demonstrates myeloblasts. Numerical abnormalities of chromosome 8 may be more common in patients with leukemia cutis.¹⁵ There is also a trend toward a shorter remission duration in patients with leukemia cutis.¹⁵

Unlike myeloid sarcomas and leukemia cutis, Sweet syndrome involves a benign dermal infiltration by neutrophils.² Sweet syndrome occurs most commonly in advanced myelodysplastic syndrome and AML, and is characterized by fevers and painful red raised lesions.² This syndrome responds well to steroids.^{4,16}

CNS LEUKEMIA

CNS leukemia associated with AML is not very common, and CNS prophylaxis is not routine [unlike with acute lymphoblastic leukemia (ALL)].¹⁷ The incidence of meningeal disease has been reported to be as high as 15% in adults.^{4,18} It tends to occur more commonly with the monocytic and myelomonocytic subtypes and is associated with higher white blood counts, t(8;21), and the inv (16).^{4,12} Symptoms typically occur secondary to elevated intracranial pressure and include headache, blurred vision, and vomiting.¹² Cranial nerve palsies, secondary to infiltration of cranial nerve roots, particularly abducens palsy leading to a lateral strabismus, may occur.¹² Ophthalmologic examination may reveal retinal infiltration and/or papilledema.¹² Cerebral masses are rare, but may occur in patients with M4eo and inv(16).⁴

HYPERLEUKOCYTOSIS

Patients with high white blood counts and blast counts can present with symptoms of leukostasis secondary to hyperleukocytosis.³ Hyperleukocytosis is defined as a blast count of greater than 100,000/mm³ and occurs more commonly in patients with acute monocytic or myelomonocytic leukemia.^{2,4} A high early mortality is observed in patients with hyperleukocytosis.² With hyperleukocytosis, inelastic myeloblasts pack and plug blood vessels, leading to leukostasis and thrombus formation.¹² Specific signs and symptoms can include shortness of breath, hypoxia, diffuse pulmonary infiltrates, headache,

blurred vision, heart failure, myocardial infarction, and priapism.^{2,4,12} Leukostasis more commonly occurs with a rapidly rising blast count.¹² Blasts can also invade and disrupt arterioles, leading to hemorrhage.^{12,19} Although there are no randomized controlled trials, patients with hyperleukocytosis should be leukapheresed to help bring the blast count down. Cytotoxic therapy should be initiated as soon as possible. If a definitive diagnosis has not been made, hydroxyurea can be used in conjunction with (or in place of) a pheresis until a diagnosis is made and definitive chemotherapy is started. A single dose of cranial radiation may also have some benefit in patients presenting with CNS symptoms and high white blood counts.^{19,20} Patients with hyperleukocytosis should not be transfused with packed red cells until they have received appropriate cyto-reductive treatment, since transfusion can increase blood viscosity and worsen symptoms.

LABORATORY ABNORMALITIES IN HYPERLEUKOCYTOSIS

Pseudohyperkalemia can be present in patients with a high white blood count secondary to breakdown of white cells in vitro with subsequent release of potassium.² Other spurious laboratory data that can be seen in association with hyperleukocytosis include a falsely elevated platelet count (secondary to white cell fragments), pseudohypoxemia (secondary to oxygen consumption by leukocyte cells), falsely prolonged coagulation tests, and pseudohypoglycemia.^{4,21-24} Pseudohypoxemia and pseudohypoglycemia can be avoided by placing samples on ice and performing tests immediately.^{4,14}

TUMOR LYSIS

Tumor lysis syndrome is usually seen 1–5 days after the initiation of chemotherapy in patients with AML and high circulating blast counts.²⁵ In response to chemotherapy, leukemic cells lyse, leading to hyperphosphatemia, hyperkalemia (or hypokalemia), hypocalcemia, an elevated lactate dehydrogenase (LDH), and hyperuricemia. Hyperuricemia results from breakdown of nucleotide precursors in leukemic cells to hypoxanthine and xanthine, and subsequent conversion to uric acid.²⁵ Renal failure can occur secondary to precipitation of calcium phosphate crystals or uric acid in the renal tubules.²⁵⁻²⁸ Patients at risk for tumor lysis should be aggressively hydrated and started on allopurinol. Allopurinol, an inhibitor of xanthine oxidase, decreases the production of uric acid.²⁵ Rasburicase, a novel recombinant form of urate oxidase, converts uric acid to allantoin.²⁵ Allantoin is five to ten times more soluble than uric acid, thus allowing for more rapid urinary excretion.^{25,29} Rasburicase should be considered for patients with renal dysfunction or high serum uric acid (i.e., >10).²⁵ The drug should not be administered to patients with G6PD deficiency, as an

additional by-product of the drug is hydrogen peroxide, which can lead to hemolytic anemia or methemoglobinemia in these patients.²⁵ Alkalinizing the urine may also increase the solubility of uric acid.^{25,30} Electrolytes, uric acid, and LDH should be monitored carefully in tumor lysis syndrome.²⁵ Any electrolyte abnormalities should be corrected appropriately.

CLINICAL FEATURES ASSOCIATED WITH SPECIFIC AML SUBTYPES AND/OR CYTOGENETIC ABNORMALITIES

ACUTE MYELOID LEUKEMIA WITH INV(16) OR VARIANT

AML with inv(16) is characterized by abnormal bone marrow eosinophilic precursors. Most will be associated with a pericentric inversion of chromosome 16.³¹ Less commonly, patients will have a translocation between two homologous of chromosome 16.³¹ CD2 is often aberrantly expressed.¹⁷ Associated clinical features include a good prognosis with high-dose cytarabine, hyperleukocytosis, young age at diagnosis, and an increased risk for CNS involvement.^{17,32-34} Extramedullary sites of disease, including cervicotonillar involvement and generalized lymphadenopathy, are particularly common, with a 33% incidence.¹⁷ An increased incidence of acute pulmonary syndrome (pulmonary infiltrates, hypoxia, fever, and impending respiratory failure) has also been reported in patients with AML and inv(16) (54%) versus patients with the same diagnosis but without inv(16) (9%).³⁵

ERYTHROLEUKEMIA

Erythroleukemia can occasionally be familial.³⁶⁻³⁸ Signs or symptoms which occur more commonly with this subtype include synovitis, serositis, effusions, bone pain, and immunologic abnormalities.^{4,36,39} Rheumatologic symptoms tend to respond to anti-inflammatory agents.^{36,39} Specific immunologic abnormalities include hypergammaglobulinemia, a positive Coombs test, a positive antinuclear antibody test, and an elevated rheumatoid factor titer.^{36,39} Cytogenetics demonstrate aneuploidy in almost two-thirds of patients.^{4,40,41}

ACUTE MEGAKARYOCYTIC LEUKEMIA

Patients with acute megakaryocytic leukemia rarely present with high blast counts or extramedullary involvement.³⁶ Platelet counts are often normal or elevated at presentation,³⁶ while LDH levels are usually markedly elevated, with an isomorphic pattern.^{36,42} Osteosclerotic and osteolytic lesions may be present.^{4,43,44} Acute megakaryocytic leukemia in infants is associated with a t(1;22)(p13;q13) abnormality.^{4,45} This translocation involves fusion of OTT on chromosome 1 with MAL on chromosome 22, thus leading to

activation of platelet-derived growth factor.^{4,46} This activation may lead to the megakaryocytic proliferation and fibrosis seen in acute megakaryocytic leukemia.^{4,46} These infants present with extensive organomegaly.⁴ Acute megakaryocytic leukemia is also the most common acute leukemia seen in patients with Down syndrome^{47,48} and may be transient, resolving spontaneously.

ACUTE BASOPHILIC LEUKEMIA

This leukemia often arises from a blast crisis of CML.^{36,49} Patients may present with increased histamine levels and urticaria.³⁶ By flow cytometry, many cases will express CD9 and some will express CD7 or CD10.^{10,50}

SECONDARY LEUKEMIAS

Secondary leukemias are classified as a distinct type of AML in the new WHO classification. They may develop in patients with a preceding hematologic disorder [including myelodysplasia (MDS)], inherited genetic disorder (Bloom or Fanconi anemia), or history of exposure to radiation or chemotherapy.³ Leukemias secondary to chemotherapy fall into two major categories: those associated with topoisomerase inhibitors and those associated with alkylating agents. Chromosomal translocation 6, involving the mixed lineage leukemia (MLL) gene at 11q23 are significantly associated with secondary leukemias.⁵¹ Eighty-five percent of AML cases with 11q23 abnormalities develop after exposure to topoisomerase II inhibitors, such as etoposide.³ The leukemias are most often monocytic or myelomonocytic in lineage, occur shortly after chemotherapy (2–3 years), and usually are not preceded by MDS.³ Three to ten percent of patients who receive alkylating agents as part of their therapy for Hodgkin's disease, non-Hodgkin's lymphoma, ovarian cancer, breast cancer, or multiple myeloma develop secondary AML.^{3,52} The incidence of this leukemia peaks at 5–10 years after treatment, is often preceded by MDS, and is characterized by deletions of chromosomes 5 and/or 7.^{3,53-55}

NATURAL KILLER CELL ACUTE LEUKEMIA

This form of leukemia typically falls under M0 [in the French—American—British (FAB) classification] or AML minimally differentiated (WHO classification). It is characterized by a unique immunophenotype, with both myeloid and natural killer cell markers, suggesting that it arises from a precursor common to both natural killer cell and myeloid lineages.⁵⁶ The typical immunophenotype is CD33⁺, CD56⁺, CD11a⁺, CD13^{lo}, CD15^{lo}, CD34[±], HLA-DR⁻, CD16⁻.⁵⁶ Morphologically, the cells have deep invaginations in the nuclear membrane, scant cytoplasm, and fine azurophilic granules.⁵⁶ These granules often stain positive for myeloperoxidase and Sudan black B.⁵⁶ Because of the

morphology and absence of HLA-DR on flow cytometry, this entity can sometimes be confused with the microgranular variant of acute promyelocytic leukemia (APL).⁵⁶ However, it lacks the characteristic translocation [t(15;17)] and patients tend to have a poor prognosis.⁵⁶

DIABETES INSIPIDUS

Diabetes insipidus is a rare complication of AML.⁵⁷ Patients present with polyuria, polydipsia, and a low-serum antidiuretic hormone (ADH) level.⁵⁸ Cytogenetic abnormalities associated with cases in the literature include monosomy 7, deletions of chromosome 7, and chromosome 3 abnormalities.^{57,59} The reason for these specific associations is unknown.⁵⁷ However, the proposed mechanism involves leukemic infiltration of the neurohypophysis. Magnetic resonance imaging (MRI) demonstrates a “bright spot” in the neurohypophysis prior to treatment.⁵⁹ Both MRI findings and ADH release subsequently resolve after chemotherapy.⁵⁹

THROMBOCYTOSIS

Thrombocytosis is rare in AML, and when seen it is usually associated with chromosome 3q abnormalities.⁶⁰ Platelet counts as high as 1 million/mm³ have been reported.^{60–62} Typically, patients are asymptomatic,⁶⁰ and may have a preceding history of MDS.⁴ Expression of the *EVI 1* gene (3q26.2) is thought to be involved.^{4,63,64}

COAGULOPATHY

Coagulopathy is most commonly associated with APL, which is characterized by the cytogenetic abnormality t(15;17) or variant. Although APL is the most curable subtype of AML in adults, it needs to be recognized and treated immediately because of the risks of significant bleeding.⁶⁵ Patients with coagulopathy should be transfused to keep their platelets above 50,000/mm³ and transfused with cryoprecipitate to keep their fibrinogen within the lower limits of normal. Fresh frozen plasma should be used to correct an abnormal prothrombin time or partial thromboplastin time. Heparin and antifibrinolytics, such as amicar, do not have a standard role in the treatment of APL-induced coagulopathy, as trials have demonstrated a similar rate of hemorrhagic death in patients with APL treated with heparin, antifibrinolytics, or supportive care.^{66,67} Initially, it was thought that the coagulopathy in APL was secondary to release of granules from the leukemic promyelocytes.^{36,68,69} However, it is more likely that the coagulopathy is secondary to release of plasminogen activator from leukemic cells; while there is no increase in platelet turnover, there is an increase in fibrinogen turnover and an increase in fibrin/fibrinogen degradation products with a decrease in α_2 -antiplasmin levels, suggesting activation of plasmin.^{36,70–74} Recent data suggest that annexin II, a receptor for fibrinolytic proteins, is increased in patients with APL.⁷⁵

High levels of annexin increase the production of plasmin.⁷⁵ All-*trans*-retinoic acid (ATRA) should be initiated concurrent with chemotherapy in patients with APL. ATRA induces differentiation of leukemic cells into mature granulocytes and decreases the incidence of coagulation and bleeding.⁷⁶ In addition, ATRA blocks annexin II messenger RNA production through a transcriptional mechanism.⁷⁵ Patients with the microgranular variant of APL tend to present with hyperleukocytosis in addition to coagulopathy.⁷⁷ Coagulopathy can also occur in the other subtypes of AML, especially the monocytic forms and patients with high white blood cell counts.³⁶

HYPOKALEMIA

Hypokalemia occurs more frequently in patients with monocytic and monoblastic leukemias.³⁶ The mechanism involves excess lysozyme (muramidase) production, which may damage the proximal renal tubule, leading to proximal renal tubular acidosis and hypokalemia.⁴

MAKING THE DIAGNOSIS

On a routine complete blood count (CBC), most patients with AML are anemic and thrombocytopenic.⁷⁸ The white blood count is variable, with 20% of patients having white blood counts less than 5000/mm³ and 20% of patients with white blood counts greater than 100,000/mm³.⁷⁸ High white blood counts and hyperleukocytosis are more common in the monocytic leukemias.^{36,79} Although blasts are usually present in the peripheral blood, a subset of patients present with “aleukemic leukemia.”

A review of the peripheral blood film and a bone marrow aspirate/biopsy is part of the initial diagnostic work-up and is essential for distinguishing AML from other hematologic disorders such as ALL, MDS, or AML arising in the setting of MDS (Table 3.1).³ Occasionally, immature blasts can be confused with metastatic carcinoma, plasma cell neoplasms, or lymphoma.⁷⁷ The peripheral blood film and bone marrow slides should be air-dried and stained with a polychrome dye such as Wright–Giesma.¹²

Based on the new WHO criteria, the diagnosis of AML is made when at least 20% of nucleated cells in the bone marrow or peripheral blood are myeloid blasts.¹¹ The previous FAB classification system required 30% blasts to make a diagnosis of AML. The major reason for lowering the blast threshold is that patients with 20–30% blasts (previously considered as RAEB-t, refractory anemia with excess blasts in transformation) have an identical prognosis to those with 30% blasts.² The percentage of blasts should be determined on a 500 cell count on well-stained bone marrow aspirate slides or a 200 cell differential on peripheral blood smears.^{10,11} In certain

Table 3.1 Specimen submission requirements and diagnostic utility

Diagnostic study	Specimen requirements	Tests performed	Diagnostic utility	Comments
CBC and differential	2.5 mL whole blood in 4 mL (EDTA) lavender top tube. Fill tube to at least half of fill volume	Automated CBC with differential; manual review of smear	Determine absolute leukocyte count and blast count; assess for anemia and thrombocytopenia; evaluate blast morphology; rule out quantitative or qualitative abnormalities in other cell types, including dysplastic features, presence of nucleated red blood cells, and/or microangiopathic changes	Blood remaining after CBC may be used for cytochemistry, flow cytometry, and molecular analysis
Bone marrow aspirate	Bone marrow aspirate smears with extra unstained smears for cytochemistry, iron stain, or other studies as necessary	Wright–Giemsa stain for routine morphology and cell differential count	Determine blast percentage and evaluate blast morphology; assess quantitative and qualitative abnormalities in myeloid, erythroid, and megakaryocytic lineages	High quality smears are essential for accurate diagnosis; iron stain useful to assess iron stores and presence of ringed sideroblasts; make touch preps of biopsy if dry tap
Bone marrow biopsy	Bone marrow core biopsy ideally >1 cm in length. Place in appropriate fixative (B5, acid zinc formalin, or buffered formalin)	Hematoxylin–eosin stain for routine histologic examination with immunostains (CD34, TdT, CD79a, Hgb, CD20, CD3, MPO, CD61, CD10, and CD31) as necessary	Determine overall cellularity and percentage and lineage of blasts; assess residual normal hematopoietic elements; evaluate for associated fibrosis and/or dysplastic features; rule out associated disorders that mimic leukemia	Immunostains may aid in diagnosis, especially in the absence of flow cytometry (dry tap)
Cytochemical stains	Unfixed, fresh air-dried bone marrow aspirate smears	May include MPO, nonspecific esterase, chloroacetate esterase, PAS, and Sudan black B	Assess lineage and differentiation of blasts. MPO and Sudan black B are used as sensitive markers of myeloid differentiation (positive defined as staining $\geq 3\%$ blasts). Nonspecific esterase is a marker of monocytic differentiation. Abnormal erythroid precursors show “block-like” cytoplasmic staining with PAS	Negative MPO and/or SBB stains do not exclude a diagnosis of AML; enzyme activity degrades over time, so fresh unfixed material is necessary

table continues

Table 3.1 continued				
Diagnostic study	Specimen requirements	Tests performed	Diagnostic utility	Comments
Flow cytometry	4 mL bone marrow in 4 mL (EDTA) lavender top tube; 4 mL whole blood in 4 mL (EDTA) lavender top tube, 7 mL (ACD) yellow top tube or 4 mL heparinized (sodium or lithium) green top tube; or 4 mL bone marrow in a heparinized syringe or heparinized green top tube. Store at room temperature. Samples should be <30 h old	Usually includes CD45 with myeloid markers CD13, CD33, CD117, and CD65; monocytic marker CD14; T- cell markers CD2, CD5, and CD7; B- cell markers CD19, and CD20; non-lineage- specific markers HLA-DR, CD10, CD34, and TdT; NK cell marker CD56; megakaryocytic marker CD61; may also include CD79a, cCD22, cCD3, cIgM, sIgM, and MPO	Determine lineage of blasts and evaluate for aberrant antigen expression; rule out precursor T or precursor B acute lymphoblastic leukemias and acute leukemia of ambiguous lineage. Baseline phenotype of blasts may be helpful for excluding relapse or monitoring minimal residual disease following treatment	Bone marrow aspirate is preferred. Helps in recognition of minimally differentiated AML; immunophenotypic patterns can help identify AML with t(8;21) and t(15;17). Blast percentage by flow cytometry may not correlate with aspirate smear if hemodilute sample submitted
Cytogenetics	2–3 mL bone marrow in 4 mL heparinized (sodium) green top tube. Peripheral blood may be alternate sample if circulating immature cells present (>1,000/ μ L). Store at room temperature; do not refrigerate or freeze	GTG-banded chromosome analysis; minimum 20 metaphases analyzed (when available)	Gives global information about cell karyotype; identifies nonrandom abnormalities with prognostic significance	First pull of aspirate preferred. Do not collect specimen in lithium heparin or EDTA. Excess cells from cytogenetics may be used for FISH analysis
Molecular analysis by FISH	8 mL whole blood in two 4 mL (EDTA) lavender top tubes; 4 mL bone marrow from (EDTA) lavender top tube	May include BCR-ABL, t(15;17), t(8;21), inv(16), MLL rearrangement, and RAR α rearrangement	Gives specific information about presence or absence of a particular genetic abnormality	Helpful at diagnosis, especially when cytogenetic sample not submitted or no growth
Molecular analysis by polymerase chain reaction (PCR)	5 mL whole blood in (EDTA) lavender top tube; 2–3 mL bone marrow in (EDTA) lavender top tube; refrigerate	May include t(9;22), t(15;17), inv(16), t(8;21), MLL rearrangement, and FLT3 rearrangement, as necessary	Gives specific information about presence or absence of a particular genetic abnormality. Helpful for minimal residual disease monitoring	Heparinized tube unacceptable due to interference with PCR

circumstances, 20% blasts are not needed for the diagnosis. For example, cases with *inv(16)*, *t(8;21)* or *t(15;17)* are diagnosed as acute myeloid leukemia regardless of blast percentage according to WHO guidelines. In acute monocytic and myelomonocytic leukemias, promonocytes are also counted as monoblasts for the diagnosis.^{10,11,81} In acute erythroleukemia, blasts are counted as a percentage of non-erythroid cell if erythroid precursors marrow comprise >50% of the differential count.

On morphologic review, myeloblasts in patients with AML typically have delicate nuclear chromatin, three to five nucleoli, and a variable number of fine myeloperoxidase granules in the cytoplasm⁸² (Figure 3.1). Auer rods (azurophilic granules within lysozymes) are pathognomonic for AML³ (Figure 3.2). “Faggot cells,” blast with bundles of Auer rods, are also characteristic in certain AML subtypes (AML with maturation and APL).³⁶ Phi bodies, fusiform or spindle-shaped rods, which are similar to Auer rods and stain with myeloperoxidase, may also be present.^{4,83}

Other AML subtypes may have distinct morphologic features in the blood and bone marrow. In the monocytic/monoblastic subtype of AML, the nucleus of the monoblasts is often indented and contains one to four large nucleoli.³⁶ A moderate amount of cytoplasm is present (Figure 3.3). Patients with acute myelomonocytic leukemia often have a significant monocytosis in the peripheral blood.¹⁰ Acute myeloid

leukemia with *inv(16)*, is characterized by abnormal eosinophils.^{36,84,85} In acute erythroleukemia, abnormal erythroblasts with giant multinucleate forms, nuclear budding, and nuclear fragmentation are found in the bone marrow.³⁶ (Figure 3.4). On review of a peripheral blood film, nucleated red blood cells are often present.^{36,86,87} Bone marrow fibrosis, which can make bone marrow aspiration difficult, is typical of acute megakaryoblastic leukemia and acute panmyelosis with myelofibrosis.^{10,47} Megakaryoblasts in acute megakaryoblastic leukemia typically have a high nuclear/cytoplasmic ratio, varying size, and pale agranular cytoplasm.³⁶ Malignant proliferation of all three myeloid cell lines is present in acute panmyelosis with myelofibrosis.¹⁰ Finally, acute basophilic leukemia is characterized by striking basophilic granularity in myelocytes, and cells stain strongly with toluidine blue.³⁶

MDS is differentiated from AML on the basis of percentage of blasts in the bone marrow. AML arising from MDS is characterized by dysplastic maturation of the hematopoietic precursors and certain chromosomal abnormalities (such as loss of part or all of chromosome 5 or 7).³ In addition, patients may have a preceding history of low blood counts. AML can often be differentiated from ALL on morphologic grounds. Lymphoblasts tend to be smaller in size, with little cytoplasm and indistinct nucleoli.⁷⁷

Figure 3.1 Acute myeloid leukemia with *t(8;21)(q22;q22)*: Peripheral blood smear shows a blast with an Auer rod (arrow) and a neutrophil with characteristic salmon-colored cytoplasmic granules (upper left); bone marrow aspirate shows blasts admixed with maturing myeloid cells (bottom left); and bone marrow biopsy is hypercellular with blasts admixed with maturing myeloid cells and eosinophils. (Wright–Giemsa stain, left panels; hematoxylin–eosin stain, right panel)

Figure 3.2 Acute myeloid leukemia with $t(15;17)(q22;q21)$: Features of blasts include multiple Auer rods (upper left), hypergranular cytoplasm (lower left), and bilobed nuclei (upper and lower right panels). This leukemia is often associated with a low white blood cell count, and characteristic blasts containing multiple Auer rods may require a careful search to identify. (Wright–Giemsa stain)

Figure 3.3 Acute monoblastic leukemia: Blasts have moderate amounts of cytoplasm and nuclei with one to two nucleoli (left panel). Monocytic differentiation is demonstrated in the blasts by positive cytochemical stain for nonspecific esterase as shown by red-brown cytoplasmic staining (right panel). (Wright–Giemsa stain, left panel; nonspecific esterase stain [α -naphthyl butyrate], right panel)

Figure 3.4 Acute erythroleukemia: An increase in erythroid elements with dysplastic features including megaloblastoid chromatin and nuclear fragmentation is evident in this bone marrow aspirate smear (left panel). PAS stain is useful to identify abnormal “blocklike” cytoplasmic staining in immature erythroid precursors (right panel). (Wright–Giemsa stain, left panel; PAS stain, right panel)

However, immunophenotyping and immunohistochemistry are used to make a definitive diagnosis. By flow cytometry, myeloblasts usually express the cell surface antigen markers CD13 and CD33. Cells of myeloid origin usually will be myeloperoxidase positive by cytochemical or immunostains.¹⁰ In minimally differentiated AML (M0), blasts do not express myeloperoxidase cytochemically; however, they are myeloid antigen positive (CD13 and CD33) based on flow cytometry.⁸²

When performing a bone marrow aspirate, a small amount of the first pull of the aspirate should be placed on a slide, as hemodilution may make it difficult to interpret the aspirate. At least 5 mL of aspirate should be sent in heparinized tubes for flow cytometry and cytogenetics. If an aspirate cannot be obtained secondary to fibrosis or a “packed” marrow, these studies can be performed on the peripheral blood if enough peripheral blasts are present. Flow cytometry can also be attempted on a biopsy specimen by performing an extra biopsy, placing the sample in saline, and “teasing” the cells from the marrow. Although bone marrow aspirates are usually obtained from the posterior iliac crest, a sternal aspirate can be performed if a sample cannot be obtained. Immunophenotyping by flow cytometry is helpful in diagnosing and subclassifying AML.⁸⁸ The most commonly used monoclonal

antibodies in the diagnosis of AML are CD13, CD14, CD15, CD33, CD34, and HLA-DR⁴⁷: CD13 and CD33 both are myeloid markers; CD34 and HLA-DR both are stem cell markers; CD14, monocytic; and CD15, myeloid-granulocytic.⁸⁹ Myeloid antigens such as CD14, CD15, and CD11b expressed on more differentiated myeloid cells may be found in AMLs with myeloid or monocytic maturation.⁹⁰ CD14 and CD64 are the best markers for monocytic differentiation.^{10,91} The platelet glycoproteins CD41, CD42, and CD61 are usually present in acute megakaryocytic leukemia.^{47,92} Flow cytometry may be particularly helpful in diagnosing the microgranular variant of APL. With the microgranular variant, granules are not readily seen by light microscopy⁷⁷ (Figure 3.5). However, unlike the other AMLs, APL is both CD34 negative and HLA-DR negative by flow cytometry.⁴⁷ In certain instances, flow cytometry may also provide prognostic information. The presence of CD56 in both M2 and M3 AML appears to correlate with adverse prognosis.^{88,93–96}

Immunostains used in evaluating bone marrow biopsies include myeloperoxidase (myeloid), hemoglobin A (erythroid), and CD34, CD79a, CD61, TdT (PAS, non-specific esterase are cytochemical stains, not immunostains). Biopsies can be stained for these markers if an aspirate for flow cytometry cannot be obtained to better subclassify the AML.

Figure 3.5 Acute myeloid leukemia with $t(15;17)(q22;q21)$: The hypogranular variant is often associated with an elevated white blood count with most blasts having lightly granular to almost agranular cytoplasm, but still retaining the typical bilobed nucleus (left panel). A cytochemical stain for myeloperoxidase (right panel) demonstrates intense cytoplasmic positivity as shown by blue-black granules. (Wright–Giemsa stain, left panel; myeloperoxidase stain, right panel)

Cytogenetics are needed to assess prognosis, risk-adapt therapy, as well as to subclassify the AML. Cytogenetic abnormalities most commonly involve translocations and inversions of genes encoding transcription regulators.⁹⁷ Particular cytogenetic abnormalities are associated with specific clinical features and prognosis. Based on the new WHO classification, AML with specific cytogenetic abnormalities [t(8;21) (q22;q22), t(15;17)(q22;q21), 11q23 abnormalities, and variants inv(16)(p13q22) and t(16;16)(p13;q22)] are classified as AML independently of the proportion of blasts in the bone marrow¹² (Figure 3.6). Fluorescence in situ hybridization (FISH) for t(15;17) inv(16), t(8;21) or 11q23 rearrangement should be performed if there is suspicion for one of these rearrangements, especially if cytogenetics are normal or unsuccessful since identification of an abnormality can affect both prognosis and therapy. FISH can be more rapid and sensitive than routine cytogenetics. In the future, other molecular markers, such as the presence or absence of fms-like tyrosine kinase 3 (FLT3) and assessment of multidrug resistance markers may become a standard part of the initial evaluation.

THE FAB AND WHO CLASSIFICATION OF AML

The FAB classification was composed of eight AML subtypes: M0–M7. These subtypes were distinguished based on both the degree of differentiation and the cell lineage.³ Cytochemical stains, including myeloperoxidase, nonspecific esterase, and sudan black B, were used in conjunction with morphology to identify the subtype.⁴⁷ This classification system did not require immunophenotyping to make a diagnosis, except in the M0 subtype (minimally differentiated AML subtype). Cytogenetics were also not incorporated into this classification system. The WHO classification system differs from the FAB classification in several aspects. The blast percentage for AML is decreased from 30 to 20%. In addition, biological, clinical, and prognostic markers (such as cytogenetics) are incorporated into the classification. Such factors allow us to better define the disease and risk-adapt therapy. The new WHO classification for AML recognizes four distinct entities: (1) AML with specific cytogenetic abnormalities, (2) AML with multilineage dysplasia

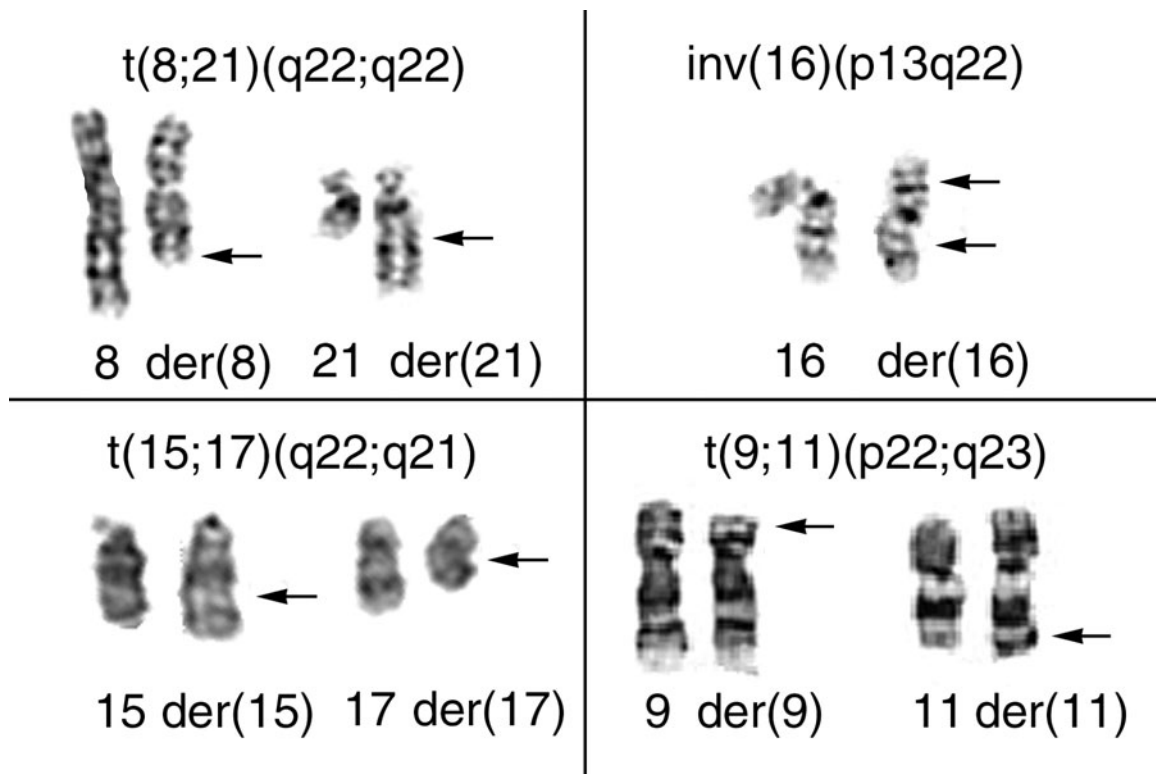

Figure 3.6 Critical nonrandom chromosome abnormalities that define disease subtypes included in the WHO entity “acute myeloid leukemia with recurrent genetic abnormalities” include $t(8;21)$, $t(15;17)$ and variants, $inv(16)$ and variants, and $11q23$ abnormalities. For each pair of GTG-banded chromosomes shown, the normal homologues are shown on the left, and abnormal homologues on the right; arrows mark chromosome breakpoints. These abnormalities can also be detected by molecular methods, including RT-PCR and FISH

(with or without prior MDS), (3) therapy-related AML and MDS (alkylating-agent-related or epipodophyllo-toxin-related), and (4) AML not otherwise classifiable.^{1,12,98,99}

OTHER ACUTE LEUKEMIA ENTITIES

In addition to diagnosing and subclassifying AML, flow cytometry is needed to recognize the entities of undifferentiated acute leukemia, bilineage leukemia, and biphenotypic leukemia.¹⁰ Lineage-specific antigens include myeloperoxidase (myeloid), cytoplasmic CD3 (T-lymphoblasts), cytoplasmic CD22 (B-lymphoblasts), cytoplasmic IgM (B-lymphoblasts) and cytoplasmic CD79a (B-cell lymphoblasts).¹² In undifferentiated acute leukemias, no lineage-specific antigen is detected,¹⁰ and often only one lineage-associated antigen (such as CD13 or CD33) is positive by flow.¹⁰ Non-lineage specific primitive stem cell markers, such as CD34, CD38, and HLA-DR, may be present.⁹⁰

Bilineage leukemia occurs when blasts derive from two distinct lineages.¹⁰ These leukemias are sometimes associated with the Philadelphia chromosome, $t(9;22)$, or the MLL gene, $11q23$.⁹⁰

In biphenotypic leukemias, blasts are positive for two or three distinct lineages on the same cell.¹⁰ Specific criteria are used to make this diagnosis. One commonly used scoring system is the Royal Marsden criteria.^{12,100} Blasts with greater than two points for two or more lineages are considered biphenotypic,¹² and are considered distinct from AML with aberrant coexpression of lymphoid markers.⁸⁸ CD7 is the most frequent lymphoid-associated antigen expressed in such cases.⁸⁸

CLINICAL WORK-UP

A full history and physical examination should be performed with special attention to any preceding history of blood disorder or malignancy, past chemotherapy or radiation treatments, occupational exposure, family history, general performance status, age of the patient, signs/symptoms of infection, and extramedullary signs of leukemia involvement. Risk factors associated with adverse outcome in AML include age greater than 60 years, poor performance status, secondary AML, white blood count greater than $30,000/\text{mm}^3$ and an elevated LDH.^{1,3,101} Tests performed at diagnosis should include a CBC with differential, comprehensive metabolic

panel, uric acid, LDH, prothrombin time, partial thromboplastin time, fibrinogen, and chest X-ray (with posterior anterior and lateral views). HLA typing (serology) should also be performed in case a patient becomes alloimmunized to random donor platelet transfusions and requires HLA-matched platelets during his or her treatment course. HLA typing at the DNA level should be performed on any patient who may be a stem cell transplant candidate in the future. It is best for HLA typing to be done prior to the initiation of chemotherapy, when more cells are present. A multiple gated acquisition scan should be done to assess cardiac function, as induction chemotherapy regimens for AML include an anthracycline. In addition, an indwelling venous catheter (i.e., Hickman catheter) should be placed for blood draws, blood product transfusions, fluid management, and antibiotic administration.² A lumbar puncture is not a routine part of the work-up unless there is clinical suspicion for CNS leukemia.

Patients who are neutropenic and febrile should have blood cultures drawn and should be started on appropriate broad-spectrum antibiotics. Most patients will also require transfusions of packed red cells and

platelets because of their anemia and thrombocytopenia. Blood products should be leukoreduced to prevent transmission of cytomegalovirus, alloimmunization, and to decrease the risk of nonhemolytic febrile transfusion reactions.⁷⁸ Products should be irradiated to prevent the risk of graft-versus-host disease from the blood products themselves, especially if the patient is a potential stem cell transplant candidate.⁷⁸ Pooled random donor platelets (with exposure to six to eight donors per transfusion) are used initially, and single donor or HLA-matched platelets are used if patients become refractory to pooled platelets.¹⁰² Patients who are not bleeding and are not having procedures done should be transfused for platelet counts less than or equal to 10,000/mm³.^{102,103} Hydration and allopurinol should be initiated to decrease the risk of tumor lysis syndrome in patients with high circulating blast counts. It is important to have a frank discussion with the patient prior to treatment regarding the diagnosis, prognosis, tests needed for work-up, length of hospitalization, potential complications of treatment, need for transfusions, and treatment plan.

Chapter 4

TREATMENT FOR ACUTE MYELOID LEUKEMIA IN PATIENTS UNDER AGE 60

Richard M. Stone

INTRODUCTION

Acute myeloid leukemia (AML) is a disorder characterized by a malignancy of the bone marrow stem cell at either a pluripotent or committed stage of development, which leads to an overproliferation of leukemic cells (blasts), which can be shown to have either cytochemical and/or immunophenotypic features of myeloid (including monocytoid, erythroid, or megakaryocytic) lineage. A brief list of the pathophysiologic abnormalities leading to this malignancy include unbridled proliferation, failure to undergo normal maturation, the inability to undergo programmed cell death, and overreliance on angiogenic mechanisms. The disordered growth in the myeloid stem cell compartment leads to the patient's death from bone marrow failure, unless a successful therapeutic strategy is employed. The fundamental differences in disease biology and clinical response between AML arising in younger (generally considered to be less than 60 years in age) versus older adults have led to different therapeutic approaches in these groups. This chapter deals with the therapeutic strategies available for those younger adults who are by and large able to withstand (and benefit from) intensive chemotherapy and stem cell transplantation.

The major challenge in the management of the adult, age 18–60 years, with AML is to employ the available therapies in a fashion that will maximize the chance of a cure for any individual. The chance of long-term disease-free survival for an adult in this age group today is approximately 33%.^{1,2} However, our recent knowledge of risk at presentation, largely due to chromosome findings at diagnosis, suggests that some patients with AML can expect long-term disease-free survival rates in the range of 70%, while others are rarely cured.³ These vastly different prior probabilities of success with available therapy suggest that, with appropriate use of so-called risk-adapted approaches,

one could prevent overtreatment in the good prognosis groups and maximize treatment in those destined to do poorly. Moreover, increasing knowledge about the specific pathophysiological events at the genetic level⁴ also gives rise to the hope that therapy could target the specific genetic lesion or lesions in a given patient's leukemic cells, thereby improving the therapeutic index and leading to a higher cure rate with less toxicity.

DIAGNOSIS AND CLASSIFICATION

Once the diagnosis of acute leukemia is suspected on the basis of abnormal blood counts, immature cells appearing in the peripheral blood differential, or the finding of extramedullary leukemia (especially in central nervous system, gums, or meninges, particularly in patients with monocytic subtypes), one should undertake a full diagnostic work-up that includes delineation of the AML subtype, as well as the definition of the risk group. In fact, the classification system for AML is evolving from the cytochemical and morphologically based French—American—British scheme⁵ to the cytogenetically centered World Health Organization (WHO) system.⁶ The WHO classification system acknowledges the critical impact of cytogenetics on prognosis as well as our improved pathophysiological understanding based on genes at balanced translocation breakpoints.

Although most subtypes of AML are treated in a similar fashion at least initially, it is important to recognize the 10–15% of AML patients who have acute promyelocytic leukemia (APL),⁷ characterized by malignant cells that appear as heavily granule-laden malignant promyelocytes with frequent Auer rods. These heavily myeloperoxidase-positive APL cells generally possess the characteristic t(15;17) cytogenetic abnormality, with a resultant PML-RARA rearrangement detectable

on reverse transcription polymerase chain reaction analysis. APL is treated in a distinct fashion (see Chapter 6).

In addition to the definition of the AML subtype and risk strata, it is imperative to assess the underlying medical state of the patient, determining if any issues such as cardiac, renal, or pulmonary dysfunction might compromise the ultimate therapeutic plan. Finally, given the possibility that the patient might become a candidate for allogeneic stem cell transplant at some point, patient and sibling HLA typing should be carried out shortly after diagnosis.

TREATMENT STRATEGIES

INTRODUCTION

Historically, the treatment of newly diagnosed AML is divided into phases. Induction therapy is given to patients to reduce the tumor burden at diagnosis, presumed to be 10^{12} cells (1 kg), by approximately three orders of magnitude down to a level at which leukemic cells are no longer detectable in the blood or bone marrow. Although the definition of complete remission⁸ has undergone some degree of evolution, in general, the reduction in leukemic cells should occur concomitantly with the resumption of normal hematopoiesis and reasonably normal blood counts. Induction chemotherapy usually is given over approximately 1 week. During that time, patients are monitored carefully for signs of tumor lysis syndrome,⁹ in which a rapid release of intracellular contents including potassium and phosphate may cause hyperkalemia, hyperphosphatemia, and secondary hypocalcemia. Secondly, the large load of purine metabolites can lead to high uric acid levels, with the development of renal failure on the basis of urate nephropathy.⁹ Tumor lysis syndrome is much less common in AML than in the somewhat more chemotherapy-sensitive lymphoproliferative leukemias, but it is generally accepted that AML patients should receive IV fluids and allopurinol to help prevent this complication. Alkalinization of the urine with the administration of intravenous sodium bicarbonate to maintain uric acid in its more soluble urate form is generally not necessary or advisable. The lysis of leukemic cells can result in exposure to tissue factor and other procoagulants, causing disseminated intravascular coagulopathy (especially in APL),¹⁰ with associated bleeding and/or thrombosis.

Certain patients with AML, particularly those with monocytic subtypes (whose blasts tend to be “sticky”), who present with an absolute blast count of 75,000/uL or greater can experience life-threatening problems with leukostasis. Such complications could include cerebral or pulmonary dysfunction due to plugging of small capillaries in these organs. Treatment for this actual or impending condition is

aggressive use of intravenous hydration and cytoreductive measures: usually hydroxyurea¹¹ and occasionally leukopheresis.

Complete remission is usually achieved 4–6 weeks after beginning induction chemotherapy. At that time, patients generally have recovered from the nonhematologic toxicities of induction chemotherapy, including gastrointestinal and integumentary disruption. After a 1–3-week rest, postremission chemotherapy should be administered to reduce the residual undetectable leukemic burden down to a level compatible with cure. The optimal strategy to achieve such a reduction in residual leukemic cells is controversial; the three major options being several cycles of intensive postremission chemotherapy, high-dose chemotherapy with autologous stem cell rescue (sometimes termed “autotransplant”¹²), and allogeneic transplant from a histocompatible sibling or unrelated donor. While perhaps not completely proven by prospective clinical trials, the choice amongst these options is generally based, at least in part, on the cytogenetic findings at diagnosis.³ The overall goal of induction and postremission therapy is to prevent leukemic relapse. Just as in the case with failure to achieve remission with standard chemotherapy, a relapse generally signifies a chemotherapy-resistant leukemic cell. Patients may achieve a second complete remission after reinduction chemotherapy (more likely if the initial disease-free interval is greater than 1 year).^{13,14} Consolidation of such second remissions should include a high-dose approach (either an autologous or allogeneic transplant)^{15,16} if there is to be any possibility of long-term disease-free survival.

INDUCTION CHEMOTHERAPY

A disappointing fact concerning the treatment of younger adults with AML is that the agents used for induction therapy now are much the same as three decades ago. Three days of an anthracycline (generally, daunorubicin or idarubicin) in conjunction with 7 days of continuous infusional cytarabine (100–200 mg/m² per day)¹⁷ remains the standard approach. It has been the practice in the Cancer and Leukemia Group B (CALGB) and other cooperative groups to perform a bone marrow examination approximately 2 weeks after the start of induction chemotherapy.¹ If a sufficient degree of myeloblast reduction is not achieved, then 2 days of the same anthracycline and 5 days of cytarabine are administered as a reinduction cycle. Occasionally, serial bone marrows are necessary to clarify whether or not a reinduction cycle should be administered. Approximately 30% of younger adults with AML will require a second course (so-called “2 + 5” reinduction).¹ Although not certain, the requirement for such a reinduction may indicate a worse long-term prognosis.¹³ In contrast to a 20–25% death rate in older adults, the mortality associated with induction therapy in younger adults is generally under 10%.¹

Many attempts to modify or augment standard induction chemotherapy have been made without any clear improvements. Whether one anthracycline is better than another remains controversial. A trial comparing doxorubicin to daunorubicin during induction indicated that doxorubicin was associated with an increase in gastrointestinal complications, without an improvement in response.¹⁷ Several trials conducted in the 1980s^{18,19,20} reported a benefit to an idarubicin-based induction compared to daunorubicin; the improved results may have been due to a nonequivalence of the myelosuppressive dose of idarubicin. Although 6-thioguanine is widely used in the United Kingdom and throughout Europe,^{2,21} randomized trials comparing 3 + 7 with or without the addition of this agent have not shown a clear-cut benefit with the three-drug versus the two-drug approach.²¹ Given the success of high-dose cytarabine (at least 1–1.5 g/m² per dose) in the relapse²² and postremission settings,¹ investigators have tried to either substitute high-dose cytarabine for standard doses²³ or add high-dose cytarabine onto 3 + 7²⁴ during induction. Although a single institution trial demonstrated a 90% complete remission rate and a 50–60% long-term survival benefit with high-dose cytarabine added on to standard 3 + 7,²⁴ a cooperative group trial failed to show a benefit for the more aggressive induction.²⁵ The substitution of high-dose cytarabine for standard-dose cytarabine has also been attempted; although an improved disease-free survival was noted in certain subgroups, there was no clear overall survival benefit.²³ The addition of etoposide, tested by the Australian Leukemic Study Group, was also associated with an improved disease-free, but not an overall, survival advantage.²⁶ It is not clear whether induction therapies that are associated with a disease-free survival benefit, but not an overall survival benefit, are advantageous.

POSTREMISSION THERAPY

There is an absolute need to administer postremission chemotherapy in order to yield any chance for the patient to experience long-term disease-free survival. This fact was originally recognized after two trials in the 1970s showed that some chemotherapy led to at least a small long-term survival rate compared to no postremission chemotherapy in which virtually 100% of the patients succumbed to their disease.^{27,28} Given our understanding that remission is achieved at a relatively high leukemic burden, this is not surprising. Several studies in the 1980s solidified the concept that intensive chemotherapy represented the standard of care in postremission chemotherapy. High-dose cytarabine was recognized as being biochemically distinct from standard doses of cytarabine; patients resistant to standard-dose cytarabine could enter a remission when doses of 1.5 g/m² or greater were administered.²² A phase II study documented a 40% likelihood of long-term disease-free survival in

patients achieving remission who received high-dose cytarabine.²⁹ Two cooperative groups in the United States performed randomized trials in the 1980s, comparing standard doses of cytarabine to high-dose ara-C in the postremission setting.^{1,30} The Eastern Cooperative Oncology Group compared standard-dose ara-C to one cycle of high-dose ara-C and showed a superior disease-free survival in patients receiving the more intensive arm.³⁰ CACGB study 8525 probably represents the most important turning point in the chemotherapy-based approach to AML in the last 40 years.¹ In this trial, newly diagnosed patients with AML (adults of all ages) were enrolled and given standard 3 + 7 induction chemotherapy, with daunorubicin and cytarabine. Patients achieving remission were randomized to four cycles of either (a) ara-C at 100 mg/m² by continuous infusion for 5 days or (b) cytarabine at 400 mg/m² per day by continuous infusion for 5 days, or (c) high-dose cytarabine at 3g/m² over 3 h given q 12 h on days 1, 3, and 5 (total six doses). All patients then received an additional four cycles of outpatient daunorubicin for 1 day and low-dose cytarabine for 5 days at 100 mg/m² daily. In adults under the age of 60, the best results (superior disease-free and overall survival) were seen in those who were randomized to the high-dose cytarabine. The 45% long-term disease-free survival in such patients achieving remission was comparable to that observed with allogeneic stem cell transplant, and established high-dose cytarabine as the treatment of choice in the postremission setting.

Subsequent trials and practices have deviated from the precise schedule of postremission therapy in CALGB 8525. First, Bloomfield and colleagues showed that not all types of AML benefited equally from the intensive arm.³¹ Specifically, most of the benefits of high-dose cytarabine were noted in patients with inversion of chromosome 16 or t(8;21). Both of these abnormalities were recognized to confer a favorable prognosis³ and also to represent abnormalities of the core-binding factor heterodimer transcription factor.³² The precise reason why such patients' leukemic cells are so sensitive to intensive chemotherapy remains unknown, but the relatively good prognosis characteristic of these cytogenetic abnormalities has been documented in studies worldwide. Subsequent studies have shown that inversion 16 patients actually do somewhat better than those with t(8;21).³³ Also, clear from reanalysis of CALGB 8525^{1,31} and data from other sources³ is that a subgroup of patients (about 15% of the total) with complex abnormalities or deletion of all or part of chromosomes 5 and/or 7 has a poor prognosis even when intensive postremission chemotherapy is applied. In part because of the difficulty of administering four cycles of postremission intensive chemotherapy followed by four cycles of maintenance chemotherapy, subsequent studies conducted by the CALGB have employed three cycles of high-dose ara-C. It does seem

clear that at least three cycles of high-dose ara-C are required to obtain benefit in patients with good prognosis chromosomal abnormalities.³⁴

A subsequent CALGB trial randomized patients in remission to receive three cycles of high-dose ara-C or three cycles of a so-called noncross-resistant combination of chemotherapy regimens that included one cycle of etoposide/cyclophosphamide and one cycle of diaziquone (AZQ)/mitoxantrone. No relapse-free or overall survival differences in the randomized arms were seen.³⁵ While relatively long-term low-dose chemotherapy (maintenance chemotherapy) is routinely employed in the management of patients with acute lymphoblastic leukemia, its use in AML remains controversial. Whereas older studies failed to show benefit for patients receiving maintenance chemotherapy,³⁶ the good results seen in CALGB 8525 (in which patients received four cycles of a maintenance-type chemotherapy regimen) and recent results from the German Leukemia Cooperative Group³⁷ have suggested that reexploration of the role of maintenance chemotherapy in AML is appropriate.

Given the adoption of high-dose ara-C or similarly intense regimens as the standard of care for adults with AML, studies have attempted to understand the risk factors for high-dose ara-C-induced cerebellar toxicity^{38,39} and to define the role of stem cell transplantation compared to such intense therapy. Even though high-dose ara-C is useful and is associated with a much lower mortality rate than allogeneic stem cell transplantation, the associated neurotoxicity can be devastating, especially if irreversible, as is the case about 50% of the time. The incidence of high-dose ara-C-associated cerebellar toxicity can be lowered if older patients (who do not seem to benefit from this approach)^{1,40} and/or those with elevated serum creatinine or impaired liver function are given alternative postremission therapy.

ROLE OF HEMATOPOIETIC STEM CELL TRANSPLANTATION

Improvements in supportive care, as well as the use of high-dose chemotherapy, have made intensive postremission chemotherapy a more attractive option as primary postremission management for most adults with AML in first remission. Similarly, improvements in management of patients after allogeneic stem cell transplantation, including improved graft-versus-host disease prophylaxis, and more recently, the ability to perform molecular histocompatibility typing, have resulted in steadily improving the outcome for patients undergoing allogeneic stem cell transplantation. Furthermore, high-dose chemotherapy with autologous peripheral stem cell transplantation is yet another feasible option that can be employed in the postremission management of the younger adult with AML. Four important prospective randomized controlled trials have attempted to define the optimum

postremission management of patients with AML, under the age of 50–60, who are in first remission. The trials were all conducted in the 1980s and 1990s, both during the time when intensive high-dose ara-C based chemotherapy was coming into frequent use and when the aforementioned improvements in allogeneic transplantation were being seen. The trial design in each case was similar in that the patients were enrolled at diagnosis; those in remission deemed to be candidates for further aggressive therapy were allocated to allogeneic stem cell transplantation if a sibling donor was identified; and other patients were randomly allocated to chemotherapy or autologous stem cell transplantation. In the case of the trial performed by the Medical Research Council (MRC) in the United Kingdom,⁴¹ patients in each randomized group received the same postremission standard chemotherapy, but those randomized to autologous transplant received this at the conclusion of all therapy. Unfortunately, even after over 2000 patients were enrolled in these trials, the answer remains unclear. In the first published trial,⁴² those allocated to allogeneic transplant or randomized to autologous transplant enjoyed a superior relapse-free survival than those randomized to chemotherapy; however, there was no statistically significant improvement in overall survival in those groups, possibly due to salvage of patients in the chemotherapy group, who later relapsed, with an eventual stem cell transplant. The MRC trial⁴¹ did show a relapse-free survival benefit for those randomized to autologous transplant, but again there was no overall survival benefit; this was really a comparison of autologous transplant to no further therapy, in any event. It might have been a “more fair” trial if those randomized to chemotherapy received another cycle of chemotherapy in comparison to the high-dose approach. A French trial showed absolutely no difference in relapse-free survival or long-term survival in the three groups.⁴³ The United States Intergroup trial⁴⁴ actually showed a statistically superior survival for those randomized to chemotherapy, presumably due to unforeseen excess toxicity in the groups that were either allocated to the allogeneic transplant or randomized to high-dose therapy with autologous stem cell rescue.

Given our increased understanding of the heterogeneity of AML based on the chromosome findings at diagnosis,³ it is not surprising that several of the aforementioned studies comparing chemotherapy to transplantation were reanalyzed based on the impact of each of the potential treatment strategies on patients with various karyotypic risk groups. Unfortunately, none of these studies were prospectively powered to answer questions regarding the advisability of any given treatment based on a certain cytogenetic risk group. Not surprisingly, those patients who present with a favorable chromosomal abnormality at diagnosis (abnormalities of core-binding factor, either inversion of chromosome 16 or t(8;21)) fare well with any of the therapies.⁴⁵

Consequently, most authorities recommend that high-dose ara-C-based chemotherapy be the primary postremission strategy applied to this favorable group of patients, thereby reducing their risk of toxicity. Patients with unfavorable chromosomal abnormalities, such as monosomy 7 or the loss of chromosome 5, should have an allogeneic transplant in first remission.

Given the contemporary favorable results with matched unrelated donor transplants, for the selected young adult who presents with poor chromosomal features at diagnosis, an unrelated matched transplant in first remission could be considered. However, for the 70% of patients who have normal or so-called intermediate chromosomal abnormalities, the benefit of a transplant in terms of reducing the leukemia relapse rate is offset almost exactly by the toxicity of the transplant. Therefore, it is difficult to recommend an optimal strategy for this relatively large group of patients. Patients who have intermediate prognosis chromosomal abnormalities and a sibling donor require a frank discussion of the risks and benefits of each of the approaches. In general, it might be appropriate to delay allogeneic transplant until relapse or second remission, although patients must understand that such delay could compromise their chances for being able to have the transplant if not doing well in the long term. Moreover, children seem to have a more clear-cut benefit from allogeneic transplant as postremission therapy.⁴⁶ The younger the adult patient, the more such a strategy makes sense.

TREATMENT OF APL

The therapeutic approach to patients with APL differs from that in the other histologic subtypes of AML. This topic is discussed briefly here, while more comprehensive discussion appears in Chapter 6.

The use of chemotherapy in conjunction with all-*trans*-retinoic acid (ATRA) is now the most widely accepted standard approach for the induction management of patients with APL. Many questions remain about optimal chemotherapy. Nonetheless, once a diagnosis of APL is established, patients should begin therapy with ATRA because this strategy rapidly ameliorates the disseminated intravascular coagulopathy which can be life threatening. An anthracycline should be started within a few days of beginning ATRA. Studies have conclusively shown that concomitant use of chemotherapy plus ATRA is superior to chemotherapy alone or ATRA followed by chemotherapy.^{47,48} Whether or not cytarabine should be included routinely in the induction management of APL is controversial. The Spanish PETHEMA group has had excellent results without the use of this drug.⁴⁹ After the chemotherapy is completed, ATRA should be maintained until remission is achieved, an event that may occur at a later time after the initial initiation of induction chemotherapy compared with other

subtypes of AML. Once remission has been documented, at least two cycles of an anthracycline-based consolidation regimen are appropriate.^{48,49} The need for ara-C in the postremission setting remains controversial. APL is the only type of AML for which maintenance therapy has a clear-cut and widely accepted role.^{48,50} Maintenance chemotherapy with ATRA is indicated; the addition of oral antimetabolite therapy, in a manner analogous to that done in pediatric acute lymphoblastic leukemia, will further decrease the relapse rate.⁴⁸

For APL in relapse, arsenic trioxide should be administered. This drug yields a complete remission rate of 85%, even in highly pretreated relapse patients; 85% of those achieving remission do so at a level below the detectability rate for the polymerase chain reaction (PCR)-amplified PML-RARA and fusion transcript.⁵¹ Patients in second remission can be maintained with ATRA or arsenic trioxide; or, if the leukemia is undetectable by PCR analysis, patients should undergo stem cell harvest followed by high-dose chemotherapy with autologous peripheral cell rescue.⁵² Given the highly successful and responsive nature of this disease, clinical research is under way, in which patients receive limited amounts of chemotherapy. Investigators of MD Anderson have treated patients with ATRA and gemtuzumab ozogamicin with good initial results.⁵³

TREATMENT OF RELAPSED DISEASE

Patients with relapsed AML cannot be cured with standard chemotherapy. On the other hand, relapsed leukemia is generally treated with reinduction therapy for two reasons. First, this is an important part of the effort to get a patient in second remission, which may have palliative benefit. Most importantly, once the disease is under control, high-dose chemotherapy with hematopoietic stem cell transplant is possible. Second, patients in second remission can be salvaged with high-dose chemotherapy and autologous peripheral stem cell rescue (so-called autologous transplant) with the likelihood of disease-free survival in a second remission being about 30%.⁵⁴ In most cases, if an allogeneic donor is available, then it is preferable to consider an allogeneic stem cell transplant. With improved molecular HLA typing, in the absence of a sibling donor, an unrelated molecularly matched donor is an acceptable alternative. Allogeneic transplant can be used in situations where the remission is incomplete; however, this procedure is more likely to be successful if the patient is in fact in a second remission. This topic is covered in greater detail in Chapter 9.

The optimal therapy to use to induce a second remission is not clear. Although in this era most patients under the age of 60 with AML have received a high-dose ara-C-based consolidation regimen during first remission, the same regimen can be used for reinduction. If the first remission duration, the most

important prognostic factor for success with reinduction,⁵⁵ is greater than 1 year, then standard reinduction therapy can be given with a good chance of success. Otherwise, high-dose ara-C or a combination of high-dose ara-C plus mitoxantrone and etoposide⁵⁶ can be employed. Patients with a relatively short first complete remission (CR) duration are reasonable candidates to be enrolled on clinical trials involving novel chemotherapeutic agents and/or targeted agents.

NOVEL THERAPIES

The burgeoning understanding of the pathophysiology of AML has spurred the development of a host of investigational therapies. Table 4.1 lists a categorization of these therapies and classifies them into therapies that inhibit proliferation, promote apoptosis, improve chemotherapeutic effect, or work by immunotherapeutic means. Because AML is a rare disease that is already associated with fairly effective therapy, the challenge of bringing any of these therapies to improve the natural history of patients with AML is daunting indeed. Nonetheless, there have been two agents relatively recently approved for use in AML.

Table 4.1 Categories of novel therapies for AML

Drug-resistance modifiers Cyclosporine A Quinine PSC-833
Proteasome inhibitors (e.g., bortezomib)
Proapoptotic approaches (e.g., oblimersen and 18-mer anti-bc1-2)
Signal transduction inhibitors "RAS"—targeted (e.g., farnesyl transferase inhibitors, such as tipifarnib and lonafarnib) Tyrosine kinase targeted FLT3 (e.g., PKC 412, CEP 701, and MLN 518) c-kit (e.g., imatinib)
Downstream signal inhibitors
Novel cytotoxic chemotherapy Nucleoside analogs (e.g., troxacitabine and clofarabine) Alkylating agents (e.g., amonafide)
Immunotherapeutic approaches Antigens known anti-CD33 (e.g. gemtuzumab ozogamicin) anti-GM-CSF receptor Antigens unknown stimulate immune system (IL-2 and GM-CSF) present tumor antigens effectively dendritic cell fusion transfer hematopoietic growth factor genes

Just as ATRA was first shown to be effective by investigators in the People's Republic of China,⁵⁷ the first reports of the efficacy of arsenic trioxide⁵⁸ also emanated from that country. Studies done at Memorial Sloan Kettering Cancer Center⁵⁹ and at other US centers⁵¹ demonstrated that intravenously administered arsenic trioxide led to remission in 85% of patients with a relapsed APL. The biological effect of arsenic trioxide occurs via both a promotion of differentiation and an enhancement of apoptosis, but the precise biochemical mechanism remains elusive. The optimal setting for the use of arsenic trioxide in the initial management of AML is being studied as both an alternative to chemotherapy, when used with ATRA,⁶⁰ and an early postremission consolidation. Toxicities of arsenic trioxide include prolongation of the QT interval, mandating the close monitoring of electrolytes and electrocardiograms.⁶¹

Approximately 90% of patients with AML have blasts that express the CD33 antigen on the cell surface⁸; consequently, the humanized monoclonal antibody toxin conjugate gemtuzumab ozogamicin binds to AML cells in 90% of cases. After binding to the cell surface and subsequent internalization, the acidic microenvironment results in release of the calicheamicin toxin, which binds to double-stranded DNA, thereby promoting cell death. A phase I trial demonstrated the feasibility of the intravenous administration of gemtuzumab ozogamicin and was associated with some remissions in relapsed patients.⁶² The subsequent phase II trial involving 142 patients yielded a complete remission rate of 30% (half of whom had relatively low platelet count at the time of remission).⁶³ The phase II trial resulted in the approval of this agent for the treatment of older adults with relapsed AML not deemed to be chemotherapy candidates. As a single agent, significant activity seems to be limited to those with relapsed disease after an initial disease-free interval of at least 3–6 months. The role of gemtuzumab ozogamicin as an adjunct to chemotherapy or in minimal disease settings is being explored.

One of the most important strategies is harnessing our understanding of leukemic pathophysiology to design drugs which will inhibit signaling pathways promoting neoplastic cell growth and survival. Mutations in the FLT3 transmembrane tyrosine kinase occur in 30% of patients with AML. Such mutations are either a 3-33 amino acid repeat in the juxtamembrane region (internal tandem duplication; ITD) which occurs in about 25%, or a point mutation in the so-called activation loop which resides in the cytoplasmic tail (which has a 5% incidence).⁶⁴ ITD mutations, particularly if they occur in a homozygous fashion,⁶⁵ are associated with an adverse prognosis and may account for a subgroup of patients with normal karyotype, who fare relatively poorly.⁶⁶ FLT3 mutations have been preclinically shown to confer growth factor independence in leukemic cell lines and to

produce a fatal myeloproliferative syndrome in murine models.⁶⁴ Small molecules that inhibit FLT3 have been shown to kill such activated cell lines and model leukemias in mice. Early clinical trials with several FLT3 inhibitors have shown biological activity.^{67,68} Farnesyl transferase inhibitors, such as tipifarnib (originally thought to target a posttranslational modification of the *ras* proto-oncogene), also produce remissions in advanced⁶⁹ and untreated older patients⁷⁰ with AML.

There are several new chemotherapeutic agents, most notably the developmental novel nucleoside analogs troxacitabine⁷¹ and clofarabine,⁷² which have produced remissions in patients with relapsed and/or refractory AML. Certain agents such as oblimersen,⁷³ an 18-mer nucleotide that inhibits the translation of the antiapoptotic bcl-2 protein, are being developed, not as a single agent, but to enhance chemotherapeutic efficacy. One of the reasons for intrinsic disease resistance in certain AML patients, particularly those who are above 60, is the relatively high expression of proteins, such as MDR1, which confer drug resistance.⁷⁴ Several clinical trials have attempted to determine whether so-called drug-resistance reversal agents can enhance chemotherapeutic efficacy. Although one randomized trial in relapsed AML showed a survival benefit when

cyclosporine A was added to a salvage regimen containing ara-C and daunorubicin,⁷⁵ other studies⁷⁶ have been less promising.

Immunotherapeutic approaches remain a mainstay of therapy in AML, through the mechanism of graft versus leukemia noted following allogeneic stem cell transplantation.⁷⁷ Allogeneic stem cell transplantation, discussed elsewhere, offers, albeit at a significant risk of treatment-related toxicity, an effective antileukemic approach. Whether such a “graft-versus-leukemia” effect can be harnessed without needing to employ high-dose chemotherapy or chemoradiation therapy and receipt of allogeneic stem cells is a subject of active research. Leukemia vaccines have been created, in some cases using leukemia-specific peptides which, presented in the context of an HLA molecule, could engender an immune response.⁷⁸ Alternatively, manipulating tumor cells to allow more effective antigen presentation by either dendritic cell fusion⁷⁹ or transfection with a gene encoding a relevant cytokine⁸⁰ may augment antitumor immunity. Generalized stimulation of the immune system with BCG was ineffective⁸¹; however, two major randomized trials conducted by the CALGB are determining whether interleukin-2,⁸² employed at the conclusion of all-planned postremission therapy, might decrease the relapse rate.

Chapter 5

TREATMENT APPROACH TO ACUTE MYELOID LEUKEMIA IN OLDER ADULTS

Mikkael A. Sekeres

Statistically, it is probably no accident that the first reported case of leukemia (by Velpeau in 1827¹) occurred in a 63-year old. Acute myeloid leukemia (AML) is a disease of older adults. In the United States, the median age is 68 years and the age-adjusted population incidence is 17.6 per 100,000 for people 65 years of age or older.² Compare this to an incidence of 1.8 per 100,000 for people under the age of 65 years.² Therefore, of the estimated 11,900 new AML diagnoses in the United States in 2004, over half will affect patients 60 years of age or older,³ a population considered “elderly” in the leukemia literature.^{4–11}

Older adults with AML, when compared to younger patients with the same disease, have a poor prognosis and represent a discrete population in terms of disease features (including the biology of the disease and the incidence of secondary leukemia), treatment-related complications, and overall outcome (Table 5.1). As a result, older patients require distinctive management approaches to determine whether standard treatment, investigational treatment, or low-dose therapy or palliative care is most appropriate.

DISEASE FEATURES

CYTOGENETICS

Older adults with AML have a lower incidence of favorable chromosomal abnormalities and a higher incidence of unfavorable abnormalities compared to younger adults with AML.^{12–14} In an analysis of outcome of 1213 adult patients with de novo AML assigned varying doses of postremission therapy, only 2% of older patients (≥ 60 years) had the favorable t(8;21), compared to 9.4% of younger patients (< 60 years). Similarly, 3.4% of older patients had inv(16) or t(16;16) compared to 10.4% of younger patients.¹⁵ At the opposite end of the spectrum, with respect to unfavorable cytogenetics, 9.1% of older adults had the -7 abnormality compared to 3.2% of younger adults; 6.2%

of older adults had the $+8$ abnormality compared to 4% of younger adults; and 18.3% of older AML patients had complex cytogenetics (defined as three or more cytogenetic abnormalities, not including core-binding factor cytogenetics) compared to only 7.1% of younger patients. Looking specifically within a population of older adults with AML, an analysis of 1065 older patients with de novo and secondary AML enrolled in the Medical Research Council (MRC) AML 11 trial (in which patients were randomized to one of three remission induction regimens and further randomized to postremission therapy) found that 4% of patients had a t(15;17), 2% had a t(8;21), and only 1% had inv(16). Patients fortunate enough to have one of these abnormalities had a survival advantage over other patients. Poor-risk cytogenetics included a complex karyotype (defined here as five or more abnormalities), which was found in 14% of patients, a $+8$ abnormality in 10% of patients, a -7 abnormality in 8%, a del(5q) in 8%, and -5 abnormality in 5% of older AML patients.¹³

BONE MARROW BIOLOGY

In older adults, AML is more likely to arise from a proximal bone marrow stem cell disorder,¹⁶ such as myelodysplastic syndrome (MDS),¹⁷ and with leukemia-specific abnormalities in more than one hematopoietic cell lineage.¹⁸ This may explain the different disease behavior in this group, as well as prolonged neutropenia following chemotherapy.⁶ Older adults with AML also are more likely to have reduced proliferative capacities in normal hematopoietic stem cells,¹⁹ which also may affect blood count recovery following intensive chemotherapy.

DRUG-RESISTANCE GENES

The expression of genes that mediate drug resistance occurs with increased frequency in this age cohort.²⁰ MDR1, the so-called p-glycoprotein (gp170) chemotherapy efflux pump, was found in 71% of leukemic blasts in subjects in a Southwest Oncology Group study

Table 5.1 Comparison of older and younger adults with AML

Characteristic	Older AML patients ^a	Younger AML patients ^a
Population incidence ^b	17.2	1.8
Favorable cytogenetics		
t(8;21)	2.0%	9.4%
inv 16 or t(16;16)	3.4%	10.4%
t(15;17)	4.0%	6–12%
Unfavorable cytogenetics		
–7	9.1%	3.2%
+8	6.2%	4.0%
Complex	18.3%	7.1%
MDR1 expression	71%	35%
Secondary AML	24–56%	8%
Treatment-related mortality^c	25–30%	5–10%
Complete remission^c	39–61%	65–73%
Long-term disease-free survival^c	5–15%	30%

^a In general, older AML patients are defined as 60 years of age or older and younger AML patients as below 60 years of age.

^b New diagnoses, per 100,000 US citizens per year. Older/younger division occurs at 65 years.

^c Rates following remission induction therapy with an anthracycline- or anthracenedione-based regimen.

Reprinted from Stone RM, O'Donnell MR, Sekeres MA: Acute myeloid leukemia. *Hematology Am Soc Hematol Educ Program* 98–117, 2004, copyright American Society of Hematology, U.S.A.

of AML patients over the age of 55 years. Compare this to an incidence of 35% in younger AML patients.^{21,22} MDR1/p-glycoprotein expression is associated with lower complete remission (CR) rates and more chemoresistant disease. In addition, defects in the MSH2 protein involved in DNA mismatch repair and genome protection are expressed with greater frequency in this population.²⁰ Abnormalities of DNA mismatch repair due to defective MSH2 expression could play a key role in leukemogenesis, in particular in AML arising in older patients or secondary to previous chemotherapy.

PRIOR STEM CELL INSULT

Older adults with AML are more likely to have a secondary leukemia arising from an antecedent MDS or from prior therapy with chemotherapy or radiation therapy for another cancer.^{23,24} Patients with this type of AML are predisposed to having abnormalities in chromosome 5 and/or 7.^{12,14} Secondary AML (AML that arose after MDS, myeloproliferative disorders, and therapies or other malignancies) comprises 24–56% of AML diagnoses in older patients.^{8,22,25} Compare this to the prevalence of approximately 8% in younger AML patients in the MRC AML 10 trial.¹² AML arising from prior bone marrow stem cell disorders, particularly when the process is greater than 10 months in duration

prior to the development of AML, is less responsive to chemotherapy, resulting in shorter event-free survival, a lower CR rate, and conferring a worse prognosis.²⁶

RESPONSE TO THERAPY

Compared to younger patients under the age of 60 years with AML, older adults are not as tolerant of or responsive to remission induction and consolidation chemotherapy. Treatment-related mortality following remission induction therapy, accounting for 5–10% of deaths in younger patients, may be as high as 25–30% in older adults.^{7,27–29} These estimates can be considered low, as they derive from clinical trials requiring minimal performance statuses and often excluding patients with certain comorbidities or known secondary AML. High mortality rates likely result from inherent disease biology, an increased prevalence of comorbid disease, and a differential metabolism of induction regimen drugs, particularly cytarabine, resulting in supratherapeutic drug levels.^{7,30,31} Concern over potential treatment-related toxicities may result in undertreatment of disease. Paradoxically, administration of full-dose daunorubicin, for example, may result in a reduction in early deaths by effecting a more rapid CR.¹⁸

The outcome of older adults with AML is worse than that of similarly treated younger patients with the same disease. Adults under the age of 60 years treated with an induction regimen consisting of an anthracycline combined with cytarabine have a 65–73% chance of attaining a CR, while those over 60 years of age have a 39–61% chance of a CR.^{6,7,27,28,32–35} Moreover, long-term disease-free survival occurs in approximately 30% of younger adults (or, 45% of those entering a CR), compared to only 5–15% long-term disease-free survival in adults over the age of 60 years.^{6,7,28,35–39} The disease features of older adults with AML already elucidated provide the likely explanation for this dismal survival. Again, these numbers represent an optimistic prediction of this population's overall outcome. Thus, approximately 10 patients need to be treated with intensive induction chemotherapy to effect long-term disease-free survival in one. One out of four of those treated patients will not leave their remission induction hospitalization alive.

INDICATIONS FOR TREATMENT

For 85–95% of older AML patients, any therapy ultimately will be purely palliative. Treatment options range from supportive care (blood and platelet transfusions when needed, antibiotics to treat infections, and growth factor support) to low-dose chemotherapy (e.g., hydroxyurea or low-dose cytarabine arabinoside) or investigational agents, and high-dose chemotherapy (anthracycline- or anthracenedione-based remission induction therapy). The decision of whether or not to offer remission induction therapy (on the part

of physicians) or to receive it (on the part of patients) therefore is not straightforward.

Only two clinical trials have compared immediate aggressive induction chemotherapy with an anthracycline-based regimen to an alternative approach in older adults with leukemia. One trial, conducted by the European Organization for Research and Treatment of Cancer Leukemia Group, randomized 60 patients to receive either an anthracycline-based intensive induction regimen or a “wait-and-see” approach followed by mild chemotherapy for palliation of leukemia-related symptoms, begun a median of 9 days after diagnosis.⁴⁰ Patients randomized to the intensive therapy group survived a median of 10 weeks longer than those randomized to the “wait-and-see” approach (21 weeks vs 11 weeks, $P = 0.015$)—for a survival time only 16 days longer than the amount of time they spent hospitalized to receive therapy.

The other multi-institutional study randomized 87 patients over the age of 65 years to receive either an anthracycline-based induction regimen or low-dose cytarabine therapy.⁴¹ Fifty-two percent of patients receiving intensive therapy achieved a CR, while only 32% of those receiving low-dose cytarabine entered a CR. On the other hand, the frequency of early deaths was higher in the intensive chemotherapy group (31% vs 10%). Although the CR rates and early death rates were statistically significantly different between the groups, the overall survival (OS) (12.8 months in the intensive therapy group and 8.8 months in the low-dose cytarabine group) was not. In addition, for both studies, the cost in early deaths, length of hospital stay, and transfusion support was substantial.

Given these equivocal results, algorithms of how to approach older AML patients have been proposed.^{9,10,18} These suggest that, in the absence of adverse prognostic factors (such as poor-risk cytogenetics, poor performance status, significant comorbidities, or age 80 years or above), patients be offered intensive therapy, including enrollment in clinical trials that use intensive therapy. Alternatively, patients should be given the opportunity to participate in a clinical trial using less intensive therapy, or they should be offered nonintensive therapy or best supportive care.

Our policy is to base treatment decisions on individual patient preference after an *informed* discussion has taken place that incorporates *modified* risk estimates and *functional* patient age (Figure 5.1), without using absolute cutoffs for prognostic factors or chronological age.

Patients overestimate their chance for cure and 1-year survival, and underestimate the potential for treatment-related mortality. One single-center study found that 74% of patients estimated their chance to be cured by remission induction therapy to be greater than or equal to 50%, and almost 90% estimated their chance of being alive in 1 year to be greater than or equal to 50%. Almost two-thirds of patients reported that they were not offered treatment options other than the one

they chose, despite physician documentation of alternatives in all cases.⁴² As a communication gap exists between the extent to which physicians believe they are informing patients and what patients report their understanding to be, an informed discussion of treatment options should include multiple explanations by different health care personnel, the use of educational materials, and testing patient understanding.

Outcome and treatment-related mortality estimates should be modified to reflect baseline prognostic factors. For example, patients who fall into the “very elderly”¹⁰ category (80 years or older) can attain a CR with intensive therapy, but their chance of doing so is 30%, and only 7% of treated patients are alive at 1 year.⁴³ Patients with more than one poor prognostic factor also have diminished CR rates. Taking into account cytogenetics, secondary AML, and MDR1 expression, older AML patients with one of these prognostic factors had CR rates of 44%, compared to CR rates of 24% when patients had two factors and 12% when they had three.^{9,22} Conversely, older patients with *de novo* AML, no MDR1 expression, and intermediate or favorable cytogenetics have CR rates of 72–81% and the potential for a 34% 5-year OS rate.^{13,22}

Functional patient age refers to patients who function at an age much younger than their chronological age might suggest, and thus may derive more benefit from therapy.⁴⁴ Formal instruments used to evaluate functional status include The Older American Resources and Services Questionnaire, the Medical Outcomes Study Short Form 36, the Functional Assessment of Cancer Therapy scale, the Charlson Comorbidity Index, and the Karnofsky Performance Status scale, among others.^{45–50} An 80-year-old patient scoring well on a functional status evaluation may be a more appropriate candidate for remission induction therapy than a 70-year-old scoring poorly.

TREATMENT OPTIONS

REMISSION INDUCTION THERAPY

The backbone of remission induction therapy in AML patients consists of an anthracycline (daunorubicin or idarubicin) or anthracenedione (mitoxantrone) and cytosine arabinoside (ara-C),^{6–8,23,32,33,51–58} a regimen that has not changed in over two decades. Typically, daunorubicin is given at a dose of 45 mg/m²/day for 3 days, or idarubicin is given at a dose of 12 mg/m²/day for 3 days, or mitoxantrone is given at a dose of 12 mg/m²/day for 3 days, in combination with ara-C, which is administered as a continuous infusion at 100 or 200 mg/m²/day for 7 days. (*Frequently referred to as 7 + 3 chemotherapy.*) In general, studies have compared different anthracyclines and anthracenediones, varied doses and schedules, and added additional agents with some improvement in CR rates, but without any effect on OS rates (Table 5.2). It is reasonable to tailor the aggressiveness of daunorubicin and ara-C administration

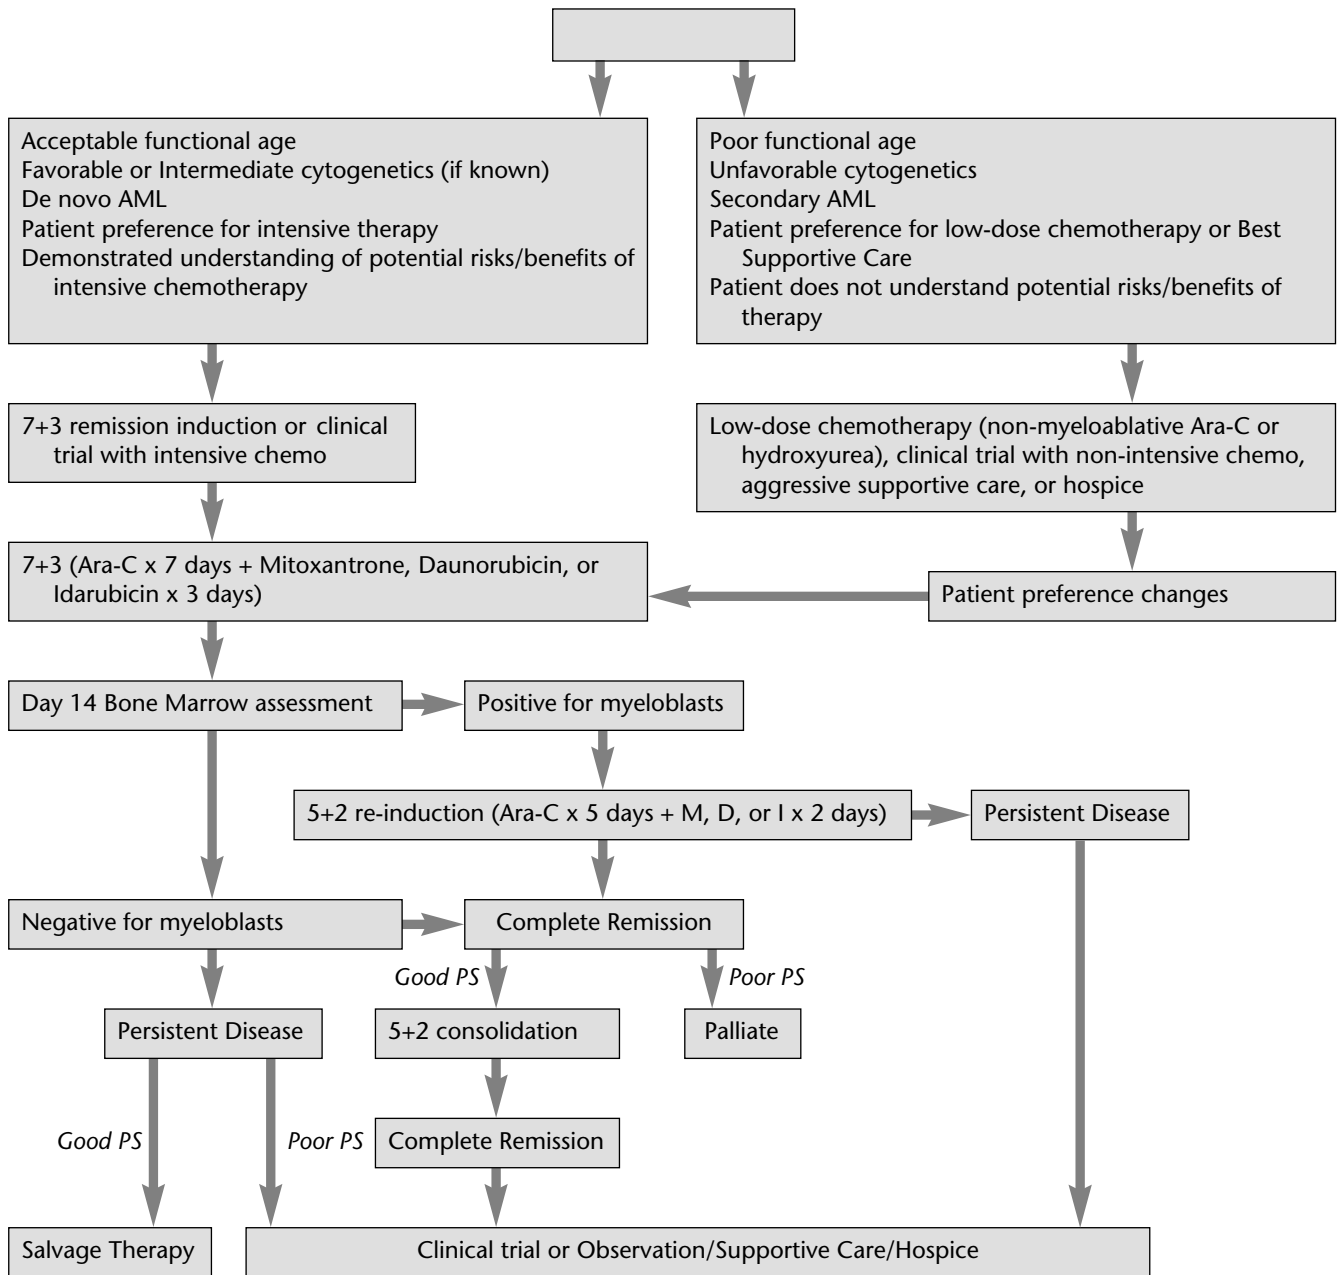

Figure 5.1 Approach to treating older AML patients

to the functional age of the older AML patient, with the understanding that, theoretically, some degree of efficacy may be compromised.

Comparing anthracyclines and anthracenediones

A phase III trial of 489 patients over 60 years of age compared an induction regimen consisting of mitoxantrone and ara-C to the standard of daunorubicin and ara-C.⁴ A CR was achieved by 47% of patients treated with mitoxantrone, compared to 38% of patients treated with daunorubicin, a difference that did not achieve statistical significance. Early and postinduction death rates were similar, as were toxicities, with the exception that those treated with mitoxantrone had a significantly higher rate of severe

infections and a trend toward a longer duration of aplasia. OS was similar for both groups.

In older adults with AML, idarubicin may have advantages over daunorubicin that include reduced cardiac toxicity, circumvention of multidrug resistance (MDR), and oral administration.⁵⁹ A number of trials have compared the two induction regimens,^{60–63} with the majority demonstrating a CR advantage in the idarubicin arm for younger adults, but no reproducible survival advantage. An overview of trials comparing idarubicin to daunorubicin for induction therapy showed similar overall induction failures in patients over 60 years of age receiving either of the two treatment arms; an improved CR rate in the idarubicin arm when compared to daunorubicin (50.5% vs 46.1%);

Table 5.2 Randomized studies defining remission induction therapy in older adults

Goal	Remission induction agents	Complete remission	Overall survival	Comments	Reference
Compare anthracyclines and anthracenediones	M (8 mg/m ² /day) + A (100 mg/m ² /day) vs D (30 mg/m ² /day) + A (100 mg/m ² /day)	47% vs 38% <i>P</i> = 0.07	39 weeks (median) 9% (5 years) vs 36 weeks (median) 6% (5 years) <i>P</i> = 0.23	Early and postinduction death rates were similar for both arms. Patients receiving mitoxantrone had a significantly higher rate of severe infections (25.1% vs 18.6%) and a trend toward a longer duration of aplasia (22 vs 19 days)	4
	I (8–20 mg/m ² /day) + A (100–200 mg/m ² /day) vs D (45–50 mg/m ² /day) + A (100–200 mg/m ² /day)	51% vs 46% <i>P</i> = ND	33.6 weeks (median) vs 29.9 weeks (median) <i>P</i> = 0.58	Early induction failure tended to be higher with idarubicin, while late induction failure was lower. Myelosuppression was greater in patients receiving idarubicin	64
	I (8 mg/m ² /day) + A (100 mg/m ² /day) + E (100 mg/m ² /day) vs M (7 mg/m ² /day) + A (100–200 mg/m ² /day) + E (100 mg/m ² /day)	45% vs 50% <i>P</i> = 0.52	7 months (median) 21% (2 years) vs 7 months (median) 21% (2 years) <i>P</i> = ND	No difference between groups in degree of myelosuppression or in early death rates	65
Vary 7 + 3 dose	D (60 mg/m ² /day) + A (100 mg/m ² /day) vs D (30 mg/m ² /day) + A (100 mg/m ² /day)	54% vs 42% <i>P</i> = 0.038	16% (5 years) vs 10% (5 years) <i>P</i> = 0.11	The 30 mg daunorubicin arm was closed prematurely due to higher response rates in the 60 mg arm, resulting in 42 patients receiving lower dose daunorubicin, and 130 patients receiving the higher dose	34
	D (45 mg/m ² /day) + A (100 mg/m ² /day) vs D (45 mg/m ² /day) + A (200 mg/m ² /day)	44% vs 38% <i>P</i> = 0.68	11.0 weeks (median) vs 9.6 weeks (median) <i>P</i> = 0.23	This study has been criticized for short overall survival times	27
Add agents	D (50 mg/m ² /day) + A (100 mg/m ² q 12 h) + T (100 mg/m ² q 12 h) vs D (50 mg/m ² /day) + A (100 mg/m ² q 12 h) + E (100 mg/m ² /day) vs M (12 mg/m ² /day) + A (100 mg/m ² /day)	62% vs 50% <i>P</i> = 0.002 ^a vs 55% <i>P</i> = 0.04 ^b	12% (5 years) vs 8% (5 years) <i>P</i> = 0.02 ^a vs 10% (5 years) <i>P</i> = 0.1 ^b , 0.2 ^c	There were no significant differences in myelosuppression or other toxicities, though neutrophils were slower to recover in the mitoxantrone arm. Patients receiving ADE had higher rates of induction death (26%, compared to 16% for DAT and 17% for MAC)	29
	D (60 mg/m ² /day) + A (100 mg/m ² /day) + E (100 mg/m ² /day) vs D (40 mg/m ² /day) + A (100 mg/m ² /day) + E (60 mg/m ² /day) + P (10 mg/kg/day)	46% vs 39% <i>P</i> = 0.008	7 months (median) vs 2 months (median) <i>P</i> = 0.48	Because of concern about excessive mortality on the ADEP arm (25 deaths vs 12 on the ADE arm), it was closed early to further accrual	11
	D (45 mg/m ² /day) + A (200 mg/m ² /day) vs D (45 mg/m ² /day) + A (200 mg/m ² /day) + GM-CSF (5 μg/kg/day)	54% vs 51% <i>P</i> = 0.61	10.8 months (median) vs 8.4 months (median) <i>P</i> = 0.10	Median duration of neutropenia was 15 days in the GM-CSF arm and 17 days in the placebo arm (<i>P</i> = 0.02). The duration of hospitalization did not differ between the arms; nor did the rates of life-threatening infection, or persistent leukemia	6

and no difference in OS in this population.⁶⁴ Another study compared an induction regimen consisting of idarubicin, ara-C, and etoposide to mitoxantrone, ara-C, and etoposide in 160 patients over the age of 60 years.⁶⁵ There was no statistically significant difference between the two therapy arms in terms of CR rates, neutrophil and platelet recovery (approximately 25 days in both arms), median disease-free survival, 2-year survival, and in treatment-related toxicities.

An Eastern Cooperative Oncology Group (ECOG) study randomized 349 newly diagnosed AML patients older than 55 years to receive ara-C with either daunorubicin, idarubicin, or mitoxantrone as remission induction therapy.⁶⁶ Two hundred thirty-six patients underwent subsequent randomization to priming with granulocyte-macrophage colony-stimulating factor (GM-CSF) versus placebo. The overall CR rate was 42%, the median disease-free survival was 7 months and OS was 14 months, and therapy-related toxicity was 16%, with no statistically significant differences among the induction regimens. Interestingly, the CR rate and OS were greater for the first 113 patients who did not have a delay in receiving their induction regimen due to priming regimen versus placebo randomization.

Although some debate exists regarding the equivalency of anthracycline and anthracenedione dosing in comparative trials, given the lack of survival benefit of one agent over another, we consider the three to have equivalent efficacy in the population of older patients with AML, and thus to be interchangeable.

Varying 7 + 3 doses

There is evidence that higher doses of anthracyclines may affect higher CR rates.^{67,68} A direct comparison was conducted by the German AML Cooperative Group. In their study, daunorubicin at a dose of 60 mg/m²/day was compared to daunorubicin at a dose of 30 mg/m²/day in combination with ara-C and 6-thioguanine. The higher dose of daunorubicin

resulted in a significantly higher CR rate compared to the lower dose,^{69,70} but there was no difference in OS. There has never been a prospective comparison of daunorubicin at doses of 45 mg/m²/day versus 60 mg/m²/day in older adults, and thus we cannot recommend the higher dose.

Similarly, there does not seem to be a benefit to higher doses of ara-C in remission induction therapy. One study randomized 326 patients to receive ara-C at 100 mg/m²/day or ara-C at 200 mg/m²/day combined with daunorubicin.²⁷ For patients of age 60 years or older, CR rates were actually lower in the higher dose arm, though not significantly, and median OS was similar for both groups, though this study has been criticized for short survival times.¹⁸

Additional remission induction agents (7 + 3 + . . .)

Another approach is to take advantage of the biological characteristics relatively specific to AML in older adults and add experimental agents to standard anthracycline- or anthracenedione-based therapy. A phase I study of 31 patients of 56 years of age or older with AML involved remission induction therapy which consisted of mitoxantrone, etoposide, and PSC 833, a cyclosporine analog capable of inhibiting the p-glycoprotein efflux pump.⁷¹ The median age of enrolled patients was 71 years, and 70% expressed p-glycoprotein, as would be expected in this population.²² The overall CR was 50% after a single induction attempt, and the overall median survival was approximately 9 months at the study's termination. A phase III study comparing daunorubicin, ara-C, etoposide, and PSC 833 to daunorubicin, ara-C, and etoposide, on the other hand, had to close accrual to the PSC 833 arm after the first 120 patients were enrolled when an interim analysis revealed an increased early mortality rate compared to the standard arm.⁸ Cyclosporine A works in similar ways to overcome the p-glycoprotein pump, thus increasing

intracellular anthracycline levels, and is still being evaluated in studies.^{72–74}

In direct or historical comparisons, no survival advantage has been found in older AML patients, with the addition to standard 7 + 3 therapy of etoposide or thioguanine.^{8,51,65,75} The MRC AML 11 trial randomized 1314 older patients to receive DAT (daunorubicin, ara-C, and thioguanine), ADE (daunorubicin, ara-C, and etoposide), or MAC (mitoxantrone and ara-C).²⁹ Patients randomized to the DAT arm had significantly higher CR rates, whereas those randomized to the ADE arm had higher rates of induction death, and those receiving MAC had higher rates of resistant disease. There were no substantial differences in long-term survival among the three remission induction arms.

Gemtuzumab ozogamicin

While standard induction regimens affect the replication of all bone marrow stem cells, antibody-targeted therapy has the potential of selectively ablating malignant myeloid cells while sparing normal stem cells. Gemtuzumab ozogamicin (GO, CMA-676, or Mylotarg) is a humanized monoclonal antibody that targets the CD33 antigen, expressed in 90% of patients with AML.^{76–78} It is conjugated to the toxin calicheamycin. GO was approved by the Food and Drug Administration for the treatment of older AML patients with relapsed or refractory AML who are not candidates for other cytotoxic chemotherapy and whose myeloblasts express CD33. This was based on phase 2 data showing overall response rates of 26% and a median relapse-free survival of 6.8 months.^{79,80} GO is now being used as single-agent up-front therapy or in combination with 7 + 3 in older AML patients. It will be discussed in more detail in the relapsed or refractory AML setting in Chapter 9.

Hematopoietic growth factors

In the majority of AML patients, death results from bleeding or infectious complications.⁸¹ This is particularly true in older adults with AML. The utility of hematopoietic growth factors (HGF), including granulocyte colony-stimulating factor (G-CSF) and GM-CSF, for ameliorating the myelosuppressive complications of AML therapy in older adults has been studied extensively.^{6,35,36,38,39,67,82,83} These prospective, randomized trials were also designed to determine whether or not HGF had detrimental effects in the inappropriate stimulation of leukemic cell proliferation and thus resistance, or whether they had beneficial effects in “priming” leukemic cells to proliferate prior to the administration of S-phase specific chemotherapy agents such as ara-C.^{10,84} With the exception of one ECOG study that demonstrated a CR rate and OS benefit in patients randomized to the GM-CSF arm (compared to patients receiving no growth factor support),⁶⁷ these trials found that while HGF are safe, reduce the duration of neutropenia (by a range of 2–6 days), and do not support leukemia cell proliferation,

they also do not reliably improve the CR rate, the length of hospitalization, the induction death rate, or prolong survival.

POSTREMISSION THERAPY

No randomized trial has ever demonstrated that *any* amount of postremission therapy in older AML patients provides better outcomes than does *no* postremission therapy. That being said, the only studies demonstrating that long-term disease-free remission is possible in older AML patients have included remission induction and postremission therapy.^{4,5,7,27–29,32,35,69,83} Standard postremission therapy consists of a repeat of remission induction therapy, single-agent ara-C, or 2 days of an anthracycline or anthracenedione (the same type of drug given at the same doses as with remission induction therapy) combined with 5 days of ara-C, again given at the same dose as with remission induction therapy (*frequently referred to as 5 + 2* postremission therapy), for one to two cycles.⁸⁵

Intensive postremission chemotherapy

Younger adults with AML benefit from intensified doses of ara-C therapy in the postremission setting, while older adults, particularly those with liver or kidney abnormalities, do not (Table 5.3).^{5,7,30} The Cancer and Leukemia Group B (CALGB) studied 1088 patients with de novo AML who were randomized in first CR (following daunorubicin/ara-C remission induction therapy) to receive one of three postremission therapies: four courses of ara-C at 100 mg/m²/day for 5 days as a continuous intravenous infusion, at 400 mg/m²/day for 5 days as a continuous intravenous infusion, and at 3 g/m² in a 3-h infusion every 12 h on days 1, 3, and 5.⁷ Three hundred forty-six patients were over 60 years of age. Only 29% of older patients were able to tolerate all four courses of ara-C at 3 g/m². Neurotoxicity occurred in 32% of older patients in the high-dose arm. Despite the higher rate of toxicity in older adults, disease-free and OS rates in this age group did not differ among the three postremission therapy arms.

A subsequent CALGB study randomized older AML patients in CR following remission induction therapy to one of two postremission regimens: ara-C at 100 mg/m²/day by continuous intravenous infusion over 5 days for four monthly courses, or ara-C at 500 mg/m² every 12 h in combination with mitoxantrone for six doses, over four monthly courses.⁵ Although similar numbers of patients in each arm were able to complete all four postremission courses, survival was again similar at a cost of more toxicity in the higher dose ara-C arm. In another study, the mortality rate among older patients receiving high-dose postremission therapy was 57%, compared to a rate of 13% among younger patients.³⁷ Given the toxicity of intensive postremission chemotherapy without a gain in survival, it is difficult to justify such treatment in older AML populations.

Table 5.3 Randomized studies defining postremission therapy in older adults

Goal	Postremission agents	Completion of all post-remission cycles	Survival	Comments	Reference
Establish therapy intensity	A (100 mg/m ² /day × 5 days) vs A (400 mg/m ² /day × 5 days) vs A (3 g/m ² q 12 h days 1, 3, 5)	71% vs 66% vs 29% P = ND	≤16% (DFS, 4 years) vs ≤16% (DFS, 4 years) vs ≤16% (DFS, 4 years) P = 0.19	Remission induction with daunorubicin + ara-C. Because of concerns about excessive neurotoxicity in older patients receiving ara-C at 3 G/m ² (32% of 31 patients), it was closed early to further accrual. Overall survival at 4 years in older patients regardless of postremission therapy was 9%	7
	A (100 mg/m ² /day × 5 days) × 4 cycles vs M (5 mg/m ² q 12 h days 1–3) + A (400 mg/m ² q 12 h days 1–3) × 2 cycles	71% vs 78% P = ND	11 months (DFS, median) vs 10 months (DFS, median) P = 0.67	Remission induction with daunorubicin + ara-C. Higher toxicities, including hemorrhage, infection, dysrhythmias, and malaise, were experienced in the mitoxantrone/ara-C arm. Median overall survival times were 1.6 years in the ara-C arm and 1.3 years in the mitoxantrone/Ara-C arm	5
Establish therapy duration	D (50 mg/m ² /day × 2 days) + A (100 mg/m ² /day × 7 days) + T (100 mg/m ² q 12 h × 7 days) × 1 cycle vs D (50 mg/m ² /day × 2 days) + A (100 mg/m ² /day × 7 days) + T (100 mg/m ² q 12 h × 7 days) × 1 cycle; D (50 mg/m ² /day × 2 days) + A (100 mg/m ² /day × 5 days) + T (100 mg/m ² q 12 h × 5 days) × 1 cycle; C (600 mg/m ² × 1 day) + O (1.5 mg/m ² × 1 day) + A (100 mg/m ² /day × 5 days + Pred (60 mg/m ² × 5 days) × 2 cycles	100% vs 61% P = ND	23% (OS, 5 years) vs 22% (OS, 5 years) P = NS	Patients randomized to prolonged postremission therapy had a higher 5-year disease-free survival (23% vs 16% for the DAT arm) and lower relapse risk at 5 years (73% vs 81% for the DAT arm), but also more deaths in first complete remission (8% vs 3% in the DAT arm). Differences were not significant	29
	M (8 mg/m ² /day × 1 day) + A (100 mg/m ² /day × 7 days) or D (30 mg/m ² /day × 1 day) + A (100 mg/m ² /day × 7 days) × 1 cycle vs M (8 mg/m ² /day × 1 day) + A (100 mg/m ² /day × 7 days) or D (30 mg/m ² /day × 1 day) + A (100 mg/m ² /day × 7 days) × 1 cycle + maintenance with A [10 mg/m ² q 12 h × 12 days (q 42 day)] × 8 cycles	ND	15% (OS, 5 years) vs 13% (OS, 5 years) P = 0.29	Disease-free survival favored the maintenance therapy arm (at 5 years, 13% vs 7%, P = 0.006). No information is available regarding treatment compliance or toxicity	4

Protracted postremission chemotherapy

There does not appear to be any additional survival benefit attained from administering one to two cycles of postremission therapy, or in treating older AML patients with maintenance therapy. In the MRC AML 11 trial, 371 patients who entered a CR following anthracycline- or anthracenedione-based remission induction therapy were randomized to receive either one cycle of DAT consolidation therapy or DAT along with three additional cycles of ara-C-based consolidation therapy (for a total of four cycles of postremission therapy).²⁹ Of patients randomized to the long consolidation course, 61% were able to complete all four cycles. Survival was similar at 5 years for patients randomized to the short and long consolidation arms.

In the phase III trial performed by the Leukemia Cooperative Group of the European Organization for the Research and Treatment of Cancer and the Dutch–Belgian Hemato-oncology Cooperative Hovon Group, patients over 60 years of age were randomized to remission induction regimens consisting of mitoxantrone and ara-C versus daunorubicin and ara-C.⁴ Following one cycle of consolidation therapy, 151 patients in CR were further randomized to receive low-dose ara-C maintenance therapy, or to no further treatment. Actuarial disease-free survival was longer for those receiving low-dose postremission therapy compared to those not receiving therapy, with 5-year DFS being 13 and 7% respectively. OS, though, was similar.

Postremission stem cell transplantation

An even more aggressive approach than induction therapy followed by consolidation or intensification for older adults with AML consists of stem cell transplantation. This topic will be covered in greater detail in Chapter 100. Nonmyeloablative allogeneic stem cell transplants take advantage of a graft-versus-leukemia effect using a less intensive preparative regimen with lower up-front mortality. The reduced treatment-related mortality and ability to perform these transplants in the outpatient setting make them an appealing option for the older AML patient with few comorbidities and an adequate performance status. Preliminary studies that include older AML patients have demonstrated that durable CRs are attainable with this treatment,^{86,87} though follow up is still less than 3 years.

CLINICAL TRIALS

Remission induction therapy for older adults with AML is no panacea, with 5-year survival rates resembling those of patients with advanced lung cancer.² It is thus reasonable to consider investigational agents for older AML patients up front, particularly as these patients have a disease that resembles the advanced MDS or secondary AML.^{22,88} Potential targets for antileukemia therapy are explained in more detail in

Chapter 9. They include specific signaling molecules required for the maintenance of the leukemic state, such as tyrosine kinases; over expression of *bcl-2*, an antiapoptosis signal; DNA methylation, associated with suppression of regulatory genes and with disease progression; indirect pathways that maintain leukemogenesis, including angiogenesis and drug resistance; and investigational agents with mechanisms of action that differ from anthracyclines, anthracenediones, and ara-C, such as nucleoside analogs, farnesyl transferase inhibitors, and MDR modulators.^{89–95}

LOW-DOSE CHEMOTHERAPY/SUPPORTIVE CARE

In the setting of a poor functional age, serious comorbid medical conditions, and particularly patient preference, less intensive chemotherapy or aggressive supportive care may be more appropriate treatment options. Drugs such as hydroxyurea (generally given in doses of 500–3000 mg/day, adjusted to the degree of leukocytosis and/or treatment-related thrombocytopenia) and low-dose ara-C (at a dose of 10 mg/m²) are well tolerated and will reduce leukocytosis for a period of time, though neither will impact survival.⁹⁶ We use the phrase *aggressive supportive care* to emphasize that symptoms will be treated vigorously and to distinguish this modality from hospice. Blood and platelet transfusions should be administered to alleviate symptoms stemming from anemia and thrombocytopenia, and antibiotics initiated when appropriate. In addition, integrative therapies such as Reike, therapeutic touch, and herbal medicines may be used by the willing patient. These latter interventions often can be facilitated with involvement of a multidisciplinary team of physicians, nurses, case managers, social workers, therapists, and clergy. Hospice services should be instituted within 6 months of anticipated demise, though some hospice organizations prohibit blood product transfusions, which we consider to be palliative in this population and which may result in improved quality of life in terminal cancer patient populations.⁹⁷

SUMMARY

Managing AML in older adults can be challenging on a number of levels. While the majority of this population will not enjoy long-term disease-free survival because of disease features and treatment-related complications, a small subset will derive a survival benefit from aggressive chemotherapy approaches. Factors such as functional age can be used to assess which patients might benefit from remission induction and postremission therapy, and which would be done a disservice with such treatment. Studies are needed to assess the trade-off between the slim chance of long-term survival that might be attained with chemotherapy and the quality-of-life issues of low-dose or aggressive supportive therapy.

Chapter 6

TREATMENT APPROACH TO ACUTE PROMYELOCYTIC LEUKEMIA

James L. Slack

INTRODUCTION

Acute promyelocytic leukemia (APL) is a clinically and genetically distinct subtype of AML caused by fusion of the promyelocytic leukemia (*PML*) gene, on chromosome 15, with the retinoic acid receptor α (*RARA*) gene, on chromosome 17. The fusion of *PML* (or one of the rare variant partner genes) with *RARA* results in a hybrid protein (*PML-RARA*) that interferes with function of both the wild-type *PML* and *RARA* genes. The end result is a block in myeloid differentiation, disruption of cellular growth control, and development of clinical APL. The disease was first described clinically in 1957,¹ and the classic reciprocal chromosomal translocation [t(15;17)(q22;q21)] that characterizes APL was identified by Rowley et al. in 1977.² Almost three decades later, the molecular pathogenesis of APL is reasonably well understood,³ and modern treatment regimens have been developed that lead to the cure of more than 70% patients. From a clinical perspective, the challenge is to further increase this cure rate, while reducing (or eliminating) side effects and long-term toxicities associated with intensive chemotherapy. Well-designed clinical trials continue to be the best option for most patients with APL, for it is only in the context of such trials that clinicians can learn how to safely de-escalate therapy in low-risk patients while maintaining excellent outcomes in patients who present with higher risk disease.

APPROACH TO THE PATIENT WITH APL

PROGNOSTIC FACTORS

While the presence of the t(15;17) or *PML-RARA* fusion confers an overall “good” prognosis to APL patients, there nevertheless exists a subset of APL patients who are at high risk of relapse or death despite best available therapy. In 2000, Spanish (PETHEMA: Programa de

Estudio y Tratamiento de las Hemopatías Malignas) and Italian (GIMEMA: Gruppo Italiano Malattie Ematologiche dell’adulto) APL investigators defined low-, intermediate-, and high-risk subgroups of APL patients based on presenting white blood cell (WBC) and platelet counts (low risk: WBC count <10,000/ μ L and platelet count >40,000/ μ L; intermediate risk: WBC count <10,000/ μ L and platelet count <40,000/ μ L; high risk: WBC count >10,000/ μ L).⁴ Based on the above analysis, as well as on data from numerous other groups, it is now well known and accepted that APL patients who present with WBC counts of more than 10,000/ μ L have a high risk of treatment failure, due both to an increased incidence of deaths during induction and to a higher risk of relapse. Specific genetic findings, such as the bcr-3 *PML* breakpoint⁵ and internal tandem duplication (ITD) of the *FLT3* gene,⁶⁻⁹ as well as microgranular morphology, are associated with high WBC count, but have not, in general, been found to have independent prognostic significance in patients treated with modern all-*trans*-retinoic acid (ATRA)-based regimens. Also, there is no independent prognostic significance of chromosomal abnormalities in addition to the t(15;17) in patients treated with ATRA-containing regimens.^{10,11} Certain immunophenotypic findings seem to be associated with poor prognosis, specifically expression of CD2, CD34, and CD56, but only CD56 expression has been shown to have independent prognostic significance.^{12,13}

THERAPEUTIC MONITORING

APL patients who enter morphologic complete remission (CR) after a single round of induction therapy will often be reverse transcriptase polymerase chain reaction (RT-PCR) positive, and a small minority will have low numbers of residual abnormal promyelocytes. In general, neither finding indicates failure of induction therapy, and such patients should proceed promptly to consolidation. However, a positive RT-PCR result at the end of consolidation, at least in patients treated according to

the Italian consolidation regimen, seems to indicate treatment failure.¹⁴ In the Italian study, among 23 patients (out of 683) who were RT-PCR positive at the end of consolidation, 7 were treated “preemptively” with salvage therapy and stem cell transplant, while treatment was delayed in the remaining 16 until development of hematologic relapse. All seven patients treated early (i.e., with persistent molecular disease) were alive, compared to only 2 of the 16 patients treated at the time of hematologic relapse.¹⁴ After consolidation, APL patients who are RT-PCR negative should undergo routine molecular monitoring (e.g., every 2–4 months for at least 2 years) to detect incipient relapse.^{15,16} As is discussed below in depth, two successive positive RT-PCR assays (at a sensitivity of 1 in 10⁴) are highly predictive of subsequent hematologic relapse and cannot be ignored. It is currently not known if blood can substitute for bone marrow for the RT-PCR assays; therefore, bone marrow is the preferred source for collection of cells and isolation of mRNA. A single negative RT-PCR assay has little clinical significance in APL, even at the end of consolidation, and serial monitoring is key to early detection of relapse. Finally, while quantitative RT-PCR assays have been developed and are undergoing clinical testing,^{17,18} qualitative RT-PCR assays at a sensitivity of 1 in 10⁴ remain the “gold standard” for detection of minimal residual disease, and clinicians caring for APL patients need access to a reliable laboratory that can provide this type of serial molecular monitoring.

TREATMENT OF NEWLY DIAGNOSED APL

OVERVIEW OF TREATMENT RESULTS IN THE “ATRA ERA”

Table 6.1 presents the results of treatment of over 3000 APL patients from four continents and eight major leukemia cooperative groups since the advent of ATRA-based therapy in approximately 1990. In virtually all of these patients, the diagnosis of APL was confirmed by modern molecular or cytogenetic techniques, and all received ATRA during induction therapy, either alone or in combination with chemotherapy. While it is beyond the scope of this chapter to discuss each trial in detail, careful analysis of the aggregate results illuminates many of the successes (and some of the failures) of treatment of APL over the last 15 years. The most obvious success is the long-term survival rate of approximately 80%, which compares to a rate of 30–40% in the pre-ATRA era.³³ Although 80% is a spectacular number, 5–10% of APL patients die early during induction, another 10% die of refractory disease, and 10% are successfully treated for relapsed APL (but are subjected to the side effects and long-term toxicities of salvage therapies). Furthermore, with the exception of one study,²⁰ the event-free survival (EFS) of patients with high-risk disease is relatively poor, generally around 50–60%. Thus, as we enter the era of

“third-generation” ATRA-based protocols, exemplified by the APL2000²⁰ and AIDA2000²⁶ studies, our challenge is to better manage patients during the initial induction period (particularly those who present with high WBC counts), and to choose appropriate therapies based on accurate risk-group assessment. Questions remain, and newer approaches are under study,³⁴ but curative, safe treatments for virtually all patients with APL are now available, and it is fair to say that survival free of disease should be attainable for up to 95% of APL patients who survive induction therapy. Assuming a 5% rate of early death, and a small number of relapses and deaths in CR, the EFS target for all future trials of APL should be 85–90%, and anything below this number should be considered unacceptable.

INDUCTION THERAPY

All of the trials given in Table 6.1 incorporated ATRA into induction therapy and, with few exceptions, reported CR rates are greater than or equal to 90%. What, then, is the best strategy for induction therapy of APL? While the choice of “best” induction therapy may differ for specific subsets of patients, for most patients the weight of evidence supports the use of ATRA, 45 mg/m²/day in divided doses until CR, plus anthracycline-based chemotherapy started on day 2 or 3 (to allow partial improvement of the coagulopathy by ATRA). The choice of anthracycline (daunorubicin vs idarubicin), and the dose, vary by center and group, but excellent results have been achieved using 12 mg/m² of idarubicin on days 2, 4, 6, and 8,³⁵ as well as 60 mg/m² of daunorubicin on days 3–5.²⁰ This type of combined strategy minimizes the incidence of APL differentiation syndrome, results in disease control in virtually all patients and, in experienced hands, leads to CR rates of more than 95%. Satisfactory rates of CR can also be achieved using ATRA alone for induction, but long-term disease control may be inferior.²¹

COMPLICATIONS OF INDUCTION THERAPY

The vast majority of APL patients who fail induction do so not because of resistant disease, but because of fatal hemorrhage [usually central nervous system (CNS)], retinoic acid (RA) syndrome (also called “APL differentiation syndrome”), or infection. Rates of early death are, at least historically, much higher in patients with high WBC counts,^{29,32,36} as high as 24% in some studies. The Spanish Group has reported an early death rate of 8.4% in 642 patients treated with simultaneous ATRA and idarubicin (AIDA) between 1996 and 2003 in two successive studies³⁶; 58% of the early deaths were due to hemorrhage, 31% due to infection, and 10% due to RA syndrome.³⁶ The rate of early death did not decrease in the more recent LPA99 study, despite the prophylactic use of prednisone (to prevent RA syndrome) and tranexamic acid (to improve the coagulopathy). Renal dysfunction (creatinine >1.4 mg/dL) and high WBC count (>10,000) were the only independent predictors of early death. It is

N, number of enrolled patients; NR, not reported; ED, early death (i.e., death during induction); CR, complete remission; EFS, event-free survival (any event, i.e., death or relapse, after enrollment on study); OS, overall survival; RR, relapse rate; HR EFS, event-free survival in patients with high WBC at diagnosis (>10,000/μL unless otherwise specified).

^a Data from the Australasian Leukemia and Lymphoma Group.¹⁹

^b Data from the European APL Group.^{20–23} Results for the APL91 study are from the ATRA arm of that study; EFS and OS are reported at 4 years for the APL91 and APL 93 studies. Data for the APL93 study reported here are for 18–60-year-old adults. EFS, OS, and RR reported for the APL2000 study are at 2 years, and are from the group of patients of age below 60, with WBC count of less than 10,000/μL, who were treated on the ara-C arm of that study (see text for details). EFS, OS, and RR for similar patients treated without ara-C are 83, 90, and 12%.²⁰

^c Results from the German AML Cooperative Group.^{24,25} EFS and OS are reported at 4 years; high-risk EFS refers to patients with initial WBC count of more than 5000/μL.

^d Data from the Italian GIMEMA Cooperative Group.^{26,27} For the AIDA93 trial, EFS is reported as of June 2003, while OS is reported at 5.7 years, with median follow up of surviving patients 2.3 years. The data reported for AIDA0493 are from reference [26], and include patients treated on the “AIDA” trial after 1997 (all of whom received 2 years of ATRA-based maintenance). Median follow up in this trial was 4.5 years. Median follow up for the AIDA2000 trial was 2 years. EFS in both studies is reported at 2 years and was calculated by subtracting the ED rate in each group from the reported DFS. Although no EFS was reported for high-risk patients, the cumulative incidence of relapse (CIR) for high-risk patients in the AIDA0493 trial was 29%, versus 2% for high-risk patients in the AIDA2000 trial (see text for details).

^e Results from the Japanese Acute Leukemia Study Group.²⁸ EFS and OS are reported at 6 years for the JALSG92 study and at 5 years for the JALSG97 study.

^f Results from the Medical Research Council (United Kingdom) Adult Leukemia Working Party.²⁹ Outcome data are at 4 years. The EFS for high-risk patients (WBC count >10,000/μL) was calculated by subtracting the ED rate in this group (24%) from the reported DFS (53%).

^g Results from the North American Intergroup protocol 0129.^{30,31} All data relate to patients on the ATRA arm of this study. EFS and OS are reported at 5 years.³⁰

^h Data from the Spanish cooperative group PETHEMA.³² EFS in both the LPA96 and LPA99 trials was calculated by subtracting the ED rate in each study from the reported DFS (71 and 79%, respectively for the entire study group, and 66 and 77%, respectively, for the high-risk group). Both EFS and OS are reported at 3 years. The median follow up was 48 months for LPA96 study and 21 months for LPA99 study. The CIR at 3 years for high-risk patients in the LPA96 study was 34.2%, and 21% in the LPA99 study (see text).

also notable that older adults (≥60 years) were more likely to die of infection (56%) than hemorrhage (37.5%).³⁶

As the incidence of resistant disease is exceedingly small (less than 1% in most series), strategies to improve CR rates in APL have focused on prevention and/or effective treatment of bleeding and RA syndrome. Although both ATRA and chemotherapy improve the coagulopathy in APL,^{37,38} ATRA acts more rapidly, and its use is associated with a more controlled improvement in bleeding and in parameters of disseminated intravascular coagulation and fibrinolysis.³⁹ Because of this, all patients with a morphologically confirmed (or strongly suspected) diagnosis of APL, particularly those with evidence of significant coagulopathy (or frank bleeding), should be started on ATRA immediately. All patients with APL should receive

aggressive blood product support, including platelet transfusions, in an attempt to maintain a platelet count of 50,000/μL or above, and fresh plasma or cryoprecipitate to maintain fibrinogen levels of 100 mg/dL or higher. This platelet threshold can be adjusted downward as the coagulopathy improves, but 50,000/μL should be the initial target for all patients, particularly around the time of initiation of chemotherapy. The role of heparin therapy in patients who receive ATRA-based induction continues to be controversial.^{38,40} As noted above,³⁶ and although the issue remains unsettled,⁴¹ antifibrinolytic agents such as tranexamic acid and ε-aminocaproic acid do not appear to be effective, and may in fact be detrimental, by increasing the incidence of thrombosis.^{42–44} In the recently reported APL2000 trial,²⁰ the rate of early death was 3% or less in

all groups of patients except those of age 60 or above with WBC count of more than 10,000/ μ L, suggesting that clinicians experience with ATRA, and use of aggressive supportive care measures, may finally be improving the obstinate 8–10% induction death rate that has plagued almost all APL trials.

APL DIFFERENTIATION SYNDROME

The pathophysiology and treatment of RA syndrome or “APL differentiation syndrome” have recently been reviewed,^{45,46} and knowledge of the manifestations of this potentially fatal complication of induction therapy is essential to all clinicians who treat APL. The most common presenting symptoms^{47–49} are respiratory distress, fever, pulmonary infiltrates, weight gain, and pleural/pericardial effusions. Less common signs and symptoms include renal failure, cardiac failure, hypotension, and bone pain. These symptoms can develop at virtually any time after presentation (and may be present *before* any therapy), but the median time to development is between weeks 1 and 2 after the start of induction.^{47–49} The differential diagnosis includes sepsis/acute respiratory distress syndrome, as well as pulmonary hemorrhage, and the outcome can be fatal if the disorder is not recognized, diagnosed correctly, and properly treated. Treatment of RA syndrome is with corticosteroids (given at the earliest time possible), generally dexamethasone 10 mg q 12 h, and temporary discontinuation of ATRA, at least in severe cases. ATRA can (and should) be safely restarted after the syndrome resolves, and RA syndrome is exceedingly rare in patients who receive ATRA during consolidation or maintenance phases of their treatment. Thus, there should be no hesitation in subsequent use of ATRA in patients who may have developed RA syndrome during induction. The incidence of RA syndrome seems to be lower in patients who receive combined ATRA/chemotherapy induction,⁴⁷ and it may be lower in patients who receive prophylactic steroids, but it is clearly not “a problem of the past” and remains a significant clinical issue in the treatment of APL.⁴⁶ Finally, note that APL differentiation syndrome also occurs in patients treated with arsenic trioxide for newly diagnosed or relapsed APL,⁵⁰ and approximately 50% of such patients develop leukocytosis, which can be marked. In general, the leukocytosis is self-limiting and does not require therapy, but patients with leukocytosis who develop symptoms or signs of coexistent APL differentiation syndrome require treatment with corticosteroids.⁵⁰

CONSOLIDATION THERAPY

The choice of appropriate postremission therapy will depend on the patient’s risk of relapse, which can be estimated based on presenting WBC and platelet counts.⁴ APL patients in low- and intermediate-risk groups can generally be successfully consolidated with anthracyclines alone. In recent trials published by the PETHEMA and GIMEMA groups, relapse rates of

patients in low and intermediate risk groups were less than 10%, following consolidation with anthracyclines plus ATRA or anthracycline alone (patients generally received induction with idarubicin and ATRA, and 2 years of ATRA-based maintenance).^{26,32} However, in the PETHEMA LPA99 trial,³² patients with high WBC counts continued to have a high risk of relapse (21%), despite addition of ATRA during each course of consolidation, and increased intensity (by approximately twofold) of anthracyclines. High-risk patients appear to be faring somewhat better in the recent AIDA2000 trial,²⁶ with a relapse rate (at 2 years) of only 2%. Consolidation therapy in this patient group was intensified by addition of ara-C during cycle 1, VP-16 during cycle 2, and ara-C and 6-TG during cycle 3. (All patients also received 15 days of ATRA with each course.) High-risk patients in the APL2000 trial, all of whom received ara-C during consolidation, also have excellent early outcomes, with rates of relapse below 5%.²⁰ To summarize, consolidation therapy in APL should include, at a minimum, two cycles of ATRA plus anthracyclines; however, APL patients who present with WBC counts of more than 10,000/ μ L, and perhaps APL patients who express CD56, require additional, or alternative, therapy in addition to standard ATRA and anthracyclines. While further dose escalation of anthracyclines may be possible, current evidence suggests that a significant percentage of high-risk patients may be cured by incorporating ara-C into the induction and/or consolidation regimens. Whether other agents (e.g., arsenic trioxide and gemtuzumab ozogamicin) could substitute for ara-C in this role is not yet known, but this question, at least for arsenic trioxide, is being addressed in the current North American Intergroup trial.

MAINTENANCE THERAPY

Data from two trials published in the mid-1990s suggested that maintenance therapy with ATRA and/or chemotherapy, generally 6-mercaptopurine (6-MP) plus methotrexate (MTX), was beneficial in increasing the cure rate of APL. For example, in the APL93 study, the 5-year risk of relapse was 39, 29, 24, and 13% in patients who received, respectively, no maintenance, ATRA alone, 6-MP/MTX alone, or combined ATRA/6-MP/MTX.⁵¹ In the group of patients with high WBC count (more than 5000/ μ L in this study), the relapse risk was 47% without maintenance, but only 8% if patients received ATRA/6-MP/MTX.⁵¹ In the North American Intergroup 0129 study,³⁰ 5-year disease-free survival was 74% in patients who received ATRA during both induction and maintenance, compared to 55% for patients who received ATRA only during induction. In contrast to the above results, GIMEMA investigators²⁷ found no differences in molecular disease-free survival according to any of the four maintenance arms (ATRA/6-MP/MTX, ATRA alone, 6-MP/MTX alone, or no maintenance). The ultimate role of maintenance therapy in APL may be difficult to precisely define, as its usefulness

may depend on both patient-specific (i.e., risk category) and treatment-specific (i.e., intensity of induction and consolidation therapy) factors. However, currently, ATRA- or arsenic-trioxide-based maintenance therapy is strongly recommended for all patients, and it should be considered mandatory in high-risk patients. Commonly used regimens include 45 mg/m²/day of ATRA every other week, or ATRA at the same dose for 15 days out of each 3-month period. Standard maintenance doses of 6-MP and MTX are 60 mg/m²/day and 20 mg/m²/week, respectively. Treatment should be continued for at least 1 year, but 2 years may be preferable.⁵¹ Maintenance therapy is generally well tolerated, but serious complications can occur, particularly in patients receiving 6-MP and MTX (\pm ATRA), and include abnormal liver function tests, cytopenias with potentially serious infections, and opportunistic infections such as *Pneumocystis carinii* pneumonia.⁵¹

SPECIAL TOPICS IN APL MANAGEMENT

NOVEL TREATMENT APPROACHES

Investigators from Shanghai^{52,53} have recently reported results in 61 newly diagnosed APL patients who received induction therapy with combined ATRA (25 mg/m²/day) plus arsenic trioxide (0.16 mg/kg/day). All patients subsequently received three courses of consolidation chemotherapy, and five cycles of maintenance with sequential ATRA, arsenic, and 6-MP and MTX. Among the 61 patients, 58 (95.1%) entered CR at a median of 26 days and, with a follow up of 20–39 months, all of them were relapse free.⁵² Similar results, at least for induction, have been reported by Wang et al.,⁵⁴ with a CR rate in 80 newly diagnosed patients treated with low-dose ATRA plus arsenic of 92.5%; there were two early deaths (2.5%), and four cases of resistant leukemia, but no data were presented on long-term outcomes. Estey et al.³⁴ have treated 44 newly diagnosed APL patients with ATRA (45 mg/m²/day) plus arsenic trioxide (0.15 mg/kg/day) added at day 10 (with addition of one dose of gemtuzumab ozogamicin if the presenting WBC count was above 10,000/ μ L or if disease persistence was documented by RT-PCR); treatment with ATRA/arsenic trioxide was continued for 6 months from CR. The rate of CR was 89%, there were four early deaths (9.14%), and 36 of 39 patients were alive in CR at early follow up. Finally, investigators from Iran⁵⁵ and India⁵⁶ have separately reported results with arsenic trioxide alone as the sole treatment of APL. Rates of CR, were 85.6 and 86% respectively, for the two studies and, relapse rates were approximately 25%.^{56,56} In patients with a WBC count lower than 5000 μ L, and a platelet count higher than 20,000 μ L at diagnosis, the EFS was 100%.

Studies such as these must be viewed in context of the data summarized in Table 6.1, particularly the more recent trials. While results with arsenic trioxide

alone and ATRA plus arsenic trioxide are encouraging, the number of patients treated to date is relatively small, follow up is short, and extensive experience with these agents is limited to selected centers and countries. In addition, the toxicities of arsenic trioxide and ATRA are not trivial, and there is, as yet, no standardized strategy for postremission therapy in patients who receive this type of induction. Despite these caveats, treatment with arsenic trioxide alone, or arsenic trioxide combined with ATRA, may well be suitable for selected patients with low-risk APL, or for patients who are not candidates for, or who refuse, cytotoxic chemotherapy.

THE ROLE OF ARA-C

While ara-C has historically been relegated to a minor role in the treatment of APL,⁵⁷ more recent data suggest that certain patients, particularly those with high-risk APL, may derive considerable benefit from the addition of ara-C to their treatment. The German AML Co-operative Group,^{24,25} which uses high-dose ara-C during induction, is one of the only groups to report essentially equivalent outcomes in patients with high and low WBC counts, suggesting that high-dose ara-C overcomes the negative prognostic impact of high WBC count. In the recently reported AIDA 2000 trial,²⁶ intensification of consolidation therapy with ATRA and ara-C in high-risk patients led to a cumulative incidence of relapse of 2%, well below the 29% relapse rate seen in the earlier AIDA 0493 trial, and significantly below the 9% relapse rate noted in “intermediate-risk” patients consolidated with anthracyclines and ATRA alone. Finally, the European APL Group²⁰ has reported preliminary results of a randomized trial in which low-risk patients (below the age of 60 and with WBC counts of less than 10,000/ μ L) were randomized to receive (group A) or not receive (group B) ara-C during induction and consolidation. All high-risk patients (WBC count >10,000) received standard-dose ara-C during induction and high-dose ara-C (1 or 2 g/m² every 12 h for eight doses) during consolidation. The preliminary results demonstrate significantly improved EFS (93.6% vs 83.4%) and decrease in relapse rate (3.8% vs 11.9%) in low-risk patients randomized to receive ara-C. Perhaps even more striking, in the nonrandomized high-risk patients (groups C and E, WBC counts >10,000/ μ L), the relapse rates were 2.6 and 0% respectively, and EFS was extremely impressive, at 88.4% (group C, age <60) and 78.3% (group E, age >60). As reported by the Italian²⁶ and Spanish groups,³² cure rates with ATRA- and anthracycline-based therapies are excellent in low-risk patients (WBC count <10,000/ μ L and platelet count >40,000/ μ L) and are generally acceptable in intermediate-risk patients (WBC count <10,000/ μ L and platelet count <40,000/ μ L), so the need for ara-C in these “low-risk” subgroups remains unclear. However, if longer follow up validates the data from the randomized portion of the APL2000 trial,

incorporation of ara-C into the treatment regimen of even low-risk patients may need to be seriously reconsidered. In summary, while the role of ara-C in the treatment of APL remains far from settled, an argument can be made that this agent, particularly at high or intermediate dose, benefits patients with high-risk APL, and as such it should be seriously considered for inclusion into the treatment of all such patients.

TREATMENT OF APL IN ADULTS OF AGE 60 OR ABOVE

The outcome of treatment of APL in older adults (defined as age 60 or above) remains suboptimal, with rates of EFS and OS of only 55–60% in most studies (Table 6.2). Recently reported results from several large European studies^{22,25,58,59} highlight the issues involved in treating this patient population and offer insight into how treatment might be improved. As noted in Table 6.2, CR rates in older adults are approximately 85%, which is marginally, but significantly, lower than the 90–95% rate of CR reported for younger adults treated in the same trials. In the Italian, Spanish, and German AMLCG trials, patients received induction with concurrent ATRA and chemotherapy, while most patients in the European APL93 trial (those above 65 years) were induced with ATRA alone. The comparatively low CR rate seen in all four studies (regardless of induction strategy) was due to a higher rate of deaths during induction, around 15%, which is approximately double of that seen in younger adults. Most of this excess in early deaths is due to infection, as rates of resistant disease, and deaths due to RA syndrome and hemorrhage, are generally similar between older and younger adults.^{22,25,58,59} Induction strategies that avoid cytotoxic chemotherapy (with its attendant neutropenia) may be preferable in older adults, particularly those above the age of 70, or with compromised performance status. An appropriate choice for such patients might be ATRA alone, arsenic trioxide alone, or combined ATRA/arsenic trioxide.

The inferior EFS and OS in older adults also relates to a comparatively high rate of deaths during consolidation and maintenance (deaths in CR), again largely due to neutropenia-related infections. This rate of 10–20% could presumably also be improved by decreasing the intensity of the consolidation and/or maintenance therapies. Indeed, a subset of patients in both the APL93 and GIMEMA studies summarized in Table 6.2 received attenuated consolidation (those above 65 years in the APL93 study, and most patients treated after 1997 in the GIMEMA study). In the latter study,⁵⁹ the 3-year disease-free and OSs were not different among patients who received three or one cycle of anthracycline-based consolidation (all patients received 2 years of ATRA-based maintenance), suggesting no loss of efficacy with decreasing intensity of therapy. However, the PETHEMA Group⁵⁸ has reported the lowest rates of relapse (8.5%) and deaths in CR (9.2%) in adults of age 60 or above, and no planned dose attenuation for older adults was used in that study. The relapse rates in each of the four studies given in Table 6.2 are comparable to relapse rates seen in adults of age below 60, suggesting that, as opposed to most other subtypes of AML, there is no inherent difference in disease biology between APL arising in older versus younger adults. There is a suggestion, however, particularly from the PETHEMA study, that a lower percentage of adults of age 60 or above present with high WBC counts, suggesting that older adults may have an inherently *better* prognosis, at least in terms of disease-related prognostic factors.

Treatment strategies in older adults should thus focus on reducing doses or cycles of chemotherapy, or perhaps omitting chemotherapy altogether. Careful molecular monitoring is mandatory to safely apply this approach, and a certain degree of flexibility is needed to tailor the wide range of therapies available to each patient's clinical course. As with younger patients, risk-adapted strategies³² should be used, with more intensive regimens reserved for patients who present with

Table 6.2 Outcomes of therapy for APL in adults of age 60 or above

Study	N	CR (%)	ED (%)	EFS (%)	OS (%)	RR (%)	Deaths in CR (%)
APL93 ^a	129	86	14	53	58	16	18.6
APL2000–Low WBC ^b	47	98	2	79	90	11	NR
APL2000–High WBC ^b	16	87	13	78	78	0	NR
LPA96/LPA99 ^c	104	84	15	64	NR	8.5	9.2

German AMLCG ^e	32	78	19	54	57	17	NR

N, number of patients enrolled; NR, not reported; ED, early death (death during induction); CR, complete response; EFS, event-free survival (any event, i.e., death or relapse, after enrollment on study); OS, overall survival; RR, relapse rate.

^a Results from the European APL Group.²² EFS, OS, and RR are reported at 4 years.

^b Data are from the European APL Group²⁰; EFS, OS, and RR are reported at 2 years. The high WBC count group received intensified induction and consolidation with ara-C.

^c Results from the PETHEMA Group.⁵⁸ Median follow up was 36 months; EFS, OS, and RR were reported at 6 years.

^d Results from the GIMEMA Group (AIDA93 and amended AIDA97 studies).⁵⁹ OS was reported at 6 years. For ease of comparison, the EFS was estimated from the reported DFS (59%) and subtraction of the early death rate (12%).

^e Data are from the German AML Cooperative Group.²⁵ EFS, OS, and RR reported at 4 years.

high-risk features, mainly WBC count of more than 10,000/ μ L. Given that the disease biology is, if anything, more favorable in older adults, there is no reason to believe that, given proper treatment and supportive care, such individuals should not have a cure rate at least equal to younger adults.

TREATMENT OF RELAPSED APL

Despite the tremendous advances in the treatment of APL discussed above, a small, but significant, percentage of patients will relapse. In the long-term follow up of the APL93 trial,⁵¹ which enrolled 576 patients between 1993 and 1998, 134 (23.3%) patients eventually relapsed (out of 533 who achieved CR). Although most of these relapses occurred within 2.5 years of achieving CR, a substantial percentage (29%) occurred after 2.5 years, with one relapse occurring over 8 years from CR. In the North American Intergroup trial,³⁰ late relapses were also seen, although by far the highest risk period was the first 2 years after CR. Patients with APL, particularly those who present with high WBC counts, are at risk for relapse in the CNS and other extramedullary sites, including skin and ear.⁶⁰⁻⁶⁴ Whether this risk has increased in the "ATRA era" is unclear,⁶² but of the 22 clinical relapses noted in the PETHEMA LPA96 and LPA99 trials,³² 6 (27%) occurred in the CNS. Most patients with extramedullary relapse will be found to have occult (i.e., molecular) or overt leukemia in the marrow, and treatment should be directed not only at the site of extramedullary involvement but also at clearance of systemic disease. The high rate of CNS relapse among APL patients with a WBC count of more than 10,000/ μ L may warrant routine intrathecal prophylaxis in this group of patients, and such a strategy has been adopted by the European APL Group in their APL2000 trial.²⁰

As modern management of APL patients includes serial monitoring for residual disease using RT-PCR, many patients are identified with so-called molecular relapse, generally defined as two successive positive PML-RARA RT-PCR assays performed 2-4 weeks apart. Assuming an assay sensitivity of 1 in 10^4 , such a finding is highly predictive of subsequent clinical relapse. While there is little doubt that molecular relapses are a harbinger of hematologic relapse, and thus require treatment, there is very little agreement about what constitutes appropriate therapy in this increasingly common clinical situation. There is no formal proof that treatment of molecular relapse leads to better outcomes compared to treatment at the time of hematologic relapse, but Lo Coco et al.⁶⁵ have presented compelling evidence in support of "preemptive" therapy, i.e., at the time of molecular relapse. In that study, among 12 patients with molecular relapse who achieved second molecular CR following salvage with ATRA, ara-C, and mitoxantrone, 10 were alive in sustained

molecular remission at the time of the report, for a 2-year survival of 92%. This compared to a 2-year survival estimate of 44% in a previous series of 37 patients treated by the same investigators with identical therapy, but at the time of hematologic relapse.

While clinicians may be reluctant to subject patients with positive RT-PCR results to intensive chemotherapy (\pm stem cell transplant), some type of treatment needs to be offered. Options include (1) gemtuzumab ozogamicin⁶⁶, (2) arsenic trioxide, (3) ATRA (in patients who have not received ATRA within 6 months), (4) standard anthracycline- or ara-C-based chemotherapy, or (5) some combination of the above. Most of the listed agents should convert patients to molecular negativity, but there is no consensus regarding which agent is most effective in this setting, nor is there consensus regarding the duration of therapy, or the type of further intensification (e.g., stem cell transplant) to offer (if any) after achievement of second molecular remission.

Treatment of frank hematologic relapse requires a more aggressive approach, generally incorporating autologous or allogeneic stem cell transplant in second CR. The best option for initial salvage therapy is probably arsenic trioxide, which has been shown to lead to CR rates of 85-95% in relapsed APL.⁶⁷⁻⁷¹ However, the quality of CRs induced by arsenic trioxide is unclear,^{72,73} and most clinicians view arsenic trioxide as a "bridge" to stem cell transplant. The goal of salvage therapy, whatever the agent, is attainment of second molecular CR, which is a mandatory prerequisite prior to proceeding to stem cell harvest and possible autologous stem cell transplant. The role of autologous and allogeneic stem cell transplant in the treatment of relapsed APL has received considerable recent attention.⁷⁴⁻⁸⁰ Initial data from Meloni et al.,⁷⁹ and more recent results from the European APL Group,⁷⁵ suggest that autologous stem cell transplant may cure as many as 75% of patients who are in molecular remission at the time of stem cell harvest and transplant. Investigators from the Cancer and Leukemia Group B, using a high-dose ara-C/etoposide consolidation/mobilization regimen, have reported an EFS of 74% in APL patients transplanted in second CR.⁷⁷ Given the good results with polymerase-chain-reaction-negative autografts in relapsed APL, allogeneic transplant is generally recommended only for those patients who are persistently molecularly positive, or who may have failed previous autologous transplant.^{75,78} The role of stem cell transplant in the treatment of relapsed APL has recently been challenged by Au et al.,⁶⁷ who treated 42 patients with relapsed APL with a regimen of arsenic trioxide (intravenous or oral), followed by idarubicin consolidation and, in most patients, maintenance with oral arsenic trioxide. With short follow up, 38 of the 42 patients were in hematologic and molecular remission, some of them after subsequent retreatment with arsenic trioxide plus ATRA. If results such as these hold up, the role of stem cell transplant in APL will need to be

reexamined; however, at present, autologous or allogeneic transplant offers the best hope for long-term survival for the majority of patients with relapsed APL.

SUMMARY

The majority of APL patients are now cured with ATRA- or arsenic-trioxide-based regimens combined with anthracycline chemotherapy, but a small percentage of patients fail such therapy and require special attention. In particular, a better understanding of the APL-associated coagulopathy is needed, so that effective therapies can be designed to decrease (or eliminate) early deaths secondary to bleeding. Further exploration of non-

myelosuppressive treatments is warranted, especially in low-risk patients or patients with comorbidities that preclude use of aggressive chemotherapy. Finally, patients with high-risk APL require intensified therapy, e.g., with high-dose ara-C or perhaps arsenic trioxide. The goal for the next decade of APL clinical research will be to maintain cure rates for all APL patients while reducing side effects and long-term toxicities of treatment. Patients and physicians alike will continue to benefit from enrollment of patients in carefully designed clinical trials that ask critical questions and provide a framework for rational incorporation of alternative, less-toxic therapies for some or all APL patients. In this way, cure rates will be maintained, the field will move forward, and the ultimate goal of cure of all patients with APL may one day be realized.

Chapter 7

APPROACHES TO TREATMENT OF SECONDARY ACUTE MYELOID LEUKEMIA AND ADVANCED MYELODYSPLASIA

Elihu Estey

GENERAL ISSUES

Within this chapter, secondary acute myeloid leukemia (AML) and secondary “advanced myelodysplasia (MDS)” (International Prognostic Scoring System categories intermediate-2 and high) are combined based on the likelihood that these illnesses have similar natural histories^{1,2}; the somewhat arbitrary criteria used to distinguish them³; and, after account is made for other covariates such as cytogenetics and age, their similar response to therapy.⁴

Secondary AML/MDS can mean disease that is diagnosed only after a period of abnormal blood counts (antecedent hematologic disorder, or AHD) or that has arisen following cytotoxic therapy for another illness. In the vast majority of cases, these illnesses are other malignancies, although cases developing after treatment of a “nonmalignant” disease (such as rheumatoid arthritis) with drugs such as methotrexate would also qualify. Using the above definition and using more than one month as the criterion for an AHD, one-half of the 1990 patients treated at M.D. Anderson Hospital from 1991 to present for AML/advanced MDS were secondary cases. Of these cases, 708 had an AHD but no prior chemotherapy (PCH), 108 had PCH without an AHD, and 162 had both an AHD and a PCH. The great majority of these patients received ara-C at 1–2 g/m² either daily for 4 or 5 days or 1.5 g/m² daily by continuous infusion for 3–4 days combined with idarubicin, fludarabine, topotecan, or troxacitabine. The differences among these regimens are medically insignificant,^{5,6} and they are considered together as “standard chemotherapy” (SCH).

Table 7.1 depicts results of SCH in the aforementioned M.D. Anderson patients. Note that the differ-

ence in complete remission (CR) rate between de novo patients (66%) and the highest CR rate in the three groups of secondary patients (47%) is greater than the difference between the highest (47%) and lowest CR (40%) rates in the three secondary groups. In general, the same is true when considering probabilities of relapse-free survival (RFS) or survival (Table 7.1, Figure 7.1). These observations provide a rationale for considering patients with a history of PCH or an AHD as secondary AML, to be contrasted with de novo cases (Figure 7.2).

Whether the poor results in secondary AML/MDS are due to some inherent, not currently identified, characteristic of this type of AML/MDS or rather to the presence of other covariates is unclear. The principal predictors of outcome with SCH in AML/MDS are performance status, age, and cytogenetics; the former two are associated with treatment-related mortality (TRM) and the latter with resistance to therapy. Of note, each of these is unevenly distributed between de novo and secondary cases (Table 7.2). Patients with de novo disease are on average 10 years younger, but are twice as likely to have a poor performance status (Zubrod 3 or 4). The association between de novo AML/MDS and poor performance status likely reflects the higher white blood cell count and the correspondingly greater risk for organ infiltration in de novo disease. The tendency of secondary cases to have a relatively high proportion of prognostically unfavorable cytogenetic abnormalities (–5/–7) and a relatively low proportion of better prognosis abnormalities [inv(16), t(8;21)] is well known.⁷ In light of these inequalities, it is reasonable to compare outcome in de novo and secondary patients who share a given karyotype, age range, and performance status. Tables 7.3 and 7.4 do so for

Table 7.1 Outcome in de novo and secondary AML/MDS

AHD	PCH	Patients	CR rate (%)	Probability RFS			Probability survival		
				0.5 y	1 y	2 y	0.5 y	1 y	2 y
No	No	998	66	0.72	0.50	0.33	0.68	0.50	0.35
Yes	No	708	45	0.65	0.35	0.20	0.58	0.38	0.20
No	Yes	108	47	0.51	0.32	0.18	0.46	0.32	0.14
Yes	Yes	162	40	0.59	0.39	0.26	0.49	0.24	0.16

patients under the age of 60 years and 60 or above, respectively. These tables indicate that for every cytogenetic group, with the exception of *inv(16)/t(8;21)*, and in both younger and older patients, the de novo patients have both higher CR rates and longer RFS. Figures 7.3 to 7.5 depict the effect of the de novo/secondary distinction on survival. Goldstone et al. have also noted that secondary disease (an AHD or PCH) remains associated with a worse outcome after accounting for age and cytogenetics.⁸

There are three broad options for treatment of secondary AML/MDS: palliative care only, SCH, or investigational therapy, preferably in the context of a clinical trial. As relapse rates begin to decline sharply once 2–3 years have elapsed from the CR date, patients alive in CR at these times can be considered “potentially cured.”⁹ Multiplying CR rate by RFS probability indicates that only 10% of secondary cases are predicted to be alive in first CR at 2 years from treatment date if given SCH (Table 7.1). Under these circumstances, investigational therapy may be necessary at some point in the majority of patients with secondary AML/MDS.

It is critical to ask whether there are groups of patients with secondary AML/MDS who should, or plausibly might, receive SCH, which in any event is intuitively preferred by patients and physicians, given the fewer number of unknowns involved. Tables 7.3

and 7.4 indicate that both older and younger patients with *inv(16)* or *t(8;21)* should receive SCH. As made clear by Beaumont et al.,¹⁰ standard treatment should also be recommended for patients with secondary acute promyelocytic leukemia (APL). Younger patients with secondary AML and a normal karyotype have a 20% likelihood of remaining alive in first CR at 2 years (a CR rate of $0.69 \times$ an RFS of 0.29; Table 7.3). Whether this result is sufficiently high to justify the use of SCH, given that it is distinctly possible that investigational therapy could be considerably worse, is a subjective decision, except in cases where an internal tandem duplication or mutation of *FLT3*¹¹ is present and tips the scales to a recommendation for investigational therapy. In the other groups depicted in Tables 7.3 and 7.4, the results with SCH are so poor (less than or equal to 10% probability of potential cure) that investigational therapy is preferred, given that even if it proves worse than SCH, it cannot be much worse. The recommendation that all patients with secondary AML with the exception of those with *inv(16)* or *t(8;21)* and, quite plausibly, those under age 60 with good performance status and a normal karyotype are candidates for investigational therapy is, in general, in accord with the recommendation of the National Comprehensive Cancer Network,¹² a consortium of academic medical centers. In those older patients in whom this recommendation cannot be carried out, the option of

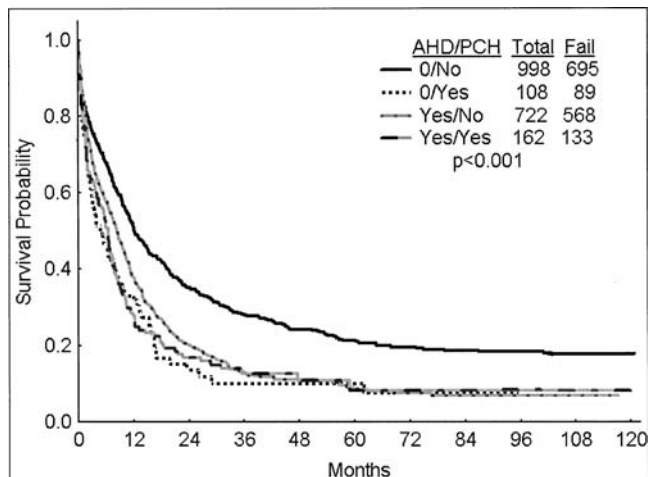

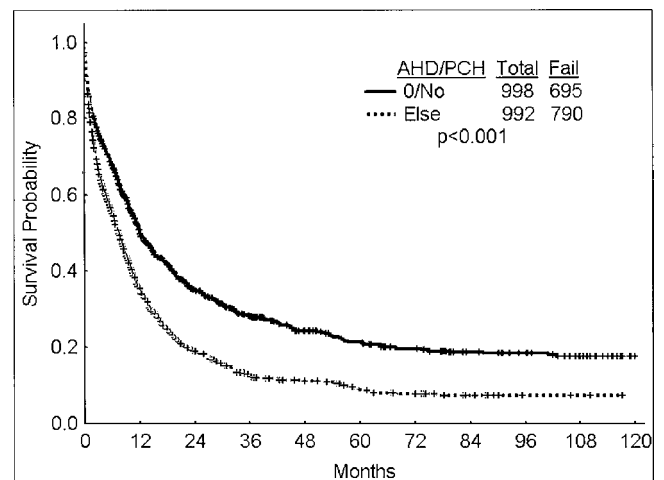

**Figure 7.1** Survival probabilities of M.D. Anderson patients according to AHD and PCH status**Figure 7.2** Survival probabilities when patients with PCH or AHD are considered as one group (secondary AML/MDS) and compared to de novo patients (neither AHD nor PCH)

Table 7.2 Associations with other covariates

Predictors	De novo cases	Secondary cases
Median age	55	66
Performance status Zubrod 3 or 4	126 (13%)	69 (7%)
−5/−7	180 (18%)	335 (33%)
Inv(16) or t(8;21)	128 (12%)	22 (2%)
Normal	932 (39%)	337 (33%)
Other	265 (26%)	294 (29%)
Insufficient	47 (5%)	32 (3%)

palliative care should be strongly considered given that the 20–30% risk of TRM rate with SCH is not commensurate with the benefits offered by this type of therapy.

Before proceeding to a discussion of investigational therapy, the role of allogeneic stem cell transplant should be discussed. In patients in first CR, “standard” transplant, i.e., using cyclophosphamide and total body irradiation or oral busulfan and cells from an HLA-identical or 1-antigen mismatched sibling donor, is distinguished from “investigational” transplant. The largest trials comparing SCH with standard transplant (allogeneic stem cell transplantation or allo SCT) in first CR minimize selection biases by including patients in the transplant group if they had a donor regardless of whether they had a transplant. These indicate that, on average, patients in the no donor group and donor groups have similar survival.^{13,14} No trials address this issue in a similar fashion, restricting attention to patients with secondary AML/MDS. However, there are studies that examine the effect of having a donor in subgroups defined by other prognostic factors. The largest study to examine the effect of cytogenetics¹⁵ found a trend for patients with inv(16) or t(8;21) to live longer if assigned to chemotherapy rather than allo SCT, while patients with prognostically intermediate karyotypes [any but inv(16), t(8;21), −5, −7, 5q−, 7q−, or more than three abnormalities] lived longer with allo SCT, but only if patients were younger than 35. Most importantly, outcome was similarly poor in the adverse karyotype group (−5, −7, 5q−, 7q−, or more than three abnormalities) regardless of whether patients were assigned to

allo SCT or chemotherapy. Similarly, autologous SCT does not affect prognosis in these patients.¹⁶ Both the Medical Research Council (MRC) AML 10 and AML 12 trials^{15,17} and a previous MRC study¹⁸ make clear that the principal determinant of outcome remains the prognostic group regardless of patients’ donor status. Further suggestion that similar prognostic factors are operative for allo SCT and chemotherapy are data indicating that (1) in patients transplanted in second CR, RFS is influenced by length of the first chemotherapy-maintained CR, as is the case when patients receive chemotherapy to maintain a second CR,¹⁹ and (2) allo SCT does not appear to alter the poor prognosis of patients with FLT3 mutations.²⁰ Furthermore, although approximately 90% of allo SCT survivors are in good health years after the procedure,²¹ they are clearly at increased risk for subsequent development of solid cancers^{22,23}; a similar risk is not apparent in long-term survivors of chemotherapy.⁹ Thus, unless secondary AML is thought to represent a unique prognostic group, there is no compelling evidence to recommend that patients with secondary AML in first CR receive conventional SCT. If, however, a decision is made to proceed to allo SCT once first CR is observed, administration of consolidation therapy prior to transplantation appears to be of no value.²⁴

INVESTIGATIONAL APPROACHES

As noted above, it is unlikely that secondary AML/MDS possesses unique therapeutic targets. Indeed, because the chromosomal abnormalities characteristic of secondary AML/MDS more frequently occur in older than in younger patients with de novo AML, many of the former may really have “secondary” AML, consequent to prolonged exposure to toxins. Similarly, many patients considered to have de novo AML would be classified as having secondary AML had they happened to visit a physician and have an AHD detected in the months before they were found to have AML. Given these facts, a discussion of investigational approaches to secondary AML is in reality a general discussion of such approaches in worse prognosis AML/MDS. As the ability of the patient to withstand therapy is an important consideration and is often a

Table 7.3 Outcome in patients under age 60 with performance status 0–2 by cytogenetics and de novo versus secondary distinction

Cytogenetics	De novo cases		Secondary cases	
	CR rate	RFS at 2 years	CR rate	RFS at 2 years

function of age, older and younger patients will be discussed separately. In each, general issues and strategies will be the focus, rather than a comprehensive list of all new agents in testing.

OLDER PATIENTS

Detailed studies of the effect of age on outcome in AML suggest that, all else being equal, each additional year increases the risk of death by approximately the same amount.²⁵ Older patients with AML/MDS are commonly defined as those of age 60 years and above. Given that CR rates in older patients with secondary AML/MDS following SCH are less than 50% (Table 7.4), investigational approaches should be employed at diagnosis. There are three general types of investigational therapies that might be offered to these patients: high-intensity (HI) regimens, low-intensity regimens (LI), and nonablative allogeneic transplant. HI regimens [e.g., clofarabine plus ara-C^{26,27} or triapene plus ara-C] are those that produce not only several weeks of severe myelosuppression, but also cause damage to organs, such as the gut or lung. This damage contributes to the 20–30% rate of TRM characteristic of previous HI. This rate, as well as advances in molecular biology, have sparked interest in the development of LI. Examples are the farnesyl transferase

inhibitor R115777^{28,29}; the FLT3 inhibitors PKC412 and CEP701^{30,31}; other tyrosine kinase inhibitors such as PTK787 and SU5416^{32,33}; histone deacetylase (HDAC) inhibitors such as SAHA; and hypomethylating agents such as decitabine^{34,35} and 5-azacytidine.³⁶

Single-agent studies in high-risk MDS/AML suggest that, in addition to being more “rational” than chemotherapy (CT), LI may have beneficial effects.^{28–36} First, they appear to produce less TRM and morbidity than CT. Second, they can produce so-called minor responses (MRs). An example is of “marrow CR” in which, although blood counts remain low, blasts are reduced to “normal” levels in the marrow (<5%) and blood. However, these studies also suggest that CR rates may be considerably lower with HI than with LI, with CR defined as a marrow CR plus “normal” blood counts.^{28–36} Thus, most likely, LIs will need to be combined either with each other or with HIs. However, if LI is to be combined with HI in older patients, the HI should presumably be of a type not associated with high rates of TRM. Such combinations, e.g., of LI with low-dose ara-C, can thus be operationally considered “LI” despite the use of chemotherapy. The observations of low CR rates have also prompted an

**Figure 7.3** Survival probabilities in patients with a normal karyotype according to de novo versus secondary distinction**Figure 7.4** Survival probabilities in patients with intermediate-risk cytogenetics [normal, +8, del11q, and miscellaneous abnormalities not including –5/–7, inv(16), or t(8;21)] according to de novo versus secondary distinction

Figure 7.5 Survival probabilities in patients with chromosome 5 and/or 7 abnormalities according to *de novo* versus secondary distinction

International Working Group (IWG) sponsored by the National Cancer Institute (NCI) to publish criteria for response in MDS, intended with trials of LI in mind, which recognize various categories of MR.³⁷ Such MRs are also being noted in studies of LI in AML.²⁸⁻³¹ However, as noted by the authors of the IWG report, “it will be important to apply these guidelines prospectively and to critically assess their validity and usefulness.”

This statement assumes particular significance given our comparison of the effects on survival of achieving CR versus achieving MR with HI.³⁸ At M.D. Anderson, we stratified 314 patients with high-risk MDS or AML who survived HI but failed to achieve CR according to whether they exhibited MR on the date they were removed from study. We considered MRs as marrow CR, or as CR with incomplete platelet recovery (CR_p) (with less than 5% marrow blasts, normal neutrophil count, and platelet transfusion independence). We then compared survival time in patients according to whether they achieved (1) marrow CR, (2) CR_p, (3) CR as usually defined (CR_p and a platelet count >100,000), or (4) none of the above. Survival was dated from date of CR or from date the patient was removed from study. Results are shown in Figure 7.6. Although patients who achieved an MR (marrow CR, CR_p) may have done better than patients who did not, the most striking difference was between patients who achieved CR and those who did not.

Findings were similar in patients with high-risk MDS and in those with AML. The results did not reflect differences in time to CR versus time to resistance date or between the times to resistance date in the various subsets of resistant patients. Thus, the observations suggest that only CR potentially lengthens survival in these diseases after administration of HI. This observation is perhaps not surprising. In particular, if many CRs are transient and thus contribute little to an increase in survival time, it may be unrealistic to

expect responses, such as MRs, which are qualitatively inferior to CR, to be associated with a survival benefit. Whether MR will have less effect than that of CR in increasing survival when patients are given LI rather than HI is unknown. However, the data in Figure 7.6 have two consequences. First, they provide an ethical basis for administering either *HI* or *LI* as the initial investigational therapy to older patients with secondary AML/MDS. Specifically, the figure suggests that if the beneficial effect of LIs on TRM is accompanied by a lower CR rate, LI and HI may have equivalent effects on survival. Second, the data emphasize the importance of assessing the relationship between survival and the various categories of MR. Such assessment is facilitated by the short survival of patients of age 60 and above with secondary AML/MDS.

The discussion to date has focused on survival as the principal outcome of interest. However, although they may not improve survival time in older patients with secondary AML/MDS, a major advantage of LIs is the possibility that they will provide better “quality of life” (QOL) than do HIs. Thus, unlike HIs, LIs are often administered by mouth and, in principle, require less time in hospital.³⁹ However, if HI is more likely to produce a CR than LI, and if achievement of CR is necessary to lower the risk of infection and hemorrhage that are frequent contributors to morbidity in older patients with AML/MDS, HI may be more likely to improve QOL than LI. The above discussion stresses the need for reproducible QOL measurements in patients receiving investigational HI or LI.

A third type of investigational approach in older patients with secondary AML/MDS involves nonablative allogeneic transplant (minitransplant). Minitransplantation relies essentially entirely on a graft-versus-leukemia effect; the purpose of the attenuated doses of chemotherapy used as the preparative regimen is to allow the donor cells to engraft. The source of stem cells is often the blood rather than the bone marrow.⁴⁰⁻⁴²

Figure 7.6 Subsequent survival in chemotherapy patients according to initial response (see text for details)

While it is clear that minitransplant produces TRM rates to “only” 20% in patients up to age 75, the potential benefit is less clear. Part of the difficulty in assessing the effectiveness of minitransplant, as well as of various HIs or LIs, is the selection bias that accompanies the initial investigations of these agents. Other avenues of active investigation within transplantation include use of intravenous, rather than oral, busulfan to overcome the erratic pharmacology of the latter,⁴³ anti-CD45 radiolabeled antibodies as a component of the pretransplant “preparative regimen,”⁴⁴ and use of alternative donors (e.g., unrelated, umbilical cord blood).⁴⁵ While use of such donors should expand the impact of allo SCT, it is unclear whether donors can be identified within a relevant time frame, particularly if use of donor cells is envisioned during induction. However, it may be possible to wait longer before beginning treatment than is commonly appreciated.⁴⁶ This may be particularly true in patients with secondary AML/MDS, who usually present with lower circulating blast counts, than in de novo patients.

YOUNGER PATIENTS

TRM rates are usually less than 10% in patients under the age of 60. Partly as a consequence of lower TRM rates and again in contrast to older patients, younger patients with secondary AML/MDS generally have CR rates of more than 50% (Tables 7.3 and 7.4). As a result, a case could be made for beginning investigational therapy only once CR has occurred. This approach avoids the ethical issue that might arise consequent to giving investigational therapies to patients with such CR rates, which may be worse than SCH. On the other hand, there is evidence that an induction regimen can influence CR duration.⁴⁷ As a practical issue, patients in CR are often ineligible for trials of new agents; this is unfortunate given the short remissions seen in many such patients. Under these circumstances, it is reasonable to administer investigational regimens to younger patients undergoing remission induction for secondary AML/MDS, provided appropriate statistical designs are used (see next section). In younger patients with secondary AML/MDS and abnormalities of chromosomes 5 and/or 7, new regimens should be used at the time of diagnosis since the CR rate in such patients with SCH is less than 40% (Table 7.3). Because younger patients have relatively low TRM rates, reasons to avoid HIs in these patients are less compelling than in older patients, particularly in combination with LIs such as PKC412 or R115777; indeed, trials combining these and similar agents with HI (such as 3 + 7 or even high-dose ara-C) have been proposed or are in progress. Investigational treatments in younger patients thus include both the agents discussed in the section on older patients and exploration of further dose intensification. As an example of the latter, the Cancer and Leukemia Group B (CALGB) has reported that patients under age 60 tolerate daily daunorubicin

doses of 90 mg/m² in combination with ara-C at 100 mg/m² given daily for 7 days and etoposide 100 mg/m² daily.⁴⁸ Heretofore, daunorubicin doses rarely exceeded 60 mg/m² daily. The CALGB is now comparing the 90- and 60-mg/m² doses.

As noted above, patients with a normal karyotype or abnormalities other than $-5/-7$ can plausibly begin investigational therapy once CR has occurred. While pharmaceutical companies have provided only a limited number of agents intended for use in patients in remission, commercially available agents can be used for investigational purposes in this setting. For example, 5-azacytidine and decitabine have been approved for use in MDS.³⁶ The drugs' effectiveness may reflect their ability to demethylate inappropriately hypermethylated genes,³⁶ thus inducing reexpression of these genes, which might include various “tumor suppressors.” There are reasons to think that combinations of demethylating agents and HDAC inhibitors might be particularly effective in this regard. Valproic acid, a pediatric anticonvulsant, is an HDAC inhibitor, although a less potent one than SAHA or depsipectide. Thus, a combination of 5-azacytidine and valproic acid could be investigated, for example, in patients in remission. Analogous trials could be formulated using commercially available drugs or focusing on the investigational approaches to transplantation, which are described at the conclusion of the section on older patients.

NEW METHODS FOR CLINICAL TRIALS OF INVESTIGATIONAL AGENTS

The likelihood that many combinations and permutations of LIs, with each other and with HIs, will be investigated in the future leads to consideration of desirable elements to incorporate in the relevant statistical designs. These elements include the need to (1) randomize early in the investigative process; (2) formally monitor multiple outcomes; (3) account for the possibility that the effects of a given treatment may depend on the treatments given before or after; and (4) develop strategy that views drug development as a process rather than as a series of unconnected trials. Topics (2) to (4) are examples of the general problem of “multiplicities.” Most statistical designs underlying LI protocols have not focused on these issues.

NEED FOR EARLY COMPARISON/RANDOMIZATION

The great majority of LIs are tested in single-agent phase II trials. This practice reflects the conventional phase II → phase III paradigm. Specifically, phase II trials are “exploratory,” designed to establish activity, with the idea that comparative trials (phase III) should be conducted only after activity has been observed. A fundamental problem with this formulation is that

phase II trials are inherently comparative. In particular, patients are vitally interested in whether a particular therapy is superior to another. The comparative nature of phase II trials is implicit in the designs governing their conduct, as these designs specify minimally acceptable response rates,⁴⁹ derived via comparison with other available therapies.

Although phase II trials are thus inherently comparative, the current emphasis on single-arm, nonrandomized phase II trials provides an unreliable basis for treatment comparison because of treatment-trial confounding.⁵⁰ Indeed, it is logically inconsistent that the need to avoid confounding trial and treatment effects is addressed by randomizing in phase III, yet is ignored in the evaluation of phase II data that determines whether the phase III trial will be conducted in the first place. These considerations emphasize the desirability of randomization among various treatments and strategies in the early stages of their development. Designs for this purpose have been described.⁵⁰ In general, these designs call for randomization of a relatively small number of patients among a relatively large number of therapies. Enrolling fewer patients on each trial permits a larger number of treatments to be investigated. This ability is useful because preclinical rationale is an imperfect predictor of clinical success. Thus, although interferon is the only drug currently known to prolong survival in chronic myeloid leukemia (CML), its mechanism of action remains unknown. The development of all-*trans*-retinoic acid (ATRA) for APL is now cited as an exemplar of the “bench-to-bedside” paradigm. However, it is important to remember that the initial Chinese reports of high CR rates were greeted with skepticism in the West; presumably, there would have been less skepticism if a bench-based rationale were readily apparent. Indeed, with the exception of imatinib, most of the drugs that have improved outcome for patients with leukemia (2-chlorodeoxyadenosine in hairy cell leukemia, interferon in CML, ATRA and arsenic trioxide in APL) are examples of “bedside-to-bench” development. If preclinical rationale cannot yet replace empiricism, we should examine a larger number of therapies. Thus, rather than randomizing 240 patients between a standard and an investigational induction regimen, we might be better served by randomizing the same 240 patients among a standard and three investigational induction regimens. It is true that such trials will be nominally “underpowered.” However, this argument ignores the false negative rate inherent in the selection of which investigational regimen to study. For example, if there are three potential regimens that could be investigated and if preclinical rationale is, as argued above, a poor predictor of clinical results, then limiting ourselves to one regimen in effect potentially entails a false negative rate of 67%. Simply put, the most egregious false negative results when a treatment is not studied at all.

NEED TO MONITOR MULTIPLE OUTCOMES

It is commonly accepted that adaptive monitoring (interim analyses) of clinical trials can lower the risk that future patients will receive a therapy already shown to be ineffective/toxic in earlier patients. Adaptive monitoring of most LI trials is limited to interim analyses of response rate, with response defined so as to include MR, which typically is observed much more commonly than is CR.^{28–36} The presence of MR indicates that the LI has activity and thus might be worthy of further investigation. However, as emphasized above, the relationship between MR and survival or QOL generally is unknown. Thus, making response the sole focus of interim analyses overlooks the reality that patients are likely to be concerned with response only to the extent that it is known to lead to longer survival and/or a better QOL. This is particularly true in secondary AML/MDS given the short life expectancy of patients with this condition. Indeed, because formal “stopping rules” in trials of LIs are based on response and not on survival, a scenario in which all patients on a trial “respond” but nonetheless die sooner than might be expected if standard HI could, in principle, lead to erroneous continuation of the trial. Because death rates in LI trials are typically monitored informally and on an ad hoc basis, such trials often have very undesirable “operating characteristics” (OCs). OCs include quantities such as the probability of early termination if a treatment arm is truly associated with a higher mortality rate, or the probability of selecting a given treatment if it is truly superior to others, as well as expected sample size.⁵⁰

Survival time usually cannot be fully assessed until several months after entry onto such a trial, while response (MR or CR) can. Because, however, appreciable numbers of secondary AML/MDS patients die within a few months of presentation (e.g., 20–30% at 2 months if given HI), some information about survival is available early on. It follows that both response and survival should be formally monitored several months after beginning a given therapy. Accrual into a treatment arm would stop if either the death rate was too high or the response rate too low. It is possible that a high early death rate might transform into a low later death rate. Similarly, a low response rate might have no effect on survival. However, it is unlikely that patients would accept such possibilities, which should be assessed retrospectively.

Another example is of the use of investigational therapy during remission induction in younger secondary AML/MDS patients in whom SCH produces CR rates in excess of 60% (Table 7.3). The primary goal of using investigational therapy during induction is to improve RFS. Obviously then, this outcome must be monitored. However, because the investigational therapy might reduce a relatively high existing CR rate, it is also important to monitor CR rate. Trade-offs between

CR and RFS can be specified. For example, a high probability that there will be a 5% absolute decrease in CR rate might not cause early stopping, provided there is an equally high probability of a 20% improvement in RFS. These considerations underscore the desirability of including mechanisms for multiple-outcome monitoring in trials in secondary AML/MDS.^{51,52}

NEED TO CONSIDER STRATEGIES AS WELL AS TREATMENTS

Monitoring multiple outcomes simultaneously, ideally based on desirable trade-offs among these outcomes, is an example of a “multiplicity.” A second type of multiplicity arises because a given patient with secondary AML/MDS (or cancer) typically receives multiple treatment regimens. Administration of one therapy may affect outcome with a subsequent therapy. For example, because “targeted therapies” may affect multiple targets, a therapy directed at target “X” may also “down (or up) regulate” target “Y,” thereby influencing response to a future therapy aimed at Y. It is possible that patients of age 60 and above with high-risk MDS or secondary AML/MDS might have less TRM if given LI first, and HI only should LI fail. However the reverse approach might be preferable if HI’s antileukemia effect is significantly greater than that of LI, outweighing any reduction in TRM with the LI first strategy. Thus, the issue is evaluation of a multicourse treatment strategy, rather than a particular treatment, with a goal of assessing which is the preferable sequence of

treatments. Conventional statistical designs for LI trials regard each therapy as a distinct entity, thus paying little formal attention to the issue of the sequence in which two or more therapies are administered. It follows that new designs should address this issue.⁵³

NEED TO VIEW DEVELOPMENT OF SECONDARY AML/MDS THERAPY AS A PROCESS

It might be useful to consider drug development as a “process” rather than, as it is currently thought of as, a series of unconnected trials. In this process, referred to as “continuous phase II,”⁵⁴ patients are randomized among a number of treatments or strategies. Arms that perform better get used more often. Arms that perform relatively poorly are dropped. An arm that does well enough is recommended for inclusion in a larger cooperative group trial. As more treatments become available, patients are, “seamlessly,” randomized among them, without suspending accrual between trials. Application of the continuous phase II processes speeds up drug development. We believe this paradigm is realistic because new statistical designs, based on Bayesian approaches, provide the requisite flexibility and versatility,⁵⁰⁻⁵⁴ while the recent emergence of powerful computational technology has made the Bayesian paradigm a practical reality. In particular, the OCs of Bayesian designs can now be readily assessed, and conduct of trials monitoring multiple outcomes can be based on a relatively simple user interface.⁵⁵

Chapter 8

DEFINITION OF REMISSION, PROGNOSIS, AND FOLLOW-UP

Mikkael A. Sekeres and Matt E. Kalaycio

INTRODUCTION

The previous chapters in this book have taken us through the epidemiology of acute myeloid leukemia (AML); its pathology and molecular biology; and the nuances of making the diagnosis, treatment options for both younger and older adults, and for special populations of AML patients [such as those with acute promyelocytic leukemia (APL) and secondary AML]. This chapter will address the next step in the thought process about AML, defining remission, predicting which patients are more or less likely to enter a remission and enjoy long-term disease-free survival, and it will provide guidelines for following AML patients once they have achieved a remission.

DEFINITION OF REMISSION

In broad terms, a complete remission (CR) in AML is defined as the inability to detect leukemia, using standard tests (i.e., peripheral blood smears, bone marrow biopsy and aspirate, and flow cytometry) to the greatest extent possible. It does not indicate or imply cure, though patients may mistake the two and assume that CR and cure are equivalent.¹ Another way of approaching this concept is to consider the following thought experiment. When a patient presents with AML, he or she presumably has 10^{12} leukemia cells, which would be approximately the same number of cancer cells present in 1 cm^3 of tissue in a solid malignancy [and that would be considered a pathologic enlargement on computed tomographic scan].² Standard remission induction therapy usually reduces this number by three or four logs, to 10^9 or 10^8 myeloblasts (the amount required to decrease the number of blasts in the bone marrow to less than 5%, in the setting of recovered peripheral blood cell counts).³ In other words, in the setting of a CR, a patient may still have

between 100 million and 1 billion leukemia cells, necessitating further cycles of chemotherapy to promote further log reductions in blasts, with an ultimate goal of reducing blasts to a finite number, at which point it is hypothesized that the patient's immune system can eliminate the residual leukemia. Only at this point can a patient be said to be cured. In AML, remission status is assessed after a patient's peripheral blood values have recovered, usually between 4 and 6 weeks after the start of remission induction therapy.

The first widely accepted definition of remission in AML was published in 1990 by a National Cancer Institute-sponsored workshop that took place in 1988 on definitions of diagnosis and response in AML.^{4,5} This definition was developed for use in clinical trials, though it has been widely applied outside of the trial setting. A CR was defined as a bone marrow biopsy and aspirate, demonstrating normal cellularity with normal erythropoiesis, granulopoiesis, and megakaryopoiesis (typically defined in the context of a bone marrow cellularity of 20%), and containing no more than 5% blasts. In addition, the peripheral blood had to contain at least 1500 granulocytes/ mm^3 and 100,000 platelets/ mm^3 for at least 4 weeks in the absence of intervening chemotherapy. The authors went on to comment that CRs were the only responses worth reporting in phase III trials, as lesser responses [e.g., partial responses (PRs)] do not have an impact on survival (the leukemia equivalent of being "a little bit pregnant"). The goal of these definitions was to make clinical trials comparable and interpretable, though the authors concede the lack of evidence supporting portions of their recommendations.

Over the subsequent decade, improvements in diagnostic criteria for AML⁶ and insights into the biology and genetics of the disease⁷⁻¹⁰ necessitated revisions of these guidelines. An international group of investigators met in Madrid, Spain, in 2001 to develop revised recommendations that incorporated these new insights

Table 8.1 Criteria for a morphologic CR in AML

Morphologic leukemia-free state
<5% blasts in a bone marrow aspirate
No blasts with Auer rods or persistence of extramedullary disease
Absence of a unique phenotype by flow cytometry identical to what appeared in the initial specimen
Absolute neutrophil count <1000 granulocytes/mm ³
Platelet count >100,000/mm ³

and novel therapeutics, and the results of their efforts were published in late 2003.¹¹

The authors report different definitions for CR. The first, and most commonly used, is a morphologic CR (Table 8.1). This definition requires that a patient enter a morphologic leukemia-free state, defined as fewer than 5% blasts in a bone marrow aspirate; no blasts with Auer rods or persistence of extramedullary disease; and absence of a unique phenotype by flow cytometry identical to what appeared in the initial specimen (i.e., no persistence of aberrant markers, such as CD7). In the setting of a morphologic leukemia-free state, the patient must demonstrate an absolute neutrophil count of at least 1000 granulocytes/mm³ (the old criteria required 1500) and 100,000 platelets/mm³. Absent are requirements for minimal bone marrow cellularity, minimal hemoglobin values (though patients should be transfusion free), and duration of response, as it was recognized that the 4-week requirement of maintenance of normal blood counts was often impossible in patients undergoing postremission therapy (which often occurs within 4 weeks). The authors also acknowledge that the bone marrow blasts percentage cutoff of 5% is entirely arbitrary.

Subcategories of patients who fulfill the definition of morphologic CR include the following:

1. Those who enter a cytogenetic CR. Patients in this category revert to a normal karyotype at CR from an abnormal one. This category is recommended for use primarily in clinical studies.
2. Those who enter a molecular CR (CRm). Reverse transcriptase polymerase chain reaction (RT-PCR) techniques are sensitive in detecting residual leukemia in AML typified by a specific genetic defect, including the PML/RARA in t(15;17), or the AML1/ETO fusion in t(8;21). The sensitivity of RT-PCR falls in the range of detecting one positive cell in 1000–10,000 cells. The prognostic implication of CRm is well established in monitoring APL¹² and chronic myelogenous leukemia (CML),^{13–15} and will become more so in other types of leukemia.
3. Those who enter a morphologic CR with incomplete blood recovery (CRi). In the past, this has been referred to as a CR with the exception of recovery of platelet counts, and was used first on a broad scale

in studies that led to the eventual approval by the Food and Drug Administration for gemtuzumab ozogamicin.^{16,17} This category was developed for patients who fulfilled the requirements of a morphologic CR, but with residual neutropenia or thrombocytopenia. These patients do not seem to enjoy the same survival as those who enter a full morphologic CR.

A partial remission is defined as restoration of peripheral blood counts to similar values as in a CR, and a decrease in bone marrow blast percentage by 50% or above, to a total of no more than 25% (but more than 5%, unless Auer rods are present, in which case 5% or less is acceptable to meet the PR definition). Partial remissions are to be used only in the setting of phase I or II trials, in which a signal of activity (in the setting of acceptable safety) may be needed to expand drug testing in a subgroup of patients.

PROGNOSIS IN AML

Although many clinical and pathologic features of AML have prognostic relevance, only a few prognostic factors are universally agreed upon, validated, and impact clinical practice. Nonetheless, newer biologic markers of prognosis are likely to supplant older clinical markers in the near future.

Age

As discussed further, and in greater detail in Chapter 5, age greater than 60 years invokes many adverse features that make separation of age from other poor prognostic markers difficult. Nonetheless, the prognosis gets progressively worse for patients with AML and age greater than 60 years, with each incremental decade of age above 60 years. For patients less than age 60, however, age has proven more difficult to prove as an adverse risk factor, suggesting that biologic features of the leukemia, rather than age alone, are most important in predicting outcome.

In the large trial of cytarabine dose-intensification reported by Mayer et al., the remission rate was 75% in patients of age below 40 years and 68% in those of age 40–60 years, but 4-year disease-free survival was 32 and 29%, respectively.¹⁸ Similarly, Zittoun et al. failed to find an adverse impact of increasing age between 10 and 59 years on disease-free survival in a large trial testing the value of stem cell transplant.¹⁹ In contrast, both the Medical Research Council (MRC) and the Southwest Oncology Group and Eastern Cooperative Oncology Group (SWOG/ECOG) intergroup trials found worse survival with age increasing from 18 to 55 years.^{20,21} Thus, the impact of age on prognosis in patients less than 60 years of age is uncertain.

APL has an incidence that is similar among all age groups, including the group greater than 60 years of age. There is no evidence that the biology of APL is

different in older versus younger patients. Yet, the survival for older patients with APL is significantly worse than it is for younger patients, and it cannot be explained by an inability to tolerate treatment, since remission rates are similar. The experience of APL supports the contention that age is an independent adverse prognostic factor in AML.

Antecedent hematologic disorders

Some hematologic disorders, such as advanced myelodysplastic syndrome (MDS) and CML, invariably result in transformation to acute leukemia. Others, such as myelofibrosis with myeloid metaplasia, polycythemia rubra vera, and aplastic anemia, do not always terminate in acute leukemia. However, all hematologic disorders that do transform to acute leukemia share an equally poor prognosis with available therapies. In fact, many clinical trials of treatment for acute leukemia exclude patients with antecedent hematologic disorders (AHD) for this very reason. The influential Cancer and Leukemia Group B (CALGB) study that found higher doses of cytarabine after remission improve survival compared to lower doses excluded patients with AHD.¹⁸ Other studies group patients with AHD with those previously exposed to cytotoxic treatments, such as chemotherapy, making distinctions with regard to one group or another difficult.

However, some studies included patients with AHD and analyzed them separately from those with treatment-related AML. One study retrospectively compared 44 patients with an AHD to 152 patients without such a history. The remission rate was lower in patients with an AHD (41% vs 73%), and was only 23% in AHD patients older than 64 years.²² For patients with AHD who achieved remission, disease-free survival was 17% at 3 years versus 29% ($P = 0.02$) in patients without AHD. Others have reported similar results, but the confounding variables of age and cytogenetics cloud the potential independent adverse prognostic impact of an AHD.

Some patients with AML present with no history of AHD, but have dysplastic changes in their marrow at diagnosis. These patients also have a worse prognosis compared to patients without such morphologic abnormalities.^{23,24}

Although some patients who transform from a myeloproliferative disorder into AML achieve remission with standard induction chemotherapy, the duration of response is brief.²⁵ In a study of 91 cases of myelofibrosis that transformed into AML, 24 patients were treated with standard induction chemotherapy.²⁶ Of these, none achieved a CR. Although 10 patients reverted to chronic phase disease, their median survival was only 6 months. Importantly, the treatment-related mortality rate was 33% and the median survival of patients treated with chemotherapy (3.9 months) was not significantly different than that achieved without intensive chemotherapy (2.1 months).

Prior cytotoxic therapy

Patients treated with cytotoxic chemotherapy or radiotherapy for both malignant and nonmalignant conditions are at risk for subsequent, or secondary, AML. Patients with secondary leukemia have an extremely poor prognosis with standard treatments. Secondary leukemias are frequently characterized by clonal cytogenetic abnormalities that by themselves connote a worse prognosis (see below). In one series, only 29% of patients with secondary AML or MDS achieved remission with standard induction chemotherapy, and only 13% of patients survived 2 years.²⁷ Other recent series confirm these dismal results.^{28,29}

However, some secondary leukemias have a more favorable prognosis and should be recognized. Patients with secondary AML characterized by favorable cytogenetics, such as $t(8;21)$ and $inv(16)$, have a worse prognosis compared to patients with favorable cytogenetics and de novo AML, but have a significantly better prognosis than other patients with secondary AML and should be treated with curative intent.^{30,31} Rarely, APL is induced by exposure to chemotherapy.³² When this happens, remission rates and survival are similar to those achieved in the setting of de novo APL.³³

Other clinical factors

Some studies suggest that higher white blood cell counts correlate with a worse prognosis,³⁴ but other studies refute this assertion.³⁵ In a large study of over 1000 patients, no clinical factor was found to significantly influence survival when cytogenetics and response to treatment were factored in.²¹ A recent study suggests that race may be an important, and heretofore unrecognized, prognostic factor. African-American men with AML have a significantly worse remission rate and survival compared to other patients with AML, including African-American women.³⁶

We have reviewed our own experience in older patients with AML treated with a uniform induction chemotherapy regimen.³⁷ Patients who present with a high lactate dehydrogenase level or significant anemia have a survival of less than 5 months.³⁸ Consistent with reports from larger trials, we found that a delay from diagnosis to the institution of therapy adversely impacts survival.^{39,40} In aggregate, these observations suggest that those patients may be identified at diagnosis who will not benefit from standard induction chemotherapy. Furthermore, a leukocyte nadir count of less than $0.04/\mu\text{L}$ correlates with a poorer prognosis.⁴¹

Biologic factors

Evidence is quickly accumulating that biologic factors intrinsic to the leukemic clone have as much, if not more, prognostic significance as do more traditional clinical factors. Cytogenetic analysis has become critical to the management of AML. Further details as to the molecular aberrations induced by cytogenetic

Table 8.2 Pretreatment cytogenetic risk groups for overall survival in AML

abnormalities in AML are discussed in Chapter 2. Whether functionally relevant to leukemic pathogenesis or not, the presence or absence of cytogenetic abnormalities provides important prognostic information that is relevant to both younger and older adults with AML.⁴²

Three large, multi-institutional efforts have explored the prognostic significance of cytogenetics in detail. As displayed in Table 8.2, there is general agreement as to the prognostic significance of many, but not all, abnormalities.^{43–45} Some of the discrepancy may lie in the patient population analyzed. For example, the CALGB study included all patients up to age 86 years, while the other two studies limited their analysis to patients less than 56 years of age. The CALGB study also excluded patients with the t(15;17). The MRC study included children. The SWOG/ECOG and MRC studies each analyzed the results of one study, while the CALGB study compiled data from several clinical trials (as shown in Figure 8.1).

Another complicating factor with regard to the prognostic role of cytogenetics is that all three studies analyzed patients treated differently from the patients in other studies. For example, the CALGB has argued that patients with favorable risk cytogenetics should

be treated with multiple cycles of high-dose cytarabine.^{46,47} However, other studies, such as the one analyzed by the MRC, show similar survival rates without such therapy.^{44,48}

Allogeneic stem cell transplant is often recommended for patients with poor-risk cytogenetics and an available HLA-matched donor. In the SWOG/ECOG study, this approach led to a 5-year overall survival of 44%, compared to 13–15%, in patients treated with chemotherapy alone or autologous stem cell transplant.⁴³ In contrast, the MRC study showed no benefit to allogeneic transplant for patients with poor-risk cytogenetics in first CR.⁴⁹ Nonetheless, the poor results of chemotherapy in all studies, and the relatively better results with allogeneic transplant in most studies, suggest that transplant remains the treatment of choice for patients with poor-risk cytogenetics in first CR.^{50,51}

The study of clonal cytogenetic abnormalities has led to the discovery of abnormal and dysregulated genes that result in specific AML phenotypes. Gene expression profiles by microarray analysis confirm the prognostic relevance of cytogenetic risk groups and suggest that other risk groups may yet be identified.^{52,53} For example, patients with normal cytogenetics have a

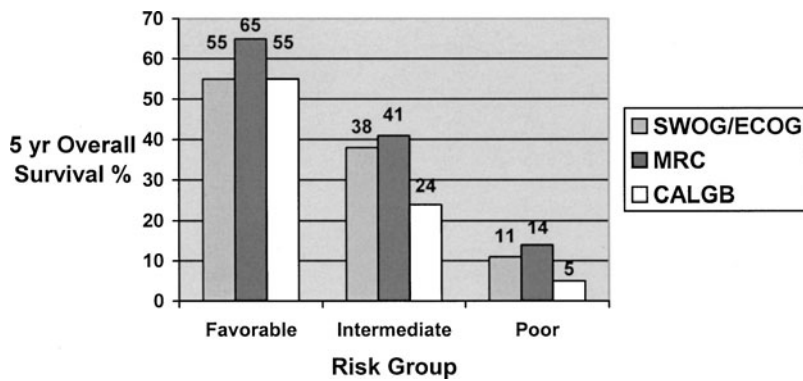

Figure 8.1 Five-year overall survival in AML varies by cytogenetic risk group. SWOG/ECOG, Southwest Oncology Group/Eastern Cooperative Oncology Group⁴³; MRC, Medical Research Council of Great Britain⁴⁴; CALGB, Cancer and Leukemia Group B⁴⁵

poor prognosis when FLT3 mutations are identified.^{54–59} Conversely, the presence of CCAAT/enhancer binding protein- α (CEBP- α) mutations⁶⁰ and the presence of cytoplasmic nucleophosmin due to translocations involving the *NPM* gene seem to result in a more favorable prognosis.⁶¹ The identification of prognostically relevant molecular pathways should allow for the development of small molecules capable of targeting these pathways and improving survival.

Follow up

Recommendations for follow up of patients diagnosed with AML who undergo remission induction and postremission therapy and who attain a CR are somewhat arbitrary. While they are based on the recommendations of leukemia experts, they are not grounded in any evidence-based literature that the degree and frequency of surveillance translates to earlier detection of recurrent leukemia, or that this would result in improved survival.

The National Comprehensive Cancer Network has published guidelines on surveillance of AML patients who have attained a remission.⁶² This group recom-

mends routinely following patients with complete blood cell counts every 2–3 months for the first 2 years following attainment of remission, and then every 4–6 months for 3 more years, for a total of 5 years of follow up. Bone marrow biopsies should be obtained only in the setting of worrisome peripheral blood counts, and not otherwise regularly, unless a patient is enrolled in a clinical trial that calls for this surveillance.

We recommend obtaining a bone marrow biopsy and aspirate at the conclusion of postremission therapy to document a CR. As is shown in Figure 8.2, we then follow patients with complete blood cell counts every month for 1 year after the postremission therapy CR, and then every 2 months for 1 year. For the third year, we follow patients every 3–4 months for 1 year, and then for years 4–5, every 4–6 months for 2 years, for a total of 5 years of follow up. We further recommend obtaining bone marrow biopsies only in the setting of worrisome blood counts, and urge assessment of cytogenetics at those times to document persistent disease on a molecular level or cytogenetic evolution, which could indicate disease progression and/or treatment-related bone marrow disorders. During the

Figure 8.2 Routine follow up of AML patients. CBCD, complete blood cell count with differential

follow-up period, patients should also resume contact and routine checkups with their primary care physicians.

SUMMARY

Established criteria should be used to establish whether or not AML patients have entered a remission follow-

ing standard chemotherapy regimens. Prognostic factors, particularly cytogenetics, are useful in determining the most appropriate risk-adapted approach to postremission therapy, which may include bone marrow transplantation for those in high-risk AML groups. Patients should be followed for 5 years after postremission therapy with routine blood tests, with bone marrow examinations reserved only for suspicion of relapsed disease.

Chapter 9

TREATMENT OF RELAPSED OR REFRACTORY ACUTE MYELOID LEUKEMIA AND NEW FRONTIERS IN ACUTE MYELOID LEUKEMIA THERAPY

Frederick R. Appelbaum

INTRODUCTION

While there are few easy problems in medical oncology, caring for the patient with relapsed or refractory acute myeloid leukemia (AML) is among the most challenging. Patients and their families are understandably disappointed, frightened, and desperate upon learning that initial therapy did not provide the hoped for results. And their concerns are justified, as treatment for recurrent leukemia is generally far less effective than initial therapy. Further, the physician has only a limited amount of information to help in the selection of therapy since, while there are a large number of studies and review articles dealing with initial therapy of AML, far less is written about recurrent disease. There is also much greater heterogeneity among patients by the time they relapse than at initial diagnosis. Despite, or better, because of the challenges posed by recurrent AML, there are many good reasons to focus on the topic. Given our current abilities and success rates in treating de novo AML, the majority of patients with AML will eventually fall into this category. Further, although outcomes are not outstanding, many patients who have relapsed can still be cured. And finally, this is where research is most needed.

DEFINITIONS

Although the terms “primary induction failure,” “relapsed,” and “refractory” are often used, consistent definitions are lacking. “Primary induction failure” is

generally used to describe those patients who fail to respond to an initial induction attempt. What constitutes an “induction attempt” is less certain. If induction is taken to mean a single cycle of standard-dose cytarabine plus daunomycin, at least 40% of failing patients will achieve a complete remission (CR) with a second cycle of treatment.^{1,2} Although failure to achieve a CR with one cycle of therapy ultimately indicates a poor prognosis, because almost half of patients who fail a single cycle will still achieve a CR with a second cycle of the same therapy, the term primary induction failure should be reserved for patients who fail two cycles of standard-dose therapy. Less is known about patients who fail a single-induction cycle containing high-dose cytarabine. The term “refractory AML” has been used to describe a subset of relapsed AML that is unlikely to respond to further salvage chemotherapy. Hiddemann et al. were among the first to provide a system of definitions and, based on a study of 180 patients, defined “refractory” as patients who had failed initial induction therapy, those who relapsed within 6–12 months of first CR, and those in second or subsequent relapse.³ Estey et al. performed a retrospective study of 206 patients treated with chemotherapy for recurrent AML at the MD Anderson Cancer Center and were able to identify four groups, based principally on the duration of first CR.⁴ Patients with an initial CR in excess of 2 years had a 73% likelihood of obtaining a second CR. Those with an initial CR duration of 1–2 years had a 47% CR rate. Patients with an initial CR lasting less than 1 year or with no initial CR receiving their first salvage attempt had a subsequent

Table 9.1 Categories of previously treated active leukemia

Category	Comment
Primary induction failure	Following two cycles of conventional dose therapy
Refractory	First relapse after initial remission of <6 months duration, or second or subsequent relapse
Relapse, poor risk	First relapse after initial remission of 6–24 months
Relapse, good risk	First relapse after initial remission of >24 months
Posttransplant relapse	

CR rate of 14%. And those receiving a second or subsequent salvage attempt had a 0% CR rate. Both Hiddemann's and Estey's definitions focused on the likelihood of obtaining a second CR. In a subsequent publication, Estey et al. also considered the likelihood of obtaining long-term survival without transplantation and reported that the only group of nontransplanted relapsed patients with survival above 10% 2 years after salvage therapy was the group with an initial CR duration of greater than 2 years.⁵ The studies described so far were limited to patients who received aggressive chemotherapy as their initial treatment. Few studies describe the course of patients with AML who relapse after receiving hematopoietic cell transplantation (HCT) as first-line therapy, where it has been examined that the time from marrow transplantation to relapse was the most important predictor of response to reinduction therapy.⁶ Thus, at present, as shown in Table 9.1, at least five categories of patients can be defined based on the therapeutic options available to them, their likelihood of obtaining a subsequent remission, and the probability of remaining in remission: primary induction failure, refractory AML, relapsed poor prognosis AML, relapsed favorable prognosis AML, and posttransplant relapse.

There are data to suggest that patient's age, performance status, and cytogenetics also predict the likelihood of obtaining a second CR with salvage chemotherapy. For example, in a review of 254 patients undergoing reinduction therapy, Kern et al. reported that early death during reinduction most closely correlated with patient age, while unfavorable chromosomal abnormalities were associated with a lower CR rate.⁷ However, in a multivariate analysis, the only factor associated with time to treatment failure was the duration of first remission. Thus, at present, few data suggest that there are factors independent of the ability to obtain a first CR and its duration to predict response rates or duration following salvage chemotherapy.

There are several categories of patients excluded from the above definition system. Patients with acute promyelocytic leukemia are not included, as their therapy is now so distinct from that used for the

majority of AML patients. Also not included are the very elderly or infirm who were not initially treated with aggressive chemotherapy, or who at relapse are not considered to be candidates for such treatment.

COMBINATION CHEMOTHERAPY FOR PATIENTS IN FIRST RELAPSE

RETROSPECTIVE STUDIES

A number of retrospective studies have described the outcome of combination chemotherapy for patients with AML in first relapse. At least five have included more than 100 patients (see Table 9.2).^{3,8–11} Most of these reports were summaries of multiple regimens and included a fairly wide range of categories of patients. In these five studies, the early death rate ranged from 8 to 32% and the CR rate varied from 30 to 51%. The duration of CR2 was in the range of 5–7.5 months, and the median survival in these trials was 4–10 months. While it is difficult to extract principles of treatment from these retrospective studies, they do provide a realistic sense of what can be expected with fairly standard chemotherapy. They also help confirm the influence of duration of CR on subsequent outcome and the influence of age. For example, in the study reported by Keating et al., the CR rate was 62% in those with a first CR of longer than 12 months versus 19% in those with a shorter first remission, and the CR rates were 36% in those younger than 60 versus 14% in those older than 60 years.⁹ While a number of other smaller retrospective studies have reported somewhat more encouraging results, the potential impact of patient selection and the biases imposed by the choice to report and publish these series is substantial, arguing that such studies should be interpreted with considerable caution.

PROSPECTIVE PHASE II TRIALS

A number of prospective phase II trials exploring various regimens as treatment for AML in first relapse have been published and are included in the excellent summary by Leopold and Willemze (see Table 9.3).^{12–27} These have generally included a fairly limited number

of patients (from 20 to 63) and have reported CR rates ranging from 40 to 68%. Given the relatively small size of these studies and the potential powerful influence of patient selection on outcome, it is difficult to evaluate the relative merits of these regimens based on these reports. Nonetheless, several of the regimens described in these papers have found their way into common usage. For example, combinations of mitoxantrone, etoposide, and cytarabine (MEC) produced response rates of 60–68% as described by Archimbaud et al. and Vignetti et al. and are now commonly used.^{12,13} The

FLAG regimen combining fludarabine, cytarabine, and granulocyte colony-stimulating factor (G-CSF) provided a 50% response rate and is likewise commonly prescribed.¹⁹ These regimens have not been compared in any systematic manner to other regimens.

PROSPECTIVE RANDOMIZED PHASE III TRIALS

A limited number of phase III randomized trials focusing on the treatment of recurrent AML have been published (see Table 9.4). In a study addressing the question of cytarabine dosing, Kern et al. compared high-dose

versus intermediate-dose cytarabine when combined with mitoxantrone.²⁸ They reported a trend toward a higher CR rate (52% vs 44%) and a slightly longer duration of second remission (median of 5 vs 3 months) with the higher dose regimen. However, because of a greater early death rate with the higher dose regimen, no benefit in overall survival was seen.

Several studies have addressed the impact of adding other drugs to high-dose cytarabine. Vogler et al. asked whether there was any benefit from adding etoposide to high-dose cytarabine, and reported that CR rates were similar (40% with cytarabine alone vs 45% with cytarabine and etoposide).²⁹ They also did not see a difference in remission duration in the two arms of the study. Karanes et al. asked whether there was any benefit from adding mitoxantrone to high-dose cytarabine.³⁰ They reported a significantly higher CR rate with the addition, but no improvement in overall survival.

A third group of studies has attempted to evaluate the impact of the addition of hematopoietic growth factors to chemotherapy for recurrent AML. Thomas et al. asked whether the addition of granulocyte-macrophage colony-stimulating factor (GM-CSF) to the MEC combination improved outcome. In this study, GM-CSF was given during chemotherapy in an effort to recruit cells into cycle, thereby sensitizing them to GM-chemotherapy. The CR rates in both arms of the study were remarkably high (81% without GM-CSF vs 89% with CSF), but not different from each other.³¹ The median survival was somewhat better than seen in other studies (8.5 vs 10 months, respectively). Ohno et al. studied the addition of G-CSF to the MEC combination and reported CR rates of 54% with G-CSF versus 42% without G-CSF.³²

A final group of studies addressed whether inhibition of the multidrug-resistance pump using cyclosporine might benefit patients. In a randomized trial, List et al. found that adding cyclosporine to a combination of high-dose cytarabine and daunomycin led to significantly less treatment failure due to drug resistance, and improved both disease-free survival and overall survival.³³ However, a smaller study from the Dutch group, which tested the addition of cyclosporine to the combination of mitoxantrone and etoposide, found that although the CR rate was higher with cyclosporine (53% vs 43%), there was no improvement in overall survival, possible due to inadequate postinduction therapy as a result of the toxicities of the reinduction treatment.³⁴

The experience of the Dutch group is typical. All of these aggressive reinduction regimens are accompanied by significant toxicities, including the risks of significant organ damage and the acquisition of infections, which may make further therapy, including HCT, difficult or impossible. Thus, the search for effective, less toxic therapies continues.

SINGLE-AGENT THERAPY

Gemtuzumab ozogamicin consists of a humanized anti-CD33 antibody conjugated to a potent chemotherapeutic, calicheamicin. The drug was developed based on the observation that most AML blasts express CD33, while normal stem cells and nonhematopoietic tissue do not. By targeting CD33, an effective, less toxic therapeutic might result. A large trial in patients with AML in first relapse showed that gemtuzumab ozogamicin used as a single agent resulted in complete responses in 26% of patients (approximately half of whom attained a CR with the exception of platelet recovery, or a CR_p), and with less toxicity than might be expected with high-dose chemotherapy.³⁵ Based on these results, the drug was approved by the Food and Drug Administration for the treatment of older patients with recurrent AML in which blasts express CD33. Subsequent studies have shown that, in some combinations, gemtuzumab ozogamicin may contribute to the development of veno-occlusive disease of the liver, so that care should be taken in combining this agent.

HEMATOPOIETIC CELL TRANSPLANTATION

PRIMARY INDUCTION FAILURE

Several studies have shown that some patients who fail primary induction therapy can still be cured if treated with allogeneic transplantation. For example, the European Bone Marrow Transplant Group reported long-term survival in 20% of such patients treated with matched sibling transplantation.³⁶ These results emphasize the importance of HLA-typing patients and family members at the time of diagnosis so that valuable time will not be lost should induction therapy fail. This is particularly important if the patient does not have a matched sibling and an alternative source of stem cells, such as a matched unrelated donor or unrelated cord blood, must be identified.

TRANSPLANTATION AS SALVAGE THERAPY FOR PATIENTS WITH MATCHED SIBLINGS

Although there are no randomized trials to prove the point, retrospective comparisons suggest that HCT should be considered for almost all patients of age 55 or less with matched siblings who relapse after an initial remission. There are occasional patients with long first remissions (greater than 2 years according to the MD Anderson data) who may do as well with chemotherapy, reserving transplantation for a subsequent relapse, but such patients are uncommon.³⁷

Whether patients with AML in first relapse should undergo reinduction therapy before proceeding to transplant from a matched sibling is an unresolved question. A study from Seattle of 126 patients transplanted in untreated first relapse reported a 28% 5-year disease-free survival.³⁸ This result is only slightly less

than what might be expected for matched sibling transplants for AML in second remission. For example, the European Transplant Group reported a 35% 3-year disease-free survival rate among 459 patients transplanted in second remission from matched siblings.³⁹ However, on an average only approximately 50% of patients in first relapse will be successfully reinduced, 10–15% may die during the reinduction attempt, and others may develop complications that would preclude subsequent transplantation. The results of transplantation in first relapse appear best in those without substantial numbers of circulating blasts. Thus, for those patients with matched siblings where relapse is found early, proceeding straight to allogeneic transplant can be recommended. However, for those with substantial numbers of circulating blasts or those for whom considerable time is required to identify the donor or arrange the logistics for transplantation, reinduction will be necessary.

Discussions of the separate elements of the transplant procedure are included in Chapter 92. However, there have been no randomized trials, addressing the best preparative regimen, source of stem cells, or form of graft-versus-host disease (GvHD) prophylaxis specifically focused on the treatment of AML in first relapse or second remission.

Because of the acute toxicities associated with the high-dose preparative regimens commonly used in the treatment of AML, as well as an increased incidence of GvHD in older patients, allogeneic transplantation in the past was generally restricted to younger patients, generally those less than age 55–60 years. It has long been appreciated that much of the antileukemic effects of allogeneic HCT came from the graft-versus-tumor (GvT) effect. Thus, in an effort to bring the benefits of allogeneic transplantation to an older population of patients, investigators have begun devising strategies to insure allogeneic engraftment without the use of high-dose therapy. A number of reduced-intensity regimens have been developed and used in the treatment of relapsed acute leukemia. These have varied in intensity from low-dose regimens, such as the Seattle regimen consisting of fludarabine 30 mg/kg for 3 days plus 200 cGy total body irradiation (TBI) with posttransplant mycophenolate mofetil and cyclosporine, to regimens of somewhat greater intensity, such as the busulfan 8 mg/kg, fludarabine, and antithymocyte globulin regimen.⁴⁰ The Seattle regimen is able to insure engraftment in the large majority of patients and, in patients ranging in age from 50 to greater than 70 years, has been associated with a 100-day nonrelapse mortality of 5–8% and an overall non-relapse mortality of less than 20%.⁴¹ These reduced-intensity regimens have not been, in general, effective for patients in frank relapse, but results in second-remission patients are encouraging. The Seattle group recently reported on a group of 39 patients with AML in second remission who were not

candidates for ablative transplants and recorded the disease-free survival at 3 years as slightly in excess of 40%.⁴²

TRANSPLANTATION AS SALVAGE THERAPY FOR PATIENTS WITHOUT MATCHED SIBLINGS

Patients with AML in second remission but lacking matched family member donors are candidates for either autologous or matched unrelated HCT. Randomized trials comparing the two have not been reported. Relatively small individual trials of autologous transplantation in second remission report 3-year disease-free survival rates ranging from 21 to 52%, with registry data settling at about 30% disease-free survival.⁴³ Better results can be expected in patients with longer first remissions. A retrospective matched pair analysis of the outcome of 340 patients with AML in second remission treated with either autologous or matched sibling transplantation reported lower relapse rates and somewhat better survival with allogeneic transplantation (39% vs 30% at 4 years).⁴⁴ Less data are available about the use of matched unrelated donor transplants for AML in second remission. The 5-year survival rate reported by the National Marrow Donor Program in 473 patients was 31%.⁴⁵ Similar results have been published from single institutions.⁴⁶ A case-controlled study was conducted by the European Bone Marrow Transplant Group in which the outcome of 46 recipients of unrelated donor transplants for AML in second remission was compared with twice that many autologous recipients.⁴⁷ Long-term outcomes, as measured by overall survival, were similar between the groups. While this study has many shortcomings, including its retrospective nature and small sample size, without further data for direction, autologous transplantation might be considered as the best option for older patients and those with more favorable disease characteristics, such as longer first remission, while matched unrelated donor transplantation might be more appropriate for younger patients and those with more unfavorable disease.

Although the amount of data are much more limited, other sources of stem cells are being explored for patients without matched siblings or matched unrelated donors, including the use of haplomismatched donors and the use of cord blood transplants. Both of these approaches are discussed more fully in Chapters 36 and 97.

TREATMENT OF POSTTRANSPLANT RELAPSE

Patients who relapse following hematopoietic cell transplant present a unique set of problems and, in some cases, opportunities for further therapy. Patients who relapse following an autologous transplant performed for AML in first CR often will respond to further chemotherapy, and the likelihood of response correlates with the length of first CR posttransplant. The results of second allogeneic transplants after failure

of first autologous transplants have been reported.⁴⁸ Among 24 such patients, the 2-year disease-free survival was surprisingly high, at 46%. The majority of survivors were younger than 17 years and had failed a chemotherapy-only autologous transplant, so that a TBI-containing preparative regimen could be used for the subsequent allogeneic transplant. Such favorable results cannot be expected for older adults who fail a TBI-containing autologous transplant; a strategy of chemotherapy to induce a second remission followed by reduced-intensity allogeneic transplant is probably more appropriate.

Different options are available to the patient who relapses following an allogeneic transplant. Donor lymphocyte infusions (DLI) can, by themselves, induce CRS in 20–30% of patients.⁴⁹ Although experience is still limited, most data would suggest that long-term survival after DLI is more likely if patients are first treated back into CR with chemotherapy before receiving DLI. Significant toxicities can follow DLI, including transient marrow hypoplasia, and more importantly, significant GvHD. The extent of GvHD is related to both the total number of T-cells infused and the schedule, with less GVHD being associated with a fractionated infusion schedule. If patients have significant GVHD at the time of relapse, the risks of further DLI outweigh the possible gain, and for such patients options are generally limited to further chemotherapy or palliative care.

SUMMARY OF TREATMENT OPTIONS FOR RELAPSED AND REFRACTORY AML

Enrolment of patients onto well-designed clinical trials should always be at or near the top of therapeutic options. However, if an appropriate clinical trial is not available or if patients decline participation, the following represents a brief summary of therapeutic options for patients with primary induction failure or recurrent AML.

The only curative approach for patients with AML who fail primary induction is allogeneic HCT, so every effort should be made to identify a donor and proceed to transplant if the patient is a suitable candidate. If no donor is available, investigational or palliative therapy should be considered.

In considering therapeutic approaches for patients with AML who achieve a CR and then relapse, the first question to address is whether the individual patient is a possible candidate for an ablative transplant approach. If so, and if the patient is in early relapse and is known to have a matched sibling, proceeding directly to an allogeneic transplant is recommended. An autologous transplant in untreated first relapse can also be considered if stem cells were stored in first remission and the first remission was of reasonable length. If the patient is a candidate for an ablative

transplant but a donor has not been identified, no stem cells were stored, or there are substantial numbers of circulating blasts at the time relapse, then reinduction therapy is needed. Although the published literature does not permit the identification of a single regimen as the best, based on randomized trials regimens combining high-dose cytarabine with a second agent seem justified, and in at least one randomized trial the use of a multidrug-resistance inhibitor seemed to further improve outcome.³³

If patients are not transplantation candidates because of age or comorbidities, the wisdom of using aggressive chemotherapy with their accompanying toxicities should be questioned, and consideration for the use of less aggressive therapy, such as single-agent gemtuzumab ozogamicin, might be considered.

NEW FRONTIERS IN AML THERAPY

IMPROVED DIAGNOSTICS

In a relatively short time, the application of cytogenetics to clinical decision making in AML has become almost second nature—patients with t(15;17) require all-*trans*-retinoic acid, those with t(8;21) or inv(16) can be successfully managed with chemotherapy alone, while those with monosomy 7 or complex abnormalities may benefit from allogeneic transplant. Given recent advances in gene expression array analyses and, perhaps, proteomics as well, there is every reason to think that many more markers predictive of outcome should be forthcoming.^{50,51} In addition to the increased information to be gained at diagnosis, it is almost certain that we should be able to develop tests that will be capable of assaying the results of initial therapy and thus guide further treatment. Quantitative polymerase chain reaction (PCR) assays with considerable predictive power are already being applied to the treatment of acute promyelocytic leukemia and chronic myeloid leukemia (CML).^{52,53} The lack of consistent translocations makes it more difficult to develop PCR-based tests widely applicable to all AMLs, but encouraging data with multicolor flow cytometry are emerging.⁵⁴ Even without the development of any new therapies, the ability to predict those patients unlikely to be cured with chemotherapy alone and to be able to offer them a bone marrow transplant in first remission, and at the same time spare those likely cured with chemotherapy unnecessary transplant, should improve substantially the overall therapy of AML.

EMERGING THERAPIES

New therapies targeting mutational events

Mutations in receptor tyrosine kinases can be found in a substantial proportion of AML cases. The most commonly affected enzyme is FLT3, which is mutated in approximately 30–35% of cases.^{55,56} The majority of

these mutations are internal tandem repeats in the juxtamembrane domain, while a lesser number are point mutations in the activation loop of FLT3. Both types of mutations lead to constitutive activation of the tyrosine kinase and stimulation of growth-related signaling. Retroviral transduction of the activated enzyme into mice results in a myeloproliferative syndrome, but further mutations are required for the development of full-blown leukemia.⁵⁷ FLT3 mutations are more commonly seen in t(15;17) and t(6;9) AMLs, but only rarely seen with -7, -5, t(8;21), inv(16), or with mutated RAS.⁵⁸ The presence of FLT3 is correlated with a higher white count at diagnosis and a poorer overall outcome of treatment.^{59,60} Given the prominent role of FLT3 mutations in AML, efforts have been made to identify and develop compounds capable of inhibiting this tyrosine kinase. At least four compounds have entered clinical trials (reviewed in Ref. 61). CEP-701 (Cephalon, Inc, West Chester, PA) is an indolocarbazole derivative that has entered phase II clinical trials. CT53518 is a piperazinyl quinazoline and is in phase I studies. PKC412 (Novartis Pharmaceuticals, Basel, Switzerland) is a benzolystaurosporine and has been examined in phase II trials. SU11248 (Sugen, San Francisco, CA) has been examined in a phase I study. While it is too early to reach definitive conclusions, the results of early studies to date show biologic activity of all of these compounds with lowering of blast counts in peripheral blood and marrow.⁶¹ However, sustained complete remissions have not been seen with any frequency, suggesting that, unlike the situation with the tyrosine kinase inhibitor imatinib in CML, it will be necessary to combine kinase inhibitors with other drugs to get any substantial clinical benefits.

c-KIT and FMS are other receptor tyrosine kinases sometimes mutated or overexpressed in AML.^{62,63} In a study of SU5416, an inhibitor of c-KIT, only 1 of 38 c-KIT-positive AML patients had a complete response, but 7 had substantial reduction in AML blast counts.⁶⁴

RAS proteins are a group of signaling molecules downstream of many tyrosine kinase receptors which, following receipt of a signal, activate a broad range of proteins involved in cell proliferation and survival including the MAP/ERK kinase involved in cell proliferation, Rac and Rho, which affect cytoskeletal organization, and PI-3 kinase, which opposes apoptosis. Mutations in RAS are found in 15–20% of AML cases, most commonly in N-RAS.⁶⁵ RAS proteins are internally synthesized as cytosol precursors and require the addition of a farnesyl group to attach to the cell membrane and transmit signals. Therefore, there was a great interest in exploring farnesyltransferase inhibitors in AML, particularly in those cases with RAS mutations. The most encouraging data to date have been with R115777. In an initial dose-escalation study, central nervous system toxicity was found to be dose limiting at 1200 mg b.i.d. Two complete responses and eight partial responses were seen among 35 patients with recurrent myeloid malig-

nancies.⁶⁶ Recent data suggest a higher degree of activity when used in previously untreated patients. Several other farnesyltransferase inhibitors are under study.

Histones are proteins closely associated with chromatin which, in the unacetylated state, anchor the associated chromatin and repress local transcription but, when acetylated, become less anchored to chromatin allowing the structure to relax, unwind, and permit transcription. In certain AMLs, including t(8;21) and t(15;17), the abnormal fusion product resulting from the translocation is thought to bind to its normal promoter target, but also bind the transcriptional repressor complex that includes a histone deacetylase, resulting in deacetylation of the region and thus repression of gene transcription.⁶⁷ The repression of these genes may inhibit cell maturation, differentiation, and apoptosis and thus may be important in the leukemic process. On this basis, molecules that inhibit histone deacetylases are being studied as antileukemic agents, including phenylbutyrate, trichostatin, trapoxin, and depsipeptide.⁶⁸

New therapies targeting adaptive responses

The mutational events that give rise to AML may require the cell to make other adaptive changes in order to survive, particularly when stressed. Since these adaptive changes are not required of normal cells, inhibiting them may result in specific damage or death to AML cells and may specifically sensitize leukemic cells to conventional chemotherapy. One example of such an adaptive change is *Bcl-2*, the anti-apoptotic gene that is overexpressed in almost all AML samples, and whose expression is further increased following exposure to chemotherapy.^{69,70} An antisense *Bcl-2* compound can sensitize AML cells to cytarabine *in vitro*, providing a strong rationale for ongoing clinical trials combining *Bcl-2* antisense with chemotherapy in patients with recurrent AML.⁷¹

Following exposure to cell-damaging agents, AML blasts markedly increase their cholesterol content, and do so to a much greater degree than do normal bone marrow progenitors. Blocking cholesterol synthesis using mevastatin or zaragozic acid specifically sensitizes most AML cell lines and patient AML samples without a discernible effect on normal hematopoietic progenitors.⁷² Dimitroulakos et al. and Wong et al. showed that lovastatin, another inhibitor of *de novo* cholesterol synthesis, killed six of seven AML cell lines and 13 of 22 primary AML cell cultures.^{73,74} Based on these results, current trials are under way, testing combinations of standard chemotherapy combined with increasing doses of statins.

New immunotherapeutic approaches

Both antibody- and cell-based immunotherapeutic approaches are being explored in AML. As noted earlier, gemtuzumab ozogamicin, an anti-CD33 antibody calicheamicin conjugate, has been approved for

treatment of older patients with recurrent AML. Phase II trials of gemtuzumab plus standard chemotherapy for initial treatment of AML have yielded encouraging results, with CR rates in excess of 80%.^{75,76} Based on these results, randomized trials are under way, evaluating this approach as initial AML treatment.

Antibodies have also been employed to target radionuclides to the marrow and other sites of disease as part of a transplant preparative regimen. The hypothesis being tested is that by targeting higher doses of radiation to these sites and avoiding normal organs, it should be possible to provide greater antileukemic effects with less toxicity than achievable with TBI. Phase II trials using anti-CD45 monoclonal antibody labeled with ¹³¹I have yielded encouraging results, as have studies of an anti-CD66 antibody labeled with ⁸⁸Re.^{77,78} A particularly attractive approach under study is the development of an allogeneic transplant regimen combining high-dose targeted radiotherapy for tumor ablation with low-dose fludarabine/TBI to ensure engraftment.

The markedly reduced relapse rates seen with the development of GVHD following allogeneic transplantation coupled with the dramatic tumor responses sometimes seen with DI have fueled interest in the further development of cell-based therapies for AML. The central scientific challenge has been to discover methods to segregate the potentially potent GVT effects from GVHD. Several broad groups of antigens are under study as possible targets capable of this distinction. One set of targets is polymorphic minor histocompatibility antigens, with expression largely limited to hematopoietic tissues. In the setting of allogeneic transplantation, such antigens could serve as targets for donor-derived T-cell clones capable of destroying all normal and malignant host hematopoietic tissue without contributing to GVHD. A number of polymorphic minor histocompatibility antigens with expression limited to hematopoietic tissue have been identified by the groups in Seattle and Leiden, and clinical

studies involving the use of T-cell clones targeting these antigens are under way.^{79,80}

While elegant, the use of T-cell clones targeting minor histocompatibility antigens is necessarily restricted to the allogeneic transplant setting. Several classes of nonallogeneic antigens also have the potential capacity to serve as effective targets for T-cell therapy. Mutational antigens, such as the fusion product proteins found in leukemias with t(9;22), t(15;17), or t(6;9), could theoretically serve as specific targets for a cellular immune response. Attempts are being made to elicit antitumor responses to several of these antigens by immunizing patients with vaccines based on these mutant peptides.⁸¹ Perhaps the greatest potential for cell-based therapies comes from the observation that several nonmutated proteins are highly overexpressed in AML cells, including PR3 and WT1.^{82,83} Despite that these are self-antigens, because they are normally expressed at such low levels, patients are capable of generating a T-cell response to these proteins. Encouragingly, T cells with specificity to these antigens are able to selectively lyse leukemic blasts without damaging normal CD34-positive hematopoietic cells. Based on these observations, clinical trials involving the adoptive transfer of T cells specific for these antigens are under way, as are trials using these antigens as the basis for AML vaccines.

SUMMARY

Treatment of the patient with relapsed or refractory AML continues to be a difficult challenge. At the same time, the enormous increase in our understanding of the molecular and immunologic nature of leukemia is beginning to pay dividends in the recent availability of a large number of novel therapies with clear activity in AML. It is now our responsibility as scientists and clinicians to learn how to best use these therapies to benefit our patients.

Section **2****ACUTE LYMPHOBLASTIC
LEUKEMIA**Chapter **10****EPIDEMIOLOGY, RISK
FACTORS, AND CLASSIFICATION***Joseph O. Moore***INTRODUCTION**

Acute lymphoblastic leukemia (ALL) is a complex and potentially curable hematopoietic cancer that has provided numerous significant firsts in the treatment of malignant disease for children and adults alike. Historically, ALL in children was the first tumor whose treatment attained complete remission in the majority of patients, leading to long-term disease-free survival and cure with combination chemotherapy. In childhood, modern combined modality treatment produces complete response rates of up to 95% and cure rates of up to 64%. In contrast, adults have fared less well, with comparable remission rates up to 93%, but cure rates of 30% or lower in most reported series.¹⁻⁴ Reasons for this disparity are likely multifactorial and have been thought to include physician experience and expertise, more rigid adherence to protocols by pediatric oncologists, and different biology of the leukemia in children and adults. Other differences may occur in the presentation of disease, both physically and symptomatically, and in patients' tolerance to aggressive protocol-based treatment, with children more able than adults to follow and remain on an appropriately aggressive protocol. As described below, perhaps more importance lies in more favorable genomic abnormalities in childhood, while in adults very poor prognostic groups, including those expressing the t(9;22) Philadelphia chromosome, occur in almost half of patients.²

ALL treatment has influenced all aspects of cancer care. Current success has evolved incrementally, from single-agent chemotherapy to multiple drug combinations and the addition of biologic agents into complex, combined modality therapy. More recently, specific chromosome abnormalities and their associated oncogenes, proto-oncogenes, and signaling pathways have assumed enhanced importance in understanding the biology and treatment of ALL. For example, recognition of the t(9;22) and its balanced exchange of genetic material between bcr (the breakpoint combining region) and the Abelson oncogene (*c-abl*) leads to constitutive activation of the associated tyrosine kinase, producing unregulated cell proliferation. This highlights the interaction of genomics and biology, as well as introduces targeted therapy, with the introduction of the specific bcr/abl kinase inhibitor imatinib mesylate.⁵ Additionally, abnormalities of the *MLL* gene and its associated t(4;11) chromosome abnormalities are a predictor of short-duration or low-frequency complete remissions, early relapse, and poor disease-free survival. Documentation of poor overall prognosis has led to a change in therapy for these patients and their early allocation to more aggressive treatment with stem cell transplantation,³ rather than continuing with more conventional ALL therapy even if complete remission is initially accomplished.⁴

The essential need to identify specific chromosome translocations has also enhanced the importance of

Figure 10.1 FISH techniques: (a) A BCR/ABL dual fusion probe set applied to interphase nuclei. Nucleus at left shows two normal signals for the BCR locus at 22q11.2 (green) and two normal signals for the ABL locus at 9q34 (red). Nucleus at right shows one normal BCR locus (green), one normal ABL locus (red), and two fusion signals (arrows) with juxtaposition of red and green signals, reflecting the rearranged chromosomes 9 and 22. (b) It shows an MLL break apart probe set applied to interphase nuclei. In this probe set, the 5' region flanking MLL is labeled in green and the 3' region flanking MLL is labeled in red. Nucleus at left shows two fusion signals, reflecting the normal (unrearranged) MLL loci at 11q23. Nucleus at right shows one normal (unrearranged) MLL locus. The separation of the green (5' MLL) and red (3' MLL) signals (arrows) shows that rearrangement of this locus has occurred

diagnostic tools for the identification of these abnormalities rapid and reliable. These include standard cytogenetics, the more targeted fluorescent in situ hybridization (FISH) techniques [Figure 10.1(a) and 10.1(b)], and reverse transcription polymerase chain reaction (RT-PCR), each of which may identify specific chromosome abnormalities, and aid in diagnosis, monitoring of therapeutic response, and identification of minimal residual disease, as further discussed in Chapter 14.⁶⁻⁹ With both FISH and RT-PCR, it is of critical importance to identify the specific chromosome abnormality or translocation to assure specificity and accuracy of diagnosis and accurate quantitation of the proportion of cells affected.

Current treatment strategies for ALL illustrate progressive and incremental protocol development from single institutions and cooperative group programs, resulting in improved complete response and survival. Numerous groups have contributed, including the Pediatric Oncology Group,¹⁰ the French Cooperative Group,¹¹ the Cancer and Acute Leukemia Group B,¹²⁻¹⁵ the Berlin-Frankfurt-Munster Group,¹⁶⁻¹⁹ the Italian Gruppo Italiano Malattie Ematologiche Maligne dell'Adulto,²⁰ the French Leucemie Aigues Lymphoblastique de l'Adulte Group, individual institutions such as St Jude's Children's Hospital,¹⁰ Memorial Sloan-Kettering Cancer Center,^{21,22} and MD Anderson Cancer Center,²³ and other more individualized programs,²⁴ to name but a few. These protocols are described in greater detail in Chapter 13.

Current strategies also illustrate the conceptual importance of sanctuary sites of disease, areas where ALL cells may be protected from destruction by systemic chemotherapy and that require specialized prophylactic treatment targeted to the central nervous system, such as intrathecal chemotherapy delivered by lumbar puncture or an indwelling cerebrospinal access device, or radiation therapy, as might be applied to

other sanctuaries in the testicle and the mediastinum. Preventive treatment of these sanctuaries has had a major positive effect on cure and long-term survival in both children and adults.^{4,16,25}

EPIDEMIOLOGY

The specific cause of ALL is unknown in most patients, and specific epidemiologic associations can be identified in no more than 10% of childhood ALL and in a much lower proportion of adults.^{26,27} An extensive review of ALL in children by Buffler et al. details potential occupational exposures in parents of patients, and exposures to aromatic hydrocarbons and household chemicals and pesticides, ionizing radiation, low-frequency magnetic fields, diet, infections, and genetic polymorphisms.²⁶ Numerous potential predisposing features studied or established include positive associations with the specific genetic syndromes noted below, high birth weight,²⁸ ethnicity,²⁹ and a paradoxically negative relation with maternal smoking.³⁰ While extensively investigated, none of these factors offer potent predictive value for improved diagnosis and increased survival other than the increased risk of leukemia in some hereditary and genetic syndromes (see below). In adults, even fewer associations are apparent; genetic features play a negligible role in disease behavior and in defining and predicting prognosis. The following includes some genomic and other associations in children and adults.

GENETIC MUTATION

Genetic mutation plays a pivotal role in the etiology of ALL in children born with Down syndrome with the associated trisomy 21 chromosome abnormality.

Alteration and activation of the GATA-1 hematopoietic transcription factor increases the risk for development of ALL and increases the incidence of acute megakaryocytic leukemia as well.³¹⁻³⁵ That hematologic malignancies representing different cell lines may become malignant suggests that multiple signaling pathways may be affected by this and other chromosome abnormalities.³⁶ Of interest, the more detrimental chromosome abnormalities, t(9;22) and t(4;11), occur infrequently in Down syndrome.³³⁻³⁵ Favorable abnormalities of the TEL/AML1 fusion, denoted by the t(12;21) translocation, are also less frequent in Down syndrome.

ALL may also arise in the setting of the Li-Fraumeni syndrome, with associated abnormalities of p53, Bloom syndrome, and others predisposing to ALL and to multiple other cancers.³⁶

IN UTERO EVENTS

Toxic exposure in utero to maternal Epstein-Barr virus (EBV) reactivation or other viral entities such as cytomegalovirus and herpes simplex virus has been proposed as a causative factor in some infants and children with ALL.³⁷ These mutations are not believed to lead directly to ALL, but their effect in delaying cell maturation may allow more genetic abnormalities to occur.¹⁰

Monozygotic twins carry a small but definite increased risk of concordant ALL. The potential for in utero events leading to postpartum ALL was highlighted in a report of two year-old monozygotic twins, both with ALL, in whom one had two rearranged T-cell receptor δ alleles that were proposed to have occurred in utero, with the transmission of a single allele to the other twin, resulting in ALL.³⁸ Though these changes were considered critical, other abnormalities or mutations are thought to be necessary to produce ALL in vivo. This suggests that mutations produced in utero may combine with other mutations, leading to leukemia.³²

RADIATION EXPOSURE

ALLs occur less frequently following radiation exposure than do acute myeloid leukemias (AML), chronic myeloid leukemia (CML), or myelodysplastic syndromes. The incidence of ALL is modestly increased in populations exposed to ionizing radiation from an atomic bomb,^{26,39} and cases are most prevalent among younger survivors.⁴⁰ As a general rule, most other forms of radiation may produce an excess of leukemia, again mostly of myeloid origin rather than lymphoid. No study has documented an increase in ALL associated with radiation from diagnostic radiographic procedures.²⁶

TOXIC EXPOSURE

ALL is not increased by exposure to alkylating agents and epipodophyllotoxins,⁴¹ and is not usually considered to be a "secondary" leukemia.

GENE THERAPY

Gene therapy for X-linked severe combined immunodeficiency syndrome (X-SCID) has led to activation of the *LMO2* gene.^{42,43} Two of ten patients who received retrovirus vector-mediated gene transfer for X-SCID developed T-cell ALL. This was caused by insertion of the retroviral vector with *LMO2* gene activation, leading to leukemic transformation. In normal hematopoiesis, CD34-positive cells may develop into all hematopoietic cell lines. In the lymphoid series, these may differentiate into either B cells or T cells. Ex vivo infection of hematopoietic stem cells by the retrovirus encoding IL2 R gamma c is followed by reinfusion, and it results in activated chromosome translocations with *LMO2*, including t(11;14)(p13;q11), or t(7;11)(q35;p13). This represents a classic activation of signaling pathways by the retrovirus-transformed cells leading to T-cell ALL.⁴²⁻⁴⁴

In adults with ALL, abnormalities of cell cycle regulatory genes are frequently present and may be determinants in leukemogenesis. These include the retinoblastoma gene (Rb), p53, p15 (INK4B), and p16 (INK4A).⁴⁵ Pui has detailed and elucidated the initial abnormalities, chromosome aberrations, and their cell signaling consequences in a comprehensive review of ALL, with detailed genomic pathways.^{10,33}

RISK FACTORS

Risk factors, further detailed in subsequent chapters, are a part of the epidemiology of ALL, both with regard to initial factors leading to ALL and factors associated with success or failure of treatment. ALL may occur at any age, but is most frequent in childhood (before age 15), with a consistent incidence in the third to eighth decades of life.⁴⁶ In adults, family history and a history of immunologic abnormalities are usually not present. Family history of lymphoma may be present without a definite association being drawn.^{27,40}

Risk factors for ALL include Caucasian race as compared to African-American or other ethnic groups in the United States. Rates of ALL are also higher in Northern and Western Europe, North America, and Oceania versus in Asian and black populations.⁴⁰ In Israel, Jews have a higher incidence of leukemias, but paradoxically lower rates of ALL.⁴⁶

Exposure to human T-cell leukemia virus 1 may produce a T-cell leukemia presenting with hypercalcemia, bone or skin lesions, lymph node enlargement, which occur in several ethnic populations, such as Japanese from the island of Kyushu and U.S. immigrants from the Caribbean. An initial, more indolent T-cell leukemia may evolve to a very aggressive T-ALL that is treated with great difficulty and responds poorly, with little chance of survival.⁴⁴ ALL can also occur as a

blastic transformation of CML, and in this setting it is always associated with a $t(9;22)$.

CLASSIFICATION

The classification of ALL has followed the historical evolution of technology, with cellular morphology by microscopic appearance, immunophenotyping of cell surface markers, lymphocyte subset analysis, and more recently, chromosome evaluation and genomic identification.

Leukemia was first identified and described by Virchow as *weisses blut* (white blood) due to hyperleukocytosis (elevated white blood cell count), and was further categorized initially using supravital stains of peripheral blood.⁴⁷ Subsequent identification of leukemias by cell origin, required separation into groups of myeloid and lymphoid leukemias. Additionally, the identification of acute and chronic varieties of each required more sophisticated techniques of special enzymatic stains, leading to the evolution of our current skills in morphology, cell surface identifications, genomics, and biology as incorporated in the current World Health Organization (WHO) classification.⁴⁸

MORPHOLOGIC CLASSIFICATION

The French–American–British (FAB) classification system separated AML and ALL based on the visual microscopic appearance of blast forms in peripheral blood and bone marrow, as well as on the activity of selected special enzymatic stains, such as peroxidase, specific and nonspecific esterase, and periodic acid–Schiff for glycogen.⁴⁹ Morphologic classification with the FAB system separates three forms of ALL. ALL includes⁵⁰:

Figure 10.2 L1—uniform small peripheral lymphoid blasts with minimal to moderate cytoplasm, effaced chromatin, and occasional to more numerous nucleoli

Figure 10.3 L2—variable-sized peripheral blood lymphoblasts with variable chromatin pattern and more frequent nucleoli

L1—Small lymphocytic variant with uniform small cells having a more “mature” appearance (Figure 10.2).

L2—Variable cell size with large and small cells in the same sample (Figure 10.3). In adults, this variant has a poorer prognosis compared with L1 ALL based on the more frequent presence of the Philadelphia chromosome p190 variant (rather than p210, as with CML), with similar response rates but more rapid relapse and diminished long-term survival.^{18,33,48}

L3—Burkitt lymphoma/leukemia, with small uniform lymphoid blasts characterized by vacuolated cytoplasm containing glycogen, and frequent mitotic figures denoting rapid growth (Figure 10.4).

Although classified as a form of ALL, the L3 (Burkitt) variant differs in many respects from other forms of ALL. L3 ALL presents in developed countries as an aggressive disease, often with intra-abdominal lymph

Figure 10.4 L3—Burkitt leukemia in bone marrow with uniform blast forms, cytoplasmic vacuoles, and increased mitoses

Table 10.1 Estimated frequency of specific genotypes of ALL in children and adults

ALL genotype	Children (%)	Adults (%)
Hyperdiploidy >50 chromosomes	25	7
TEL/AML1 t(12;21)	22	2
MLL rearrangements [e.g., t(4;11), t(11;19), t(9;11)]	8	10
TAL1 lp32	7	12
E2A/PBX1 t(1;19)	5	3
BCR/ABL t(9;22)	3	25
HOX11L2 5q35	2.5	1
MYC t(8;14), t(2;8), t(8;22)	2	4
LYL1 19p13	1.5	2.5
Hypodiploidy <45 chromosomes	1	2
HOX11 10q24	0.7	8
MLL/ENL	0.3	0.5
Others	22	23

Genetic lesions that are exclusively seen in cases of T-cell lineage leukemias are shaded in gray. All other genetic subtypes are either exclusively or primarily seen in cases of B-cell lineage ALL.

Adapted from data presented in Pui CH, Relling MV, Downing JR: Acute lymphoblastic leukemia. *N Engl J Med* 350:1535–1548, 2004.

node enlargement and a high growth fraction, in contrast to its African variant, which is associated with EBV and usually presents in a more indolent manner, often as a jaw mass (lumpy jaw), and responds to more modest treatment.⁵¹ The non-African variant is treated with hyperfractionated alkylating agents and cycle-active treatment rather than with conventional ALL protocols, which produce inferior results.^{23,52} Several unique chromosome translocations include the typical t(8;14) involving the immunoglobulin gene *IgH* (on chromosome 14, a site frequently involved with a variety of malignant lymphomas and leukemias of lymphoid origin) and the *c-myc* proto-oncogene. Less usual variant translocations t(2;8) and t(8;12) are also seen in morphologically typical Burkitt-type leukemia.⁵³

Demonstration of these abnormalities may not be readily apparent by conventional cytogenetics, FISH or even RT-PCR may be required to identify the exact chromosome abnormality and establish cellular origin when morphology suggests Burkitt leukemia or another abnormality, but is not demonstrated by initial chromosome analysis.^{6–10}

Table 10.2 Proposed WHO classification of lymphoid neoplasms

B-cell neoplasms
Precursor B-cell neoplasm
Precursor B-lymphoblastic leukemia/lymphoma (precursor B-cell acute lymphoblastic leukemia)
Mature (peripheral) B-cell neoplasms ^a
B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma
B-cell prolymphocytic leukemia
Lymphoplasmacytic lymphoma
Splenic marginal zone B-cell lymphoma (+/– villous lymphocytes)
Hairy cell leukemia
Plasma cell myeloma/plasmacytoma
Extranodal marginal zone B-cell lymphoma of MALT type
Nodal marginal zone B-cell lymphoma (+/– monocytoïd B cells)
Follicular lymphoma
Mantle-cell lymphoma
Diffuse large B-cell lymphoma
Mediastinal large B-cell lymphoma
Primary effusion lymphoma
Burkitt lymphoma/Burkitt-cell leukemia
T-cell and NK-cell neoplasms
Precursor T-cell neoplasm
Precursor T-lymphoblastic lymphoma/leukemia (precursor T-cell ALL)
Mature (peripheral) T-cell neoplasms ^a
T-cell prolymphocytic leukemia
T-cell granular lymphocytic leukemia
Aggressive NK-cell leukemia
Adult T-cell lymphoma/leukemia (HTLV1+)
Extranodal NK/T-cell lymphoma, nasal type
Enteropathy-type T-cell lymphoma
Hepatosplenic gamma-delta T-cell lymphoma
Subcutaneous panniculitis-like T-cell lymphoma
Mycosis fungoides/Sezary syndrome
Anaplastic large-cell lymphoma, T/null cell, primary cutaneous type
Peripheral T-cell lymphoma, not otherwise characterized
Angioimmunoblastic T-cell lymphoma
Anaplastic large-cell lymphoma, T/null cell, primary systemic type

HTLV1+, human T-cell leukemia virus; MALT, mucosa-associated lymphoid tissue; NK, natural killer.

^aB- and T-/NK-cell neoplasms are grouped according to major clinical presentations (predominantly disseminated/leukemic, primary extranodal, and predominantly nodal).

Adapted from Harris NL, Jaffe ES, Diebold J, et al.: World Health Organization classification of neoplastic diseases of the hematopoietic and lymphoid tissues: report of the Clinical Advisory Committee Meeting–Airlie House, Virginia, November 1997. *J Clin Oncol* 17:3835–3849, 1999.

B- AND T-CELL LINEAGE

More recently, classification of ALL has been based on B- and T-cell lineage.⁵⁴ More than 80% of cases of ALL in adults are of B-cell lineage, with 10–15% arising

from T cells.^{18,54,55} While protocol chemotherapy and overall treatment usually follow similar pathways, prognosis may be dictated by these subsets and their individual responses to treatment or propensity for relapse.^{10,33}

As the B- and T-cell classifications have evolved, these classifications have now been subdivided into diagnostic groups based on immunophenotypic groups extended to specific genetic mutations, and genomics. Treatment planning follows subset or subgroup analysis, including T-cell and mature B-cell ALL, pre-B ALL, and ALL with associated bcr/abl translocation t(9;22), or other detrimental abnormalities demonstrated. These differences in intensity of treatment and various versions of protocols will be considered in Chapter 13.^{4,10} Prognosis can now be related to specific subsets based on chromosome mutation and cell signaling pathways; the best examples of these cases, once again, are t(9;22) and t(4;11) as unfavorable predictors, while others may predict a more favorable response and prognosis.¹⁰

MORPHOLOGY, IMMUNOPHENOTYPE, AND CYTOGENETICS

Classifications based on morphology, immunophenotype, and cytogenetics (MIC) have further defined subsets of disease based on these parameters for ALL (MIC) and AML (MIC-M), and employ defined subsets of antibodies to delineate diagnostic groups.⁵⁶⁻⁵⁸ Differences in B- and T-cell incidence in children and adults respectively are detailed in an elegant manner by Pui (Table 10.1). These also relate B- and T-cell lineage to specific subsets of chromosome abnormalities and their incidence by comparison in children and adults.

WHO CLASSIFICATION

The WHO classification melds morphologic, immunophenotypic, genetic, and clinical characteristics to form a coherent and current classification separating Hodgkin's disease from the non-Hodgkin's lymphomas and differentiating B-cell neoplasms from those of T- and NK (natural killer)-cell origin (Table 10.2). Precursor B- and precursor T-cell leukemias encompass the multiple subsets of ALLs, considered in more detail in the subsequent chapters.⁵⁹ An obvious short coming of the WHO system is that its classification does not speak to individual subsets, which may and should require individualization of treatment. Ongoing studies detailing the diagnostic groups above, and studies in animal models such as the zebra fish, will likely supplant current classification systems by defining causative signaling pathways and subsets of disease. These will enhance current prospects for genome-based targeted therapy, such as with the addition of imatinib mesylate to the treatment of bcr/abl-positive ALL, and will lead to more targeted and effective therapy for individual disease subsets in the future.

SUMMARY

ALL was the first acute leukemia to achieve complete remission, leading to cure in a large proportion of patients, initially in childhood and more recently extending to all age groups. All aspects of leukemia epidemiology, classification, and biology, and more recently, understanding of genomic abnormalities and mechanisms of leukemogenesis, have been advanced by work with ALL and extended to other malignant tumors.

Chapter 11

MOLECULAR BIOLOGY, PATHOLOGY, AND CYTOGENETICS OF ACUTE LYMPHOBLASTIC LEUKEMIA

Meir Wetzler, Krzysztof Mrózek, and Clara D. Bloomfield

INTRODUCTION

Acute lymphoblastic leukemia (ALL) is characterized by distinctive morphologic, immunophenotypic, cytogenetic, and molecular genetic features, some of which have important clinical implications for both diagnosis and predicting response to specific treatment regimens, while the role of others is yet to be defined. This chapter focuses on the cytogenetic and molecular aberrations in ALL. Pathologic and immunophenotypic information is provided where it is clearly associated with the cytogenetic and/or molecular aberration.

MORPHOLOGY

Until recently, ALL was classified based on morphology and cytochemistry according to the French-American-British (FAB) schema, which includes three major subtypes: L1, L2, and L3.¹ However, recent studies have failed to show prognostic significance of the L1 and L2 categories, and their designation has not had a high reproducibility rate among morphologists. Based on these findings, and as a result of improved understanding of the biology of these disorders, the 2001 World Health Organization (WHO) classification considers ALL as a form of lymphoma with a distinctive presentation. Initial classification is based on immunophenotype, and according to FAB, cases considered L1 and L2 are classified under precursor B- and T-cell neoplasms as precursor B-lymphoblastic leukemia/lymphoma and precursor T-lymphoblastic leukemia/lymphoma.² In addition to immunophenotype, the WHO classification incorporates molecular, cytogenetic, morphologic, and clinical features in defining disease entities, as described by the WHO Advisory Committee.² Table 11.1 shows a comparison between the two classifications.

In the WHO classification, FAB L3 is classified as one of the mature B-cell neoplasms and is designated Burkitt lymphoma/leukemia. It remains a separate entity char-

acterized by its morphologic, immunophenotypic, cytogenetic, molecular, and clinical features. The blasts are characteristically medium in size, with dispersed chromatin, multiple nucleoli, and a moderate amount of deep blue cytoplasm with vacuoles. The classic “starry sky” description is derived from the presence of light-colored macrophages (stars) interspersed among sheets of dark blue blasts (sky). Oil red staining can be used to highlight the vacuoles in Burkitt-cell leukemia blasts.

CYTOGENETIC ABERRATIONS

Cytogenetic aberrations can be structural, e.g., reciprocal and unbalanced translocations, deletions, dicentric chromosomes or inversions, or numerical, e.g., gain of

Table 11.1 Comparison of the FAB and WHO classifications of ALL

FAB classification	WHO classification ^a
≥30% blasts	≥20% blasts ^b
L1/L2 (morphology subgroups)	Precursor B-cell ALL (cytogenetic subgroups)
	t(9;22)(q34;q11.2) <i>BCR/ABL</i> t(V;11)(V;q23) <i>MLL</i> rearranged ^c t(1;19)(q23;p13.3) <i>E2A/PBX1</i> t(12;21)(p13;q22) <i>ETV6/RUNX1 (TEL/AML1)</i> Hypodiploid Hyperdiploid >50 chromosomes Precursor T-cell ALL (cytogenetic subgroups) t(V;14)(V;q11-13)
L3	Burkitt-cell leukemia

^aIn the WHO classification, ALL and lymphoblastic lymphoma are regarded as a single entity with different clinical presentations.

^bA disease with less than 20% blasts is defined as lymphoblastic lymphoma.

^c“V” denotes various partner chromosomes and breakpoints.

a whole chromosome (trisomy) or loss of a whole chromosome (monosomy). In many instances, molecular dissection of structural chromosomal abnormalities, especially reciprocal translocations, has identified specific genes associated with leukemogenesis. The most common structural cytogenetic aberrations and their affected genes in adult ALL are shown in Table 11.2 arranged according to their frequency.

STRUCTURAL ABERRATIONS

t(9;22)(q34;q11.2)

The t(9;22)(q34;q11.2) is the single most frequent chromosomal abnormality in adult ALL, being detected in 11–34% of patients, and is associated with an unfavorable prognosis.^{3–11} It rarely occurs in therapy-related ALL.¹² The reciprocal translocation between chromosomes 9 and 22 results in the head-to-tail fusion of variable numbers of 5' breakpoint cluster region (BCR) exons on chromosome band 22q11.2 with the exon 2 of the ABL gene (named after the Abelson murine leukemia virus), located on chromosome band 9q34.¹³ The protein product of the fusion gene resulting from the t(9;22) plays a central role in the development of this form of ALL. Two main types of fusion proteins, p190^{BCR/ABL} and p210^{BCR/ABL}, each containing NH₂-terminal domains of BCR and COOH-terminal domains of ABL, are produced, depending on the location of the breakpoint within the BCR gene. The p190^{BCR/ABL} product contains the first exon of BCR and occurs in 50–78% of the ALL cases with t(9;22).^{14–17} The p210^{BCR/ABL} product contains either exon 13 or exon 14 of BCR and is less frequent in ALL. However, p190^{BCR/ABL} transcripts are frequently detected at a low level in p210^{BCR/ABL}-positive ALL.¹⁸ Clinically, there is no clear distinction between the two molecular variants of the disease,^{19–21} except for one report showing that the p210^{BCR/ABL} product is associated with older age patient²² and another report demonstrating a higher risk of relapse in p190^{BCR/ABL} ALL following allogeneic transplantation.²³ Of interest, imatinib-

containing treatment has not revealed any outcome difference between the two disease types.

Secondary chromosomal aberrations accompanying t(9;22) occur in 41–86% of adult ALL patients.^{20,21,24–27} The most common additional aberrations in a Cancer and Leukemia Group B series²⁷ were, in order of decreasing frequency, +der(22)t(9;22), 9p rearrangements, high hyperdiploidy (>50 chromosomes), +8, and –7. In this study, the presence of +der(22)t(9;22) was associated with a higher cumulative incidence of relapse, while the presence of –7 as a sole secondary abnormality was associated with a lower complete remission rate.²⁷

At the molecular level, BCR/ABL has recently been shown to activate the Src kinases Lyn, Hck, and Fgr in ALL cells.²⁸ These kinases are less frequently activated in CML, suggesting a unique downstream signaling pathway in BCR/ABL-positive ALL. Further, application of DNA microarray gene expression profiling has revealed that BCR/ABL-positive pediatric ALL is characterized by gene expression profiles distinct from other prognostically relevant leukemia subtypes. These results were recently partially confirmed and validated in samples from adult ALL patients. Finally, mutations at the ABL kinase domain are frequent and are associated with resistance to imatinib.²⁹

The cells of almost all newly diagnosed patients with t(9;22) have a pre-B-cell immunophenotype^{4,6,14}; additionally, expression of CD10^{14,29} and of myeloid markers¹⁴ is more prevalent in patients with this translocation than in other adult ALL patients. There is some preponderance of FAB L1 over L2 morphology.⁶

dic(9;12), dic(9;20), and del(9p)

Structural aberrations involving the short arm of chromosome 9 occur in 5–15% of adult ALL patients.^{6,7,9,10} They include dicentric chromosomes: dic(9;12)(p11-13;p11-13) and dic(9;20)(p11;q11), as well as deletions of 9p. Both dicentric chromosomes are associated with a favorable clinical outcome.

Table 11.2 Most frequent cytogenetic aberrations in adult ALL and their corresponding genes

Cytogenetic aberration	Genes involved ^a	Frequency (%)
t(9;22)(q34;q11.2)	BCR/ABL	11–34
del(9p)	CDKN2A and CDKN2B	5–15
t(4;11)(q21;q23)	MLL/AF4	3–7
del(12p) or t(12p)	ETV6	4–5
t(14;V)(q11;V) ^b	TCRA and TCRD	4–6
t(14;V)(q32;V) ^b	IGH, BCL11A, TCL1B, and CL11B	5
del(6q)	?	2–6
t(1;19)(q23;p13.3)	E2A/PBX1	3
t(8;14)(q24;q32)	MYC/IGH	1–2
t(2;8)(p12;q24)	MYC/IGK	
t(8;22)(q24;q11)	MYC/IGL	

^aPlease refer to text for abbreviations and references for the percentages.

^b“V” denotes various partner chromosomes and breakpoints.

Other anomalies of 9p, mainly del(9p), are most often associated with the presence of additional clonal aberrations (in up to 90% of patients); in almost one-third of the cases, the additional abnormalities include t(9;22).¹⁰ These data suggest that del(9p) likely represents a secondary cytogenetic abnormality.

11q23 aberrations

Chromosome band 11q23 harbors the mixed lineage leukemia gene (*MLL*, also known as *ALL-1*, *HTRX*, or *HRX*),³⁰ which encodes a putative transcriptional regulator. *MLL* is involved in reciprocal translocations with many partner genes, localized on different chromosomes, both in ALL and in acute myeloid leukemia (AML).³¹ While the *MLL* gene can be amplified in a subset of AML patients, its amplification is rare in ALL.³² The distribution of 11q23/*MLL* translocation partners differs between ALL and AML, with t(4;11)(q21;q23) being by far the most frequent 11q23 translocation in ALL (see below). The partial tandem duplication of *MLL*, described in AML,³³ has not been detected in ALL. 11q23/*MLL* translocations have been described in both de novo and therapy-related disease.³⁴

ALL with *MLL* rearrangements also has a unique gene expression profile.³⁵ Specifically, some *HOX* (homeobox) genes are expressed at higher levels in *MLL*-positive ALL than in *MLL*-negative ALL.³⁶ Furthermore, gene expression profiles predictive of relapse were recently identified in pediatric *MLL*-positive ALL in one study,³⁷ although they did not reach statistical significance in another. Further work in this area is on going.

t(4;11)(q21;q23) The t(4;11)(q21;q23) is the most frequent chromosomal rearrangement involving the *MLL* gene in adult ALL, being detected in 3–7% of ALL patients, and is associated with an unfavorable outcome.^{3–7,9,10} It results in two reciprocal fusion products coding for chimeric proteins derived from *MLL* and from a serine/proline-rich protein encoded by the *AF4* (*ALL1* fused gene from chromosome 4) gene.³⁸

Griesinger et al. have demonstrated the presence of *MLL/AF4* fusion gene in adult ALL patients without cytogenetically detectable t(4;11). Another study analyzed the clinical significance of the *MLL/AF4* fusion gene detected molecularly in the absence of karyotypic evidence of t(4;11), and established that patients whose blasts were *MLL/AF4* positive and lacked a t(4;11) had outcomes similar to patients without *MLL/AF4*. This study suggests that additional treatment is not needed for patients whose blasts are *MLL/AF4* positive but t(4;11) negative.

Secondary cytogenetic aberrations in addition to t(4;11) are found in approximately 40% of patients.^{6,39,40} The most common additional changes were i(7)(q10) and +6 in one series³⁹ and +X, i(7)(q10), and +8 in another.⁴⁰ With treatment carried out according to risk-adapted therapy, no difference in outcome was observed between patients with and without clonal chromosomal

aberrations in addition to t(4;11) at diagnosis,⁴⁰ although this series was relatively small.

Other balanced translocations involving 11q23 Other recurrent, albeit rare in ALL, translocations involving *MLL* include t(6;11)(q27;q23), t(9;11)(p22;q23), t(10;11)(p12;q23), and t(11;19)(q23;p13.3).⁴¹ The respective fusion partners of the *MLL* gene are *AF6*, *AF9*, *AF10*, and *ENL* (eleven-nineteen leukemia). Other less common *MLL* partners have also been described.⁴²

Almost all patients with 11q23 translocations have a CD10-negative and CD19-positive B-cell precursor ALL (pre-pre-B ALL).⁴³ Coexpression of myeloid antigens is well recognized. In one series, 21 of 24 patients with CD10–/CD19+/CD15+ immunophenotype had t(4;11).²⁰ FAB L2 morphology has been described in up to 44% of patients.⁶ Patients with 11q23 aberrations have an unfavorable outcome.^{3–10}

del(12p) or t(12p)

Abnormalities of the short arm of chromosome 12 have been described in 4–5% of adult ALL patients.^{6,7,9,10} In one series, 20 of 23 (87%) cases with abnormal 12p had net loss of 12p material: 8 caused by deletions and 12 by unbalanced translocations.⁶ It is believed that a putative tumor suppressor gene is located in chromosome band 12p12.3.^{44,45} The outcome of patients with abnormalities of 12p, who did not have t(9;22), was favorable in two adult ALL series.^{7,10}

A cryptic t(12;21)(p13;q22), commonly found in pediatric ALL and also associated with a favorable outcome, is rare in adult ALL.^{46–48} The genes involved in this translocation are *ETV6*⁴⁹ and *RUNX1* (runt-related transcription factor 1, also known as *AML1* and *CBFA2*).⁵⁰ An intriguing explanation for the favorable outcome of pediatric patients with t(12;21) may lie in the finding that the ETV6/RUNX1 protein can overcome drug resistance through transcriptional repression of multidrug resistance-1 gene expression.⁵¹ Furthermore, t(12;21) ALL is associated with a lower expression of genes involved in purine metabolism and lower de novo purine synthesis.⁵² Taken together, these data may explain the favorable outcome of childhood ALL with t(12;21).

t(14q11-13)

Abnormalities of the proximal part of the long arm of chromosome 14 have been described in 4–6% of adult ALL patients and are associated with the WHO precursor T-lymphoblastic leukemia/lymphoma designation.^{6,10} The genes involved in t(14q11-13) are T-cell receptor α (*TCRA*) and δ (*TCRD*).⁶

Translocations involving band 14q32, other than t(8;14)(q24;q32)

Abnormalities of the distal part of the long arm of chromosome 14 have been described in approximately 5% of adult ALL patients.¹⁰ The genes involved in

t(14q32) are the immunoglobulin heavy chain locus (*IGH*)⁵³ and the Krüppel zinc-finger gene (*BCL11A*)⁵⁴ on chromosome 14q32.3, both in B-lineage ALL; the *TCL1* (T-cell leukemia) gene on chromosome 14q32.1⁵⁵ and the distal region of a Krüppel-like zinc-finger transcription factor *BCL11B* (also called *CTIP2*) on chromosome 14q32.2,^{56,57} both in T-lineage ALL.

del(6q)

Deletions of the long arm of chromosome 6 have been reported in 2–6% of adult ALL patients.^{3,6–9,58} In one large series, most deletions encompassed band 6q21 (in 20 of 23 patients), with del(6)(q12q16) being present in 3 remaining patients.⁶ In most patients, del(6q) is found together with additional chromosomal abnormalities.¹⁰ It is unclear whether del(6q) represents a primary or secondary cytogenetic abnormality. The outcome of patients with del(6q) was somewhat better than that of patients with a normal karyotype in one large study,⁶ but this finding requires confirmation.

t(1;19)(q23;p13.3)

This aberration is significantly less common in adult than in pediatric ALL. It was recognized as a separate entity in adult ALL in only one series, where it was found in 3% of the patients.⁶ There are two cytogenetic variants of the (1;19) translocation: a less common balanced t(1;19)(q23;p13.3) and a predominant unbalanced der(19)t(1;19)(q23;p13.3), which is almost always accompanied by two intact chromosomes 1. The genes involved in this translocation are *E2A* (early region of adenovirus type 2 encoding helix-loop-helix proteins E12/E47) on chromosome band 19p13.3^{59,60} and *PBX1* (pre-B-cell leukemia transcription factor 1) on chromosome band 1q23.^{61,62} Rare ALL cases with t(1;19) lack the *E2A/PBX1* fusion gene.⁶³

The t(1;19) is associated with L1 morphology and CD10 and CD19 positivity in almost all cases.^{6,63} Interestingly, up to 25% of cases have been described to have Burkitt-like morphology, even though the immunophenotype was not always of the mature (positive surface immunoglobulin expression) type.^{6,63}

t(8;14)(q24;q32)

This aberration and its variants, t(2;8)(p12;q24) and t(8;22)(q24;q11), are the hallmark of Burkitt lymphoma/leukemia. As a result of t(8;14), the *MYC* gene, located at 8q24, is juxtaposed to the enhancer elements of the *IGH* gene at 14q32. In the case of variant translocations, one of the immunoglobulin light chain genes, mapped to bands 2p12 (*IGK*) and 22q12 (*IGL*), is translocated to a telomeric region of the *MYC* gene at 8q24.^{64–67} Consequently, *MYC* is activated and expressed at high levels. Because the product of the *MYC* gene, a DNA-binding protein, is implicated in the regulation of a number of other critical genes, its constitutive production results in uncontrolled proliferation of cells

with one of the translocations. In approximately 45% of ALL L3 cases, one of the primary translocations, t(8;14), t(2;8), or t(8;22), is the sole chromosomal abnormality.⁴² The most frequent secondary aberrations include unbalanced structural anomalies of chromosome 1 that lead to gain of material from its long arm, i.e., duplications of 1q, isochromosomes of 1q, and unbalanced translocations involving 1q, and trisomies of chromosomes 7 and 8.⁴²

The disease has two major clinical presentations: sporadic/immunodeficiency Burkitt lymphoma/leukemia seen in the Western world, and endemic Burkitt lymphoma/leukemia found in equatorial Africa and almost always associated with Epstein–Barr virus (EBV) infection. They differ not only in regard to clinical manifestations, but also at the molecular level.^{68–71}

Burkitt lymphoma/leukemia is associated with mature B-cell immunophenotype with surface IgM, Bcl-6, CD19, CD20, CD22, CD10, and CD79a, and is TdT, CD5, and CD23 negative.

NUMERICAL ABERRATIONS

Hyperdiploidy

A high hyperdiploid karyotype, defined by the presence of more than 50 chromosomes, is detected in 2–9% of adult ALL patients.^{3,4,6–10} The most common extra chromosomes in 30 adult patients with high hyperdiploidy (range, 51–65 chromosomes) were (in decreasing order) 21, 4, 6, 14, 8, 10, and 17.⁶ In pediatric ALL, gain of the X chromosome appears to be the most common chromosomal abnormality, being detected in nearly all children with a high hyperdiploid karyotype and in up to one-third of the patients with low hyperdiploid karyotype (i.e., 47–50 chromosomes).⁷² Interestingly, chromosomes 6, 8, and 10 were also the most common chromosomes lost in the hypodiploid group, along with chromosome 21. The reason for the involvement of these specific chromosomes in both types of aberrant karyotypes is unclear. Translocation (9;22) is a common structural aberration in patients with high hyperdiploidy; it was present in 11 of 30 (37%) patients in one series⁶ and 7 of 11 (64%) in another.²⁶ Patients with hyperdiploidy and t(9;22) were older and had shorter disease-free survival (DFS) than those without t(9;22).⁶

The mechanism leading to hyperdiploidy is unknown. Several possibilities have been suggested, including polyploidization with subsequent losses of chromosomes, successive gains of individual chromosomes in consecutive cell divisions, and a simultaneous occurrence of several trisomies in a single abnormal mitosis.⁷³

The clinical outcome of adult patients with hyperdiploid karyotypes varies in different series. In two studies, the outcome of patients with hyperdiploid karyotypes was better than that of other adult ALL patients,^{3,7,9} while other studies^{4,6,10,26} showed poor outcome for these patients except for those with near

tetraploidy.⁶ The reason for this discrepancy is unclear. In two studies,^{7,10} the analysis was restricted to patients with hyperdiploidy without structural abnormalities. The other studies^{3,4,6,9,26} did not provide information regarding structural abnormalities. A study of a larger cohort of adult ALL patients analyzing whether hyperdiploid karyotype without structural abnormalities constitutes an independent prognostic factor is warranted.

Almost all cases with high hyperdiploidy have precursor B-lineage ALL.^{6,74}

Hypodiploidy

Hypodiploidy is defined by the presence of less than 46 chromosomes. This karyotype is found in 4–9% of adult ALL patients.^{3,6,7,9,75} Patients with hypodiploid karyotypes tend to be somewhat younger than patients with a normal karyotype.^{6,7} A recent analysis grouped patients with hypodiploidy into those with near-haploidy (23–29 chromosomes), low hypodiploidy (33–39 chromosomes), and high hypodiploidy (42–45 chromosomes).⁷⁵ There were only six adult patients in this series, five of them in the low-hypodiploidy group and one in the high-hypodiploidy group. The most common losses in seven patients with hypodiploidy ranging from 30 to 39 chromosomes involved chromosomes 1, 5, 6, 8, 10, 11, 15, 18, 19, 21, 22, and the sex chromosomes.⁶ Only one study reported specifically on hypodiploidy without structural abnormalities.⁷ Patients with hypodiploidy have a DFS between 2 and 4 months, and therefore the abnormality is classified as unfavorable.⁷

Most of the patients with hypodiploidy have a B-lineage immunophenotype,^{6,7,75} although one report⁷⁴ described up to 20% of patients with T-lineage ALL.

Trisomy 8

Trisomy 8 in ALL is most often associated with other karyotypic abnormalities; it is rare as a sole abnormality.⁷⁶ Twelve of 23 (52%) patients with trisomy 8 also had t(9;22). However, patients with trisomy 8 without t(9;22) but with miscellaneous other abnormalities fared as poorly as those with trisomy 8 and t(9;22).¹⁰ It is unclear whether the adverse outcome is due to the other primary abnormalities or associated with the presence of trisomy 8 per se.

Monosomy 7

As with trisomy 8, monosomy 7 is most often associated with other karyotypic abnormalities; monosomy 7 as a sole abnormality is rare in ALL. Only one adult¹⁰ and one pediatric⁷⁷ series defined patients with monosomy 7 as a separate group. In the adult series, 9 of 14 (64%) patients with monosomy 7 had t(9;22). Patients with monosomy 7 without t(9;22) but with miscellaneous other abnormalities fared as poorly as those with monosomy 7 and t(9;22).¹⁰ It is unclear whether the adverse outcome is due to the other primary abnormalities or is associated with the presence of monosomy 7.

MOLECULAR ABERRATIONS

Molecular aberrations are divided into those that emerge from specific aberrations, gene profiling, and polymorphisms.

SPECIFIC ABERRATIONS

Extrachromosomal amplification of the *NUP214/ABL* fusion gene in T-cell ALL

Two recent studies revealed a novel genetic phenomenon in T-cell ALL: namely cryptic extrachromosomal amplification of a segment from chromosome 9 containing the *ABL* gene. Barber et al. were the first to report that amplification involving the *ABL* gene occurred in 5 of 210 (2.3%) children and 3 of 70 (4.3%) adults with T-cell ALL, even though there was no cytogenetic evidence of amplification, such as double minutes or homogeneously staining regions. The authors suggested that amplified *ABL* sequences were located on submicroscopic circular extrachromosomal DNA molecules called episomes.

SMAD3

SMAD3 [Sma and Mad (mothers against decapentaplegic) 3] is involved in signal transduction from the transforming growth factor β (TGF- β) superfamily of receptors to the nucleus.⁷⁸ SMAD3 protein was recently shown to be absent in T-cell ALL, but present in B-cell ALL and AML. The *SMAD3* transcript was intact in all leukemia subtypes. These data suggest that *SMAD3* is functioning as a tumor suppressor gene in T-cell ALL.

FLT3

FLT3 activating mutations are in general rare in ALL, but have been detected in approximately 20% of ALL specimens, with rearrangement of the *MLL* gene,^{37,79,80} 25% of hyperdiploid ALL,^{80,81} and in the rare subset of CD117/KIT-positive, CD3-positive ALL.⁸² Interestingly, the internal tandem duplication of the *FLT3* gene, commonly detected in AML, has thus far not been seen in ALL. FLT3 inhibitors (e.g., PKC412 and CEP-701) can suppress *FLT3*-positive ALL cells in vitro and therefore warrant clinical trials.^{79,83}

TLX1

Gene expression profiles in T cell ALL identified five different signature patterns involving different oncogenes: *TLX1* (*HOX11*), *TLX3* (*HOX11L2*), *TAL1* plus *LMO1/2*, *LYL1* plus *LMO2* and *MLL-ENL*.⁸⁵ Only the *TLX1*-expressing samples were associated with a favorable outlook in children^{86,87} and adults⁸⁸ with T cell ALL.

Cryptic t(5;14)(q35;q32) and the overexpression of the *TLX3* gene

TLX3 gene expression represents one of the five oncogenes involved in T-cell ALL. This gene is located on chromosome 5q35 and was found to be transcriptionally

activated as a result of a translocation between chromosomes 5 and 14, t(5;14)(q35;q32).⁸⁴ A study of samples from 23 childhood T-cell ALL patients revealed that this translocation was cryptic in five of them,⁸⁴ which was corroborated by larger studies.^{85,86} Overexpression of *TLX3* was reported by one group⁸⁷ to bestow poor prognosis but this has not been substantiated by other, larger studies.^{85,86}

NOTCH1

NOTCH1 point mutations, insertions, and deletions producing aberrant increases in NOTCH1 signaling are frequently present in T-cell ALL.⁸⁸⁻⁹⁰ Further, NOTCH1 signaling was shown to be required for sustained growth and, in a subset of cell lines, for survival. Finally, experiments with small-molecule inhibitors of γ -secretase, a protease required for normal NOTCH signal transduction and the activity of the mutated forms of NOTCH1, showed inhibitory activity in T-cell ALL with NOTCH1 mutations. These results provide a rationale for clinical trials with NOTCH1 inhibitors, such as γ -secretase antagonists.^{89,90}

GENE PROFILING

Relapse-classifying gene sets

Several groups have identified distinctive gene sets in diagnostic samples from patients whose disease subsequently recurred.^{91,92} In spite of the different age groups studied (pediatric⁹¹ vs adult⁹²), assortment of array platforms, and diverse treatment protocols, all Affymetrix ALL array data and two sets of cDNA arrays validated the predictability of these gene sets to delineate the following cytogenetic prognostic groups: hyperdiploidy, T-lineage ALL, t(12;21), t(4;11), and t(1;19).⁹³

Resistance-classifying gene sets

A different gene profile was identified when leukemia cells were tested for in vitro sensitivity to the four most commonly used drugs in ALL, i.e., prednisolone, vincristine, asparaginase, and daunorubicin.⁹⁴ Interestingly, only three genes for which results were significant in these analyses, *RPL6*, *ARHA*, and *SLC2A14*, have previously been associated with resistance to doxorubicin. Two gene expression profiles that differed according to sensitivity or resistance to the four drugs were compared with treatment outcome. These two gene sets were significantly and independently predictive of outcome. They are now being analyzed in prospective studies to tailor treatment according to patterns of resistance.

POLYMORPHISMS

Pharmacogenetics is the study of genetic variations in drug-processing genes and individual responses to

drugs.⁹⁵ It enables the improved identification of patients at higher risk for either disease relapse or chemotherapy-associated side effects.

More than 20 years ago, it was recognized that the activity of thiopurine-S-methyltransferase (TPMT), the enzyme involved in the metabolism of 6-mercaptopurine and 6-thioguanine, differs among patients and that approximately 1 in 300 individuals demonstrates reduced enzymatic activity.⁹⁶⁻¹⁰⁰ Molecular testing to identify this polymorphism was developed shortly thereafter^{101,102} and showed good correlation with the enzymatic activity. Based on molecular testing, it has become clear that homozygous carriers for one of the three *TPMT* mutant alleles experience severe myelotoxicity and increased risk of relapse due to treatment delays.^{103,104} Interestingly, patients with the mutated *TPMT* alleles have a significantly higher risk of developing secondary brain tumors if treated with whole-brain radiation.¹⁰⁵ Similarly, there was a trend toward increased risk of secondary AML in patients with decreased enzymatic activity.¹⁰⁶

Similarly, single-nucleotide polymorphisms involving four of the enzymes involved in methotrexate metabolism have been implicated in increased relapse risk or toxicity in pediatric ALL patients: methylenetetrahydrofolate reductase,¹⁰⁷⁻¹¹¹ reduced folate carrier,¹¹²⁻¹¹⁴ thymidylate synthetase,^{115,116} and methylenetetrahydrofolate dehydrogenase.¹¹¹

FUTURE DIRECTIONS

We believe that progress in cytogenetic and genetic dissection of ALL will lead to risk-adapted treatment in adult ALL, as is already being accomplished for pediatric ALL. Currently, allogeneic transplantation in first remission is offered to adults with unfavorable karyotypes. The future promises more refined approaches, based on the information from genetic analyses, which will hopefully lead to improved outcome in adult ALL.

Chapter 12

CLINICAL FEATURES AND MAKING THE DIAGNOSIS

Ronald M. Sobecks

CLINICAL FEATURES

DISEASE PRESENTATION—

Patients with acute lymphoblastic leukemia (ALL) present with signs and symptoms related to impaired hematopoiesis from progressively worsening bone marrow involvement. Anemia may result in fatigue, light-headedness, dyspnea, and pallor. Patients with thrombocytopenia may develop petechiae, purpura, and hemorrhage. Fevers and infections also commonly occur due to neutropenia. Approximately one-third of patients have been reported to have infections, hemorrhage, or constitutional symptoms at the time of diagnosis.¹⁻³ Clinical characteristics for patients presenting with ALL are given in Table 12.1.

Leukocytosis is often observed at the time of initial disease presentation, and the German Multicenter Trial GMALL 03/87 and 04/89 reported that 51% of their adult patients had a white blood cell (WBC) count of more than $30 \times 10^9/L$.¹ Investigators at MD Anderson Cancer Center noted that 26% of their adult ALL patients had a WBC count of more than $30 \times 10^9/L$ and 39% had a WBC count between 5 and $30 \times 10^9/L$.¹² The French Group on Therapy for Adult ALL LALA 87 Trial observed that 31% of adult B-cell ALL patients and 55% of T-cell ALL patients had an initial WBC count of $30 \times 10^9/L$ or above.⁴ The GIMEMA 0496 study found that 32% of their adult pro-B-cell ALL patients had an initial WBC count of more than $50 \times 10^9/L$.¹³ Patients with T-cell ALL have been reported to have a WBC count greater than $100 \times 10^9/L$ in 25% of adult patients and in 50–77% of children.⁵⁻⁷ In addition, 40–50% of children with B-cell ALL have been noted to have an initial WBC count of more than $20-25 \times 10^9/L$.^{8,14}

Anemia occurs frequently when patients present with ALL. A hemoglobin of less than or equal to 8 g/dL has been noted in about 30% of adult pro-B-cell ALL patients,¹ while a hemoglobin of less than 12 g/dL has been observed in 85% of B-cell ALL and 65% of T-cell ALL patients.⁴ Investigators at MD Anderson Cancer Center found that 69% of their adult ALL patients had

an initial hemoglobin of less than 10 g/dL.¹² Fifty-five percent of children with T-cell ALL treated at St Jude Children's Research Hospital were noted to have an initial hemoglobin of less than 11 g/dL.⁷ French investigators observed that 42% of their children and 60% of infants with ALL had presenting hemoglobin levels of less than 8 g/dL.⁹ More than 80% of children on Children's Cancer Group (CCG) trials were also found to be anemic at diagnosis, with a hemoglobin level of less than or equal to 10 g/dL.⁸

Thrombocytopenia is also commonly observed at the time of diagnosis. Kantarjian et al. noted that 74%

Table 12.1 Signs and symptoms at the time of ALL diagnosis

	Reported (%) ^a
Hemorrhage	35–38
Infection	12–38
B symptoms	27–33
Lymphadenopathy	
B cell	21–46 (adult), 17–60 (child)
T cell	67–71 (adult), 79 (child)
Hepatomegaly	
B cell	13–50 (adult), 3–50 (child)
T cell	34 (adult), 41–72 (child)
Splenomegaly	
B cell	30–49 (adult), 5–80 (child)
T cell	52 (adult), 54–84 (child)
CNS involvement	
B cell	5–9 (adult), 2–5 (child)
T cell	9–11 (adult), 8–17 (child)
Mediastinal mass	
B cell	2–6 (adult), 0.2–11 (child)
T cell	40–91 (adult), 39–54 (child)
Pleura involvement	9–40 (adult), 5–7 (child)
Testis involvement	2–4 (adult), 2 (child)
Skin involvement	2
Kidney involvement	2

^aIncidences were obtained from Refs. 1–11.

of their adult ALL patients had a presenting platelet count of less than $100 \times 10^9/L$.¹² French investigators similarly reported that approximately 70% of both their B- and T-cell ALL patients had platelet counts of less than or equal to $100 \times 10^9/L$ at the time of presentation.⁴ The Cancer and Leukemia Group B Study 8364 had found that the initial median platelet counts for B- and T-lineage disease were 47 and $61 \times 10^9/L$, respectively.¹⁰ Of approximately 3700 cases of childhood ALL enrolled on CCG trials, 35–50% had initial platelet counts of less than $50 \times 10^9/L$, 31–36% had platelet counts between 50 and $150 \times 10^9/L$, and 19–29% had platelet counts of more than $150 \times 10^9/L$.⁸

Patients with mature B-cell ALL (Burkitt-type) commonly present with bulky disease from rapid proliferation of the neoplastic cells. Hyperuricemia and a high serum lactate dehydrogenase (LDH) are often observed. Investigators at MD Anderson Cancer Center have reported that 42% of such patients had an initial LDH of 620–4999 U/L, 27% had a level of 5000–10,000 U/L, and 31% had a level of more than 10,000 U/L.¹⁵ They also noted that hepatomegaly, splenomegaly, and lymphadenopathy occurred in 31, 23, and 19% of these patients, respectively. At presentation, 27% of these patients had an initial WBC count of $10 \times 10^9/L$ or above, 65% were anemic with a hemoglobin level of less than 10 g/dL, and 77% had a platelet count of less than $100 \times 10^9/L$. As patients with mature B-cell ALL are treated, they also frequently develop tumor lysis syndrome that may further worsen hyperuricemia, which may in turn lead to renal insufficiency. There may also be hyperkalemia, hyperphosphatemia, and a resultant hypocalcemia (see Chapter 107).

EXTRAMEDULLARY DISEASE

Central nervous system disease

Central nervous system (CNS) ALL has been defined as more than five WBCs per microliter of cerebrospinal fluid (CSF) with leukemic lymphoblasts identified after cyto centrifugation.^{16,17} There has been some controversy as to whether the presence of blasts in the CSF predicts for more CNS relapses or inferior CNS leukemia-free survival in childhood ALL when the total CSF WBC count is less than $5/\mu L$.^{18,19} This is also unknown for adult ALL patients.

At the time of diagnosis, fewer than 5% of children and fewer than 10% of adult ALL patients present with CNS disease.²⁰ The leukemic cells may traverse superficial cerebral veins into the arachnoid circulation, which then may result in impaired cerebral perfusion. These neoplastic cells can then enter the CSF, resulting in morning headache, emesis, papilledema, signs of meningeal irritation, and impaired cerebral function.²¹ In addition, compromise of cranial nerve circulation from leukemia can lead to neuropathies, such as optic neuritis.²² Endocrinopathies may also

develop from hypothalamic or pituitary involvement.²³ Leukemic infiltration of the leptomeninges may lead to other neurologic symptoms, such as paraparesis.

Adolescent patients, children, and infants have a higher risk of CNS disease than do adults.²⁴ Approximately 10–40% of patients with mature B-cell ALL (Burkitt-type) develop CNS disease.^{15,25,26} This increased incidence is most notable in older ALL patients. Prior to the use of modern ALL treatment regimens, patients with T-cell disease were also more likely than those with B-cell phenotypes to develop CNS disease.²⁴ In addition, a high leukocyte count, a high serum LDH, and extramedullary disease have been associated with an increased risk of CNS leukemia.^{27,28}

Patients with ALL who develop CNS recurrences have a worse prognosis and are at increased risk for systemic relapses. With the use of standard therapies for CNS prophylaxis, the risk of CNS relapses has decreased for both children and adults from approximately 40–50% to 10% or below.^{29–31} Of 439 adult ALL patients treated at MD Anderson Cancer Center who achieved a complete remission, 32 (7%) developed a CNS disease relapse.³² However, when these investigators compared initial characteristics for patients with or without a CNS recurrence, they found no significant differences between the groups with respect to age, WBC count, platelet count, percentage of bone marrow or peripheral blood blasts, bone marrow cellularity, serum LDH, immunophenotype, French–American–British (FAB) classification, or Philadelphia chromosome status.

Testicular disease

Patients who develop testicular disease may present with increased testicular size and firmness, as well as nodular lesions in one or both testes that may be painless. The majority of leukemic infiltration involves the interstitium of the testis on the endothelial side.³³ It has been suggested that in children a risk factor for testicular involvement is age older than 10 years during the onset of puberty.³⁴

Using autopsy series, ALL involving the testes has been reported to occur in approximately 30–90% of cases.³⁵ With the use of more effective modern treatment regimens, this incidence may now be considerably lower.³⁶

Testicular disease is rare at the time ALL is initially diagnosed. However, testicular involvement is more commonly observed at the time of a disease recurrence, which usually antedates a systemic relapse within months.³⁷ The Children's Cancer Group reported that, among 3712 childhood ALL cases, there were 113 (8.3%) isolated testicular relapses, 38 (2.8%) concurrent marrow and testicular relapses, 4 (0.3%) concurrent marrow, testicular, and CNS relapses, and 4 (0.3%) concurrent testicular and CNS relapses.³⁸

Lymphatic

Lymphadenopathy is frequently observed and is somewhat more common in T-cell ALL than in B-cell ALL.^{1-3,5,9,11} Hepatomegaly and splenomegaly are also commonly identified at the time of disease presentation, and these are also found more often among T-cell phenotypes.^{1,2,5,7,9,11} Furthermore, lymphadenopathy and hepatosplenomegaly occur more commonly in children than in adults with T-cell ALL.⁵ Although mediastinal masses have been reported in approximately 40–90% of patients at the time of diagnosis of T-cell ALL,^{3-7,10} they have also been identified in B-cell ALL patients, but at a much lower frequency.^{1,4,9-11}

MAKING THE DIAGNOSIS

The diagnosis of ALL is usually established by a bone marrow examination from which morphologic assessment, as well as immunophenotypic, cytogenetic, and molecular analyses, may be obtained. Patients presenting with circulating lymphoblasts may also have the diagnosis established by performing these analyses on a peripheral blood sample. ALL and lymphoblastic lymphoma are considered to be the same disease biologically. When patients present with extensive blood and bone marrow involvement with more than 25% blasts, the disease is categorized as ALL. For patients having disease confined to mass lesions and having less than or equal to 25% blasts in the bone marrow, the diagnosis of lymphoblastic lymphoma is used.³⁹ For patients with lymphoblastic lymphoma, the diagnosis may be established by a biopsy of an involved lymph node(s) or mass lesion(s). An adequate amount of tissue should be obtained to perform the appropriate immunophenotypic, cytogenetic, and molecular analyses.

CNS disease may be detected by a lumbar puncture for CSF cytologic and flow cytometric analyses. Usually, this procedure is not performed initially when there are circulating lymphoblasts in the peripheral blood, as this may theoretically introduce disease into the CSF. Alternatively, a traumatic lumbar puncture may contaminate the CSF specimen with blood containing leukemic lymphoblasts, which could then result in a false positive test for CNS leukemia.

MORPHOLOGIC ASSESSMENT

A detailed discussion of the pathology of ALL is presented in Chapter 11. The initial morphologic classification for ALL was formulated by the FAB Cooperative Group,⁴⁰ which proposed three morphologic subtypes (L1, L2, and L3). The L1 subtype is composed of small cells with a homogeneous nuclear chromatin pattern, regular nuclear shape, and scant cytoplasm that is only slightly to moderately basophilic. The L2 subtype contains cells of more heterogeneous size and are larger than those of the L1 subtype. These blasts also have a more heterogeneous nuclear chromatin pattern, a

cytoplasm of variable amount and degree of basophilia, an irregular nuclear shape, and they may have nucleoli that are detected more readily compared to L1 blasts. The L3 subtype consists of blasts of large, uniform size with finely stippled chromatin and regular nuclear shape. Prominent nucleoli are commonly observed, and there are moderate amounts of cytoplasm with deep basophilia and lipid vacuoles. A “starry sky” appearance is often observed, which results from the ingestion of apoptotic neoplastic cells by histiocytes.⁴¹ Although many mitotic figures may be observed, the amount may be greater for T- compared to B-cell phenotypes.

Cytochemistry assessment demonstrates that the lymphoblasts in ALL are negative for myeloperoxidase and Sudan black B stains. Periodic acid-Schiff reaction and nonspecific esterase may be positive.⁴² Terminal deoxynucleotidyl transferase (TdT) is also positive in most cases of ALL.

IMMUNOPHENOTYPIC ASSESSMENT

Specific ALL phenotypes, such as T- or B-cell-lineage disease, cannot be distinguished by morphologic assessment. Immunophenotyping by flow cytometric analysis provides a rapid and accurate method to characterize distinct ALL subtypes. As distinguished in the World Health Organization Scheme, these consist of early precursor B-cell ALL, common B-cell ALL, precursor B-cell ALL, mature B-cell (Burkitt-type) ALL, precursor T-cell ALL, and T-cell ALL.⁴¹⁻⁴³ Table 12.2 shows the specific lymphoid markers that are expressed with the various ALL subtypes. Further discussion of immunophenotyping for ALL is found in Chapter 11.

MOLECULAR GENETIC ANALYSIS

Genetic alterations in ALL may be detected by cytogenetic, fluorescent in situ hybridization (FISH), and reverse transcriptase polymerase chain reaction (RT-PCR)

Table 12.2 Immunophenotypes of ALL subtypes

Surface markers	
<i>B lineages</i>	
Early precursor B cell	TdT+, CD19+, HLA-DR+, cCD79a+, cCD22+
Common B cell	TdT+, CD19+, HLA-DR+, CD10+
Precursor B cell	TdT+, CD19+, HLA-DR+, CD10+, clg+
Mature B cell	CD19+, CD20+, HLA-DR+, CD10+, CD22+, CD79a, slg+
<i>T lineages</i>	
Precursor T cell	TdT+, CD2+, CD7+, cCD3+
T cell	TdT+, CD1a+, CD2+, CD5+, CD7+, sCD3+

TdT, terminal deoxynucleotidyl transferase; c, cytoplasmic; s, surface; lg, immunoglobulin.

Table 12.3 Genotypes in adult and childhood ALL^{41,42,44}

Cytogenetic abnormality	Genetic alteration	Childhood frequency (%)	Adult frequency (%)
t(9;22)	BCR/ABL	3–4	25–29
t(12;21)	TEL/AML1	22–29	2
t(4;11), t(11;19), t(9;11)	MLL	8	10
t(1;19)	PBX/E2A	5–6 ^a	3
t(8;14), t(8;22), t(2;8)	MYC	2	4
5q35	HOX11L2	3	1
19p13	LYL1	2	3
10q24	HOX11	1	8
1p32	TAL1	7	12
Hyperdiploid (>50)		25	7
Hypodiploid (<45)		1–5	2

^aThe frequency is approximately 25% for childhood precursor B-cell ALL.

analyses. These diagnostic techniques allow for precise determination of specific ALL genotypes that provide important prognostic information. Molecular genetic alterations in ALL are given in Table 12.3. DNA microarray analysis may also provide unique gene expression profiles which will continue to refine the classification of ALL subtypes.^{45,46} Chapter 11 also specifically reviews the molecular biology of ALL. As FISH and RT-PCR are more sensitive techniques at detecting prognostically important cytogenetic abnormalities than is traditional karyotyping, we recommend use of one of these modalities to determine the presence of t(9;22) or t(4;11).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for ALL includes acute myeloid leukemia, aplastic anemia, chronic myeloid leukemia in lymphoid blast crisis, a minimally differentiated and reactive bone marrow with increased hematogones, bilineal acute leukemia in which two

distinct leukemic populations coexist, and biphenotypic acute leukemia in which a single leukemic population coexpresses a sufficient amount of both myeloid and lymphoid markers. Although chronic lymphoid leukemia and other lymphoid malignancies with circulating lymphoma cells may initially be considered in the differential diagnosis of ALL based upon an initial complete blood count and differential, ALL is usually easily distinguished from these diseases by morphologic review and immunophenotyping.

Lymphoblastic lymphoma and Burkitt lymphoma are biologically the same disease as their leukemic counterparts. However, their differential diagnosis also includes other aggressive lymphomas, thymoma, and other solid tumors from the respective anatomic locations in which they are found. An adequate biopsy specimen from which appropriate morphologic, immunophenotypic (e.g., TdT), and molecular studies (e.g., BCR/ABL) can be performed usually allows the diagnosis to be definitively established.

Chapter 13

TREATMENT APPROACH TO ADULT ACUTE LYMPHOBLASTIC LEUKEMIA

Elizabeth S. Rich, Cara A. Rosenbaum, and Wendy Stock

In acute lymphoblastic leukemia (ALL), normal hematopoiesis is suppressed by accumulation in the bone marrow of clonal, malignant lymphoblasts. Arrested at various stages of development, different subtypes of ALL are characterized by distinct immunophenotypic, cytogenetic, and molecular features. In contrast to pediatric ALL, where cure rates approach 80%, only one-third of adult patients with ALL achieve long-term disease-free survival (DFS). To improve the outcome of patients with adult ALL, insight gained from the characterization of ALL has led to a risk-adapted approach to therapy.¹ Further understanding of the biology of this disease will refine this risk-adapted approach, with the ultimate goal of improving the cure rates of adult patients with ALL.

BACKGROUND

ALL is a relatively rare disease in adults, representing approximately 20% of adult acute leukemias. The estimated number of new cases of ALL in the year 2003 in the United States was 3600. The age-adjusted incidence is 1.6 per 100,000 in adults.² There is a bimodal distribution to the incidence of the disease, with an initial peak in early childhood and a second smaller peak in patients older than 50 years.³ Secondary acute leukemias can occur following chemotherapy or radiation treatment for other malignancies. Although most of these leukemias are myeloid, an increasing number of ALL cases are being reported following exposure to chemotherapy with topoisomerase II inhibitors. These therapy-related ALL cases have been associated with chromosomal rearrangements involving the *MLL* gene and typically occur within 2 years of initial exposure to the chemotherapeutic agent(s).⁴ A longer time to development of leukemia has been observed following exposure to alkylating agents and the development of therapy-related leukemias.

PROGNOSTIC FACTORS AND RISK STRATIFICATION

Recognized prognostic factors in adult ALL that impact on treatment allocation are discussed below (Table 13.1).

AGE AT DIAGNOSIS

Most clinical trials⁵⁻⁹ have noted a marked difference in both complete remission (CR) rate and DFS in ALL patients, depending on patient age. Both comorbid medical conditions resulting in increased toxicity of induction and postremission therapy and the presence of higher risk biologic features contribute to the adverse prognosis of older adults with ALL. DFS is consistently less than 20% in patients older than 60 years. Shorter remission duration in older adults is also a consequence of the higher frequency of adverse cytogenetic features, including the t(9;22)(q34;q11), or Philadelphia chromosome, which may occur in as many as 40% of adults older than 50 years.^{10,11}

LEUKOCYTE COUNT AT PRESENTATION

The majority of clinical studies have identified a high presenting white blood cell (WBC) count as an adverse prognostic factor that influences both CR rate and duration.^{5,12-14} Despite intensification of recent regimens, lower remission durations in this subset of patients persist, particularly in those with precursor B ALL and WBC counts of higher than 100,000/ μ L.¹⁵ The same degree of hyperleukocytosis has not been as clearly associated with an adverse prognosis in precursor T ALL, in which patients routinely present with higher WBC counts.

FAILURE TO ATTAIN A CR IN LESS THAN 4-5 WEEKS

Several clinical studies have identified the importance of time required to attain first remission as a significant prognostic factor in adult ALL.^{8,16}

Table 13.1 Prognostic factors in adult ALL identifying risk groups for treatment—stratification

Prognostic factor	Ref	Good risk	Standard risk	Poor risk
Clinical age	5, 6–16	<30 years	30–60 years old	60 years
Presenting WBC		<30,000/uL	<30,000/uL	>30,000/uL (precursor B)
Time to CR		<2–4 weeks	2–4 weeks	>2–4 weeks
Immunophenotype	17–19	Mature B-Burkitt type Precursor T	Precursor B	Pro-B early T (only 1–3 T-cell markers)
Molecular/cytogenetics	20	High hyperdiploid t(8;14), t(2;8), or t(8;22)	Normal karyotype	t(9;22)/BCR-ABL t(4;11)/MLL-AF4 + (8) del(7)
MRD ^a	21–28	<10 ⁻⁴ after induction <10 ⁻⁴ or negative during first years		>10 ⁻³ after induction >10 ⁻⁴ or increasing during first year of therapy

^aRemains to be validated in a large, prospective series.

CYTOGENETICS/MOLECULAR GENETICS

Cytogenetic abnormalities occur in about 60–70% of adults with ALL and are among the most important prognostic factors; therefore, cytogenetic analysis is a critical component of the diagnostic workup.^{14,21} The Cancer and Leukemia Group B (CALGB) stratified patients into three prognostic groups based on cytogenetics: poor [including t(9;22), t(4;11), -7, and +8]; normal diploid; and miscellaneous (all other structural aberrations), with DFS rates of 11, 38, and 52%, respectively.²⁹ In this series, a higher frequency (35%) of patients with precursor T ALL had a normal karyotype. In particular, all larger series have identified that the presence of the Philadelphia chromosome, t(9;22) (q34;q11), and translocations involving the *MLL* gene on chromosome 11q23—the most common of which is the t(4;11)(q21;q23)—are independently associated with short CR duration and survival.^{20,21,30} The Philadelphia chromosome is the most common recurring abnormality (overall 25–30%) in adult ALL, and it increases in frequency with age. Allogeneic stem cell transplantation (allo SCT) in first remission is advocated for these high-risk patients and is discussed below. In contrast, patients with precursor T ALL and the t(10;14) appear to have durable remissions.⁵

MINIMAL RESIDUAL DISEASE STUDIES

Polymerase chain reaction (PCR) and flow cytometry have been used to monitor the persistence of the leukemic clone during treatment in an attempt to identify patients in morphologic and cytogenetic remission, but in whom there is persistence of subclinical or minimal residual disease (MRD), which may increase the risk of relapse. These sensitive techniques rely on the ability to identify a unique marker of the leukemia cells. For example, PCR techniques monitor a

recurring fusion gene (e.g., *BCR-ABL*) or a clone-specific rearrangement of the immunoglobulin heavy chain or T-cell receptor gene.¹⁹ MRD monitoring by flow cytometry of an aberrant immunophenotype of the leukemic blasts (e.g., presence of myeloid antigens on a lymphoid progenitor cell) can be identified at diagnosis and used for MRD monitoring. These molecular techniques have far greater sensitivity than standard cytogenetic analysis and may detect anywhere from one leukemia cell in a background of 10,000 to 1 million normal cells. Using both semiquantitative and more precise quantitative techniques, a number of studies in both pediatric and adult ALL have now provided preliminary evidence that MRD detection at specific time points following achievement of remission is an independent prognostic factor that may predict early relapse.^{22–26}

RISK-ADAPTED THERAPY

The factors described above can be used to provide a general risk assessment for prognosis and treatment planning. As many as 75% of adults with ALL can be considered relatively “high risk,” with an expected DFS of 25–35%. Only approximately 25% of patients can be considered “standard risk,” with anticipated survival rates of more than 50%. Nevertheless, until recently, most adults with ALL have been treated similarly regardless of patient-specific clinical and biologic risk features. To date, “risk-adapted” therapy in adult ALL has focused primarily on two disease subsets: patients with mature B-cell (Burkitt-type) ALL and those with Philadelphia-chromosome-positive (Ph+) ALL. These two groups are considered separately in the “Treatment” section that follows. The role of dose intensification with SCT in first remission and age-adapted therapeutic strategies will also be reviewed.

TREATMENT STRATEGIES IN ADULT ALL

Treatment programs in adult ALL have evolved from the successful strategies employed in pediatric ALL and incorporate multiple active agents into complex regimen-specific sequential therapies. The goal of these dose-intensive regimens is rapid cytoreduction with restoration of normal hematopoiesis; prevention of the emergence of drug-resistant subclones; prophylaxis of sanctuary sites such as the central nervous system (CNS); and eradication of persistent MRD with prolonged maintenance chemotherapy. Therapy is generally divided into several phases: induction, postremission consolidation or intensification, CNS prophylaxis, and maintenance therapy.

REMISSION INDUCTION THERAPY

Prednisone, vincristine, and L-asparaginase, based on pediatric regimens, formed the backbone of early trials in adult ALL. CR rates were 40–65%, with remission duration of only 3–7 months. However, the addition of an anthracycline (daunorubicin or doxorubicin) increased the CR rate to between 72 and 92%, and increased the median remission duration to approximately 18 months.^{6,31–34} CR rates were similar when different anthracyclines (daunorubicin and mitoxantrone) were compared during induction therapy in a CALGB trial.³⁵ Intensification of the daunorubicin dose during induction has been reported to improve CR rates and DFS,^{36,37} and was the focus of a recently completed trial in the CALGB.³⁸

From several pediatric ALL clinical trials, it appears that dexamethasone provides better antileukemic activity than prednisone; in part, this may be because of its ability to achieve higher drug levels in the CNS.^{39–41} The MD Anderson adult ALL trials have used dexamethasone during induction and postremission therapy as part of their “hyper-CVAD” regimen.⁴² The CALGB is exploring the substitution of dexamethasone for prednisone during induction and postremission therapy.

L-Asparaginase has resulted in significant toxicities, including hepatotoxicity, neurotoxicity, pancreatitis, and coagulopathy in older adults with ALL, and its importance in adult ALL regimens remains somewhat controversial. A retrospective analysis performed by the CALGB demonstrated a marginal benefit in DFS for adults who received all prescribed doses of L-asparaginase in comparison to those who failed to receive all recommended doses.⁴³ Currently, the optimization of L-asparaginase pharmacokinetics utilizing the polyethylene glycol conjugate of this agent is being studied in both pediatric and adult regimens.

The usual four-drug induction regimen (anthracycline, glucocorticoid, vincristine, and L-asparaginase) yields CR rates of up to 75–95% (see Table 13.2), and it has been difficult to demonstrate further improvement with additional drugs. The German Multicenter ALL

Cooperative Group (GMALL) has also used a 5–7-day “prophase” with prednisone and cyclophosphamide given prior to standard induction therapy for cytoreduction in an effort to minimize the risk of tumor lysis and its complications.⁵⁰ Randomized studies have not demonstrated a benefit to the addition of agents such as cyclophosphamide or cytarabine,^{49,51} although the addition of these agents to specific subsets of ALL may improve outcome.

To avoid exposure to the toxicities of L-asparaginase, steroids, and vincristine, investigators at Memorial Sloan Kettering Cancer Center have studied an alternative induction regimen for adults with ALL. This effective approach employs high-dose cytarabine and mitoxantrone and has resulted in a CR rate of 84%.⁵² L-Asparaginase has been omitted from the hyper-CVAD regimen at MD Anderson.⁴² The key components of hyper-CVAD consist of alternating cycles of fractionated doses of cyclophosphamide, high-dose methotrexate (MTX), and cytarabine with intensive CNS prophylaxis, followed by 2 years of maintenance with 6-mercaptopurine (6-MP), MTX, vincristine, and prednisone (POMP). In a long-term follow-up of results for this hyper-CVAD regimen in ALL, the overall CR rate was 92%. With a median follow-up of 63 months, the 5-year survival and CR duration rates were 38%.⁵³

CONSOLIDATION/INTENSIFICATION

Although induction CR rates are 90% in many series of adult ALL, the long-term DFS over the last decade remains 25–50%, despite attempts to modify and improve postremission therapy through schedules with a variety of drugs that are active in ALL. These agents include oral and higher doses of intravenous MTX, antimetabolites such as 6-MP and 6-thioguanine, low- and high-dose cytarabine, and etoposide. In addition, many of the drugs that are used during induction therapy (anthracyclines, glucocorticoids, vincristine, and L-asparaginase) have also been reintroduced during postremission therapy. The value of postremission dose intensity has been addressed in several large prospective clinical trials with promising results. In a large phase II study from the CALGB, patients received both early and late intensification courses of treatment with eight drugs followed by maintenance chemotherapy for 2 years after diagnosis.⁴⁴ Compared to previous CALGB trials where less intensive postremission therapy was administered, the median remission duration and survival improved to 29 and 36 months, respectively. Investigators at MD Anderson center have also explored dose intensification in their hyper-CVAD regimen. As mentioned above, the median survival for 288 patients treated between 1992 and 2000 was 32 months, with a 5-year survival of 38%.⁵³

Successive German multicenter trials have evaluated the impact of subset-specific dose intensification during postremission therapy.⁵⁴ Recently, patients

Table 13.2 Results of recent chemotherapy studies in adult ALL

Trial	Ref	Year	Number of patients	Randomized	Intervention /Design	CR rate (%)	PFS% (years)	Comments
CALGB 9111	44	1998	198	Yes	Benefit of G-CSF and consolidation	82	23 months ^a	G-CSF improved CR rates, decreased induction deaths, but did not improve DFS or OS
PETHEMA ALL-89	45	1998	108	Yes	Benefit of delayed intensification	86	41% (5 years)	No benefit to intensification
MDACC	42	2000	203	No	“Hyper-CVAD” alternating cycles of intensive therapy	91	39% (5 years)	No L-asparaginase/no cranial RT is administered in this regimen
MRC UKALL XA	46	1993	618	Yes	Benefit of early or late intensification	88	28% (5 years)	No clear benefit to intensification, but decrease relapses in patients with early intensification
University of California (San Francisco) #8707	47	2002	84	No	Intensified/cyclical but shortened postremission therapy	93	52% (5 years)	Approach may be effective for standard-risk ALL
GMALL 05/93	48	2001	1200	Yes	(a) Intensification by risk group (b) Intensification of maintenance therapy	86	47% (5 years)	Long-term follow up ongoing
GIMEMA ALL 0288	49	2002	794	Yes	(a) Addition of cyclophosphamide to induction (b) Benefit of early intensification	82	2 years ^a	Neither induction nor postremission intensification improved CR or DFS

^aMedian survival

with standard-risk B-lineage ALL received high-dose MTX, while T-ALL patients received postremission cyclophosphamide and cytarabine, and high-risk B-lineage patients received both high-dose MTX and high-dose cytarabine.⁴⁸ The median remission duration was 57 months for standard-risk patients, with a 5-year survival of 55%. However, this approach did not appear to improve the outcome of high-risk patients except for those with pro-B ALL who achieved a continuous CR rate of 41%, in contrast to only 19% for other high-risk patients. The outcome for high-risk patients, with SCT in CR1, has been explored by other groups and is discussed below.

NEWER “TARGETED” AGENTS

Recently, monoclonal antibodies targeted to epitopes present on lymphoblasts have also been evaluated. Rituximab, a chimeric humanized mouse antibody directed against CD20, which is expressed in approximately 20% of ALL cases, is being explored as an adjunct to standard chemotherapy in frontline and salvage therapy. Initial reports suggest that its addition may improve response rates, but with short-term follow-up⁵⁵; longer follow-up will be needed to determine its potential to improve DFS. Campath-1H is a monoclonal humanized form of a rat antibody active against CD52, an antigen on nearly all normal B and T lymphocytes that may be present on the surface of most cases of ALL.^{56,57} Although the experience with this antibody in relapsed, refractory ALL has been limited, Campath-1H has been shown to clear blasts from the peripheral blood after failure of traditional chemotherapy.^{57,58} The CALGB has recently begun testing the feasibility of incorporating Campath-1H into the initial treatment of adult ALL in an attempt to eradicate MRD in early CR1 (CALGB 10102).

Other novel agents are being considered for addition to frontline therapy for this disease subset. For example, clofarabine, a purine analog, was recently approved for refractory or relapsed pediatric ALL.⁵⁹ Nelarabine (GW506U78), a prodrug of guanosine arabinoside, has been shown to have activity in relapsed precursor T ALL.^{60–62}

CNS PROPHYLAXIS

Although only 2–10% of adults with ALL present with CNS involvement at diagnosis,⁶³ 50–75% of patients will relapse in the CNS at 1 year in the absence of CNS-directed therapy.^{64,65} The diagnosis of CNS leukemia requires the presence of more than five leukocytes per microliter in the cerebrospinal fluid (CSF) and the identification of lymphoblasts in the CSF differential.⁶⁶ Patients with CSF involvement may be asymptomatic, or can present with headache, meningismus, malaise, fever, or cranial nerve palsies. False-negative CSF results may occur in patients with predominantly cranial nerve involvement. Mature B-cell ALL, high serum lactate dehydrogenase (LDH) levels, and high proliferative index (more than 14% of lymphoblasts in the G2M/S

phase of the cell cycle at diagnosis) have been associated with a higher risk of CNS disease in adult ALL.⁶³

There is no consensus regarding the best approach for CNS prophylaxis in adult ALL. Concomitant use of cranial irradiation and IT therapy is often toxic and may result in delays in delivery of postremission intensification therapy. Alternative strategies have included triple IT therapy with MTX, cytarabine, and a corticosteroid without cranial irradiation,⁶⁷ or IT therapy combined with high-dose systemic therapy with CSF-penetrating drugs, including MTX, cytarabine, L-asparaginase, and corticosteroids. Systemic administration of dexamethasone achieves higher CSF levels than of prednisone and has a longer half-life in the CSF than prednisone.⁶⁸ As discussed previously, in a randomized pediatric trial, dexamethasone resulted in a lower incidence of CNS relapse compared to prednisone.³⁹ Although some studies suggest that CNS relapse rates of less than 5% can be achieved in adults with ALL using combination IT and high-dose systemic chemotherapy without cranial irradiation,^{42,63,69} in the GMALL studies, attempts to omit or postpone CNS irradiation led to higher CNS relapse rates.⁷⁰ The omission of CNS irradiation may be of particular concern for patients with precursor T ALL; the pediatric oncology groups in the United States have generally continued to use prophylactic irradiation for high-risk patients with T-lineage disease. Future trials may explore a risk-oriented approach to CNS prophylaxis, with the goals of minimizing toxicity and optimizing efficacy.

MAINTENANCE CHEMOTHERAPY

Long-term maintenance therapy typically consists of 6-MP given daily and MTX weekly for 18–36 months, often with the addition of periodic “pulses” of vincristine and prednisone or dexamethasone. Maintenance therapy is based on the theory of using prolonged exposure to antimetabolites to kill slowly dividing, potentially drug-resistant subclones remaining after induction and consolidation therapy, and has been demonstrated to reduce relapse rates in randomized trials in pediatric ALL. Although there have been no randomized studies justifying the use of maintenance therapy in adult ALL, attempts at omitting maintenance therapy in several different adult ALL studies have yielded unchanged or inferior results.^{35,71,72} Importantly, there appears to be no benefit to prolonged maintenance therapy for patients with mature B-cell ALL who respond well to short-term dose-intensive regimens, as described below, and rarely relapse beyond the first year of treatment.

STEM CELL TRANSPLANTATION

Allo SCT in first remission

The overall role of allo SCT in CR1 remains controversial; however, for ALL patients with adverse cytogenetics, including the t(9;22) and t(4;11), allo SCT in CR1 is the treatment of choice.

Survival for adult ALL patients following matched sibling allo SCT in first remission is approximately 50% (range, 20–80%).⁷³ The International Bone Marrow Transplant Registry (IBMTR) compared 251 patients who received intensive postremission chemotherapy with 484 patients who received matched sibling allo SCT.⁷⁴ Although 9-year DFS rates were similar—32% for chemotherapy and 34% for allo SCT—a higher recurrence rate of 66% was observed for chemotherapy patients versus 30% for those receiving allo SCT, with treatment-related mortality being the main cause of failure in patients who received allo SCT.

Allo SCT and autologous stem cell transplantation (auto SCT) in first remission were compared in a large French multicenter trial (LALA 87).⁷⁵ Based on an intent-to-treat analysis, survival at 10 years was 46% for those receiving allo SCT compared to 31% for those receiving consolidation chemotherapy alone ($p = 0.04$). The value of allo SCT was even more apparent after patients were classified into standard-risk and high-risk groups. High-risk was defined as having one or more of the following factors: presence of the Philadelphia chromosome (Ph+), null ALL, age above 35 years, WBC count more than $30 \times 10^9/L$, and time to CR more than 4 weeks. In the high-risk group, the overall survival (OS) at 10 years was 44%, versus only 11% for the control arm ($p = 0.009$). In the standard-risk group, there did not appear to be a distinct survival advantage for allo SCT over chemotherapy. These results support the value of allo SCT in first CR for high-risk patients.

Based on the results above, the LALA-94 trial evaluated the benefit of a risk-adapted postremission approach in ALL and concluded, in a recently published paper, that allo SCT improved DFS in high-risk ALL in first CR.⁷⁶ Auto SCT did not confer a significant benefit over chemotherapy for high-risk ALL.

The Medical Research Council (MRC) UKALL12/ECOG 2993 study is the largest prospective randomized trial designed to evaluate the role of allo SCT as postremission therapy in adult ALL, and accrual is ongoing.⁷⁷ All patients receive two phases of induction therapy and are assigned in first remission to receive allo SCT if they have a histocompatible sibling donor, while those without a related donor are randomized to auto SCT versus consolidation and maintenance chemotherapy. More than 1300 patients have been recruited, and the results reported so far have focused on the Ph+ patients ($n = 875$). An intention to treat analysis showed a significantly reduced relapse rate of 24% in Ph- patients assigned to allograft ($n = 190$) in comparison to 60% for those randomized to auto SCT or chemotherapy ($p = 0.0001$). There was an improved 5-year event-free survival (EFS) of 52% in patients assigned to allo SCT versus 36% for the randomized group ($p = 0.05$) that was most noticeable for patients classified as standard risk (5-year EFS of 64% for allo SCT vs 46%, $p = 0.05$). In contrast to the LALA study,

these data suggest that allo SCT may be beneficial for all younger adult ALL patients (of age below 50) in first remission, regardless of risk group; however, the trial is ongoing and definitive conclusions cannot yet be made.

Recently, the French Cooperative Group (GOE-LAMS) published its results of 198 patients with precursor B ALL who were randomized to early allo SCT in CR1 (if HLA-matched sibling donor available) or to consolidation/intensification therapy followed by auto SCT in CR1.⁷⁸ These investigators found a significant benefit to allo SCT in CR1. Using an intent to treat analysis, OS at 6 years was 75% for ALL patients younger than 50 years who received allo SCT, compared to 40% for those receiving auto SCT.

Autologous Stem Cell Transplantation

The prospective, randomized studies described above in adult ALL demonstrate that relapse-free survival is inferior for auto SCT when compared to allo SCT. Moreover, no advantage in survival has been demonstrated with auto SCT compared with continued postremission chemotherapy alone.⁷⁹ DFS at 3 years following auto SCT in first remission in two of the largest trials reported was only 28–39%,^{80–82} which is not better than survival rates reported in recent chemotherapy trials of adult ALL. Therefore, auto SCT does not currently have a role in the treatment of ALL, outside of the setting of a clinical trial.

RISK-ADAPTED THERAPY

MATURE B-CELL ALL

Clearly, a separate disease from the precursor cell acute leukemias, mature B-cell (Burkitt-type) ALL, is the least common subtype of ALL, comprising fewer than 5% of adult ALL cases. Patients with mature B-cell ALL must be identified at diagnosis, as specific therapeutic strategies have been shown to improve outcome dramatically for this disease subset.

Although the peak incidence is seen in children and young adults, patients older than 60 years make up one-third of adult cases.⁸³ The distinction between mature B-cell ALL and Burkitt lymphoma with marrow involvement is arbitrary; absence of extramedullary disease would favor the former.⁸⁴ Lymphoblasts of the FAB-L3 subtype express monoclonal surface immunoglobulin (sIg) along with B-cell-associated antigens CD19, CD20, and CD22. Certain characteristic cytogenetic abnormalities define the disease: The t(8;14), t(2;8), or t(8;22) represent variant translocations of the *c-myc* proto-oncogene at band 8q24 to the immunoglobulin gene at either the heavy chain or light chain locus, respectively.

The recent improvements in outcome for adults with mature B-cell ALL have resulted from adaptation of successful pediatric regimens. The French were the first to

apply pediatric protocols to the therapy of adults with mature B-cell ALL, and were able to provide a CR rate of 79%, with a 3-year OS of 57%.⁸⁵ In what remains as the largest published series of adults to date with this disorder, Hoelzer et al. reported CR rates of 63 and 74%, and 4–8-year OS rates of 49–51%, respectively, in 59 adults treated with the pediatric Berlin-Frankfurt-Münster (BFM) protocols B-NHL 83 and B-NHL 86.⁸⁶ These protocols shared several important components: a cytoreductive prephase with low-dose cyclophosphamide and prednisone given 1 week before the start of intensive therapy, intermediate- to high-dose cytarabine, podophyllotoxins, doxorubicin, vincristine, high-dose MTX, fractionated high-dose cyclophosphamide/ifosfamide, aggressive IT chemotherapy, and tailored cranial radiotherapy for patients with CNS disease, all given in repeated cycles of short duration over a 4–6-month period. Relapse rarely occurred after the first year; thus, prolonged maintenance was not necessary.

An alternative successful approach using similar principles is the hyper-CVAD regimen developed at the MD Anderson Cancer Center.⁸⁷ Twenty-six patients with B-cell ALL and a median age of 58 years were treated with eight cycles of hyperfractionated cyclophosphamide, vincristine, doxorubicin, and dexamethasone, alternating with courses of high-dose intravenous MTX and cytarabine, with prophylactic CNS therapy consisting of MTX and cytarabine. A CR rate of 81% was attained, with a 3-year OS of 49% and a 3-year DFS of 61%. Overall, the hyper-CVAD regimen produced favorable results for all patient subsets, except for those presenting with very high LDH, CNS disease, and age over 60 years.

To improve response rates, the CALGB has also recently studied two separate cohorts of patients with advanced Burkitt lymphoma and mature B-cell ALL treated with intensive, pediatric-derived protocols, with the two cohorts differing in degrees of CNS-directed therapy given.^{88,89} The first cohort was treated with a modified GMALL BFM protocol consisting of a pretreatment phase, fractionated ifosfamide and cyclophosphamide, high-dose MTX, vincristine, dexamethasone, and doxorubicin, alternating with etoposide and cytarabine by continuous infusion. Triple IT CNS therapy and prophylactic cranial irradiation were given to all patients. For the 24 B-cell ALL patients, CR rates of 75% were attained, with 3-year leukemia-free survival (LFS) and OS of 61 and 46%, respectively. Significant and often irreversible neurologic toxicity was noted with this intensive CNS-directed therapy; it was thus amended to reduce the number of IT injections, and cranial irradiation was omitted except for those with overt CNS or high-risk disease. A second cohort with this modified approach resulted in CR, 3-year LFS, and OS rates of 68, 67, and 50%, respectively, and CNS failure rates were not increased. Most importantly, severe neurologic toxicity was dramatically reduced from 60 to 23%. The authors con-

cluded that high-dose antimetabolites and IT chemotherapy alone can prevent CNS failure, and cranial radiotherapy may be omitted in the absence of proven CNS involvement. The results of these and several other treatment programs that have been developed for Burkitt lymphoma and mature B-cell ALL are summarized in Table 13.3.

Recently, the therapeutic focus for mature B-cell ALL has turned to the addition of the monoclonal antibody, rituximab, for these strongly CD20⁺ leukemias. Preliminary results of the MD Anderson group, in which combining rituximab was combined with the hyper-CVAD regimen, demonstrated a CR rate of 93% and 1-year DFS of 86%.⁹⁴ Their preliminary data suggest a particular advantage for older adults treated with this approach. The CALGB also has a phase II study under way, in which patients with Burkitt lymphoma and leukemia are treated with rituximab and a high-intensity chemotherapy regimen. The GMALL study group has a similar prospective trial underway, with rituximab for the treatment of B-cell ALL and Burkitt lymphoma.

For treatment of advanced Burkitt lymphoma and mature B-cell ALL, both allo SCT and auto SCT are generally reserved for salvage therapy in relapsed or refractory disease. The general consensus has been that there is no role for this therapy in first CR in the standard-risk patient, as intensive high-dose chemotherapeutic regimens now yield such high CR rates and few long-term relapses. However, allogeneic stem cell transplant may be considered for patients with high-risk presenting features or for those failing to attain a CR within 4 weeks of initiation of therapy.

PHILADELPHIA-CHROMOSOME-POSITIVE ALL

The t(9;22) occurs in 20–30% of patients with adult ALL. Although the remission rate is approximately 60–80% with intensive induction therapy, Ph+ ALL is not considered curable with standard chemotherapy, with long-term survival rates of less than 10%.^{29,95} To improve outcome in Ph+ ALL, efforts have focused on dose intensification with allo SCT in first remission, which is currently the recommended treatment. In a preliminary report from the MRC UKALL X11/ECOG E2993 study, the EFS was 38% at 3 years for 35 patients with Ph+ ALL who received postremission allo SCT in CR1, compared to only 5% for those who received postremission chemotherapy or auto SCT in CR1.⁹⁶ Although difficult to compare because of variability in patient characteristics and treatment regimen, other small series report survival rates between 30 and 60%,^{97–102} and all share the conclusions that Ph+ ALL patients appear to do best when an allo SCT is performed in first remission. For Ph+ ALL patients without HLA-matched sibling donors, the efficacy of matched unrelated donor (MUD) transplants has also been evaluated. In one small series of 18 young patients (median age was only 25 years) with Ph+ ALL

CR, complete remission; LFS, leukemia-free survival; OS, overall survival; EFS, event-free survival; NR, not recorded; L3, mature B-cell ALL.

^a Only data for intensive, high-dose chemotherapy protocols included; includes patients with mature B-cell ALL or stage IV Burkitt lymphoma unless specified, some data extrapolated.

who underwent a MUD allo SCT, the DFS at 2 years was 49% in this selected group, which is similar to the rates reported for HLA-matched sibling transplants.¹⁰¹ With improvements in graft-versus-host disease prophylaxis, MUD transplants are also being explored in older patients with Ph+ ALL in CR1.

Imatinib mesylate (STI571, Gleevec; Novartis, East Hanover, NJ), a selective inhibitor of the BCR-ABL tyrosine kinase,¹⁰² has shown promise in the treatment of Ph+ ALL. A CR rate of 29% was achieved in a group of 56 recurrent and refractory Ph+ ALL patients who received imatinib at 400 mg or 600 mg daily,¹⁰³ although only 6% of patients sustained a response of at least 4 weeks. Because of these promising results in highly refractory patients, imatinib is being tested by a number of groups for its ability to reduce disease burden prior to and following allo SCT or auto SCT (for patients without an HLA-matched sibling donor) for Ph+ ALL in CR1.^{104–107} Preliminary results from these studies are encouraging, with high CR rates (79–100%) when imatinib was combined with induction chemotherapy. The majority of these patients were eligible for an allo SCT in early CR1. With limited follow-up, DFS rates of 78–90% are reported in these studies.

Combining imatinib with nontransplant chemotherapy may be a particularly promising approach for older Ph+ patients for whom allo SCT may not be feasible. The GMALL has initiated a randomized multicenter phase II study to determine the safety and efficacy of imatinib in Ph+ ALL patients greater than 55 years of age as first-line single-agent induction therapy, with administration of postremission consolidative chemotherapy for a duration of up to 1 year. Preliminary results suggest that combination treatment is tolerable, and early response rates appear favorable, with a CR rate of 93% for older Ph+ patients (median age of 67). This impressive CR rate compares favorably to a historical control CR rate of only 44% for a similar older high-risk group of patients.¹⁰⁸ Second-generation-targeted tyrosine kinase inhibitors (nilotinib, Novartis, Hanover, NJ, and dasatinib, Bristol-Myers Squibb, NY) that overcome imatinib resistance are now being tested in patients with relapsed Ph+ ALL. Thus, it appears that the principles that have resulted in the spectacular success of molecular targeted therapy using imatinib in patients with CML may now be applied to improve outcome for this most challenging subset of ALL.

ALL WITH 11q23 (MLL) ABNORMALITIES

The t(4;11)(q21;q23) is the most common recurring abnormality involving the *MLL* gene on chromosome 11q23, and it occurs in 5–10% of adult ALL cases.^{109–111} Patients often present with high leukocyte counts, hepatosplenomegaly, and CNS involvement. Survival for these patients is poor with chemotherapy alone, with DFS less than 15% at 5 years.²⁹ In contrast, when an allo SCT is performed in CR1, the GMALL reported

more than 50% of patients with the t(4;11) achieving long-term DFS.¹¹² These investigators attributed their good results to the combination of high-dose cytarabine and mitoxantrone intensification followed by allo SCT. Based on these data, the current recommendation is to identify a donor for allo SCT early in CR1 for patients with the *MLL* gene rearrangements. In addition, they may benefit from intensive cytoreduction with a high-dose cytarabine-based regimen that may be given as early consolidative therapy while a suitable donor is being identified.

AGE-STRATIFIED THERAPY

A series of systematic clinical trials in children with ALL has resulted in such high cure rates for the majority of patients (EFS of more than 75% for most patients) that current risk-adapted clinical trials in the pediatric cooperative groups are beginning to explore less intensive therapy for very good risk patients, with the goal of achieving similar results with fewer long-term side effects. In contrast, as discussed in detail above, the outcome for ALL in adults is considerably less favorable, with overall cure rates of less than 30%. Factors contributing to this marked difference include significant differences in the molecular genetics of adult ALL, with a higher incidence (30% in adults and 5% in children) of the unfavorable (9;22) Philadelphia chromosome translocation in adults and a virtual absence of the favorable *TEL-AML1* fusion gene resulting from a cryptic translocation, the t(12;21).^{113–115} In addition, other negative risk factors include comorbid medical conditions in the aging population and poorer tolerance of chemotherapy, particularly of intensive treatment with L-asparaginase and higher dose MTX, drugs that have been used with great success in the pediatric population.¹¹⁶

ADOLESCENT ALL

From subset analyses of both pediatric and adult ALL clinical trials, the adolescent and young adult (AYA) population has a distinctive outcome. In pediatric studies, adolescents are considered a high-risk group, receiving more intensive treatment with the intent of improving outcome to achieve the successes noted in good-risk children of age 2–10.^{117,118} In the adult cooperative groups, AYA have traditionally received similar treatment to older adults and have been viewed as a relatively good risk group.⁵ Several retrospective analyses have recently unveiled some striking differences in the outcome of AYA patients, depending upon “the door” they enter at the time of their diagnosis in determining enrollment on pediatric versus adult clinical trials.^{119–121} Retrospective comparisons of pediatric versus adult clinical trials for ALL in North America, France, and the Netherlands all reached similar conclusions: AYA patients fared significantly better when

Table 13.4 Outcome comparison of adolescent/young adults with ALL on pediatric versus adult clinical trials

Cooperative group	Study period/ number of patients	Age (years)	CR (%)	EFS (%)
North America ¹¹⁹	1988–1998	16–21		
CCG 1882 (pediatrics)	196 patients		96	64
CALGB 8811–9511 (adults)	103 patients		93	38
French ¹²⁰	1993–1994	15–20

HOVON 5 and 18 (adults)	73 patients		91	31
				46

they were treated on pediatric protocols, despite that CR rates for AYA patients were generally comparable between adult and pediatric trials (Table 13.4).

Factors Affecting Treatment Outcome: Drug Dosage, Schedule, the Doctors, and the Patients

All of these studies have engendered vigorous debate about whether the disparity in outcome for AYAs on pediatric versus adult trials can be accounted for primarily by differences in the drug regimens and planned dose intensity, or whether the precision with which actual dose was delivered might have a significant role in patient outcome. In general, the pediatric regimens contained significantly higher cumulative doses of nonmyelosuppressive drugs, including glucocorticoids, vincristine, and L-asparaginase. In addition, more frequent IT therapy was administered in the pediatric regimens, and maintenance therapy was generally administered for longer periods of time. As these are retrospective studies, dose delivery has been difficult to examine and may be influenced significantly by differences in adult versus pediatric physician attitude and experience with treatment of ALL. In addition, the attitudes, family support, and compliance of AYAs treated by adult versus pediatric oncologists may be different and relevant.

OLDER ADULTS WITH ALL

A review of the annual age-specific leukemia incidence in the United States underscores the observation that ALL is relatively uncommon in the middle adult years, but increases rapidly in incidence over the age of 60. These patients have only rarely been included in clinical trials, and as yet, there are no optimal treatment programs available.

In a recent report from the northern counties of England, approximately one-third of ALL cases in adults occurred in patients older than 60 years.¹²² Various treatment approaches have been taken in this older group of patients, but the outcomes are uniformly poor (Table 13.4). Investigators at the MD

Anderson Hospital have reported on 52 patients treated with infusional vincristine, adriamycin, and dexamethasone (VAD). This regimen produced a high CR rate with relatively low toxicity in older patients.⁶ In the most recent CALGB trials, a CR rate of 65% was observed in older patients (60–80 years old, with a median age of 65).^{5,44} Nevertheless, the 3-year survival in all three of these reports remains poor. The low tolerance of elderly patients for intensive chemotherapy remains one of the obstacles to increasing the overall cure rate in adults.¹²³ It is now estimated that as many as 40–50% of patients older than 60 years are Ph+; therefore, the focus on novel nonmyelosuppressive molecular targeted treatment strategies, as discussed above, is particularly needed for this very high risk group of patients. As previously discussed, the promising early results of combination chemotherapy with imatinib in older patients with Ph+ ALL are an example of the potential to significantly improve CR rates and, perhaps, OS in elderly patients with ALL.

SUPPORTIVE CARE

Infectious disease complications secondary to neutropenia are the primary cause of treatment-related morbidity and mortality in acute leukemia, and the risks seem to be especially high in older patients.⁴⁴ Several studies have focused on preventing prolonged neutropenia in adults with ALL, with prophylactic use of granulocyte-stimulating growth factors.^{44,124} Two sequential studies of granulocyte colony-stimulating factor (G-CSF) use during induction therapy performed by the GMALL demonstrated a reduction in the duration of neutropenia, a reduction in the number of nonviral infections, and less frequent interruptions in chemotherapy schedules. These benefits, however, did not translate into improved DFS or OS.¹²⁵

In 1998, the CALGB published results of its large, prospective, randomized trial of G-CSF given during

induction and consolidation chemotherapy.⁴⁴ Subjects who received G-CSF required fewer days to neutrophil recovery following induction chemotherapy for ALL. Subjects in the G-CSF group also had a shorter hospitalization time, a higher CR rate (87% vs 77%), and fewer induction deaths (5% vs 11%). However, G-CSF did not allow for a compressed course of chemotherapy or shorten the overall time required to undergo induction and consolidation. Nevertheless, in patients older than 60 years, the CR rate for patients receiving G-CSF was 81%, compared with 55% in the placebo arm. Despite the improvement in CR rates in older adults, however, none of the studies has demonstrated improvement in DFS or OS when hematopoietic growth factors were added to standard therapies.¹²⁶

TREATMENT ALGORITHM

Our current approach to treatment of adult ALL is beginning to incorporate these principles of risk adapted therapy. We advocate strongly the participation in clinical trials for adults with ALL. For younger patients, we have turned our focus to trying to achieve the same improvements in outcome noted by the pediatric cooperative groups for high-risk adolescents, where DFS is now routinely over 70%. To this end, an intergroup trial (CALGB and SWOG) will treat patients younger than 30 years with a regimen that is currently being used in the Children's Oncology Group (COG) for all adolescents and other high-risk children with ALL. The ECOG continues to explore the benefit of allo SCT in first remission for suitable younger patients, and their preliminary results also appear encouraging.

Current clinical trial efforts for adults with precursor B and T ALL have been directed toward the addition of novel targeted agents to reduce MRD and prolong DFS. Based on preliminary results from the GMALL and MD Anderson Cancer Center, the incorporation of rituximab into front-line therapy for CD20⁺ precursor B ALL appears promising. The ongoing CALGB study, as noted above, explores the substitution of dexamethasone for prednisone during induction and postremission therapy, and incorporates an alternative monoclonal antibody, Campath-1H, during postremission therapy for CD52⁺ precursor B and T ALL.

For suitable patients with a t(9;22), t(4;11), or other high-risk ALL, an allo SCT in first remission remains our treatment of choice. For the t(9;22) patients, the addition of imatinib to frontline therapy may improve outcome. We are participating in a US intergroup trial that explores the addition of imatinib pre- and post-stem cell transplant. Based on the exciting preliminary results described above in the section on Ph⁺ ALL, the incorporation of imatinib into standard induction and postremission therapy for older patients with ALL is rational, appears to be well tolerated, and significantly increases CR rates, with further follow up needed to validate the improvement noted in DFS and OS.

Finally, the outcome for patients with mature B-cell ALL has steadily improved, using short course-intensive therapy with fractionated alkylating agents, high-dose MTX and cytarabine, and intensive CNS prophylaxis. The addition of rituximab for these strongly CD20⁺ patients may further improve response rates and has been incorporated into frontline therapies for mature B-cell ALL in both North American and European cooperative group trials.

Chapter 14

DEFINITION OF REMISSION, PROGNOSIS, AND FOLLOW-UP

Meir Wetzler

INTRODUCTION

This chapter will define remission, prognosis, and follow-up criteria for acute lymphoblastic leukemia (ALL). As opposed to acute myeloid leukemia (AML), where the International Working Group has established the definitions¹ [see Chapter 8], no such project was undertaken in ALL.

DEFINITION OF REMISSION

The importance in achieving a consensus on the definition of remission is to allow comparison of results from an assortment of studies and different institutions to provide the basis on which to make decisions about the care of patients. Consensus, as such, is required, but its achievement is compounded by the quality of the bone marrow specimen and the experience of the pathologist evaluating it. A morphologic complete remission (CR) is defined as having a neutrophil count $\geq 1.0 \times 10^9/L$, platelet count $\geq 100 \times 10^9/L$, normal bone marrow cellularity with trilineage hematopoiesis, with $<5\%$ blasts and resolution of all extramedullary disease.¹ Note that hemoglobin concentration or hematocrit are not included when evaluating remission status, but the patient has to be transfusion independent. Partial remission (PR) is not used for studies in which the objective is cure, but is used for phase I and II studies, conducted in patients with refractory or relapsed disease. In such cases, the aim is to record any significant activity. PR is then defined as $\geq 5\%$ but $<20\%$ blasts.

HEMATOGONES

Occasionally it is difficult to distinguish between persistent disease and the presence of hematogones.²⁻⁴ Hematogones are nonmalignant lymphoid progenitor cells found in the bone marrow, and are similar to lymphoblasts. Hematogones are usually heterogenous in size and are nonclonal. If the ALL blasts express

myeloid markers, the hematogones, by definition, are devoid of these and therefore can be distinguished from leukemia blasts. If the hematogones do not express myeloid markers, it is difficult to distinguish them from leukemia blasts. Most experts would recommend repeating marrow examinations, weekly or every other week, until either the disappearance of the hematogones or emergence of the leukemic clone.

MORPHOLOGIC CR

Morphologic CR without complete recovery of platelet count is not considered a category of CR in AML patients.¹ The same is true for ALL patients. Time to platelet recovery seems to predict outcome of patients with de novo ALL who have achieved CR.⁵ In one study, patients who did not achieve platelet recovery by day 48 had a significantly worse outcome than those who achieved platelet recovery by day 12. Therefore, in ALL, morphologic CR without platelet count recovery ($\geq 100 \times 10^9/L$) should not be regarded as CR.

Finally, the definition of CR in AML was previously associated with a requirement for a 4-week duration of persistent remission to qualify as a CR. However, in ALL, postremission therapy is administered without any delays, and therefore the definition of CR should not be time dependent; retrospective designation of CR based on subsequent clinical course is not recommended. This correlates with the recently revised definition of CR in AML.¹

IMMUNOPHENOTYPIC CR

Patients who achieve morphologic CR can be further categorized based on additional and more sensitive methods. Flow cytometry identifies leukemia-associated marker patterns on the surface of, or inside, the blasts. These patterns include over-expression (e.g., for B lineage: CD10, CD19, CD20) as well as under-expression (e.g., CD45) of markers compared with their expression on normal lymphoid cells. Overall, persistence of a unique phenotype determined by flow cytometry, e.g., CD10 and CD20 coexpression, has been associated with worse outcome and should be viewed as

Table 14.1 Sensitivity of minimal residual disease detection by flow cytometry

Disease	Sensitivity ^a	References
Adult T ALL	1: 1 × 10 ⁴	13
ALL (age ≥14 years old)	1: 2 × 10 ³	14
Adult and childhood ALL	TdT <100 × 10 ³ , CD10 >50 × 10 ³ , CD19 >11 × 10 ^{3b}	10
Childhood ALL	1:1 × 10 ⁴	11
Childhood ALL	1:1 × 10 ⁴	12
Childhood ALL	1 blast/μL	15
Pre-B cell line	1:1 × 10 ⁶	6
Breast cancer	1:1 × 10 ⁷	7
Breast cancer	1:1 × 10 ⁷	8

^aRatio of malignant cell and normal nonmalignant cells.

^bMolecules per cell.

residual disease.^{6–15} However, the sensitivity and reliability of these tests depend on the number of cells to be analyzed (Table 14.1). Flow cytometry allows detection of one abnormal cell in 10⁶ cells, if at least 10⁷ cells are analyzed. Such large numbers are rarely available during remission, and therefore a more realistic sensitivity to detect minimal residual disease would be one abnormal cell in 10⁴–10⁵ cells.¹⁶ This level of sensitivity is achievable only if the antibodies can clearly distinguish the leukemic blasts from normal cells. In addition, antibodies with nonspecific light scattering will lower the sensitivity of the test. It is therefore recommended to use serially diluted leukemic blasts with normal cells to confirm the level of sensitivity. Finally,

clonal evolution may cause disappearance of one or more antigens detected at diagnosis.^{17–23} Therefore, after taking into consideration all the caveats mentioned above, lack of minimal residual disease by quantitative flow cytometry at the end of remission induction therapy was associated with better clinical outcome in some studies of adult ALL patients.^{10,13–15} However, because of a multitude of methods and lack of consensus, it is still not possible to make a clear recommendation of how to use flow cytometry to detect minimal residual disease.

CYTOGENETIC CR

There are no prospective studies to evaluate the role of complete cytogenetic remission in ALL. Cytogenetic analysis, based on at least 20 metaphases, can detect one residual metaphase, resulting in a sensitivity of 5%. As was described earlier, flow cytometry and molecular testing (see below) can detect one abnormal cell in 10³–10⁴ normal cells. Minimal residual disease, detected by either of these two methods, was proven to be an independent prognostic factor in ALL (see above for flow cytometry and below for molecular target). Therefore, complete cytogenetic remission should be evaluated prospectively in ALL clinical trials to determine its significance for the prediction of outcome.

MOLECULAR CR

Molecular CR has been associated with clinical outcome in ALL^{12,24–40} (Table 14.2). However, the degree of sensitivity may have an impact on the correlation with clinical outcome. For example, Roberts and colleagues⁴¹ detected one abnormal cell in 10⁵ or more normal cells, and concluded that their finding did not predict relapse because the test either detected preleukemic or nondividing cells. Detecting one abnormal cell in 10⁴ or fewer

Table 14.2 Sensitivity of minimal residual disease detection by molecular analyses

Disease	Molecular target	Sensitivity	References
ALL (age ≥15 years old)	<i>IgH</i>	1–5:10 ² –10 ³	29

^aOnly 2 patients were followed for MRD.

normal cells has been shown to predict outcome,^{24,26,28,29,31-35,39,40} while others were able to demonstrate prediction of outcome with more sensitive tests.^{12,25,27,30,34,36} These tests varied in their techniques, studying either tumor-specific DNA to detect residual malignant B cells by immunoglobulin gene rearrangement or residual malignant T cells by T-cell receptor genes,^{12,24-27,29,31,32,38,39} or tumor-specific RNA to detect fusion gene transcripts (e.g., *BCR/ABL*, *TEL/AML1*, *MLL/AF4*)^{36,40,42,43} or aberrantly expressed genes [e.g., *FLT3*,^{33,44} *WT1*,^{28,30,35} *HOX11*³³]. The tests also differed in the time points to analyze minimal residual disease, e.g., day 11 versus end of induction. Therefore, a molecular CR must incorporate the sensitivity of the test and timing, and also the gene analyzed to allow comparisons among different studies. Because of these issues, it is not possible to make a clear recommendation of how to use molecular testing to detect minimal residual disease outside of a correlative study to a clinical trial.

TREATMENT FAILURE

Treatment failure has not been defined specifically for ALL, and therefore the revised criteria set forth recently for AML should be used,¹ with some modifications. Treatment failure includes all patients who did not achieve a CR, or in phase I or II trials, a PR, and should be subclassified into several categories. "Treatment failure due to refractory disease" should be defined differently than it is in AML¹ because the induction treatment in ALL spreads over at least 3 weeks. One could define treatment failure as patients who have persistent peripheral blood blasts 7 days from initiation of induction treatment,^{45,46} or persistent bone marrow blasts (>5%) 14 days from initiation of induction treatment.^{45,46} Table 14.3 demonstrates the number of patients analyzed for each recommendation. "Treatment failure due to complications from aplasia" was described in AML¹ but, to the best of our knowledge, was not described in ALL. "Finally, treatment failure of indeterminate cause" should be defined for ALL. It can include two categories as described for AML¹ with modifications due to different treatment regimens. One category should include those patients who die less than 7 days after initiation of treatment and the other category should include those patients who survive seven or more days after the initiation of treat-

ment, whose most recent peripheral blood smear does not show persistent leukemia, and who did not have a bone marrow examination subsequent to therapy.

RELAPSE

Relapse is defined as in AML¹: that is, morphologic relapse, after achievement of CR, is the reappearance of leukemic blasts in the peripheral blood or $\geq 5\%$ blasts in the bone marrow, or the reappearance of cytologically proven extramedullary disease. Genetic or molecular relapse is defined by reappearance of a cytogenetic or molecular abnormality.

PROGNOSTIC FACTORS

Prognostic factors in adult ALL represent an evolving concept and depend on the advent of new research findings. Independent prognostic factors that were established by more than one group are summarized in Table 14.4. Other prognostic factors that emerged in small studies asking a particular question about one or another factor are beyond the scope of this Chapter.

FOLLOW-UP

The follow-up of ALL patients is intended to measure the duration of survival or remission. As in AML,¹ four different categories are used: overall survival, relapse-free survival, event-free survival, and remission duration. The main reason to have an assortment of definitions is to handle the possibility of competing events. For example, there can be two competing events for survival: relapsed disease or massive myocardial infarction. Even though both are fatal, only one counts toward ALL treatment outcome.^{80,81} In another manner, the massive myocardial infarction may have precluded ALL relapse from occurring.

OVERALL SURVIVAL

Overall survival is measured from the time of diagnosis to the time of death from any cause. If the patient is not known to be deceased, overall survival is censored on the date the patient was last known to be alive. Overall survival is usually not subject to competing risks. However, if overall survival following regimen A is sought, and the patient is then undergoing an allogeneic transplantation and dies from transplant-related complications, death from transplantation becomes a competing risk for regimen A.

RELAPSE-FREE SURVIVAL

Relapse-free survival is used only for patients who achieve CR and is calculated from the date CR was attained to the time of relapse or death, whichever occurs first. As described above, if the patient is not

Table 14.3 Number of patients analyzed for persistence of peripheral blood and bone marrow blasts during remission induction

	Number of patients	Reference
Day 7	255	45
Day 7	79	46
Day 14	299	45
Day 15	437	47

Table 14.4 Prognostic factors in adult ALL

Risk factor	Note
Age	Age at diagnosis is one of the most important pretreatment risk factors, with advancing age being associated with a worse prognosis. Chronic and intercurrent diseases impair tolerance to aggressive therapy; acute medical problems at diagnosis may reduce the likelihood of survival. ⁴⁸⁻⁵⁸ ■ High risk: age >60 years
Performance status	Performance status, independent of age, also influences the ability to survive induction therapy, and thus respond to treatment. ^{54,57} ■ High risk: poor performance status.
Leukocyte count	A high presenting leukocyte count is an independent prognostic factor; duration of CR is inversely related to the presenting leukocyte count. ^{48-50,53,55,58-61} ■ High risk: leukocyte count >30,000/ μ L in B-lineage disease and >100,000/ μ L in T-lineage disease
Immunophenotype	Immunophenotype at diagnosis is an independent prognostic factor. In brief, T-lineage immunophenotype confers better outcome than B lineage and the presence of 6 or more T-cell markers is associated with favorable prognosis. ^{48,54,61-63} ■ High risk: B-lineage disease.
Karyotype	Chromosome findings at diagnosis are an independent prognostic factor. In brief, t(9;22), +8, t(4;11), -7, and hypodiploid karyotypes are associated with unfavorable outcome; normal karyotype, +21, and del(9p) or t(9p) confer an intermediate outcome; and del(12p) or t(12p) and t(14q11-q13) may be associated with favorable outcome. ^{48,54,55,61,64-70} ■ High risk: t(9;22), +8, t(4;11), -7, and hypodiploid karyotypes
HOX11 oncogene ^a	The expression of HOX11 oncogene has a favorable outcome in adult T-lineage ALL. ⁷¹ ■ High risk: lack of HOX11 gene expression
Multidrug resistance	The expression of multidrug resistance proteins is associated with an unfavorable outcome in adult ALL. ⁷²⁻⁷⁷ ■ High risk: expression of multidrug resistance proteins
Bone marrow biopsy morphology	Persistence of normal residual hematopoiesis and intense leukemic cells mitotic activity are associated with favorable outcome. ⁷⁸
Lactic dehydrogenase (LDH) level	High LDH level is associated with poor outcome ⁵⁴ and with CNS disease in some studies. ^{54,79} ■ High risk: elevated LDH
Cytoreduction	Eradication of the leukemic blasts from the peripheral blood or bone marrow at day 7 or day 14 was shown to be associated with a favorable outcome. ^{45-47,53} ■ High risk: lack of cytoreduction
Achievement of CR	In addition to pretreatment variables, achievement of CR correlates with prognosis in ALL. ^{58,61} ■ High risk: lack of achievement of CR with the first cycle of chemotherapy

^aEven though this factor was described only once in adult ALL, several studies described its significance in pediatric ALL and therefore this factor is mentioned herein.

known to have relapsed, or deceased, relapse-free survival is censored on the date the patient was last seen. Relapse-free survival is not subject to competing risks.

EVENT-FREE SURVIVAL

Event-free survival is measured from the date of diagnosis until treatment failure, defined as either resistant disease, disease relapse, or death from any cause, whichever occurs first. If none of these events occur, the event-free survival is censored at the date the patient was last seen. Event-free survival, for patients who do not achieve a CR, is defined as the time to progression, or death, whichever occurs first. As with

overall survival and relapse-free survival, event-free survival is not subject to competing risks.

REMISSION DURATION

Remission duration, as the name suggests, is reserved only for patients who achieve CR, and is calculated from the date CR was attained to the date of relapse. For patients who die without a report of relapse, remission duration is censored at the date of death, regardless of the cause. Finally, for patients whose disease does not relapse, remission duration is defined until the day the patient was last seen. This is the only measure, of the above four, as defined by Cheson and colleagues,¹ subject to competing risks (e.g., death without relapse).

Table 14.5 Proposed follow-up for adult ALL patients

Category	How?	How often?
Remission status	Ask about constitutional symptoms and symptoms of anemia, thrombocytopenia, and granulocytopenia	Every month during the first year, every 3 months for the second and third years posttherapy, and then at least every 6 months for 3 years
Remission status	Look for pallor, petechiae, lymphadenopathy	Every month for 1 year posttherapy, and then every 3 months for 2 more years, and at least every 6 months for 3 years
Remission status	Complete blood count with differential	Every month for 1 year posttherapy, and then every 3 months for 2 more years, and at least every 6 months for 3 years
Remission status	Bone marrow aspiration and biopsy for morphology and cytogenetics	Once, 3 months post completion of chemotherapy, and then no specific guidelines, unless on clinical trial
Remission status	PCR for specific chromosomal aberrations	No specific guidelines
Remission status	PCR with patient-specific junctional regions of rearranged immunoglobulin or T-cell receptor genes	No specific guidelines
Remission status	Flow cytometry to detect specific phenotypes	No specific guidelines
Avascular necrosis	Ask about pain in hips while walking	With each history taking as mentioned above
Heart failure	Ask about swollen ankles, shortness of breath, etc.	With each history taking as mentioned above
Sterility	Ask about pregnancies	With each history taking as mentioned above
Hypothyroidism	Ask about cold intolerance, fatigue, somnolence	With each history taking as mentioned above

PCR, polymerase chain reaction.

Other definitions of outcomes have been used in clinical trials.¹ For example, when postremission therapy was studied, all patients had to be in a CR at the time of enrollment, and therefore time until relapse or death should be measured from the date of study entry following CR.

LONG-TERM FOLLOW-UP

Follow-up plans for patients on a clinical trial should adhere to the scheme described in the study. There is no consensus for the follow-up of patients not enrolled on clinical trials. A general recommendation

(Table 14.5) would be to follow the patients monthly during the first year, every 2 to 3 months during the second and third years, and then at least every 6 months during the next 3 years. At 6 years and thereafter, patients can be monitored annually with history and physical examination, complete blood count with differential, and careful attention for second malignancies, heart failure, sterility, avascular necrosis, and hypothyroidism—all potential sequelae of therapy. Assessment of minimal residual disease should preferably be associated with clinical trials.

Chapter 15

TREATMENT OF RELAPSED OR REFRACTORY ACUTE LYMPHOBLASTIC LEUKEMIA AND NEW FRONTIERS IN THERAPY

Nicole Lamanna and Mark A. Weiss

INTRODUCTION

One of the great success stories of medical oncology has been the treatment of acute lymphoblastic leukemia (ALL) in children. Through a strong cooperative group effort, the recruitment of a high proportion of afflicted patients, and the conduct of multiple randomized trials, there have been successive improvements in treating childhood ALL, so that now 60–75% of the children with ALL can achieve long-term disease-free survival.¹ Unfortunately, adults with ALL do not fare as well. Despite complete remissions (CRs) in 60–90%, long-term disease-free survival still remains at 20–40%.^{2,3} In addition to deaths (5–10%) during remission induction, approximately 10–25% of patients have resistant disease. Even for patients who achieve a CR, 60–70% will relapse, often within 2 years of achieving the remission (a time when most patients are still receiving maintenance therapy). Management of both primary refractory and relapsed patients poses a great challenge to clinicians; it occurs commonly, and long-term survival in these patients is typically poor. Newer treatment strategies and novel agents are urgently needed to improve the prognosis for these patients. This chapter will review some of the prognostic features that influence the likelihood of failing to achieve a CR, chemotherapy strategies often employed in the salvage setting, stem cell transplantation, and special cases, including patients with Philadelphia (Ph)-chromosome disease, patients with central nervous system (CNS) relapse, and the use of newer agents.

PROGNOSTIC FEATURES

While several analyses of prognostic features in ALL have been performed, two classic multivariate analyses, one by the German multicenter group and another by the Memorial Sloan-Kettering Cancer Center (MSKCC) group, were reported in 1988. These and other studies indicate the importance of five prognostic features: white blood cell (WBC) count at diagnosis, age, leukemic cell immunophenotype, cytogenetics (particularly Philadelphia-chromosome-positive disease), and the time to achieve CR.^{4,5}

An elevated WBC count at the time of diagnosis is associated with a poor prognosis. The multivariate analyses indicate that there is both a reduced likelihood of achieving a CR, as well as a shorter duration of remission, and ultimately worse overall survival. In part, the poor prognosis associated with an elevated WBC reflects an increased disease burden, but it is also related to the propensity of poor cytogenetic subtypes (i.e., t(4:11) and t(9:22)) to present with hyperleukocytosis. Different studies have used different WBC levels as their cutoff for an adverse feature. In the MSKCC study, WBC counts greater than 10,000/ μ L were associated with a lower frequency of achieving a CR, and counts greater than 20,000/ μ L were associated with a shorter duration of CR. In the German study, WBC counts greater than 30,000/ μ L carried an adverse prognosis.

Older age in adult ALL patients is also associated with a worse prognosis, and similar to an elevated WBC count, age is probably a continuous variable (i.e.,

the older the patient, the worse the prognosis). Different studies have defined different ages as having a poor prognosis; the German group identified age 35, while the MSKCC study identified age 60.

The immunophenotype of the leukemic cell also has prognostic significance.⁴⁻⁶ Traditionally, T-cell disease has had a favorable prognosis, pre-B-cell (common) ALL an intermediate prognosis, and mature B-cell disease was associated with a poorer prognosis (using conventional treatments). Recently, however, modern intensive treatment regimens designed specifically for this rare subtype have improved the prognosis for patients with mature B-cell (Burkitt's type) lymphoblastic disease, and it is no longer considered to have a comparatively poor prognosis.^{7,8}

Cytogenetic abnormalities, specifically t(9;22) (Philadelphia-chromosome-positive disease) and t(4;11), portend poor prognoses. These patients are essentially never cured by chemotherapeutic regimens, with 5-year disease-free survival rates of 0–15%, using conventional therapy. A minority may be cured with an allogeneic transplant in first CR.^{9a-c} Also unclear is the impact that therapy with the tyrosine kinase inhibitor imatinib mesylate will have on Philadelphia-chromosome-positive disease. Another karyotype, t(8;14), involving the c-myc locus, has traditionally carried an unfavorable prognosis, though again, this may change with current intensive therapy.

Many studies have shown that the time to achieve a CR during remission induction therapy carries significant prognostic implications. The likelihood of being cured diminishes with the greater amount of time it takes the patient to achieve a CR. Notably, time to CR greater than 4 or 5 weeks substantially diminishes the likelihood of cure.⁵ However, it is uncertain whether a shorter duration in achieving a CR reflects an innate sensitivity of the disease to the chemotherapeutic agents used, or whether the rapid cyto-reduction of the leukemic cell mass minimizes the development of drug resistance and thus ultimately allows for the cure of the patient.

Note however the above-listed prognostic features relate primarily to initial therapy. At relapse, the prognosis is poor, with only a small fraction of patients salvaged. In this setting, long duration of first remission and isolated sanctuary site relapse are the two most important favorable prognostic factors.

CHEMOTHERAPY STRATEGIES

Several common treatment strategies have been used in patients who have refractory or resistant ALL. One option is to administer a regimen that is similar to the original remission induction therapy, particularly if there has been a long duration of remission prior to their eventual relapse (>1–2 years). However, this strategy is likely to be ineffective in patients with primary

refractory disease. Variations on traditional induction therapy, usually including vincristine, prednisone, and an anthracycline intensified with cyclophosphamide and/or L-asparaginase, are frequently used in the salvage setting. A second CR can occasionally be achieved in the subset of patients who had a long first remission or who developed recurrent disease after completing maintenance chemotherapy.¹⁰ Even one of the most favorable reports, however, achieved a CR in only 44% of the patients.¹¹ Furthermore, the median survival for these patients was only 8 months, and 3-year survival was only 10%.

As many patients develop recurrent disease within the first 2 years of achieving their first remission, the likelihood of achieving a second CR with regimens similar to the remission induction therapy is low.¹²⁻¹⁵ Likewise, for those patients whose disease is primarily refractory to standard remission induction therapy, simply repeating the same induction treatments is usually futile. Thus, another option is to use other agents that are relatively distinct from the agents used in the traditional induction treatment programs. One of the most commonly used agents in this setting is cytarabine arabinoside (ara-C) administered at a high dose. As a single agent, high-dose cytarabine (given at doses of, for example, 2–3 G/m² every 12 h for 6–12 doses) may induce a CR in approximately 30% of patients with relapsed or refractory ALL.¹⁵ In combination with other agents, such as L-asparaginase,¹⁶⁻¹⁸ doxorubicin,¹⁹ idarubicin,²⁰⁻²² or mitoxantrone²³⁻²⁶, higher response rates can be achieved, with CRs as high as 72% reported. An example of such a regimen is the combination of high-dose cytarabine with a single high-dose of idarubicin, which was reported by the MSKCC group as producing a CR in 44–58% of the patients.^{27,28} Of course, a direct comparison of these regimens is impossible given the differences in patient characteristics, the number of prior regimens and doses and schedules of the agents used, as well as the variable use of subsequent autologous or allogeneic stem cell transplantation and noncomparative trials.

Unfortunately, for many patients, even if a second CR is achieved, it is notoriously difficult to maintain, and each subsequent response is of a shorter duration than the prior one. Thus, in general, patients with a suitable allogeneic transplant option that is not precluded by age, performance status, or other concurrent illness should be referred for such a transplant in second CR.

STEM CELL TRANSPLANTATION

ALLOGENEIC TRANSPLANTATION

Allogeneic transplantation with an HLA-matched identical sibling has been performed in adults with ALL in a number of settings. In a small subset of patients, this dose-intensive treatment has the ability to

eradicate residual leukemia in patients whose disease is refractory to conventional chemotherapy. However, there are three main prerequisites that should be met prior to a patient undergoing this intense procedure. First, it is imperative that the patient be in an acceptable physical condition to withstand the demands and complications of the transplant. Secondly, it is preferable that the patient be in CR or in a minimal disease state to decrease the likelihood of relapse after transplant. Finally, a suitable donor must be identified and available. It is generally recommended that at the time of initial diagnosis the patient and immediate family members have HLA typing performed, as the process can be time consuming and, if done at the time of relapse, can cause unwanted delays. If no immediate family member is identified as a match, we recommend no additional testing until a transplant is needed (at the time of relapse). At such a time, a more extended family search can be performed along with a preliminary search of unrelated donors. The initial search through the National Marrow Donor Program (NMDP) registry is performed free of charge and is a one-time search used to identify potential candidates. An international search can also be initiated depending on the patient's racial and ethnic background, and depending on whether or not a match is found using the NMDP. Unfortunately, the lack of availability of human leukocyte antigen (HLA)-matched donors often limits the utility of this approach. In one study by Davies et al., the outcome of 115 consecutive patients with recurrent ALL were examined over a 2-year period.²⁹ A matched related donor was identified in 35%. Of the 75 patients without a related donor, 58 patients had an unrelated donor search initiated. Only 37% of these patients had an unrelated donor identified. Finding a matched unrelated donor is even more complicated if the patient has a diverse ethnic or racial background.

Even if a suitable donor is identified, allogeneic transplant is not a panacea for treating relapsed ALL. Limitations of transplant in patients with ALL are highlighted by reviewing patterns of failure. Patients with ALL who undergo allogeneic transplantation suffer from both treatment-related mortality as well as a significant rate of relapse. This differs from patients with acute myeloid leukemia (AML), who fail allogeneic transplantation primarily because of treatment-related mortality. This appears to be due to the "graft-versus-leukemia" effect in which the transplanted (donor) immune system eliminates residual leukemic cells being less effective in ALL than in AML or chronic myeloid leukemia (CML). Supporting this concept is data from the International Bone Marrow Transplant Registry, which compared identical twin (syngeneic) transplants to HLA-identical sibling (allogeneic) transplants.³⁰ As with graft-versus-host disease, the graft-versus-leukemia is more pronounced in the allogeneic transplants as compared with syngeneic transplants. The results of the

IBMTR study demonstrated a significantly higher rate of relapse in the syngeneic transplants for patients with AML or CML, but not for those patients with ALL, implying that graft-versus-leukemia is less potent in ALL compared to its effect in CML or AML. Another example supporting the concept that graft-versus-leukemia is less active in ALL comes from an analysis of studies of donor T-cell infusions used to treat relapsed leukemia after allogeneic stem cell transplant. In the "classic" study, donor lymphocyte infusions produced complete responses in 73% of patients with CML, 29% of patients with AML, and 0% of patients with ALL.³¹

The use and timing of allogeneic transplantation in adult patients with ALL is another dilemma. At the Fred Hutchinson Cancer Center, in 192 adults with ALL transplanted in second CR or beyond, the 5-year disease-free survival was only 15%.³² Another more recent study demonstrated a similar outcome for transplants performed beyond first CR, and included a treatment-related mortality rate of 43%.³³ There have been two large comparative studies of allogeneic transplant versus standard chemotherapy for patients in first CR. Neither study was able to demonstrate improved survival for the transplant arm and therefore with the exception of patients with t(9;22) and t(4;11) allogeneic transplant in first remission cannot be routinely recommended.^{34,35}

AUTOLOGOUS TRANSPLANTATION

Autologous transplantation for adult ALL is even less successful than allogeneic transplantation.³⁶ In part, this is likely related to the amount of disease burden prior to autologous transplantation and whether the residual leukemia cells were sufficiently eradicated prior to reinfusion. Many investigators have attempted to purge residual disease *ex vivo* by using different chemotherapeutic agents or monoclonal antibodies.³⁷⁻⁴¹ Not only are results of autologous transplantation disappointing in second CR, but even in first CR this modality has a limited applicability. Both a non-randomized and a randomized trial in patients in first CR have shown no benefit to autologous transplantation compared with maintenance chemotherapy.^{42,43} Therefore, autologous transplantation in patients with relapsed ALL should still be considered investigational and not routinely recommended to patients in first CR outside of a clinical trial.

PHILADELPHIA-CHROMOSOME-POSITIVE DISEASE

Patients with Ph-chromosome-positive ALL (Ph+ ALL) have a poor prognosis even with modern treatment regimens. Thus, it is generally recommended that these patients undergo allogeneic transplantation in first CR, as this strategy is curative in a minority of patients.^{44,45} The development of imatinib, a tyrosine kinase

inhibitor with relative specificity for bcr-abl, has dramatically altered the natural history and treatment of patients with CML.⁴⁶ Imatinib also has some activity in Ph+ ALL, although less so than in patients with CML, with only 29% of relapsed or refractory patients achieving a CR.⁴⁷ In addition, the median time to progression for responding patients is only 2.2 months, illustrating the development of resistance to imatinib in this patient group.^{48,49} A recent study investigated prognostic factors for response to imatinib mesylate therapy in patients with ALL.⁵⁰ Prior CR <6 months, WBC count $>10 \times 10^9/L$, circulating peripheral blood blasts at diagnosis, additional Ph chromosomes, and at least 2 bcr-abl fusion signals were all associated with a significantly inferior frequency of response and response duration to imatinib mesylate. Given the disappointing responses seen in patients with Ph+ ALL compared with patients with CML treated with imatinib mesylate, many investigators are evaluating the role of imatinib mesylate combination chemotherapy in both the initial treatment setting⁵¹ as well as in the relapsed setting.⁵²

CNS RELAPSE

Approximately 10% of patients who have received appropriate CNS prophylaxis will develop relapse in the CNS. Systemic relapse can often be identified simultaneously or shortly after CNS relapse is documented. Therefore, it is generally recommended that in addition to the treatment for CNS disease, patients should receive systemic reinduction chemotherapy. Treatment of established CNS disease often requires a combination of radiotherapy and intrathecal chemotherapy. The radiotherapy should be administered to the whole brain, consisting of 1800–2400 cGy (in 150- to 200-cGy fractions). Higher doses should be avoided due to both the risk of late toxicity (such as cognitive deficits or necrosis) as well as the potential later requirement of total body irradiation as part of the conditioning regimen for an allogeneic transplant. In addition, despite encouraging results in children, spinal radiotherapy should be avoided in adults, as the dose of radiotherapy to marrow-bearing areas subsequently limits the ability to administer necessary systemic chemotherapy. Furthermore, although this approach can help control the CNS disease, it does not prolong survival, as these patients typically succumb to relapsed system disease.⁵³ Intrathecal or intraventricular therapy for patients with established CNS disease should include methotrexate (12–15 mg) or ara-C, preferably administered intraventricularly via an Ommaya reservoir. It should be administered as often as two to three times per week with at least 1 day off between doses until the cerebrospinal fluid (CSF) is cleared of leukemic blasts, then twice a week for 2–3 weeks, and then twice a month for 2 or 3 additional months (total of 8–12 doses). Patients who develop CNS disease despite prophylaxis with intrathe-

cal methotrexate, and those patients who do not clear the blasts promptly from the CSF (within two treatments), should receive intraventricular therapy with ara-C at a dose of 60 mg.

NEW THERAPIES

As the overall survival for adult patients with relapsed or refractory ALL remains poor, newer therapies are needed. In addition to different combination chemotherapy strategies with traditional agents, investigators are examining the role of newer, investigational agents in the treatment of these patients.

Clofarabine. Clofarabine is a nucleoside analog that is a hybrid of fludarabine and cladribine. In a small phase II study of refractory or relapsed patients with ALL ($n = 12$), there was one CR (8%) that lasted 4 months.^{54a} Clofarabine has recently been approved by the FDA for use in pediatric ALL.^{54b}

Nelarabine. Nelarabine is a prodrug of ara-G. Evaluation of this arabinosyl analog of deoxyguanosine has shown some promising activity.^{55,56} In a phase I study of 26 patients, there were 10 responses (five CRs); 7/8 patients with T-cell ALL, 1 with T-lymphoid blast crises of CML, 1 with T-cell lymphoma, and 1 with B-cell CLL.⁵⁵ Interestingly, responses were not observed in patients with B-lineage ALL, and some investigators believe that one mechanism of T-cell selective cytotoxicity may result from high ara-GTP accumulation in T cells resulting in an S-phase dependent apoptosis, which may lead to a T-cell specific signal for the induction and liberation of soluble Fas ligand, thereby inducing an apoptotic response in neighboring non-S-phase cells.⁵⁷

Alemtuzumab. Alemtuzumab is a monoclonal antibody that binds to CD52, an antigen present on nearly all normal B and T lymphocytes. It has been approved by the Food and Drug Administration for use in patients with chronic lymphocytic leukemia (CLL) who are refractory to fludarabine, and it has been studied extensively in patients with CLL.^{58–60} The experience of alemtuzumab in patients with refractory or relapsed ALL is limited.⁶¹ It has been incorporated into purging techniques for autologous transplant, in conditioning regimens for allogeneic transplant, and used as an immunosuppressant for graft-versus-host disease.^{62–64}

CONCLUSION

Unfortunately, the treatment of patients with relapsed or refractory ALL remains a daunting challenge to investigators and treating physicians. Hopefully, as we gain more insight into the biology of this disease, we can improve not only upon the treatment of patients

who have relapsed, but also on initial treatment strategies, thereby minimizing those who require treatment in the relapsed setting. In addition, as we develop better techniques to assess for minimal residual disease, perhaps allowing for earlier intervention before overt clinical relapse, we may improve the outcome of these patients. Currently, the best chance for patients with relapsed disease is to induce a second CR (for suitable

patients we favor high-dose cytarabine with high-dose anthracycline) followed by an allogeneic transplant.

Section **3****CHRONIC MYELOGENOUS
LEUKEMIA**Chapter **16****EPIDEMIOLOGY, RISK FACTORS,
AND CLASSIFICATION OF
CHRONIC MYELOID LEUKEMIA***Tariq I. Mughal and John M. Goldman***INTRODUCTION**

Chronic myeloid leukemia (CML), historically also known as chronic myelogenous leukemia, chronic myelocytic leukemia, and chronic granulocytic leukemia, is a form of chronic myeloproliferative disease (CMPD) with a well-defined genetic defect known as the Philadelphia (Ph) chromosome.^{1,2} The Ph chromosome is associated with a *BCR-ABL* fusion gene expressed as an oncoprotein, p210BCR-ABL, which is generally considered as the initiating event for the chronic phase of CML. All CMPDs are clonal hematopoietic stem cell disorders characterized by proliferation in the bone marrow of one or more of the myeloid cell lineages that

gradually displaces normal haematopoiesis (Table 16.1). The remaining forms of CMPD do not have a specific genetic defect and the diagnosis, for the most part, relies upon clinical and hematologic features. The recent observations supporting the notion of JAK2 as a candidate gene involved in the molecular pathogenesis of some of the CMPD, specifically polycythemia vera, essential thrombocythemia and primary myelofibrosis, should herald an enhanced understanding of these disorders and might lead to a new classification of these disorders and, perhaps, novel treatments.³⁻⁵ In this chapter, we review the epidemiology, risk factors, and classification of CML.

CML originates in an abnormal hematopoietic stem cell, which acquires a Ph chromosome, and the *BCR-ABL* fusion gene, which is considered to be the principal pathogenetic event^{6,7} (Figure 16.1). The Ph chromosome and the *BCR-ABL* gene are found in all myeloid lineage cells and some, but not all, B and T lymphocytes. Clinically, CML is a biphasic or triphasic disease that is usually diagnosed in the initial “chronic” phase and then spontaneously evolves after a median time of 4–5 years into an “advanced” phase, which resembles an acute leukemia. The transformation into an advanced phase (called blast crisis) can occur abruptly or via a period of acceleration (called accelerated phase).

EPIDEMIOLOGY

CML is the most common of the CMPDs. It accounts for about 15–20% of all cases of adult leukemias, but less than 5% of all childhood leukemias. It is slightly more common in males than in females and occurs exceedingly rarely during the first decade of life. It has a median age of onset of about 50 years. The incidence of CML is about 1–1.5 per 100,000 persons per annum.⁸ There appears to be no association with social class or ethnicity, and its incidence appears to be remarkably constant worldwide.⁹ Some reports suggest a slightly higher prevalence in some parts of India and China, in particular Hong Kong, but these remain unconfirmed.

RISK FACTORS

Almost all cases of CML have no identifiable predisposing factors, and even when there might be a plausible causal link, it is extremely difficult to incriminate any factor in individual patients. Exposure to ionizing radiation is the only known etiological factor; the incidence of CML was increased to a minor but significant degree in patients treated with radiation therapy for ankylosing spondylitis or metropathia hemorrhagica.^{10,11} The most compelling link between radiation exposure and CML comes from a [Life Span] study of survivors of the atomic bomb explosions in Hiroshima and Nagasaki (Japan) in 1945.^{12,13} There was an increased risk of CML among the survivors. An increased risk of leukemia, but not of CML, has also been reported in an area immediately surrounding the British nuclear fuel facility at Calder Hall in Cumbria, U.K. (although a government commission of enquiry was unable to confirm this).

There are no firm associations of exposure to toxic chemicals or any infectious agent and CML.

Chemicals that damage the bone marrow, in particular aromatic hydrocarbons and benzene, appear to predispose to acute myeloid leukemia (AML), but it is impossible to be certain that leukemia would not have developed in a particular patient in the absence of exposure to the suspect substance. Recently, it has been shown that benzene activates an oncogene that causes AML.

Though a small number of families with a high incidence of CML have been reported, there is no confirmed familial predisposition and no definite association with human leukocyte antigen (HLA) genotypes and CML.¹⁴ Interestingly, two HLA types are associated with a decreased incidence of CML.¹⁵ Relapse of CML originating in donor cells following related allogeneic stem cell transplantation has been recorded.¹⁶ It is also noteworthy that only rarely does the identical twin brother or sister of a person with CML also develop leukemia. In a study of 40 pairs of identical twins in which one twin had CML, there was no instance in which the other twin developed CML.

Unlike the case in certain common epithelial cancers, there are no known dietary or social habits that increase the risk of acquiring CML. Smoking cigarettes has been weakly implicated. This link is dependent on the duration of exposure and the age of starting to smoke.

CLASSIFICATION

The classification of CML, though not entirely straightforward, has recently been the subject of much revision by the World Health Organization (WHO).¹⁷ Patients with classical CML have a well-defined disease characterized by splenomegaly, leukocytosis, and the finding of a *BCR-ABL* fusion gene in all leukemic cells. The classical Ph chromosome is easily identifiable in 80% of CML patients; in a further 10% of patients, variant translocations may be “simple,” involving chromosome 22 and a chromosome other than chromosome 9, or “complex,” in which chromosome 9, 22, and additional chromosomes are involved. About 8% of patients with classical clinical and hematologic features of CML lack the Ph chromosome and are referred to as the cases of “Ph-negative CML.” About half such patients have a *BCR-ABL* gene and are referred to as Ph-negative, *BCR-ABL*-positive cases. The remainder, perhaps less than 5% of patients with hematologically “acceptable” CML, are *BCR-ABL* negative, and some of these have mutations in the *ras* gene. These patients are usually classified as having Ph-negative, *BCR-ABL*-negative CML or atypical CML (sometimes also referred to as subacute myeloid leukemia), chronic myelomonocytic leukemia (CMML) or chronic neutrophilic (CNL) (Table 16.2). Children may have a disease previously referred to as juvenile CML, and now juvenile myelomonocytic leukemia (JMML). Importantly, in none of these variants is there a Ph

Table 16.2 Classification of CML and its variants

chromosome. Patients with atypical CML, CMML, and JMML usually have clinical and hematological features that suggest an overlap between CMPD and myelodysplastic syndrome (MDS), and the contemporary classification of myelodysplastic/myeloproliferative diseases is appropriate (Table 16.3).

CNL is a rare disease, which is of considerable academic interest since it is sometimes associated with a Ph chromosome and a BCR-ABL related oncoprotein, the

p230¹⁸; currently fewer than 100 patients with Ph-positive CNL have been reported worldwide. CNL affects older adults, compared to CML. It is of considerable interest that in about 20% of the reported cases, there was an associated malignancy, typically multiple myeloma, but none of these patients exhibited clonality in their myeloid cells. Distinctions among chronic phase, accelerated phase, and blast crisis CML are discussed in Chapter 17.

Chapter 17

MOLECULAR BIOLOGY, PATHOLOGY, AND CYTOGENETICS

Michael Deininger

Chronic myeloid leukemia (CML) is probably the most extensively studied malignancy and has served as a pacemaker for the development of new concepts and strategies in oncology. It was the description of the first CML cases, independently by Bennet¹ and Virchow,² which led to the term “leukemia,” Greek for “white blood.” CML was the first human cancer consistently associated with a chromosomal abnormality, the Philadelphia (Ph) chromosome.³ It was also the first malignancy that was faithfully reproduced in an animal model based on precise knowledge of the causal molecular lesion.⁴ Lastly, CML was the first malignant condition, where the identification of the causal abnormality led to a specific therapy.⁵ Despite intensive efforts, important aspects of CML pathogenesis are not well understood, such as the mechanisms underlying the progression to blast crisis. This chapter reviews the pathogenesis of CML, with a slight emphasis on clinical applications. Due to the wealth of data, this review cannot be comprehensive, and many important aspects had to be omitted because of space constraints.

MORPHOLOGY

CHRONIC PHASE

Approximately 85% of patients with CML are diagnosed in the chronic phase.⁶ A presumptive diagnosis can be established based on a Giemsa-stained peripheral blood or bone marrow aspirate. The peripheral blood demonstrates variable degrees of leukocytosis with a striking left shift in the white blood cell differential, basophilia, and less frequently, eosinophilia. Thrombocytosis is also common as is a moderate degree of anemia (Table 17.1).⁷ The morphology of the peripheral blood cells is normal; dysplasia is not a typical feature of CML and points to alternative diagnoses (see below). In the bone marrow, cellularity is increased with a predominance of granulopoiesis over erythropoiesis. Basophils and eosinophils may be increased, usually in proportion to their numbers in

the peripheral blood. Megakaryocytes are frequently increased in numbers, tend to be small and hypolobulated (micromegakaryocytes), and form clusters or sheets. Other findings include pseudo-Gaucher cells or sea-blue histiocytes, both representing macrophages that are unable to metabolize the increased glucocerebroside load associated with the high cell turnover. Bone marrow histology yields additional information and is mandatory in the case of a “dry tap,” as it may reveal increased blasts that are not apparent on the blood smear. Various degrees of reticulin fibrosis are a common finding, particularly in patients with more advanced disease.⁸ Angiogenesis is also increased but vessel density is not part of standard histologic reports, since it requires special stains.⁹ Overall, the morphologic findings allow establishing the diagnosis of a myeloproliferative syndrome, consistent with CML. However, a definitive diagnosis of CML should be made only after the presence of the Ph chromosome, or the *BCR-ABL* translocation has been documented by cytogenetic or molecular techniques (see below).

ACCELERATED PHASE

The diagnostic criteria for accelerated phase have been a matter of debate and the issue has not been resolved

Table 17.1 Blood white cell differential count at diagnosis ($n = 90$)

	Percent of total leukocytes
Myeloblasts	3
Promyelocytes	4
Myelocytes	12
Metamyelocytes	7

^aRefers to peripheral blood or bone marrow.

completely. The most widely accepted criteria are given in Table 17.2.¹⁰ Percentages of blasts, promyelocytes, and basophils, as well as thrombocytopenia that is not related to therapy, were all demonstrated to be independent adverse prognostic indicators in multivariate analysis, and these parameters were used to define accelerated phase in the recent large trials of imatinib in advanced CML.¹¹ It is controversial whether clonal evolution (CE), i.e., the presence of cytogenetic abnormalities in addition to the Ph chromosome, is indicative of accelerated phase at diagnosis in the absence of any of the other criteria. However, there is consensus that CE in a patient undergoing therapy indicates disease progression. In addition to the criteria in Table 17.2, a number of “soft” parameters are used clinically, such as decreased responsiveness to drug therapy, increasing splenomegaly, or pronounced B symptoms. Although features like this are clearly suggestive of disease progression, they are difficult to cast into an unambiguous definition and therefore should not be used in isolation to establish a diagnosis of accelerated phase.

BLASTIC PHASE (BLAST CRISIS)

A diagnosis of blastic phase is made when more than or equal to 30% blasts are present in the blood or bone marrow. Immunophenotyping is mandatory to determine whether the blasts have myeloid (60–70% of cases) or lymphoid differentiation (20–30% of cases), since this has major implications for optimal management. In the case of myeloid blast crisis, the blasts may fulfill the diagnostic criteria for any of the French–American–British (FAB) subgroups, but myelomonocytic differentiation is most frequent. Immunophenotypic analysis reveals positivity for myeloperoxidase and myeloid markers (CD13, CD14, and CD33). Lymphoid blast crisis usually has a pre-B-cell phenotype, with positivity for B-cell markers (CD19 and CD20), CD10, and TdT.^{12,13} T-lymphoid blast crisis is extremely rare. Approximately 10% of cases are undifferentiated or biphenotypic. Regardless of the phenotype, the blasts almost invariably express the CD34 antigen. A diagnosis of blastic phase is also established in the case of extramedullary disease, with the exception of liver or spleen involvement.

CYTOGENETICS

CONVENTIONAL G BANDING AND R BANDING

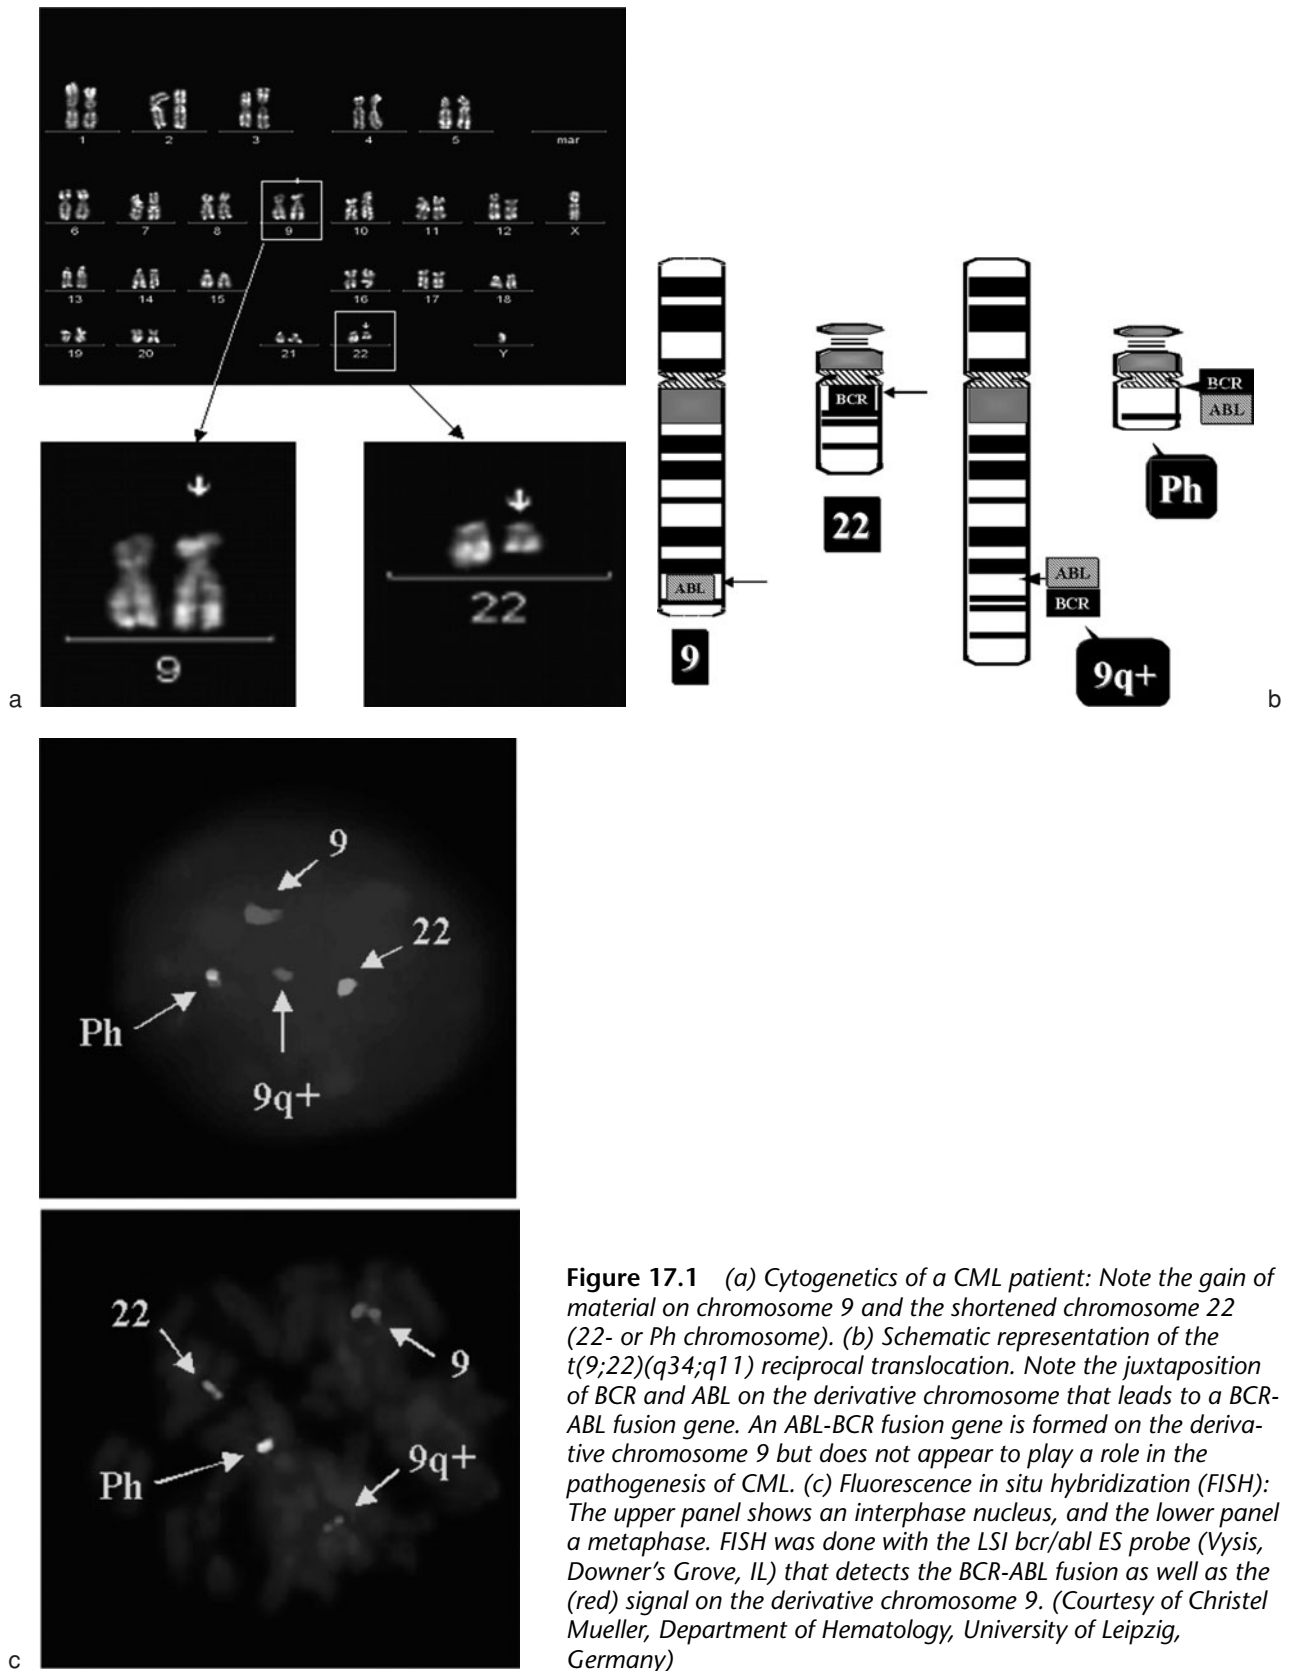

The cytogenetic hallmark of CML is the Ph chromosome, which is demonstrable in approximately 90%

of patients with a diagnosis of CML based on clinical and morphologic criteria. The Ph chromosome, originally thought to be a shortened chromosome 22 and thus referred to as 22⁻³ is the result of a reciprocal translocation between the long arms of chromosomes 9 and 22 [t(9;22)(q34;q11)].¹⁴ As a consequence, genetic sequences from the *BCR* gene on 22q34 are fused 5' of the *ABL** gene on 9q11, and vice versa, generating a *BCR-ABL* fusion gene on the derivative chromosome 22 and an *ABL-BCR* fusion gene on the derivative chromosome 9 [Figure 17.1(a) and 17.1(b)].^{15,16} Approximately 10% of patients with typical CML are negative for the t(9;22)(q34;q11) by conventional G- or R-banding techniques. In approximately half of these patients, the *BCR-ABL* translocation is detectable by fluorescence in situ hybridization (FISH) or reverse transcription polymerase chain reaction (RT-PCR), a situation referred to as cryptic or silent Ph translocation. The clinical course of these individuals is not different from classical Ph-chromosome-positive CML, while the remaining 5% of patients have truly *BCR-ABL*-negative disease. According to the World Health Organization, CML is defined by presence of the *BCR-ABL* translocation, and thus the term Ph-negative or *BCR-ABL*-negative CML should not be used any longer. Depending on specific features, it may be possible to classify such patients as having chronic myelomonocytic leukemia if there is persistent monocytosis of more than 10⁹/L, or atypical CML if there is prominent dysgranulopoiesis. Otherwise, the disease should be referred to as chronic myeloproliferative disease, unclassifiable. The exclusive definition of CML as the *BCR-ABL*-positive disease has become even more important with the advent of imatinib as a specific targeted therapy for this disorder.¹⁷

FLUORESCENCE IN SITU HYBRIDIZATION

Fluorescent probes to detect the *BCR-ABL* translocation have become widely available and are equally suitable for analysis of metaphases and interphases [Figure 17.1(c)]. Using FISH on metaphase spreads allows for analysis of several hundred cells, which increases the sensitivity for detection of residual disease by one order of magnitude.¹⁸ Analysis of interphase nuclei permits making a diagnosis of CML in cases that fail to grow metaphases. FISH on interphase nuclei from the peripheral blood correlates with bone marrow cytogenetics.¹⁹ However, the fact that the Ph status of B cells is unpredictable can lead to over- or underestimation, when unselected peripheral blood white cells are analyzed.²⁰ For diagnostic purposes, it

* The correct designation of ABL is ABL-1, as there is the ABL-related gene (ARG) that is referred to as ABL-2. However, as “ABL” is still much more commonly used in the medical literature than ABL-1, ABL will be used throughout this chapter.

is crucial to establish the false-positive and false-negative rates of the probe set used, which vary significantly between different commercially available kits.²¹ The obvious disadvantage of FISH is that it screens only for the presence of the *BCR-ABL* translocation, and does not detect other cytogenetic abnormalities.

DELETIONS FLANKING THE *BCR-ABL* BREAKPOINT

It was recently observed that 10–15% of CML patients harbor large deletions, flanking the breakpoint on chromosome 9 and, less frequently, chromosome 22, or both.^{22,23} Patients with such deletions have a much shorter survival with interferon-alpha-based therapy and appear to have a shorter time to progression on imatinib.²⁴ These observations led to the speculation that the deleted region may contain a tumor suppressor gene. One candidate on chromosome 9q is PRDM12, a zinc-finger protein, which may function as a negative transcriptional regulator.^{25,26} Deletions on the derivative chromosome 9 are detectable with most commercially available FISH probes.²⁷ In addition, patients with loss of genetic material on either side of the breakpoint are negative for *ABL-BCR* mRNA.²⁸ This however does not fully account for the fact that about one-third of CML patients fail to express this reciprocal fusion mRNA.²⁹ Although the prognostic significance of deletions flanking the *BCR-ABL* breakpoint awaits evaluation in a prospective fashion, “deletion status” should become part of diagnostic reports.³⁰ It has recently been shown that the frequency of deletions is much higher in patients with so-called variant Ph translocations that involve one or two chromosomes in addition to chromosomes 9 and 22. These variants may be generated at the time of the initial translocation event or, less frequently, may be acquired during disease progression, where they represent an unusual form of clonal cytogenetic evolution (see below).³¹ The inferior survival of patients with variant Ph translocations could be convincingly attributed to high frequency of derivative chromosome 9 deletions, as elimination of this group of patients eliminated the difference.³¹

CYTOGENETIC CLONAL EVOLUTION (CE)

The acquisition of nonrandom karyotypic abnormalities in addition to the Ph chromosome is referred to as CE. CE is strongly associated with disease progression, occurring in more than 50% of patients with blastic transformation.³² Although many different chromosomal abnormalities have been reported, there are a few specific changes that account for the majority of cases.³³ Hyperdiploid karyotypes predominate, most commonly trisomy 8, 19, 21, or a second Ph chromosome. Another frequent finding is isochromosome 17, while monosomy 7, loss of the Y chromosome, and reciprocal translocations, such as t(3;21)(q21;q26), are relatively rare. Progressively more abnormalities are

often acquired during further disease progression. Intriguingly, the sequence of acquisition of these additional changes is apparently nonrandom, following certain “routes” of CE,³³ and there are geographical and ethnic differences, whose etiology is not understood.³⁴ Events like t(3;21)(q21;q26) that involves the *EVI-1* gene, a transcription factor, may conceivably dysregulate myeloid cell differentiation, a key feature of blastic transformation, and thus explain the phenotype of blast crisis compared to chronic phase. However, in most instances, it is not known how the recurrent chromosomal changes may contribute to the loss of cell differentiation that characterizes blast crisis. It should be noted that nonrandom chromosomal abnormalities have been detected in the Ph-chromosome-negative cells of some patients, with a complete cytogenetic response to imatinib.³⁵ This yet unexplained phenomenon should not be referred to as CE.

MOLECULAR PATHOGENESIS

MOLECULAR ANATOMY OF THE *BCR-ABL* FUSION

The breakpoints in *ABL* are spread over a large genomic region and may occur 5' of *ABL* exon Ib, between *ABL* exons Ia and II or, most frequently, between the two alternative first *ABL* exons (Figure 17.2) (reviewed in Ref. 36). Despite this variation, the *ABL* portion in the fusion mRNA and protein is usually constant, encompassing *ABL* exons 2–11. This is thought to be the result of posttranscriptional processing of the primary transcript. In contrast, the breakpoints in *BCR* localize to three distinct breakpoint cluster regions (*bcr*),¹⁶ which are associated with the three major types of *Bcr-Abl* fusion proteins. Breaks in the minor *bcr* (*m-bcr*) give rise to an e1a2 fusion mRNA and a 190-kd protein (p190^{*BCR-ABL*}) that is found in two-third of patients with Ph-chromosome-positive acute lymphoblastic leukemia (ALL) and in rare patients with CML. Unlike typical CML, these patients are characterized by monocytosis.³⁷ Breaks in the major *bcr* (*M-bcr*) result in e13a2 or e14a2 fusion mRNAs (previously referred to as b2a2 and b3a2, according to the original numbering of exons within the major breakpoint cluster region) and a 210-kd protein (p210^{*BCR-ABL*}). p210^{*BCR-ABL*} is typical of CML but also occurs in one-third of patients with Ph-chromosome-positive ALL.³⁶ Many efforts were made toward identifying consistent differences between patients expressing e13a2 (b2a3) or b14a2 (b3a2). However, the only association that seems to stand the test of time is the notion of slightly higher platelet counts in patients with e14a2 transcripts.³⁸ The third recognized cluster, termed micro-*bcr* (*μ-bcr*), is localized in *BCR* intron 19 and generates a 230-kd protein (p230^{*BCR-ABL*}) that is associated with the rare and relatively benign condition of chronic neutrophilic leukemia.³⁹ The fact that the *Abl* portion

Figure 17.2 Location of the breakpoints in BCR and ABL and structure of the various BCR-ABL mRNAs. Breakpoints in ABL are spread over a large genomic region and may occur upstream of exon 1b, between exons 1a and 11, or between exons 1b and 1a. In contrast, breakpoints in the BCR cluster in defined breakpoint cluster regions (bcr), a fact that led to the gene's naming. ABL exons 2–11 are contained in the BCR-ABL mRNA, regardless of the breakpoint location, as a result of splicing. In contrast, different types of fusion mRNA and protein are generated from the different breakpoint cluster regions in BCR. (Reproduced from Deininger et al.: *Blood* 96:3343, 2000; with permission)

in the different fusion proteins is constant while the Bcr portion is variable provides circumstantial evidence that the transforming principle is likely to reside in Abl, while the Bcr part appears to modify the disease phenotype, with retention of a larger BCR portion rendering the disease less aggressive. Although the three major types of BCR-ABL fusion mRNA account for more than 99% of cases of Bcr-Abl-positive leukemia, many more BCR-ABL variants have been seen in anecdotal cases or small series of patients.³⁸ Most of these variants have atypical breakpoints in BCR, generating fusion mRNAs, such as e6a2⁴⁰ or e8-insert-a2, where the open reading frame is retained by interposition of intronic sequences. However, fusions between BCR exon 1 and ABL exon 3 have also been described in CML patients.⁴¹ Due to the small numbers of reported cases, it has been difficult to convincingly ascribe a particular clinical phenotype to any of these rare BCR-ABL variants; however, the general theme seems to be that the retention of more BCR sequences within the fusion protein attenuates the disease, consistent with the observations in the major types of Bcr-Abl fusion proteins.

HEMATOPOIETIC LINEAGE INVOLVEMENT

CML is frequently referred to as a stem cell disease, since all three myeloid lineages (granulopoiesis, megakaryopoiesis, and erythropoiesis) carry the Ph chromosome. Data regarding the lymphoid cell compartment have been more conflicting, and there is

apparently variation between different patients. In most patients, at least a proportion of the peripheral blood B cells are Ph positive.⁴² Mature T cells are usually Ph negative,⁴³ while T-cell precursors were found to be positive in one study.⁴⁴ The existence of myeloid and B-lymphoid (and in rare instances T-lymphoid) blastic transformation (see below), as well as the observation that endothelial cells may be Ph positive,⁴⁵ is further support for the involvement of an early progenitor cell. There is still controversy as to whether Ph-positive ALL with a p210^{BCR-ABL} fusion and lymphoid blast crisis are different entities or not.⁴⁶ The fact that the hematopoiesis that recovers after intensive chemotherapy is usually Ph negative in the case of ALL but Ph positive in the case of lymphoid blast crisis argues for two distinct entities. The ability of interferon alpha,⁴⁷ autologous stem cell transplantation,⁴⁸ and, more impressively, imatinib⁵ to restore Ph-negative hematopoiesis in many patients indicates that normal hematopoietic progenitor cells survive in the presence of the CML cell clone. Remarkably, the most primitive stem cell compartment appears to be predominantly Ph negative in early phases of the disease, despite the fact that the peripheral myeloid cells are almost exclusively Ph positive.^{49,50} This has led to the notion that Bcr-Abl initially favors the expansion of committed progenitor cells (such as colony-forming units granulocyte-macrophage), while the stem cell compartment may be more resistant. Clearly, the question how the Bcr-Abl-positive cell clone outcompetes normal hematopoiesis is at the very heart of CML pathogenesis and is discussed in more detail further below.

MULTISTEP VERSUS SINGLE-STEP PATHOGENESIS

It is generally thought that Bcr-Abl alone is necessary and sufficient to induce the chronic phase of CML. This notion is supported by murine disease models (see below), the ability of certain therapies to restore Ph-negative polyclonal hematopoiesis,^{35,51,52} and the lack of detectable genetic abnormalities in addition to the Ph chromosome in newly diagnosed patients. However, there are some arguments against this view. Mathematical modeling suggested that the epidemiology of chronic phase CML is more compatible with two or three genetic events than with one.⁵³ X-chromosome-based clonality studies in Ph-negative Epstein-Barr-virus-transformed B-cell lines from CML patients showed evidence for “skewing” toward the genotype of the leukemia clone in a subset of patients, consistent with a clonal abnormality that predated the acquisition of the Ph chromosome.⁵⁴ Lastly, BCR-ABL mRNA is detectable at very low levels in the blood of many healthy individuals, suggesting that Bcr-Abl alone may not be sufficient to induce the CML phenotype.^{55,56} Another observation pointing to the possibility of a pathological “pre-Philadelphia” state is the observation of cytogenetic abnormalities in the

Ph-negative cells of some patients, with a cytogenetic response to imatinib.^{35,57,58} Although in the vast majority of cases the respective abnormalities, many of them typical of myelodysplastic syndromes, are not present in Bcr-Abl-positive cells, arguing against the acquisition of Ph as a secondary event, it remains possible that the Ph-negative hematopoiesis as a whole is abnormal. In this scenario, different abnormal clones would emerge, including the Bcr-Abl-positive clone that has the greatest proliferation capacity and leads to clinical CML.

THE PHYSIOLOGICAL FUNCTION OF THE TRANSLOCATION PARTNERS

Abl is a 145-kd nonreceptor tyrosine kinase with multiple and complex functions. Two isoforms (Abl-A and Abl-B) exist that differ in their N-terminal regions, depending on the usage of exon Ia or exon Ib (Figure 17.3). Only Abl-B, which is 19 amino acids longer than Abl-A, is myristoylated at the N-terminus,⁵⁹ a feature that has recently been linked to autoinhibition of kinase activity.^{60,61} Further toward the C-terminus, there is a Src homology (SH) 3 domain that interacts with proline-rich domains of other proteins, an SH2 domain capable of binding to phosphorylated tyrosine residues of interacting proteins, and an SH1 domain, which carries tyrosine kinase activity.³⁶ While the N-terminus exhibits a high degree of homology to other nonreceptor tyrosine kinases, such as Src, the C-terminus is unique to Abl. Three DNA-binding domains, a nuclear localization signal, nuclear export signal, a proline-rich region, and an actin-binding domain can be defined within the C-terminus. Under physiological circumstances, Abl is nuclear, and its tyrosine kinase activity is tightly regulated.

The function of Abl has been studied extensively, and a very complex picture has emerged (for reviews, see Refs. 62 and 63). There is evidence for an inhibitory role of Abl in cell cycle regulation, which led to the notion that it may be considered a tumor suppressor.⁶⁴ A number of studies have implicated Abl tyrosine kinase in the regulation of the cellular response to DNA damage, by interaction with several proteins involved in DNA repair or response to genotoxic stress.^{65–70} Yet other data suggest a role in the signal transduction from and to integrin receptors on the cell surface,^{71,72} and there is evidence for activation of Abl kinase upon ligand binding to the platelet-derived growth factor receptor.⁷³ Mice with homologous disruption of the ABL locus suffer from high perinatal mortality and have multiple defects, including defective immune function and skeletal abnormalities, and suffer from a poorly characterized wasting syndrome.^{74,75} However, there is no indication that the rate of spontaneous tumors is increased in these mice, arguing against a tumor suppressor function of Abl. Importantly, simultaneous disruption of the ABL-related gene, ARG, also referred to as ABL-2, is embryonically lethal, due to a failure of neuronal development, which argues that the ARG may partially compensate for the loss of Abl function in the ABL knockout mice.⁷⁶ The mechanism underlying the tight regulation of Abl kinase activity in physiological conditions has recently been clarified, at least for the Abl-B isoform, by a combination of mutational structure function analysis and crystallography.^{60,61} These studies revealed a critical role for the N-terminal cap region of the protein, which inhibits the kinase by an intramolecular interaction. This does not exclude that other mechanisms, such as transacting molecules, may also be involved in regulating the kinase.⁷⁷

Figure 17.3 Structure of the Abl protein. The type Ia isoform is slightly shorter than type Ib, which contains a myristoylation (myr) site for attachment to the plasma membrane. Note the three Src-homology (SH) domains situated toward the NH₂-terminus. Y393 is the major site of autophosphorylation within the kinase domain, while phenylalanine 401 (F401) is highly conserved in PTKs containing SH3 domains. The middle of the protein is dominated by proline-rich regions (PxxP) capable of binding to SH3 domains and also harbors one of three nuclear localization signals (NLS). The carboxy-terminus contains DNA as well as G- and F-actin-binding domains. Phosphorylation sites by Atm, cdc2, and PKC are shown. The arrowhead indicates the position of the breakpoint in the Bcr-Abl fusion protein. (Blood 96:3343, 2000; with permission)

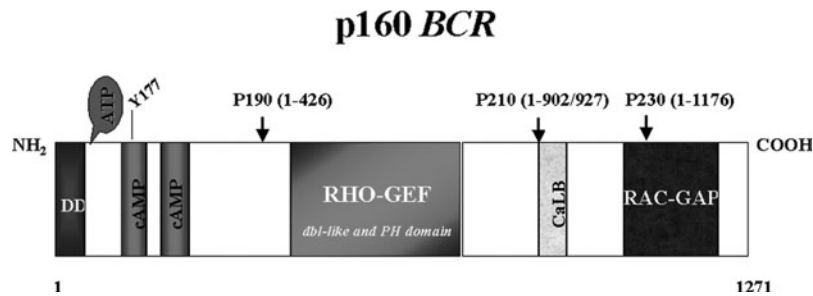

Figure 17.4 Structure of the Bcr protein. Note the dimerization domain (DD) and the two cAMP kinase homologous domains at the N-terminus. Y177 is the autophosphorylation site crucial for binding to Grb-2. The center of the molecule contains a region homologous to Rho guanine nucleotide exchange factors (Rho-GEF) as well as dbl-like and pleckstrin homology (PH) domains. Toward the C-terminus a putative site for calcium-dependent lipid binding (CaLB) and a domain with activating function for Rac-GTPase (Rac-GAP) are found. Arrowheads indicate the position of the breakpoints in the Bcr-Abl fusion proteins. (*Blood* 96:3343, 2000; with permission)

The function of BCR (Figure 17.4) is even less well understood than that of Abl. The N-terminus contains a dimerization domain as well as a serine/threonine kinase activity. The center of the molecule is dominated by dbl-like and pleckstrin homology (PH-) domains that have guanine nucleotide exchange function for small G proteins, including RhoA, Rac, and Cdc42. The C-terminus has GTPase-activating function for Rac (reviewed in Ref. 36). In contrast to ABL knockout mice, BCR knockout mice are practically normal, and an increased oxidative burst of their neutrophils is the only recognized anomaly.⁷⁸

ESSENTIAL FEATURES OF THE BCR-ABL PROTEIN

Mutational analysis of Bcr-Abl identified several domains and amino acid residues that are crucial to the molecule's capacity to transform hematopoietic cells. Most importantly, deletion of the tyrosine kinase function abrogates transformation and leukemogenicity,⁷⁹ although more recent data suggest that even the kinase-dead protein may modify certain cellular functions, such as adhesion and migration.⁸⁰ A second critical structural motif is the N-terminus of BCR that contains the dimerization domain.⁸¹ This domain can be replaced by other sequences that allow dimerization; for example, ETV-6 in the Etv-6-Abl fusion protein that has sporadically been found in patients with ALL.⁸² Since the N-terminus of Abl is crucial to the autoregulation of the kinase, it is conceivable that the principal consequence of dimerization is the abrogation of autoinhibition.^{60,61} Many other motifs within Bcr-Abl have important functions but are not essential to leukemogenesis. Rather than that, they modulate the aggressiveness of the disease or influence its phenotype in murine models of Bcr-Abl-positive leukemia. For example, tyrosine 177 of BCR is crucial to the induction of myeloid but not lymphoid leukemia,⁸³ and deletion of the Abl SH3 domain attenuates the disease.⁸⁴

ACTIVATION OF SIGNALING PATHWAYS

As a result of the constitutive tyrosine kinase activity, multiple substrates are tyrosine phosphorylated in Bcr-Abl-positive cells, including the oncoprotein itself. As mentioned above, Bcr-Abl has several functional domains that are capable of binding other proteins in tyrosine-dependent and -independent manners. Additional binding sites are generated by autophosphorylation. The net result is a multiprotein complex held together by multiple protein-protein interactions.^{85,86} In addition, Bcr-Abl phosphorylates a host of substrates that are not directly bound to the protein but impact on crucial cellular functions. Examples include adhesion protein like paxillin and tensin or the focal adhesion kinase (reviewed in Ref. 36).

Research over the past two decades has revealed that multiple signaling pathways are activated in Bcr-Abl-transformed cells. This includes the Ras/Raf/mitogen-activated kinase pathway,⁸⁷ phosphatidylinositol 3 kinase (PI3 kinase),⁸⁸ STAT5,⁸⁹ Myc⁹⁰, and many others (reviewed in Refs. 36,91). Overall, there is extensive redundancy. For example, Ras may be activated in two different ways. One possibility is binding of the adapter protein Grb-2 to phosphorylated tyrosine 177 that subsequently binds and activates the GTP exchange factor Sos, which in turn stabilizes Ras in the active GTP-bound form.⁹² The second option is activation via the adapter protein Shc, which requires the Abl SH2 domain but not tyrosine 177.⁹³ Studies in cell lines frequently indicated important or even essential functions for individual pathways, suggesting that the respective pathways may be attractive therapeutic targets. However, data obtained in murine models of Bcr-Abl-positive leukemia that employed knockout animals to test for the requirement of certain signaling components *in vivo* were usually less convincing. For example, the induction of a myeloproliferative syndrome in mice is not impaired in animals with a

homozygous deletion of the *STAT5A* and *STAT5B* genes⁹⁴ or the inter leukin 3 (IL-3) and granulocyte-macrophage colony-stimulating factor genes.⁹⁵ Although the rather aggressive phenotype of the murine CML models raises the question whether more subtle effects would be detectable with a model that is closer to the clinical disease, these observations support the view that the redundancy within the signaling network of Bcr-Abl-transformed cells may compensate for the loss of individual components.

BIOLOGICAL PROPERTIES OF CML CELLS

Compared to their normal counterparts, CML progenitor cells are able to enter the cell cycle in the absence of growth factors,⁹⁶ although they are not cytokine-independent.⁹⁷ Nonetheless, the reduced requirement for external stimuli may lend a growth advantage to CML cells that is sufficient to outcompete normal hematopoiesis over time. There is evidence that autocrine production of IL-3 and granulocyte colony-stimulating factor by CML progenitor cells may be the underlying mechanism.⁹⁸ In addition to inducing proliferation, Bcr-Abl has been shown to inhibit apoptosis by multiple mechanisms, including upregulation of the antiapoptotic protein Bcl-X_L and downregulation of proapoptotic Bim.^{99–103} A third biological feature that characterizes Bcr-Abl-positive cells is a perturbation of their adhesion to stroma¹⁰⁴ and migration in response to chemokines such as SDF-1,¹⁰⁵ which may explain extramedullary hematopoiesis. It has been difficult to link certain biological properties to the activation of specific signaling pathways that are activated by Bcr-Abl, and the issue is complicated by the fact that much of the data are derived from studies in cell lines rather than primary CML cells. Proliferation and inhibition of apoptosis are strictly dependent on Bcr-Abl kinase activity, whereas the defects in adhesion and migration are not completely reversible upon inhibition of Bcr-Abl.¹⁰⁶ If this is clinically significant in the setting of targeted therapy of CML with imatinib remains to be seen.

MECHANISMS OF DISEASE PROGRESSION

One could argue that CML would not pose a clinical problem if the disease remained in the chronic phase. Clinical observation holds that the time-to-disease progression is extremely variable from patient to patient, with some individuals progressing to blast crisis within weeks from what seemed a diagnosis of standard chronic phase disease, and others remaining stable for many years, even with conventional hydroxyurea-based therapy. The mechanisms underlying disease progression are not well understood. Studies from a number of laboratories have suggested that the expression of Bcr-Abl may adversely affect several DNA repair pathways.^{107–111} It is thought that over time this favors the accumulation of additional genetic abnormalities, such as the inactivation of tumor suppressor genes. Another possibility is that accelerated

loss of telomere length predisposes the CML cells to the acquisition of additional chromosomal abnormalities. In fact reduced telomere length correlated with an adverse prognosis.¹¹² However, no consistent genetic abnormalities have been associated with disease progression. Deletions of the *INK4A* locus, resulting in inactivation of the p16 cyclin-dependent kinase inhibitor and—presumably—p14^{ARF}, occur in approximately 50% of patients with lymphoid blast crisis, without impacting prognosis.^{113,114} Deletion of p53 has been observed in another subset of patients¹¹⁵ and deletion of the retinoblastoma susceptibility gene in isolated cases.¹¹⁶ All these abnormalities fail to explain the most striking feature that distinguishes blastic from chronic phase CML, namely the block of differentiation. In acute myeloid leukemia (AML), the concept that two types of mutations are required to induce the disease phenotype has recently received much attention.¹¹⁷ According to this model, a type I mutation, such as an activating mutation of Ras or a tyrosine kinase, leads to increased proliferation and reduced apoptosis, while differentiation is maintained. A second, type II mutation, such as the AML1-ETO fusion, affects a transcription factor that is crucial for myeloid cell differentiation. The result is a differentiation block that leads to the full AML phenotype. Experimental evidence in support of this concept has accumulated from murine leukemia models. For example, transplantation of murine bone marrow cells expressing constitutively active Flt3 into syngeneic recipients induces a myeloproliferative syndrome, but coexpression of Aml1-Eto induces acute leukemia. Similarly, transplantation of bone marrow cells expressing both Bcr-Abl and a NUP98-HOXA9 fusion protein induces AML.¹¹⁸ In contrast to AML, translocations involving the core-binding factors CBF β and AML1 have only occasionally been observed in blast crisis, and there is little evidence for point mutations in these key regulators of myeloid differentiation. A more attractive candidate is EVI-1/MDS-1, a transcription factor that is affected by several chromosomal aberrations, such as t(3;21)(q26;q22), inv(3)(q21q26), or t(3;3)(q21q26), that belong to the recurrent non-random abnormalities in patients with transition to blast crisis.³³ In addition, increased expression of EVI-1 mRNA has been observed in patients with blast crisis.¹¹⁹ Mice transplanted with bone marrow cells expressing both Bcr-Abl and Aml1-Evi-1 develop AML, and both components of the chimeric protein are required for induction of this phenotype.^{120,121} Very recently, an AML1-EVI-1 fusion protein has been shown to suppress the transcription factor CEBPA in AML.¹²² CEBPA has also been implicated by a study that showed that CEBPA expression is inhibited in blast crisis cells as a result of posttranscriptional modification by the poly (rC) binding protein hnRNP E2.¹²³ Another transcription factor implicated in blast crisis is Wnt, whose activation in progenitor cells may

endow them with increased self-renewal capacity,¹²⁴ which however does not readily explain their failure to differentiate. Lastly, it should be mentioned that increased expression of Bcr-Abl protein¹²⁵ and methylation of the ABL promoter¹²⁶ have also been linked to disease progression.

MURINE MODELS OF Bcr-Abl-POSITIVE LEUKEMIA

In a seminal study Daley and colleagues showed that transplantation of murine bone marrow infected with a Bcr-Abl retrovirus into lethally irradiated syngeneic recipients induced a myeloproliferative syndrome that resembled human CML.⁴ This study provided strong evidence that Bcr-Abl is the causative agent responsible for CML and suggested that no additional abnormalities are required for leukemogenicity. However, disease penetrance with the model was relatively low. In addition, a proportion of mice developed atypical Bcr-Abl-positive tumors, such as macrophage tumors. Subsequent studies showed that the conditions used for retroviral infection of murine bone marrow greatly impact the phenotype of the disease.¹²⁷ For example, mice transplanted with marrow harvested from donor mice not treated with 5-fluorouracil almost invariably develop B-cell ALL, not a myeloproliferative syndrome. Another important variable is the promoter used to drive the expression of Bcr-Abl. Thus, a more recently developed model uses the promoter of the murine stem cell leukemia and employs high viral titers for transduction.¹²⁸ With this approach, 100% of animals develop a myeloproliferative syndrome resembling CML with a latency of approximately 25 days. Although the refinements to the murine disease model have greatly increased its usefulness, one remaining concern is that the Bcr-Abl-positive myeloproliferative syndrome, though phenotypically resembling chronic phase CML, is in reality a very aggressive and rapidly lethal leukemia, in contrast to the chronic phase of human CML. This

may be due the fact that levels of Bcr-Abl protein are much higher than in human CML cells.

Transgenic approaches placing Bcr-Abl under the control of the Bcr promoter were initially not successful, due to embryonic lethality.¹²⁹ However, with the use of a tetracycline-repressible system and enhancer elements of the SCL locus, it has recently been possible to generate transgenic mice that develop a myeloproliferative syndrome that reproduces some of the features of chronic phase CML and is reversible on re-exposure to tetracyclin.¹³⁰

SUMMARY

CML is defined by the presence of a *BCR-ABL* fusion gene that gives rise to a cognate chimerical protein with constitutive tyrosine kinase activity. Cytogenetically, the *BCR-ABL* translocation is evident as a Ph chromosome, but some 5% of patients have a cryptic translocation that is detectable only by FISH or RT-PCR. It is thought that the *BCR-ABL* translocation occurs in a pluripotent hematopoietic stem cell and is the only event required for the induction of chronic phase CML, although this has been questioned. Bcr-Abl tyrosine kinase activity maintains a complicated and redundant network of signaling pathways, individual components of which are frequently dispensable for malignant transformation. The biological hallmarks of CML cells, increased proliferation, reduced apoptosis, and perturbed adhesion to extracellular matrix, are almost exclusively dependent on Bcr-Abl's tyrosine kinase activity, indicating that the latter is an ideal therapeutic target. The mechanisms underlying disease progression are not well understood. Analogy to AML suggests that the function of a transcription factor may be disrupted that is essential for coordinated myeloid cell differentiation.

Chapter 18

TREATMENT APPROACH TO CHRONIC-PHASE CHRONIC MYELOGENOUS LEUKEMIA

Jorge E. Cortes

The treatment of chronic myelogenous leukemia (CML) has been characterized in recent years by some of the most remarkable achievements in the treatment of cancer.¹ Some of the best results obtained with allogeneic stem cell transplantation (SCT) have been reported in CML, and some of the leading observations that triggered our current knowledge about graft-versus-leukemia effect and the immunology of transplant were pioneered in CML. CML was probably also one of the first malignancies in which a biologic agent, interferon alpha (IFN- α), was able to eliminate the disease, substantiated by the achievement of a complete cytogenetic remission in a fraction of all patients treated. Most recently, the introduction of imatinib mesylate represents one of the best examples of a target-specific therapy that has resulted in complete responses for the majority of patients with this disease. The availability of several treatment modalities that may improve the survival of patients with any malignancy is welcome. The current challenge, however, is to learn to integrate these strategies in a way that will result in the greatest probability of long-term survival for most patients diagnosed with CML. It is no longer a matter of treatment options, but of treatment strategies. In this chapter, we will discuss the current treatment alternatives for patients with CML in chronic phase. This is an evolving field not free of controversy, and the major elements of this controversy will be discussed here. Although IFN- α has been largely replaced by imatinib as the centerpiece of the management of patients with chronic-phase CML, the lessons learned from IFN- α are important and will therefore be discussed first.

IFN- α

Treatment with IFN- α resulted in a complete cytogenetic remission (i.e., 0% Philadelphia-chromosome (Ph)-positive metaphases) in 5–25% of the

patients treated. A partial cytogenetic response (i.e., 1–34% Ph-positive metaphases) was achieved in 10–15% of the patients treated, for a major cytogenetic remission rate (i.e., 0–34% Ph-positive) of 30–35%.² With the addition of other agents, particularly cytarabine, a complete cytogenetic response was achieved in up to 35% of patients and a major remission in up to 50%.^{3–7} Achieving a complete cytogenetic remission was associated with an improved survival: 78% of the patients who achieved a complete response are alive at 10 years.⁸ Patients with a partial cytogenetic remission have a survival advantage (39% at 10 years) over those with a minor cytogenetic response (i.e., 35–95% Ph-positive) or no cytogenetic response (25% at 10 years), although survival is not as favorable as that for patients achieving a complete remission. Thus, the goal of therapy in the IFN- α era became achievement of a complete cytogenetic remission, in contrast to the hematologic response, which was the goal of therapy in the hydroxyurea/busulfan era.

Among patients who achieve a complete cytogenetic remission, there is a significant variability in terms of their molecular response. Patients who retain high levels of minimal residual disease by quantitative polymerase chain reaction (Q-PCR) have a high probability of relapse, whereas 80% of those with levels <0.045% remained in remission after 3 years.⁹ Furthermore, approximately 30% of patients who achieve a complete cytogenetic remission have undetectable disease by PCR (i.e., achieve complete molecular remission). These patients are cured from CML, with none having relapsed after a median follow-up of 10 years.⁸ Among those with residual disease by PCR, 40–60% have remained in cytogenetic remission after 10 years in what has been called “functional cure.” Although this finding emphasizes the significance of achieving a molecular remission, it also points to the

fact that some patients might live with low levels of minimal residual disease with no clinical evidence of CML. This has been attributed to immune mechanisms stimulated by IFN- α . In fact, cytotoxic T lymphocytes specific for PR1, a peptide derived from proteinase 3, which is overexpressed in CML, are found in patients in complete remission after IFN- α therapy (or SCT) but not in those without complete cytogenetic remission or those treated with chemotherapy.¹⁰ These lymphocytes may be responsible for the elimination or control of the residual leukemic cells.

STEM CELL TRANSPLANTATION (SCT)

The results, techniques, and practical aspects of SCT will be described in detail in Chapter 37. However, some important aspects of SCT in CML and its integration with other treatment options are discussed here. First, SCT may be curative for a significant fraction of eligible patients who receive a transplant from a human leukocyte antigen (HLA)-identical sibling. Unfortunately, because of the requirements for age, adequate organ function and performance status, and availability of donor, only a fraction of patients are eligible for this procedure. The expected proportion of all patients with CML that may be eligible for a stem cell transplant is unknown, but considering that the median age is 66 years,¹¹ it is probably a small percentage.

The expected results with this procedure can be exemplified by a recent series from Seattle.¹² This study used targeted busulfan plus cyclophosphamide as the conditioning regimen for 131 patients in early chronic phase with a median age of 43 years (range, 14–66 years). At 3 years, the projected nonrelapse mortality rate was 14%, and 78% were projected to be alive and free of disease. Among survivors, 60% had extensive chronic graft-versus-host disease (GVHD) 1 year after transplantation, but only 10% had a Karnofsky score less than 80%. Interestingly, 11% of patients had minimal residual disease documented by PCR, but had not relapsed at the time of the report, suggesting that a mechanism such as immune surveillance could prevent relapse of the disease.¹² This phenomenon would be similar to the “functional cure” described with IFN- α . Occasionally, patients may relapse many years after SCT. Few series have analyzed the very long-term results of SCT, and thus the magnitude of this problem is difficult to measure. A recent series analyzed the very long-term follow-up of 89 patients transplanted at a single institution.¹³ Twenty-eight (32%) were alive 10 or more years after their transplant. The mean time to hematologic or cytogenetic relapse was 7.7 years, with five patients relapsing more than 10 years after transplantation.

Results with SCT for patients transplanted in more advanced stages of the disease (accelerated or blast

phase) are worse, with 5-year survival probabilities of 40–60% for patients in accelerated phase and 10–20% for those in blast phase. Patients in blast phase who are transplanted in second chronic phase may have long-term outcomes similar to those of patients in accelerated phase. For patients who do not have a sibling donor, transplantation from a matched unrelated donor (MUD) is an option. The results with MUD transplants have been inferior, mostly because of the increased risk of GVHD. The long-term disease-free survival rate after MUD transplant for young patients transplanted within 1 year from diagnosis is 57% compared to 67% for those receiving transplants from matched siblings.¹⁴ The results with MUD are, however, improving in recent years with decreasing rates of GVHD and improving probability of long-term survival with the use of molecularly matched donors, although this may further limit the availability of donors. In an attempt to make the SCT option available to more patients, nonmyeloablative transplants have been used for those of older age or with other health considerations that would otherwise prevent them from receiving a SCT. Long-term results are not yet available with these techniques, but early results in small series report disease-free survival rates as high as 85% at 70 months.¹⁵ If these results hold in larger series with long-term follow-up, stem cell transplant would be applicable for the more typical patients (i.e., median age 66 years) who have matched sibling donors. The use of alternative donors, such as cord blood or haploidentical donors, is still in early investigational stages and has not demonstrated any advantage over nontransplant investigational options.

One important aspect to consider in the setting of other effective treatment options is the timing of SCT. Earlier results from the IBMTR suggested that SCT performed after 12 months from the time of diagnosis had a significantly inferior outcome. Recently, it has been suggested that transplant within the first 24 months,¹⁶ and in some series within 36 months,¹⁷ have similar outcomes to those performed within the first 12 months. Thus, decisions regarding SCT must be made early and reevaluated at early time points in patients who are treated with imatinib but are transplant candidates. These considerations will be further discussed later in the chapter.

Another important consideration is the possible effect that prior therapy with other agents may have on the results expected with stem cell transplant. Some studies had suggested that prior therapy with IFN- α adversely affected the outcome after transplantation.¹⁸ However, several subsequent trials demonstrated that no such adverse effect exists.^{19–22} Some early observations suggest that prior therapy with imatinib has no adverse impact on the outcome after SCT.^{23,24} Although these observations are still limited and have short follow-up, there is little reason to believe that a significant effect may be observed.

IMATINIB MESYLATE

The first clinical use of imatinib mesylate (imatinib) in CML was among patients who had failed prior therapy with IFN- α -based therapy or who could not tolerate this therapy. In a dose-finding study, using daily doses of 25–1000 mg daily, few responses were observed at doses of up to 250 mg daily.²⁵ However, 98% of patients receiving a dose of at least 300 mg daily achieved a complete hematologic response (CHR), and 54% achieved a cytogenetic response. In addition, imatinib proved to be well tolerated at doses up to 1000 mg, with no dose limiting toxicity identified, and a maximum tolerated dose was not reached.²⁵ A dose of 400 mg daily was selected for a subsequent study including 454 patients in late chronic phase who had failed or were intolerant to IFN- α therapy.²⁶ At the most recent update, a CHR was achieved in 95% and a major cytogenetic response in 60% (complete in 48%). After a median follow-up of 18 months, the progression-free survival rate was 89%, and 95% of the patients were alive.²⁶ Similar results have been reported in more recent, smaller series.^{9,10} The use of imatinib in this setting is now over 5-years old, and longer-term follow-up has been reported in a cohort of 261 patients treated at a single institution.²⁷ A major cytogenetic response has been achieved in 73% of patients, including a complete response in 61%. Responses have been durable, with over 90% of patients who achieved a complete cytogenetic response maintaining a major response. With a median follow-up of nearly 4 years, 80% of patients were alive and free of progression and 86% are alive. More importantly, the molecular responses to imatinib have continued to improve, with 31% of patients with a BCR-ABL/ABL ratio of <0.05% and 15% with undetectable BCR-ABL transcripts by nested PCR. These results show that the favorable response to imatinib is durable after 4 years for the majority of patients; these results may continue to improve with continuation of therapy.²⁷

These favorable results have been confirmed with imatinib in early chronic-phase CML when used as first-line therapy. A multicenter randomized trial compared imatinib with IFN- α and low-dose ara-C in patients with previously untreated, early chronic-phase CML (IRIS trial).²⁸ After a median follow-up of 18 months, the estimated rate of a major cytogenetic response was 87% in the imatinib group and 35% in the IFN- α plus ara-C group ($p < 0.001$). The estimated rates of complete cytogenetic response were 76% and 15%, respectively ($p < 0.001$). At 18 months, the estimated rate of freedom from progression to accelerated or blastic phase was 97% in the imatinib group and 92% in the IFN- α group ($p < 0.001$). The toxicity profile and quality of life were significantly better for patients treated with imatinib.²⁹ However, a survival advantage could not be demonstrated in this study for patients treated with imatinib, mostly due to

early crossover from IFN- α to imatinib (by protocol design or by patient's choice) in over 85% of the patients randomized to IFN- α . An analysis of imatinib-treated patients compared to a historical control treated with IFN- α -based therapy shows the significant survival advantage that would be expected with the higher rate of cytogenetic and molecular responses seen with imatinib.³⁰ A recent update of the IRIS trial reported a rate of complete cytogenetic response of 86%. These responses have been durable, with 93% of patients who achieved a complete cytogenetic response still having this response after 60 months. The estimated survival free of transformation at 5 years is 93% and the overall survival is 89% (95% if only CML-related deaths are considered). Another independent series of 50 similar patients treated with the standard dose (400 mg) of imatinib reported similar results: a major cytogenetic response in 90% and a complete cytogenetic response in 72%.³¹ Thus, imatinib has become the standard initial therapy for patients with CML. A discussion regarding the decision between transplant and imatinib and treatment algorithms will be presented at the end of this chapter.

DOSE

The standard imatinib dose for patients treated in chronic phase is 400 mg daily. The selection of this dose after the dose-finding phase I study was somewhat arbitrary, as no dose limiting toxicity was identified at doses of up to 1000 mg daily.²⁵ It also provided some suggestion of improved responses with higher doses, as few responses were observed at the lowest doses, and 53% of those treated with 140–250 mg daily had a hematologic response (11% had a cytogenetic response). Nearly all patients treated at doses of 300 mg or higher had a hematologic response and 54% achieved a cytogenetic response.²⁵ Thus, current recommendations are to avoid treating patients with less than 300 mg of imatinib daily. Furthermore, there is a growing evidence that higher doses of imatinib (600–800 mg daily) may result in significantly higher response rates (and faster responses) compared to the standard dose. One study used 800 mg daily for patients who had failed prior IFN- α -based therapy but had never received imatinib.³² A complete cytogenetic response was achieved in 90% of the patients, compared to the historical 48% with standard dose in a similar population. More importantly, 50% of the patients had undetectable levels of BCR-ABL with nested PCR.³² A subsequent study used the same approach for untreated patients with CML in early chronic phase. Among 114 such patients treated with 800 mg of imatinib daily (in two divided doses of 400 mg), a complete cytogenetic response was achieved in 90%, most within 6 months of the start of therapy. After 18 months of therapy, 28% of the patients had undetectable BCR-ABL by nested PCR,

compared to 4–10% with standard dose imatinib.³² A third study, from a different group, used 600 mg of imatinib and previously untreated patients with early chronic-phase CML, increasing the dose to 800 mg if responses were not progressing according to predetermined desired endpoints. After 6 months of therapy, 79% of patients had achieved a complete cytogenetic response. Patients who received the target dose with no dose reductions had a significantly better molecular response than those receiving lower average doses, even if higher than the standard, suggesting improved molecular responses with increasing doses.³³ Thus, although today the standard dose of imatinib for chronic-phase CML is still 400 mg daily, the data summarized above suggest that this may be changing in the near future.

MONITORING

For many years, hematologic response was the goal of therapy with agents such as hydroxyurea and busulfan. The most important legacy of the IFN- α era was to demonstrate that achieving a cytogenetic response would prolong the survival of patients with CML.^{8,34} The goal of therapy became achieving a major, and particularly a complete cytogenetic response. With most patients achieving a complete cytogenetic response on imatinib, the goal of therapy is shifting again now toward achieving a molecular response. Eliminating all evidence of minimal residual disease (at least according to currently available techniques) is associated with improved probability of long-term remissions in many tumors. This is clearly true also in CML.

The clinical significance of molecular monitoring in CML is best documented in patients treated with an SCT. Patients who have BCR-ABL detectable by PCR, particularly if later than 6 months after transplant, have a significantly higher probability of relapse.^{35,36} Furthermore, Q-PCR has become an important tool to determine the risk of relapse. Patients with the highest levels of BCR-ABL transcripts have the highest risk of relapse.^{35,36} Molecular monitoring with Q-PCR is thus routine after SCT. Indeed, early intervention (e.g., donor lymphocyte infusion) is frequently indicated based on increasing levels of BCR-ABL transcripts, with the best results obtained when intervention occurs at the first evidence of relapse. Among patients treated with IFN- α , there is a considerable heterogeneity in the levels of BCR-ABL transcripts detectable among those who achieve a complete cytogenetic response. However, the risk of relapse is minimal for patients with levels below the median, while most of those with higher levels lose their response.⁹ Indeed, approximately one-third of patients who achieve a complete cytogenetic response have undetectable BCR-ABL transcripts by nested PCR, and none of these patients has lost this response after 10 years.⁸

Despite the relatively brief follow-up available for patients treated with imatinib, there is mounting evidence that molecular monitoring has important clinical implications. The IRIS trial demonstrated a significantly improved molecular response with imatinib compared to IFN- α at each time point from the achievement of complete cytogenetic response.³⁷ Overall, after a median follow-up of 18 months, nearly 40% of the patients treated with imatinib had a 3-log reduction of BCR-ABL transcripts, and 4–10% had undetectable BCR-ABL levels. This magnitude of response was rare among patients treated with IFN- α . This may have been due, in fact, to the short follow-up for patients treated with IFN- α , as over 80% of patients crossed over to the imatinib arm after a short period of time. Still, with the significantly higher rate of complete cytogenetic responses achieved with imatinib, it is likely that a significant difference would have been observed even if patients had continued IFN- α therapy. Furthermore, obtaining a molecular response earlier has important clinical implications. Among patients who achieved a complete cytogenetic response with imatinib, those who had at least a 3-log reduction in BCR-ABL transcripts at 12 months from the start of therapy had a significantly better probability of progression-free survival compared to those who had a less pronounced reduction.³⁷ In another study of patients in chronic phase, who had achieved a complete cytogenetic response after imatinib therapy, those who achieved levels of BCR-ABL/ABL ratio of <0.05% (i.e., major molecular response) had a significantly lower probability of losing their cytogenetic response compared to those who did not reach these levels.³⁸ The difference was even more significant when considering only patients who achieved a complete molecular response (i.e., undetectable BCR-ABL). Similarly, those who had achieved a major molecular response after 12 months of therapy had a significantly better predicted probability of a sustained complete cytogenetic remission.³⁸ A third study with a relatively smaller cohort of patients confirmed a longer duration of complete cytogenetic response for patients who had a maximum reduction of BCR-ABL transcripts of at least 2 logs.³⁹ It has also been suggested that patients who have lower levels of transcripts detectable after the first few months of therapy with imatinib have a significantly lower probability of developing point mutations conferring resistance to imatinib. Thus, it is evident from these studies that the objective of therapy in the imatinib era should be to achieve at least a major molecular response, and that achieving this response early increases the probability of a long-term durable response.

A recommended algorithm for monitoring patients receiving therapy with imatinib is presented in Table 18.1. At the time of diagnosis, it is recommended that all patients have a regular karyotype as well as Q-PCR

Table 18.1 Recommendations for monitoring of patients treated with imatinib

Timing	Recommended tests and frequency
At diagnosis	• Cytogenetics, Q-PCR, ?FISH
First year	• Cytogenetics every 3–6 months • Q-PCR every 3–6 months
After first year	• Cytogenetics every 6–12 months • Q-PCR every 3–6 months

Q-PCR = quantitative polymerase chain reaction; FISH = fluorescent in situ hybridization.

(real-time PCR) done. As will be discussed later in this chapter, the first 12 months of therapy may be the most critical to establish the long-term prognosis of the patient, and therefore to make treatment decisions. Thus, during these first months, repeat monitoring is recommended every 3–6 months. This should include Q-PCR and cytogenetics. The major inconvenience of monitoring with cytogenetics is the need for a bone marrow aspiration. However, this is the only test to date that gives reliable information regarding other chromosomal abnormalities. The presence of additional chromosomal abnormalities may reduce the probability of response to imatinib and the overall survival.^{40–42} In addition, 6–8% of patients who respond to imatinib may develop chromosomal abnormalities in the Ph-negative metaphases.^{42–44} Although the long-term implications of these abnormalities are still uncertain, it is important to recognize and follow this phenomenon. After the first 12 months of therapy, Q-PCR should be performed at least every 6–12 months and a routine cytogenetic analysis every 12 months. Fluorescent in situ hybridization can be used to monitor the cytogenetic response between cytogenetic analysis, as it can be done in peripheral blood. However, even with the newest probes, there is a small percentage of false positivity. For the determination of molecular response, a Q-PCR (i.e., real-time PCR) is needed. Unfortunately, this test is not widely available. Furthermore, there is considerable heterogeneity between the reports from different laboratories, and the results from many laboratories that offer this test have not been clinically validated. In addition, the analysis of the results from the IRIS trial, the largest to date to report on molecular monitoring, initiated molecular monitoring only after the patients achieved complete cytogenetic response. To determine the log reduction at different time points, a baseline was derived from results obtained from 30 patients. Thus, a 3-log reduction in fact corresponds to levels of <0.036%, which is a 3-log reduction from the standardized base line of 36% for the sample cohort. Using each patient's individual baseline value to determine the 3-log reduction has not been validated as an important endpoint.

CONTINUATION OF THERAPY

Once a patient starts therapy with imatinib, early endpoints are predictive of longer-term response and should be followed carefully. The initial report on patients in chronic phase treated with imatinib after IFN- α failure showed that patients who have no cytogenetic response after 3 months of therapy have only a 12% probability of later achieving a complete cytogenetic response with continuation of therapy. In contrast, patients who have achieved at least a minor cytogenetic response after 3–12 months of therapy have a 35–50% probability of later achieving a complete response.⁴⁵ A similar analysis of patients with previously untreated chronic-phase CML derived from the IRIS population has recently been presented.⁴⁶ Patients with no or minor cytogenetic response after 3 months of therapy have a 50% probability of achieving a complete cytogenetic response at 2 years. However, patients with no cytogenetic response after 6 months of therapy have only approximately a 10% probability of achieving a complete cytogenetic response at 2 years, compared with 50% for those with at least a minor response. After 12 months of therapy, only those patients who have achieved a partial cytogenetic response have a reasonable probability of achieving a complete response with continuation of therapy.⁴⁶ These observations have been incorporated into the treatment algorithm proposed in Figure 18.1.

DISCONTINUATION OF THERAPY

An important consideration is whether imatinib therapy can be safely discontinued for patients who have an adequate response (e.g., complete cytogenetic or molecular response) and if so when to do it. There is only limited published information in this regard, including case reports or small series.^{47–49} Two patients have been reported to have a sustained response after discontinuation of therapy. However, one series of three patients and one patient from another series have all lost their response after discontinuation of therapy following a complete molecular response. Interestingly, the responses were lost rapidly (i.e., within 3–6 months) after discontinuation of therapy, uncovering more rapid kinetics of the disease than are traditionally recognized. In at least two patients where imatinib was reinitiated, patients again rapidly responded, suggesting that resistance to imatinib had not evolved, but rather that continuation of therapy was required. It has been suggested that the earliest, probably quiescent, progenitor cells in CML are insensitive to imatinib *in vitro*.⁵⁰ It is conceivable that these progenitors might trigger proliferation of leukemia once the inhibitory pressure of imatinib is eliminated. In view of these observations, even when limited, the current recommendation is to continue therapy with imatinib indefinitely.

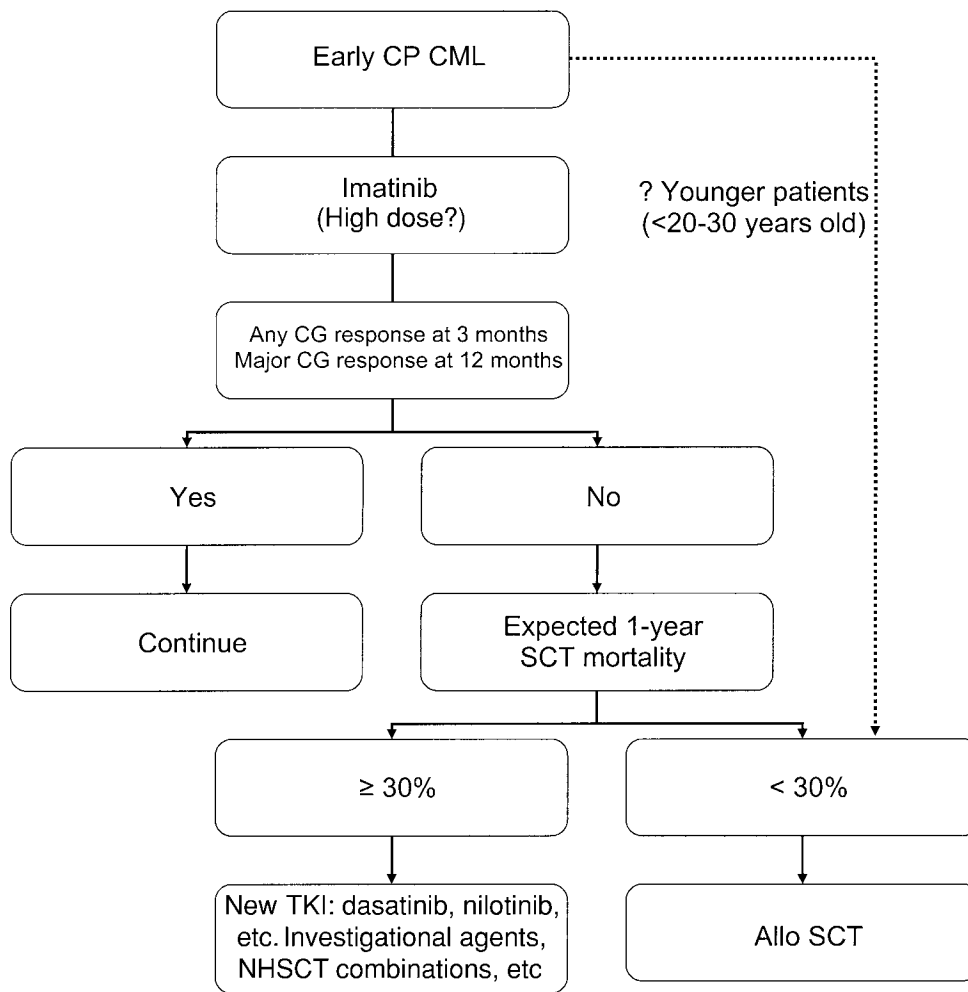

Figure 18.1 Proposed treatment algorithm for patients with CML in early chronic phase. TKI, tyrosine kinase inhibitors)

MANAGEMENT OF MYELOSUPPRESSION

Overall, imatinib is well tolerated. Probably the most common adverse event with imatinib is myelosuppression. Grade 3 or higher neutropenia (i.e., neutrophils $<1 \times 10^9/L$) occurs in up to 35–45% of patients, and thrombocytopenia in 20–25%.^{26,28,32,51,52} Severe anemia is less common, occurring in 5–10% of the patients. All of these are more common in patients who have failed prior therapies (e.g., IFN- α), and are dose-related, occurring more frequently among patients treated with higher doses. Patients who develop grade 3 or higher neutropenia or thrombocytopenia may have a lower probability of achieving a cytogenetic response. The adverse prognosis is particularly noticeable among patients whose myelosuppression lasts longer than 2 weeks.^{51,53} This has been attributed to a decreased dose intensity, as the current recommendation is to interrupt therapy in patients who develop this degree of myelosuppression and reduce the doses for those who take more than 2 weeks to recover.⁵⁴ To try to overcome these events, hematopoietic growth factors have been used. Most patients who develop neutropenia respond rapidly to the use of filgrastim (G-CSF)^{55–57,}

allowing for more continued therapy with imatinib and improved response in many instances. A similar effect has been reported with oprelvekin (interleukin-11) for patients with thrombocytopenia.⁵⁸ Patients with anemia do not carry an inferior prognosis.⁵⁹ This is probably due to the fact that most patients have only grade 1 or 2 anemia, and it is not currently recommended to interrupt therapy for anemia grade 3 or higher. There have been reports about the effective use of erythropoietin^{59,60} and darbepoetin⁶¹ for these patients. Although these short series suggest that the use of these growth factors is safe in these settings, their use is not currently standard or approved and should be considered with caution. In addition, most patients who develop myelosuppression will not need hematopoietic growth support. This adverse event is more frequently seen during the first few months of therapy. Treatment interruption is frequently all that is needed for recovery, and most patients will not even require dose reductions. Myelosuppression after the first 3 months of therapy is less common and it is in this setting that it may represent a more significant management problem, particularly when prolonged or recurrent.

Table 18.2 Management of adverse events associated with imatinib therapy**Myelosuppression**

Monitor CBC weekly for 2–3 months, then every 4–6 weeks

Hold therapy for grade ≥ 3 neutropenia or thrombocytopenia:

- ANC $< 1 \times 10^9/L$
- Platelets $< 50 \times 10^9/L$

Do not hold for anemia

Monitor CBC at least weekly after holding

Restart when ANC $\geq 1 \times 10^9/L$, platelets $\geq 50 \times 10^9/L$

- If recovery occurs within 2 weeks, restart at the same dose
- If recovery takes longer than 2 weeks, decrease the dose (not less than 300 mg/d)

Consider use of growth factors (G-CSF, IL-11, EPO) for patients with recurrent myelosuppression

Nonhematologic toxicity

Manage grade ≤ 2 toxicity early. Some suggestions include

Adverse event	Management
Nausea	Antiemetics (Compazine, Zofran, etc)
Diarrhea	Anti-diarrhea (Imodium, Lomotil, etc)
Skin rash	Topical and/or systemic steroids, antihistamines
Peripheral edema	Diuretics
Periorbital edema	Preparation H
Muscle cramps	Tonic water, quinine, calcium supplements
Bone aches	Nonsteroidal anti-inflammatory agents
Liver dysfunction	Monitor frequently

Hold therapy for grade ≥ 3 toxicity or persistent grade 2 toxicity not responding to optimal management
Restart therapy at a lower dose when toxicity resolves to grade ≤ 1

CBC, complete blood count; ANC, absolute neutrophil count.

MANAGEMENT OF OTHER TOXICITIES

Although nonhematologic adverse events are relatively common with imatinib, these are frequently mild, and can be managed easily. Grade 3 or higher adverse events are seen seldomly, and only 2–3% of the patients require permanent discontinuation of therapy because of toxicity. A guideline for the management of the most common adverse events is presented in Table 18.2. Early intervention is important to help avoid more significant problems and unnecessary treatment interruptions and dose reductions. There has been some concern regarding the possibility of late adverse events with prolonged therapy with imatinib in view of its inhibition of c-kit and platelet derived growth factor receptor (PDGFR). However, to date, there is no evidence of any unexpected late complications.

TREATMENT RECOMMENDATIONS

The most complex and controversial aspect of therapy is the treatment algorithm for a patient with previously untreated CML in early chronic phase. The results with imatinib, particularly with higher doses, are excellent. The one major drawback of imatinib treatment is the relatively short follow-up, as this modality has been used for patients with previously untreated chronic-phase CML for only approximately 6 years and as a first line of therapy for approximately 5 years. As the results continue to improve, imatinib would become the preferred therapy for all patients, as it is associated with minimal toxicity and with no treatment-related mortality. If an extrapolation can be made from the IFN- α data, it is reasonable to expect that a significant proportion of patients may be cured with imatinib. Seventy-eight percent of patients who achieve a complete cytogenetic response with IFN- α are alive after 10 years, but only 25–35% of patients achieve this response with IFN- α -based therapy. With imatinib, 80–90% of patients achieve this response. Responses also occur earlier with imatinib, and early responses are associated with an improved long-term outcome. More importantly, the rate of molecular responses is significantly higher with imatinib, suggesting that there are not only more, but better responses with this agent compared to IFN- α . However, the immune modulation that is associated with IFN- α therapy is lacking with imatinib. Immune phenomena are thought to be responsible for the long-term durable cytogenetic and hematologic responses after IFN- α therapy, even in the setting of minimal residual disease (i.e., “functional cures” or dormant state).^{10,62} Allogeneic SCT can be curative in a significant proportion of patients eligible to receive this approach. Besides availability of a donor and age, the major consideration of whether or not to pursue this therapy is the risk of early mortality and the long-term complications. Early mortality is usually lowest among younger patients, particularly those younger than age 20–30 years. Most studies of SCT emphasize the results in the first few years, but late relapses and complications should also be taken into consideration. Extensive chronic GVHD can be seen in as many as 60% of the patients treated,¹² and late relapses can occur in some patients.¹³ All of these issues need to be evaluated when deciding on SCT, and the local experience at the site where the transplant is to be performed needs to be taken into account. When alternative transplant options are being sought, the increased risks and lack of long-term data should be recognized. Matched unrelated transplants may be associated with increased mortality and GVHD, although molecular matching has decreased these risks considerably. Thus, if the local experience is favorable, these transplants could be considered for younger patients.

Nonmyeloablative conditioning regimens have allowed offering transplantation to patients in older age groups or with comorbid conditions. The early mortality is decreased with these transplants, though late complications may be similar to full ablative regimens. These are still relatively new options and there is little long-term data on efficacy and late complications. As longer-term follow-up becomes available regarding the incidence of late relapses and complications, these options may become more standard. Transplantations with alternative donors, such as mismatched and haploidentical donors and umbilical cords, should be considered investigational and considered only when other options have failed.

For a patient who has no option for a stem cell transplant, the decision regarding frontline therapy is simple and the treatment of choice is undoubtedly imatinib. More controversial at this time is the proper dose at which treatment should be initiated. The standard dose is 400 mg daily. However, as mentioned earlier, results with higher doses have strongly suggested that these doses are more effective and well tolerated for the majority of patients. Ideally, all patients should be included in clinical trials looking at either high-dose imatinib or imatinib-based combinations. Several trials of this nature are currently being performed around the world. For the patient who will not be entered in a clinical trial, although higher doses may be preferred, they may not be practical for financial or other considerations. In such instances, the standard dose can be initiated. Close monitoring is of the utmost importance in such cases, and increasing the dose when response goals are not being met at the desired times should be encouraged.

The decision regarding therapy is more complicated and controversial for young patients who have a fully matched sibling. Results with transplant are best among those younger than age 25–30 years, and SCT should be given consideration. As a patient's age increases, the risks involved with transplantation also increase. For most patients, an initial trial with imatinib is probably adequate. However, if the decision is made to start therapy with imatinib, it is important, particularly in the case of the younger patients with an adequate sibling donor, to monitor the patient closely with cytogenetic and molecular monitoring to be certain that the response is progressing as desired.

The proposed ideal goals for patients being treated with imatinib are presented in Table 18.3. For a patient who has not achieved a hematologic response by 3 months, or a minor cytogenetic response by 6 months or partial by 12 months, changing therapies should be strongly considered. What the alternative therapy should be in these cases varies from patient to patient. Increasing the dose of imatinib to 800 mg daily would be the first choice for patients who are being treated with standard dose of imatinib and have had no significant nonhematologic toxicity. If the patient has had hematologic toxicity at the lower doses, the use of hematopoietic growth factors can be considered. For patients who have already been taking higher dose imatinib, and who have the option of an allogeneic stem cell transplant, this option should be considered if the expected 1-year mortality is <40%.

Some scenarios are controversial, and sufficient information may be lacking to make strong recommendations. Patients who achieve a complete cytogenetic remission but have less than a 3-log reduction in transcript levels have a worse prognosis than those who have at least a 3-log reduction. However, the progression-free survival at 3 years is still 92% and it probably does not justify a change in therapy, particularly when there is a significant risk of mortality or other serious complications. Patients who show an increase in transcript levels after reaching a nadir also pose a dilemma. It has been suggested that a twofold increase may herald the appearance of mutations,⁶³ but this data has not been confirmed by other studies. Also, the short survival proposed for patients with P-loop mutations has not been confirmed in other studies. Thus, at this time, strong recommendations cannot be made based on molecular monitoring alone, particularly when the risks involved with the proposed new therapy are high. The same can be said about the appearance of chromosomal abnormalities in Ph-negative metaphases that occurs in up to 16% of patients. The few instances in which such patients have been diagnosed with myelodysplastic syndromes have been based on soft criteria. Indeed, in many instances these abnormalities may spontaneously disappear. Thus, in the absence of clear data suggesting that these changes affect the long-term outcome of patients, they deserve no more than careful monitoring.

Table 18.3 Recommendations regarding continuation of therapy with imatinib by response at various times after initiation of imatinib therapy

Response	Months of treatment			
	3	6	9	12
No CHR	Change	Change	Change	Change
CHR, >95% Ph-positive	Continue	Change	Change	Change
CHR, 35–95% Ph-positive	Continue	Continue	Continue	Change
CHR, 1–35% Ph-positive	Continue	Continue	Continue	Change

CHR, complete hematologic response.

CONCLUSION

The introduction of imatinib has changed our considerations for treatment for patients with CML in chronic phase. For most patients, imatinib should be the standard and therapy should be optimized with the intention to achieve a molecular remission as early as possible. Controversy exists regarding the ideal

strategy for young patients with the option of an allogeneic stem cell transplant, and probably either option is appropriate as a first-line therapy. Adequate management is particularly important in these patients if one is to optimize the probability of achieving long-term durable remissions and minimize the risks for the majority of patients with CML.

Chapter 19

TREATMENT APPROACH TO ACCELERATED-PHASE OR BLAST-CRISIS CHRONIC MYELOGENOUS LEUKEMIA

Eric J. Feldman

INTRODUCTION

Until recently, the progression to blast phase was considered inevitable for almost all patients with chronic myelogenous leukemia (CML).¹ Except for a minority of patients able to tolerate interferon and achieve a complete cytogenetic response, or for those with an HLA-matched sibling and young enough to survive a bone marrow transplant, most patients entered the blastic phase of CML and died within 6 months to a year.² Fortunately, advances in both transplantation and nontransplantation therapy have improved the outlook for patients with chronic-phase CML, and by extension, have changed the way in which patients entering the blast phase present and are approached therapeutically.

Imatinib mesylate, widely available by the year 2000, is currently the initial treatment of choice for the majority of patients with CML. Although follow-up is short, preliminary results have demonstrated that close to 80% are achieving complete remissions and less than 10% of the patients have progressed to blast phase by 4 years.³ Concurrently, the development of large marrow donor registries, coupled with improved transplantation techniques for older patients and for those undergoing unrelated donor transplants, have led to an increased use of transplantation for patients unresponsive to imatinib, who in the past would have been deemed ineligible for this procedure.⁴

Although the duration of response to imatinib is still unknown, and concerns over drug resistance have emerged, several situations seem probable: (1) a significant percentage of patients treated with imatinib will be long-term survivors and will not enter the blast phase; (2) patients entering the blast phase of disease will have already been treated with imatinib, which may influence their ability to respond to subsequent

therapy; and (3) an increasingly higher percentage of chronic-phase CML patients will undergo hematopoietic stem cell transplantation at the development of clinical or laboratory evidence of imatinib failure with an expanding pool of “acceptable” donors. It is with this background we can examine the treatment options available to patients in the advanced phases of CML.

IMATINIB MESLATE IN ACCELERATED- AND BLAST-PHASE CML

Although it is unlikely that patients, nowadays, will enter blastic or accelerated phase without having received prior treatment with imatinib, it is worthwhile to review the results of imatinib therapy in imatinib-naïve patients for historical interest, as well as to gain some understanding of the role of bcr/abl in the growth and proliferation of CML cells during transformation to the blast phase.

The clinical development of imatinib mesylate followed the traditional development of cytotoxic agents in leukemia with the finding of the maximally tolerated dose in a phase I study⁵ and then subsequent phase II evaluations in subsets of CML patients. Two separate trials evaluated the efficacy of imatinib in CML patients in accelerated phase and in blastic phase, with further subset analysis of patients in either myeloid or lymphoid blast transformation.⁶⁻¹⁰

The accelerated-phase study, reported by Talpaz et al.,⁶ included 181 confirmed patients with accelerated phase as defined by a set of criteria that had been demonstrated retrospectively to correlate with survival rates compared to chronic-phase patients, and that were different than that of blastic-phase patients. These criteria included the presence of 15–30% blasts, or 30% blasts and promyelocytes, or 20% basophils in the

blood or marrow, or a platelet count less than 100×10^3 /L unrelated to anticancer therapy. Patients were treated with 400 or 600 mg of imatinib daily. Overall, 69% of the patients achieved a sustained hematologic response, 34% complete, and the rest either achieved a blast percentage in the marrow under 5% with incomplete peripheral blood recovery (marrow response) or a return to a second chronic phase (no criteria for accelerated disease as defined above). The rate of complete cytogenetic response was 17%, and the 1-year progression-free and overall survival was 59 and 74%, respectively. Patients treated with 600 mg compared to 400 mg realized greater benefit with a higher overall cytogenetic responses (28% vs 16%) and better progression-free and overall 1-year survival rates (67 and 78% vs 44 and 65%), with no significant increases in toxicity.

Although the definition of accelerated phase of CML by hematologic criteria, as outlined above, was used in the initial studies of imatinib, subsequent patients have been labeled accelerated phase purely on the basis of clonal evolution, i.e., the development of chromosomal abnormalities in addition to a single t(9;22). In an analysis by O'Dwyer et al., the results of treatment with imatinib at a dose of 600 mg was evaluated based on the criteria used for defining accelerated phase.¹¹ Patients with accelerated disease based on hematologic criteria without clonal evolution had a significantly worse response rate and time to treatment failure compared to patients with clonal evolution as the sole criterion for defining accelerated disease. Patients with clonal evolution alone had a major cytogenetic response rate of 73% and a treatment failure rate at 1 year of 0% compared to a major cytogenetic response rate of 31% and a 1-year treatment failure rate of 28% in patients with hematologic criteria alone for accelerated disease. Patients with both hematologic and clonal evidence of accelerated disease did the worst of all three groups, with cytogenetic response rates of 12.5%, a 1-year treatment failure rate of 67%, and a median time to treatment failure of 8 months. This experience suggests that patients with clonal evolution alone, without other evidence of accelerated disease, have a similar response rate to that of patients with chronic-phase disease, provided they receive doses of 600 mg or higher of imatinib.

The myeloid blast-phase study reported by Sawyers et al.⁹ included 229 evaluable patients with more than 30% blasts in the blood or marrow, with a myeloid phenotype demonstrated by immunophenotypic and cytochemical evaluation. As in the accelerated-phase study, patients were treated with either 400 or 600 mg of imatinib. Overall, 31% of the patients achieved a sustained hematologic response. Hematologic responses were complete in only 8% of the patients, with the majority being classified as a return to chronic phase. Major and complete cytogenetic responses were observed in 16 and 7%, respectively. Patients previously untreated for the blast phase of disease fared better, experiencing an

overall and complete hematologic response (CHR) rate of 36 and 9%, compared to 21 and 6%, respectively, for patients who had received prior induction chemotherapy for blast-phase disease. Major cytogenetic responses were observed in 16% of the patients, in whom 7% were complete. The median survival for all patients was 6.9 months, with 32% of the patients still alive at 1 year. The impact of the dose of imatinib was significant, with overall hematologic responses of 34% for patients treated with 600 mg compared to 9% for patients receiving 400 mg of imatinib. Cytogenetic responses were also significantly better with the higher doses of imatinib (18% vs 6%).

Transformation of CML to a lymphoid blast phase is less common than myeloid transformation, and patients in this category treated with imatinib have been grouped together with patients with Ph+ acute lymphoblastic leukemia. In both phase I and phase II studies, imatinib demonstrated efficacy in lymphoid blast-phase patients similar to responses seen in patients with myeloid blast phase.¹⁰ Overall, 25% of the patients in lymphoid blast phase achieved a sustained hematologic response to imatinib, but responses were generally of short duration, with a median time to progression of 2.2 months. Similar to patients with Ph+ ALL, imatinib alone has limited efficacy in lymphoid blast phase, and further development is based on the incorporation of imatinib into chemotherapy-based regimens.¹²

In addition to the inability of imatinib alone to control established lymphoid blast disease, imatinib has been shown, in some instances, to fail to prevent the onset of lymphoid transformation in patients in chronic phase. Sudden onset of blast-phase disease, especially lymphoid transformation, has been observed in patients prior to the development of imatinib, including patients who had a complete cytogenetic response on treatment with interferon alpha or postallogeic transplantation.¹³ Recent observations have demonstrated a similar phenomenon in patients in cytogenetic remission on imatinib.¹⁴ In addition, complete response to imatinib does not protect against the development of meningeal involvement by lymphoid blast cells. In several patients, meningeal relapse occurred despite control of marrow disease.¹⁵ Imatinib levels in these patients were demonstrated to be approximately 2 logs lower in the cerebrospinal fluid compared to plasma.¹⁶

The results of these trials in patients with advanced phases of CML have demonstrated that imatinib, a relatively specific tyrosine kinase inhibitor of bcr/abl, was effective in inducing sustained responses, which compared favorably to results with more intensive chemotherapy-based regimens. Importantly, imatinib's biologic activity in these patients with advanced disease demonstrated that signal transduction mediated by the BCR/ABL protein was still a relevant target for therapeutic inhibition, but that mech-

anisms of resistance, genetic reexpression or mutation of BCR/ABL, and/or clonal evolution, leads to eventual loss of clinical activity and progression of disease.^{17,18} Efforts to overcome resistance have included dose escalation of imatinib¹⁹ and the addition of other chemotherapeutic or molecularly directed agents to imatinib.^{20,21} Other efforts currently underway are the development of newer tyrosine kinase inhibitors with activity in the mutated forms of BCR/ABL.²²

CHEMOTHERAPY FOR ACCELERATED- AND BLAST-PHASE CML

Prior to the development of imatinib, the outlook for patients entering the advanced phases of CML was dismal. Chemotherapy was the mainstay for these patients, and the choice of chemotherapeutic agents generally followed the treatment plans for acute myeloid and lymphoblastic leukemia: patients with accelerated or myeloid blast phase received cytarabine/anthracycline-based regimens, while patients with lymphoid transformation received standard vincristine/prednisone-based protocols. Although imatinib may now be considered the treatment of choice for patients with CML entering the accelerated or blast phase, most patients in the future will have already received imatinib as part of treatment for chronic-phase disease, and thus chemotherapy must still be considered as an important part of therapy. What has changed, however, is that patients entering advanced phases will have been treated with imatinib, and whether this changes the efficacy of chemotherapy is yet to be determined.

Several experiences using acute myeloid leukemia AML-type chemotherapy for patients with advanced-phase CML have been published. Problems arise in the interpretation of the outcomes of these studies. First, institutional differences exist in the response criteria used, which makes the comparison of results often suboptimal. Most investigators agree on the definition of a CHR, which has been defined using acute leukemia criteria with the necessity of achieving <5% blasts in the bone marrow and recovery of neutrophil and platelet counts. Partial or incomplete responses, however, are frequently included in the overall response rates, and the definitions of responses that are not complete are inconsistent. Patients achieving all criteria for CHR, but with incomplete platelet recovery, have been designated "hematologic improvement" (HI) or complete remission with incomplete platelet recovery (CRp). Other response criteria have included the term "return to chronic phase," which has been defined differently in some series. By some criteria, this category of response requires the disappearance of blast-phase features, defined as peripheral or marrow blast percentage under 15%, basophils under 20%, blasts plus promyelocytes under 30%, and return of platelet counts to >100,000/L. Other criteria for return to a second

chronic phase have called for a blast percentage in the blood of 5% and less than 10% in the marrow, with no defined criteria for recovery of neutrophils or platelets.

In addition to problems associated with nonstandardized response criteria, differences in criteria that distinguish accelerated from blast phase have been used (discussed earlier), making comparisons between treatment outcomes unclear. An important by-product of the development of imatinib, and the international collaborations required for its rapid development, was the adoption of more universally accepted definitions of disease stage, as well as a greater standardization of response criteria. Undoubtedly, in the future this will lead to easier interpretations of clinical studies in patients with CML; however, most chemotherapy-based regimens for advanced-phase CML were evaluated prior to imatinib; therefore, making direct comparisons between studies harder.

CYTARABINE-BASED COMBINATION REGIMENS

The largest series incorporating AML-type chemotherapy in patients with myeloid blast phase (blast count > 30%) involved 162 patients treated at MD Anderson Cancer Center over an 11-year period from 1986 to 1997.²³ Ninety patients received intensive combination chemotherapy, largely high-dose cytarabine-based. Overall, 28% of the patients responded to treatment, with CHR in 8% of the patients, and an additional 7% achieving all criteria for CHR, but with incomplete platelet count recovery. In addition, 11% of the patients achieved a return to chronic phase, and 2% of the patients were termed a partial response. The duration of response was approximately 4 months, which corresponded with survival as well. In a series of patients treated at the Karolinska Hospital in Sweden,²⁴ 47% of 83 patients with accelerated or myeloid blast-phase disease, treated with an anthracycline/cytarabine-based regimen, achieved a return to chronic phase, the definition of which was less stringent than the MD Anderson data. Overall survival was similar, however, in the 4–6 month range. In this series, patients with accelerated-phase disease had similar responses to those of blast-phase, although they demonstrated a slight, but statistically insignificant, improvement in survival. These studies, as well as numerous other smaller experiences,^{25–29} have demonstrated that standard AML-type regimens have limited efficacy in advanced-phase patients and, despite widespread application, it is not clear that higher-doses of ara-C are better than standard doses in this setting.

SINGLE-AGENT THERAPY

A number of novel chemotherapeutic agents have been studied as single agents in advanced-phase disease. To

date, the most promising agents have been the hypomethylating agents, decitabine (5-aza 2'-deoxycytidine) and azacitidine (5-azacytidine). These agents act in part by reversing the methylation, or silencing, of numerous tumor suppressive genes that exert antiproliferative effects, thus potentially reversing or slowing the progression of CML. Decitabine has been the most extensively studied hypomethylating agent in CML, whereas azacitidine has been used more commonly in patients with myelodysplastic syndrome.³⁰ In a study conducted at MD Anderson Cancer Center, 64 myeloid blast-phase and 51 accelerated-phase Ph+ CML patients were treated with repetitive monthly cycles of decitabine. In blast-phase patients, 28% achieved a response, which included a CHR in approximately 9%. In accelerated patients, a 55% overall response rate, with an approximate 23% CHR rate, was observed.³¹ Response durations and survival rates were quite poor in blastic phase patients, with a 3-year survival rate of only 5%. Accelerated-phase patients had significantly better outcomes, with 3-year survival rates of 27%, again pointing out the importance of distinguishing between these stages of CML. Despite the myelosuppressive properties of decitabine, only 3% of all patients treated died of complications of cytopenias. These results suggested that single-agent decitabine, although still relatively ineffective, resulted in equivalent outcomes to that of the high-dose cytarabine-based regimens with less toxicity.

Several other agents have been tried alone or in combination with cytarabine in patients with advanced-phase CML. These have included topotecan, carboplatin, homoharringtonine, amsacrine, and mithramycin.³²⁻³⁶ None have demonstrated enhanced activity compared to standard antileukemia agents. Most recently, troxacitabine, a novel nucleoside analog, has been evaluated both in AML and in myeloid blast-phase CML.³⁷ Of particular interest is that this agent has been tested in patients either previously treated with imatinib or in imatinib-naïve patients. In an initial phase II evaluation in myeloid blast phase, 6 of 16 (37%) of patients responded to troxacitabine in a cohort in which only 3 patients had received prior treatment with imatinib.³⁸ In a subsequent larger trial, a 13% response rate was seen in 51 myeloid blast-phase patients in whom 93% had progressed on treatment with imatinib.³⁹ Although no specific data have been reported for response rates for cytarabine-based regimens or hypomethylating agents comparing outcomes by prior exposure to imatinib, the results with troxacitabine suggest that patients progressing on treatment with imatinib may be particularly resistant.

LYMPHOID BLAST PHASE

Approximately one-fourth of patients entering blast phase will have a lymphoid phenotype compared to the more common presentation of a myeloid or

undifferentiated blastic phase. Patients entering lymphoid phase are often younger and less often have a prior accelerated phase documented compared to patients entering myeloid blast phase. A sudden onset of blast phase is more common in patients entering lymphoid blast phase, and in fact can occur in patients seemingly in stable chronic phase responding to therapy with interferon and/or imatinib.⁴⁰ There appears to be no evidence that prior treatment with interferon selects for patients entering the lymphoid blast phase, however.

Therapy for patients in lymphoid blast phase is generally more successful than for patients with myeloid transformation, as more patients enter a second chronic phase, which is durable enough to consider a hematopoietic stem cell transplant (see below). In a review published by the MD Anderson Cancer Center, overall, 49% of patients responded to therapy.⁴¹ In this series, patients given traditional drugs used to treat acute lymphoblastic leukemia (vincristine, prednisone, cyclophosphamide, adriamycin) had a higher rate of return to a chronic phase compared to patients treated with high-dose ara-C or methotrexate combined with L-asparaginase (61% vs 33% and 25%, respectively). Other series, however, have demonstrated high response rates (50%+) using high-dose cytarabine/anthracycline-based regimens.⁴² Median survival rates for lymphoid blast-phase patients are approximately 9 months, compared to the median 3-4 months observed in patients with myeloid blast-phase disease. As with patients with myeloid blast phase, the impact of prior treatment with imatinib on the effectiveness of subsequent chemotherapy for lymphoid blast phase is, at present, unknown.

ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION THERAPY

Most patients with an HLA-compatible donor, sibling or otherwise, will preferentially undergo transplantation therapy while still in chronic phase.⁴³ This will occur either as initial treatment or in patients not responding to interferon or imatinib therapy. The results of transplantation therapy for patients in blast phase are poor, and many institutions are reluctant to perform this procedure unless the patient is able to achieve a second chronic phase with chemotherapy or imatinib prior to transplantation. The decision not to offer transplantation to patients with advanced-phase CML has been based on results from cooperative groups and/or large single institutions that have reported long-term survival for transplantation in blast phase of 0-14% and survival rates for accelerated-phase patients of 15-20%.^{44,45} On the other hand, since no other therapies exist for these patients that are associated with long-term survival, many patients are transplanted in advanced phases of disease for want of better treatment.

To better identify patients likely to survive transplantation, despite entering the advanced phases of disease, several groups have employed prognostic scoring systems generated from multivariate analyses of transplantation outcomes in relatively large numbers of patients. One of these scoring systems, the Gratwohl Score, based on results of transplantation in patients reported by the European Blood and Marrow Transplantation Group, has been widely used.⁴⁶ In this scoring system, a higher score (associated with a worse survival) is given based on several pre-transplantation variables predictive for poor outcome, including increasing patient age, advanced stage of disease, incompatibility of donor and recipient, prolonged time from diagnosis to transplant, and donor–recipient sex mismatch. Thus, a young patient (age, 20–40) with an HLA-identical sibling match, transplanted within 12 months of diagnosis may still be a suitable candidate for transplantation, even in the accelerated or blast phase of disease, whereas a patient above the age of 40 in blast phase undergoing a matched unrelated transplantation would have a small chance for long-term survival. Although improvement continues in the supportive care and treatment of graft-versus-host disease for patients undergoing allogeneic hematopoietic stem cell transplantation, transplantation of CML in the advanced stages should be avoided with every effort being made to identify those patients unlikely to be long-term survivors with nontransplan-

tation therapy and plan transplantation prior to disease progression to accelerated and blast phase.

FUTURE DIRECTIONS IN THERAPY FOR ADVANCED-PHASE CML

The success of imatinib will clearly result in fewer patients with CML progressing to the advanced phases. Is blastic phase CML a disease of the past? Further observational time will let us know what percent of patients with CML will be cured with imatinib. Although leukemia cells resistant to imatinib have been detected in patients with CML, this has mostly occurred in advanced-phase patients who received imatinib for the first time, having received prior treatment with other agents.⁴⁷ The incidence of imatinib resistance so far in newly diagnosed chronic-phase patients is still quite low. However, if imatinib resistance is observed, these patients will be at risk for progression to blast-phase disease, and thus future development of therapies in CML will clearly be aimed at preventing the emergence of imatinib-resistant subclones with therapies that may enhance the activity of imatinib⁴⁸ and/or the use of newer inhibitors with effectiveness in mutated forms of bcr/abl. Initial clinical investigation of these new agents are planned for advanced-phase patients progressing on treatment with imatinib.

Chapter 20

DEFINITION OF REMISSION, PROGNOSIS, AND FOLLOW-UP

Matt E. Kalaycio and Ilka Warshawsky

DEFINITION OF REMISSION

As the therapy of chronic myelogenous leukemia (CML) has improved over the years, the definitions of response have changed. Before the recognition that allogeneic hematopoietic stem cell transplant (HSCT) could cure CML, the treatment of CML was palliative. Thus, remission meant that the blood counts were normalized and symptoms were controlled. This definition is inadequate today.

Table 20.1 lists the three categories of remission in CML, namely hematologic, cytogenetic, and molecular, as well as their most common definitions.

HEMATOLOGIC REMISSION

Hematologic remission is the goal of purely palliative therapy. Hematologic remission does not impact the natural history of CML to a significant degree. In the Italian CML Study Group trial comparing palliative hydroxyurea or busulfan with interferon α , complete hematologic remission was obtained in 68–87% of patients after 8 months of any therapy.¹ Those patients treated without interferon had a median survival of 52 months and only 29% were alive at 6 years. These results are comparable to what one might expect in the absence of any therapy.^{2,3} In contrast, patients treated with either interferon or imatinib enjoy both increased hematologic remission rates and improved survival compared to hydroxyurea or busulfan. The improved survival rates achieved by interferon and imatinib stem directly from their ability to induce cytogenetic remission, a characteristic both hydroxyurea and busulfan lack.

CYTOGENETIC REMISSION

Cytogenetic remission is defined as a reduction in the number of identifiable Philadelphia (Ph⁺) chromosomes by standard metaphase karyotypic analysis. The degree of reduction determines the completeness of remission, and this degree of reduction has prognostic significance with regard to survival. The importance of

achieving a major or complete cytogenetic remission (CCR) is highlighted by the results of several randomized clinical trials comparing interferon- α to chemotherapy such as hydroxyurea. In these studies, the only patients achieving a significant cytogenetic remission were those treated with interferon.^{1,4,5} For patients achieving CCR on interferon, the 10-year overall survival rate was 72%.⁶

With interferon alone, however, only a minority of patients actually achieved a CCR. In a randomized trial of interferon alone versus the combination of interferon plus low-dose cytarabine in chronic-phase CML patients, the combination treatment arm induced more major cytogenetic remissions than did the interferon alone arm (35% vs 21%; $P = 0.001$).⁷ This difference translated into a 5-year overall survival advantage for the combination arm of 70% versus 62% ($P = 0.02$). Thus, cytogenetic remission, and in particular CCR, is an important endpoint not only to determine efficacy, but also to maximize the chances for long-term disease-free survival.

Cytogenetic analysis is the gold standard method for predicting clinical outcomes in CML and is typically performed on bone marrow samples. However, there are many practical disadvantages to monitoring CML therapy by bone marrow cytogenetics, including the requirement for proliferating cells and the poor sensitivity (typically 5%) for detecting low-level minimal residual disease. Fluorescent in situ hybridization (FISH) allows for detection of the *bcr/abl* translocation in either metaphase or interphase cells. Because interphase cells are suitable, FISH can be performed on blood leukocytes. Moreover, large numbers of cells can be examined, which increases the sensitivity over that of metaphase cytogenetics. A negative FISH result correlates very well with CCR.^{8,9}

MOLECULAR REMISSION

Reverse transcriptase-polymerase chain reaction (RT-PCR) is the most sensitive method for detecting the *bcr/abl* transcript. A complete molecular remission means that the *bcr/abl* transcript cannot be detected by

Table 20.1 Definitions of remission in CML

Remission	Definition	5-Years survival with interferon
Hematologic		
Complete	Normal WBC and PLT Normal WBC differential No palpable splenomegaly No symptoms referable to CML	30–40%
Partial	Decrease of WBC to <50% of the pretreatment level and <20,000/ μ L Or Normal WBC, but persistent splenomegaly or abnormal WBC differential	
Cytogenetic		
Complete	0% Ph+ metaphases Or Absence of FISH signal	86%
Major	1–34% Ph+ metaphases	80%
Minor	35–90% Ph+ metaphases	60%
None	91–100% Ph+ metaphases	20%
Molecular		
Complete	No detectable <i>bcr/abl</i> transcripts	NA
Major	>3-log reduction in <i>bcr/abl</i> transcripts	

RT-PCR.¹⁰ Before the advent of imatinib for the treatment of CML, the only therapeutic modality capable of inducing a complete molecular remission was allogeneic HSCT. In fact, molecular relapse or failure to induce molecular remission after HSCT predicts hematologic relapse and is an indication for salvage therapy including donor lymphocyte infusions.¹¹ Thus, a complete molecular remission is tantamount to cure after HSCT and is the ultimate goal of non-HSCT therapies if they aspire to cure CML.

Imatinib can induce molecular remission, though not as uniformly or as quickly as with an allogeneic HSCT. At a dose of 400 mg daily in untreated patients with chronic-phase CML, imatinib induces a complete molecular remission in fewer than 5% of patients.¹² Although higher doses of imatinib may induce a higher rate of complete molecular remission, most patients in CCR still have detectable *bcr/abl* transcripts.¹³ For these patients in CCR who still have detectable *bcr/abl* transcripts, a reduction in the number of these transcripts may be just as important as complete molecular remission.

A note of caution must be inserted when considering the definition of a complete molecular response as determined by RT-PCR analysis. RT-PCR techniques may fail to detect extremely low levels of *bcr/abl*, and lab-to-lab differences in methodology preclude the practical comparison of results generated between laboratories. To account for variations in methodology and RT-PCR sensitivity, optimal post-therapy moni-

toring of disease is better accomplished using quantitative rather than qualitative RT-PCR assays. The log reduction in *bcr/abl* transcripts compared to a baseline level obtained at the time CCR was achieved has been introduced as a method to standardize the reporting of molecular responses after treatment for CML.¹² In general, a 3-log reduction in the number of detectable *bcr/abl* transcripts constitutes a major molecular remission.

PROGNOSIS

CML has a variable prognosis largely determined by clinical features present at diagnosis. Clearly, patients in chronic phase have a better prognosis than those in either accelerated or blast phase (see Chapters 19 and 20). However, patients in chronic phase may also be risk stratified according to what treatment they receive.

CML TREATED WITH HYDROXYUREA (OR BUSULFAN)

A large study of patients treated mostly with hydroxyurea was the basis for the first widely recognized prognostic scoring system. Sokal et al. performed a multiple regression analysis of 625 chronic-phase patients aged 5–45 years and identified age, spleen size, hematocrit, platelet count, and the percentage of circulating blast cells as significant prognostic factors.¹⁴ The “Sokal” scoring system devised by this analysis classifies

patients into risk categories that predict survival in patients treated with hydroxyurea.

CML TREATED WITH INTERFERON

As interferon became the treatment of choice, the validity of the Sokal system came into question. To address the question of prognostic factors in patients treated with interferon, Hasford et al. analyzed data on 1303 patients aged 10–85 years and treated with interferon.¹⁵ This analysis identified age, spleen size, percentages of circulating blasts, basophils, and eosinophils, as well as platelet counts as significant prognostic factors. The resulting “Hasford” score was then validated on 322 different patients. This scoring system categorizes patients treated with interferon into low, intermediate, and high risk for survival, and does so more effectively than the Sokal score.¹⁶

Many, if not most, patients initially treated with interferon are now taking imatinib. Whether the Sokal and/or Hasford scoring systems are appropriate for prognostic determination in patients treated with imatinib is uncertain. In fact, in a study of 351 patients treated with imatinib after failure of interferon, age did not appear to be a significant prognostic indicator as it was in both the Sokal and Hasford scoring systems.¹⁷

Marin et al. studied 145 patients treated with imatinib after failure of interferon in chronic-phase CML.¹⁸ The analysis identified two independent predictors of progression-free survival after 3 months of therapy. Both a neutrophil count $<1 \times 10^9/L$ and $\geq 65\%$ Ph+ metaphases predicted poor survival. Patients who had neither risk factor had an 18-month survival of 100% compared to a survival of 33% if they had both. The investigators concluded that myelosuppression from imatinib and failure to achieve cytogenetic remission after 3 months predicts poor survival in patients treated with imatinib. Sneed et al. confirmed this observation in a study of 143 patients treated with imatinib after failure with interferon.¹⁹ In this study, drug-induced grade III myelosuppression reduced the CCR rate from 63–36% ($P = 0.001$).

CML TREATED WITH IMATINIB

Imatinib has not been available for a long enough period of time to make firm conclusions with regard to long-term prognosis using the Sokal and Hasford scoring systems. Data are becoming available, however, with regard to the ability of imatinib to induce cytogenetic and molecular remissions that perhaps can be used as surrogate markers of long-term prognosis.

In the International Randomized Study of Interferon and STI-571 (IRIS) trial, patients with chronic-phase CML were randomized to treatment with either the combination of interferon and cytarabine or imatinib at a dose of 400 mg/day. The IRIS investigators attempted to calculate Sokal and Hasford scores at the time of enrollment into the trial. Unfortunately, 30% of patients lacked the necessary values to calculate the

prognostic score. However, for those patients with a high-risk Sokal or Hasford score, the rates of CCR at 18 months were 56% and 66%, respectively, for patients treated with imatinib.²⁰ At the time the study was published, the duration of follow-up was too short to determine with confidence the applicability of either scoring system to survival in patients treated with imatinib. In contrast, a study of 77 patients treated with imatinib 400 mg daily in combination with interferon showed that both the Sokal and Hasford systems were useful in predicting major cytogenetic remission rates.²¹ In this study, only 23% and 17% patients with high-risk scores by Sokal and Hasford criteria, respectively, achieved a major cytogenetic remission. Thus, firm conclusions about the applicability of these scoring systems to patients treated with imatinib await further analysis. Given the uncertainty surrounding the applicability of the Sokal and Hasford scoring systems, these scoring systems should not be routinely applied to patients treated with imatinib.

The prognostic scoring systems applied to patients with CML may be supplanted by newer, biologically-based, prognostic factors. Derivative chromosome 9 deletions are found in 10–15% of patients with chronic-phase CML at diagnosis.^{22,23} The presence of these deletions clearly portends a worse prognosis in patients treated with either hydroxyurea or interferon and does so independently of either the Sokal or Hasford scores.²⁴ Patients harboring derivative chromosome 9 deletions have a better prognosis when treated with imatinib, but may not have as favorable a prognosis as those patients treated with imatinib in the absence of deletions.²⁵ In addition, the prognosis of patients with derivative chromosome 9 deletions treated with allogeneic HSCT may be poorer compared to those patients without deletions.²⁶

Additional analysis of the IRIS trial has provided insight into other potential markers of prognosis in patients treated with imatinib for chronic-phase CML. Approximately 25% of patients fail to achieve CCR with imatinib 400 mg daily. These patients have a median progression-free survival of 85% at 24 months of follow-up. In contrast, patients achieving a CCR with imatinib have a 95–100% 24-month progression-free survival ($P = <0.001$) depending on the degree of molecular remission.^{12,20} Therefore, the features of patients that predict for failure to achieve CCR with imatinib are also likely to portend poor survival and these patients might be suitable candidates for allogeneic HSCT as an initial treatment strategy.

Another strategy to predict outcome in patients treated with imatinib may be to monitor the quantitative reduction in *bcr/abl* transcript levels. In one study of 106 patients treated with imatinib and monitored by quantitative RT-PCR, the probability of a major cytogenetic response was significantly higher in patients with a *bcr-abl/bcr* ratio $<20\%$ after 2 months of imatinib therapy.²⁷

Some patients have CML that is intrinsically resistant to imatinib at diagnosis. As many as 23% of untreated CML patients fail to achieve major cytogenetic remission after 6 months of imatinib dosed at 400 mg daily.²⁰ These patients generally acquire resistance to imatinib, although imatinib resistant mutations in *bcr/abl* have been reported before the treatment begins.^{28,29} Acquired mutations that confer resistance are not useful as a prognostic tool at diagnosis. However, once recognized, some acquired mutations are associated with a worse prognosis than others.³⁰ There is no consensus as to how the detection of such mutations should guide therapy and whether or not allogeneic HSCT can impact on an otherwise poor prognosis.

CML TREATED WITH ALLOGENEIC HSCT

The prognosis for patients initially treated with HSCT is generally favorable (see Chapter 37). However, certain clinical features do predict for improved survival after HSCT. The European Group for Blood and Marrow Transplantation (EGBMT) registry analyzed data in 3142 patients treated for CML between 1989 and 1997.³¹ They developed a prognostic risk score based on known risk factors for outcome after HSCT such as age, donor/recipient gender, donor/recipient histocompatibility, stage of disease, and time from diagnosis to transplant. The scoring system that came of this analysis is given in Table 20.2. The total score derived from this system not only predicts transplant-related mortality, but also 5-year leukemia-free survival as depicted in Table 20.3.

Stem cell transplantation, however, is not a static field. Techniques are continually improving, as are reported results. Indeed, in a recent report of a single-institution experience of HLA identical sibling allogeneic HSCT, the reported 3-year disease-free survival

Table 20.2 The EGBMT prognostic scoring system for patients with CML treated with HSCT

Risk factor		Score
Donor	HLA identical sibling	0
	Matched unrelated donor	1
Disease stage	First chronic phase	0
	Accelerated phase	1
	Blast crisis of higher chronic phase	2
Age of recipient	<20 years	0
	20–40 years	1
	>40 years	2
Gender combination	Other	0
	Male recipient female donor	1
Times from diagnosis to HSCT	≤12 months	0
	>12 months	1

Table 20.3 The EGBMT scoring system predicts treatment-related mortality and leukemia-free survival

Score	Treatment-related mortality (%)	5-year leukemia-free survival (%)
0	20	62
1	23	61
2	31	44
3	46	34
4	51	28
5	71	37
6	73	15
7 (only 4 patients)	NA	NA

was 78% in 131 patients treated for chronic-phase CML.³² Thus, the prognostic scoring systems of the past may not apply to the modern HSCT techniques available today.

The prognostic information available to the newly diagnosed patient with CML is both a blessing and a curse. While the patient may take comfort in knowing that cure is possible (and likely) with allogeneic HSCT, the relative safety, but lack of long-term prognostic information, of imatinib clouds decision making with regard to optimal treatment approaches. Clearly, patients with accelerated- or blast-phase CML should proceed as soon as possible to HSCT. For patients in chronic-phase CML, the issues are more controversial.

To sort through these issues, an expert panel was convened to provide treatment recommendations. They recommend that all patients be initiated on treatment with imatinib at diagnosis.³³ “Selected” patients may be considered for HSCT prior to a full therapeutic trial of imatinib. Although the panel does not elaborate on the definition of “selected,” one could imagine that a young patient with high-risk features, such as anemia, splenomegaly, and thrombocytosis, would be a good candidate for an initial transplant approach. Failure to achieve CCR on imatinib, or failure to tolerate imatinib, is also an indication for HSCT.³³ The National Comprehensive Cancer Network (NCCN) has offered similar and more comprehensive guidelines.³⁴

FOLLOW-UP

CHRONIC PHASE

The patient with chronic-phase CML treated with imatinib requires close monitoring to determine response and to adjust therapy accordingly. Complete blood counts should be monitored weekly for at least 1

Table 20.4 Recommended follow-up evaluations for patients with CML in chronic phase being treated with imatinib

	First year		Subsequent years		
	Every 3 months	Every 6 months	Every 3 months	Every 6 months	Every 12 months
<i>Blood sample</i>					
CBC and diff	X		X		
FISH analysis	X				
QT-PCR		X*		X*	
<i>Bone marrow</i>					
Histology		X			X
Cytogenetics		X			X

*Only if negative for *bcr/abl* by FISH.

month following the initiation of therapy. In the absence of significant myelosuppression, the monitoring interval may be successively increased up to about every 3 months.^{33,35} A recommended approach to *bcr/abl* monitoring is provided in Table 20.4.

An assessment of treatment response should be made at 3-month intervals in the first year of therapy. Failure to tolerate imatinib or to achieve hematologic remission by 3 months is an indication for either increasing the dose of imatinib or proceeding to HSCT in appropriate patients.^{33,36} More than half of patients will have achieved a major cytogenetic remission with imatinib at 3 months of follow-up.²⁰

However, a bone marrow exam should be performed annually to include standard karyotype analysis even in the setting of a CCR. The development of additional cytogenetic abnormalities to the Ph⁺ clone predicts for relapse and progression to accelerated-phase disease after a response to imatinib.³⁷ Emerging results of treatment with imatinib have revealed another disturbing finding. Some patients develop clonal cytogenetic abnormalities in Philadelphia-chromosome-negative (Ph⁻) hematopoietic progenitors.³⁸ Although fewer than 10% of treated patients have been identified with Ph⁻ clonal evolution,³⁹ the appearance of trisomy 8 and monosomy 7 among the reported abnormalities is a cause for concern. Indeed, several case reports of myelodysplasia, but not acute leukemia, have been reported in this setting.^{38,40,41} Clonal evolution in a patient with chronic-phase CML should prompt a discussion of allogeneic HSCT as a viable treatment alternative.

If a patient achieves a CCR after 6–12 months of imatinib therapy, most investigators recommend imatinib be continued indefinitely. These patients are likely to have a relatively favorable prognosis although cure is by no means assured. The prognosis is particularly favorable if while in CCR, the level of *bcr/abl* transcripts becomes either undetectable or reduced more than 3-logs as determined by RT-PCR. These patients in molecular remission enjoy 100%

progression-free survival after 24 months of imatinib therapy.¹²

As previously discussed, patients who fail to achieve cytogenetic remission within 6 months of treatment with imatinib have a poorer prognosis, and one mechanism of imatinib resistance is mutations in *bcr/abl*. A second mechanism for imatinib resistance is up-regulation of *bcr/abl* by gene amplification, and these patients are candidates for either dose-escalation of imatinib or allogeneic HSCT.^{29,42–46} Indeed, accelerated-phase CML with *bcr/abl* gene amplification responds better to a daily dose of 600 mg of imatinib than to a daily dose of 400 mg. Patients with chronic-phase CML resistant to 400 mg of imatinib may also achieve responses with higher doses.³⁶ However, these responses tend not to be durable, and alternative treatments, such as HSCT, have been recommended.⁴⁷ Similarly, patients who fail to achieve a major molecular remission, or have increasing titers of *bcr/abl*, after 9–12 months of imatinib therapy are candidates for alternative treatments including HSCT.

With regard to mechanisms of imatinib resistance, unfortunately, there is no practical widely available test that reliably distinguishes mechanisms of resistance to imatinib.

ACCELERATED- AND BLAST-PHASE CML

The follow-up of patients with advanced CML depends largely on whether or not they are HSCT candidates. Although some patients with accelerated-phase CML can achieve relatively durable remissions (see Chapter 19), cure is unlikely, and progression is often rapid. Thus, patients with advanced CML should be considered for HSCT even if they respond favorably to imatinib therapy.

Not all patients are transplant candidates, however, and these patients will need to be monitored for evidence of progressive disease. Dose escalation of imatinib is a viable treatment option for patients progressing on standard doses. Whether combinations of imatinib with other active agents will prove beneficial is uncertain, but participation in clinical trials is recommended.

Chapter 21

NEW FRONTIERS IN THE TREATMENT OF RELAPSED OR REFRACTORY CHRONIC MYELOGENOUS LEUKEMIA

Seema Gupta, Javier Pinilla-Ibarz, Peter Maslak, and David Scheinberg

INTRODUCTION

The introduction of imatinib mesylate to the therapy of chronic myeloid leukemia (CML) radically changed the clinical management of patients with this disorder and ushered in the era of effective targeted therapy for this disease. The results from the initial clinical studies have established imatinib as the standard for newly diagnosed therapy of chronic phase CML. As an increasing number of patients are treated with imatinib and as the long-term follow-up data on the durability of responses to imatinib continue to evolve, attention has focused on both the development of resistance to this therapy and the potential clinical implications such resistance has on the management of this disease.

Questions regarding the ultimate efficacy of imatinib have been framed in the context of whether this agent can eliminate the clonogenic BCR/ABL-positive leukemia cell. While most patients who successfully undergo allogeneic stem cell transplantation are rendered BCR/ABL negative via reverse transcriptase polymerase chain reaction (RT-PCR), this is generally not the case with imatinib. Instead, data suggest that quantitative PCR and the ability to induce a 3-log reduction below the baseline BCR/ABL transcript is predictive of long-term response. The results from a large randomized international study demonstrated that patients who were able to achieve a ≥ 3 -log reduction (major molecular response or MMR) in BCR/ABL by RT-PCR had a better prognosis than those who were unable to do so.¹ In this trial, 58% of patients who were in complete cytogenetic remission (CCR) at the 12-month mark did not progress over the next 12 months.¹ Patients who were in a CCR and who did not

achieve a ≥ 3 -log reduction had a 5% chance of disease progression. In this study, however, an MMR was achieved in 39% of the patients who were randomized to imatinib therapy but only 2% of patients randomized to the IFN- α plus ara-C arm. In addition, early and prompt reduction in the BCR/ABL transcript level has been shown to be predictive of CCR.^{2,3} In another study, 106 patient samples were analyzed and the level of BCR/ABL transcript at 2 months predicted for major cytogenetic response (MCR) at 6 months. Both of these studies raise the issue of the clinical relevancy of current available surrogate endpoints and whether qualitative or quantitative measurements should be used to gauge the efficacy of therapy. While complete eradication of the leukemic clone to a level undetectable by the most sensitive method available could be the ultimate goal of therapy, the ability to achieve long-term survival may also correlate with a decrease in the amount of minimal residual disease below a "critical" level. In this scenario, trace amounts of the disease may be present, but not clinically relevant as a patient continues in complete clinical remission.

IMATINIB RESISTANCE—EVOLUTION OF THE TARGET

Published criteria defines primary resistance to imatinib mesylate as the inability to reach complete hematologic remission (CHR) by 3 months, MCR (defined as $\leq 35\%$ of cells positive for the BCR/ABL transcript) by 6 months, or CCR by 12 months of therapy. Approximately 20–30% of newly diagnosed patients are resistant to imatinib using such criteria.^{1,2} MD Anderson Cancer Center (MDACC) has reported that

primary resistance can be reduced to about 10% by increasing the standard administered dose of imatinib to 800 mg/day.³ Acquired resistance to imatinib may, however, develop as the neoplastic cells exhibit alternative mechanisms to maintain sufficient amounts of active BCR/ABL signal to maintain growth. Clinically, acquired resistance is defined as the loss of an established hematologic, cytogenetic, or molecular response or the progression of disease to an accelerated or blastic phase. In the large randomized imatinib study discussed above, approximately 8% of patients had an acquired resistance to imatinib by 18 months on treatment.¹

Clinical resistance may develop by several mechanisms, including BCR/ABL gene amplification, incomplete inhibition of BCR/ABL cells with the subsequent selection of resistant cells, BCR/ABL gene mutations, and possibly, increased expression of the *MDR-1* gene encoded P-glycoprotein. Increased expression of BCR/ABL by chromosome or gene amplification appears to be the most common mechanism of acquired resistance in vitro.^{4,5} In the clinical setting, however, several studies have shown that another common cause of acquired resistance is the development of mutations in the kinase domain of BCR/ABL.⁶⁻⁸ Several groups have reported at least 20 different point mutations from the leukemic cells of patients resistant to imatinib. The two most common kinase domain mutations, T315I and E255K, change the conformation of the protein and prevent the binding of imatinib to the BCR/ABL protein.^{6,9,10} Although these mutations were not identified in patient samples taken prior to initiation of therapy with imatinib, they were most likely present in undetectable quantities at the time of diagnosis. This has been shown in patients with Ph-positive ALL prior to therapy with imatinib.¹¹

Under the selective pressure of imatinib treatment, these resistant molecules emerge, giving rise to progressive disease. When patients are identified as becoming imatinib resistant, direct sequencing of BCR/ABL can be employed to define the possible mechanism of resistance. Such a strategy may, in the future, help guide treatment decisions as alternative targets and agents become available. Table 21.1 summarizes some novel therapies for treatment of imatinib-resistant CML.

STRATEGIES FOR OVERCOMING IMATINIB RESISTANCE

DOSE ESCALATION OF IMATINIB

If clinical resistance is modulated by an increase in the amount of BCR/ABL, it might be possible to overcome the resistance by increasing either the dose of imatinib or the ability of imatinib to bind to its target. Mutations such as T315I and E255K confer steric changes that are difficult to overcome even with higher doses of imatinib. Other mutations, such as M244V, F311L, and M351T, however, may be overcome by escalating the dose of imatinib.⁷ Certain other mutations, namely those in the ATP phosphate-binding loop (P loop), such as E255K, may confer a poor prognosis. In one Australian study, 12/13 patients with mutations in the P loop had a median survival of only 4.5 months.⁷ Mutations in the activation loop (A loop), downstream from the A loop, and in the imatinib-binding regions of the kinase may be at least partially sensitive to higher doses of imatinib. As these different mutations retain varying sensitivities to imatinib, it is rational to attempt dose escalation in such patients.

Table 21.1 Novel therapies to treat imatinib-resistant CML

Therapy	Mechanism	Developmental status
Transplantation (auto or allo)	GvL	Established therapy
Dose escalation of imatinib (600–800 mg)	Inhibition of partially resistant bcr/abl mutants	Phase II/III trials ongoing
Geldanamycin, 17-AAG, ATO, siRNA, ribozymes	Downregulation of intracellular BCR/ABL levels	Preclinical/phase I/II
PD173955, PD166326, AP23464, BMS354825	Second-generation tyrosine kinase inhibitors	Preclinical/phase I/II/III
FTIs (tipifarnib), zolendronate	Inhibition of downstream Ras signaling pathway	Phase I
Rapamycin, CCI-779	Inhibitor of downstream effector m-tor in PI-3 kinase pathway	Phase I
Leptomycin B	Nuclear entrapment of bcr/abl preventing its antiapoptotic effect	Preclinical
PSC833, verapamil	P-glycoprotein inhibitors	Preclinical
HHT	Plant alkaloid, unknown	Phase I/II
Bortezomib	Proteasome inhibition	Phase I/II

Alternatively, the upregulation of the BCR/ABL signal through mechanisms of gene amplification may also be amenable to dose escalation. In this scenario, the intrinsic sensitivity of the cell is retained, and the desired clinical effect is a function of the dose-response curve. Critical levels of imatinib are needed to inhibit BCR/ABL function and may be achieved by increasing the doses of the agent. The experience reported by MDACC demonstrates better responses when higher doses of imatinib are used as initial therapy, and has laid the groundwork for this strategy.

DOWNREGULATION OF INTRACELLULAR BCR/ABL LEVELS

Noxious stimuli to cells activate the synthesis of some proteins while inhibiting the synthesis of others. The heat-shock proteins are molecular chaperones that stabilize the tertiary conformation of key cellular proteins, including proteins involved in signal transduction. Misfolding of proteins can produce inactive aggregated forms. Heat-shock protein 90 (hsp90) is a specific molecular chaperone that affects the stability and function of multiple oncogenic proteins, including BCR/ABL.^{12,13} Geldanamycin is a benzoquinone ansamycin antibiotic that inhibits hsp90 by competitively binding to an ATP-binding pocket in the amino terminus of the hsp90 molecule.^{12–14} Inactivation of hsp90 causes dysfunction and rapid degradation of their “client proteins” (including Raf-1, v-Src, p185^{c-erbB-2}, and BCR/ABL)^{13,15,16} via the proteasome pathway. A less toxic analog of geldanamycin, 17-AAG, has been shown in preclinical studies to down regulate BCR/ABL in Ph-positive cell lines K562 and transfected HL60.¹³ When the hsp90 protein is inhibited, BCR/ABL is rendered sensitive to cellular physiologic mechanisms and can be degraded by the ubiquitin-proteasome pathway -3 activating the intrinsic apoptotic pathway.¹³ This appears to be the mechanism of action of this class of drugs. Preclinical laboratory studies have shown that BCR/ABL point mutations isolated from imatinib-resistant CML are degraded *in vitro* by both geldanamycin and 17-AAG. This effect has been demonstrated in both the T3151 and E255K cell lines.¹⁷ In both cell lines, the BCR/ABL protein was depleted at a low concentration of geldanamycin (30 nm).¹² Leukemic blasts taken from three patients with CML blast crisis, who progressed while on imatinib, have been shown *in vitro* to be susceptible to 17-AAG-induced apoptosis.¹⁸ These laboratory observations have raised the possibility of combining other therapeutic agents with 17-AAG in an effort to reverse the drug-resistant phenotype in patients with advanced stage disease.

Arsenic trioxide (ATO) represents a novel agent that has shown preclinical activity in the treatment of imatinib-resistant CML by inducing alteration of mitochondrial inner transmembrane potential, leading to the release of cytochrome c with subsequent caspase

activation and apoptosis.¹⁹ Recently, ATO has also been shown to interfere with the translation of BCR/ABL by inhibition of ribosomal p70S6 kinase activity.^{20,21} Based on this rationale, the ATO and imatinib combination has been studied in numerous Ph-positive cell lines. Studies using the K562 and HL60/BCR/ABL cell lines have shown that the proapoptotic activity of imatinib is enhanced in the presence of ATO.²¹ Cotreatment of K562 and transfected MO7p210 cells with approximately equipotent doses of ATO and imatinib additively inhibited growth proliferation.²² In colony-forming assays using CML patient samples, the combination of ATO and imatinib showed increased antiproliferative activity compared to imatinib alone.²² The additive effect of the ATO in combination with imatinib has initiated several phase I and II clinical trials examining the combination.

Interruption of the messenger RNA (mRNA) of mutant BCR/ABL may also be a target for therapeutic intervention. Antisense oligonucleotides could be designed that are complementary to the sequences on mutant BCR/ABL fusion transcripts. These small molecules would interfere with translation by physically blocking ribosome access to mRNA of the aberrant CML cells without affecting normal cells. Other mechanisms may potentially play a role in the antisense effects on BCR/ABL. DNA–RNA hybrids are more susceptible to RNase activity, and several studies have shown that this strategy is feasible in CML cells *in vitro*.^{23–26} However, these agents have been difficult to study and implement in humans, even though they can be delivered relatively safely. This difficulty may, in part, be due to the long half-life of the BCR/ABL protein *in vivo* and the inability to deliver the drug in a manner that will allow it to be present in the cell for longer periods of time (i.e., 24–48 h). In addition, poor uptake of these antisense oligonucleotides into cells may prohibit their clinical usefulness. A similar strategy is based on RNA interference (RNAi). Several groups have reported *in vitro* BCR/ABL inhibitory effects, using small interfering RNA oligonucleotides (siRNA) in CML cell lines.^{27–29} Ribozymes (RNA) and DNazymes (DNA) are designed to hybridize to specific RNA molecules and initiate hydrolysis of phosphodiester bonds in the target RNA. These strategies have all shown promise in the preclinical setting, but the clinical feasibility in imatinib-resistant patients has not yet to be established.

SECOND-GENERATION TYROSINE KINASE INHIBITORS

Agents that have a different conformational binding to BCR/ABL than imatinib provide another potential approach to imatinib-resistant CML. Such compounds may be particularly useful in patients who have developed point mutations in the ABL domain and are no longer able to bind imatinib in the kinase pocket and inhibit ATP binding. Second-generation tyrosine

kinase inhibitors may still be able to bind the appropriate binding site and block ATP from binding. Several of these agents are currently being developed in both the laboratory and the clinic. PD173955 (Pfizer) is a more potent inhibitor of BCR/ABL than is imatinib. Unlike imatinib, this small molecule has been shown to bind Abl independent of its phosphorylation state.³⁰ Hence, more potent tyrosine kinase inhibitors may be able to maintain activity against mutated clones. PD166326 (Pfizer), a novel compound in the pyridopyrimidine class of tyrosine kinase inhibitors, has been shown to be a potent inhibitor of BCR/ABL tyrosine kinase activity and BCR/ABL-dependent proliferation.³¹ The activity of PD166326 against BCR/ABL-induced leukemia in an in vivo mouse model has recently been reported (N Wolff, ASH 2003). PD166326- and imatinib-treated mice had improved survival, lower white blood cell (WBC) count, and less splenomegaly than placebo-treated mice, suggesting that PD166326 was superior to imatinib in decreasing the overall leukemic burden. Thus, in this CML animal model, the novel tyrosine kinase inhibitor PD166326 exhibited greater antileukemic activity than imatinib, suggesting that further development of this or a related compound may lead to even more potent drugs for the treatment of human CML. The investigators have postulated that, similar to the experience with combination chemotherapy, combinations of different kinase inhibitors at the initiation of therapy may suppress the emergence of resistant clones and improve therapeutic outcomes.

In vitro data on the novel dual selective SRC/ABL inhibitor, AP23464 (ARIAD pharmaceuticals, Cambridge, MA), has shown that this drug inhibits in vitro growth of cells that express either wild-type BCR/ABL or the most prevalent mutations induced by imatinib in BCR/ABL: Q252H, Y253F, E255K, M351T, or H396P.³² AP23464 was approximately eightfold more potent than imatinib in inhibiting the growth of Ba/F3 cells expressing wild-type BCR/ABL. Also, AP23464 inhibited the growth of Ba/F3 cells expressing all mutant forms of BCR/ABL except for T315I at the same nanomolar concentrations as the wild type.³² Studies to assess the in vivo activity of AP23464 and key analogs are currently in progress.

Another second-generation tyrosine kinase inhibitor that is currently in clinical trials is BMS-354825. The studies are being conducted in patients with chronic phase CML who are resistant to imatinib.³³

INHIBITORS OF THE DOWNSTREAM PATHWAYS

Ras signaling

Activation of the Ras signaling pathway is essential for BCR/ABL function. After BCR/ABL has activated Ras, Ras requires several additional posttranslational modifications, including prenylation. Prenylation involves adding a lipid anchor to the target protein, which

facilitates binding of this protein to cellular membranes, allowing them to function as intermediates in the process(es) of signal transduction. In the Ras pathway, prenylation is catalyzed by farnesyl protein transferase; the farnesyl transferase inhibitors (FTIs) interfere with this step by inhibiting this enzyme. Given the central role that the *ras* oncogene plays in controlling cellular metabolism, multiple FTI compounds are currently being developed and tested across a wide range of hematologic malignancies. A phase I/II study of tipifarnib, an FTI, in patients with a spectrum of myeloproliferative disorders reported preliminary results in 23 patients.³⁴ Tipifarnib was administered at a dose of 300 mg p.o. b.i.d. for 21 days every 4 weeks. Clinical WBC responses [normalization of WBC, complete remission (CR); or >50% WBC count reduction, partial remission] were seen in 5 of 21 (24%) evaluable patients. No cytogenetic responses were seen in six evaluable patients. Grade 2 anemia and greater than grade 3 thrombocytopenia were the most common hematologic toxicities.³⁴ Two other phase I studies of tipifarnib in combination with imatinib for the treatment of CML have also been reported. Cortes et al. conducted a phase I study of the combination of tipifarnib with imatinib in patients with CML in chronic phase who had failed imatinib therapy.³⁵ Doses of tipifarnib of 300 mg p.o. b.i.d. for the first 14 days of each 21-day cycle were administered with imatinib 300 mg daily. Subsequent doses of 300 and 400 mg, and 400 and 400 mg, respectively, in the same schedule were also administered. Nine patients were treated; three at each dose level. Hematologic responses were seen in patients with abnormal blood counts but none of the patients achieved a cytogenetic response.³⁵ A second phase I trial also combined tipifarnib with imatinib, but in patients with accelerated (AP) or blastic phase (BP) of CML with hematologic relapse or cytogenetic resistance to imatinib. Imatinib was given at 600 mg p.o. daily and combined with escalating doses of tipifarnib (200–600 mg p.o. b.i.d.). The combination therapy was administered for 21 days. Of the six evaluable patients, in the first cohort, three patients reached a complete hematologic response. No cytogenetic responses were seen.³⁶

Zolendronate, a bisphosphonate, has been shown to inhibit downstream signaling of Ras in vitro. Additional in vitro and murine model studies have shown synergy between imatinib and zolendronate, providing a rationale for examining this combination in the clinical setting.³⁷

PI-3K/AKT pathway

PI-3 kinase activation is essential for the BCR/ABL-mediated transformation of cells. PI-3 kinase is a heterodimer consisting of catalytic (p110) and regulatory (p85) segments. BCR/ABL interacts with the p85 subunit. Two PI-3 kinase inhibitors are currently in

clinical development. Wortmannin and LY294002 are active compounds and synergize with imatinib *in vitro*.^{38,39} Wortmannin is a naturally occurring compound and is highly unstable in solution, making it a challenging compound to develop clinically.

Several downstream effectors in this PI-3 kinase pathway have been identified. One is m-TOR, which is involved in the phosphorylation of several signaling proteins, including the S6 ribosomal protein, an important target of BCR/ABL.⁴⁰ Inhibitors of m-TOR, such as rapamycin, have been attractive as possible therapeutic agents in CML. These agents have already undergone phase I/II clinical testing in a variety of other tumors and are currently beginning clinical trials in CML.⁴¹

OTHER NOVEL APPROACHES TO THERAPY OF RELAPSED CML

Imatinib-resistant cell lines have been shown to overexpress the multidrug-resistance drug transport protein P-glycoprotein. Sensitivity to imatinib could be partially restored *in vitro* when the cells were exposed to verapamil or PSC833, both P-glycoprotein inhibitors.⁴²

Leptomycin B is a novel therapeutic responsible for nuclear entrapment of BCR/ABL. BCR/ABL exerts an antiapoptotic effect in the cytoplasm of cells. Leptomycin B is an inhibitor of the nuclear export of BCR/ABL, preventing it from reaching the cytoplasm, thus abrogating its antiapoptotic effect on cells. It has also been shown that nuclear BCR/ABL induces apoptosis of cells *in vitro*.⁴³ Nuclear entrapment is thus another potential therapeutic strategy for imatinib-resistant disease.

Homoharringtonine (HHT) is a plant alkaloid derived from the *Cephalotaxus fortunei* tree, known to have antileukemia activity when first used by the Chinese in the treatment of both acute myeloid leukemia (AML) and CML in the late 1970s.^{44,45} MDACC has performed several studies in the pre-imatinib era using HHT alone and in combination with IFN- α in chronic phase CML, and has demonstrated the ability of this drug to induce CR. Seventy-two percent of 58 patients in late chronic phase were able to achieve a CHR with HHT alone. However, only 31% of patients had a cytogenetic response. *In vitro* data suggests that there is a synergistic effect of HHT in combination with imatinib *in vitro*, providing a potential rationale for combination therapy in resistant patients.⁴⁶

The ubiquitin-proteasome pathway is the primary intracellular pathway responsible for the degradation of proteins. Proteasome inhibitors are being investigated as potential therapies in a wide variety of hematologic malignancies. Inactivation of NF- κ B appears to be crucial in the activity of proteasome inhibitors. NF- κ B is inhibited in the cytoplasm through binding to I κ B, a substrate for proteasomes.⁴⁷ In CML, BCR/ABL activates NF- κ B-dependent transcription, and NF- κ B is

necessary for BCR/ABL-mediated cell proliferation.⁴⁸⁻⁵⁰ PS-341 is a potent and selective inhibitor of the proteasome that has shown significant clinical activity in multiple myeloma. *In vitro*, PS-341 induced significant growth inhibition and apoptosis in several BCR/ABL-positive cell lines, including both imatinib-sensitive and -resistant cell lines.⁵¹ Clinical studies in imatinib-resistant patients are ongoing.

IMMUNOTHERAPY

ROLE OF ALLOGENEIC TRANSPLANTATION

Since the first demonstration of its curative potential, allogeneic stem cell transplantation has played an important role in the management of CML. The results for a wide range of these clinical studies are reviewed in Chapter 37. The ability of both interferon and imatinib to affect the natural history of the disease has altered the initial treatment paradigms, and some debate has surrounded both the institution and the timing of stem cell transplantation in the course of therapy. Such treatment decisions are tempered by consideration of the risk/benefit ratio particularly, as it pertains to specific groups of patients.

Despite the current controversy surrounding the most appropriate time to proceed with allogeneic stem cell transplantation in CML, the experience with this modality has proven valuable as proof of concept regarding the clinical efficacy of immunotherapy. The model of the “graft-versus-leukemia” (GvL) effect has been further refined and, in turn, has given rise to immunology-based therapeutic strategies, such as donor leukocyte infusions (DLI) and reduced intensity, nonmyeloblastic transplantation (“mini-transplants”). Such approaches have been pioneered in CML and applied, with varying degrees of success, in other forms of human leukemia.

SPECIFIC IMMUNOTHERAPY WITH BCR/ABL-DERIVED PEPTIDE VACCINES

As discussed above, many clinicians still consider allogeneic stem cell transplantation to be the “gold standard” for curative therapy in CML by virtue of the long-term survival achieved and the ability of this modality to render the patient BCR/ABL negative using PCR-based assays. The importance of the immunologic properties of the graft has received a great amount of attention, with attempts to recapitulate a GvL effect while separating it from the side effects of conventional transplantation regimens undertaken by a number of investigators. The potential to induce and then employ specific antileukemic immune effectors is attractive and has seen realization in the formulation of a vaccine strategy for this disease.

The unique amino acid sequences encompassing the b3a2, b2a2, or e1a2 in BCR/ABL breakpoints can be considered truly tumor-specific antigens because they

contain sequences that are not expressed in any normal cellular protein. Despite the intracellular location of these proteins, short peptides produced by cellular processing of the fusion protein products can be presented on the cell surface within the cleft of HLA molecules, and in this form, they can be recognized by T cells.⁵²⁻⁵⁴ Several investigators have demonstrated the immunogenicity from fusion-region-derived peptides of p210-b3a2 in the context of MHC class I and class II. By screening large numbers of fusion peptides from the junctional sequences of CML, several peptides have been derived from the b3a2 CML breakpoint that bind with high, intermediate, or low affinity to HLA-A0201, A3, A11, and B8.^{53,55-58} Recent mass spectrometry studies have further demonstrated the presence of cell-surface HLA-associated BCR/ABL peptides previously described as binders of HLA-A0301 in primary CML cells from HLA-A3-positive patients.⁵⁹ This is the first direct evidence of naturally processed and expressed endogenous BCR/ABL peptides on the surface of CML cells. Support for the immunogenicity of synthetic BCR/ABL fusion peptides capable of interacting with class II MHC molecules has been accumulating as well. Peptides corresponding to the b3a2 fusion sequences have been shown to bind DR3 (DRB1*0301), DR4 (DRB1*0402), and DR11 (DRB1*1101), and b3a2 peptides have been shown to induce HLA-DR1 (DRB1*0101), DR2 (DRB1*1501), DR4 (DRB1*0401), DR9 (DRB1*0901), and DR11 (DRB1*1101) restricted proliferative responses of CD4-positive T lymphocytes and cytotoxic cell responses associated with DRB1*0901.^{55,60-64} Indirect evidence for processing and recognition of p210-b3a2 class II has been described.^{60,64,65} Evidence for immunogenicity on class I and class II b2a2 and e1a2 peptides-derived breakpoint translocations have also been reported.

Based on the immunogenic evidence of b3a2 peptides-derived translocation, the Memorial Sloan-Kettering Cancer Center (MSKCC) Group initiated studies to evaluate the safety and immunogenicity of a multidose, multivalent BCR/ABL breakpoint peptide vaccine in CML patients, with a b3a2 breakpoint.

Based on these results, a phase II trial in adult CML patients with any HLA type and a b3a2 breakpoint was undertaken. Patients were vaccinated five times over a 10-week period using a preparation of six peptides (100 µg each) and the immunologic adjuvant QS-21 (100 µg). Immunologically responding patients received three additional monthly vaccinations, and those with continued response received another three bimonthly vaccinations. Immune and clinical responses were measured. All 14 patients developed delayed-type hypersensitivity (DTH) and/or CD4 proliferative responses, and 11 of 14 patients showed IFN-γ release by CD4 ELISPOT. A peptide-specific CD8-positive IFN-γ ELISPOT was found in four patients; two of them had received an allogeneic stem cell transplantation prior to relapse. Four patients in

hematologic remission had a decrease in Ph percentage (three concurrently receiving IFN-α and one on imatinib), and three patients in molecular relapse after allogeneic transplant became transiently PCR negative after vaccination. Two of these patients received DLI after the first vaccination in an attempt to vaccinate the naive donor leukocytes within the recipient (vaccination by proxy). All five patients on IFN ultimately reached a complete cytogenetic remission. These results suggested that a tumor-specific BCR/ABL breakpoint peptide-derived vaccine could be safely administered to patients and that such a vaccine could elicit measurable peptide-specific CD4 immune responses in all treated patients, including patients post stem cell transplantation, on interferon, or on imatinib. A causal relationship between clinical response and vaccination, however, remains unclear and requires further study in the context of well-designed clinical trials.

Recently, an Italian group has reported results using the same BCR/ABL vaccine. In this study, 16 evaluable patients with CML in chronic phase with at least one of a group of designated specific HLA subtypes (HLA A3, A11, B8, DR11, DR1, or DR4) were treated. Patients with a b3a2, BCR/ABL breakpoint were vaccinated subcutaneously six times over a 12-week period (every 2 weeks) using a preparation of five peptides mixed with QS-21 and granulocyte-macrophage colony-stimulating factor (GM-CSF) the day before and the day of vaccination. Patients who responded immunologically received two booster vaccinations at 4- and 8-month interval from the date of the last vaccination. As in the prior study, no significant toxic effects were observed. Thirteen of 16 patients developed CD4 proliferative responses and 9 of 16 DTH. In 10 patients treated with imatinib, 5 of 9 patients became CCR after three to six vaccinations.⁶⁶ Three of the five CCR patients were also able to achieve a molecular response. In six patients treated with IFN-α, two had a CCR. These results supported the findings from the MSKCC Group regarding the safety and measurable peptide-specific CD4 immune responses in all treated patients, and provide a rationale for future clinical trials in the context of minimal residual disease induced by imatinib.⁶⁶

SELF-ANTIGENS FOR IMMUNOTHERAPY OF CML

Proteinase 3, a serine protease stored in azurophilic granules, is a differentiation antigen associated with myeloid granule formation and is overexpressed in a variety of myeloid leukemia types, including CML cells. Therefore, it has been considered a possible target antigen for specific active immunotherapy. CTLs specific for an HLA-A2.1-restricted nonpolymorphic peptide (PR1) derived from proteinase 3 have shown HLA-restricted cytotoxicity, and selectively inhibit CML progenitors over normal marrow cells.^{67,68} PR1-specific T cells have been identified by HLA-A2-PR1 peptide HLA tetramers in a majority of CML patients

who responded to either IFN- α or allogeneic stem cell transplantation.⁶⁹ PR1-specific CTLs isolated from these patients were capable of lysing fresh leukemia cells. Follow-up studies in patients with relapsed CML revealed a selective loss of the high-avidity PR1-CTL population by tetramer determination. A functional PR1-specific CTL immune response was also lost prior to CML relapse, suggesting a possible therapeutic role for “add back” of high-affinity PR1-CTL.

The results of a phase I vaccine trial using a PR1 peptide in patients with HLA A0201 have been reported. This trial included a total of 15 patients: 6 with CML (interferon resistant or relapsed after stem cell transplantation), 8 with AML (smoldering relapse or \geq second CR), and 1 with MDS with no detectable antibodies to proteinase 3 (antineutrophil cytoplasmic autoantibody negative). Patients were treated with three dose levels of PR1 peptide in incomplete Freud's adjuvant (Montanide ISA-51) and 70 μ g of GM-CSF every 3 weeks for three injections. Eight of 15 patients (53%) had some evidence of immune response to the peptide vaccine as assessed by tetramer staining and flow cytometric detection of intracellular IFN- γ . In this group, five patients experienced a clinical response, including three patients with a molecular response and one with a cytogenetic response. In one patient, tetramer sort-purified PR1-CTL obtained after vaccination showed PR1 specificity

against peptide-pulsed T2 cells, as well as significant lysis of BM cell at diagnosis but not at remission. This study provided evidence that peptide vaccination against PR1 of leukemia patients can elicit highly active specific cellular immunity against leukemia.

CONCLUSION

The introduction of imatinib therapy has altered the paradigm for the clinical management of patients with CML. Despite the overwhelmingly positive results with this agent, a potential flaw with a targeted therapy like imatinib is that the target needs to be present in a form or amount that is sensitive to this specific modality in every clonogenic cell. The inherent genetic instability of CML poses both a theoretical and practical problem for single-agent therapy. Patients who have primary resistance to imatinib or who develop resistance following therapy require alternative approaches to control and ultimately cure the disease. As new targets are identified, agents can be introduced to complement imatinib and administer as part of combination therapy. Alternatively, immunologic approaches will continue to be used for patients who fail first line therapy as the models of active specific immunity are refined and the adoptive cellular therapies receive more widespread application.

CHRONIC LYMPHOCYTIC LEUKEMIA

Chapter 22

MOLECULAR BIOLOGY, PATHOLOGY, AND CYTOGENETICS OF CHRONIC LYMPHOCYTIC LEUKEMIA

Martin J.S. Dyer and Randy D. Gascoyne

INTRODUCTION

CLL is a disease of a subtype of mature B cells characterized by expression of a specific combination of cell surface molecules: CD5⁺, CD19⁺, CD23⁺; surface immunoglobulin (sIg) and CD20 are expressed at only low levels. Histologically, the disease is rather bland, and usually, should present little problem in diagnosing. However, despite the morphological homogeneity, the disease varies enormously in prognosis, with some patients requiring no treatment for many years, if ever, while others die rapidly with chemotherapy-resistant disease.

In the basic biology of CLL, considerable progress has been made. The paradigm of CLL we have lived with for the past 40 years, that CLL is a disease of immunologically inert mature B cells, arising due to suppressed apoptosis, is being increasingly challenged. In the peripheral blood, viability of CLL cells appears to be dependent on intercellular contact with specialized subsets of dendritic or “nurse-like” cells, while other cell types may fulfil comparable roles in other sites.^{1,2} In vivo metabolic labeling with heavy water suggests an unexpectedly high turnover of cells³ (see also www.kinemed.com). Studies on the sequences of the expressed immunoglobulin (IG) variable region (IGHV) gene sequences are shedding new light on the

possible pathogenesis of this disease. Furthermore, a subclinical expansion of CLL cells has been described, which appears to be the equivalent of monoclonal gammopathy of undetermined significance (MGUS).⁴

Within molecular cytogenetics analysis, progress has been hampered by the lack of a consistent cytogenetic lesion. The most common abnormality, involving deletion of a small region of chromosome 13q14, may involve loss of expression of micro RNA gene expression.⁵ Clinically, molecular genetic analysis of the tumor cells, not only by molecular cytogenetics but also by mutational analysis of IGHV sequences, are now mandatory components for diagnosis in CLL and will eventually predict therapy.⁶ Notably, patients with mutated IGHV have a much better prognosis than those with germline segments.⁷ Similarly, patients with deletions and mutations involving either the p53 gene on chromosome 17p13.3 or the ATM gene on 11q23.1 fare badly.⁸ Determining the nature of the molecular events associated with these different subgroups is now a major challenge.

FAMILIAL CLL

It is apparent from several studies that there is a familial clustering of cases of CLL, perhaps in as many as 5% of cases.^{8,9} The pedigrees are not normally large,

usually affecting only two generations. The genetic defect(s) underlying the familial form of the disease remain unknown but are now the subject of a number of epidemiologic and molecular studies. A number of “candidate genes” have been investigated, but none has shown involvement. Application of whole genomic techniques to these cases may allow identification of the key gene(s). Conventional comparative genomic hybridization has been used in order to identify regions of recurrent genomic loss in DNA from patients with familial CLL; four areas of loss were identified, including Xp11.2-p21, Xq21-qter, 2p12-p14, and 4q11-q21.¹⁰ Use of bacterial artificial chromosomes (BAC) arrays would greatly enhance the resolution of this analysis.¹¹

Cases may show anticipation, with both generations often presenting concurrently; whether this reflects trinucleotide expansion, as seen in neurological disorders that exhibit this phenomenon (increasing expansion being associated with an earlier age of onset of disease), is not yet clear. However, anticipation is not a feature of all series and may reflect ascertainment bias.

Please see <http://www.icr.ac.uk> for further information and how to enter families into an international collaborative study.

CD5⁺ B CELLS AND THE POSSIBLE ROLE OF CLONAL LYMPHOCYTES OF UNKNOWN SIGNIFICANCE IN CLL

CLL is a disease of CD5⁺ B cells. CD5 is a highly conserved single-chain 67-kDa transmembrane glycoprotein containing three scavenger receptor cysteine-rich (SRCR) domains. CD5 expression is found on all human T cells, but only on a subset of B cells. Despite its sequence conservation, CD5 expression in T cells and B cells varies widely from species to species; in some, all B cells are CD5 positive. Studies on CD5-deficient mice have shown that CD5 functions as a negative regulator of B-cell receptor-mediated signaling. Murine CD5⁺ (B1) B cells may represent a distinct lineage of B-cell development, arising early and self-renewing, producing low affinity, polyreactive antibodies that may contribute to the development of autoimmune diseases.¹² Whether CD5 expression in human B cells marks a functionally distinct lineage, or whether it reflects its function as an activation antigen, is unclear.

Both CD5⁺ and CD5⁻ B cells may be found in the peripheral blood of normal individuals. It seems likely that CLL arises from the former. The evidence for this comes from an intriguing recent finding of clonal CD5⁺ B cells with the composite immunophenotype typical of CLL (namely CD19⁺/CD5⁺ with low CD20 and CD79b) in the peripheral blood of 3.5% of normal individuals older than 40 years.⁴ These cells, detected by four-color flow cytometry, were present at low levels (median, 0.013; range, 0.002–1.458 × 10⁹ cells/L), and in most

cases, represented only a minority of B cells (median, 11%; range, 3–95%). Clonality was demonstrated using *IGH* PCR, and sequence analysis showed the presence of mutated *IGHV* sequences. Moreover, these cells are markedly increased in frequency in first-degree relatives of patients with the familial form of CLL.¹³

The precise significance of these cells is not clear; in analogy with the situation in myeloma, they have been termed *clonal lymphocytes of uncertain significance* or “CLUS.” Long-term follow-up will be necessary to determine whether the relationship between the low-level “CLL” cells and clinical disease is similar to that seen in MGUS and myeloma. More recently, another study has not only confirmed these findings of low-level CLL-like cells in the peripheral blood of normal individuals, but has also shown the presence of clonal B cells with different immunophenotypes.¹⁴ In both studies, the frequency of clonal cells increased with age.

Further study of these populations should allow insights into the pathogenesis of both familial and sporadic forms of CLL.

CYTOLOGY/HISTOPATHOLOGY

The key diagnostic feature of CLL relies on a careful examination of the peripheral blood smear. In a typical case, there is a lymphocytosis of small, round, mature-appearing lymphocytes with scant amounts of cytoplasm and mature chromatin. Typically, the chromatin has a characteristic clumped appearance with absent nucleoli. Disrupted lymphocytes, known as smudge cells, are a common finding in CLL (Figure 22.1). A lymphocytosis of 5 × 10⁹ lymphocytes/L has been a mandatory part of the diagnostic criteria (see Chapter 23), although this will have to be reviewed in light of the description of CLUS.

Figure 22.1 Typical peripheral blood smear in CLL showing small cells with clumped nuclear chromatin and occasional smudge cells

Figure 22.2 Bone marrow showing minimal nodular pattern of involvement

A small number of larger cells resembling prolymphocytes may be seen at diagnosis. Characteristically, these account for <10% of the WBC differential. In time the prolymphocytes can increase, leading to a variant form of CLL referred to as CLL/PL. This represents a type of progression of CLL. In most cases, prolymphocytes account for <55% of the total WBC. The morphology in these cases is characteristically dimorphic, a finding that is particularly helpful for diagnosis. An uncommon form of CLL may occur and is referred to as CLL of mixed cell type. Such cases demonstrate a spectrum of morphologies and thus differ from the typical dimorphic appearance of CLL with scattered prolymphocytes.

The bone marrow in CLL is virtually always involved, but a number of differing presentations may be encountered. These include a nodular pattern, interstitial, mixed, and diffuse (Figures 22.2 and 22.3).

Figure 22.3 Heavy, diffuse bone marrow involvement in CLL. A growth center can be identified in the biopsy

Some data suggest that these histologic patterns may have independent prognostic relevance in CLL. Occasionally, bone marrow biopsies may reveal the presence of growth centers, a characteristic histologic finding in the lymph nodes of patients with CLL. These represent scattered pale-staining areas where focal collections of prolymphocytes and so-called paraimmunoblasts reside. As the name indicates, this is where tumor growth is thought to occur and where one would typically encounter the otherwise uncommon mitotic figures.

A predominantly lymph-node-based form of the disease can occur, and is referred to as small lymphocytic lymphoma (SLL). The lymph node histology, immunophenotype, and cytogenetic/molecular alterations are identical to classic CLL. Although this represents an uncommon diagnosis, some cases of SLL may never develop an absolute lymphocytosis. This fact alone lends credence to the suggestion that CLL and SLL are related, but unknown factors that distinguish a predominantly leukemic disease from a tissue-based illness are poorly understood. As noted above, the histology of CLL and SLL are identical. The infiltrates are diffuse, but the presence of growth centers imparts a pseudofollicular architecture that is diagnostic. This finding is the result of scattered growth centers that produce an alternating dark and light staining pattern (Figures 22.4 and 22.5). The lightly staining areas harbor prolymphocytes and paraimmunoblasts, larger cells with more vesicular chromatin and prominent nucleoli. Occasional cases may lack prominent growth centers and typically these same cells are scattered diffusely throughout the lymph node. This can lead to problems with the diagnosis if the typical cytological appearance of the CLL/SLL cells is not appreciated. In some cases, growth centers may begin to sheet-out, suggesting histologic transformation. Importantly, this finding is not tantamount to the so-called Richter's syndrome, but rather represents a form of disease progression. Immunohistochemical staining of

Figure 22.4 Low magnification image of a lymph node in CLL with "pseudo-follicular" pattern

Figure 22.5 Higher magnification of the same lymph node showing growth centers with increased prolymphocytes and paraimmunoblasts

Figure 22.6 Peripheral blood smear with "atypical" CLL. Cells have slightly less clumped chromatin and more flowing cytoplasm

sections of lymph nodes involved by CLL/SLL demonstrate weak expression of CD20 (stronger within the growth centers), expression of CD79a, coexpression of CD5 and CD23, and absence of cyclin D1.

CLL in most cases is easily diagnosed based on a combination of morphology and immunophenotypic findings. Rarely, cases are encountered where the distinction from other lymphoid leukemias or lymphomas is difficult, requiring ancillary studies such as cytogenetics, fluorescent in situ hybridization (FISH), and molecular genetics. In particular, the differential diagnosis of CLL includes a small group of other lymphoid malignancies with B cells coexpressing CD5. This list includes mantle cell lymphoma (MCL) and uncommon cases of marginal zone lymphoma (MZL) that may show CD5 expression. MCL typically has a distinct morphology, characterized by a cytologic spectrum rather than the typical dimorphic appearance of CLL. The peripheral blood may be involved at diagnosis in as many as one-third of cases. MCL in most cases reveals a small number of circulating blast cells, a feature that is never seen in CLL. However, rare cases exist that appear to overlap these two diseases, making accurate subclassification difficult. For these uncommon cases, other strategies can then be used to help distinguish between CLL and MCL. The immunophenotype of MCL is different from CLL in the majority of cases. The expression of CD20 is typically brighter than CLL, the cells express more sIg, they fail to express CD23, and virtually always express FMC7, an unusual epitope associated with the CD20 molecule. When a combination of morphology and immunophenotype do not allow a distinction between CLL and MCL, then FISH and/or standard cytogenetic studies are useful. MCL always shows the presence of a disease-defining translocation $t(11;14)(q13;q32)$ involving *CCND1* (cyclin D1) on chromosome 11. This translocation is never seen in CLL/SLL.

Lastly, infrequent cases of CLL are characterized by an atypical morphology (Figure 22.6). Such cases often show unusual morphologic features such as nuclear irregularity and more abundant, flowing cytoplasm. The cells may coexpress CD11c, a variable finding in typical CLL. These cases contain the subset of CLL in which the $t(14;19)(q32;q13)$ involving *BCL3* on chromosome 19q13 appears to be more common and tends to be associated with more aggressive clinical behavior. Chronic B-cell leukemias in which the cells lack CD5 coexpression should not be designated as CLL. Such cases frequently represent splenic MZL and may be associated with a slightly different morphology and the presence of some cells showing villous cytoplasmic projections. In the absence of other evidence to support a diagnosis of splenic MZL, based solely on the peripheral blood examination, such cases should be labeled as chronic B-cell leukemia, not otherwise specified.

IMMUNOPHENOTYPE

The immunophenotype of most cases of CLL allows ready distinction from other malignancies of mature B cells using only a limited panel of antibodies. The coexpression of CD5 and CD23 in the presence of low-level expression of CD20 and sIg is diagnostic (Table 22.1). CD23-negative CLL is rare and has been associated with a poor prognosis; whether it harbours specific genetic abnormalities is not yet known.

A more comprehensive analysis of the CLL cell surface has been performed assessing expression of a variety of other cell surface molecules in order to differentiate possible prognostic subgroups.¹⁸ All B-CLLs express the phenotype of activated B cells with overexpression of the activation markers CD23, CD25, CD69,

Table 22.1 The immunophenotype and functions of some of the molecules associated with CLL

CD antigen	Expression in lymphoid cells	Functions and comments
CD5	All T cells B-cell subset CD5 ⁺ DLBCL Mantle cell lymphoma Most (All) CLL	1. Negative regulator of B-cell receptor (BCR) signalling. 2. Stimulates autocrine IL10 production inhibiting apoptosis.
CD23/ FCεR2	Activated B cells Rare in DLBCL MCL usually negative. Most CLL	1. A key molecule for B-cell activation and growth. 2. Low-affinity IgE receptor. 3. Soluble forms (released by catalytic activity of ADAM 8/15/28) have potent mitogenic activity. Levels correlate with disease activity. 4. Upregulated by IL4.
CD79b	B-cells—component with CD79a of the BCR LOW expression in CLL.	CD79a/b heterodimer is critical for BCR signaling and regulates allelic exclusion, proliferation, differentiation, anergy, and apoptosis in mature B cells. ΔCD79b, an alternative splice transcript, is expressed preferentially in CLL.
CD20 FMC7	Broad expression in B-cell malignancies LOW expression in CLL.	Tetraspan family member. Only 47 amino acids in one loop potentially exposed at the cell surface. Mediates store-operated cation entry. Localized to microvilli. ¹⁵ FMC7 is a CD20 epitope.
CD38	Broad hemopoietic expression. High-level expression on plasma cells. High expression in poor prognosis CLL.	CD38 is a cyclic ADP-ribose hydrolase.
ZAP70	Normal T cells Various B-cell and T-cell malignancies Low-level expression in CLL with unmutated <i>IGHV</i> gene segments.	Intracellular kinase that transduces signals from the T-cell antigen receptor involved in BCR signaling in CLL. ¹⁶ May also be involved in CXCR4/SDF1 signaling Predominantly nuclear expression in CLL ¹⁷

and CD71, whereas, conversely, all exhibit down-regulation of CD22, FcγRIIb, CD79b, and IgD, molecules known to be down-regulated by cell triggering and activation. This composite phenotype is typical of memory B cells and is consistent with the gene expression profile of CLL.

The immunophenotype of CLL proliferation centers, however, differs significantly from that of cells in the peripheral blood.^{2,16} Such cells express Ki67, high-levels of CD20 and CD23, and unlike cells in the peripheral blood survivin. Whether cells in the proliferation centers preferentially express activation-induced cytidine deaminase (AID), an enzyme necessary for somatic hypermutation (SHM), class-switching of the *IGH* genes, and expressed in only a subclone in CLL, is not yet known.¹⁹ These and other data discussed below indicate that the proliferating cells in CLL may have a different phenotype and behavior from the bulk of cells in the peripheral blood.

The best molecule for prognostic evaluation is the intracellular tyrosine kinase, ZAP70.²⁰ This molecule was found to be expressed in CLL from gene expression profiling (GEP) experiments. This was an unanticipated finding, as until then ZAP70 had been described as a T-cell specific molecule involved in signal transduction from the T-cell receptor for antigen. ZAP70 expression has since been described in a variety of B-cell malignancies, where its expression is unexpectedly within the nucleus rather than the cytoplasm (Table 22.1). Its functions in B-cell malignancies are unknown, although it has been suggested that, as in T-cells, it may be involved in signal transduction from the B-cell receptor (BCR) for antigen (reviewed in Ref. 16). The major clinical interest in ZAP70 in CLL is that expression correlates strongly with absence of mutations within the *IGHV* region gene segments (qv), and may substitute for *IGHV* mutational analysis. ZAP70 expression may be detected by flow cytometry,

although problems with using this method include expression in residual T-cells and the low-level expression of the molecule in CLL.²¹ High ZAP70 expression correlates with a more aggressive clinical course.

CYTOGENETICS AND MOLECULAR CYTOGENETICS

Regular cytogenetic analysis of CLL is confounded by the low proliferative rate of the bulk of the cells and the presence of residual normal T cells. Comprehensive analysis has been performed by a number of dedicated centers worldwide, where conditions for CLL cytogenetics have been optimized. From these studies it is clear that, unlike the related diseases of mature B cells, such as follicular lymphoma or MCL, there is no obvious consistent cytogenetic lesion in CLL.

A number of recurrent abnormalities have been identified, although the molecular consequences of some remain to be unequivocally identified. Practically, these lesions can be readily detected using interphase FISH methods, either using individual BAC clones or using CLL specific BAC arrays.²² However, interphase methods will miss many of the complex cytogenetic events that may occur in CLL.²³ A further problem is that many of these events, including both 11q and 17p13 deletions, are secondary and thus only present in a fraction of cells at diagnosis; this may limit the clinical use of BAC arrays, whose sensitivity is not presently adequate to detect such minor changes.

As with acute lymphoblastic leukemia (ALL), detection of these genomic abnormalities is associated with specific prognostic groups and will form the basis for stratified therapy in future clinical trials.²⁴

Del(13)(q14): Loss of a region of 13q14 is the commonest lesion seen in CLL, one allele being lost in about 40% of the cases and both alleles in about 10–20% by interphase FISH analysis. Some of these deletions may be extremely small and may therefore be missed by interphase FISH. Deletions of this region in the absence of other abnormalities are associated with good prognosis disease in CLL. More recently, it has become apparent that deletions of this region may be seen not only in several other B-cell malignancies including MCL, diffuse large B-cell non-Hodgkin's lymphoma (DLBCL), and myeloma, but in solid tumors as well.

These data strongly suggest the presence of a tumor suppressor gene (TSG) within this region. However, despite characterization of many transcripts within the deleted region, the nature of the involved gene remains obscure (see for example Ref. 25 and references therein). According to Knudson's hypothesis for "classical" TSGs, deletion of one allele should be associated with mutation of the other; no mutations have been found in any of the candidate genes.

Similarly, no hypermethylation of the promoter regions, which would also result in reduced expression, has been observed in CLL. Haploinsufficiency, where loss of one allele alone results in a phenotype, may be the answer to this conundrum, but validation will require careful *in vivo* modeling.²⁶

Another possibility is that the 13q14 deletion may involve micro-RNAs (miRNAs), 19–22 nucleotide long genes that regulate key processes including apoptosis and proliferation.²⁷ Some miRNAs are developmentally regulated and some are B-cell specific; some are directly involved in chromosomal translocations, indicating a direct role in the pathogenesis of neoplasia.²⁸ It has been suggested that the target genes in CLL may be two adjacent miRNAs, miRNA15 and 16, clustered together on chromosome 13q14 within the final intron of the *DLEU2* gene⁵ (see also <http://www.sanger.ac.uk/Software/Rfam/mirna/index.shtml>). Furthermore, the same group has used an miRNA array to demonstrate that specific subgroups of CLL may be associated with specific miRNA "signatures."^{29,30} However, these data are controversial and need to be confirmed. The possible role of many of the other 206 miRNAs so far identified in the pathogenesis of B-cell malignancies remains to be investigated; it is of some considerable interest that many map to the sites of recurrent DNA damage in malignancy.

Del(11)(q22.3-q23.1): Deletions of this region are observed in about 12–15% of the cases. These deletions are molecularly variable and often secondary, but tend to be associated with progressive disease occurring in younger men with bulky lymph node disease. The association with poor prognosis may not be present in elderly patients with deletions of this region, about 50% of which appear to involve the gene that causes ataxia-telangiectasia, the *ATM* gene. This gene comprises 63 exons and encodes a huge protein of 3056 amino acids; consequently, mutational analysis is technically difficult. Mutations of *ATM* are seen in all cases of T-cell prolymphocytic leukemia and may also be found in 50% of CLL patients with 11q deletions. However, some of these "mutations" may in fact represent rare germline polymorphisms.

The ATM protein is an important cell cycle checkpoint kinase that functions as an activator/regulator of a wide variety of downstream proteins, including p53, checkpoint proteins RAD17 and RAD9A, and DNA repair proteins. Loss of ATM functions results in loss of responses to DNA damage, and consequently genomic instability.³¹

Del(17)(p13): deletion of the short arm of chromosome 17 is seen in about 5–7% of cases of CLL at diagnosis. This is often a secondary abnormality and therefore may be seen in only a fraction of the neoplastic cells. The target gene of this deletion is cases *TP53*, although deletion of one allele with no *TP53* mutations in the remaining allele may occur, suggesting the presence of another, more telomeric TSG on chromosome 17p.

Abnormalities within the *TP53/ATM* axis have a profound impact on the biological behavior of CLL; patients with either abnormality, but particularly those with *TP53* mutations, fare badly with conventional chemotherapy. Their detection may be an indication for early therapy with agents such as CAMPATH-1H (alemtuzumab), where elimination of the neoplastic cells does not depend on p53 function. Given the importance of changes in *TP53* and *ATM* to eventual clinical outcome, and the difficulties in assessing both genes, a simple functional assay may be of value. The response to ionizing irradiation in terms of increased p21 expression allows a direct assessment of both p53 and ATM functions.³²

Although the consequences of *ATM* and *TP53* inactivation are similar, they are by no means identical. Genome-wide expression experiments have indicated that the worse response of patients with *TP53* mutations may reflect the loss of p53-dependent apoptotic pathways.³³

Trisomy 12: This abnormality occurs in about 15% of CLL patients and again is usually only seen in a fraction of the cells. The percentage of cells with trisomy 12 often does not increase with transformation. The specific molecular consequences of this abnormality, which again is not specific for CLL, are not clear.

IG TRANSLOCATIONS IN CLL

Although *IG* translocations are rare in CLL³⁴ and probably comprise no more than 5% of cases, they have allowed the identification of a number of genes of interest. They appear to be associated with aggressive disease. The presence of a t(11;14)(q13;q32) in a mature B-cell malignancy precludes the diagnosis of CLL; MCL in leukemic phase, a specific subtype of MCL, is most likely. Detection of *IGH* translocations is now performed by interphase FISH, but these methods have not been used to detect *IG* light chain translocations in any large series of CLL patients.

***BCL2*:** All cases of CLL express high levels of *BCL2* RNA and protein. It has been suggested that this high-level expression is due to hypomethylation of the *BCL2* promoter. Chromosomal translocations involving *BCL2* are rare and probably occur in no more than 2% of the cases. *BCL2* translocations may be secondary events in CLL. The prognostic implication of *BCL2* translocations in CLL is uncertain, as the levels of protein expression are very high in cases lacking the translocation.

The nature of *BCL2* translocations in CLL suggests a pathogenetic mechanism distinct from that seen in follicular non-Hodgkin's lymphoma. Unlike *BCL2* translocations in follicular lymphoma, in CLL, most involve the *IG* light chain gene segments. The breakpoints within *BCL2* are also different; most breakpoints in CLL involve the 5' region of the gene within the variant cluster region.

***BCL3*:** Originally identified by its involvement in t(14;19)(q32;q13), *BCL3* is a member of the IκB family of proteins, which mediates transcriptional up-regulation of NFκB target genes through interaction with p50/p52 homodimers. The translocation is not specific for CLL and occurs in several B-cell malignancies.

***BCL11A*:** This gene, which encodes a Krüppel zinc finger protein, was cloned from its direct involvement in t(2;14)(p13;q32) in cases of aggressive CLL. How *BCL11A* transforms B cells remains unknown. It is a transcriptional repressor that binds directly to *BCL6*; however, *BCL6* is not usually expressed at high levels, if at all, in CLL. *BCL11A* translocations are rare in CLL. All cases to date have retained germline *IGHV* segments, despite having undergone class switch recombination.

IGHV AND BCL6 MUTATIONAL ANALYSIS IN CLL

SHM of the *IGHV* gene segments is an essential component in the generation of high affinity antibodies during the immune response. This process introduces targeted mutations primarily into the complementarity determining regions (CDRs) of productively rearranged *IGHV* segments at extremely high rates. *IGHV* mutational analysis should reflect the history of a B cell: mutations indicate encounter with antigen in the germinal center, while unmutated *IGHV* sequences indicate antigen naïve B cells. SHM is potentially a dangerous, mutagenic process, and errors in SHM have been implicated in the pathogenesis of B-cell lymphomas through the generation of *IG* chromosomal translocations. SHM may also act on other non-*IG* genes in both normal and malignant B cells.

Mutational analysis of *IGHV* gene segments in CLL has been and continues to shed significant light on the pathogenesis of the disease (reviewed in Refs. 16 and 35). In 1999, two groups independently showed that the presence or absence of *IGHV* mutations defined prognostically important subgroups of CLL; patients lacking *IGHV* mutations fared worse than patients with mutated sequences. One simple interpretation of these data is that the unmutated CLL represents malignant transformation of antigen naïve B cells. However, these data are not consistent with either the activated B-cell phenotype of CLL, or the gene expression profile, both of which are most similar to memory B cells with continued environmental stimulation.

Mature B cells depend on maintained stimulation via the BCR for antigen, and loss of this complex results in rapid B-cell death by apoptosis.³⁶ One possible explanation for the presence of unmutated *IGHV* in CLL might be the strength of antigenic stimulation with persistent environmental or autoantigenic stimulation driving at least the early phases of development of the neoplastic clone. Such cells might persist and be

antigenically challenged without negotiating a classical germinal center reaction. If persistent exogenous antigenic stimulation were confirmed, it would be analogous to the development of extranodal mucosa-associated lymphoid tissue lymphomas, which have been shown to be dependent on chronic antigenic stimulation of an increasing number of microbial antigens.³⁷

Consistent with this hypothesis of recurrent antigenic stimulation is the restricted *IGHV* and *IG* light chain (*IGL*) repertoires in at least some cases of CLL.^{35,38,39} Individual *IGHV* segments tend either to be mutated or unmutated and to have similar if not identical CDRs. For instance, in one study of class-switched non-IgM producing CLL, five cases of sIgG⁺ CLL were found to share CDR motifs not only in the heavy chain but also in the light chain. Three-dimensional modeling indicated that these antibodies could bind the same antigenic epitope. On the basis of the restricted antibody responses to carbohydrate antigens, it was suggested that this epitope might be a carbohydrate determinant.³⁸ In a study of 1220 CLL patients, 164 (13.8%) had VH1-69 and of these 163 were in germline configuration³⁹; moreover, there appeared to be marked restriction in the CDR3 region in at least 15 of these patients, who also had the same light chain gene. These data suggest that there is either a strong antigenic selection process, or that B cells bearing this particular combination of *IG* recombination events are somehow more sensitive to transformation. The presence of such restricted antibody specificities allows new experimental approaches into the pathogenesis of CLL.

However, not all mutated CLL behave “well.” It is apparent from several series that patients with mutations in the *IGHV3-21* segment have progressive disease.⁴⁰ In at least some cases this would appear to be due to an association with the TP53 mutation.⁴¹

BCL6 mutations, clustering within the region subject to chromosomal translocations in follicular and DLBCL and presumably arising due to the actions of SHM, have been reported in CLL.³⁴ In two reports there was concordance between presence of *IGHV* mutations, but not in the third. This controversy remains to be resolved. In contrast to DLBCL, where SHM-induced mutations may commonly occur in other proto-oncogenes, such mutations appear to be rare in CLL.

GENOME-WIDE GEP

GEP experiments using either the Lymphochip or Affymetrix arrays have shown that all CLL samples have a remarkably consistent profile, independent of *IGHV* mutational status, consistent with their origination from memory B cells. In this regard, CLL differs from other B-cell diseases such as DLBCL, where the profile differs markedly from case to case. CLL

expresses genes not expressed in normal memory B cells, including ROR1 receptor tyrosine kinase and CD200, and conversely, lacks expression of other genes normally expressed in normal memory cells, such as histone H2AX and RAD9. The biological relevance of these observations remains to be determined; some of these may be of direct pathological significance in the development of CLL.

Despite the relative constancy of the CLL gene signature, a number of genes were identified whose expression segregated with the presence or absence of mutations. As mentioned earlier, *ZAP70* expression correlated most strongly with the unmutated *IGHV* subset of CLL. Other genes differentially expressed between the two subsets of disease included *BCL7A*, *FGFR1*, and *PAK1*. Many of the genes that were more highly expressed in unmutated CLL were induced during activation of blood B cells.

More recent GEP experiments have focussed on responses of CLL to irradiation-induced DNA damage and defining pathways that mediate resistance.^{33,42}

BIOLOGY OF CLL

An observation made years ago is that CLL B cells isolated from the peripheral blood undergo rapid apoptosis in vitro. The rate of apoptosis varies substantially, but there appears to be no simple correlation between rates of apoptosis in vitro and clinical outcome. A similar rapid rate of in vitro apoptosis is also observed in B cells derived from involved lymph nodes in patients with follicular lymphoma. As both populations express large amounts of BCL2 protein, these data may indicate that BCL2 alone is insufficient to suppress “spontaneous” apoptosis.

CLL cells in vivo do not appear to undergo such rapid apoptosis; work has been done to elucidate signaling pathways that maintain the viability in vitro, as definition of these pathways might define new therapeutic targets. A number of signaling pathways have been implicated, including IL4, IL7, CXCR4/SDF1, BAFF, and integrin signaling; the possible clinical relevance of these remains to be determined. Comparison of experiments is difficult because of differing culture conditions used. Serum-free conditions for the maintenance of CLL cells in vitro have been defined, but have not been widely used.⁴³ Also, in most cases adequate definition of the CLL cells used in the experiments, in terms of both *IGHV* mutational and molecular cytogenetic analysis, has not been performed.

Spontaneous apoptosis may be suppressed simply by either

- a) *culturing at high density*,⁴⁴ most in vitro experiments use much lower concentrations of cells (10⁶ cells/mL) than those actually seen in a patient, or
- b) *culturing in the presence of albumin*.⁴⁵

Culturing CLL in the presence of adherent cells from a wide variety of sources, including marrow mesenchymal cells, may also prevent apoptosis.^{46,47} The presence in the peripheral blood, specialized dendritic or “nurse” cells may maintain the viability of CLL for prolonged periods.¹

Prevention of proteolytic degradation of the anti-apoptotic molecule MCL1 appears to be a key event in most of these experiments⁴⁸; the rapid turnover of this protein may make it a target for a variety of therapeutic approaches. However, all of the above techniques do not result in proliferation of CLL cells, but rather in maintained viability. CLL cells in the blood are in the G₀ phase of the cell cycle. As with spontaneous apoptosis, a large number of simple manoeuvres, such as CpG dinucleotide stimulation along with IL2, or TNF α and IL6, can result in proliferation.⁴⁹

However, the physiological and biological relevance of all of the above observations is not clear. Nor is it certain that cells derived from the peripheral blood are the correct population to be studied. Few studies have been done on either bone marrow or lymph node CLL cells, which may differ considerably from cells within the blood.

Moreover, a number of interesting studies in vivo suggest that CLL, rather than being a disease of suppressed apoptosis with only gradual accumulation of cells, may in fact, like other malignancies, be a disease of proliferation. First, there is evidence using metabolic labeling with D₂O or heavy water and mass spectrometry that patients with clinical stage A disease with stable peripheral blood lymphocytes may nevertheless turnover the entire clone in a matter of months.³ Secondly, and less directly, B-CLL cells have been shown to have significantly shorter telomeres than those in autologous neutrophils and B cells from healthy age-matched subjects; patients with unmutated *IGHV* genes had significantly shorter telomeres than those in mutated *IGHV* genes.^{50,51} These data suggest that a considerable number of cell divisions

must have occurred in the leukemic cells after their genesis.

Taken together, these results indicate that CLL may be rapidly turning over in vivo and that several cell-cell interactions are required in order to maintain the viability of CLL cells. The necessity for persistent signaling suggests new therapeutic approaches.

There are also profound immunological defects in CLL whose biology remains poorly understood. Suppression of residual normal B cells as detected by low serum immunoglobulin levels is a feature, and worsens with disease progression. One explanation might be the release of immunosuppressive cytokines, such as IL10 or TGF β , from CLL B cells. However, there are also marked abnormalities of the T-cell populations in CLL. Somewhat surprisingly, their numbers are usually increased in CLL and their persistence may be essential for progression of CLL (reviewed in Ref. 16).

CONCLUSIONS

Historically, CLL has lagged behind the other B-cell malignancies in terms of molecular and biological analysis. This situation is now changing rapidly. We are beginning to make progress in our understanding of the basic biology of CLL. The paradigm of gradual accumulation of apoptotic defective mature B cells is now being replaced by a much more complex and dynamic picture of proliferating CLL stem cells⁵² continued superantigen drive, and persistent stimulation by a variety of different stromal and perhaps T cells, with constant turnover of cells in the periphery. The nature of the CLL stem cell and the nature of the initiating genetic events in this cell population are key aims; identification of both would hopefully allow the development of more effective and targeted therapies, along the lines of the paradigm established in chronic myeloid leukemia and imatinib.

Chapter 23

CLINICAL FEATURES AND MAKING THE DIAGNOSIS

*William G. Wierda, Joan H. Admirand,
and Susan M. O'Brien*

INTRODUCTION

Chronic lymphocytic leukemia (CLL) is characterized by accumulation of monoclonal malignant B cells in blood, lymph nodes, liver, spleen, and bone marrow. These cells have a unique immunophenotype and biology. With time, patients may develop progressive lymphocytosis, lymphadenopathy, hepatosplenomegaly, anemia, and thrombocytopenia. Prior to the availability of flow cytometry, cytogenetic, and molecular analyses, the diagnosis was made based on an elevated white blood cell count with morphologic examination of the blood smear demonstrating characteristically small, well-differentiated lymphocytes. Some patients also presented with lymphadenopathy and/or hepatosplenomegaly. Flow cytometry has made evaluation and characterization of B-cell lymphoproliferative diseases more precise and has enabled identification of subgroups of patients with clinically distinct diagnoses. Karyotypic analyses, including standard metaphase chromosome analysis and fluorescence in situ hybridization (FISH), have also been key in identifying subgroups of patients with B-cell lymphoproliferative diseases. Still, CLL remains a diagnosis for which diverse clinical courses are observed and are dictated by characteristics of the individual patients' leukemic clone. Continued work to identify important and significant prognostic factors will enable identification of clinical entities that represent distinct diseases within the group of patients currently diagnosed with CLL. In this chapter, we will review diagnostic criteria and clinical characteristics of patients with CLL.

EPIDEMIOLOGY

CLL is the most common adult form of leukemia in Western society. According to a recent analysis of the Surveillance Epidemiology and End Results database,¹ the annual overall age-adjusted incidence in the United

States between 1997 and 2001 was 3.5/100,000 people: 5.0/100,000 for males and 2.5/100,000 for females. This is a disease of older adults with distinct and unique clinical characteristics and concerns. The majority of individuals are diagnosed when over 65 years of age, and the incidence increases with increasing age. The incidence for individuals over age 70 years is 50/100,000. The median age at diagnosis between 1997 and 2001 was 72 years: for males 70 years and 74 years of age for females. This median has risen over the past 10–15 years, likely due to aging of the U.S. population. The 5-year survival (1995–2000) was 73% overall: 71% for males and 76% for females. The median age at death was 78 years: 76 for males and 81 years for females.

In the United States, CLL is most common in the Caucasian population and less common in African-Americans and individuals from the Far East. The age-adjusted annual incidence between 1975 and 2001 for Caucasians was 3.9/100,000 and for African-Americans 2.8/100,000.¹ CLL is rare in individuals of Japanese ancestry.

Ghia et al. screened blood from 500 unselected healthy individuals over age 65 and identified a population of monoclonal (by light-chain analysis) CD5⁺/19⁺/23⁺ B cells in 3.8% of these individuals.² These asymptomatic individuals did not have lymphocytosis or clinical evidence of disease, and did not fulfill diagnostic criteria for CLL. Whether or not some or all of these individuals will progress to fulfill diagnostic criteria or develop symptomatic disease is unclear. Nevertheless, this indicates that the incidence of a monoclonal lymphoproliferative process is potentially much more common in the elderly population than has been previously appreciated.

The demographics of newly diagnosed patients are different today than 20 years ago. Due to the widespread availability of routine automated blood counts, a large proportion of patients is diagnosed based on incidental finding of lymphocytosis in the absence of any significant symptoms. These patients are therefore

being diagnosed at an earlier stage. The overwhelming majority of patients present to private practice physicians and are followed and treated in this setting. Patients followed and treated at tertiary referral centers tend to be younger and more heavily pretreated. The median age for both previously untreated and previously treated patients on clinical trials at such institutions is roughly 60 years of age.

CLINICAL PRESENTATION

The clinical presentation of CLL patients is diverse, with variability in presenting symptoms, physical examination findings, and laboratory test results. As noted above, patients often present without any symptoms, and the diagnosis is made on the basis of an elevated absolute lymphocyte count found on routine complete blood count (CBC). Less commonly, patients present with nontender lymphadenopathy, and are noted to have an elevated blood lymphocyte count on further evaluation. Some patients present with concomitant illnesses such as infection or chronic rhinitis, or less commonly, autoimmune phenomena such as autoimmune hemolytic anemia (AIHA) or immune thrombocytopenia purpura (ITP).

CRITERIA FOR DIAGNOSIS

The National Cancer Institute (NCI) sponsored a working group in 1988 that developed criteria and guidelines for clinical protocols, as well as general-practice recommendations for patients with CLL.³ In 1996, the criteria and guidelines were revised to those in current use.⁴ These guidelines importantly include indications for treatment and criteria for evaluating response to treatment. The diagnosis of CLL requires a sustained absolute lymphocytosis of greater than 5000 lymphocytes/ μ L. This value is also important for making the academic distinction between CLL and small lymphocytic lymphoma (SLL), in which the absolute lymphocyte count is less than 5000 lymphocytes/ μ L. Patients with greater than 55% prolymphocytes on differential or greater than 15,000 prolymphocytes/ μ L meet the diagnostic criteria for prolymphocytic leukemia (PLL). Morphologic assessment and flow cytometry immunophenotyping are critical to confirming the diagnosis of CLL and will be discussed subsequently in this chapter.

Although a bone marrow aspirate and biopsy are not required for making the diagnosis of CLL, if performed, the aspirate smear should show greater than 30% of nucleated cells to be lymphocytes according to the NCI criteria.⁴ Evaluation of the sectioned bone marrow core biopsy will identify the pattern of involvement, which has prognostic value. As the bone marrow is always involved and is the last to be cleared with standard chemotherapy, a bone marrow exami-

nation is most helpful in evaluating response to treatment and is required to confirm complete remission. A bone marrow aspirate and biopsy are also useful in evaluating patients with thrombocytopenia to differentiate between an autoimmune process and lack of platelet production due to CLL marrow infiltration.

DIFFERENTIAL DIAGNOSIS

A malignant lymphoproliferative disorder should be suspected when the absolute lymphocyte count is greater than 5000 lymphocytes/ μ L. The differential diagnosis for patients with lymphocytosis, lymphadenopathy, and/or organomegaly includes numerous malignant lymphoproliferative disorders (Table 23.1). These include CLL, PLL, adult peripheral T-cell lymphoma, natural killer cell leukemia, mantle cell lymphoma, marginal zone lymphoma (nodal, extranodal, or splenic), hairy cell leukemia, SLL, lymphoplasmacytic leukemia, and follicular center lymphoma in a leukemic phase. Distinguishing CLL from other lymphoproliferative disorders is based on morphology and, more importantly, on immunophenotype (Figure 23.1).

Lymphocytosis may be reactive and therefore polyclonal and benign (Table 23.2). This must be distinguished from the malignant monoclonal lymphoproliferative disorders. Reactive lymphocytosis may be due to viral or bacterial infections. In addition, individuals may have elevated lymphocyte counts following splenectomy. For B-cell lymphoproliferative diseases, monoclonality is usually established by immunoglobulin (Ig) light-chain restriction.⁵

Table 23.1 Differential diagnosis for monoclonal B-cell lymphoproliferative disorders

Clonal lymphocyte population	Disease
B Cell	Chronic lymphocytic leukemia Mantle cell lymphoma Follicular lymphoma Hairy cell leukemia Splenic marginal zone lymphoma Splenic lymphoma with villous lymphocytes Lymphoplasmacytoid lymphoma B-cell prolymphocytic leukemia
T Cell	Sezary syndrome Large granular lymphocyte leukemia Adult T-cell leukemia/lymphoma HTLV-1 ⁺ T-cell leukemia T-cell prolymphocytic leukemia

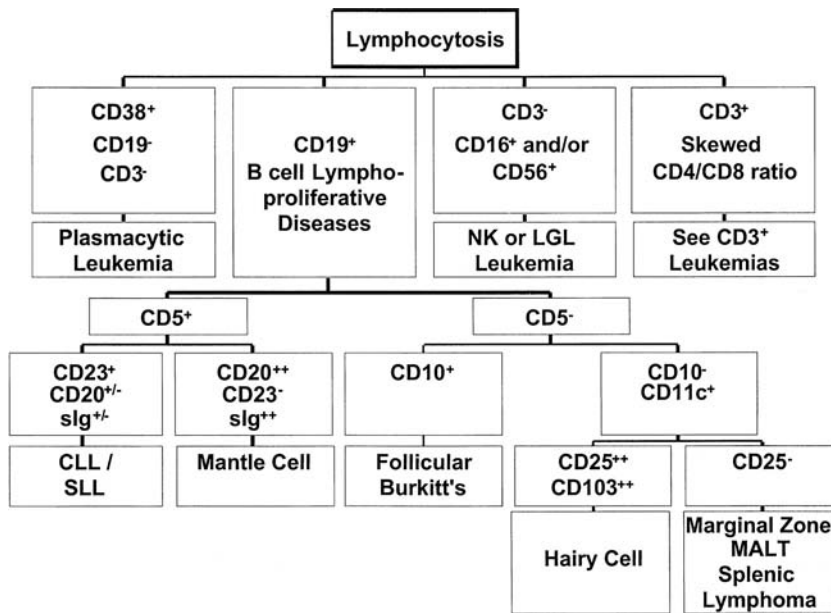

Figure 23.1 Characterization of malignant lymphocytosis by flow cytometry. Lymphoproliferative disorders are characterized by flow cytometry based on T- and B-cell markers. This figure further classifies CD19+ lymphoproliferative diseases based on B-cell markers

SYMPTOMS

Many patients are asymptomatic at diagnosis, particularly patients with early stage disease. Symptoms may include weakness, malaise, fatigue, night sweats, and low-grade fever without evidence of infection. Unintentional weight loss is not common but if it reaches or exceeds 10% body weight in a 6-month period, it is an indication for treatment. Classical B symptoms are uncommon in patients with CLL, and if present in those with long-standing disease may indicate transformation to large-cell lymphoma (Richter transformation). Less commonly, patients may complain of rheumatology-type symptoms, such as arthralgias and myalgias. These rheumatologic symp-

toms may be associated with rheumatoid factor.⁶ It is uncommon for progressive adenopathy to produce pain, airway or vascular compromise, or obstruction of the gastrointestinal tract. Organomegaly, particularly splenomegaly, also occurs with progressive disease. Splenomegaly is usually painless, but may cause early satiety and bloating. Patients with CLL can have exaggerated reactions to mosquito or other insect bites.⁷⁻⁹ The pathophysiology for this hyperresponsiveness is unknown.

PHYSICAL FINDINGS

The most common finding on physical examination is adenopathy, which is most easily appreciated in the cervical, axillary, and inguinal regions. Adenopathy is typically symmetric, but may be more prominent in a particular region of the body, such as the neck. If adenopathy is asymmetric, or there is rapid increase in a localized nodal group, suspicion should be raised for Richter transformation. Organomegaly typically involves the spleen; hepatomegaly due to leukemic infiltration is less common. Although extranodal involvement is rare, patients may develop leukemic infiltrates in the skin,^{10,11} mucosa-associated lymphoid tissue,^{12,13} or lungs.¹⁴⁻¹⁶ Central nervous system involvement with leukemia is rare, but can cause headache, meningitis, cranial nerve palsy, mental status changes, or coma.¹⁷ The kidneys or collecting system may be involved with leukemia.¹⁸⁻²¹ This is rare and difficult to document by histology. When present, it may be characterized by a progressive rise in creatinine that improves following treatment. Overall, patients with extranodal involvement tend to have more aggressive disease and a worse prognosis.

Table 23.2 Benign lymphocytosis

Lymphocyte population	Etiology
B Cell	Postsplenectomy Persistent polyclonal B-cell lymphocytosis
T Cell	Viral infection (EBV, CMV, influenza, hepatitis, HTLV) Bordetella pertussis Syphilis Mycobacterium tuberculosis Serum sickness Thyrotoxicosis Addison disease Postsplenectomy

EBV, Epstein-Barr virus; CMV, cytomegalovirus; HTLV, human T-lymphotrophic virus.

LABORATORY FINDINGS

BLOOD FINDINGS

In previously untreated patients, lymphocytosis must be present. Lymphocytosis may be affected by treatment, and some patients may have prominent adenopathy with minimal lymphocytosis following treatment. The leukemic cells of patients with CLL are typically small-to-medium size, well differentiated, and have a thin rim of cytoplasm and a dense, homogenous, round nucleus that is slightly eccentrically located [Figure 23.2(a)].²² The chromatin is clumped and nucleoli are usually not prominent. Prolymphocytes are larger with dispersed chromatin, a single nucleolus, and more abundant cytoplasm [Figure 23.2(b)]. For typical CLL, there should be fewer than 10% prolymphocytes.²³ CLL with increased prolymphocytes (CLL/PL) is defined by more than 10% but fewer than 55% prolymphocytes. Patients with greater than 55% prolymphocytes or greater than 15,000

prolymphocytes/ μL meet the diagnostic criteria for PLL. Smudge cells may be present on the peripheral blood smear of patients with CLL [Figure 23.2(c)].²⁴ These are leukemia cell artifacts that result from rupture of fragile lymphocytes with processing and preparation of the blood smear. Patients with CLL almost never experience leukostasis syndrome. With a rising absolute lymphocyte count, there is a relative reduction in the number of neutrophils; previously untreated patients may develop neutropenia (≤ 500 neutrophils/ μL). This may be a dilution effect, but may also be due to reduced production as a result of CLL bone marrow infiltration.

STAGING

Stage has prognostic importance for patients with CLL. It is also used as a guide to initiate treatment. Staging is most useful at diagnosis, prior to administration of any treatment. There are two major staging systems:

Figure 23.2 Morphology and histology of CLL in peripheral blood and lymph node. (a) Peripheral blood smear of a patient with CLL ($1000\times$ magnification). Typical CLL lymphocytes are small and well differentiated, with round nuclei and clumped chromatin. (b) Peripheral blood smear of a patient with PLL. Prolymphocytes comprise greater than 55% of cells and are larger with dispersed chromatin, prominent, single nucleoli, and abundant cytoplasm ($1000\times$ magnification). (c) Peripheral blood smear of a patient with CLL, illustrating “smudge cells” ($500\times$ magnification)

the Rai staging system,^{25,26} used in the United States, and the Binet staging system,²⁷ used more commonly in Europe (Table 23.3). The Rai staging system was initially proposed as a five-stage system, with stage 0 characterized by lymphocytosis, stage I by adenopathy, stage II by organomegaly, stage III by anemia, and stage IV by thrombocytopenia.²⁵ This five-stage system was simplified into three stages, consisting of low risk (stage 0), intermediate risk (stages I and II), and high risk (stages III and IV).²⁶ The estimated median survival for patients with low-risk disease was >10 years, for intermediate-risk disease 7 years, and for high-risk disease 1.5–4 years. The Binet system is a three-stage system and is based on the number of lymph node sites involved and the presence or absence of cytopenias. Generally, patients progress through the stages with progression of their disease, in the absence of treatment.

The prognostic significance of stage is more obvious for patients with advanced-stage disease. However, the majority of patients are diagnosed with early stage disease, of whom about half will have an indolent clinical course and the other half will have a more progressive course. Therefore, significant effort has gone into identifying prognostic factors for patients with early stage disease that predict for rapidly progressive disease. Recently identified important prognostic factors that have been identified include immunoglobulin heavy-chain variable (IgV_H) gene mutational status,^{28,29} expression of surface CD38,^{29,30} and ZAP-70 expression.^{31–34} These prognostic factors are most useful for

counseling patients with early stage disease, as approximately half of these patients will be nonprogressors with an indolent clinical course and half will have progressive disease, requiring treatment in a short period.

EVALUATION OF PATIENTS WITH CLL

Initial evaluation (Table 23.4) of patients suspected of having CLL should begin with a complete history and physical examination. There are no known associations between CLL and environmental exposures; therefore, exposure history is usually noncontributory. There is a strong association between genetics and risk for CLL,^{35–37} making family history an important part of the evaluation. Physical examination should concentrate on evaluation for adenopathy and hepatosplenomegaly. CBC with differential and morphologic examination of the blood smear provides both diagnostic and staging information. Immunophenotype analysis of blood or bone marrow is also required. Phenotypic markers for a complete workup should include Ig light chains (κ and λ), CD5, CD19, CD23, CD20, CD79b, FMC7, CD11c, CD22, CD25, CD10, and CD38 (prognostic). Karyotype analysis by FISH for 13q deletion, 17p deletion, 11q deletion, and trisomy 12 yields useful prognostic information for counseling patients; standard metaphase karyotype is of lower yield and will often miss 13q deletion. Serum chemistries should be performed, including serum creatinine, especially if it is likely that treatment will be initiated. Measure of serum β -2-microglobulin

Table 23.3 Staging systems for CLL

Staging system	Simplified three-stage system	Clinical features at diagnosis	Estimated median survival (years)
Rai stage			
0	Low risk	Lymphocytosis in blood and marrow only	>10
I	Intermediate risk	Lymphocytosis and lymphadenopathy	7
II		Lymphocytosis and splenomegaly and/or hepatomegaly	
III	High risk	Lymphocytosis and anemia (Hgb <11 g/dL)	1.5–4
IV		Lymphocytosis and thrombocytopenia (PLT <100,000/ μ L)	
Binet stage			
A		Blood and marrow lymphocytosis and <3 areas of palpable node/organ enlargement (cervical, axillary, or inguinal; liver or spleen)	>7
B		Blood and marrow lymphocytosis and \geq 3 areas of palpable node/organ enlargement (cervical, axillary, or inguinal; liver or spleen)	<5
C		Same as B with anemia (Hgb <11 g/dL for men and <10 g/dL for women) or thrombocytopenia (PLT <100,000/ μ L)	<2

Hgb, hemoglobin; PLT, platelets.

Table 23.4 Evaluation of newly diagnosed patients with CLL

Essential studies

- History and physical examination
- CBC and differential
- Morphologic examination of peripheral blood smear
- Immunophenotype of blood or bone marrow aspiration
- Markers include surface Ig (IgM, IgD, and IgG), Ig light chains (κ and λ), CD5, CD19, CD20, CD23, CD79b, CD11c, CD22, CD38, CD10, and FMC7
- Cytogenetic analysis with FISH for 13q deletion, 11q deletion, trisomy 12, and 17p deletion
- Serum chemistries including creatinine, β -2-microglobulin, quantitative Ig
- Serial CBC to determine lymphocyte doubling time

Optional studies

- Bone marrow aspirate and core biopsy
- Leukemia cell ZAP-70 expression
- IgV_H* gene sequence

provides prognostic information.^{38,39} Quantitative immunoglobulin levels should be obtained to assess for hypogammaglobulinemia. Occasionally, IgG or IgM will be elevated, in which case serum protein electrophoresis with immunofixation can be obtained to evaluate for the presence of a monoclonal paraprotein.^{40,41} If available, ZAP-70 expression should be measured as a prognostic marker. Further evaluation should be directed by clinical judgment. If AIHA is suspected, then reticulocyte count, direct and indirect Coomb test, haptoglobin level, lactate dehydrogenase, and fractionated bilirubin should be evaluated. Radiographic studies are not required for staging; however, they should be obtained when clinically indicated.

IMMUNE DEFECTS

The immune system is composed of unique and diverse effector cells and soluble factors (proteins) that must be carefully orchestrated in order to carry out innate and adaptive protective functions. CLL B cells disrupt the immune function of patients with CLL (Table 23.5). The most evident manifestation of immune dysfunction is the increased risk and frequency of infection. Many patients with CLL succumb to infection or ineffectively treated autoimmunity.⁴²⁻⁴⁴ The treatments used for CLL, such as purine analogs, further immunosuppress patients and put them at increased risk for opportunistic infections and may exacerbate or unmask autoimmunity.⁴⁵⁻⁴⁷

HUMORAL DEFECTS

Immunoglobulin

Hypogammaglobulinemia is a common and progressive immune defect in patients with CLL and is another factor that increases the risk of infection.^{44,48} Furthermore, dysregulated humoral immunity is associated with ineffective production of antigen-specific antibodies.⁴⁹

Hypogammaglobulinemia is not always present at diagnosis, but frequently develops as the disease progresses. It follows that the incidence increases with duration of disease and with advancing stage.⁵⁰⁻⁵² It is progressive and tends to be irreversible; immunoglobulin levels rarely return to normal even in those patients achieving complete remission with treatment. This refractoriness to recovery may be related to prolonged lymphopenia induced by purine analogs.

Table 23.5 Immune defects in patients with CLL

Defect	Characteristic
T cell	Inverted blood CD4/CD8 ratio Poor T-cell response to mitogens Defective expression of function-associated surface molecules Increased CD8 ⁺ suppressor cell function Anergy/hyporesponsive skin testing
B cell	Reduced number in blood Reduced immunoglobulin production
Neutrophil	Quantitative decrease in neutrophils Functional defects—chemotaxis, phagocytosis, and chemiluminescence
Hypogammaglobulinemia	Overall decreased serum immunoglobulin levels Decreased serum IgG3, IgG4, and IgA Decreased mucosal IgA and IgM
Complement Deficiency	Decreased C1 and C4 C1 esterase inhibitor deficiency

Hypogammaglobulinemia is directly related to morbidity and mortality in patients with CLL since it increases the risk for infection with encapsulated bacteria, and infection is the cause of death in 30–50% of patients with CLL.^{52–55} Also, reduced mucosal IgA and IgM are risk factors for developing respiratory tract infections, such as pneumonia. The risk of morbidity and mortality appears to increase when IgG levels fall below 700 mg/dL; reduced serum IgA levels are also correlated with shorter survival.⁵⁶ It is intriguing that certain isotypes and subclasses tend to be more commonly affected, particularly IgG3 and IgG4.^{55,57} Some patients have marked hypogammaglobulinemia but do not develop infections, leading to speculation that certain Ig subclasses may be more critical for protection than currently appreciated.

AUTOIMMUNITY

Although CLL is characterized by progressive hypogammaglobulinemia and defective T-cell immunity, a paradoxical event is the development of autoimmunity in some patients with this disease. The autoimmune targets are predominately hematopoietic cells, specifically mature red blood cells, platelets, or red blood cell precursors. AIHA is the most common feature and together with ITP may occur in as many as 35% of patients.^{58,59} Much less commonly, patients may develop a lupus-like condition⁶⁰ or rheumatoid arthritis.⁶ The mechanism by which patients develop this autoimmunity is unclear. Occasionally, such events can be severe, refractory to treatment, and lead to significant morbidity and mortality.

Autoantibodies are more common in the elderly population,⁶¹ nearly as frequent as seen with individuals with CLL; however, the incidence of AIHA is higher in patients with CLL than normal age-matched individuals. CLL is the most common cause of secondary AIHA.⁶² AIHA in CLL is characterized by production of polyclonal antibodies against mature red blood cells. These are “warm antibodies” and are demonstrated with the Coomb test. The autoantibodies are typically IgG isotype, indicating participation of activated T cells and memory cells. The prevalence of AIHA increases with advanced stage and progression of the disease.⁶³ CLL B cells have been shown to produce Ig with low-level autoreactivity, but there is no evidence that the leukemia cells produce the autoantibodies responsible for AIHA or ITP. A significant proportion of patients (over 20%) with CLL have positive direct Coomb tests; however, not

all of these patients will develop clinically significant AIHA. In addition, not all patients with active hemolysis will have a positive direct or indirect Coombs tests.

Treatment, particularly with the purine analog fludarabine, has been associated with development of AIHA.^{64,65} However, randomized trials comparing fludarabine to alkylating-agent-based therapy have not shown a significantly higher incidence of AIHA in patients receiving fludarabine. The mechanism for treatment-induced autoimmunity is likely unmasking of autoimmunity after alteration of T-lymphocyte populations.

ITP occurs in 2–5% of patients with CLL.^{58,63,66} ITP is more difficult to diagnose than is AIHA due to a lack of reliable diagnostic laboratory tests. Antiplatelet antibody studies are unreliable. In addition, there are other causes for thrombocytopenia patients with CLL. Specifically, thrombocytopenia may be caused by progressive bone marrow infiltration by leukemia cells with disease progression. In addition, splenomegaly that develops with disease progression may contribute to thrombocytopenia through sequestration. Despite this, it is unusual for marrow infiltration or splenomegaly to result in a platelet count less than 10,000/ μ L. If patients develop thrombocytopenia to this degree in the absence of cytotoxic chemotherapy, then ITP is high on the differential diagnosis.

Similarly to AIHA, ITP results from production of polyclonal antibodies of IgG isotype. Production of such antibodies implies the participation of activated T cells in this reaction and production of memory cells. Cytotoxic chemotherapy has also been reported to trigger ITP in patients with CLL. Notably, approximately one-third of patients with ITP associated with CLL also have a positive direct Coomb test.⁶⁷

CONCLUSIONS

Great progress has been made over the past 10–20 years in characterizing B-cell lymphoproliferative diseases, particularly CLL. Immunophenotypic analysis, as well as molecular genetics, has significantly contributed to this characterization. However, significant heterogeneity still exists in the clinical courses of patients diagnosed with this disease. Further progress in defining subsets of patients with a more homogeneous prognosis will likely be aided by further identification of molecular aberrations in this disease.

Chapter 24

INDICATIONS FOR TREATMENT AND TREATMENT APPROACH FOR CHRONIC LYMPHOCYtic LEUKEMIA

Kanti R. Rai and Bhoomi Mehrotra

The answer to the question of when to initiate cytotoxic therapy in a patient with chronic lymphocytic leukemia (CLL) has been modified and refined in the past 5 years, and to some extent that process of “refinement” is, perhaps, still an ongoing one.¹

“WAIT & WATCH” POLICY INITIALLY UPON DIAGNOSIS

CLL is one of the few hematologic malignancies in which it is advisable not to start treatment merely because a patient has just been diagnosed with this disease. Except for circumstances when, at the time of diagnosis, certain unusual clinical findings are present (discussed below), patients with CLL are initially followed on a “wait and watch” basis.²

A newly diagnosed patient without symptoms, and in whom the disease was discovered because of a routine (or yearly) medical checkup, or accidentally in the process of investigations of unrelated problems, is kept under observation, and is asked to return to the clinic at 3-month intervals for re-evaluation.²

WHEN TO INITIATE CYTOTOXIC THERAPY

The method we have used in our clinic for deciding to institute therapy in a CLL patient who has been under observation since the initial diagnosis is based on any of the following features:

1. Development of symptoms attributable to CLL.
2. Evidence of progressive increase in the extent of disease.
3. Development of disease-related complications.

“USUAL” SYMPTOMS ATTRIBUTABLE TO CLL

In CLL, the usual disease-related symptoms are the same as “B” symptoms found in lymphomas²: profound night-sweats; weight loss (10% or more from usual weight over 6–12 month period) without trying; fever without overt infections and extreme fatigue. Emergence of any of these symptoms in a previously asymptomatic patient is an indication for therapy.

ASSESSMENT OF EXTENT OF DISEASE

Clinical staging continues to remain a readily available method of assessing the extent of disease in a patient with CLL. The five-part Rai system, or its three-part modification (Table 24.1), and the Binet system (Table 24.2) are being used both in the clinic as well as in clinical investigations.³

In the Binet system, there are five areas of lymphoid enlargement identified in a focused physical examination: (1) cervical; (2) axillary; (3) inguino-femoral (whether unilateral or bilateral on each site is counted as one site); (4) spleen; and (5) liver. In both systems, no additional weight is given to large, bulky tumor sizes of the palpable organs. However, the disease is considered to be active and progressive if the size of any palpable mass rapidly increases, and that becomes an appropriate reason to consider initiating cytotoxic therapy. Worsening of clinical stage, from the low-risk to the intermediate- or high-risk category is evidence, also, of disease progression and initiation of therapy.

Both the Binet and Rai staging systems were formulated before computerized axial tomography (CAT) scanning had become routine, and when enlargement of lymph nodes, spleen, or liver were recognized, they became clinically palpable.¹ To this day, for assignment of stage of a disease, only findings upon a physical

Table 24.1 Rai Staging System in CLL

Risk-Category (Modified Rai)	Clinical Stage	Criteria	Median Survival (Months)
Low Risk	0	Lymphocytosis only	120+
	1	Lymphocytosis + Palpably enlarged Lymph nodes	95
Intermediate Risk	II	Lymphocytosis + Palpably enlarged Spleen and/or liver	72
	III	Lymphocytosis + Anemia (hemoglobin <11 gm%)	30
High-Risk	IV	Lymphocytosis + Thrombocytopenia (platelets < 100,000/mm ³)	30

examination are taken into account, for it is recognized that if CAT scans are made the basis for staging, few patients would fall into stage 0 (low-risk category), because it is likely that CAT scan would reveal an enlarged node in the chest, abdomen, or pelvis. Similarly, many of Binet's stage A patients might become stage B, and their respective prognostic and clinical implications would become unclear. In view of both systems of staging having certain weaknesses, and that their true value is to provide some direction for decision making for therapeutic intervention and assessment of success or failure of any therapy, clinical staging in CLL should continue to be based only on findings following physical examination.

In addition to clinical staging, certain other features also have been recognized as helpful in decision-making of whether initiation of treatment is indicated.

Table 24.2 Binet Staging System in CLL

Clinical Stage	Criteria	Median Survival (months)
A	Two or fewer sites of palpably enlarged lymph nodes, spleen or liver	120+
B	Three or more sites of palpable enlarged lymph nodes, spleen or liver	61
C	Anemia (hemoglobin < 10gm%) and/or thrombocytopenia (platelet <100,000/mm ³)	32

Rate of increase in absolute lymphocyte count

In an untreated patient, if the absolute lymphocyte count (ALC) is increasing at a rapid rate, doubling in a short period, usually considered to be less than 6 months, (although some observers consider doubling in less than 12 months as rapid rate), the disease is progressing rapidly, and therapy should be started. It is our opinion that this feature of rapid lymphocyte doubling time should not be enough if it exists as a sole feature, i.e., in absence of "B" symptoms or worsening of clinical stage, etc. Also, the height of the ALC should also be taken into account; for example, ALC doubling from a relatively low number, e.g., 6000 to 12,000/mm³ in 6–12 months in an asymptomatic patient carries less weight than a high baseline, e.g., 100,000/mm³ ALC projected to be doubling in the same period of 6–12 months. Similarly, hyperlymphocytosis, for example, an ALC of 250,000/mm³ or higher, might cause hyperviscosity of circulating blood, and thus pose an increased risk of thromboembolic events in the microcirculation in an organ, with potentially catastrophic results. Thus, hyperlymphocytosis by itself in some circumstances should become a trigger to initiate therapy.

Is histopathologic pattern of lymphoid infiltration in the biopsy specimens of bone marrow by itself a factor in decision making? In our opinion, although a diffuse infiltration pattern is generally associated with a worse prognosis than nodular or interstitial (nondiffuse) patterns, this feature is not powerful enough to deserve to be factored in making this decision.

Other clinical characteristics that have been reported to be helpful in determining whether CLL is active or progressing are elevated serum levels of β_2 -microglobulin, thymidine kinase, and soluble CD23.¹ Although each one of these tests has some validity as

a prognostic marker in CLL, none of them has been tested and proven to be powerful in prospectively conducted studies; nor have they been consistently used by all clinicians. Therefore, we have not integrated any of these in our decision-making algorithm in this disease.

ROLE OF OTHER DISEASE-RELATED COMPLICATIONS

CLL patients are known to be at an increased risk of developing autoimmune hematologic complications. The most frequent among these is Coombs positivity with or without resulting autoimmune hemolytic anemia (AIHA) and immune thrombocytopenia (ITP). Pure red cell aplasia (PRCA) is a relatively rare complication, while immune neutropenia is extremely rare in CLL. When AIHA, ITP, or PRCA occur even in a patient who has not received any prior cytotoxic therapy, we consider these complications indications for instituting therapy.

Finally, a small minority of CLL patients develop Richter's transformation in the form of diffuse large cell lymphoma or prolymphocytic leukemia. Both of these conditions might have developed from the original CLL clone or from a new clone as a separate, new malignancy. Both of these conditions have been known to occur in patients who had received prior chemotherapy regimens for CLL, and also in previously untreated patients. These complications have been treated with a wide range of chemotherapy agents, but unfortunately none has been found to be consistently and reproducibly effective.

IMPACT OF RECENTLY IDENTIFIED BIOLOGIC AND CYTOGENETIC PROGNOSTIC MARKERS ON TREATMENT DECISIONS

Considerable degrees of excitement and hopes for improving the treatment of CLL have recently been generated following the discovery of four prognostic features.

MUTATION STATUS OF *IgVH* GENES

Leukemic lymphocytes of nearly 50% of the CLL patients have somatic mutations in *IgVH* genes, and the remaining 50% have unmutated *VH* genes.^{4,5} There is a strong correlation between longer survival and overall better clinical course among patients with mutated *VH* genes compared to their unmutated counterparts. Thus, it is reasonable to consider the unmutated *VH* gene patients for early therapeutic intervention. This, we believe, will happen in the foreseeable future, but at this moment, the testing for the mutation is neither generally available (it is labor intensive and costly), nor has its methodology been standardized. Also, there is a lack of consensus among experts as to how to define "mutated." Does it require 2% mutations, or 2.5%, or 3%? This is not a trivial issue,

because the counterparts of each of these ratios will thus be called unmutated, and whether those patients labeled "unmutated" will have to have more than 98% homology, more than 97.5%, or more than 97% homology is a matter which is yet to be resolved. Once this is resolved, it is possible that a symptom-free, early stage CLL patient who might otherwise be followed on wait-and-watch basis would become a candidate for immediate chemotherapeutic intervention if that patient has unmutated *VH* genes. However, at this time we include this parameter only in research-based investigational therapeutic trials.

COEXPRESSION OF CD38 ON LEUKEMIC B LYMPHOCYTES

It has been observed that CLL patients whose leukemic lymphocytes do not coexpress CD38 have a better prognosis than those who are CD38 positive.⁴ Thus, it would seem logical to include CD38 positive patients (similar to *VH*-unmutated patients) among those in whom early intervention will be appropriate. This recommendation also appears reasonable, but there is a lack of agreement as to whether 30% or greater positivity should be considered CD38 positive, or the threshold should be set at 13%. As in the case of *VH* mutations, we believe that defining when CD38 is called positive will be resolved soon, but until that happens, in our clinical practice, we do not make therapeutic decisions on that basis alone.

ZAP-70 EXPRESSION IN CLL B LYMPHOCYTES

CLL patients whose leukemic lymphocytes do not have ZAP-70 positivity have been reported to have strong correlation with mutated *VH* status.^{6,7} However, we have not yet allowed introduction of ZAP-70 in clinical practice, and in decision-making for initiation of therapy, because other laboratories have found testing for ZAP-70 difficult to reproduce from one time to the next. Until the issues of correct methodology and predictable reproducibility of results have been resolved, we consider it premature to incorporate this test for making a decision if therapeutic intervention is appropriate.

FISH CYTOGENETICS IN CLL

It has previously been shown that conventional cytogenetics, using banding techniques, provide inconsistently reliable results in CLL because leukemic lymphocytes in this disease do not readily yield readable metaphases.⁸ The development of fluorescence in situ hybridization (FISH) techniques and the availability of DNA probes for all chromosomes of interest in CLL have made it possible to study chromosomal abnormalities in this disease. Using FISH, we now can divide CLL patients into distinct prognostic categories based on chromosomal abnormalities.⁸ Patients with 13q deletions as a single abnormality have the best survival. High-risk abnormalities and the shortest

survival were observed with 11q del and 17p del, while trisomy 12 (12+) and no chromosomal abnormality patients form the intermediate survival group.⁸ As FISH methodology has become standardized, we believe that low-risk or intermediate-risk (by clinical staging) group patients who are free of symptoms but have 17p del or 11q del could be considered for early intervention, especially when they participate in a prospectively randomized study with one arm consisting of wait and watch (currently the standard of practice for patients in these clinical stages), and the other arm consisting of some regimen of effective chemotherapy.

TREATMENT APPROACH FOR PATIENTS WITH CLL

Once we have made an assessment that a patient with CLL, who has been on a “wait and watch” method of follow-up, should start cytotoxic therapy, we first try to determine what our therapeutic endpoint should be. This assessment is made on a case-by-case basis and, therefore, is highly individualized. For example, for a relatively young patient with no other major comorbid conditions, we would take an aggressive approach with an intent to achieve a complete remission or a good quality partial remission, and then, as the next step, depending upon the ability of the

patient to actively participate in the decision-making process, we would engage the patient in a discussion of whether he/she would be willing to enter any prospectively conducted clinical trials aimed at elimination of minimal residual disease with targeted monoclonal antibody therapy in an adjuvant setting, or with hematopoietic stem cell transplantation following a nonmyeloablative conditioning regimen. The latter courses are still unproven for their ability to achieve a cure or even to improve the duration of remission and survival time, but are accompanied by a higher likelihood of treatment-related morbidity and mortality.

If, on the other hand, we are dealing with an older patient whose actuarial life expectancy is considered to be about 10 years, aggressive and curative therapeutic approaches would be inappropriate, because of a treatment-associated significant incidence of morbidity and mortality. In those cases, a palliative approach is indicated, with the objective of relief of symptoms and reduction of body burden of overall tumor mass, while, to a certain extent, preserving the quality of life. Additionally, if these patients have other major comorbid conditions, our treatment objective would be rather conservative, and palliative therapy aimed at relief of symptoms but with less potential toxicity would be the recommended method of management.

Chapter 25

RESPONSE CRITERIA, PROGNOSIS, AND FOLLOW-UP IN CHRONIC LYMPHOCYtic LEUKEMIA

Emili Montserrat

RESPONSE CRITERIA

The *National Cancer Institute–Working Group* (NCI-WG) and the *International Workshop on Chronic Lymphocytic Leukemia* (IWCLL) independently proposed criteria for assessing response in patients with chronic lymphocytic leukemia (CLL) (Table 25.1), the NCI proposal having gained wider acceptance and being the one usually employed.^{1,2}

These criteria have proved to be extremely useful to conduct and compare trials, thereby contributing to progress in CLL therapy. Nevertheless, these proposals were elaborated in an era in which no effective therapy for CLL existed. Today, treatment of CLL is based on

purine analogs, particularly fludarabine, along with other agents. This results not only in a high complete remission (CR) rate but also in the disappearance, in many instances, of minimal residual disease (MRD)—a situation difficult to envisage when NCI-WG and IWCLL criteria were proposed.

Because of this, classical response criteria are now somewhat obsolete. For example, according to such criteria, patients with less than 30% lymphocytes in a bone marrow aspirate may be classified as complete responders, provided clinical and laboratory findings return to normal. In addition, patients with lymphoid aggregates in bone marrow biopsy are considered to be in nodular partial response, yet these nodules may

Table 25.1 Chronic lymphocytic leukemia: Response criteria

Response	IWCLL criteria	NCI-WG criteria
CR	No evidence of disease	Absence of lymphadenopathy, hepatomegaly, splenomegaly or constitutional symptoms. Normal blood count: neutrophils $> 1.5 \times 10^9/L$, platelets $> 100 \times 10^9/L$, Hb > 11 g/dL, lymphocytes $< 4.0 \times 10^9/L$, BM biopsy with normal cellularity and lymphocytes $< 30\%$.
nPR		CR criteria with presence of lymphoid aggregates in bone marrow biopsy
PR	Change from stage C to stage A or B; from stage B to A	50% reduction in blood lymphocytes and 50% reduction in lymphadenopathy and/or 50% reduction in splenomegaly and/or hepatomegaly. Neutrophils $> 1.5 \times 10^9/L$ or 50% improvement over baseline; platelets $> 100 \times 10^9/L$ or 50% improvement over baseline; Hb > 11.0 g/dL (not supported by transfusion) or 50% improvement over baseline.
SD	No change in the stage of the disease	No CR, PR, or PD.
PD	Change from stage A disease to stage B or C, or from stage B to C	At least one of the following: $> 50\%$ increase in the size of at least two lymph nodes or new palpable lymph nodes; $\geq 50\%$ increase of splenomegaly or hepatomegaly or appearance if there was no transformation to a more aggressive histology, Richter or prolymphocytic leukemia; $> 50\%$ increase in the absolute number or circulating lymphocytes.

CR = complete response; nPR = same as CR with presence of lymphoid aggregates in bone marrow biopsy; PR = partial response; SD = stable disease; PD = progressive disease.

represent either leukemic or nonneoplastic T cells. In other words, some patients considered to be in CR by current criteria can still harbor leukemic cells, whereas others who are deemed to be in partial remission (PR) may have achieved CR.

A step forward in evaluating the response in CLL has been the assessment of MRD by either allele-specific polymerase chain reaction (PCR) or four-color cytofluorometry, classical combinations being CD19/CD5/CD79b/CD20 or CD19/CD5/CD43/C20.³⁻⁵ However, these combinations are less effective in situations where leukemia cells lack CD20, e.g., in patients treated with combinations including rituximab. Antigenic combinations that circumvent that problem include CD79b/CD43/CD19/CD5; CD81/CD22/CD19/CD5; and CD20/CD38/CD19/CD5.⁶ Although PCR has a slightly higher sensitivity than four-color cytofluorometry, both methods are similarly useful from the clinical point of view, and four-color cytofluorometry is cheaper and more widely applicable.

Analyzing MRD may be useful for assessing and monitoring the response to therapy. There is already proof that eradicating MRD results not only in longer freedom-from-progression but also longer survival,^{3,7-9} making the MRD eradication a desirable goal in CLL therapy.

Note that some patients considered in NCI-WG PR because of treatment-related cytopenias (normalization of peripheral blood cell counts is a requisite for CR in classical response criteria) may have achieved an MRD-negative status, and these patients have a better prognosis than those in CR by NCI-WG criteria but with persistent MRD.⁹ This indicates that MRD status may be more important than NCI-WG criteria to predict outcome after therapy.

A practical point is, therefore, that with the newer, more effective, but also more myelotoxic treatments, a time window of 2–3 months that would allow patients to recover from treatment-related cytopenias should be required before evaluating response and that treatment-related cytopenias should not necessarily disqualify for CR. Also, and more importantly, MRD-negative CR should be incorporated as a new response category in the assessment of CLL therapy.

Another criticism to current response criteria is that the disappearance of immunologic abnormalities that may be present before treatment (e.g., hypogammaglobulinemia, autoimmune hemolytic anemia (AIHA), positive Coombs test) is not considered as a criterion for CR. This is not an easy issue since current therapies cause a profound immunosuppression and may trigger autoimmune phenomena.¹⁰ However, whether the outcome of patients in whom the immunologic abnormalities are corrected upon treatment is better than those in whom such abnormalities persist should be investigated.

Finally, the assessment of lymphadenopathy, splenomegaly, and hepatomegaly is made clinically both when assessing clinical stage and when evaluating response to therapy. The role of imaging studies (e.g.,

CT scans) in staging and response to therapy evaluation should be evaluated.

PROGNOSIS

The median survival of patients with CLL is about 10 years. Some patients have a survival not different from that of the general population, but there are others who have a rapidly fatal course. Clinical stages have been the most useful prognostic parameters in CLL^{11,12} (Table 25.2; Figure 25.1). They, however, have some limitations. For example, an important condition of all prognostic parameters is that they identify a *substantial* proportion of patients with different outcome. Since the majority of patients with CLL are diagnosed on the occasion of routine medical examinations, when still asymptomatic, most patients (70–80%) are in early clinical stage at diagnosis, thus limiting the prognostic value of clinical stages.^{13,14} Moreover, progressive and indolent forms of the disease are not identified. In addition, the mechanisms accounting for cytopenias are not taken into consideration, yet there is some indication that patients with cytopenias of immune origin may have a better outcome than those in whom the cytopenia is caused by a massive infiltration of the bone marrow by neoplastic cells.^{15,16}

Because of the limitations discussed above, other prognostic factors able to increase the prognostic power of clinical stages have been proposed. In addition to clinical stages, other widely used prognostic factors include the degree of bone marrow infiltration, blood lymphocyte levels, lymphocyte doubling time, and lymphocyte morphology. A number of serum markers, including lactate dehydrogenase (LDH), thymidine kinase, B2-microglobulin, CD23, CD25, and CD20 serum levels have also been found to be good indicators of survival (reviewed in Refs. 17,18).

Differences in the natural history of CLL and its prognosis reflect the biological heterogeneity of the disease, which is rapidly unfolding. Thus, in up to 90% of the patients it is possible to detect cytogenetic abnormalities by fluorescent in situ hybridization studies. Although nonspecific, there are interesting correlates between some cytogenetic aberrations and clinical features and prognosis. For example, patients with del(13q) as a single anomaly have an excellent prognosis whereas those with del(11q) or del(17p) do not respond to chemotherapy and tend to have a rapidly evolving disease. Moreover, trisomy 12 is associated with atypical morphology and immunophenotype of the leukemic cells, and del(6q) is more frequently observed in patients whose lymphocytes display plasmacytoid features and intermediate prognosis.¹⁹⁻²¹ Also, overexpression of *MDR-1* and *MDR-3* genes and P-glycoprotein detection on neoplastic cells has been correlated in some studies with resistance to therapy and poor prognosis.^{22,23}

Table 25.2 Staging systems for chronic lymphocytic leukemia

Staging system	Stage	Clinical features	Median survival (yrs)
Rai			
Low-risk	0	Lymphocytosis alone	14.5
Intermediate-risk	I	Lymphocytosis Lymphadenopathy	7.5
	II	Lymphocytosis Spleen or liver enlargement	
High-risk	III	Lymphocytosis Hemoglobin < 11 g/dL	2.5
	IV	Lymphocytosis Platelets < 100,000/microliter	
Binet			
Low-risk	A	No anemia, no thrombocytopenia < 3 lymphoid areas* enlarged	15.5
Intermediate-risk	B	No anemia, no thrombocytopenia ≥ 3 lymphoid areas enlarged	5.5
High-risk	C	Hemoglobin < 10 g/dL or Platelets < 100,000/microliter	3

*The Binet staging system takes into consideration the following lymphoid areas: lymph nodes (whether unilateral or bilateral) in the head and neck, axillae, and groin; spleen, and liver.

Figure 25.1 Chronic lymphocytic leukemia. Survival of a large series of patients from the Hospital Clínic, Barcelona, according to Binet's clinical stages

The mutational status of *IgVH* genes separates CLL into two forms with distinct presenting features and outcome. Thus, as compared to those with *IgVH* mutations, patients with unmutated *IgVH* genes have a more malignant disease, including evidence of advanced, progressive disease, atypical cell morphology, adverse cytogenetic features, and resistance to therapy.^{24–26} The prognostic significance of *IgVH* mutations is independent from that of clinical stages and cytogenetic abnormalities. Unfortunately, studying *IgVH* mutations is not yet possible on a routine basis, hence the interest

in finding a surrogate for *IgVH* mutations easily applicable in clinical practice. CD38 expression on leukemic lymphocytes correlates, although not absolutely, with *IgVH* mutations; moreover, CD38 expression may vary over time.²⁷ Recently, it has been demonstrated that ZAP-70 expression on leukemic cells, as evaluated by cytofluorometry or PCR, strongly correlates with *IgVH* mutations and has important prognostic significance by itself. The expression of ZAP-70 in more than 20% of neoplastic lymphocytes correlates with unmutated *IgVH* genes and conveys a poor prognosis.^{28–31} It has

also been shown that high expression of activation-induced cytidine deaminase mRNA is associated with unmutated *IgVH* gene status and unfavorable cytogenetic aberrations in CLL³²; however, the clinical applicability of this test has not yet been established.

Besides findings at diagnosis, evolutive features are also important in prognosis. In about 3–10% of patients, the disease undergoes transformation into a more aggressive type, most commonly large-cell lymphoma (Richter syndrome), which is usually revealed by fever, weight loss, night sweats, enlarged lymphadenopathy, and increased LDH serum levels.^{33–35} The prognosis of such an event is poor, with a median survival of less than 6 months.

Patients with CLL may also experience transformation into prolymphocytoid leukemia (PL), in which larger lymphocytes (prolymphocytes) coexist with small, typical CLL cells; the prognosis of the so-called CLL/PL is poorer than that of the typical CLL.³⁶

In addition, the outcome of patients with CLL can be blurred by the appearance of second malignancies to which patients with CLL are prone.^{37,38} Risk assessment, however, is not easy because of the variability in the criteria used to evaluate it. In a study based on data from population-based cancer registries, the observed/expected ratio was 1.20, with an increased risk for Kaposi sarcoma, malignant melanoma, larynx cancers, lung cancer, and also bladder and gastric cancer in men. No relationship was found between the characteristics of the disease and its treatment with the incidence of second cancers.³⁷ Recently, cases of myelodysplasia/acute leukemia have been reported in patients treated with chlorambucil and fludarabine³⁹; because of the increasing use of purine analogs in combination with other agents in CLL therapy, physicians should be alert to this possible complication.

Hypogammaglobulinemia may be observed in up to 60% of the patients with advanced disease, and

contributes to the increased risk for infections, occasionally opportunistic, that patients with CLL may present and that are the most important cause of death.^{40,41}

Patients with CLL may also develop AIHA, which can be triggered by treatment; although it usually responds to corticosteroids, some fatal cases of AIHA have been reported.⁴²

As previously discussed, response to therapy is an important prognostic parameter in itself,^{7–9,43–45} the higher the degree of response the better the outcome. Thus, the patients who achieve MRD-negative status have a better prognosis than those with inferior response to therapy, including those in CR by classical criteria but with persistence of MRD.⁹ In addition, the detection of MRD predicts clinical relapse with the exception of patients submitted to allogeneic transplantation, thus reflecting the importance of a graft-versus-leukemia effect in such a context.^{46,47}

FOLLOW-UP

There is no consensus on how to follow patients with CLL and, in fact, no specific recommendations have been made by the NCI-WG,¹ the IWCLL,² or in some more recent guidelines.^{41,42} Follow-up must be individualized on the basis of the characteristics of the patient and the disease. Patients with low-risk disease do not need to be monitored as frequently as those with poor prognostic features. Thus, patients with low-risk, stable disease may be evaluated every 6–12 months, whereas those with high-risk disease need to be seen at shorter intervals, e.g., every 3 months. Attention must be paid to the appearance of signs of disease progression or complications such as those discussed above, including disease transformation, second neoplasias, autoimmune phenomena, hypogammaglobulinemia, or infections.

Chapter 26

TREATMENT OF CHRONIC LYMPHOCYTIC LEUKEMIA

Matt E. Kalaycio

INTRODUCTION

Once the diagnosis of chronic lymphocytic leukemia (CLL) is made (Chapter 23) and there is an indication to begin therapy (Chapter 24), treatment should then begin without delay. The initial treatment has traditionally been palliative, as no treatment to date has demonstrably prolonged overall survival. However, new paradigms are emerging that promise to increase complete remission (CR) rates and eliminate minimal residual disease (MRD). These innovative strategies (Table 26.1) may yet prove to prolong survival and are the subject of intense investigation.

INITIAL TREATMENT WITH CHEMOTHERAPY

CHLORAMBUCIL VERSUS FLUDARABINE

Introduced into clinical practice in the early 1960s, chlorambucil (CLB) is an orally administered alkylating agent with significant activity against CLL. In two prospectives, randomized trials of CLB versus observation in patients with asymptomatic, low-risk disease, the overall response (OR) rates to CLB 0.1 mg/kg daily or 0.3 mg/kg for 5 days monthly were 76% and 69%, respectively.¹ More recently, a randomized trial of CLB 20 mg/m² every 28 days versus fludarabine (FLU) 25 mg/m² daily for 5 days monthly for 6 months in patients with symptomatic CLL showed an advantage for FLU versus CLB in response rate and progression-free survival (PFS).² The results of this study largely relegated CLB to the treatment of older and more infirm patients who were felt to be unable to tolerate FLU.

FLUDARABINE VERSUS FLUDARABINE PLUS CYCLOPHOSPHAMIDE

The observation of higher than expected response rates with the combination of FLU with cyclophosphamide (CTX)³ prompted prospective, randomized trials of the combination compared to FLU alone. These studies

consistently demonstrated improved response rates and longer PFS for the combination treatment.⁴ Although toxicities were increased and there was no improvement in overall survival with the combination, the improved response rates and prolonged PFS strongly suggest that in patients able to tolerate intensive therapy, the combination of FLU plus CTX is preferred to FLU alone.

INITIAL TREATMENT WITH MONOCLONAL ANTIBODIES

RITUXIMAB

As CLL cells express CD20, there is a rationale to treat the disease with the anti-CD20 monoclonal antibody rituximab. In one study, 44 untreated but symptomatic patients were treated with rituximab 375 mg/m² weekly for 4 weeks. The response rate was 51%, but only 4% of patients achieved a CR after the first course.⁵ With additional courses administered every 6 months, the remission rate improved to 59%, but with only a 9% CR rate. The median PFS was 18.6 months.

ALEMTUZUMAB

CD52 is expressed on all hematopoietic cells, including CLL. Alemtuzumab is an anti-CD52 monoclonal antibody that is effective against advanced lymphoid malignancies. In a study of 41 patients treated with alemtuzumab, given at a dose of 30 mg subcutaneously three times per week for 18 weeks, the OR rate was 87%, with a CR rate of 19%.⁶ A randomized comparison of alemtuzumab versus CLB untreated but symptomatic patients with CLL is being completed.

INITIAL TREATMENT WITH CHEMOTHERAPY PLUS MONOCLONAL ANTIBODIES

FLUDARABINE PLUS RITUXIMAB

The combination of FLU and rituximab was studied in a randomized, Phase II trial of concurrent therapy

Table 26.1 Common treatment regimens for chronic lymphocytic leukemia

Agent	Dose	Method	Frequency	Duration
Chlorambucil	20–40 mg/m ²	Oral	Once monthly	6 months
Fludarabine	25 mg/m ²	IV	Daily for 5 days every 28 days	6 months
Fludarabine	25 mg/m ²	IV	Daily for 5 days	6 months
Cyclophosphamide	250 mg/m ²	IV	Daily for 3 days every 28 days	
Fludarabine	25 mg/m ²	IV	Daily for 5 days	6 months
Cyclophosphamide	250 mg/m ²	IV	Daily for 3 days	
Rituximab	375 mg/m ²	IV	First cycle	
	500 mg/m ²	IV	Monthly every 28 days	
Pentostatin	4 mg/m ²	IV	Every 28 days	6 months
Cyclophosphamide	600 mg/m ²	IV		
Rituximab	375 mg/m ²	IV	(with second cycle)	
Alemtuzumab	1 mg	IV	Day 1	12 weeks
	10 mg	IV	Day 2	
	30 mg	IV	Day 3, then thrice weekly	
Or				
Alemtuzumab	30 mg	SQ	Thrice weekly	12 weeks

versus sequential therapy in untreated, but symptomatic, patients with CLL. One hundred and four patients were randomized to either FLU 25 mg/m² daily for 5 days monthly for 6 months, or FLU at the same dose and schedule plus rituximab 375 mg/m² on day 1 and 4 of the first cycle, then on day 1 of the subsequent 5 cycles. All patients were then treated with rituximab 375 mg/m² weekly for 4 weeks as consolidation therapy. The remission rate for patients enrolled on the concurrent arm was 90%, while the remission rate was 77% for patients on the sequential arm; there was no difference in either PFS or overall survival.⁷ Furthermore, patients receiving the concurrent regimen experienced more grade 3 or 4 neutropenia compared to those on the sequential arm (74% vs 41%, respectively) and grade 3 or 4 infusion-related toxicity (20% vs 0%, respectively).

FLUDARABINE PLUS RITUXIMAB PLUS CYCLOPHOSPHAMIDE

After finding the combination of FLU, CTX, and rituximab (FCR) to be active in relapsed and refractory CLL, investigators at the MD Anderson Cancer Center tested FCR in untreated, but symptomatic patients. They treated 224 patients with FLU 25 mg/m² and CTX 250 mg/m² for 3 days every 28 days, for six courses. In addition, rituximab 375 mg/m² was given the day prior to the first dose of FLU, and then 500 mg/m² was given on the first day of the subsequent five courses. The OR rate was 95%, and an impressive 70% achieved a CR.⁸ The median PFS at the time the study was published had not been reached, with a median of 48 months of follow-up. Toxicity was significant, but manageable, with myelosuppression and infections relatively frequent. This combination is

being compared to other regimens in randomized clinical trials, but given the extraordinary results FCR is a standard first-line therapeutic option.

CONSOLIDATION THERAPY TO ELIMINATE MINIMAL RESIDUAL DISEASE

A CR by current criteria (see Chapter 25) goes beyond the former definition of the absence of detectable disease by histologic review of a bone marrow sample. Modern flow cytometric techniques are capable of detecting CLL clones well below our ability to see them histologically. The presence of residual disease that eludes our ability to detect it histologically is known as minimal residual disease (MRD). Nearly every study that has explored the clinical importance of MRD has concluded that patients with MRD following a course of cytotoxic treatment have a worse prognosis than do those who have no detectable MRD.^{8,9} Other studies suggest that treatment of MRD improves survival in those who have it successfully eradicated.^{10–12} However, it is not proven that the elimination of MRD in those patients who have it will improve their otherwise poor survival. The treatment of MRD remains an area of active investigation, but cannot yet be considered standard therapy.

RELAPSED OR REFRACTORY CLL

MONOCLONAL ANTIBODIES

CD20 is only dimly expressed on CLL cells. In advanced CLL, treatment with rituximab at standard doses results in only a 15% response rate.¹³ Higher doses can achieve

higher response rates, but PFS is generally short.^{14,15} Furthermore, the use of rituximab earlier in treatment is likely to result in rituximab resistance. Thus, as a single agent, rituximab has a limited role in the treatment of advanced CLL.

Alemtuzumab has been explored as a treatment for relapsed or refractory CLL in several clinical trials. A consistent response rate of 30–40%, and PFS of approximately 1 year in responders, is reported by these studies when the drug is administered at 30 mg as an IV infusion three times a week for 3–4 months.^{16–20} Alemtuzumab is particularly useful in the treatment of CLL characterized by 17p deletions that are known to be chemotherapy resistant.²¹ The drug is associated with significant and sometimes severe infusion reactions, however. These reactions are muted, with no apparent loss of efficacy, when alemtuzumab is administered subcutaneously, though this administration route in no way abrogates its immunosuppressive side effects.^{22,23} Patients treated with alemtuzumab require antimicrobial prophylaxis against bacteria, *Pneumocystis jirovecii*, and *Herpes* viruses.²⁴ In addition, there is a substantial risk of cytomegalovirus reactivation and infection that requires a high level of suspicion for fevers of undetermined origin at a minimum, and possibly oral prophylaxis.^{25–27}

CHEMOTHERAPY PLUS MONOCLONAL ANTIBODIES

The limited single-agent activity of the monoclonal antibodies has led to combination treatment strategies. The FCR regimen has been shown to have superior activity to other FLU-based regimens.²⁸ In a study of 177 relapsed or refractory patients treated with FCR, the overall remission rate was 73%.²⁹ The median time to progression was 28 months, but 39 months for those patients who achieved a CR.

Another regimen combines the purine analog pentostatin 4 mg/m² with CTX 600 mg/m² IV on 1 day every month for 6 months. Rituximab 375 mg/m² is added with the second cycle. This regimen results in an OR rate of 75%, but unlike the FCR regimen, was given with prophylactic antibiotics and routine hematopoietic growth factor support.³⁰

Patients previously treated with purine analogs such as FLU usually remain responsive to purine analogs as long as their disease does not progress or relapse within 6 months of treatment. Those who do progress or relapse with 6 months are considered “FLU refractory” and respond poorly to purine analog-based treatment. These patients are candidates for alemtuzumab or investigational approaches.

FUTURE DIRECTIONS

As long as CLL remains incurable, multiple new avenues of research will be explored for patients with CLL. Newer approaches target antigenic determinants,

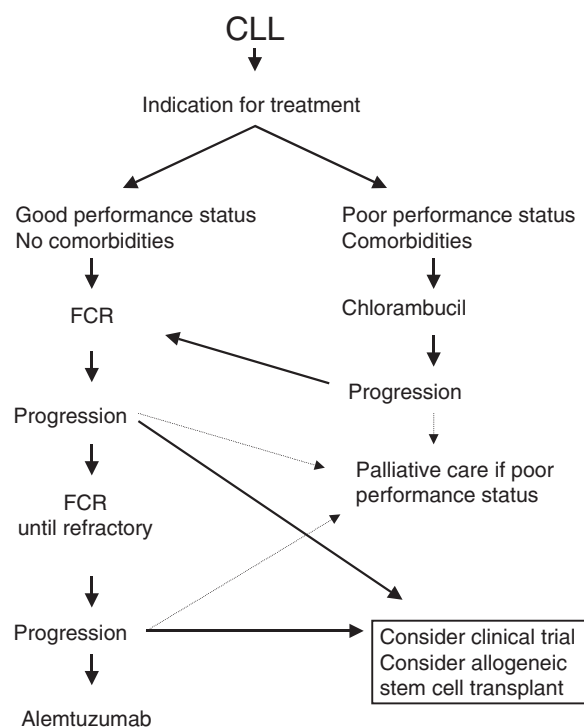

enhance apoptotic pathways, improve allogeneic stem cell transplantation, and explore vaccination strategies. Some of these exciting approaches are nearing use in the clinic.

FLAVOPIRIDOL

Flavopiridol inhibits cyclin-dependent kinases that may induce apoptosis. With a pharmacokinetically guided dose schedule of a 30-mg IV bolus, followed by a 30–50-mg 4-hour infusion, 45% of patients with advanced CLL achieved a remission that lasted approximately 1 year.³¹ This regimen, however, is associated with significant toxicity, including a severe tumor lysis syndrome that excludes patients with a white blood cell count greater than 200/μL and mandates hospitalization for aggressive hydration and prophylactic rasburicase. The drug is also myelosuppressive, with 100% grade 3–4 neutropenia.

LENALIDOMIDE

Lenalidomide is an immunomodulatory agent with an uncertain mechanism of action in CLL. In one trial of 45 patients treated orally with 25 mg daily for 21 days of a 28-day cycle, 47% of patients achieved a remission.³² Treatment was complicated by a “flare reaction” characterized by a transient worsening of disease in the setting of fevers and sweats. This reaction could be prevented or treated by corticosteroids and dose-

(Consider clinical trial at all decision points)

Figure 26.1 Treatment approach to chronic lymphocytic leukemia

escalation rather than by initiating therapy at 25 mg per day. Myelosuppression was also commonly experienced.

OBLIMERSEN

As a single agent, the anti-BCL2 antisense oligonucleotide, oblimersen, induced remission in less than 10% of patients and was complicated by a cytokine release syndrome characterized by fever, hypotension, and back-pain.³³ However, in a randomized study of FLU and CTX administered either with or without an infusion of oblimersen, a higher response rate was induced in the treatment arm that included oblimersen.

BENDAMUSTINE

Bendamustine is a bifunctional alkylating agent that induced remission in 75% of patients with relapsed or refractory CLL in one study.³⁴ In another study, a remission rate of 56% was achieved in a similar population of patients.³⁵ The toxicity of bendamustine is largely limited to myelosuppression, infections, and allergic skin reactions.

SUMMARY

The treatment of CLL is evolving as investigators test new treatments and new combinations. The optimal approach has yet to be defined. In Figure 1, the approach taken by the group at the Cleveland Clinic Taussig Cancer Center is outlined. Treatment is delayed until the onset of symptomatic progression, at which time the most effective therapy, FCR, is administered in the hope that a higher CR rate will translate into longer remission and improved overall survival. Post-remission treatment is investigational. Treatment with FCR is continued until the patient becomes FLU refractory. If no clinical trial is available, alemtuzumab is given.

The approach outlined in Figure 26.1 largely assumes that all patients have the same disease. As discussed in Chapter 25, this assumption is false. Unfortunately, we are currently unable to offer patients with adverse risk factors, such as ZAP-70 expression, treatment options that are known to improve their prognosis. Risk-adapted approaches to CLL are as desperately needed as are new drugs and methods, which advocate for accrual to innovative clinical trials.

Chapter 27

AGGRESSIVE TRANSFORMATION AND PARANEOPLASTIC COMPLICATIONS OF CHRONIC LYMPHOCYTIC LEUKEMIA

Terry J. Hamblin

AGGRESSIVE TRANSFORMATION

There is much confusion about aggressive transformation in chronic lymphocytic leukemia (CLL). Unlike chronic myeloid leukemia where such a transformation is the rule, in CLL it is rare. Moreover, transformation to acute lymphoblastic leukemia (ALL), although reported in the literature,¹ is a myth based on a misunderstanding of the nature of CLL. We can, however, recognize different ways in which CLL can transform (Table 27.1).

RICHTER'S SYNDROME

Incidence

In 1928, Maurice Richter described an aggressive lymphoma occurring in a patient with CLL.² Richter's syndrome is now recognized as a rare but regular culmination of CLL. In the largest series of cases, Robertson et al.³ reported 39 patients with Richter's syndrome among 1374 with CLL (2.8%). The accuracy of this estimate of prevalence is not clear. Patients with CLL are often elderly when diagnosed, and elderly patients dying of disseminated cancer may never have the type of cancer elucidated. This point was emphasized by a series of 1011 patients from Rome.⁴ There were 12 cases of Richter's syndrome among the 207 aged under 55 years (5.9%), but only 10 among the 807 cases over 55 (1.2%). As the authors stated, "the rate of lymphomas in the old age group is possibly underestimated, because very old patients with advanced and unresponsive disease are not always submitted, for ethical reasons, to surgical biopsies." On the other hand, both the MD Anderson Cancer Center and the University "La Sapienza" in Rome are special places that attract the most difficult cases. It is probable that nonprogressive, uncomplicated cases of CLL not requiring treatment are underrepresented in both series and that Richter's syndrome is even rarer than has been reported.

Definition

It has been accepted that any type of aggressive lymphoma occurring in a patient with CLL may be called Richter's syndrome. Thus, cases of diffuse large B-cell lymphoma, Hodgkin's disease,⁵ and even high-grade T-cell lymphoma⁶ have received that appellation.

Clinical features

Richter's transformation is often characterized by sudden clinical deterioration and development of systemic symptoms of fever and weight loss.³ There is usually a rapid enlargement of lymph node masses, especially of retroperitoneal lymph nodes. Hepatomegaly and splenomegaly are common, and extranodal disease is often seen. A rise in serum lactate dehydrogenase is usual, and in nearly half the patients, a monoclonal immunoglobulin can be detected. Hypercalcemia may be seen and this may or may not be accompanied by lytic bone lesions.

Pathogenesis

It is clear that there are at least two separate phenomena involved: the first is a true transformation to a clonally related, aggressive lymphoma, and the second is the occurrence of a clonally unrelated, new tumor, perhaps because of diminished immune surveillance.

Clonally related tumors The relationship between CLL and aggressive lymphoma was originally tested by examining the light-chain type of the surface immunoglobulin,⁷ but this is not sufficient to either confirm or refute an origin from a single clone, and subsequent studies have used a combination of immunophenotyping,⁸ karyotyping,⁹ fluorescent in situ hybridization,¹⁰ restriction fragment length polymorphism analysis,¹¹ reaction with anti-idiotypic antibody,¹² and immunoglobulin variable

region heavy-chain (*IgVH*) gene sequencing.¹³ The conclusion of these studies is that sometimes the two tumors are clonally related and sometimes they are not. An interesting study using *IgVH* gene sequencing showed that in five out of six patients whose CLL used unmutated *IgVH* genes, the diffuse large-cell lymphoma (DLCL) clone evolved from the CLL clone, whereas in the two CLL patients whose disease used mutated *IgVH* genes, the DLCL clone was unrelated to the CLL clone.¹³

With the recognition that Hodgkin's disease is a tumor of B cells, it is perhaps less surprising than would have been thought a decade ago that Reed–Sternberg cells should have an identical IgH CDRIII sequence to that of the CLL cells in two out of three cases of Hodgkin's disease supervening in CLL.¹⁴ A remarkable case was investigated by van den Berg et al.¹⁵ in which histology demonstrated a composite lymphoma consisting in part of small-cell lymphoma, in part Hodgkin's disease, and in part anaplastic large-cell lymphoma. All three tumors were clonally related. The CLL component was CD5 negative.

Clonally unrelated tumors If the second lymphoid tumor is not clonally related, is it any more than part of the spectrum of second cancers long been believed to occur in patients with CLL?¹⁶ Among more recent studies, Davis¹⁷ found a relative risk for second lymphoid tumors of 4.5 and for nonlymphoid tumors of 2.3 among 419 patients with CLL in Washington. Travis¹⁸ analyzed data for 9456 patients with CLL from the National Cancer Institute's Surveillance, Epidemiology, and End results (SEER) program. The observed over expected (O/E) ratio for second malignancies was 1.28 (confidence intervals [CI] 1.19–1.37). Significant excesses were found for cancers of the lung and brain, melanoma (including intraocular melanoma), and

Hodgkin's disease. A Danish study of 7391 patients again found standardized incidence ratios of 2.0 for men and 1.2 for women for second malignancies.¹⁹ Increased risks were found for carcinoma of the kidney, nonmelanomatous skin cancer and sarcoma for both sexes, and lung and prostate cancer for men. A more recent evaluation of the SEER program,²⁰ now totaling 16,367 patients, found a standardized incidence ratio for second malignancies of 1.2 (CI 1.15–1.26), with significant excesses for Kaposi's sarcoma (O/E 5.09) and melanoma (O/E 3.18) and cancers of the larynx (O/E 1.72) and lung (O/E 1.66). In men, brain cancers were more common (O/E 1.91), and in women cancers of the stomach (O/E 1.76) and bladder (O/E 1.52) were commoner.

These figures need to be interpreted with caution. In many series, cancers diagnosed concurrently with or before the CLL are included. Since CLL is diagnosed as an incidental finding in 75% of cases and is clinically silent in a large proportion of patients, there is an inbuilt bias in favor of diagnosing CLL in cancer patients who have more blood tests than the general population. Patients with cancer are often nonspecifically unwell before the diagnosis of cancer is made and will have blood tests to investigate this, with the result that the inconsequential CLL is diagnosed before the cancer reveals itself. In addition, patients with CLL are seen more frequently by doctors than members of the general population, and other cancers are more readily detected.

It is also possible that treatment of CLL, particularly with alkylating agents, predisposes the patient to the development of a second malignancy. This may account for the higher incidence of bladder cancer among women in the latest SEER analysis. Some excesses in specific tumors may be the consequence of data dredging, especially if the tumor excess is confined to one sex.

One important question is whether the immunodeficiency of CLL is what that leads to second malignancies. Kaposi's sarcoma is a disease of impaired immunity, and both melanomas and renal cell cancers are tumors known to be influenced by the immune system. It is also likely that the excess of lymphomas is mediated by the immune deficiency. However, apart from these, any increase in second cancers may be more apparent than real.

The suspicion that clonally unrelated lymphomas occurring in CLL might be virally induced was raised by Momose et al.²¹ Occasionally, apparent Reed–Sternberg cells can be found scattered among the small lymphocytes in the lymph node histology of CLL. Among 13 cases where these were found, Momose et al. detected Epstein–Barr virus (EBV) RNA in 12 by in situ hybridization. Three of these cases later developed disseminated Hodgkin's disease. Rubin et al.²² studied two cases of Richter's syndrome with Hodgkin's disease characteristics in which they found EBV DNA in the lymph nodes using the polymerase chain reaction (PCR) and EBV

latent membrane protein (LMP) in the Reed–Sternberg cells by immunohistochemistry.

Matolcsy et al.²³ found EBV genome integration in the DLCL component but not the CLL component of a case of Richter's syndrome where the clones were unrelated. Petrella et al.²⁴ reported two further cases where EBV could be detected in Reed–Sternberg cells by *in situ* hybridization. A Japanese case was reported by Otsuka et al.²⁵ in which EBV nuclear antigen and LMP could be detected in the DLCL cells and *in situ* hybridization revealed the presence of EBV-encoded small RNA. Ansell et al. studied 25 patients with Richter's syndrome presenting to the Mayo Clinic.²⁶ Four showed evidence of EBV in the DLCL cells: three with a B-cell phenotype were positive for LMP, and EBV DNA and RNA, and one with a T-cell phenotype was positive for EBV RNA. Six further cases (four from Italy and two from Belgium) of Hodgkin's disease supervening on CLL all support the hypothesis that this is often an EBV-driven event.^{27,28} In a delicate study using single-cell PCR, Kanzler et al.²⁹ enunciated the principle that Hodgkin's disease may be clonally unrelated to the CLL, in which case it is driven by EBV, but in rare cases it is clonally related to the CLL and in these cases EBV cannot be detected. The same may be said for DLCL, though cases with a T-cell immunophenotype are presumably always clonally unrelated. The evidence for EBV involvement in Richter's syndrome is very sparse except in the case of Hodgkin's disease, and for the vast majority of cases of DLCL occurring in patients with CLL, there is no information as to pathogenesis.

That lymphomas may arise from EBV-driven clones in CLL questions the wisdom of treating CLL with agents that reinforce the already-present immunodeficiency, especially in patients without poor prognostic factors. Agents such as fludarabine and alemtuzumab are potent immunosuppressants and their use may lead to EBV reactivation.³⁰

Treatment

Richter's syndrome has a poor prognosis. A study of 25 patients from France in 1981⁵ reported a median survival of 4 months and a complete remission rate following intensive chemotherapy of 24%. Seventeen years later a survey of the experience of the MD Anderson Cancer Center in Houston³¹ found a median survival of 6 months. There have been no large-scale studies of treatment of Richter's syndrome, but the MD Anderson reported two phase II studies of combination chemotherapy regimens. The first³² described the use of hyper-CVXD (fractionated cyclophosphamide, vincristine, DaunoXome, and dexamethasone) in 29 patients. Although there were 11 complete responses, they were mostly short lived. There was a treatment-related mortality of 20% during the first course of therapy, and the median survival was only 10 months. The second trial³³ was of the combination of fludara-

bine, cytarabine, cyclophosphamide, cisplatin, and granulocyte-macrophage colony-stimulating factor in 15 patients with Richter's syndrome together with a small number of other patients with refractory low-grade lymphomas. Only one patient achieved a complete remission, and there was considerable toxicity.

Despite these dismal results, there have been anecdotal reports of good responses to conventional chemotherapy for both the Hodgkin's and non-Hodgkin's varieties of Richter's syndrome.^{34–36} Allogeneic stem cell transplantation has been reported in eight patients, three of whom were alive at 14, 47, and 67 months.³⁷ An interesting patient was reported by Espanol et al.³⁸ Richter's syndrome developed in a patient 4 months after an allogeneic stem cell transplant for CLL. Complete remission and full donor chimerism was obtained by withdrawal of immunosuppression and donor lymphocyte infusions.

PROLYMPHOCYTOID TRANSFORMATION

Definition

Prolymphocytes are large lymphocytes, some 10–15 μm in diameter compared to 7–10 μm for CLL cells. They have round or indented nuclei with chromatin that is less dense than that of CLL cells, but more dense than that of lymphoblasts. They possess a single prominent nucleolus. The cytoplasm is more abundant than that of a typical CLL cell, and in Romanowsky-stained specimens it is pale blue and agranular. Although small numbers of prolymphocytes are usually found in CLL, there is a distinct B-cell prolymphocytic leukemia (PLL) that is completely unrelated to CLL. Clinically, splenomegaly without lymphadenopathy is the rule, but it is defined by the presence of >55% circulating prolymphocytes.³⁹ It is immunophenotypically distinct, with strong positivity for surface immunoglobulin, CD20, CD22, CD79b, and FMC7, while it is negative for CD23 and mouse rosettes. The reaction with CD5 is controversial. Most cases are CD5 negative, but perhaps 20% are CD5 positive. This may be explained by the discovery of a splenomegalic form of mantle cell lymphoma with t(11;14) that morphologically resembles PLL.^{40,41}

Prolymphocytoid transformation of CLL was first reported by David Galton's group at the Royal Postgraduate Medical School in London.⁴² It was specifically noted that the cells retained the immunophenotype of CLL cells. In a series of papers,^{43–46} the Galton Group defined typical CLL as having <10% prolymphocytes and CLL/PLL as those cases with between 10 and 55% prolymphocytes. Although as a group patients with CLL/PLL had more surface immunoglobulin than those with typical CLL, there was no sudden transition from a lower density at an earlier stage of the disease, and the immunophenotype of small and large cells was indistinguishable.

Contrary to the common perception, in a study of 55 cases of CLL/PLL,⁴⁴ half showed a stable picture

without a progressive increase in prolymphocytes. The prognosis of this group was similar to that of stable CLL without prolymphocytes. In one-third of cases, the increase in prolymphocytes was unsustainable, and in only 18% was there a definite progression toward a more malignant phase of the disease. In a multivariate analysis of prognostic factors in CLL/PLL, only an absolute number of prolymphocytes and spleen size were of independent prognostic significance. The median survival for patients with prolymphocytes $>15 \times 10^9/L$ was 3 years.³⁹

Karyotype

Cellular morphology seems to be closely related to karyotype. In a study of 544 patients, Matutes et al.⁴⁷ found trisomy 12 in 18%. Thirty-one percent of these had CLL/PLL compared to 10% of the whole series. Subsequent studies have shown that such atypical morphology is also associated with a deletion at 6q21⁴⁸ and t(14;19) translocations,⁴⁹ both of which are associated with an adverse prognosis. Even more significantly, 80% of patients with p53 abnormalities have CLL/PLL morphology.⁵⁰

Oscier et al. found evidence of karyotypic evolution in 16% of 112 patients with CLL studied by sequential cytogenetic studies.⁵¹ Finn et al. found a higher incidence of 43% in 51 patients.⁵² The most common extra abnormality was a structural abnormality of 6q21. Bea et al. found sequential increases in chromosomal abnormalities in six out of ten patients with Richter's transformation or other types of clinical progression.⁵³

Treatment may induce evolution. It may be thought of as a selective pressure-inducing change. Just as antibiotics can select for drug-resistant bacteria, similarly chemotherapy may kill only the susceptible cells, allowing drug-resistant cells to regrow. These may be morphologically more extreme, karyotypically different, and may express greater amounts of CD38.⁵⁴

Implications for management

Merely finding increased numbers of prolymphocytes in the blood is not necessarily an indication of transformation of CLL. The increase may be transient, indicative of a recent infection or other unknown event. Some karyotypic abnormalities (such as trisomy 12) are associated with $>15\%$ circulating prolymphocytes; yet these patients may remain stable for many years. Increasing numbers of prolymphocytes and karyotypic evolution usually have a poor prognosis. Most authors have been unable to attach an independent prognostic effect to deletions at 6q21, but acquisition of p53 abnormalities at 17p13 carries the worse possible prognosis.⁵⁵⁻⁵⁷ This is often associated with morphologic change (prolymphocytoid transformation⁵⁰ or Richter's syndrome⁵³) and drug resistance.⁵⁸

The indications for treatment in CLL/PLL are the same as those for CLL itself: systemic symptoms and bone marrow failure. The presence of prolymphocytes

should raise the possibility of abnormalities of the p53 pathway, indicating potential drug resistance and a call for nonstandard therapy, such as alemtuzumab or high-dose methylprednisolone.

TRANSFORMATION TO ACUTE LEUKEMIA

Transformation of CLL to ALL used to be regularly reported. The first report mentioned blast cells with surface immunoglobulin, which would be uncharacteristic for classical ALL.⁵⁹ One of the two cases in this study had surface IgM κ , with rheumatoid factor activity on both lymphocytes and lymphoblasts, and it now seems more likely that this and subsequent cases represent either a Richter-like transformation of CLL with peripheral blood spillover of the high-grade lymphoma cells, or a similar high-grade transformation of a different B-cell lymphoma with a superficial resemblance to CLL.

In at least one of the reported cases, the CD5 antigen was retained during the blastic phase,⁶⁰ which raises the possibility of a blastic version of mantle cell lymphoma occurring in a patient with the type of mantle cell lymphoma that closely resembles CLL,⁴¹ and this seems certainly to be the explanation for the most recent case report where both the small-cell version and the blastic version had the t(11;14) translocation.⁶¹ However, in another case the blasts were shown to be terminal deoxynucleotidyl transferase positive,⁶² and in this and other cases the blast cells had the characteristics of ALL.⁶³ In such cases, however, it has not been established that the ALL belongs to the same clone as the CLL.

There is no convincing evidence that CLL ever transforms into ALL.

PARANEOPLASTIC COMPLICATIONS

Although there are a few paraneoplastic complications of CLL of uncertain origin, the majority are caused by altered immunity (Table 27.2). For unknown reasons, CLL has a profound effect on the normal immune system, although it has been suggested that CLL is a tumor of regulatory B cells, and exerts its effect in this way.⁶⁴ The altered immunity manifests itself as immune deficiency, which will not be considered in this chapter, and autoimmunity.

AUTOIMMUNITY

The association of autoimmune disease and CLL is well known but misunderstood. There is no general tendency for patients with CLL to develop autoimmune disease. The only autoimmune conditions seen in CLL with any frequency are autoimmune hemolytic anemia (AIHA) and immune thrombocytopenia (ITP). A few other rare conditions occur in CLL more commonly than would be expected, but the common autoimmune diseases, such as rheumatoid arthritis,

Table 27.2 Paraneoplastic complications of CLL

Autoimmune
Antibody produced by tumor
Cold agglutination syndrome
Acquired angioedema
Some cases of glomerulonephritis or nephrotic syndrome
Antibody produced by residual lymphoid tissue
Autoimmune hemolytic anemia
Immune thrombocytopenia
Immune neutropenia
Pure red cell aplasia
Paraneoplastic pemphigus
Some cases of glomerulonephritis or nephrotic syndrome
Nonimmune
Hypercalcemia
Severe reactions to insect bites
Obscure and uncertain
Bell's palsy
Peripheral neuritis
Parkinson's disease
RS3PE

thyroid disease, pernicious anemia, and systemic lupus erythematosus (SLE) are no commoner in CLL than in age-matched controls.⁶⁵

Autoimmune hemolytic anemia

Using the technique of differential agglutination, Berlin was the first to show shortened red cell survival in nine patients with CLL.⁶⁶ Later, Wasserman et al.⁶⁷ found hemolytic anemia in 9 of 58 consecutive patients with CLL, with 5 out of 7 testing positive in the direct antiglobulin test. Following this, a series of studies suggested that AIHA occurs at some time in the course of CLL in 10–26% of cases.⁶⁸

AIHA is commoner in CLL than in the general population. The reported prevalence varies from 1.8 to 35%.^{69,70} The disparity is because prevalence is closely related to stage and progression. In stable stage A disease, Hamblin et al.⁶⁵ found a prevalence of 2.9%, compared to 10.5% in stage B and C disease and 18.2% in progressive stage A disease.

From a different point of view, CLL is the commonest known cause. In a large series of patients with AIHA, Engelfriet et al.⁷¹ found that 14% were associated with CLL, compared to 7% for SLE, the next most common cause. However, in about half the cases of AIHA no cause is found. AIHA occurs about eight times more commonly in CLL than in other forms of non-Hodgkin's lymphoma, and about two and a half times more commonly than in Hodgkin's disease.

Immune thrombocytopenia

Minot and Buckman⁷² reported that half their patients with CLL had thrombocytopenia at presentation. Once an immune cause for thrombocytopenia had been recognized, Harrington and Arimura⁷³ reported seven cases of ITP occurring in CLL. Ebbe et al.⁷⁴ reported five more cases and suggested that the prevalence of ITP in CLL was 2%, and this was confirmed by Hamblin et al.⁶⁵ and Dührsen et al.⁷⁵ However, the numbers were small in all three series and the reliability of the diagnoses suspect. The diagnosis of ITP in CLL depends on the presence of isolated thrombocytopenia, and normal or increased bone marrow megakaryocytes with an excess of early forms. More sophisticated, though not entirely reliable, tests are increased mean platelet volume and platelet distribution width, and detection of platelet antibodies in the serum or on the platelet membrane.

The diagnosis of ITP is difficult. Bone marrows heavily infiltrated with CLL cells make megakaryocytic numbers difficult to assess. Tests for platelet antibodies are still unsatisfactory. Increased levels of platelet-associated IgG was found in 30% of thrombocytopenic patients with CLL and 10% of nonthrombocytopenic patients.⁷⁶ Even higher rates were found in non-Hodgkin's lymphomas. This test is known to have a high false-positive rate. The diagnosis is often made by exclusion and confirmed by response to therapy. About one-third of patients with ITP secondary to CLL also have a positive direct antiglobulin test (Evans' syndrome), a much higher rate than for primary ITP.⁷⁷

Autoimmune neutropenia

When a CLL patient becomes neutropenic, it is usually because of marrow infiltration or treatment. Early reports of immune neutropenia in CLL⁷⁸ probably referred to the well-recognized syndrome of large granular lymphocytic (LGL) leukemia with neutropenia.⁷⁹ A study from Crete⁸⁰ reported higher numbers of CD3⁺, CD8⁺, and CD57⁺ cells in neutropenic patients with CLL and demonstrated that CD8⁺ cells from neutropenic patients exerted a greater suppressive effect on colony-forming unit–granulocyte-macrophage colony growth than that of similar cells from nonneutropenic patients. More recently, it has been suggested that the secretion of high levels of Fas ligand is the cause of the neutropenia that is sometimes seen in B CLL.⁸¹ Antineutrophil antibodies seem to be involved only rarely, if at all.

Pure red cell aplasia

Although well recognized in CLL,⁸² pure red cell aplasia (PRCA) is also a frequent complication of LGL leukemia; indeed, this is probably its commonest cause.⁸³ Nevertheless, Chikkappa et al.⁸⁴ recognized PRCA in 23 cases of B CLL, and subsequently it has been reported on at least five occasions.⁷⁷ From their own cases, Chikkappa et al.⁸⁴ estimated the prevalence

at 6%, but this seems an exaggeration. In our series, about 1% of our 800 unselected patients with CLL have developed PRCA. The recent spate of cases of PRCA following treatment with erythropoietin has provided an easy assay for determining the autoimmune nature of PRCA.⁸⁵

Other types of autoimmune disease

The idea that CLL was regularly associated with all types of autoimmune disease was reinforced by reviews by Miller⁸⁶ and Dameshek.⁸⁷ However, in an elderly population, autoantibodies are recognized quite commonly. Hamblin et al.⁶⁵ found that 21.5% of a control population of individuals over 60 years of age had tissue-specific autoantibodies detected by immunofluorescence. In an age-matched series of 195 patients with CLL, the prevalence of autoantibodies was exactly the same. Dührsen et al.⁷⁵ confirmed this. However, there are three conditions that should be looked at more closely.

Nephrotic syndrome and glomerulonephritis Nephrotic syndrome occurs more commonly in CLL than would be expected by chance. In 1974, Dathan et al.⁸⁸ reported two patients with CLL who developed nephrotic syndrome caused by an immune complex glomerulonephritis. Almost immediately, Cameron and Ogg⁸⁹ reported another three cases, but subsequent letters to the same journal were rejected because there were so many. This complication is therefore much commoner than the 50 cases, mostly in the form of single case reports, uncovered by a PubMed search. Either membranous glomerulonephritis or membranoproliferative glomerulonephritis may be seen on renal histology. There have been two reports of anti-neutrophil cytoplasmic antibodies, one of which followed treatment with fludarabine.^{90,91}

Acquired angioedema As with hereditary angioedema, the acquired form is characterized by recurrent bouts of angioedema and abdominal pain. It is caused by a deficiency of the inhibitor of the first component of complement (C1-INH). It differs from the hereditary form in that there is no family history, and the onset is not until the fifth decade of life. Type I is associated with lymphoproliferative diseases, including CLL, and type II with autoantibodies. The normal C1-INH molecule has a molecular weight (MW) of 105 kd, with a binding site for the serine protease C1s. The autoantibodies recognize two synthetic peptides (peptides 2 and 3) that span the reactive site of the molecule.

A study of six cases of acquired angioedema (AAE) demonstrated that the autoantibodies were monoclonal whether or not they were associated with a lymphoproliferative disease⁹²; and the distinction may well be an artificial one, depending on how hard a lymphoproliferative disease is to find. In both types of AAE,

a nonfunctional C1-INH molecule of MW 95 kd is found in the serum. The mechanism of action of the antibody is to cause or allow the cleavage of the C1-INH molecule, rendering it inactive.⁹³

Blistering skin diseases The first report of a patient with CLL and a pemphigoidlike skin disease was by Oppenheim in 1910,⁹⁴ although the two patients reported by Sachs in 1921⁹⁵ had a more secure diagnosis of CLL. In 1974, Cuni et al. described a single case of bullous pemphigoid, established by the presence of antibasement membrane antibody.⁹⁶ In their review of the literature, they discovered 16 other cases of CLL with either bullous or vesicular skin lesions. Goodnough and Muir⁹⁷ reported the next case 6 years later, but in the same year Laskaris et al.⁹⁸ reported two cases of CLL associated with oral pemphigus.

The confusion over pemphigus and pemphigoid was resolved when Anhalt et al.⁹⁹ described paraneoplastic pemphigus. The clinical features are of painful erosions of the oropharynx, and vermilion borders of the lips that are resistant to conventional treatment. There is severe pseudomembranous conjunctivitis. There are several types of itchy cutaneous lesions including confluent erythema with skin denudation, and papules on the trunk and extremities forming target lesions, with central blistering. Anhalt reported that patients with this condition had often been previously misdiagnosed as pemphigus vulgaris or erythema multiforme. Histologically, he observed three elements: suprabasilar intraepithelial acantholysis, necrosis of individual keratinocytes, and vacuolar interface change. Immunofluorescence studies revealed the presence in the serum of antibodies that reacted with the intracellular spaces, such as is seen in pemphigus vulgaris or foliaceus. However, direct immunofluorescence studies of the skin also demonstrated complement deposition along the basement membrane typical of bullous pemphigoid.

Investigation of patients' sera showed immunoprecipitation of a complex of four polypeptides from keratinocyte extracts with MWs of 250, 230, 210, and 190 kd, respectively. Subsequently, several groups confirmed this pattern of autoantibodies,¹⁰⁰⁻¹⁰² but two groups also found an antibody against a 130-kd component.^{103,104} These antigenic components have subsequently been identified. The 130-kd glycoprotein is characteristically involved in pemphigus vulgaris. It has been cloned and sequenced¹⁰⁵ and termed desmoglein 3. It belongs to the cadherin family of cell adhesion molecules. Antibodies to the 230-kd polypeptide are characteristically found in the sera of patients with bullous pemphigoid. The protein is known as BPAG2,¹⁰⁰ is intracellular, and localizes to the hemidesmosomal plaque. The 250-kd protein is desmoplakin I,¹⁰⁰ the 210-kd protein is envoplakin,¹⁰⁶ and the 190-kd protein is periplakin.¹⁰⁷

Although it is rare, paraneoplastic pemphigus is a discrete autoimmune blistering skin disease with characteristic clinical features, a pathognomonic pattern of antibody specificity, and an association with lymphoid tumors. It may occur in an array of lymphoid tumors, and especially in Castleman's disease, but about 30% of cases occur in CLL.¹⁰⁸

Mechanisms of autoimmunity in CLL

Secretion of autoantibody by tumor cells Perhaps the simplest explanation for autoimmune disease in CLL would be that the autoantibodies were the product of the tumor. Using a sensitive immunoblotting technique, Beaume et al.¹⁰⁹ found monoclonal immunoglobulin in the sera of 80% of CLL patients. However, the light-chain type was the same as that of the surface immunoglobulin in only half the cases. In CLL, serum monoclonal immunoglobulins cannot be assumed to have been produced by the tumor.

There is some evidence that CLL lymphocytes may be induced to produce autoantibodies. When stimulated with phorbol ester cells, 12 of 14 patients with CLL secreted IgM that reacted with a variety of autoantigens.¹¹⁰ Similar polyreactive antibodies have been described by Sthoeger et al.¹¹¹ The antibodies were of the same light-chain types as the surface Ig of the CLL cells, and therefore not the product of contaminating normal B cells. These findings give weight to the hypothesis that CLL is derived from a B cell of separate lineage akin to the Ly-1 (CD5) B cell of mice, although this hypothesis is in increasing disrepute.⁶⁸

Sthoeger et al.¹¹² reported two cases of CLL with AIHA where immunoglobulin eluted from direct antiglobulin positive red cells reacted with anti- κ , but not anti- λ antibodies. In addition, the CLL cells produced in culture a monoclonal IgM that reacted with red cells, though more strongly at 4°C than at 37°C. Most agree that the antibody in AIHA is polyclonal and the product of the residual lymphoid tissue, and not of the tumor cells. A study by Sikora et al.¹¹³ demonstrated that the monoclonal Ig rescued from CLL cells was not responsible for a concurrent warm antibody AIHA.

On the other hand, in cold agglutination syndrome, most cases seem to be caused by a monoclonal IgM. The molecular basis for this reaction is now understood. A rat monoclonal antibody, 9G4, raised against the surface IgM of a B-cell lymphoma recognized a shared idiotypic determinant on all anti-I or anti-i cold agglutinins.¹¹⁴ B cells from patients with cold agglutination syndrome were immortalized with EBV. The 9G4-positive lines were investigated for the use of immunoglobulin V_H genes and found exclusively to use the V_{4-34} gene.^{115,116} This specificity was retained whether the V_H gene was in germline configuration or showed evidence of somatic mutation. The detailed biochemistry of both the reaction with red cells and with the 9G4 monoclonal has been elucidated.¹¹⁷

However, cold agglutination syndrome is rare in CLL. CLL cells do not usually secrete enough immunoglobulin for it to be detected by conventional methods. Thus although 6 of 78 patients with persistent cold agglutinins had CLL,¹¹⁸ the definition then in use for CLL would not have excluded diseases like splenic marginal zone lymphoma, which has a greater propensity for secreting large amounts of monoclonal immunoglobulin. The same is true of the single case report from Feizi et al.¹¹⁹ and the single case of CLL with cold agglutination syndrome reported by Hamblin et al.⁶⁵ which, in retrospect, had a spillover lymphoma. A more recent case was also CD5 negative,¹¹² an almost certain indication that this also was a different type of lymphoma. In this case, the heavy-chain gene used by the surface immunoglobulin was $DP54$ and not V_{4-34} , an indication that the cold agglutinin was not the product of the tumor. In the last 5 years, we have seen a single patient with long-standing cold agglutination syndrome who developed definite CLL during his last illness. Both his anti-I antibody and the surface immunoglobulin used the V_{H4-34} gene; the same is true for the case reported recently by Ruzickova et al.¹²⁰

As far as other autoimmune syndromes are concerned, there is little evidence that the autoantibodies are the product of the CLL cell. It is believed that CLL-associated angioedema,⁹² and possibly CLL-associated glomerulonephritis,¹²¹ may be caused in this way. On the other hand, a recent publication suggests that the anti-230-kd autoantibody associated with paraneoplastic pemphigus is not synthesized by CLL cells.¹²²

Autoimmunity triggered by treatment Although the suggestion that autoimmunity might be triggered by treatment in CLL was made nearly 40 years ago,¹²³ there were few corroborating reports¹²⁴⁻¹²⁶ until the association with fludarabine was realized. The first report of two cases appeared as a letter,¹²⁷ though in only one of the cases was the association with treatment secure. A contrary view was reported by investigators from the MD Anderson Cancer Center, who argued that the cases represented the natural prevalence of AIHA in CLL.¹²⁸ Five out of 112 patients treated with fludarabine developed hemolysis after between 1 and 6 courses of therapy, and a further four patients with preexisting AIHA deteriorated after fludarabine treatment, though four further patients with preexisting AIHA received fludarabine safely.

Two years later, Myint et al.¹²⁹ reported that of 52 heavily pretreated patients, 12 developed AIHA after between 2 and 6 courses of fludarabine. Since then, many reports involving well over 100 patients have confirmed the association. The frequency of hemolysis depends on how much previous treatment the patient has received. Only about 2% of patients treated for the first time develop AIHA, compared with about 5% of

patients who have received some previous treatment, and over 20% of heavily pretreated patients.

Among 1203 patients studied at University “La Sapienza” in Rome,¹³⁰ 52 cases of AIHA were observed (4.3%). In 19 patients, the AIHA was present at the time of diagnosis of the CLL, and a further 20 developed AIHA while still untreated. Ten developed AIHA while on therapy, seven on low-dose chlorambucil (1.8% of those so treated) and three on fludarabine (2.5% of those so treated). Current thinking is that AIHA triggered by treatment has been underreported in the past, and is probably as common after chlorambucil treatment as after fludarabine, but after fludarabine it is more severe and difficult to treat. Early suggestions are that the risk is less with the fludarabine/cyclophosphamide combination.

Autoimmune thrombocytopenia may also be triggered by fludarabine. Montillo et al.¹³¹ first reported relapse of CLL-associated ITP after exposure to fludarabine. Over 30 cases of fludarabine-related ITP have now been reported.⁶⁸ Only one possible case of immune neutropenia¹³² and three cases of PRCA have been reported.⁶⁸ Paraneoplastic pemphigus has been reported in five cases.⁶⁸ There have been two cases of postfludarabine glomerulonephritis.⁶⁸

The other purine analogs, cladribine and pentostatin, are also capable of triggering autoimmune complications.⁶⁸ As the best known toxicity of the purine analogs is their profound T-cell suppression, it is interesting to note that treatment with Campath-1H can also trigger autoimmunity in CLL.⁶⁸ Interestingly, paraneoplastic pemphigus may also be triggered by radiotherapy.⁶⁸

From these observations some general conclusions can be drawn. Most cases of postfludarabine autoimmunity have occurred in heavily pretreated patients. Usually, patients have previously received an alkylating agent. The complication is severe and often difficult to treat. In many cases it has been fatal. If control is achieved, then reexposure to any of the purine analogs retrigger the complication. Even alkylating agents may retrigger it. The recurrence is likely to be even more virulent. Although commonest in CLL, autoimmunity may also be induced in other low-grade lymphoproliferative diseases.

Synthesis: why is CLL complicated by autoimmunity? The cause of the autoimmune complications of CLL is unknown. Although they are a feature of all low-grade B-cell lymphomas, they are worse in CLL, just as the immunodeficiency is worse. Both the immunodeficiency and the autoimmunity are made worse by treatment. They are probably related. Noting the almost AIDS-like, CD4 T-cell suppression that occurs after treatment with fludarabine, Hamblin⁶⁸ suggested that autoimmunity in CLL is caused by loss of T-cell regulatory control of autoreactive T cells.

In most cases of AIHA, the autoantibody preferentially reacts with components of the Rh antigen. A

recent study has demonstrated that CLL cells act as the most potent antigen presenting cells for purified Rh antigen.¹³³

Treatment of autoimmune complications

Acquired angioedema Treatment of AAE has been recently reviewed by Markovic et al.¹³⁴ They recommend treatment of the CLL as the most important element of the management. The androgens, stanozolol and danazol, have been widely used for both the hereditary and acquired form of the disease and are generally successful. They act by increasing the production of C1 esterase inhibitor by the liver. For those who are unhappy taking androgenic steroids, tranexamic acid (0.5 g three times daily) is as successful in the acquired form as in the hereditary form.

Autoimmune hemolytic anemia There are no controlled trials of treatment of AIHA secondary to CLL, and treatment does not differ from AIHA in other circumstances. Prednisolone 1 mg/kg for 10–14 days has been the standard treatment for acute hemolysis for 50 years.¹³⁵ As most cases occur in progressive CLL, it would be usual to also treat the CLL, with either chlorambucil or fludarabine, but this carries a risk. For patients in whom the AIHA has been triggered by fludarabine, further exposure to purine analogs or even to any other cytotoxic drug may be hazardous. Patients failing to respond to prednisolone, or relapsing when the dose is reduced, are offered azathioprine or cyclophosphamide.

There are few data on the value of splenectomy in this condition. In a series of 113 splenectomies for AIHA, only 4 were for hemolysis secondary to CLL.¹³⁶ The hazards of splenectomy are well known, and are certainly increased in frail, elderly, immunodeficient patients. Nevertheless, it may be lifesaving.

Among 73 cases of AIHA treated with intravenous immunoglobulin (IVIg) detailed in the literature,¹³⁷ 40% responded. Doses of 0.4 g/kg/day for 5 days were effective. Only 18 of the 73 cases also had CLL. Response was transient, lasting only 3–4 weeks, but retreatment was effective.⁷⁷

Cyclosporine is used in AIHA when other modalities have failed.¹³⁸ The dose is 5–8 mg/kg/day, tapering to a maintenance dose of about 3 mg/kg/day. We aim to keep the blood level at about 100 µg/L.

The severity of hemolysis following fludarabine is often extreme, and several reports detail fatalities. Patients who develop these complications are often immunosuppressed and prone to infection. Further immunosuppressive treatment will intensify this risk. Anticipating that the complication will be difficult to control, we move rapidly to secondary treatments. Where steroids have failed, we have found success with IVIg and splenectomy, but many of our patients

have required cyclosporine and, because responses are often delayed, we move rapidly to prescribing it.⁶⁸

A special risk is the retriggering of autoimmunity by reexposure to fludarabine, cladribine, or pentostatin.⁶⁸ Even chlorambucil may retrigger the complication.⁶⁸ The current Medical Research Council trial suggests that there is no extra hazard in treating a patient with a positive direct antiglobulin test (DAT), but there is if the patient has preexisting AIHA.

Rituximab infusion is rapidly gaining favor for the treatment of autoimmune complications of CLL, especially those occurring after exposure to fludarabine. Zaja et al. reported remarkable responses in cases of AIHA, ITP, cold agglutination syndrome, and axonal degenerating neuropathy.¹³⁹

Autoimmune thrombocytopenia This complication is so rarely diagnosed that there is next to no guidance in the literature on treatment. It therefore seems wise to follow the Clinical Guidelines of the American Society of Hematology¹⁴⁰ for the treatment of idiopathic thrombocytopenic purpura, and to treat the CLL independently as required. Thus, asymptomatic thrombocytopenia should only be treated when the platelet count is $<30 \times 10^9/L$. Hospitalization should be confined to patients with mucous membrane or other severe bleeding. Conventional dose oral prednisolone is the treatment of choice for those who need any treatment (those with severe bleeding or a platelet count $<30 \times 10^9/L$).

Prednisolone is given in the same dose as for AIHA. Patients failing to respond are treated with IVIG 0.4 g/kg/day for 5 days. The response rate is higher than that for AIHA. Splenectomy is also more effective than in AIHA, with response rates of over 70% in patients unresponsive to steroids.¹⁴¹ Other treatments found to be successful in AIHA may also be tried. Unique to autoimmune thrombocytopenia is treatment with vinca alkaloids. Vincristine 1 mg i.v. weekly $\times 6$ is often effective, but vinblastine has also been used. The drugs may be given as boluses or by slow infusion.⁶⁸

ITP complicating CLL may be severe, causing intractable bleeding. Special measures may need to be taken to control the bleeding, including IVIG followed immediately by platelet transfusion. Alternatively, methylprednisolone 1 g/day i.v. $\times 3$ followed by platelet transfusion may be effective. Tranexamic acid is worth trying, as is recombinant factor VIIa.¹⁴²

Pure red cell aplasia Treatment for this complication has been reviewed by Diehl and Ketchum.⁷⁷ On the basis of literature reports of 41 treatments in 33 patients, they recommend instituting treatment to control the CLL, as this will be necessary to achieve long-term remission of the PRCA. At the same time, the PRCA is treated with prednisolone 1 mg/kg/day. If there is no response, then cyclosporine is added. The

reticulocyte count should increase within 2–3 weeks, and the hemoglobin normalize in 1–2 months. At this point, the steroid dose can be reduced and stopped. Cyclosporine should be continued for 6–7 months and then gradually withdrawn.

Paraneoplastic pemphigus This syndrome is frequently fatal⁶⁸; four of the original five patients died, and two patients who developed it following fludarabine also succumbed. One patient has survived post-fludarabine paraneoplastic pemphigus after having been treated with prednisolone 500 mg/day, cyclophosphamide 100 mg/day for several weeks, together with IVIG 120 mg over the first 3 days. Other patients with a similar syndrome, unrelated to malignancy, have responded to IVIG. Three British patients responded to the combination of high-dose steroids and cyclosporine or cyclophosphamide, although one later died from sepsis.

Rapidly progressive glomerulonephritis Treatment for glomerulonephritis involves intense immunosuppression with high-dose intravenous methylprednisolone and cyclophosphamide.⁶⁸ Plasma exchange has a role in those cases that present with renal failure requiring dialysis. Aggressive immunosuppression has the added benefit of suppressing the CLL. It is moot whether control of the CLL or control of the autoimmune process is responsible for the beneficial effect of such treatment.

NONIMMUNE COMPLICATIONS

Hypercalcemia

Hypercalcemia is a rare complication of CLL.¹⁴³ The cause is obscure. Rossi et al.¹⁴⁴ have suggested that cases of CLL might have abnormal osteoclast differentiation, leading to increased bone resorption.

Abnormal reactions to insect bites

There has long been a story that patients with CLL respond abnormally to insect bites. Two recent studies have entered the literature.^{145,146} Histology showed T- and B-cell infiltrates with prominent eosinophil infiltration and eosinophil granule deposition. One patient developed bullous lesions.

Neurologic complications

Hamblin¹⁴⁷ reported patients with various neurologic complications, including Bell's palsy, Parkinson's disease, and peripheral neuropathy. It is difficult to know whether such complications are neoplastic, paraneoplastic, or incidental. Creange et al.¹⁴⁸ reported seven cases of inflammatory neuromuscular disorders in which there was clear evidence of infiltration with CLL cells. Bell's palsy is now thought to be a complication of Herpes simplex infections in most cases, and Hamblin¹⁴⁷ reported a temporal relationship of Parkinson's disease to severe Herpes zoster infections.

RS3PE

Recurrent symmetrical seronegative synovitis with pitting edema (RS3PE) is a strange condition of old men

who are HLA-B7 positive. It is associated with hematologic disorders in 30% of cases, most commonly CLL and the myelodysplastic syndromes.¹⁴⁹

HAIRY CELL LEUKEMIA

Chapter 28

EPIDEMIOLOGY, RISK FACTORS, AND CLASSIFICATION OF HAIRY CELL LEUKEMIA

Diane M. BuchBarker

EPIDEMIOLOGY

Hairy cell leukemia (HCL) is one of the B-cell lymphoproliferative disorders and is quite rare.

There is little known about epidemiologic factors of importance in patients with HCL.

INCIDENCE

Hairy cell leukemia is an uncommon malignancy, encompassing only 1–2% of all leukemias in the United States. It is slightly lower at 1.12% of all leukemias in Mexico.¹ Incidence is reported as 2.9 per million persons per year for men and 0.6 per million persons per year for women, and is similar to that reported in England and Wales.² The incidence in Hong Kong is much lower, at only 0.0035 per million persons per year.³ The highest documented incidence is derived from nationwide information from Iceland—at 4.7 per million persons per year.⁴ Generally, the disease is indolent with a prolonged clinical course.

Patients presenting with HCL are usually in their middle ages, with the median age of 52 years at diagnosis. There is a striking male predominance, with a male/female ratio of 4:1. This male predominance holds true throughout all countries.

There is also ratio discordance with race. Caucasians have a higher frequency of HCL than other races. Jewish males have a higher risk than Jewish females or those of other religion groups.⁵

GENETIC PREDISPOSITION

There is no proven genetic predisposition to the development of HCL, although approximately 15 cases of what appears to be familial HCL have been reported over the past 20 years. They have all shared the HLA haplotype A2, Bw4, and Bw6 suggesting that these haplotypes may play a role in genetic predisposition.^{6,7}

MORTALITY DATA

In untreated patients, the rate of survival at 5 and 10 years was 34.4% and 29.6%, respectively. For splenectomized patients the 5-year survival was approximately 60% and for those receiving pentostatin, the 5-year survival was 90%.⁸

RISK FACTORS

The interest in identifying risk factors for all cancers is rising with the increasing incidences of cancer. Most likely because of the rarity of this disease, there is little information on risk factors for HCL. Studies have identified a number of potential risk factors for HCL, including occupational hazards, chemical exposure, and infectious predispositions.

CHEMICAL EXPOSURE AND HAIRY CELL LEUKEMIA

Several studies have hinted at chemical exposure as a risk factor, consistent with data seen in other hematologic

malignancies. The tendency of HCL to occur in men at a 4:1 ratio suggests that there may be occupational risk factors as well. Summaries of these studies are as follows: Hardel et al. reported on a population-based cancer registry analysis of 515 cases and 1141 controls. They identified increased risks for subjects exposed to herbicides, insecticides, fungicides, and impregnating agents.⁹ A significant association was found between HCL and insecticides, fungicides, and herbicides, with an overall odds ratio ranging from 1.5 to 2.4 in a study of 226 men with HCL reported by Clavel.¹⁰ Nordstrom et al., in the *British Journal of Cancer*, published a study that also identified exposure to the above mentioned same agents as risk factors.¹¹

OCCUPATIONAL HAZARDS AND HAIRY CELL LEUKEMIA

In the study by Nordstrom et al. data supported agriculture-related exposures as an increased risk for HCL. There was also an overall elevated odds ratio for exposure to farm animals, specifically cattle, horses, hogs, poultry, and sheep. There is, however, a question of recall bias affecting these results.¹¹ Ruiz-Arguelles reported on 27 patients with HCL in Mexico and found that the proportion of patients with leukemia to be higher in the northern region of the country where farming and agriculture is more prevalent.¹ Clavel reports on 225 men with HCL and 425 matched controls, and found that 20.8% of the cases were farmers.¹⁰

Organic solvents have been implicated in the etiology of HCL in several series.¹²⁻¹⁴ One of the larger case-control studies of 291 cases with HCL and 541 matched controls was published in the *British Journal of Hematology*¹⁵ and did not find an association with jobs involving exposure to solvents. The study admittedly lacked the power to investigate higher odds ratio for some jobs, such as spray painters. Previous studies have suggested an association with organic solvents.

INFECTIOUS EXPOSURES AND HAIRY CELL LEUKEMIA

The contribution of infectious pathogens to the etiology of cancer is being investigated for a multitude of cancers. Because of the association of Non-Hodgkin's lymphoma with Epstein-Barr virus (EB), Nordstrom reported on the correlation of exposure to Epstein-Barr virus and exposure to organochlorines as risk factors for HCL. High titres of antibodies to EB early antigen IgG, along with higher blood concentrations of chlordanes, and hexachlorobenzene were correlated with an increased risk for HCL.¹⁶

A population-based case control study performed in Sweden through a mailed questionnaire to investigate the possible role of previous medical history and medications as risk factors for HCL was conducted by Nordstrom et al. Elevated odds ratio was found in those with a history of appendicitis and pneumonia, NSAID use, as well as a history of malignancy.¹⁷ There

was no association found between cigarette smoking, alcohol, or coffee consumption and HCL.^{11,15}

RISK OF SECOND MALIGNANCIES

In an epidemiological study of HCL in Los Angeles County in 1990, it was noted that patients with a history of HCL were more than twice as likely as other cancer patients to have multiple cancer diagnoses.⁵ Since that time, multiple studies have confirmed that HCL patients have an increased risk for secondary malignancies. The rationale for this observation is probably dual. The primary treatment of HCL involves the use of nucleoside analogs, which lead to prolonged immunosuppression, with lower than normal numbers of CD4+ cells for more than 3.5 years.^{18,19} This prolonged immunosuppression leads to an increase in second malignancies.¹⁹ Cheson et al. looked at patients with either chronic lymphocytic leukemia (CLL) or HCL who had undergone treatment with Nucleoside Analogs and found a total of 150 secondary cancers in 146 patients. Most of these cases were solid tumors, with a higher than expected frequency of prostate cancer.²⁰ In a study from British Columbia, Au et al. reported that of 117 patients with HCL diagnosed between 1976 and 1996, 30.7% had at least one additional malignancy. Twenty percent were diagnosed either at the same time or within a few years of the diagnosis of HCL, with a peak incidence at 2 years afterwards. All secondary malignancies were solid tumors.²¹

Interestingly, previous studies of other immunocompromized populations found an increased incidence of hematologic malignancies, yet more solid tumors were found in patients with HCL. They were detected prior to or concomitant with the diagnosis of HCL. There is one case report of a patient with a myeloproliferative disorder (essential thrombocythemia) treated with hydroxyurea who later developed HCL.²² There have been two reports of pre-existing polycythemia vera followed by a diagnosis of HCL.²³

Interferon alpha is an effective treatment for HCL. This suggests that the immune system may help modulate disease progression.^{24,25} Multiple tumors were found in some studies either prior to or concomitant with the diagnosis of HCL, raising the suspicion that there may be an underlying impaired immune response in patients with HCL.²⁶

Not all studies support the theory that patients with HCL are at an increased risk for second malignancies. The following reported that the incidence of second malignancies was not significantly higher than expected. Fifty-four of 1,022 patients in the Italian Cooperative Group for the Study of HCL developed second cancers; this was not significantly higher than the expected rate, although the incidence of lymphoid neoplasms was significantly higher.²⁷ Data on 350 patients with HCL obtained from the M.D. Anderson Cancer Center Cancer Registry found that, although

there was an increase in the number of second malignancies, statistical significance was not achieved, and the excess malignancies were not thought to be associated with therapy.²⁸

CLASSIFICATION

Hairy cell leukemia is a rare chronic monoclonal B-cell neoplasm. There is no internationally recognized classification system for HCL. In fact, the World Health Organization classification of hematopoietic and lymphoid malignancy represents the first world-

wide consensus document on the classification of lymphoma/leukemia.

Classically, three immunophenotypic variants are described. All hairy cells express the pan-B-cell antigens CD19 and CD20. They are negative for CD5, CD10, and CD23. The classic variant coexpresses CD11c, CD25, and CD103. The variant group accounts for 10% of hairy cell cases and expresses CD11c, but not CD25. Expression of CD103 is variable. The survival of the variant form seems to be inferior to the classic type, most likely due to chemoresistance. The Japanese variant is CD11c positive, and occasionally CD103 positive, but CD25 negative.²⁹⁻³²

Chapter **29****MOLECULAR BIOLOGY,
PATHOLOGY, AND CYTOGENETICS
IN HAIRY CELL LEUKEMIA***Mirko Zuzel and John C. Cawley***INTRODUCTION**

Hairy cell leukemia (HCL) is a clonal expansion of abnormal memory-type B cells with specific features of activation, including the distinctive “hairy” morphology of the malignant cells that give the disease its name. The malignant hairy cells (HCs) display specific patterns of activated signaling components, express a spectrum of activation antigens and activated adhesion receptors, and spontaneously secrete a number of autocrine cytokines. Many recent studies clearly indicate that the pathology of HCL is, to a large extent, a direct reflection of this activated phenotype of the malignant cells.

Although HCL is a largely homogenous disease with respect to its cell-biological and clinicopathological features, no consistent abnormal cytogenetic profile has yet been demonstrated, and the nature of the oncogenic transformation of HCs remains unclear.

Here we first describe the specific cell-biological and molecular characteristics of HCs and discuss their importance for the distinctive clinicopathological features and therapy of HCL. We also present the currently known cytogenetics of this disease.

CELL AND MOLECULAR BIOLOGY**HAIRY CELLS AS MEMORY B CELLS**

It is well established that HCs are mature clonal B cells that express a range of B-cell markers (e.g., CD19, CD20, CD22) together with surface immunoglobulin which has often undergone class-switch recombination and relatively low levels of somatic hypermutation (Table 29.1). Moreover, individual HCs can express multiple heavy chain isotypes that are generated by splicing of long RNA transcripts.¹ Studies of a limited number of cases failed to show clear evidence of biased V_H gene segment usage or cell selection by antigen(s).²

Table 29.1 HCs as mature B cells

- Express strong surface immunoglobulin
- All heavy-chain isotypes except IgE potentially expressed; IgG3 predominant
- Coexpression of multiple isotypes the result of RNA splicing
- Often V_H mutated without further clonal evolution
- No clear biased usage of V_H gene segments
- Lack naïve (e.g., CD23) and germinal centre antigens (e.g., CD10, BCL-6)
- Do not express plasma-cell markers (MUM-1, CD138, BLIMP 1)

Although HCs express the plasma-cell antigen PCA1,³ and the CD85 expressed by plasma cells and other mature B cells, they have little or no propensity to differentiate into antibody-secreting cells. Recent gene expression profiling clearly places HCs, along with chronic lymphocytic leukemia (CLL) cells, at the memory stage of B-cell development.⁴ Reactivity with a phage-derived antibody known as phab V-3 and high levels of CD11c expression indicate that HCs may originate from a subpopulation of normal CD11c-positive memory B cells with similar phab V-3 reactivity.⁵ This subpopulation is V_H -mutated and possesses the memory-cell marker CD27 that has also been reported to be present on HCs.⁴

ACTIVATION FEATURES OF HAIRY CELLS

Long before the advent of CD antibodies, the distinctive morphology of HCs was highly suggestive of the activated nature of the malignant cells. Subsequent studies have indeed shown the HCs express a number of antigens (e.g., FMC7, CD22, CD25, CD72, CD40L) associated with the activation of B cells and other cell types (Table 29.2),⁶ but lack CD23, which is expressed by CLL cells and upregulated during normal B-cell activation.⁶ Moreover, certain HC-“restricted” antigens,

Table 29.2 Activation features

Upregulated activation antigens (e.g., FMC-7, CD22, CD25, CD72, CD40L)
Downregulation of antigens often reduced during activation of other cells types (e.g., CD21 and CD24)
HC-"restricted" antigens probably indicative of activation (e.g., CD11c, CD68, CD103, HC-2, cyclin D1 and TRAP ^a)
Surface microvilli and ruffles, relatively abundant basophilic cytoplasm, open nuclear chromatin

^aTRAP = tartrate-resistant acid phosphatase.

such as CD11c, CD68c, CD103, HC-2, cyclin D1, and TRAP, have also been associated with the activation of certain lymphoid and non-lymphoid cell types.⁷ Interestingly, both the CD21 and CD24 markers, normally lost after B-cell activation, are expressed by HCs only at low levels.⁶

OTHER DISTINCTIVE PHENOTYPIC FEATURES

In addition to the HC-"restricted" activation antigens alluded to above, global gene-expression analysis has identified a large number of new genes differentially expressed by HCs as compared to normal memory B cells and a range of normal and malignant B-cell-types.⁴ Genes of particular potential importance identified by this technology include those related to HC morphology, to the long-known "monocytic" features of HCs, to the adhesion and homing of the malignant cells, and to their propensity to alter the extracellular matrix of bone marrow and hepatic portal tracts. These phenotypic features are listed in Table 29.3 and will be

Table 29.3 Newly identified differentially expressed genes of potential pathogenetic importance

Morphology related pp52 (LSP-1), β -actin, Gas 7 and EPB4.IL-2
"Monocytic" features annexin 1, CD63, CPVL, CD68, c-Maf
Unusual tissue distribution CCR7 and CXCR5 chemokine receptors downregulated TIMP-1, TIMP-4 and RECK matrix metalloproteinase inhibitors upregulated
Matrix remodeling Overexpression of FGF-2 and FGFR1 confirm previous evidence for involvement of this autocrine loop in the stimulation of the production of HC-derived fibronectin responsible for the bone marrow fibrosis of HCL

considered further in the section dealing with the pathology of the disease.

ACTIVATED SIGNALLING COMPONENTS

A number of signaling components are now known to be activated in HCs. The so-far identified activation signals and their likely mutual relationships are summarized in Table 29.4. Some of these signals are transient and clearly originate from cell stimulation by components of the in vivo microenvironment, but some persist in vitro, suggesting that they are truly constitutive. It is, however, not yet clear which of these constitutive signals is a direct consequence of the still unknown oncogenic event(s), and which are attributable to autocrine cytokine production. The pathogenetic role

Table 29.4 Activation signals in HCs

Signal	Possible origin	Functional relevance
Elevated intracellular [Ca ²⁺]	Release from intracellular stores in response to autocrine cytokine. Influx via highly expressed and phosphorylated CD20	Activation messenger
Increased protein tyrosine phosphorylation	Constitutively activated Src	Downstream activation of Rho GTPases, PKCs and MAP kinases
Active Rac and Cdc42	Src-activated GEF(s)	Formation of surface ruffles and microvilli and downstream activation of MAP kinases
Activated PKCs	Upstream activators include high [Ca ²⁺], PLC-generated DAG and Src	Regulation of MAP kinases and NF κ B involved in cell survival and proliferation
Activated MAP kinases	ERK activation constitutive and PKC dependent p38 and JNK induced by external signals (e.g., TNF) and suppressed by active PKC α	ERK provides a pro-survival signal p38 is pro-apoptotic JNK stimulates CD11c expression via AP-1 complex formation
Activated NF κ B	Autocrine TNF and integrin signaling	Stimulates IAP production. Suppression of IAPs involved in the α IFN-induced sensitivity of HCs to TNF killing

of these signals will be considered in the section dealing with the pathology of the disease.

The first demonstration of a messenger that could be responsible for the activated state of HCs was provided by Genot et al., who showed elevated $[Ca^{2+}]$ in HCs and identified phosphorylated CD20 as an influx channel involved in this Ca^{2+} elevation.^{8,9} Ca^{2+} / calmodulin-dependent protein kinase II may be responsible for the CD20 phosphorylation and for the maintenance of Ca^{2+} influx.⁹ Interestingly, HC treatment with α interferon reduced CD20 phosphorylation and the cytosolic Ca^{2+} level,¹⁰ and the authors suggested that this might be a part of the mechanism of the therapeutic action of this agent in HCL.

Increased expression of Src and high protein tyrosine kinase activity in HCs have also been recognized for some time.¹¹ More recently, it was demonstrated that Src-dependent tyrosine phosphorylation is responsible for downstream activation of many other signaling components, including Rho GTPases,¹² PKCs, and MAP kinases.¹³ Rac and Cdc42, the two constitutively active Rho GTPases in HCs, are responsible for the distinctive morphological features of these malignant cells,¹² as well as for their adhesive and motile behavior on different substrates.¹⁴ In addition to regulating cytoskeletal dynamics, Rac and Cdc42 are also likely to be involved in the activation of MAPKs.¹⁵

PKC(s) involvement in activation of HCs has long been suspected, as other B cells treated with phorbol esters acquire HC-like morphology and TRAP expression. More recent work has revealed the presence in HCs of at least six PKC isoforms, of which only PKC α was consistently found to be strongly constitutively active.¹³ Furthermore, PKCs were found to be crucially

involved in the regulation of MAPKs in HCs. Thus, HC incubation with PKC inhibitors caused a rapid four-fold increase in p38 MAP kinase activation and an equally rapid downregulation of constitutive ERK activity.¹³ This was followed by pronounced shortening of cell survival, a finding in accordance with the proposed central role of the balance between activations of cytoprotective ERK and pro-apoptotic p38/JNK in the regulation of cell survival.¹⁶

HCs produce large amount of TNF and possess both TNFR1 and TNFR2.^{17,18} Autocrine TNF α increases cell survival,¹⁹ but in the presence of α IFN this pro-survival effect is converted to a pro-apoptotic one.²⁰ This cell killing is brought about by IFN-induced suppression of IAP (inhibitors of apoptosis) production regulated by the NF κ B-dependent arm of TNF signaling. HC adhesion to vitronectin and fibronectin stimulates IAP production that is not inhibited by α IFN, and can therefore provide relative protection of HCs from this IFN-induced, TNF-mediated killing.²⁰

Thus, intrinsic activation of malignant HCs is highly relevant for both pathogenesis and therapy of HCL. Therefore, studies of the signaling pathways involved may suggest new therapies, and may give some insight into the elusive nature of the primary oncogenic event(s) responsible for the intrinsic activation and developmental arrest of HCs.

ADHESION RECEPTORS

HCs are highly adherent and, on some substrates, spontaneously motile cells. This indicates that receptors involved in the adhesion and motility of these cells are constitutively activated. This conclusion is supported by the demonstration that HCs readily interact

Table 29.5 Expression and function of HC adhesion receptors

Integrins	(CD)	Possible functions
Adhesion receptors		
$\alpha_4\beta_1$	(49d/29)	Involved in binding to matrix (fibronectin, FN) and accessory cells via CD106 (VCAM)
$\alpha_5\beta_1$	(49e/29)	Involved, together with $\alpha_4\beta_1$ in binding to, and assembly of, FN matrix
$\alpha_M\beta_2$	(11b/18)	Weakly expressed. Constitutes a monocytic feature of HCs and may be involved in endocytosis
$\alpha_X\beta_2$	(11c/18)	Diagnostically important. Receptor for a number of ligands, including ICAM-1 (CD54), but function in HCs unclear
$\alpha_V\beta_3$	(51/61)	Receptor for vitronectin (VN) and PECAM-1 (CD31). Important in HC motility
$\alpha_E\beta_7$	(103/b ₇)	Diagnostically important. Receptor for E cadherin, but function in HCL unclear
Other adhesion receptors		
CD44		Highly expressed. HC receptor for hyaluronan Several isoforms expressed (VH3, V3, V6). CD44H signals for FGF-2 (bFGF) production; V3 (heparan sulphate-containing isoform) acts as a co-receptor with FGFR-1 for stimulation of HC FN production by FGF-2
L-selectin	(62L)	Little or no expression. Shed on cell activation

Table 29.6 Cytokines produced by HCs

Cytokine	Receptors on HCs	Comment
TNF- α	TNFR1 and RII present	Involved in HC survival and response to IFN therapy
IL-6	Present	Production may be induced by TNF. May participate in the proliferative effects of TNF
IL-10	Not studied	Suppresses TH1 cytokine production
GM-CSF	Receptor present	Prolongs the survival of HCs and inhibits their motility
M-CSF	Receptor present	Stimulates chemokinesis and chemotaxis of HCs
bFGF	Both FGFR1 and CD44v3 co-receptor present	Involved in FN production by HA-adherent HCs. May stimulate increased angiogenesis in HCL bone marrow
TGF β	Not studied	Elevated in HCL serum and BM. May be involved in suppression of the production and function of normal hematological cells, and stimulates BM fibroblasts to produce the collagen component of reticulin fibrosis
IFN α	Receptor present	Induces HC apoptosis in the absence of cell adhesion and may induce autocrine production of TNF

with a number of extracellular matrix (ECM) components including fibronectin (FN), vitronectin (VN), and hyaluronan (HA) (see Table 29.5). On FN, HCs firmly adhere and assume a spread morphology, whereas on VN and HA they display polarized morphology and pronounced motility.^{14,21} This spectrum of behavior is likely to reflect both differences in the interaction of various adhesion receptors with the activated cortical cytoskeleton, as well as differences in signals generated by these receptors upon ligand binding. With regard to their interaction with FN, HCs are unique among B cells because of their ability to synthesize this protein and also to assemble it into matrix,²² in a process that requires FN binding to activated $\alpha_5\beta_1$ integrin.^{23,24}

AUTOCRINE CYTOKINES

Pathogenetically relevant cytokines produced by HCs and their autocrine and paracrine effects are summarized in Table 29.6. Among these, TNF, IL-6 and GM-CSF have been reported to promote HC survival/proliferation,^{25–27} while GM- and M-CSF affect malignant-cell adhesion / motility.^{28,29} HCs also produce bFGF, TGF β , and IL-10, which are involved in processes by which HCs modify extracellular and cellular components of their microenvironment. Thus, bFGF and TGF β are respectively involved in the stimulation of FN production by HCs and of collagen by fibroblasts.^{30,31} Moreover, TGF β can inhibit normal hematopoiesis and also, together with IL-10, suppress the immune functions of T cells and monocytes.^{32,33}

In addition to responding to autocrine cytokines, HCs possess a number of receptors for cytokines produced by other cells. Thus, IL-1 is known to upregulate the surface expression of Ig and PCA-1 antigen by HCs,³⁴ while IL-4 and IL-15, alone or in synergy with other growth factors, stimulate the cells to synthesize DNA.³⁵ HCs also possess IL-2 and IL-3 receptors;

expression of the IL-2 receptor (CD25) is of diagnostic importance, but no functional effects of either IL-2 or IL-3 have so far been demonstrated.

In summary, cytokines play a part in most, if not all, pathogenetically important reactions of HCs, including their clonal expansion, their distinctive tissue homing and their influence on both cellular and extracellular components of the invaded tissues. This ultimately results in the suppression of both normal hematopoiesis and immunity—the two most damaging aspects of the disease.

PATHOLOGY

The principal distinctive pathological features of HCL (Table 29.7) have been known for more than 20 years, but their pathogenesis has only recently started to be defined. Thus, the cell-signaling and gene-expression studies described above have now largely elucidated the causes of the unusual morphology of HCs. Also, investigations of the expression and function of adhesion receptors, together with the identification of pathogenetically important cytokines, have provided data that could explain the predilection of HCs for homing

Table 29.7 Key pathological feature of HCL

- Pathognomonic HC
- TRAP expression by HCs
- BM infiltration and fibrosis
- Invasion of splenic red pulp and pseudosinus formation
- Hepatic infiltration with sinusoidal and portal tract involvement
- Lymph nodes relatively spared
- Cytopenias (especially monocytopenia), T-cell dysfunction and immune defect

to bone marrow, spleen and liver, while largely sparing other lymphoreticular sites.

CYTOLOGY AND (IMMUNO)CYTOCHEMISTRY OF HAIRY CELLS

In stained films of blood and bone marrow, HCs appear as distinctive large cells (15–30 μm in diameter) with abundant light-blue cytoplasm and peripheral hair-like protrusions. The nucleus is usually eccentric and has relatively open chromatin with inconspicuous nucleoli. HCs are unique among hemic cells in displaying strong cytoplasmic staining for tartrate-resistant acid phosphatase. Both the surface appearance and TRAP positivity of HCs are the result of the intrinsic activation described earlier.

As at the level of the light microscope, the ultrastructure of HCs corresponds to that of highly metabolically active cells. Thus, HCs display only modest peripheral nuclear chromatin condensation and possess abundant cytoplasm with plentiful mitochondria and frequent ribosomes. A relatively specific ultrastructural feature is the presence of ribosome–lamellar complexes in a variable proportion of cells (Fig. 29.1). Although these structures were described many years ago,³⁶ their nature and functions are still unclear. HCs contain a large amount of F-actin, which supports the prominent surface ruffles and microvilli best seen by scanning electron microscopy (Fig. 29.2).

Recent studies have identified a number of molecules which, by interacting with F-actin, may be involved in the generation of the hairy appearance of the malignant cells. These include pp52 (LSP-1), Gas-7, and EPB4.1L2—recently found by gene microarray analysis to be overexpressed in HCs (Table 29.3).⁴ pp52 has been previously found to be abundant in the F-actin-rich protrusions of HCs,³⁷ while, by interacting

Figure 29.1 The ultrastructure of the ribosome–lamellar complex. In the lower right part of this electron micrograph, the R–L complex is sectioned longitudinally, while on the left the complex is cut obliquely. The inset shows the complex in transverse section. In three dimensions, the R–L complex probably resembles a coiled roll of chicken wire

Figure 29.2 The surface structure of HCs. This scanning electron micrograph shows the surface of two adjacent HCs. Note the distinctive mixture of surface ruffles and microvilli

with F-actin, ectopically expressed Gas 7 induces excessive surface projections and dramatic changes in cell shape.³⁸ EPB4.1L2 is also involved in the regulation of cell shape through interaction with β -actin underneath the plasma membrane.⁴

In addition to possessing a unique morphology, HCs are unusual among lymphoid cells in displaying a spectrum of features normally associated with monocytes and macrophages. HCs are able to phagocytose a range of particles and microorganisms,³⁹ a property that has recently been linked to the specific upregulation of annexin A1, CD68, and a novel serine carboxypeptidase CPVL which was first identified in macrophages.⁴⁰ Although the expression of CD11c is possibly an activation feature of HCs and is also found on certain other lymphoid cell types, this integrin α chain, together with CD63, is commonly regarded as a macrophage marker. In addition, HCs have been shown to overexpress c-Maf, a transcription factor linked to macrophage differentiation.⁴¹ Finally, overexpression or underexpression by HCs of a number of genes outlined in Table 29.3 could be relevant for the unusual tissue distribution of HCs and for the matrix remodeling by the malignant cells that are such distinctive features of HCL.

BONE MARROW

The bone marrow (BM) is variably infiltrated by widely spaced HCs surrounded by clear areas, which impart a halo appearance. This loose packing probably reflects cell spreading on the altered ECM and has been likened to a fried-egg appearance.⁴² This appearance is also seen when HCs adhere to FN-coated surfaces in vitro.⁴³

In the BM microenvironment, the FN component of the distinctive reticulin fibrosis is largely, if not exclusively, synthesized by HCs themselves.^{22,30} As mentioned above, adhesion receptors, together with autocrine bFGF, play a key role in this matrix remodeling. It has been demonstrated that in BM and hepatic

portal tracts adhesion to hyaluronan via the standard hematopoietic form of CD44 stimulates HCs to secrete bFGF.³⁰ This bFGF binds to both FGFR1 and CD44v3 on HCs and stimulates them to produce FN.³⁰ Secreted FN is then assembled into a matrix by a process involving $\alpha_5\beta_1$ FN receptors on the malignant cells.²² The importance of HA for the initiation of this process is indicated by the absence of fibrosis in the infiltrated red pulp of the spleen, which does not contain HA.

SPLEEN

The spleen is usually the major site of HC infiltration. The malignant cells accumulate in the red pulp, while the white pulp of the enlarged spleen is greatly reduced. Within the sinuses of the red pulp, the HCs have a propensity to replace the endothelium and to remodel the sinuses so that they enlarge, forming the vascular lakes or pseudosinuses pathognomonic of the disease.⁴² The mechanism of splenic homing is likely to involve HC interaction with endothelium and also, via $\alpha_v\beta_3$ integrin, with VN present in the spleen.⁴³ The candidate chemoattractant to the red pulp is M-CSF produced by macrophages,²⁹ while the likely first step in vascular remodeling is HC interaction with endothelial cells via $\alpha_4\beta_1$ -to-VCAM binding.⁴⁴ This is followed by replacement of endothelial linings by HCs in a process that may involve $\alpha_v\beta_3$ -mediated movement of HCs in between and underneath endothelium. The likely binding partners of $\alpha_v\beta_3$ during this process could be PECAM on endothelial cells and VN on basement membranes. The tendency of HCs to remain confined to the vascular spaces of the red pulp could possibly be explained by the reduced or absent expression of the chemokine receptors CCR5 and CXCR4, and by upregulation of the metalloproteinase inhibitors TIMP-1, TIMP-4 and RECK (Table 29.3).⁴ This could severely limit or abolish the ability of HCs to receive stimuli for exit from the red pulp and to employ metalloproteinases to traverse basement membranes and invade other compartments of the spleen.

LIVER

Hepatic infiltration by HCs is a constant feature of HCL, but the organ is usually not markedly enlarged, and its general architecture remains intact. Both sinusoids and portal tracts are involved. In the sinusoids, the HCs may lie free within the lumen or be closely associated with the endothelium and adjacent hepatocytes.⁶ In the portal tracts, the infiltrate is associated with marked fibrosis. This fibrosis is likely to involve the same mechanisms as described for BM.³⁰

LYMPH NODES

Although clinical lymphadenopathy is uncommon in HCL, at postmortem some lymph node involvement is usually found. The infiltration is paracortical and at least some follicles are usually preserved.⁴² This relative sparing of lymph nodes may be the result of low or absent L-selectin (CD62L)⁷ and CCR7.⁴

In advanced disease, prominent upper abdominal lymphadenopathy may occur. The infiltrating HCs are larger and of more immature appearance than typical HCs, suggesting that such node enlargement is a consequence of disease transformation.⁴⁵

OTHER BLOOD CELLS

At presentation, most patients have evidence of suppressed hematopoiesis. Abnormalities of monocytes, T cells, NK cells, dendritic cells, platelets, and neutrophils have all been described in HCL.^{6,46} Among these, the monocytopenia of the disease and altered T-cell function have attracted particular attention because of their potential contribution to the marked immune deficiency present in active disease.

The cause of the almost complete absence of circulating monocytes remains unclear. It has been proposed that reduction in antigen presentation, as a result of monocytopenia and reduced numbers of dendritic cells, is partly responsible for the defective immune responses in HCL. However, since tissue macrophages are plentiful,⁶ abnormalities of T cells and of their interactions with antigen-presenting cells seem to be of a greater importance. T-cell abnormalities include both quantitative and qualitative defects. Overall T-cell numbers are often reduced, the CD4⁺ / CD8⁺ cell ratio is reversed, and the percentage of $\gamma\delta$ T cells is frequently increased.⁴⁷⁻⁴⁹ Moreover, the response of T cells to alloantigens in mixed lymphocyte cultures is grossly abnormal.^{48,49} This abnormality has been attributed to reduced or absent CD28 expression on a large proportion of CD4⁺, as well as CD8⁺ cells.⁴⁹ Among CD4⁺ T cells, CD45RO⁺ memory cells are grossly reduced.⁵⁰

Studies of the T-cell receptor (TCR) in HCL have demonstrated oligoclonality in most patients, with a markedly skewed repertoire of TCR β V genes.⁵¹ Moreover, some gene segments of the normal repertoire were absent from the T cells of HCL.^{49,52} Interestingly, α IFN treatment leads to both the disappearance of the selected clones and to a gradual full restoration of the normal TCR repertoire,⁵² suggesting a direct influence of the malignant cells on T-cell development in HCL. Some of the apparently expanded clones are found to recognize antigens overexpressed by (but not necessarily specific to) HCs, as is the case with overexpressed synaptojanin 2.⁵³ However, T cells that were found to be clonally expanded in HCL seem to have no cytotoxic effect on the malignant cells,⁵⁴ and therefore are unlikely to have a beneficial effect on disease progression.

Thus, although abnormalities of the immune system in HCL have over the years received considerable attention, many questions regarding the immunobiology of the disease remain to be answered. It should be pointed out, however, that the clinical importance of the immune system dysfunction in HCL has been significantly reduced by the current successful early therapy of the disease.

CYTOGENETICS

The most important aspects of the cytogenetics of HCL are given in Table 29.8. Although many karyotypic abnormalities have been described,⁵⁵ none are specific and none are consistently found in all HCL patients. Therefore, karyotypic analysis has not yet given any insight into the primary oncogenic event(s) responsible for the disease.

As pointed out by Basso et al.,⁴ HCs and CLL cells, unlike other malignant B cells, typically lack reciprocal balanced chromosomal translocations. Since these translocations are generated during Ig VDJ recombination, class switching and somatic hypermutation, their absence supports the proposition that both HCL and CLL are malignancies of mature memory B cells in which these processes are switched off.

HCL was the first hematological malignancy analyzed by comparative expressed sequence hybridization (CESH) to chromosomes.⁵⁶ This showed a consistent expression profile of different chromosome regions that carry a “splenic signature,” along with HC-specific under- or overexpressed regions.⁵⁶ Moreover, these regions contained many genes which had also been found to be differentially expressed by gene-array

Table 29.8 Cytogenetics of HCL

- No consistent or specific cytogenetic abnormality
- Absence of translocations suggests malignant transformation of post-GC-type cells
- Most frequent recurrent abnormalities involve chromosomes 5 (trisomy 5, 5q13 aberrations) and 14 (add (14)q(32) and del(14)(q))
- A range of other structural and numerical abnormalities of a number of chromosomes reported
- CESH profiling showed a uniform pattern of over- and underexpression of chromosome regions consistent with gene expression profiles established by DNA microarray analysis
- Uniform clinicopathological, DNA microarray and CESH profiles suggest that none of the described cytogenetic abnormalities play a primary pathogenetic role

analysis,⁴ and which encode proteins of potential pathogenetic importance (Tables 29.2 and 29.3). However, neither cytogenetics nor gene-expression analysis have yet identified abnormalities common to all HCL cases that could explain the remarkable homogeneity of the disease, and at the same time provide clues concerning the events responsible for malignant transformation and maturational arrest of HCs.

Chapter 30

CLINICAL FEATURES AND MAKING THE DIAGNOSIS OF HCL

*Olga Frankfurt, Martin S. Tallman,
and LoAnn C. Peterson*

CLINICAL PRESENTATION

Hairy cell leukemia (HCL) is a rare chronic lymphoproliferative disorder, characterized by circulating B lymphocytes displaying prominent cytoplasmic projections and infiltrating the bone marrow and the spleen. The disease was first described as a distinct clinicopathologic entity in 1958 by Bouroucle et al., who referred to the disorder as “leukemic reticuloendotheliosis”.¹ The descriptive term “hairy cell leukemia” was suggested by Schrek and Donnely in 1966.²

The typical patient is a Caucasian middle-aged man, presenting with splenomegaly, pancytopenia, and occasionally recurrent infections. Circulating hairy cells are usually present in the peripheral blood.³

LABORATORY FINDINGS

Although the majority of patients are generally well at the time of diagnosis, some present with symptoms related to anemia, neutropenia, or thrombocytopenia (Table 30.1). Pancytopenia is present in approximately half of the patients, and the remaining half usually exhibit a combination of cytopenias. In a series of 102 patients with HCL, 86 had anemia, 84 had thrombocytopenia, and 78 were neutropenic at the time of diagnosis.⁴ Approximately 25% of patients report weakness and fatigue, 25% suffer from opportunistic infections in the setting of neutropenia, and another quarter have easy bruising from thrombocytopenia. About 25% of patients are incidentally discovered to have splenomegaly or an abnormal peripheral blood count, at the time of evaluation for an unrelated condition.⁵

Coagulopathy, manifested by TTP and anti-factor VIII antibodies and paraproteinemia have been reported in patients with HCL.^{6,7}

PHYSICAL FINDINGS

Splenomegaly is present in 80–90% of patients with HCL. The spleen is frequently massive, and palpable at

Table 30.1 Clinical features of hairy-cell leukemia

<i>Clinical symptoms</i>	
Fatigue	25%
Repeated infections	25%
<i>Abnormal findings on physical examination</i>	
Splenomegaly	80–90%
Hepatomegaly	20–35%
Lymphadenopathy	25%
<i>Laboratory abnormalities</i>	
Circulating hairy cells	90%
Pancytopenia	70%
Anemia	80%
Thrombocytopenia	70–80%
Neutropenia	80%
Leukemic phase	20%
Liver function abnormalities	20%
Azotemia	27%
Hypergammaglobulinemia	18%
<i>Other findings</i>	
Osteolytic bone lesions	3%
Autoimmune diseases	rare

least 5 cm below the left costal margin in approximately 60% of patients.⁸ Early satiety or abdominal fullness caused by splenomegaly is present in 25% of patients at diagnosis.⁵

Hepatomegaly, rarely a significant finding, is present in 20% of patients. Unlike many other lymphoproliferative disorders, peripheral adenopathy is uncommon at diagnosis, with fewer than 10% of patients having lymph nodes larger than 2 cm. However, with the advent of computed tomography and other diagnostic imaging modalities, significant internal adenopathy can be demonstrated in about 30% of patients. Although not common at diagnosis, internal lymphadenopathy may develop after a prolonged disease course⁹ and is present in 75% of patients at autopsy.¹⁰ Such characteristic localization of HCL is likely due to the expression of the integrin

receptor, $\alpha 4\beta 1$, by the hairy cells and its interaction with the vascular adhesion molecule-1 (VCAM-1) found on splenic and hepatic endothelia, bone marrow, and splenic stroma.¹¹

Spontaneous splenic rupture, spinal cord compression with paralysis due to neuronal infiltration by leukemic cells, protein-losing enteropathy from bowel infiltration by leukemic cells, esophageal perforation, uveitis, serous and chylous ascites, and pleural and pericardial effusion have been described in patients with HCL.¹²⁻¹⁴

INFECTIOUS COMPLICATIONS

Significant neutropenia and monocytopenia predispose patients with HCL to infections from a wide variety of typical and opportunistic organisms.¹⁵ Infections with *Mycobacterium kansasii*, *Pneumocystis carinii*, aspergillus, histoplasma, cryptococcus, *Listeria monocytogene*, and *Toxoplasma gondii* have been described.¹⁵⁻¹⁷ In addition to neutropenia and monocytopenia, the milieu making patients susceptible to infections includes T-cell dysfunction, decreased numbers of dendritic and antigen-presenting cells, as well as impaired interferon production by mononuclear cells.¹⁸⁻²¹

ASSOCIATION WITH AUTOIMMUNE PHENOMENA

The association between HCL and autoimmune disorders such as scleroderma, polymyositis, Raynaud's phenomenon, and various vasculitis, has been described.^{22,23} Among the vasculopathic syndromes polyarteritis nodosa represents the most frequently associated disorder, with 18 cases reported so far. It has been suggested that a common membrane antigen expressed in leukemia cells and vascular endothelium may lead to a vasculitis by generating cross-reacting antibody.²⁴ Four cases of scleroderma in the setting of HCL have been reported.²⁵⁻²⁷ It has been postulated that sarcoidosis may be induced directly through hairy

cell antigen-mediated activation of T cells or indirectly through promotion of the nonspecific inflammatory response.²⁷ The presence of cutaneous lesions, such as erythematous maculopapules and pyoderma gangrenosum, have been noted in patients with HCL.²⁸⁻³⁰

BONE LESIONS

About 3% of patients with HCL present with painful bony lesions, most commonly involving the proximal femur. Diffuse osteoporosis, focal and diffuse osteosclerosis, as well as lytic lesions of the skeleton have been described in patients with HCL. Patients who suffer from such skeletal complications tend to have higher tumor burden, with the marrow being diffusely infiltrated by hairy cells.³¹⁻³³

DIAGNOSIS

The initial evaluation of a patient with HCL includes a history and physical examination, a complete blood count with differential count, review of the peripheral blood smear, routine serum electrolytes, blood urea nitrogen and creatinine, hepatic transaminases, a bone marrow aspirate and core biopsy, and immunophenotyping by flow cytometry of peripheral blood or bone marrow aspirate.

HISTOPATHOLOGY

Peripheral blood and bone marrow

Hairy cells can be identified in Wright's-stained blood smears from almost all patients with HCL, although the number of circulating hairy cells is usually low. The bone marrow is often inaspirable, resulting in a "dry tap". However, when aspiration is successful, hairy cells are morphologically similar to those in the blood.

The morphologic features of hairy cells are distinctive, Figure 30.1(a). They are approximately one to two

Figure 30.1 (a) Peripheral smear of a patient with hairy-cell leukemia, demonstrating classic feature of the hairy cells, including bean-shaped nucleus, homogenous, ground-glass chromatin, and abundant pale blue cytoplasm with "hairy" projections. Presence of leukocytosis is atypical for HCL. (b) Bone marrow trephine biopsy of a patient with hairy-cell leukemia, showing diffuse infiltration of hairy cells with abundant pale cytoplasm

times the size of a small lymphocyte, with nuclei that appear round, oval, indented, monocytoid, and occasionally convoluted.³⁴ The chromatin pattern is net-like in appearance and nucleoli are indistinct or absent. The amount of cytoplasm varies from scant to abundant and is pale blue-gray in color. The cytoplasmic borders are irregular and exhibit fine, hair-like projections or irregular borders. Occasionally, cytoplasmic granules are present. Examination of the bone marrow biopsy is important in the diagnosis of HCL because of its characteristic histopathology.^{35–38} In most patients, the bone marrow is hypercellular, although the cellularity may be normal or decreased, Figure 30.1(b). Hairy cell infiltration is diffuse, patchy, or interstitial, or a combination of these patterns. In patients with diffuse involvement, large areas of the bone marrow are replaced by hairy cells, with complete effacement of marrow in some patients. With patchy infiltration, subtle, small clusters of hairy cells are present focally or scattered throughout the bone marrow. Unlike most lymphomas, the hairy cells do not form well-defined, discrete aggregates; instead, they merge subtly with the surrounding residual hematopoietic tissue. In the interstitial pattern of involvement, variable numbers of hairy cells infiltrate between normal hematopoietic cells and fat, leaving the overall bone marrow architecture preserved. Hairy-cell nuclei in sections are round, oval, or indented and typically are widely separated from each other by abundant, clear, or lightly eosinophilic cytoplasm; rarely, the cells are convoluted or spindle shaped, Figure 30.2(a). The nuclear chromatin is lightly condensed, nucleoli are inconspicuous, and mitotic figures are rare or absent. Extravasated red blood cells are often observed. Reticulin stains of the bone marrow trephine biopsy in HCL show a moderate to marked increase in reticulin fibers, Figure 30.2(b). Normal hematopoietic cells are usually decreased in HCL, with granulocytes being typically more severely reduced than erythroid precursors and megakary-

ocytes. In about 10–20% of patients with HCL, the bone marrow is hypocellular. The hypocellularity may be severe and may strongly resemble aplastic anemia.³⁹

Spleen and other sites

The spleen in patients with HCL is usually enlarged, with a median weight of 1300 g.⁴⁰ Splenic involvement in HCL is characterized by diffuse infiltration of the red pulp cords and sinuses, with atrophy or replacement of the white pulp. Blood-filled sinuses, referred to as “pseudosinuses”, lined by hairy cells, are often present, but are not pathognomonic of HCL.⁴¹ The liver shows both sinusoidal and portal infiltration by hairy cells. Involved lymph nodes commonly exhibit partial effacement, with hairy cells infiltrating the paracortex and medulla in a leukemic pattern. The hairy cells often surround residual lymphoid follicles and extend through the capsule.

CYTOCHEMISTRY

Cytochemical studies demonstrating tartrate-resistant acid phosphatase (TRAP) activity, traditionally have been used to confirm the diagnosis of HCL, although the routine use of immunophenotyping for the diagnosis of chronic lymphoproliferative disorders has diminished reliance on the TRAP stain. Immunohistochemical stains for TRAP are also available and can be used in paraffin-embedded sections to demonstrate the activity of this enzyme. Similar to cytochemistry, a positive immunohistochemical stain is not pathognomonic for HCL; positivity has been reported in systemic mastocytosis and Gaucher's disease.⁴² However, the presence of cells positive for both CD20 and TRAP activity confirm the diagnosis of HCL.

IMMUNOPHENOTYPIC PROFILE

Flow cytometric immunophenotyping is a critical part of the diagnostic evaluation of HCL, and helps to distinguish it from other lymphoproliferative disorders.

Figure 30.2 (a) Bone marrow trephine biopsy showing hairy cells with spindle shape nuclei. (b) Bone marrow trephine biopsy stained for reticulin, demonstrating extensive fibrosis surrounding the individual hairy cells, typical for HCL

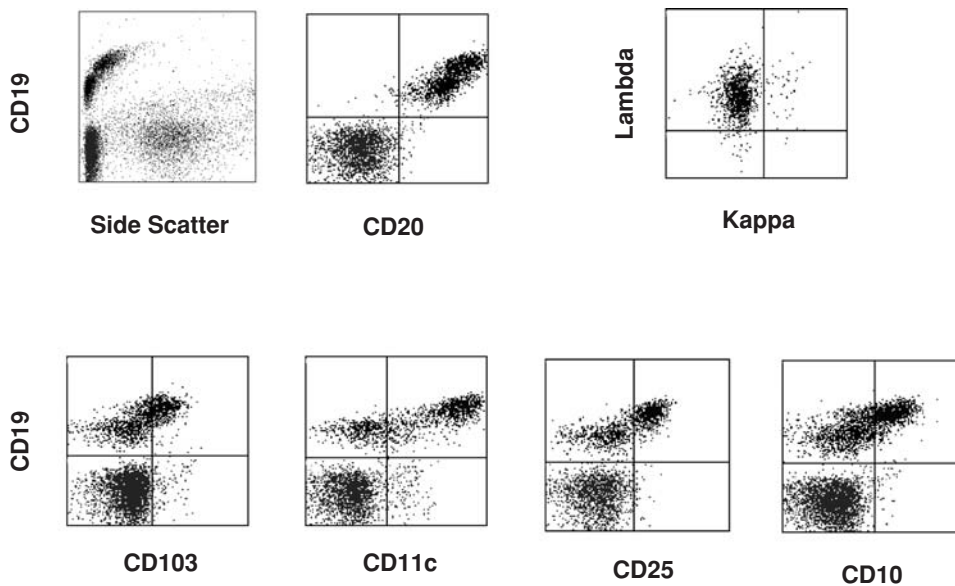

Figure 30.3 Flow immunocytometry of a patient with HCL. Hairy cells (red) express B-cell antigens CD19/CD20, λ light-chain restriction and are positive for CD11c and CD25. CD10 positivity is noted in the minority of patients with HCL

As hairy cells exhibit distinctive light scatter characteristics and immunophenotype Figure 30.3, they are identified by peripheral blood flow cytometry in most of the patients with HCL, even when the HC represent less than 1% of lymphocytes.⁴³ This observation is useful at the time of diagnosis and after therapy to assess residual disease.^{44,45}

Hairy cells show bright CD45 expression with increased forward and side scatter, resembling that of large lymphocytes or monocytes. They express one or more heavy chains and monotypic light chains. The number of cases expressing either kappa or lambda light chains is approximately equal.^{43,46}

Hairy cells strongly express the pan B-cell antigens CD19, CD20, CD22, and CD79b.⁴⁷ They also express high levels of CD11c, CD25, FMC7, and CD103 surface antigens.^{43,48} The CD11c antigen, the 150-kD α chain of the 150/95 β_2 -integrin normally expressed on neutrophils and monocytes, is expressed at levels 30-fold higher than those in chronic lymphocytic leukemia.^{49,50} CD25, the α chain of interleukin-2 (IL-2) receptor, is expressed in HCL, while the β -chain of IL-2 receptor is expressed in variant HCL.⁵¹ Serum levels of soluble IL-2 receptor can be monitored in HCL patients and correlates with disease activity following treatment.⁵²

CD103 has the greatest sensitivity and specificity for HCL. CD103 is a α^E subunit of the $\alpha^E\beta_7$ -integrin, also known as human mucosal lymphocyte 1 (HML-1) antigen due to its primary expression by intraepithelial T lymphocytes. This integrin is believed to be involved in the process of lymphocytes homing and adhesion.⁵³

CD123, a monoclonal antibody that identifies α chain of human interleukin-3 receptor, is expressed in HCL cells as well as in other acute leukemias and a variety of normal hematopoietic cells. Recently, CD123 was determined to be a useful marker for distinguishing HCL from hairy-cell leukemia variant and

marginal zone splenic lymphoma, with 91–96% sensitivity and 97–100% specificity.⁵⁴

In a small study of nine patients with HCL, CD52 was expressed in most leukemic cells in all the patients. Specifically, greater than 92% of HC stained positive in all nine cases, while 99% positivity was observed in six. The presence of CD52 on HC provides a theoretical basis for use of targeted therapy, such as the monoclonal antibody alemtuzumab, for the treatment of HCL.⁵⁵ CD10 (CALLA antigen) and CD5 are weakly expressed in 26% and 5% of patients with HCL, respectively.

IMMUNOHISTOCHEMISTRY

Several B-cell associated antibodies, including CD20, CD79a, and DBA.44, can be used in routinely processed paraffin tissue sections of the bone marrow to detect hairy cells, Figure 30.4. Although these antibodies are not specific for HCL, they can be used to document the

Figure 30.4 Immunohistochemistry stain (MB2) of bone marrow trephine biopsy indicating that hairy cells are of B-cell origin

B-cell nature of the infiltrate and highlight the extent of bone marrow infiltration at the time of diagnosis and following therapy.^{56,57} Immunohistochemical techniques can also be used to evaluate bone marrow sections for TRAP.⁴²

GENE PROFILE

Genetic and molecular events leading to the development of HCL are not well established. Cytogenetic data confirmed by comparative genomic hybridization studies show that the majority of HCL cases have a normal, or at least balanced karyotype.^{58–60} Abnormalities involving chromosomes 1, 2, 3, 4, 5, 6, 11, 13, 14, 15, 17, 19, and 20 have been reported. Among a few recurrent aberrations, are abnormalities of chromosome 5 (trisomy 5, 5q13) and chromosome 14 (add (14)(q32) and del (14)(q)).^{61–63} Overexpression of cyclin D1, found in about 50–75% of HCL cases, is not associated with genomic rearrangement of 11q13/BCL1.⁶⁴

Mutated V_H gene status in HCL cells suggests that HCL originates from an antigen-experienced memory B-cell subset. The mutation pattern and gene usage resemble that for reactive marginal zone (MZ) B cells, particularly their mutated subset, and MALT-type MZL.^{60,65}

ELECTRON MICROSCOPY

By electron microscopy inspection, hairy cells have circumferential cytoplasmic projections and a few blunt microvilli.⁶⁶ Ribosomal lamella complexes, cylindrical cytoplasmic inclusions composed of a central hollow space surrounded by the multiple parallel lamellae with ribosomal-like granules in the interlamellar space, are discovered in 50% of patients with HCL by electron microscopy.⁶⁷ However, such complexes are not pathognomonic for HCL, and have been described in other lymphoproliferative disorders.⁶⁸

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of HCL includes other B-cell lymphoproliferative disorders, and systemic mastocytosis (SM) (see Table 30.2 and 30.3).

HAIRY CELL LEUKEMIA VARIANT

HCLv is a rare clinicopathologic entity first described in 1980. Most patients with HCL reported from Japan also exhibit features similar to those of the HCLv.^{69,70} Unlike HCL, HCLv is associated with prominent leukocytosis,

Table 30.2 Differential diagnosis of hairy-cell leukemia

Hairy cell leukemia variant (HCLv)
Polyclonal hairy B-cell lymphoproliferative disorder (HBLD)
Splenic marginal zone lymphoma (SMZL)
Systemic mastocytosis (SM)
Chronic lymphocytic leukemia (B-CLL)

Table 30.3 Differential diagnosis of hairy-cell leukemia

Immunophenotype of B-cell chronic lymphoid leukemias					
Antigen	CLL	B-PLL	HCL	SMZL	HCL-v
Slg	+ (dim)	+	+	+	+
CD19	+	+	+	+	+
CD20	+ (dim)	+	+	+	+
CD22	+/-	+	+	+	+
FMC7	-	+	+	+	
CD79b	-	+	-	+	+
CD5	+	+/-	-	-	-
CD23	+	+/-	-	-	
CD25	+/-	-	+	-	+
CD11c	+/-	-	+	+/-	+/-
CD103	-	-	+	-	+/-
CD10	-	-	-	-	-

+ = most cases are positive for the antigen; - = most cases are negative; +/- = cases are variably positive; CLL = chronic lymphocytic leukemia; PLL = prolymphocytic leukemia; HCL = hairy cell leukemia; slg = surface immunoglobulin.

lack of male preponderance, aspirable bone marrow with lack of fibrosis, and absence of monocytopenia. The neoplastic cells express surface immunoglobulins with Ig light-chain restriction as well as pan-B cell antigens CD19/20. They are negative for CD5, CD10, and CD25 antigens, while CD103 and CD11c may be positive. The bone marrow typically shows an interstitial infiltrate accompanied by an intrasinusoidal component. Similar to HCL, HCLv cells have a villous cytoplasm; however, they generally exhibit a more condensed chromatin, higher nuclear-to-cytoplasm ratio, and more pronounced central nucleoli than do the cells in patients with HCL (Figure 30.5).⁷¹ TRAP staining of HCLv cells is negative.⁵⁴ The biologic relationship between HCLv and HCL remains unknown.

Figure 30.5 Peripheral smear of a patient with hairy-cell variant, demonstrating abundant cytoplasm with irregular borders and visible nucleoli (in contrast to HCL)

Figure 30.6 Bone marrow trephine biopsy of a patient with splenic marginal zone lymphoma showing (a) focal lymphoid aggregates and (b) immunostaining for CD20 delineates intrasinusoidal and interstitial infiltration by lymphocytes

POLYCLONAL B-CELL LYMPHOPROLIFERATIVE DISORDER

An entity called polyclonal hairy B-cell lymphoproliferative disorder (HBLD) has been described in Japan.^{72,73} All of the patients were females, had splenomegaly and minimal or no lymphadenopathy; persistent lymphocytosis was noted in all the patients, some having anemia and thrombocytopenia. Abnormal lymphocytes present in the peripheral blood and bone marrow had round nuclei and abundant pale cytoplasm with long microvilli and prominent membranous ruffles. They expressed CD5⁻ CD10⁻ CD11c⁺ CD19⁺ CD20⁺ CD23⁻ by flow cytometry studies. Although these findings were similar to those of HCL, the surface marker of the kappa and lambda chains was unbiased and studies of immunoglobulin gene rearrangements and expressions showed a polyclonal proliferation of B cells.⁷³

SPLENIC MARGINAL ZONE LYMPHOMA

The clinical presentation of patients with splenic marginal zone lymphoma (SMZL) may resemble that of HCL, including massive splenomegaly and absence of lymphadenopathy. However, unlike HCL, lymphocytosis is common, the lymphocytes exhibit more basophilic cytoplasm, and the cytoplasmic projections are subtle or absent; TRAP staining is usually negative

or only weakly positive.^{34,74} Both HCL and SMZL cells are of B-cell lineage and are CD19 and CD20 positive, with Ig light-chain restriction, as well as CD10 and CD5 negative. However, the SMZL cells are usually CD103 and CD123 negative.^{54,75-77} The bone marrow infiltrates are sharply demarcated from the surrounding normal tissue, and intrasinusoidal infiltration is often prominent, Figures 30.6(a) and (b). In addition, sections of spleen show predominantly white pulp involvement resembling that of low-grade lymphoma.⁷⁴

SYSTEMIC MASTOCYTOSIS

Infiltrates of systemic mastocytosis in the bone marrow may closely resemble that of HCL. However, immunohistochemical studies show that the mast cells, unlike hairy cells, are negative for B-cell antigens, but react with mast cell tryptase.⁷⁸

CHRONIC LYMPHOCYTIC LEUKEMIA

Finally, aged blood from patients with B-cell chronic lymphocytic leukemia (B-CLL) may demonstrate artifactual cytoplasmic projections due to cytoplasmic distortion. Leukocytosis in CLL is usually more pronounced than in HCL, and monocytopenia is typically absent. In addition, CLL has a distinct phenotypic profile differentiating it from HCL, including CD5 positivity.⁷⁹

Chapter 31

INDICATIONS FOR TREATMENT AND INITIAL TREATMENT APPROACH TO HAIRY CELL LEUKEMIA

Alan Saven, Andrew P. Hampshire and Lyudmila Bazhenova

INDICATIONS FOR TREATMENT

Hairy cell leukemia is an indolent lymphoproliferative disorder, which, prior to the advent of successful systemic therapy, had a median survival of 53 months. Approximately 10% of the patients diagnosed with this disorder never require therapy. This population is characterized by older age, smaller spleen size, and minimal circulating hairy cells.¹ The following criteria, though not validated, are commonly accepted as appropriate indications for therapy: neutropenia characterized by an absolute neutrophil count (ANC) $<1 \times 10^9/L$, anemia with a hemoglobin <10 g/dL, or thrombocytopenia $<(50-100) \times 10^9/L$, recurrent serious infections, or symptomatic splenomegaly. Much less commonly, bulky or painful lymphadenopathy, constitutional symptoms including fevers, chills, sweats, or weight loss, vasculitis, bone involvement, or leukocytosis with a high proportion of circulating hairy cells (white cell count $>20 \times 10^9/L$) are also indications for treatment. Bone marrow involvement, no matter what the degree, is not an indication for therapy in the absence of peripheral blood cytopenias. The early initiation of therapy results in neither a survival nor a response benefit. Therefore, a strategy of careful observation is appropriate in patients who do not meet these criteria for the initiation of therapy.

INITIAL TREATMENT APPROACH

In the past, treatment decisions regarding the initial therapy for hairy cell leukemia evaluated the merit of a 12-month course of interferon- α versus that of splenectomy. However, the success of 2-chlorodeoxyadenosine (2-CdA; cladribine) and 2'-deoxycoformycin (DCF; pentostatin) has relegated both interferon and

splenectomy to be used only in certain uncommon clinical situations.

2-CHLORODEOXYADENOSINE

Mechanism of action

Lymphocytes possess high levels of deoxycytidine kinase. Cells low in adenosine deaminase activity accumulate deoxypurine nucleotides, and cell death ensues. This is similar to the situation in severe combined immunodeficiency syndrome, in which one-third of children exhibit an adenosine deaminase deficiency. These observations led to the development of cladribine, or 2-CdA, by Professor Dennis Carson in 1980.² Cladribine is a purine nucleoside characterized by the substitution of chlorine for hydrogen at position 2 of the purine ring. This substitution confers resistance to cladribine from the action of adenosine deaminase. The high activity of deoxycytidine kinase in lymphocytes, in combination with the resistance to adenosine deaminase, drives the conversion and intracellular accumulation of 2-CdA triphosphate and its subsequent incorporation into the lymphocyte's DNA (see Figure 31.1). Once these nucleotides become incorporated into DNA, strand breakage ensues, leading to cell death. Cladribine is toxic to both resting and dividing lymphocytes, making it a therapeutically attractive candidate in low-grade lymphoproliferative disorders.

Treatment results

The first use of cladribine in the treatment of hairy cell leukemia was published in 1987 by Carrera et al.³ In 1990, investigators at Scripps Clinic in La Jolla reported on 12 patients with hairy cell leukemia treated with a single 7-day course of 2-CdA at a dose of 0.1 mg/kg daily by continuous intravenous infusion; 11 of the 12 patients achieved a complete response (CR), and the remaining patient had a partial response

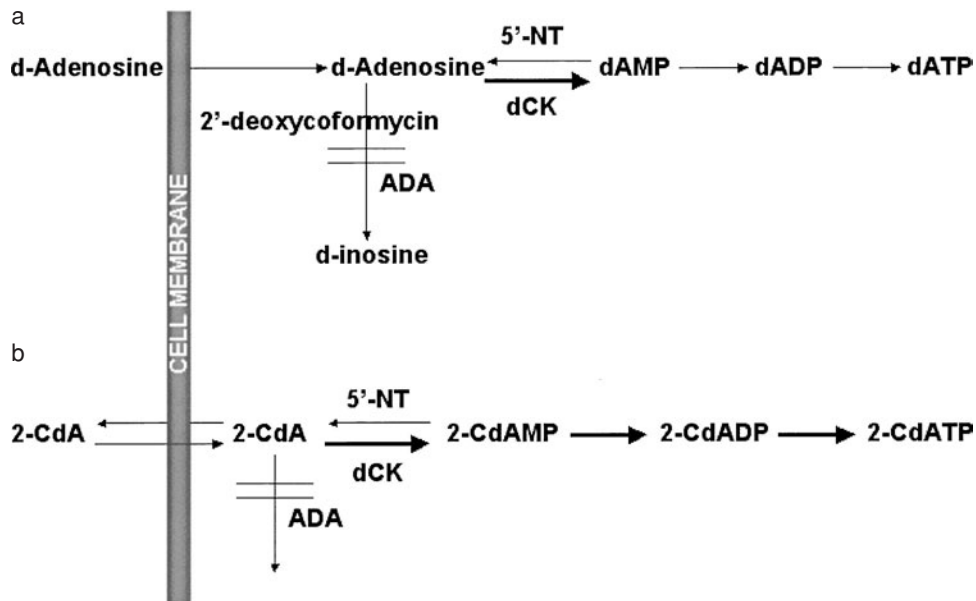

Figure 31.1 (a) Normal pathway for deoxynucleotide metabolism and the mechanism of action of 2'-deoxycoformycin (pentostatin). Deoxyadenosine is normally converted to deoxyinosine through the action of adenosine deaminase. In the congenital absence of adenosine deaminase (such as in severe combined immunodeficiency), or in the presence of DCF, a potent direct inhibitor of adenosine deaminase, deoxyadenosine triphosphate accumulates because of the high ratio of deoxycytidine kinase (dCK) relative to 5'-nucleotidase (5'-NT). This accumulation of deoxyadenosine triphosphate results in cell death. (b) Mechanism of action of 2-chlorodeoxyadenosine (cladribine). 2-CdA enters the cell through an efficient transport system. It is resistant to the action of adenosine deaminase. Because of the high ratio of deoxycytidine kinase to 5'-nucleotidase in lymphocytes, 2-chlorodeoxyadenosine triphosphate accumulates and results in DNA strand breaks, leading to cell death

(PR); on follow-up, none of the patients had relapsed, with a 15.5-month median remission duration.⁴

These encouraging results led to further investigations, and in 1998, Saven et al. published the long-term follow-up of 358 patients treated with a single course of continuous intravenous infusion of 2-CdA for 7 days.⁵ Ninety-one percent of their 349 evaluable patients achieved a CR, with resolution of peripheral cytopenias (i.e., ANC $>1.5 \times 10^9/L$, hemoglobin ≥ 12 g/dL, and platelets $>100 \times 10^9/L$), no evidence of hairy cells morphologically in the bone marrow, and resolution of all adenopathy and splenomegaly. Seven percent of the patients achieved a PR, for an overall response rate (ORR) of 98%. Twenty-six percent of these patients relapsed at a median of 29 months from therapy. An additional CR was achieved in 62% of the relapsed patients who were treated with a second course of 2-CdA; 26% of these retreated patients achieved a PR. The treatment failure rate at 48 months was 18.7% with a 96% overall survival at 48 months.

Goodman et al. reported in 2003 on the extended follow-up of these patients treated at Scripps Clinic.⁶ Of the 209 patients treated at that institution with at least 7 years of follow-up, there was a 95% CR rate and a 5% PR rate. The median response duration was 98 months.

Of the 37% experiencing a relapse, the median time to relapse was 42 months. Of these relapsed patients treated with a second course of 2-CdA, 75% achieved a CR and 17% a PR. The overall survival at 108 months was 97%.

These excellent response rates and response durations with the use of a single infusion of cladribine have been confirmed in other single-institution series (see Table 31.1). In 1992, Estey et al. reported on 46 patients with hairy cell leukemia treated at MD Anderson Cancer Center, Houston, TX.⁷ They delivered the 2-CdA by continuous intravenous infusion at a dose of 40 mg/m² per day for 7 days; the CR rate was 78% and the PR rate was 11%. Only one patient relapse was observed in the group of responding patients, but follow-up was limited at 37 weeks.

In 1996, Tallman et al. described the experience at Northwestern University in 52 consecutive patients with a 2-CdA treatment protocol of 0.1 mg/kg per day, by continuous intravenous infusion for 7 days.⁸ They observed an 80% CR rate with an 18% PR rate. Fourteen percent of the patients relapsed at a median of 24 months. Of five patients retreated with a second course of 2-CdA, two patients achieved a CR and three a PR. The overall survival at 4 years was 86%. Hoffman

et al. reported in 1997 on 49 patients with hairy cell leukemia treated at Long Island Jewish Medical Center, with a single 7-day continuous infusion of 2-CdA.⁹ They reported a 76% CR rate and a 24% PR rate. At 55-months median follow-up, there was an 80% relapse-free survival rate and a 95% overall survival rate.

In the largest study on the use of 2-CdA to treat hairy cell leukemia, Cheson et al. reported in 1998 on 979 patients treated through the Group C protocol mechanism at the National Cancer Institute.¹⁰ Of 861 evaluable patients, a CR was obtained in 50% and a PR in 37%. The relapse rate at a median follow-up of 52 months was 12%. Although the CR in this study, which the authors felt approximated general clinical practice to a greater degree than single-institution studies, was lower, this may have been related to the lack of central pathology review.

Finally, in a British study published in 1999, Dearden et al. from the Royal Marsden Hospital in London described their long-term results with both pentostatin and cladribine in patients with hairy cell leukemia.¹¹ Forty-five patients were treated with cladribine, with 84% achieving a CR, and a 16% PR rate was observed. At 45 months, the relapse rate was 29%.

Despite the durability of the responses generated by cladribine, it is clear that a proportion of patients in apparent CR without morphologic evidence of residual disease in the bone marrow actually have demonstrable disease when more sensitive tests to detect minimal residual disease are used. In a study reported by Hakimian et al. from Northwestern University, 5 of their 24 patients in apparent CR 3 months after treatment with 2-CdA had residual disease when paraffin blocks of their bone marrows were stained with anti-CD20 and anti-CD45Ro antibodies.¹² In a separate investigation, 154 complete remission bone marrow

biopsies from HCL patients treated with 2-CdA at Scripps Clinic were analyzed with anti-CD20 and DBA.44 immunostains.¹³ Overall, 50% of the biopsies exhibited staining with anti-CD20 and/or DBA.44 in hairy cells, indicating residual disease. However, in those patients with immunophenotypic minimal residual disease and normal peripheral blood counts, there was no documented increase in the number of marrow hairy cells on serial bone marrow evaluation. So, although it is clear that a significant proportion of patients in morphologic CR actually harbor minimal residual disease, the clinical significance of this finding remains unclear.

In summary, a single course of cladribine given as a 7-day continuous intravenous infusion induces a complete remission in a high proportion of patients who meet the indications for therapy. The ORR approaches 100%. With extended follow-up, the responses achieved are durable, and the majority of patients with relapsed disease achieve further responses with retreatment. However, even with extended follow-up, there is no clear plateau on the time to treatment failure curve, and it remains to be seen to what extent 2-CdA represents curative therapy.

Alternate methods of administration

A variety of different 2-CdA routes and schedules of administration have been investigated in an attempt to reproduce the high response rates seen with the 7-day continuous infusion schedule while also decreasing the associated myelosuppression and improving convenience of administration. On the basis of their earlier pharmacokinetic studies revealing a terminal half-life of 7–10 h for 2-CdA, Juliusson et al. reported in 1995 on their experience in hairy cell leukemia with daily subcutaneous injections of 2-CdA for seven consecutive

days.¹⁴ They documented a CR rate of 81% in their 73 patients, similar to the excellent rates achieved with continuous intravenous infusion. In addition, they did not observe significant injection site reactions.

Lauria et al. treated 25 hairy cell leukemia patients who had severe cytopenias (ANC $<1.0 \times 10^9/L$ prior to therapy) with a regimen of weekly 2-CdA, dosed at 0.15 mg/kg intravenously for 6 weeks.¹⁵ They observed a CR in 76% of their patients, a PR in 24%, and only a 16% incidence of severe neutropenia (ANC $<0.5 \times 10^9/L$). The median duration of response in these 19 patients, however, was only 15 months. Liliemark et al. studied the feasibility of delivering 2-CdA by the oral route.¹⁶ In 13 patients with B-cell chronic lymphocytic leukemia (CLL) and low-grade non-Hodgkin's lymphoma (NHL), they delivered intravenous, subcutaneous, and oral preparations of 2-CdA (either in liquid or capsule form) in an alternating fashion. On the basis of pharmacokinetic data, they concluded that an AUC resembling that of a 2-h intravenous infusion could be obtained with an oral preparation at double the dose.

There have been additional investigations using 2-CdA delivered as a 2-h intravenous infusion in other low-grade lymphoproliferative disorders, including CLL, NHL, and lymphoplasmacytic lymphoma. These investigations have all documented equivalent feasibility and tolerability. However, there have not been any comparative studies of 2-CdA demonstrating a superiority of any alternate mode of delivery over the traditional 7-day continuous intravenous infusion in hairy cell leukemia. Because of the excellent long-term efficacy and safety data using this route and schedule, 0.1 mg/kg of 2-CdA delivered by continuous intravenous infusion daily for 7 days remains the regimen of choice.

Acute toxicity

The major acute toxicity of 2-CdA is myelosuppression. In their long-term follow-up study, investigators at Scripps Clinic noted a 16% incidence of Grade 3 and a 71% incidence of Grade 4 neutropenia in the first 135 consecutive treated patients.⁵ Ten percent had Grade 3 and 10% had Grade 4 thrombocytopenia. Grade 3 anemia occurred in 20% and Grade 4 in 2%. Forty-two percent developed neutropenic fever, though in only 13%, was an infection documented. Of these, the most common infecting organism was *Staphylococcus*, usually associated with the indwelling intravenous catheter. Although there were several oral herpetic infections and acute dermatomal herpes reactivations, no fungal infections were found. This high rate of neutropenia with culture negative neutropenic fever was also noted at similar rates in other single-institution series with 2-CdA. Despite the frequency of myelosuppression, additional acute toxicities were uncommon. There were no significant rates of nausea, vomiting, alopecia, myalgias, neuropathy, or allergic reactions.

Given the high rate of febrile neutropenia following cladribine therapy for hairy cell leukemia, Saven et al. studied the efficacy of filgrastim priming, followed sequentially by 2-CdA and later by daily filgrastim at 5 $\mu\text{g}/\text{kg}$ until an ANC of $>2 \times 10^9/L$ for two consecutive days was achieved.¹⁷ Even though the median nadir ANC increased significantly over historical controls, and the median number of neutropenic days was 9 (compared to 22 among historical controls), no significant improvement in the percentage of febrile patients, number of febrile days, or hospitalization rates for febrile neutropenia was observed.

Delayed toxicity

The delayed toxicity profile of 2-CdA in hairy cell leukemia is dominated by its immunosuppressive effects. CD4⁺ lymphocyte counts become suppressed, and remain so for prolonged periods, after a single 7-day continuous course. The most common late infection in all series was recurrent dermatomal herpes zoster. The severity, duration, and clinical sequelae of this CD4⁺ lymphocyte depletion was characterized by Seymour et al. in a cohort of 40 patients with hairy cell leukemia treated with continuous infusion 2-CdA at MD Anderson Cancer Center.¹⁸ Prior to therapy, 18 patients had lymphocyte subsets analyzed and the median CD4⁺ count was 743/ μL (range, 58–2201/ μL) with a median CD8⁺ count of 238/ μL (range, 75–2342/ μL). Within 4 months of treatment, 25 patients had nadir lymphocyte subsets analyzed with the median CD4⁺ count suppressed to 139/ μL (range, 25–580/ μL), and CD8⁺ to 92/ μL (range, 26–879/ μL). This suppression was prolonged, with a median time of 40 months until CD4⁺ counts returned to the normal range. CD8⁺ counts returned to normal levels sooner, with a median recovery time of 23 months. The clinical implication of this profound and prolonged lymphopenia is uncertain; however, given that in this small series only one opportunistic infection, dermatomal herpes zoster, was documented. Nonetheless, the delayed toxicity profile of 2-CdA is characterized by late infections, primarily dermatomal herpes zoster. In the long-term follow-up of 358 patients at Scripps Clinic, seven (2%) suffered dermatomal herpes zoster activation within a range of 10–69 months following therapy.

In the same group of patients, with extended follow-up, Goodman and colleagues recorded 58 second malignancies among 47 patients (22% of their cohort) with an observed to expected ratio of second malignancies, compared with NCI SEER data, of 2.03 (95% confidence intervals (CI) 1.49–2.71).⁶ Debate continues regarding the degree and the nature of the risk of second malignancies in patients with hairy cell leukemia treated with cladribine or other purine analogs. It remains unclear whether any significant increased risk exists, and if so, whether this is secondary to the underlying disease or to the corresponding

therapy. A retrospective review of 350 hairy cell patients treated at MD Anderson Cancer Center and followed for 6 years, reported by Kurzrock et al., reported 26 patients with a second malignancy, for an observed-to-expected ratio of 1.34 ($p = 0.08$).¹⁹ No evidence of a treatment effect for 2-CdA, interferon- α , or DCF was observed.

The Italian Cooperative Group for the study of hairy cell leukemia reviewed 1022 patients and documented 54 malignancies, with a standardized incidence ratio (SIR) of 1.01.²⁰ Although no overall increased risk was observed, an increased risk specifically of NHL was noted (SIR = 5.3; CI, 1.9–11.5). Of the 979 patients with hairy cell leukemia treated with 2-CdA at the National Cancer Institute and described by Cheson et al., the relative risk of developing a second malignancy at a median of 3.4 years was 1.71 (CI, 1.24–2.30).²¹ Of the 117 patients with hairy cell leukemia diagnosed over a 20-year period in British Columbia, Canada, Au et al. reported 44 additional tumors in 36 patients (30.7%), with 25 of these diagnosed after the occurrence of their leukemia.²² Of these 25, 20% were nonmelanoma skin cancer. An increased rate of second malignancies was calculated compared with age- and sex-matched controls, and peaked at 2 years after treatment. There was no significant treatment effect on the risk of second malignancy, with the exception of a small group of patients initially treated with interferon- α followed by a purine analog, who had a relative risk that ranged from 1.60 to 4.31.

2'-DEOXYCOFORMYCIN

Mechanism of action

2'-Deoxycoformycin directly mimics the metabolic consequences of congenital adenosine deaminase defi-

ciency. A product of *Streptomyces antibioticus*, DCF is a tight inhibitor of adenosine deaminase that results in lymphocyte depletion (see Figure 31.1). It was first shown to have therapeutic activity in hairy cell leukemia in 1983.²³

Treatment results

Cassileth et al. reported on 50 patients with hairy cell leukemia treated with DCF and followed for a median of 39 months.²⁴ After treatment for a median of 3 months, patients achieved a 64% CR and a 20% PR rate, with relapses in 6 of the 42 responders (14%) (see Table 31.2). In another early trial through the National Cancer Institute–Canadian Clinical Trials Group, Johnston et al. documented a CR in 25 of 28 (89%) evaluable patients with all remaining patients achieving a PR (11%).²⁵ Patients were treated with 4 mg/m² intravenously weekly for three consecutive weeks, repeated every 8 weeks, and continued for two additional cycles beyond CR. Overall toxicity included a 48% incidence of fever and infection, a 62% incidence of lethargy, and a 76% incidence of nausea and vomiting. Additional side effects included anorexia, dry skin, altered taste, and paresthesias.

Early results from the Eastern Cooperative Oncology Group, reported by Spiers et al., used a regimen of 5 mg/m² given on two consecutive days every 2 weeks until a CR was attained.²⁶ In 34 patients treated with this approach, 53% achieved a CR and 38% a PR. Treatment with DCF was associated with a 96% incidence of Grade 3/4 myelosuppression, a 19% incidence of serious infection, and two treatment related fatalities. With a median follow-up of 82 months, Kraut et al. described their experience in a group of 24 patients with HCL treated with DCF delivered every other week at a

dose of 4 mg/m², again until a CR was attained.²⁷ Only 1 of the patients died, but 11 of the remaining 23 patients had relapsed at a median time of 30 months from therapy. There were no serious infectious complications, nor was there a dramatic increase in second malignancies, with the exception of epithelial skin cancers.

Similar results were observed in 50 patients treated with an identical regimen of every-other-week DCF in a French study reported by Ribeiro et al.²⁸ With a median follow-up of 33 months, responses were documented in 96% of the patients, including 44% of those who achieved a CR, 36% with a "good" PR (bone marrow involvement of <5%), and 16% with a PR. There were two deaths. The toxicity included Grade 3/4 neutropenia in 13 of the patients (26%), fever with infection in 13 patients (26%), nausea and vomiting despite the prophylactic use of antiemetics in 14 (28%), and rash in 9 patients. Second malignancies were observed in 10% of the patients.

In an Intergroup study, the response and duration of relapse-free survival in patients with hairy cell leukemia treated with interferon- α or DCF were compared and their toxicities described.²⁹ Three hundred and thirteen eligible patients were randomized to either interferon α -2a, 3 million units subcutaneously three times per week for 6 months (prolonged to a full year for an objective response) versus DCF at 4 mg/m² administered intravenously every other week (given two doses past a CR, continued to 12 months if a PR was achieved, and stopped at 6 months in the absence of a response). Crossover was allowed. While only 11% of the interferon- α treated patients achieved a CR and 27% a PR with no early deaths, 76% of the DCF patients achieved a CR and 3% a PR, with three early deaths. Grade 4 myelosuppression was significantly greater with DCF than with interferon- α , as was the incidence of suspected infections in the DCF group (53% vs 35%, respectively). The median relapse-free survival of the 134 patients who achieved a CR was significantly longer in the DCF treated group (and had not yet been reached) than the 20-month relapse-free survival calculated in the interferon- α group, after a median follow-up of 57 months. Once a median follow-up of 9.3 years had been reached, the updated relapse, toxicity, and survival data of the 154 patients initially treated with DCF, and the 87 patients treated upon crossover from interferon- α failure, was reported by Flinn et al.³⁰ The 5- and 10-year survival of 90% and 81% was no different from that calculated from an age and sex matched control population. The 5- and 10-year relapse-free survival were 85% and 67%, respectively, based on the 173 patients who achieved a CR. After lymphoid, hematologic, and epithelial skin cancers were excluded, the 25 diagnoses of solid tumors recorded was not any greater than that expected in the general population.

In summary, complete remission can be achieved in a high percentage of patients with hairy cell leukemia treated with DCF at the standard dose of 4 mg/m² intravenously given every other week until the attainment of remission. It appears that these remissions are durable despite a lack of clear evidence that the therapy is, in fact, curative.

Toxicity

The major toxicity of DCF is related to profound immunosuppression with significant granulocytopenia, as well as CD4⁺ lymphopenia. Rates of severe neutropenia vary with the regimen used, but range from 26% up to 96%. Associated rates of infection range from 26% up to 53%. Although uncommon, treatment-related deaths have been reported in many of the published series. Additional common toxicities include dermatitis, nausea, and vomiting, and less common toxicities include lethargy, altered taste, paresthesias, and conjunctivitis. Although the immunosuppression appears prolonged, there is no evidence that this results in an increase in serious delayed infections or second malignancies.

SPLENECTOMY

Splenomegaly is present in the majority of patients with hairy cell leukemia, with leukemic infiltration primarily within the red pulp.^{31,32} Therefore, removal of the spleen eradicates one of the major sites of disease accumulation.

Splenectomy was the treatment of choice for hairy cell leukemia before the introduction of effective cytotoxic therapies. In the majority of cases, the peripheral blood counts responded favorably and patients survived for years after the operation, often without additional therapy. Splenectomy removes splenic sequestration of blood elements, thereby alleviating pancytopenia. However, in situations in which pancytopenia is secondary to bone marrow infiltration by hairy cells, splenectomy is less beneficial. CR, defined as hemoglobin greater than 11.0 g/dL, granulocyte count greater than 1000/mm³, and a platelet count greater than 100,000/mm³ (Catovsky criteria), has been reported in 40–67% of patients (see Table 31.3). Improvement in at least one cytopenia is seen in up to 90% of patients. The most common hematologic parameter to improve postsplenectomy is the platelet count, often seen within days of the surgery. Patients who achieve a CR have improved survival compared to partial responders.^{33,35,37,41} However, an overall survival benefit from splenectomy has not been consistently demonstrated.^{34,36,39,42} Before the introduction of effective systemic therapies, patients who did not respond to splenectomy had a poor prognosis. Both the probability of response as well as the duration of response inversely correlates with the degree of bone marrow involvement. The duration of response to splenectomy has been evaluated extensively (see Table 31.3).

Table 31.3 Splenectomy in the treatment of hairy cell leukemia

Author	Number of subjects	CR (%)	PR (%)	Response duration (months)
Catovsky ³³	28	61	39	2.5-16
Golomb ³⁴	71	NR	91	NR
Mintz and Golomb ³⁵	26	42	58	NR
Jansen ³⁶	225	40	39	NR
Ingoldby ³⁷	21	62	24	4-31

Magee ⁴⁰	26	77	11	4-20
Van Norman ⁴¹	42	67	19	NR

CR: complete response; PR: partial response; NR: not reported.

Despite a concern about an increased incidence of infections following splenectomy, Golomb found no change in infectious complications in postsplenectomy patients.^{34,43} Nevertheless, vaccinations against encapsulated organisms are recommended prior to splenectomy.

With the advent of new, more effective treatment modalities, splenectomy has fallen out of favor. It is now considered a temporizing measure, with a median time to treatment failure of 8.3 months (range, 1–22 months). Even prior to the adoption of modern surgical techniques, including laparoscopic splenectomy, surgical mortality was low, estimated at 2% in some reports.⁴¹ Splenectomy has been safely performed at the twenty-fourth week of gestation in a pregnant patient with hairy cell leukemia.⁴⁴

Current indications for splenectomy as an initial treatment approach to hairy cell leukemia include active or uncontrolled infections in the setting of severe and refractory neutropenia secondary to hairy cell leukemia, thrombocytopenic bleeding, massive, painful, or ruptured splenomegaly, or contraindications to chemotherapy (e.g., pregnancy or medical comorbidities).

INTERFERON

When splenectomy was used commonly as a first-line treatment approach to HCL, one of every two to three patients relapsed following the procedure. Other chemotherapeutic agents were tried with limited success.^{45–47} The demonstration of activity of interferon- α against hairy cell leukemia was viewed as a significant advance, as it was the first agent that could partially eradicate the hairy cell population from the bone marrow, thus eventually changing the response criteria. However, much like splenectomy, interferon- α is only

rarely indicated in the current approach to initial management, and only under certain clinical circumstances.

The first experience with interferon in hairy cell leukemia was reported in 1984 by Quesada et al.⁴⁸ They treated seven patients with partially purified human interferon and showed a dramatic improvement in all blood counts within a 2- to 3-month period. Once recombinant interferon became available, Golomb et al. treated 69 patients with interferon α -2b at 2×10^6 U/m² subcutaneously three times weekly for a year.^{49–51} Interferon- α demonstrated an ORR of 91% with 13% of the patients achieving a CR, defined as <5% of hairy cells in the bone marrow and normalization of peripheral blood counts. Relapses were uncommon during therapy and for the first 6–9 months thereafter. Median actuarial failure-free survival was 25.4 months.

Interferon α -2a (Roferon-A, Roche, Nutley, NJ) has also been studied in hairy cell leukemia. Quesada et al.⁵² treated 25 patients with 3×10^6 U/m² of interferon α -2a daily for 4–6 months, followed by three times a week for a year. They documented a response rate of 87%, with 30% of the patients exhibiting a CR. Median time to remission was 3.5 months. Discontinuation of the treatment resulted in clinical relapse in 33% of the patients.

Numerous other trials have shown comparable results (see Table 31.4). Response rates range from 43% to 100%, the majority of which are partial. Hematologic changes follow a well-described pattern. Platelet counts increase first, often as early as 2 weeks into therapy, reaching a normal value by approximately 1.5–2 months. During the first 2 months of treatment there is a notable decrease in the white count and hemoglobin.⁵³ Full granulocytic response is usually delayed until 3–5 months. Hemoglobin response lags behind, with responses still seen as far as 9 months into the therapy.^{58,59} In general, treatment naive patients exhibit higher response rates. In addition to improving peripheral blood counts, interferon- α also reduces splenomegaly size. Interferon- α is effective in patients with an intact spleen as well as in splenectomized patients.

Neither the optimal dose nor the optimal duration of interferon therapy has been clearly established. Standard regimens include either interferon α -2b (Intron A) 2×10^6 U/m² subcutaneously three times per week for a year or interferon α -2a (Roferon-A) 3×10^6 U/m² daily for 4–6 months, followed by three times a week a for a year.

Despite impressive ORRs, between 33% and 86% patients relapse at a median of 6–30 months (see Table 31.3).^{51,56,60,62–64}

With long-term follow-up, an increased incidence of second malignancies has been noted following interferon- α treatment.⁶⁵ After a median follow-up of 91 months, 13 patients (19%) developed a second malignancy. Six were hematopoietic and seven adenocarcinomas. The excess frequency was 4.33 compared

Table 31.4 Results of interferon therapy in patients with hairy cell leukemia

Author	Type of interferon	Dose and schedule	Number of subjects	CR (%)	PR (%)	Duration (month) of response
Quesada ⁴⁸	Interferon alpha-N1	3 × 10 ⁶ U daily	7	42	57	6–10
Jacobs ⁵³	Interferon alpha-2b	2 × 10 ⁶ U/m ² , three times weekly	22	0	43	NR
Quesada ⁵²	Interferon alpha-2a	3 × 10 ⁶ U daily for 4–6 months, followed by three times weekly for 1 year	30	30	57	10+
Castaigne ⁵⁴	Interferon alpha-2 ^o Interferon alpha-2b Interferon alpha-N1	3 × 10 ⁶ U daily 2 × 10 ⁶ U/m ² , three times weekly 3 × 10 ⁶ U daily	27	7	29	NR
Thompson ⁵⁵	Interferon alpha-2b	2 × 10 ⁶ U/m ² three times weekly for 1 year	212	4	74	NR
Berman ⁵⁶	Interferon alpha-2a	3 × 10 ⁶ U daily for 4–6 months, followed by three times weekly for 18 months	35	0	69	25
Smith ⁵⁷	Interferon alpha-2a	3 × 10 ⁶ U daily for 4–6 months, followed by three times weekly for 1 year	53	2	74	NR
Golomb ⁵¹	Interferon alpha-2b	2 × 10 ⁶ U/m ² , three times weekly	69	13	62	25.4
Smalley ⁵⁸	Interferon alpha-N1	2 × 10 ⁶ U/m ² , daily for 28 days followed by three times weekly for 22 weeks	10	2	60	NR
Grever ²⁹	Interferon alpha-2a	3 × 10 ⁶ U 3 times per week	159	11	38	9–27
Rai ⁵⁹	Interferon alpha-2b	2 × 10 ⁶ U/m ² three times weekly for 1 year	64	24	49	18
Zinzani ⁶⁰	Interferon alpha-2a	3 × 10 ⁶ U daily	44	18	64	14
Damasio ⁶¹	Interferon alpha-2a	3 × 10 ⁶ U 3 times per week	64	0	90	NR

CR: complete response; PR: partial response; NR: not reported.

to the general population, and for patients with hematologic neoplasms, it was 40 times the expected frequency. However, other single institution series indicate a risk equal to the general population, but with an increase in lymphoid neoplasms.²⁰

The toxicity profile of interferon includes a mild influenza-like syndrome. This syndrome occurs in 95% of patients and is characterized by fevers, myalgias, and fatigue; it improves after 2–4 weeks despite the continuation of therapy and responds well to acetaminophen. Cutaneous side effects, including both generalized rash as well as injection site reactions, are noted in approximately 50% of the patients. Central nervous system side effects include depression and somnolence. Although transient myelosuppression is observed during the first 2 months of therapy, patients treated with interferon have fewer incidences of infections compared to an untreated cohort.⁵² Reversible liver enzyme abnormalities are observed in 20–30% of the patients.

In summary, interferon- α remains a palliative treatment strategy without observed complete eradication

of the disease. Compared to nucleoside analogs, the response is usually slower and only rarely complete. It is now rarely the initial treatment of choice, but can be considered for hairy cell leukemia patients with active uncontrolled infection, for a disease which has relapsed or is refractory to first-line therapy, or in those with an unacceptably high risk for febrile neutropenia. This may include elderly patients with medical comorbidities, which preclude the use of purine analogs, or those with significant renal insufficiency. In addition, although experience with interferon- α in pregnant patients with hairy cell leukemia is limited, safety has been demonstrated when used in similar patients with chronic myelogenous leukemia.

SUMMARY

Hairy cell leukemia is an uncommon, low-grade lymphoproliferative disorder. Although the mere documentation of the presence of this leukemia is

not itself an indication for therapy, the majority of patients will eventually require treatment for their disease. Although, historically, the initial treatment approach has evolved from splenectomy to interferon- α , contemporary treatment options include either a single-week-long course of 2-CdA, traditionally delivered by continuous intravenous infusion, or 4–6 months of DCF, given as a short

infusion every other week. Although there have been no randomized trials comparing these two approaches, both therapies result in prolonged, unmaintained remissions in the vast majority of patients. In addition, both therapies are associated with profound and prolonged immunosuppression, although the subsequent infectious complication rates are low.

Chapter 32

DEFINITION OF REMISSION, PROGNOSIS, AND FOLLOW-UP IN HAIRY CELL LEUKEMIA

Eric H. Kraut

TREATMENT AND REMISSION DEFINITION

NATURAL HISTORY

Hairy Cell Leukemia (HCL) is a chronic lymphoproliferative disorder usually presenting with pancytopenia, recurrent systemic infections, and splenomegaly.¹ The major cause of death in untreated patients is infection, usually due to an immune deficiency state related to neutropenia, monocytopenia, natural killer cell deficiency, and dendritic cell deficiency.^{2,3} Therapy prior to 1980 temporarily improved blood counts, but had no dramatic effect on the immune deficiency or overall survival, with patients dying as a result of their disease within 5 years of diagnosis.⁴ The dramatic change in survival as a result of the treatments outlined in Chapter 31 has transformed HCL from a fatal disorder to a chronic one, with some patients cured of their disease.

SPLENECTOMY

The definition of remission in a malignancy is established in order to distinguish the effectiveness of different treatment options and determine whether treatment has an impact on survival and quality of life. The development of these definitions for HCL has paralleled the improved management of this disease.

For many years, the major treatment for patients with HCL was splenectomy.⁵ Splenectomy was undertaken either due to pain and discomfort secondary to an enlarged spleen or for the cytopenias seen in this disease. Responses to splenectomy were classified according to those established by Catovsky⁶ (Table 32.1). A complete response (CR) was defined as an increase in hemoglobin level above 11 g/dL, neutrophils above $1 \times 10^9/L$, and platelets above $100 \times 10^9/L$. A partial response (PR) was the same degree of improvement in one or two of the blood elements or improvement in all three, but below the values for CR. These criteria took into account that splenectomy did

improve cytopenias in 60–100% of the patients, but did not significantly affect the bone marrow infiltration or circulating hairy cells.^{5,7} In fact, the degree of bone marrow involvement prior to splenectomy appeared to predict the degree of success with this procedure, and thus patients with marked infiltration of the marrow with hairy cells were less likely to respond.⁷

INTERFERON

In 1984, a major advance in the treatment of HCL was achieved with the evidence that alpha interferon was cytotoxic to hairy cells and could induce complete remissions in some patients.⁹ The ability to eradicate the hairy cell population from the bone marrow led to more stringent criteria for response, culminating in the consensus resolution for the response published in 1987⁸ (Table 32.1). A CR now required a hemoglobin level ≥ 12 g/dL, a neutrophil count $\geq 1500/\mu L$, and

Table 32.1 Criteria for response assessment in hairy cell leukemia⁸

Complete response	Partial response*
Neutrophils $\geq 1500/\mu L^a$	Reduction in organomegaly $> 50\%$
Platelets $\geq 100,000/\mu L$	$< 5\%$ circulating hairy cells
Hemoglobin ≥ 12 g/dL ^a	Decrease by 50% hairy cells in bone marrow
No hairy cells in bone marrow by H&E ^a	
Regression of spleen to normal by physical exam ^a	Hemoglobin ≥ 12 g/dL
No circulating hairy cells ^a	Neutrophils $\geq 1500/\mu L$
	Platelets $\geq 100,000/\mu L$

^aCatovsky⁶ definition allowed 1000 neutrophils and hemoglobin of 11 for complete remission and does not include clearance of marrow or peripheral blood for hairy cells. Partial remission just required improvement of two of three blood values to the CR definition or improvement in all three values.

clearance of hairy cells from blood and bone marrow, with resolution of organomegaly on physical exam. A PR required a 50% decrease in organomegaly and less than 5% circulating hairy cells, with normalization of the blood counts as described for a CR.

Despite its obvious activity, interferon rarely completely eliminated the hairy cells from the bone marrow, and the majority of patients were left with significant bone marrow infiltration.^{10,11} The amount of remaining hairy cell involvement in the marrow after treatment had prognostic significance, with early relapse occurring in patients with greater than 30% hairy cell infiltration.

PURINE NUCLEOSIDES

The introduction of the purine nucleosides pentostatin (2-deoxycoformycin) and 2-chlorodeoxyadenosine (2-CdA) revolutionized the management of HCL and raised the possibility of cure. Both of these drugs induce a high percentage of true complete remissions, which are durable in a significant number of patients.¹²⁻¹⁴ Using the stringent guidelines outlined in the consensus resolution, over 90% of the patients had responses, and those with responses experienced marked improvement in survival. However, using more sophisticated techniques such as flow cytometry and immunohistochemistry, up to 50% of the patients in complete remission by standard criteria have minimal residual disease remaining in their bone marrow.^{15,16} The impact of this observation on the outcome of patients is unclear.

Several investigators have examined the remission duration and survival in patients who have negative

bone marrows by morphology, but positive bone marrows by immunohistochemistry and flow cytometry.¹⁶⁻¹⁸ Tallman et al.¹⁶ evaluated 66 patients treated with either pentostatin or 2-CdA, and in complete remission by clinical and morphologic criteria. The estimated 4-year relapse-free survival was 55% in the patients with minimal residual disease by immunohistochemistry and 88% in the patients without minimal residual disease. Matutes et al.¹⁷ evaluated 23 patients after treatment with 2-deoxycoformycin and in complete remission by standard criteria. He reported no difference in relapse rates in the patients with or without minimal residual disease by immunophenotyping of bone marrow or peripheral blood.

For future clinical trials in HCL, it is reasonable to incorporate immunohistochemistry and flow data on the patient's bone marrow, and add a category of complete remission with minimal residual disease by special studies. This will provide us with information on how necessary it is to completely eradicate the hairy cell population, and give us better methods to compare new therapies.

PROGNOSIS

The change in the prognosis of patients with HCL is best demonstrated by comparing data from patients followed and treated prior to 1985, largely with splenectomy, to patients followed after treatment with interferon and the purine nucleosides (Table 32.2).

Table 32.2 Remission duration and survival

Author	N	Treatment	Median PFS	Median survival
Bouroncle ¹⁹	105	+/- Splenectomy		5.8 years
Golomb and Golde ⁴	71	+/- Splenectomy		5.8 years
Jansen and Hermans ²⁰	391	+/- Splenectomy		4 years
Ratain et al. ¹¹	69	Interferon α	25.4 months	not reached 91%/4years
Federico et al. ²¹	166	Interferon α		not reached 96%/5years
Grever et al. ¹³	17	Interferon α	20 months	not reached At 57 months
Goodman et al. ¹⁴	209	Cladribine	99 months	not reached 97%/9 years
Tallman ²²	52	Cladribine	72%/48 months	96%/4 years
Flinn et al. ²³	241	Pentostatin	85% at 60 months 67% at 120 months	not reached 90%/10 years
Kraut et al. ²⁴	24	Pentostatin		not reached 96%/6.8 years

PFS, progression-free survival.

SPLENECTOMY AND NATURAL HISTORY

Bouroncle¹⁹ reported on 105 patients followed with or without splenectomy, and noted a median survival of 5.8 years. Golomb et al.⁴ gave an update on 71 patients with a median survival, measured starting at the development of symptoms (not from diagnosis), of 70 months. Jansen and Hermans²⁰ analyzed 391 patients from multiple institutions to evaluate the effectiveness of splenectomy, and noted an overall median survival of 48 months. Patients in this series, who underwent a splenectomy, had a survival benefit. The other observation from these reports was that several parameters had prognostic importance, including the degree of cytopenias and a history of infections.

INTERFERON

Although interferon was the first drug with significant activity in HCL patients, long-term studies are limited because of the subsequent introduction of the purine nucleosides. Ratain et al.¹¹ reported on 69 patients who received alpha interferon, and noted a 91% survival at 4 years. However, the median time for a patient requiring treatment (usually due to cytopenia) was 25.4 months. Federico et al.²¹ followed 166 patients who received interferon therapy, and reported a 96% survival at 5 years, with most patients progressing by 4 years. Grever described that 12 of 17 patients who were in complete remission after interferon therapy relapsed with a median time of 20 months. Median survival had not been reached at a median follow-up of 57 months. Thus, although the disease is not eradicated, survival appears improved over splenectomy.

PURINE NUCLEOSIDES

Patients treated with either cladribine or pentostatin have a disease course that resembles patients with indolent lymphoma, with prolonged responses to therapy and overall survival longer than relapse-free survival.²² Goodman et al.¹⁴ reported on 209 patients treated with cladribine and followed them for at least 7 years. Of the 207 patients evaluated, 95% had a CR and 5% a PR. The median duration of a CR was 99 months (range, 8–172 months) and that of a PR was 37 months (range, 10–116 months). Seventy six patients (37%) relapsed after the first course of treatment, with a median time to relapse of 42 months (range, 8–118 months). The risk of relapse was increased with short disease duration prior to therapy, lower hemoglobin levels, and higher white blood counts at baseline. Sixty patients in first relapse after cladribine were retreated, with a CR rate of 75% in the 59 evaluable patients and a median duration of second remission of 35 months (range, 4–92 months). Second relapses were seen in 20 patients, with 6 of 10 patients treated again achieving CR. When survival was evaluated for all patients, only six patients (3%),

all complete responders, had died. However, only one of these patients died from causes related to disease. The overall survival rate in this series was 97% at 108 months.

Flinn et al.²³ reported a 9-year follow-up of a large intergroup study of HCL patients treated with pentostatin. A total of 241 patients were treated with pentostatin initially or after interferon failure. There were 40 deaths, with only 2 deaths due to HCL. And 201 patients were followed for a median of 9.3 years, with a Kaplan-Meier estimate of survival of 90% at 5 years and 81% at ten years. The 173 patients (71%) who achieved a confirmed CR had an overall relapse-free survival of 85% at 5 years and 67% at 10 years. There was no comment on retreatment after relapse.

Kraut et al.²⁴ reported 24 patients followed after pentostatin therapy for a median of 82 months (range, 54–104 months). Out of 24 patients 23 were alive, with one dying of refractory/recurrent disease. Twelve patients remained in remission and 11 patients relapsed. Seven patients were retreated, with 5 achieving a second complete remission. The overall survival from treatment initiation of this group was 93 months (range, 63–116 months). There have been only two documented deaths in this group, and neither related to disease.

In summary, patients treated with purine nucleosides have a dramatic increase in their survival, and few responding patients have died due to their disease. The development of other therapies for resistant disease, such as rituximab²⁵ or anti-CD-22 recombinant immunotoxin (BL 22),²⁶ and the potential benefit of splenectomy or interferon in treatment failures, may further extend survival.

LONG-TERM COMPLICATIONS

The initial concern for patients treated with the purine nucleosides was for an increased risk of infection and the development of second malignancies due to the profound long-term suppression of CD4 and CD8 lymphocytes.^{27,28} However, a significant increase in infections is not seen in patients who have responded to treatment and have normal neutrophil counts. In our series, during the 7-year median follow-up, only herpes zoster was seen in remission patients.²⁴

A variety of second malignancies have been reported in patients with HCL both prior to and following diagnosis and treatment. They include both solid tumors and malignancies of the lymphoid and hematopoietic system.³ These have been reported in the pre-chemotherapy era, as well as in long-term follow-up after treatment with interferon and purine antimetabolites. Several papers have tried to answer the question of whether the risk of second malignancy is inherently increased in hairy cell patients and/or does treatment increase the risk. In a retrospective review of 117 patients from British Columbia with a median follow-up of 5 years, there were 44 malignancies in 36

patients.²⁹ This was greater than expected when compared to age-matched controls, but there did not appear to be a relationship to treatment with interferon or purine analogs. In a study from the University of Chicago of HCL patients who received interferon, there were 13 malignancies, including six hematologic, among 69 patients.³⁰ This was more than the expected three patients, though whether this increase was drug or disease related could not be determined.

In the multicenter study comparing interferon with pentostatin treatment,²³ 241 patients were followed; 39 malignancies developed, including eight hematologic malignancies. This was slightly greater than the 26 expected, but when solid tumors alone were evaluated, there was no difference compared to age-matched controls. In a retrospective review of 725 Italian HCL patients, including patients treated with interferon and chemotherapy, the incidence of second malignancies was only 3.7%, not significantly greater than expected in this older population.³¹ It is thus not yet determined whether HCL is associated with second malignancies or the possible role of treatment in their development. Long-term evaluation will be needed to define the true risk, but as of now second malignancies have not impacted survival.

In summary, as the result of effective initial treatment of HCL patients and the ability to retreat when patients relapse, survival was similar to that predicted for the general population. Additionally, long-term complications after treatment are not frequent and do not affect overall survival.

GUIDELINES FOR FOLLOW-UP AND RETREATMENT

HCL is a low-growth malignancy, and the usual pattern of relapse that we have seen is progressive cytopenia, but only after marked marrow infiltration occurs. Thus, measurement of peripheral blood counts alone may not detect relapsed disease.

SOLUBLE INTERLEUKIN-2 RECEPTOR

The interleukin-2 (IL-2) receptor is defined by reactivity with CD25 monoclonal antibodies and is expressed on the surface of hairy cells.³² Soluble forms of the receptor (sIL-2R) are detected in the peripheral blood of hairy cell patients, and can be used as a marker of disease

response and relapse.^{25,33} We performed serial measurements of sIL-2R levels in patients after pentostatin treatment, and demonstrated that a rising sIL-2R value predicted hematologic relapse (unpublished observations). This is similar to data from other investigators, and is another means of following patients for disease progression. Additionally, it has been used effectively for determining response and predicting resistance.^{25,33}

FOLLOW-UP RECOMMENDATIONS

The efficacy of pentostatin and 2-CDA and the ability to reinstate patients has influenced our approach to follow-up. During our initial trials of pentostatin, patients routinely had repeat bone marrows while in remission, and retreatment was started with marrow repopulation. However, it has been demonstrated that the patients with a marked degree of marrow infiltration still respond to treatment^{12,22}; thus early treatment is not required.

We see patients after remission induction every 4–6 months, with blood counts and repeat sIL-2R levels performed prior to bone marrow biopsies if there is a change in blood counts. For patients not on protocol, we only perform bone marrows when treatment is indicated. The criteria for retreatment included persistent granulocytopenia $\leq 500/\mu\text{L}$, platelets $\leq 50,000/\mu\text{L}$, hemoglobin $\leq 10\text{g/dL}$, painful splenomegaly, and recurrent infections related to immune deficiency. This is more conservative than what is recommended by Goodman et al.,¹⁴ who recommend treatment for neutrophils $\leq 1000/\mu\text{L}$ and platelets $\leq 100,000/\mu\text{L}$. With our criteria, we have had no difficulties retreating patients, and have had no severe complications in patients, being observed without therapy.

SUMMARY

For many years, a diagnosis of HCL was to be feared because of a shortened survival with multiple complications from infections, marked splenomegaly, and severe anemia and thrombocytopenia. Moreover, treatment options were limited, and often only supportive measures were available. Now in the twenty-first century we can list it along with the other triumphs in medical oncology, including Hodgkin's disease and testicular carcinoma. The goals of treatment, to extend survival and improve the quality of life, have been reached.

Chapter 33

TREATMENT OF RELAPSED OR REFRACTORY HAIRY CELL LEUKEMIA AND NEW FRONTIERS IN HAIRY CELL LEUKEMIA THERAPY

Robert J. Kreitman

INTRODUCTION

As reviewed in Chapter 28, hairy cell leukemia (HCL) is a B-cell malignancy comprising 2% of all leukemias,^{1,2} and is highly responsive, but not curable, with known therapy. Patients present with pancytopenia and splenomegaly, and have malignant cells in the blood, bone marrow, and spleen with eccentric kidney-shaped spongiform nuclei and hairlike cytoplasmic projections. The diagnosis was classically made by tartrate-resistant acid phosphatase (TRAP) staining.^{3,4} More recently, the diagnosis is most accurately made by fluorescent-activated cell sorting (FACS) analysis (or flow cytometry), which demonstrates HCL cells strongly positive for B-cell antigens CD19, CD20, and CD22, and often other antigens including CD103 (B-ly7) CD11c, CD25, and CD123.⁵⁻⁷ The differential diagnosis, which is important to consider in relapsed or refractory patients, includes splenic lymphoma with villous lymphocytes (SLVL), which may be distinguished from HCL by polar distribution of villous cytoplasmic projections, lack of pancytopenia, and CD25, CD103, and/or CD123 negativity.⁷⁻⁹ HCL variant (HCLv) is a disorder comprising about 20% of HCL in which the malignant cells may have bilobed nuclei, prominent nucleoli, and may be clumped in the marrow. The HCLv cells may be CD25, CD103, CD11c, and/or CD123 negative, and patients are primarily refractory to purine analogs and other therapies.^{6,7,10-12}

TREATMENT OF RELAPSED HCL WITH STANDARD THERAPY

SALVAGE SPLENECTOMY IN HCL

In patients with pancytopenia due to relapsed or refractory HCL with hypersplenism, splenectomy provides an excellent palliative benefit. Thrombocytopenia has been reported to improve in up to 92% of patients.¹³ Early nonrandomized studies suggested a survival benefit, particularly in young symptomatic patients with large spleens and pancytopenia.^{4,14,15} Nevertheless, it is currently accepted that splenectomy does not affect long-term survival.¹⁶ Splenectomy can be accomplished safely in most patients by laparoscopy,^{17,18} which minimizes recovery time. Patients without significant anemia and with a spleen tip less than 4 cm below the left costal margin are unlikely to respond well to splenectomy.¹⁹ Although splenectomy often results in increased hairy cell infiltration into the bone marrow, blood, and abdominal lymph nodes,²⁰ some HCL patients can benefit early after splenectomy with a systemic reduction in malignant cells; complete pathologic remissions in the blood and marrow are rare. Patients with end-stage refractory HCL with transfusion dependence should not be denied splenectomy, as the procedure may be lifesaving in such patients. Nevertheless, splenectomy may be delayed for most relapsed or refractory patients wishing to try a variety of other salvage therapies.

INTERFERON IN PURINE ANALOG-RESISTANT HCL

Because interferon was used more often prior to the reported efficacy of purine analogs in HCL, there is only limited data on its efficacy in purine-resistant HCL. In 10 patients from the Intergroup study who crossed over from pentostatin to interferon, there were no responses. Interferon was effective in patients after failure of splenectomy and prior chemotherapy, but it was not clear, and perhaps unlikely, that any of these patients had received prior therapy with purine analogs.²¹ Nevertheless, interferon is a treatment recommended for relapsed HCL, particularly when cytopenias are severe and avoidance of myelotoxicity from purine analogs is a goal.²²

FLUDARABINE FOR PURINE ANALOG-RESISTANT HCL

Fludarabine is a fluorinated monophosphorylated purine nucleoside analog that resists deamination by adenosine deaminase and is cytotoxic after conversion to the triphosphate form.²³ Known better for its excellent efficacy for CLL, fludarabine is capable of inducing responses in HCL. Of four reported responses of HCL to fludarabine, one partial response (PR) was observed in HCLv, and one of four responses was a marginal response.^{24,25} Several of these patients were resistant to purine analogs. Fludarabine can also be used in combination with monoclonal antibody (mAb) therapy, as in CLL.²⁶

THE DECISION FOR NONSTANDARD BIOLOGIC THERAPY VERSUS ADDITIONAL PURINE ANALOG THERAPY

As mentioned above, both purine analogs are quite effective in HCL, even as second or even third courses. In fact, it is often unclear who should receive a repeat course of purine analog and who should receive salvage therapy. This decision depends somewhat on the toxicity of cladribine and pentostatin. Either agent has been reported to deplete resting T cells, particularly CD4⁺ lymphocytes, for up to 4 years.^{27,28} The length of prior response to the last course of purine analog is often used to decide whether to repeat the course. If the last response was brief, a repeat course of purine analog might risk cumulative overlapping damage to CD4⁺ lymphocyte populations. Furthermore, as both the likelihood and the duration of complete remission (CR) decline with repeated courses of purine analogs, the chance of benefit is lower in patients with short-lived prior response. In general, most physicians will use a repeat course of purine analog if the last response was greater than 2 years, particularly if only one prior course of purine analog was given. Patients with less than 1 year of response to prior cladribine or pentostatin should be offered other therapy. Patients having 1–2-year response to the last course of purine analog may be appropriate for nonstandard therapy, and this may also be the case for patients with a 2–4-year response to a second or later course of purine analog.

MONOCLONAL ANTIBODY THERAPY OF HCL**CD20, A TARGET FOR B-CELL MALIGNANCIES INCLUDING HCL**

CD20 is a 297-amino-acid glycoprotein that participates in B-cell activity and regulation of B-cell growth.²⁹ It has two transmembrane domains, so that both the carboxyl and amino termini are present on the cytosolic surface of the membrane. Only a small loop of 44 amino acid residues is extracellular, so CD20 is tightly held by the cell membrane and not shed. CD20 is expressed on >95% of B-cell non Hodgkin's lymphoma (NHL), but not on stem cells or plasma cells.³⁰ Its expression is lower in CLL, but higher in HCL.^{6,31}

DEVELOPMENT OF RITUXIMAB FOR TARGETING CD20⁺ CELLS

Rituximab is a chimeric anti-CD20 mAb (Figure 33.1), containing the mouse variable domains of the mAb 2B8 grafted to the human IgG1 constant domains. Rituximab kills CD20⁺ cells by several mechanisms, including (1) complement-dependent cellular cytotoxicity, (2) antibody-dependent cellular cytotoxicity, and (3) induction of apoptosis.³² Both early phase II testing and phase II pivotal testing of rituximab at 375 mg/m² per week × 4 in relapsed low-grade NHL demonstrated overall response rates of up to 48% (6% CR). The majority of toxic events were infusion related (hypotension, bronchospasm, rhinitis, pruritis, rash, urticaria, and tumor pain) and decreased with repeated dosing. Human antimouse antibodies (HAMA) were not observed. This led to Food and Drug Administration's approval of rituximab for indolent NHL. Its effect against indolent NHL was greatly enhanced by combining the drug with chemotherapy, with 95% overall response rates and 55% CR in patients receiving CHOP [cyclophosphamide, hydroxydaunomycin (doxorubicin), Oncovin (vincristine), and prednisone] plus rituximab.³³ Activity with or without chemotherapy was reported in other B-cell malignancies, including aggressive NHL, mantle cell lymphoma, CLL, and Waldenstrom's macroglobulinemia.^{34–36}

CLINICAL TESTING OF RITUXIMAB IN CLINICAL HCL TRIALS

Several case reports treating HCL with rituximab have appeared since 1999.^{37–41} Four small studies have been reported in which rituximab was administered to patients with HCL (Table 33.1). Hagberg and Lundholm reported 11 classic HCL patients treated with rituximab at 375/m²/week × 4.⁴² Three patients were newly diagnosed and eight were relapsed. All eight relapsed patients had received one to three courses of cladribine, and seven out of eight of these patients also had received one to two courses of interferon. Of the 11 patients, 7 had cytopenias as defined by hemoglobin, granulocytes,

Figure 33.1 Structure of biologic salvage therapies in HCL. Rituximab is a chimeric anti-CD20 mAb containing the mouse variable domains (V_L and V_H) of the mAb 2B8 grafted to the human IgG1 constant domains (C and C_H1-C_H3). Pseudomonas exotoxin (PE) contains 613 amino acids. Domain Ia (amino acids 1–252) is the binding domain, domain II (amino acids 253–364) is responsible for translocating the toxin to the cytosol, and domain III (amino acids 400–613) contains the ADP-ribosylating enzyme which inactivates elongation factor 2 (EF-2) in the cytosol. The function of domain Ib (amino acids 365–399) is unknown. PE38 is a truncated form of PE devoid of domain Ia and amino acids 365–380 of domain Ib. The single-chain recombinant immunotoxin anti-Tac(Fv)-PE38 (LMB-2) contains the variable heavy domain (V_H) of the anti-Tac mAb fused via the peptide linker (G4S)3 to the variable light domain (V_L), which in turn is fused to PE38. The recombinant immunotoxin RFB4(dsFv)-PE38 (BL22) is composed of the V_L from the mAb RFB4 disulfide bonded to a fusion of V_H with PE38. The disulfide bond connecting V_H and V_L is formed between two cysteine residues replacing Arg44 of V_H and Gly100 of V_L.

and platelets not greater than 12 g/dL, 1500/mm³, and 100,000/mm³, respectively. There were six CRs, including one previously reported.³⁸ One patient had a PR, and four patients had stable disease. At a median follow-up of more than 14 months, the duration of response was 1–33 months, with all responses ongoing. Of the six complete responders, only two had cytopenias. A second study was reported by Lauria et al., in which 10 patients with HCL were treated with rituximab (referred to as Mabthera, Roche, Inc).⁴³ All

of the patients were previously pretreated with purine analogs and interferon, and all had prior cytopenias. Responses included one CR (previously reported³⁷), four PRs, and three marginal responses. No patients progressed at 10–24 (median 16) months from finishing therapy. Patients responded quickly, with cytopenias correcting in all responders by 3 months, except in a partial responder who had an improvement in granulocytes from 1000 to 1200/mm³. Cytopenias corrected in some of the marginal responders as well. Splenomegaly

Table 33.1 Rituximab trials in patients with HCL

Number of patients	Prior CdA/DCF T×	Number of doses	Number of Responses	Median F/U duration (range) in months	Relapse from CR + PR	CRs–non–CRs with cytopenias	Reference
11	CdA 8/11	4	6 CR, 1 PR	14 (0–34)	0	2/6 vs 5/5	Hagberg and Lundholm ⁴²
10	CdA DCF 10/10	4	1 CR, 4 PR	16 (10–24)	0	1/1 vs 9/9	Lauria et al., ⁴³
24	CdA 24/24	4	3 CR, 3 PR	14.6	2	3/3 vs ?/21	Nieva et al., ⁴⁴
15	CdA/DCF 15/15	4–12	8 CR, 4 PR	32 (8–45)	5	5/8 vs 7/7	Thomas et al., ⁴⁵

Prior CdA/DCF T× indicates the number of patients enrolled who had prior therapy with cladribine (CdA) and/or pentostatin (DCF). Cytopenias are considered present when patients have (1) neutrophil count <1500/mm³, (2) platelets count <100,000/mm³, or (3) Hb <11g/dl.

In Thomas et al., two of the four PRs were reported as CR-RD, meaning 1–5% hairy cells in the marrow but otherwise in CR.

was present in two cases and resolved in both. Circulating hairy cells were eradicated in six of the seven patients. In a phase II trial from the Scripps Clinic, of 24 patients treated with rituximab, there were 3 CRs, 3 PRs, and 2 responders relapsed at a median of 15 months.⁴⁴ Higher activity was observed in a trial reported by Thomas et al., in which more than four doses were given.⁴⁵ Out of 15 patients, 7 who received eight doses attained a CR, and an additional patient had a CR after 12 doses. Two patients had a PR with 4 and 12 doses, and two patients had a CR with 1–5% residual marrow infiltration after 4 and 8 doses, for an overall response rate of 80%. Preexisting cytopenias were present in five of the eight CRs and in all seven patients not achieving a CR.

CONCLUSIONS OF RITUXIMAB TREATMENT IN HCL

The case reports and trials clearly show that rituximab has significant activity in HCL, with a total of 18 CRs out of 60 patients (30%) treated on the four small trials. Trials with the highest CR rates (53–55%) were small and included patients without preexisting cytopenias, but it is also possible that 8–12 doses of rituximab were more effective than 4. As rituximab was associated with minimal toxicity in HCL patients, it should be strongly considered in patients who relapse from purine analog therapy. Rituximab has also shown efficacy for treating autoimmune thrombocytopenia,⁴⁶ and was reported to effectively treat this condition as a complication from pentostatin therapy.⁴⁷

TARGETING CD52 ON HCL CELLS WITH ALEMTUZUMAB

CD52 is a 12-amino-acid glycoprotein that is present on lymphocytes at up to 450,000 sites/cell.^{48,49} It is also present on monocytes, macrophages, eosinophils, and the male reproductive tract.^{50,51} Quigley et al. at the Scripps Clinic recently reported that in nine cases of classic HCL and one of HCLv, all patients expressed CD52 on 92–100% of the HCL cells.⁵² Fietz et al. reported recently that a patient with HCL and short-lived or poor responses to cladribine, interferon, splenectomy, and rituximab had hematologic benefit with alemtuzumab.⁵³ The patient tolerated rituximab more poorly than alemtuzumab because of an allergic reaction to the former. With both mAbs, the patient had an improvement in thrombocytopenia, but failed to reverse blood transfusion dependence.

LMB-2, TARGETING CD25⁺ HCL

DEVELOPMENT OF LMB-2 FOR THE TREATMENT OF CD25⁺ MALIGNANCIES

The interleukin 2 receptor (IL-2R) is composed of α (CD25), β (CD122), and γ (CD132) chains. IL-2 binds with high affinity ($K_d \sim 10^{-11}$ M) to the complex

containing all three of them, but with low affinity ($K_d \sim 10^{-8}$ M) to CD25 alone, also called p55 or Tac.⁵⁴ In contrast, the mAb anti-Tac binds to CD25 with high affinity ($K_d \sim 10^{-10}$ M).⁵⁵ CD25 is overexpressed in a variety of hematologic malignancies, including adult T-cell leukemia (ATL) and HCL, other T- and B-cell leukemias and lymphomas, and Hodgkin's disease.^{56–58} CD25 usually far outnumbers other subunits of the IL-2R on cells, and in some tumors is the only IL-2R subunit present. To construct an anti-CD25 recombinant immunotoxin, the variable heavy domain of anti-Tac (V_H) was fused to the variable light domain (V_L), which in turn was fused to PE40.⁵⁹ Both anti-Tac(Fv)-PE40 and the slightly shorter derivative anti-Tac(Fv)-PE38 (Figure 33.1) bound well to CD25, and were very cytotoxic to CD25⁺ cell lines and activated human T cells, which mediate autoimmune disease.^{59,60} LMB-2 induced complete regression of CD25⁺ human xenografts in mice^{61,62} and killed fresh leukemic cells from patients with ATL,^{60,62} HCL, and other leukemias.⁶³ In monkeys, LMB-2 caused reversible transaminase elevations, but not death, at dose levels up to 1000 $\mu\text{g}/\text{kg}$ q.o.d. \times 3.^{62,64} Large-scale production of LMB-2 was accomplished after expression of a DNA plasmid in *Escherichia coli*.^{65–67}

ELIGIBILITY AND DOSING IN A PHASE I TRIAL OF LMB-2

The phase I trial of LMB-2 began in 1996 and included patients with a histologically confirmed diagnosis of Hodgkin's disease (HD), NHL, or leukemia with evidence of CD25 on malignant cells, except in HD not amenable to biopsy.⁵⁸ All patients had prior standard and salvage therapy (see Table 33.2), and those with indolent disease were in need of treatment. For first-time or repeat cycles, patients could not have high levels of neutralizing antibodies. LMB-2 was administered for three doses by 30-min infusion (q.o.d. \times 3). The maximum tolerated dose (MTD) was defined as the highest dose level for which 0–1 out of 6 patients had dose limiting toxicity (DLT). Patients without progressive disease or neutralizing antibodies could be retreated, and could be dose escalated to the dose level below that which new patients were permitted to receive. Plasma levels of LMB-2 were quantitated by a cytotoxicity assay and enzyme-linked immunosorbent assays.

RESULTS OF PHASE I TESTING OF LMB-2

LMB-2 was administered at 2–63 $\mu\text{g}/\text{kg}$ q.o.d. \times 3 to a total of 35 patients with chemotherapy-resistant hematologic malignancies, including 11 with Hodgkin's disease, 6 with B-cell NHL, 8 with CLL, 4 with HCL, 3 with peripheral T-cell lymphoma (PTCL), 1 with cutaneous T-cell lymphoma (CTCL), and 2 with ATL.⁶⁸ DLT was observed at 63 $\mu\text{g}/\text{kg}$ i.v. q.o.d. \times 3, the dose at which one patient had grade 4 transaminase elevations and another had nausea, vomiting, and diarrhea followed by a transient cardiomyopathy.

Table 33.2 LMB-2 in patients with HCL

Patient number	Age/sex	Prior T×	Spleen/cytopenias	HCL cells/ μ L	Dose level (μ g/kg \times 3)	Total cycles	DLT	Peak level (ng/mL)	Neut ABs	Response	% Decr HCL
15	63/M	IFN, CdA	Large/+	63,900	30	1	–	219	–	PR	99.8
30	47/M	IFN, CdA,	Absent/+	478	63	2	–	593	–	CR	100
32	60/F	IFN, CdA, DCF	Absent/+	350	63	1	Heart	1094	–	PR	99
35	35/M	IFN, CdA	Absent/+	60,700	40	2	–	487	+	PR	98

Prior treatments T- \times included interferon (IFN), cladribine (CdA), and pentostatin (DCF). Patients with absent spleens had prior splenectomy. The presence absence (+ or -) of cytopenias is also listed to indicate whether patients had ANC $<1500/\text{mm}^3$, platelets $<100,000/\text{mm}^3$, or Hb <11 g/dL on enrollment. Neutralizing antibodies (Neut ABs) were + if the serum neutralized 1000 ng/mL of the cytotoxic activity of LMB-2 toward CD25+SP2/Tac cells. Peak levels indicate the highest plasma level achieved with any of the doses of LMB-2 administered, as measured by cytotoxicity assay of plasma on SP2/Tac cells using pure LMB-2 for a standard curve. Responses included partial response (PR) or complete remission (CR). The percent decrease in circulating HCL count (% Decr HCL) as a result of LMB-2 treatment is shown.

The most common first-cycle toxicity at the MTD (40 μ g/kg q.o.d. \times 3) in nine patients was transaminase (aspartate transaminase and alanine transaminase) elevations. Nausea, fever, and weight gain were also common toxicities. Symptomatic pulmonary edema or other features of dose-limiting vascular leak syndrome (VLS) were not seen, although hypoalbuminemia was common. Reversible anaphylaxis to LMB-2 was observed in one patient who had been pretreated with anti-Tac mAb and had developed nonneutralizing anti-idiotypic antibody prior to LMB-2 enrollment. The median half-life of LMB-2 was about 4 h at the MTD. After cycle 1, only 6 of 35 patients (17%) made neutralizing antibodies at high enough levels to disqualify them from further treatment. Thus, patients were retreated for a total of two to six cycles. None of eight CLL patients receiving a total of 16 cycles developed any trace of neutralizing antibodies. PRs were observed in one patient with ATL, HD, CTCL, and CLL.

RESPONSES TO LMB-2 IN HCL PATIENTS

All four patients with HCL, who had failed at least cladribine and interferon, had major responses.⁶⁹ Patient 30 [see Figure 33.2(a)] prior to treatment had pancytopenia, with a pretransfusion hemoglobin as low as 8.5 g/dL, a platelet count of 47,000/ mm^3 , an absolute neutrophil count (ANC) of 360/ mm^3 , and an enlarged spleen and precarinal lymph nodes. The pancytopenia resolved with elimination of the tumor cells. The hairy cell count of 478/ μ L decreased $>90\%$ from just one dose of LMB-2, as assessed on day 3. By day 8, the HCL count had decreased by $>99\%$, and was cleared following cycle 2. Flow cytometry is able to quantify HCL cells making up $<0.01\%$ of the lymphocytes. The CR in patient 30 was associated with resolution of baseline splenomegaly and precarinal adenopathy, and transfusion independence. Recovery of normal counts is shown in Figure 33.2(a), with the platelet count first to recover, improving from a pre-treatment baseline of 53,000–133,000/ μ L by day 22.

The granulocyte count improved next, from a baseline of 390–1430/ μ L by 66 days after beginning LMB-2. The hemoglobin improved to normal by 150 days, and has remained above 11 for >6 years without further treatment. Three patients had PR to LMB-2 after one cycle of 30, 63, and 40 μ g/kg q.o.d. \times 3, with >98 –99.8% decreases in circulating HCL cells. CR was not achieved in these patients, probably because they could not be effectively retreated.

Figure 33.2 Complete remission of HCL patients to recombinant immunotoxins. LMB-2 patient 30 (a) received two cycles of LMB-2 at 63 μ g/kg q.o.d. \times 3. The three doses of each cycle are indicated by a coalescence of three arrows. The hemoglobin (Hb), platelet count (PLT), absolute neutrophil count (ANC), and circulating HCL count (HCL) is shown from several days before to 300 days after the first dose. Similar data are shown for BL22 patient 6 (b) who received three cycles of BL22 at 30 μ g/kg q.o.d. \times 3

BL22, TARGETING CD22⁺ HCL

RATIONALE FOR TARGETING CD22

In many B-cell lymphomas and leukemias, CD22 is displayed by the malignant cells more often than CD25.^{58,70–72} Moreover, CD25[−] HCL is one of the most common features of HCLv. These patients are overrepresented in the population of HCL patients requiring salvage therapy, because they do not respond well to standard therapy, even if previously untreated.^{10,73} CD22 is considered one of the best antigens to target in HCL and is essentially always strongly expressed.³¹ Although CD22 is found on normal B cells, it is not expressed on stem cells. As mentioned above, a variety of immunotoxin chemical conjugates have been used to target CD22⁺ leukemias and lymphomas in preclinical and clinical studies, not related to HCL.^{74–79}

PRECLINICAL DEVELOPMENT OF BL22

To produce a stable anti-CD22 recombinant immunotoxin, the variable domains of the anti-CD22 mAb RFB4 were connected by a disulfide bond instead of a peptide linker, and V_H was fused to PE38, resulting in BL22 (see Figure 33.1).⁸⁰ The disulfide bond was created by mutating Arg44 of V_H and Gly100 of V_L to cysteines. This technology had been used previously for stabilizing Fvs of a variety of different mAbs, including anti-Tac.^{81,82} Chemical reactions are not needed to make the recombinant immunotoxin, since the disulfide bond between V_L and V_H-PE38 forms automatically during in vitro renaturation of the two fragments. Complete regressions in mice of human CD22⁺ B-cell lymphoma xenografts were observed at plasma levels which could be tolerated in cynomolgus monkeys.⁸³ CRs of these xenografts were observed whether BL22 was administered by bolus injection q.o.d. × 3 or by continuous infusion. Leukemic cells freshly obtained from patients with CLL and NHL were incubated ex vivo with BL22.⁷² This study, which showed specific killing of such cells, was important for preclinical development because malignant cells freshly obtained from patients typically display far fewer CD22 sites/cell compared to cell lines.

METHODS AND PATIENTS FOR TESTING BL22 IN HCL

BL22 was administered to 16 patients with HCL as part of a phase I trial in patients with B-cell malignancies.⁸⁴ Like LMB-2, patients were dosed by 30-min infusion q.o.d. × 3. Patients without progressive disease or neutralizing antibodies to the toxin could be retreated at 3-week intervals. Disease was staged by blood counts with flow cytometry, bone marrow biopsy with immunohistochemistry, and computerized tomography. Neutralizing antibody and pharmacokinetic assays were performed by cytotoxicity assay as with LMB-2. Of 16 patients,⁸⁴ 13 had classic HCL and 3 had HCLv. As shown in Table 33.3, the median age was 54

years and the male-to-female ratio was 3/1, similar to what is reported for HCL.^{85,86} All patients were pretreated with cladribine. Patients 5, 8, 9, 11, 13, and 14 were pretreated with one course, patients 4, 6, 10, 12, and 15 with two courses, patients 3, 7, and 16 with three courses, patient 1 with five courses, and patient 2 with six prior courses of cladribine. Patients often had one or several courses of prior interferon, pentostatin, and rituximab as well. About half the patients had prior splenectomy. Circulating HCL counts were typically high in patients after splenectomy but were highest (132,000/μL) in patient 4, who had a large spleen. All three HCLv patients (14, 18, and 26) had high circulating malignant counts. Dose levels included 3, 6, 10, 20, 30, 40, and 50 μg/kg q.o.d. × 3, and patients often were retreated with a variety of different dose levels.

RESPONSE TO BL22 IN PATIENTS WITH HCL

A total of 87 cycles of BL22 were administered to 16 patients, each patient receiving 1–15 cycles (Table 33.3). A total of 11 out of 16 patients (68%) attained a CR, and 2 patients had a PR (12%). Patients 2 and 5 had marginal responses, with 98 and 99.5% reductions in circulating HCL counts, respectively, but less than 50% decreases in lymph node masses. A CR was attained in all three HCLv patients. Of 11 CRs, 6 (patients 6, 8, 9, 11, 12, and 16) had a CR after cycle 1, and patients 3, 4, 7, 10, and 13 had a CR after cycles 2, 9, 4, 3, and 2, respectively. Only one (patient 12) of the CRs had minimal residual disease in the bone marrow biopsy by immunohistochemistry at the time CR was documented. Complete clearing of circulating HCL cells was documented in 10 out of 11 CRs, and patient 7 had a decrease in HCL count from 32,000 to 1 cell/μL. Cytopenias resolved in all responders. Within the follow-up time of 4–22 (median 12) months, relapse was documented in three patients (patients 4, 7, and 12 after 8, 12, and 7 months, respectively), and all three of them were returned to CR with additional BL22. These relapses were asymptomatic in that they were detected by routine bone marrow biopsies, and the patients had not redeveloped cytopenias.

BL22 IMMUNOGENICITY, PLASMA LEVELS, AND TOXICITY IN HCL PATIENTS

High levels of neutralizing antibodies were observed in patients 5, 9, and 12 after cycles 1, 1, and 5, respectively. Patient 5 had preexisting low levels of neutralizing antibodies prior to receiving BL22. Patient 2 had low levels of neutralizing antibodies after cycle 5. Plasma levels in patients with high disease burden increased greatly on subsequent cycles after patients responded. Dose-limiting toxicity in patient 5 included a cytokine release syndrome in patient 5 with fever, hypotension, bone pain, and weight gain (VLS) without pulmonary edema, which resolved within 3 days. Patients 8 and 13 had a completely reversible hemolytic uremic syndrome (HUS),

Table 33.3 BL22 in patients with HCL

Patient number	Age/sex	Prior T×	Spleen/cytopenias	HCL cells/uL	Dose level (μg/kg × 3)	Total cycles	DLT	Peak level (ng/mL)	Neut ABs	Response	% Decr HCL
1	71/F	IFN, CdA, DCF, Ritu×	Absent/+	88,000	3	1	–	13	–	PD	–
2	54/M	IFN, DCF, CdA, B4bR	Absent/+	690	6–10	5	–	115	–	MR	98
3	42/F	CdA	Large/+	11	10–20	4	–	693	–	CR	100
4	46/M	IFN, CdA, DCF, Flud, Ritu×	Large/+	132,000	30–50	14	–	1033	–	CR	100
5	54/M	CdA, IFN	Absent/+	180	30	2	VLS	1602	+	MR	99.5
6	61/M	CdA, IFN	Large/+	1330	30	3	–	1716	–	CR	100
7	70/M	CdA, IFN	Large/+	32,000	30–40	9	–	1805	–	CR	99.997
8	50/M	CdA	Large/+	46	30	2	HUS	772	–	CR	100

13	57/F	CdA, IFN	Absent/+	38	50	2	HUS	1498	–	CR	100
14	37/M	CdA, Ritu×	Large/+	26	40	15	–	1497	–	PR	100
15	54/M	CdA	Large/+	65	40	13	–	1920	–	PR	100
16	55/M	CdA	Absent/–	6	40	2	–	1652	–	CR	100

Prior treatments T× included interferon (IFN), cladribine (CdA), pentostatin (DCF), rituximab (Ritu×), anti-B4 blocked ricin (B4bR, and fludarabine (Flud). Patients with prior splenectomy are indicated with either absent spleen or as having an accessory (Acc) spleen. The presence or absence (+ or –) of cytopenias is also listed to indicate whether patients had ANC <500/mm³, platelets <100,000/mm³, or Hb <11g/dL on enrollment. Patient 4 had splenectomy after cycle 3 due to an HCL-related bleeding disorder; the bleeding disorder responded but disease progressed in the peripheral blood prior to receiving the remaining 11 cycles of BL22. Dose-limiting toxicity included either vascular leak syndrome (VLS) or hemolytic uremic syndrome (HUS). Peak levels indicate the highest plasma level achieved with any of the doses of BL22 administered, as measured by cytotoxicity assay of plasma on Raji cells using pure BL22 for a standard curve. Neutralizing antibodies (Neut ABs) were + if the serum neutralized 1000 ng/mL of the cytotoxic activity of BL22 toward CD22⁺ Raji cells. Responses included partial response (PR) or complete remission (CR). The percent decrease in circulation HCL count (% Decr HCL) as a result of BL22 treatment is shown.

confirmed by renal biopsy. In each case, HUS presented with hematuria and hemoglobinuria by day 8 of cycle 2. These patients required 6–10 days of plasmapheresis, but not dialysis for complete resolution of renal function and correction of thrombocytopenia and anemia. Both patients achieved a CR, patient 8 prior to HUS and patient 13 afterward, and in both cases all preexisting cytopenias resolved, as well as those related to HUS.

CONCLUSIONS OF CLINICAL TESTING OF BL22 IN HCL

BL22 is the first agent since purine analogs that can induce a CR in the majority of patients with HCL, and appears at least as active as rituximab for this disease. All patients treated with HCL had prior cladribine and had responded unsatisfactorily to at least the last course, and this includes patients with HCLv. Its success in chemoresistant patients is related to its different mechanism of action compared to purine analogs, and the fact that CD22 is highly conserved at high density on HCL cells despite purine analog resistance. Lack of CR was usually related to easily identifiable factors, including low doses due to the phase I design, and secondary immune response after cycle 1, which prevented effective retreatment. Patient 14 had signif-

icant splenomegaly which required several cycles to resolve, but disease in the marrow was still evident after cycle 12. In further follow-up, this patient was actually found to enter CR finally after cycle 14. The cause of HUS in patients receiving BL22 is not known, and since HUS has not been observed in over 100 patients receiving PE38 fused to ligands other than RFB4(dsFv), the mechanism must in part be mediated by CD22.

SUMMARY

Effective therapeutic options for patients with relapsed or refractory HCL include repeated courses of purine analogs, palliative splenectomy, or interferon, rituximab, and the recombinant immunotoxins BL22 and LMB-2. Data are insufficient to determine whether BL22 is better than LMB-2 for CD25⁺ HCL, but as 20% of HCL patients have CD25[–] HCL cells, BL22 is the agent that has been developed more for this disease. Additional phase II clinical testing is under way to establish the safety and optimal dosing of BL22 for efficacy, and similar testing is also being done with rituximab.

SPECIAL TOPICS IN LEUKEMIA

Chapter 34

MANAGEMENT OF FEVER AND NEUTROPENIA IN LEUKEMIA

Robin K. Avery

OVERVIEW OF FEVER AND NEUTROPENIA

INTRODUCTION

The febrile neutropenic patient is a central topic in the management of hematologic malignancy. Empiric antimicrobial therapy for fever in the neutropenic patient has been the standard of care for decades, but opinions still vary as to the optimal antibacterial agent or agents, the nature and timing of antifungal therapy, and other issues. This chapter will review basic principles of the physical examination, laboratory studies, radiography, and clinical syndromes. It will also provide updates on the spectrum of infecting organisms, antimicrobial resistance, newer antimicrobial agents, and innovative strategies, such as outpatient and home intravenous (i.v.) therapy. A brief section will summarize highlights of infection control.

The Infectious Disease Society of America (IDSA) has published updated 2002 Guidelines for the Use of Antimicrobial Agents in Neutropenic Patients with Cancer.¹ This comprehensive document features a rating system reflecting the strength of the recommendation (A–E) and the quality of the evidence (I–III), and is highly recommended.

DEFINITION OF FEVER AND NEUTROPENIA

A commonly accepted definition of fever, used in the IDSA guidelines, is a single oral temperature of 38.3 °C (101 °F) or more, or a temperature of ≥ 38.0 °C

(100.4 °F) for ≥ 1 h. The route of temperature measurement is important. Although rectal temperatures are more accurate than oral or axillary temperatures, rectal temperatures are usually contraindicated in the neutropenic patient due to the risk of promoting bacteremia from colorectal organisms.

The definition of neutropenia used in the IDSA Guidelines is an absolute neutrophil count (ANC) of < 500 cells/mm³, or a count of < 1000 cells/mm³ if a decrease to < 500 cells/mm³ is expected.

RISK STRATIFICATION

Both the degree and duration of neutropenia are important in determining the risk for infection. Profoundly neutropenic patients, with an ANC of < 100 cells/mm³, are at highest risk for infection. Those with neutrophil counts of < 500 mm³ are at higher risk than those with counts of < 1000 /mm³. A patient who is expected to recover from chemotherapy-induced neutropenia has a different level of risk from a patient in whom neutrophil recovery is not anticipated. Neutropenia of 10 days or more duration confers greater risk. Neutropenia in patients with acute leukemia is generally of longer duration than in patients with solid tumors.

Several models of risk stratification have been developed.² Additional risk factors for infection among leukemic patients include mucosal or integumentary breaks such as mucositis, surgical wounds, pressure

ulcers, or *C. difficile* colitis; renal or other organ dysfunction; metabolic and nutritional factors; age; comorbidities such as diabetes mellitus; steroids or other immunosuppressive agents; and immune defects such as hypogammaglobulinemia. It is helpful to keep a paradigm of risk stratification in mind in assessing the febrile neutropenic patient.

HISTORY OF FEVER AND NEUTROPENIA THERAPY

In the 1960s and '70s, it was recognized that the most immediate threat came from Gram-negative infections, particularly *E. coli*, *Klebsiella*, and *Pseudomonas*, which could cause rapid overwhelming sepsis.³ Thus, empiric therapy regimens have historically been directed at preventing these Gram-negative infections. The combination of an antipseudomonal beta-lactam and an aminoglycoside has been widely used to achieve synergy against such organisms as *Pseudomonas*. Concerns about potential toxicity, and the development of third-generation cephalosporins and carbapenems, have led to a preference for monotherapy at some centers.

As discussed below, there has been a shift in recent years, from predominantly Gram-negative toward Gram-positive organisms. Whether or not to include an agent such as vancomycin in the initial regimen has been vigorously debated. The emergence of resistance factors such as extended-spectrum beta-lactamases has also caused alteration in regimens at some centers. In general, growing antimicrobial resistance should prompt frequent reconsideration of empiric antibiotic regimens.⁴

MICROBIOLOGY OF INFECTION IN THE NEUTROPENIC PATIENT

CLASSIC MICROBIOLOGY: GRAM-NEGATIVE ORGANISMS; RECENT EMERGENCE OF GRAM-POSITIVE ORGANISMS

Landmark papers on fever and neutropenia cited organisms such as *E. coli*, *Klebsiella*, and *Pseudomonas* as major pathogens,² presumed to originate from the patient's own intestinal flora. However, there has been a shift toward Gram-positive organisms, which now constitute the majority of positive blood culture isolates. Reasons cited for this include use of indwelling i.v. catheters, oral mucositis from current chemotherapy regimens, and use of quinolone prophylaxis.⁵ Catheters are most likely to become infected with cutaneous flora; oral mucositis predisposes to viridans streptococcal infection, which can be fulminant.⁶ Quinolones are powerful agents against aerobic Gram-negative bacilli, and may lead to overgrowth of organisms such as staphylococci, streptococci, and enterococci.

ANTIMICROBIAL RESISTANCE PATTERNS

The emergence of extended-spectrum beta-lactamases in *E. coli*, *Klebsiella*, and other organisms has limited

the utility of penicillins and traditional cephalosporins at some centers.⁷ Although imipenem, meropenem, and cefepime have extremely broad spectrums of activity, organisms resistant to these agents have also been described.^{4,5} Methicillin resistance in coagulase-negative staphylococci and *Staphylococcus aureus* (MRSA) has become increasingly common, as has vancomycin-resistant *Enterococcus* (VRE).

Organisms such as *Stenotrophomonas*, *Leukonostoc*, and *Corynebacterium jeikeium* are now appearing,⁵ some of which are not covered by standard antibiotics. For example, *Stenotrophomonas* is often resistant to all but sulfa-based agents.^{4,5}

Frequent reconsideration of antibiotic regimens is important. If a patient is deteriorating on therapy, consideration should be given to expanding antibiotic coverage to include the multiresistant bacteria that may be specific to that hospital. Updates from the hospital microbiology laboratory and infection control committee can provide valuable information about changing susceptibility patterns.

FUNGAL PATHOGENS, INCLUDING EMERGING FUNGI

Fungal infections occur with increasing frequency when neutropenia is prolonged (see below). In the past, most fungal infections were caused by species of *Candida* or *Aspergillus*. *Candida* are frequent colonizers of skin, oropharynx, and the gastrointestinal tract, and may cause localized or disseminated infection. *Aspergillus* spores are widespread in the environment and can also be nosocomial pathogens, particularly in relation to building construction. Sinus or airway colonization may become an invasive infection in the setting of neutropenia. Those with a history of marijuana use, gardening, farming, or construction work are at a higher risk for being colonized.

In recent years, resistance to antifungal agents has increasingly occurred. Fluconazole has been used for therapy or prophylaxis of yeast infections, as it avoids the toxicities of amphotericin B. However, pathogens such as *Candida glabrata* (frequently fluconazole resistant) and *Candida krusei* (always resistant) have emerged in the setting of increasing fluconazole usage. In addition, unusual fungi such as *Fusarium*, *Trichosporon*, *Paecilomyces*, and *Scedosporium* are seen with more frequency. Some of these display resistance to traditional antifungal agents.

CLINICAL PRESENTATIONS

HISTORY AND PHYSICAL EXAMINATION

The history should include determination of the underlying cancer, the type and date of most recent chemotherapy, concomitant immunosuppressive medications, and exposures. Symptoms relating to the sinuses, eyes, ears, respiratory and gastrointestinal systems, skin, and catheter sites are of particular

importance. The magnitude of the fever and the presence of rigors are also indicators of the severity of illness.

On physical examination, attention should be given to the sinuses, oropharynx, lung and heart exams, catheter site, abdomen, external perianal exam, and skin. Classic signs of inflammation may be absent in the setting of neutropenia. For example, pneumonia is not usually accompanied by lobar consolidation or sputum. Fever, dry cough, and dyspnea might be the only signs of pneumonitis. Peritoneal signs are often absent, and nonspecific abdominal pain might reflect appendicitis, typhlitis, or even perforated viscus. Any proptosis, chemosis, limitation of extraocular motion, or dark nasal or oropharyngeal lesions should prompt emergent surgical consultation for possible invasive fungal infection. Lethargy or focal neurologic signs should prompt emergent imaging of the central nervous system (CNS).

External perianal inspection should be performed, but internal rectal examination should be avoided.

Skin lesions may be the only clues to the etiology of a fever, and biopsy and culture of these lesions can be crucial for diagnosis (see below).

LABORATORY STUDIES

The degree of neutropenia is important, and a complete blood count with differential is essential. Renal or hepatic dysfunction may reflect acute sepsis or may be preexisting. Acidosis is worrisome for impending sepsis.

Cultures of blood and urine should be obtained, and antibiotics initiated promptly. If an i.v. catheter is present, cultures through each lumen of the catheter should be obtained in addition to a peripheral blood culture. Sputum cultures are low-yield, and bronchoscopy is more useful in the patient with pneumonitis. Lumbar punctures are rarely necessary and may be contraindicated in the thrombocytopenic patient. Stool samples for *C. difficile* and for enteric pathogens and parasites should be obtained in a patient with diarrheal illness. Any drainage from a catheter site or wound should be sent for Gram stain and cultures.

If bronchoscopy or open lung biopsy is performed, a complete panel of stains and cultures should be sent, including Gram stain and bacterial cultures; fungal; *Nocardia*; AFB stains and cultures; *Pneumocystis* stain; Legionella direct fluorescent assay and culture; and cultures for cytomegalovirus (CMV), herpes simplex virus (HSV), and respiratory viruses (influenza, parainfluenza, respiratory syncytial virus (RSV), and adenovirus).

Serologic testing is of limited value in the diagnosis of acute infection in this population. Useful antigen detection tests include cryptococcal antigen in serum or cerebrospinal fluid (CSF), and *Histoplasma* urinary antigen.

RADIOGRAPHIC STUDIES

The chest X-ray is important, but may provide incomplete information. While patchy interstitial infiltrates or a faint localized haze may reflect pulmonary infection, more sensitive chest CT (computed tomography)

scanning may reveal small nodules, cavities, the halo sign of aspergillosis, and other signs that may not be visualized on chest X-ray. The CT can guide decisions for procedures such as bronchoscopy and lung biopsy, as well as empiric therapy.

The abdominal CT scan is helpful in patients with abdominal pain, as the physical exam may lack classic signs. The CT can reveal abscesses, adenopathy, intestinal wall thickening, or phlegmon suggestive of typhlitis, lesions of hepatosplenic candidiasis, and other conditions.⁸

The brain magnetic resonance imaging (MRI) (or contrast CT if MRI is not rapidly available) is important for evaluation of mental status changes, seizures, or focal neurologic signs. Brain abscesses, septic embolic infarcts, or evidence of rapidly progressive fungal infection may be found on MRI. Additional cuts of the sino-orbital region, mastoid, and ear canal should be obtained in patients with symptoms referable to those areas.

CLINICAL SYNDROMES

Fever without localizing signs

The majority of patients display no obvious source of infection. Bacteremia may be present due to the entry of intestinal or oropharyngeal flora into the bloodstream, or catheter-related infection without external signs. Frequent exams can determine if any new localizing signs are developing. As the leukocyte count rises, previously infected areas often develop more classic signs of inflammation.

Abdominal pain and gastrointestinal symptoms

Abdominal pain should always be taken seriously, as peritoneal signs may be absent. Acute appendicitis, cholecystitis, perforated gastric or duodenal ulcers, and diverticulitis can be sources of rapid deterioration. Bacterial infections of the upper urinary tract or biliary system are more likely to be severe in the presence of obstruction due to kidney stones, tumor, or choledocholithiasis.

Neutropenic enterocolitis (typhlitis) is a feared complication involving infection of the intestinal wall. Typhlitis may progress to full-thickness involvement of the right colon, with necrosis and gangrene of the cecum. Though classically associated with *Pseudomonas*, typhlitis may be caused by other Gram-negative bacteria. Surgery may be required, but milder cases may be managed with protracted antibiotic therapy.

C. difficile colitis may occur due to use of antibiotics. Wall thickening of the colon on CT scans due to *C. difficile* may be confused with typhlitis. *C. difficile* colitis is more ominous in the setting of ileus and abdominal distention without diarrhea. Repeated plain films of the abdomen can identify colonic dilatation. A stool sample for *C. difficile* toxin assay should be obtained, but occasional false negatives may occur.

Pulmonary infiltrates

The lungs are a frequent site of bacterial, fungal, and viral infection.⁹ The radiographic pattern on Chest X-ray

(CXR) or CT is helpful. Lobar infiltrates are uncommon, but may reflect postobstructive pneumonia. Bacterial infection more commonly appears as patchy, sometimes multilobar infiltrates. Diffuse infiltrates suggest viral or overwhelming bacterial or fungal pneumonia, or noninfectious etiologies such as pulmonary hemorrhage. Nodular infiltrates are more likely to be fungal, nocardial, or mycobacterial. The presence of cavitory lesions suggests fungi, mycobacteria, bacterial lung abscess, septic pulmonary emboli, or tumor. The “halo sign” is often indicative of aspergillosis.¹⁰ Evidence of old granulomatous disease, such as calcified hilar lymph nodes, suggests dormant fungal or mycobacterial infection that could reactivate in the neutropenic patient.

Patients with pulmonary infiltrates may progress rapidly to respiratory failure and mechanical ventilation. This should prompt broadening of the antibiotic regimen, including systemic antifungal therapy. Patients whose white blood cell counts begin to recover may actually experience a respiratory exacerbation.

Bronchoscopy with bronchoalveolar lavage (BAL) is far more likely than sputum to yield a diagnosis, but BAL cultures may show no growth even in active infection, particularly with prior antibiotic therapy. The BAL is more sensitive for *Pneumocystis* than for fungi, and mycobacteria often require protracted time to grow. CMV in BAL cultures is not necessarily indicative of CMV pneumonitis. Lung biopsy can add considerably to the diagnostic yield of bronchoscopy, but severe thrombocytopenia makes transbronchial biopsy problematic. Open lung biopsy may be warranted in such situations.

Aspiration pneumonia may occur, particularly in elderly patients or those with mental status changes or severe nausea and vomiting. In this situation, bronchoscopy is often nondiagnostic or may grow mixed flora.

Infection control issues are important in patients with pulmonary infiltrates, as devastating outbreaks of respiratory viral infection have occurred (influenza, parainfluenza, RSV, and adenovirus).¹¹ During influenza season, or any time a community-acquired respiratory virus is suspected, any patient with an unexplained infiltrate should be placed in respiratory isolation initially.

Other causes of pulmonary infiltrates can mimic infection, and should be considered. These include pulmonary hemorrhage, septic pulmonary emboli, congestive heart failure, chemotherapy and radiation toxicity, and adult respiratory distress syndrome from nonpulmonary sepsis.

Ophthalmologic and otolaryngologic signs

Symptoms referable to the eye, sinuses, orbit, ear, nose, or mastoid should be considered potential emergencies. Fulminant mucormycosis or aspergillosis may progress rapidly to the CNS. Sino-orbital infection (fungal or bacterial) may lead to orbital cellulitis, abscess, meningitis, or cavernous sinus

thrombosis. Otolgic infection may lead to progression of infection in the mastoid or temporal lobe. Rapid, surgical debridement, combined with high-dose broad-spectrum therapy, represents the best chance for survival.

Focal neurologic signs and mental status changes

New focal neurologic signs or mental status changes in a neutropenic patient should prompt vigorous evaluation. Focal signs may reflect brain parenchymal abnormalities (intracranial hemorrhage, metastases, cerebral vascular accident, brain abscesses, progressive fungal infection). Antibiotic choice should include agents that cross the blood–brain barrier. Such as third-generation Cephalosporins and Vancomycin.

Seizures may result from focal abnormalities, CNS infections, or medication toxicity. Mental status changes may be a nonspecific presenting sign of sepsis or may reflect drug effect, as well as CNS infection. Among antibiotics, imipenem and ciprofloxacin may contribute to mental status changes in the elderly or in those with renal dysfunction. In addition, antiemetics, pain medications, and sleep medications may cause mental status changes. Meningitis may occur, most commonly due to *Pneumococcus*, *Listeria*, *Cryptococcus* (in patients with cellular immune defects), or other fungi, but meningeal signs are uncommon. More indolent mental status changes or focal abnormalities may reflect subacute fungal infection, bacterial brain abscess, toxoplasmosis, or progressive multifocal leukoencephalopathy.

In endemic areas (See the Centers for Disease Control and Prevention Website: www.cdc.gov for maps and more information about areas in which West Nile virus transmission is occurring), West Nile virus encephalitis should be ruled out in any patient with neurologic signs, lethargy, flaccid paralysis, or multiorgan failure. Serology from blood and CSF has been the standard for diagnosis, but molecular testing may improve diagnostic yield.

Prompt radiologic imaging should be performed in cases of suspected CNS infection, as discussed above. Lumbar puncture is problematic in thrombocytopenic patients, but if strongly indicated, can be obtained with platelet transfusion support. Space-occupying lesions and cerebral edema should be ruled out first. Rapid neurologic and neurosurgical consultation should be obtained in patients with progressive symptoms.

Skin lesions

As disseminated infections with filamentous fungi or mycobacteria are difficult to diagnose in a timely fashion, biopsies and cultures of suspicious skin lesions are often helpful. *Pseudomonas*, *Candida* spp., and *Fusarium* are particularly likely to be associated with skin lesions. Lesions of ecthyma gangrenosum most often reflect disseminated infection with *Pseudomonas*. Disseminated candidiasis can present with nodular or papular scat-

tered lesions. Dark necrotic-appearing lesions can reflect either bacterial or fungal infection. Peripheral embolic phenomena reflecting endovascular infection may occur in the absence of positive blood cultures.

Indwelling i.v. catheters

Tunneled catheters are subject to several types of infection: exit site cellulitis, bacteremia with or without external signs, tunnel infection, and septic thrombophlebitis. The most common causative organisms are coagulase-negative staphylococci, but *Staphylococcus aureus*, *Enterococcus*, Gram-negative bacilli, other skin flora, yeast, and occasionally nontuberculous mycobacteria also may be causative organisms. Decisions regarding catheter removal often must be made in the face of fever, neutropenia, and need for multilumen access. In general, tunnel infections require catheter removal regardless of the organism, and pain over the tunnel may be the only sign in a neutropenic patient. In *Candida*, VRE, or *Bacillus* infection, it is particularly important to remove the catheter, and it is often desirable to do so for *Staphylococcus aureus* and Gram-negative bacilli. On the other hand, in the absence of tunnel infection, coagulase-negative staphylococcal infection can often be cleared without catheter removal. If the catheter is to be left in place, repeat blood cultures on therapy should be obtained to document initial clearing, then again after therapy is completed, to document cure. Many clinicians recommend alternating catheter lumens for administration of the i.v. antibiotic.

Persistent positive blood cultures on therapy may reflect septic thrombophlebitis, or less commonly endocarditis, and indicates a need to remove the catheter.

CHOICE OF EMPIRIC ANTIMICROBIAL THERAPY

ANTIBACTERIAL THERAPY

Beta-lactam plus aminoglycoside therapy

Such combinations have been used for empiric therapy for decades.^{1,3} The beta-lactams chosen may be higher-generation penicillins (piperacillin, ticarcillin, mezlocillin, piperacillin-tazobactam, or ticarcillin-clavulanate) or higher-generation cephalosporins (ceftazidime or cefepime) with antipseudomonal activity. Doses should be in the high end of the dosing range. Aminoglycosides include gentamicin, tobramycin, and amikacin, used either with traditional dosing or more recently with single-daily dosing.¹² Advantages to this strategy include synergy against organisms such as *Pseudomonas*, and broad-spectrum activity, especially at centers with marked antimicrobial resistance. Disadvantages include the toxicities of aminoglycosides (nephrotoxicity, ototoxicity, and vestibular toxicity.) Measurement of serum trough levels is important, with dose adjustment whenever renal function changes.

Monotherapy

Monotherapy is used in a number of centers, and includes agents such as ceftazidime, cefepime, imipenem, or meropenem.¹³ Except for ceftazidime, these agents have Gram-positive as well as Gram-negative coverage. Advantages include a simpler regimen and less toxicity. Disadvantages include the risk of missing resistant organisms. Although randomized trials and meta-analyses have documented the efficacy of monotherapy,¹⁴ growing antimicrobial resistance may require reevaluation of this strategy in the future.¹³

Timing of Gram-positive therapy

There has been considerable debate regarding the inclusion of Gram-positive coverage (particularly vancomycin) in the initial regimen, with studies suggesting that vancomycin can be safely added later.¹⁵ However, some institutions use vancomycin because of the fulminant syndrome that can occur with viridans streptococci, including those with reduced susceptibility to penicillins, and the rise of methicillin-resistant staphylococci in patients with indwelling catheters. Vancomycin may, however, predispose to VRE infection, renal dysfunction, and rash. The Hospital Infection Control Practices Advisory Committee (HICPAC) has issued guidelines, which discourage empiric use of vancomycin except in situations where the risk of omitting it is high.¹⁶ However, the benefits may still outweigh the risks at some centers with a high rate of methicillin resistance.

Some centers choose to add vancomycin secondarily if there is no response to the initial regimen. Another strategy is to include vancomycin initially, then omit it after 48 h if cultures are negative and the catheter site shows no sign of infection. Serum trough levels of vancomycin should be monitored, and adjustments made for changing renal function. Many centers include vancomycin in the initial regimen of a critically ill patient, or when there is an evidence of catheter-related infection.

Change of therapy

When fever persists for 72 h or longer despite the initial empiric regimen, consideration should be given to changing therapy. A vigorous search for a fever source should be continued, including repeat exams, cultures, chest X-ray, and sometimes CT scans. If positive cultures have been obtained, the regimen can be adjusted accordingly but should retain broad-spectrum coverage, as the patient may still be neutropenic.

Changes in empiric therapy include (1) addition of a second agent to a monotherapy regimen; (2) changing one or more agents in the regimen, such as a carbapenem in place of a beta-lactam; (3) addition of vancomycin; and (4) addition of systemic antifungal therapy (see below).

Stopping antimicrobial therapy

With positive blood cultures, an appropriate duration of therapy should be administered, which may involve home i.v. antibiotics. For fever with negative cultures, the IDSA Guidelines state that antimicrobial therapy may be discontinued when the ANC is 500 cells/mm³ or greater for two consecutive days, if the patient has become afebrile by day 3 of antibiotics.¹ If the patient became afebrile after day 3 of antibiotic therapy, the guidelines suggest continuing therapy until the ANC has been 500 cells/mm³ or greater for 4–5 days. The more difficult question is what to do if the patient remains neutropenic. The IDSA Guidelines allow for discontinuation of therapy if the patient is afebrile 5–7 days, has defervesced by day 3, is persistently neutropenic by day 7 without positive cultures, and was initially low risk without subsequent complications. However, many centers will elect to trim the antibiotic regimen without complete discontinuation in such cases. In a patient who is at high risk, antibiotics should be continued. If the patient is still febrile on day 3, and later is afebrile but with a neutrophil count which is persistently less than 500 cells/mm³, the recommendation is to reassess and continue antibiotic therapy for two more weeks.¹

Oral therapy

As part of the trend toward risk stratification, and to avoid risks and costs of lengthy hospital-based care, there has been an increased interest in early discharge and even initial oral therapy.¹⁷ Randomized trials have demonstrated safety and efficacy of oral therapy in certain *low-risk* groups of patients.¹⁸ The presence of chills, hypotension, dyspnea, radiographic abnormalities, or localizing signs such as abdominal pain, or anything worrisome to the clinician immediately takes the patient out of the “low-risk” group. A multinational scoring system for identifying low-risk patients has been developed, which included the following: absence of symptoms or mild-to-moderate symptoms; absence of hypotension, dehydration, or chronic obstructive pulmonary disease; presence of solid tumor, absence of previous fungal infection in patients with hematologic malignancies, outpatient status, and age less than 60 years.¹⁹ Other factors cited as part of low-risk criteria include cancer in partial or complete remission, temperature less than 39 °C, normal chest X-ray, absence of rigors, respiratory rate 24 breaths/min or less, and absence of diabetes, confusion, mental status changes, or blood loss.

The oral combination most frequently used to treat fever and neutropenia is a combination of ciprofloxacin and amoxicillin–clavulanate.^{17,18} This combination is less useful at centers where there is already significant quinolone resistance. With any patient in whom oral therapy is used, the patient should be closely monitored and should be immediately placed on broad-spectrum i.v. antibiotics if fever or any other worrisome clinical change occurs.

Outpatient and home i.v. antibiotic therapy

Home i.v. antibiotic therapy is useful in the patient with resolved neutropenia who needs to complete a course of therapy for a defined infection. There has also been recent interest in early discharge of the stable neutropenic patient on home i.v. antibiotic therapy or oral therapy after initial i.v. therapy in the hospital.^{17,19} Again, this is only appropriate to consider in the patient without signs of severe infection, who is tolerating antibiotic therapy appropriate to initial culture results, and who is reliable and is closely monitored. If the patient is at high risk, continued inpatient treatment is preferred.

ANTIFUNGAL THERAPY

Timing of antifungal therapy

Early studies have shown that the risk of occult fungal infection increases sharply when the neutropenic patient has been febrile on broad-spectrum antibiotics for 5–7 days or more. Traditionally, i.v. amphotericin B has been added at this time.¹ The patient with pulmonary infiltrates is also more likely to have occult fungal infection.⁹ However, toxicities of amphotericin B have been problematic, including renal insufficiency, electrolyte abnormalities, and infusion-related chills and dyspnea. The availability of newer antifungals has expanded the choices available to the clinician. Interpretation of the literature is complicated by the multiplicity of studies and issues in clinical trial design.^{20,21}

Lipid formulations of amphotericin, including amphotericin B lipid complex (ABLC) and liposomal amphotericin, are less nephrotoxic than conventional amphotericin, but are costly; infusion-related reactions may still occur (less so with liposomal amphotericin). Fluconazole is primarily useful for prevention of infection with sensitive *Candida* species, and does not have activity against *Aspergillus*. Centers with extensive fluconazole use may see a rise in fluconazole-resistant yeast, including *C. glabrata* and *C. krusei*. Itraconazole has activity against *Aspergillus* and is sometimes used as antifungal prophylaxis. However, oral tolerability is decreased in patients with chemotherapy-induced nausea, and the i.v. formulation cannot be used in patients with renal dysfunction.

Caspofungin and micafungin are echinocandin antifungals with broad activity against yeasts and molds including *Aspergillus* (not *Cryptococcus*). They are generally well tolerated and available only in an i.v. formulation. Liver function tests should be monitored with their use.

Voriconazole is a broad-spectrum antifungal agent with both i.v. and oral formulations. It covers many *Candida* species resistant to other azoles, has excellent activity against *Aspergillus*, and also a number of emerging fungal pathogens, but not mucormycetes. As with itraconazole, the i.v. formulation cannot be used in patients with renal insufficiency. Visual symptoms occur in many patients, especially early in therapy. Patients should be warned in advance that these symptoms may occur.

Randomized trials and meta-analyses of empiric antifungal therapy

Multiple randomized trials have been performed using different antifungal agents, in patients who either have persistent fever or who require prophylaxis. A randomized trial by Winston et al. compared fluconazole (400 mg) to placebo at initiation of chemotherapy.²² Fluconazole decreased fungal colonization and superficial fungal infections, but did not clearly decrease invasive fungal infections; aspergillosis was infrequent in both groups.²² A later randomized trial of 317 patients by Winston et al. compared i.v. fluconazole versus amphotericin B for patients with persistent fever, and found no significant differences, inefficacy, and fewer infusion-related reactions with fluconazole.²³ Similarly, in another randomized trial, Boogaerts et al. found that the efficacy of itraconazole was similar to that of amphotericin B, but itraconazole was associated with fewer side effects.²⁴

Antifungal agents may also be used as prophylaxis prior to the onset of fever. The Canadian Fluconazole Prophylaxis Study Group found that fluconazole, compared with placebo, reduced invasive fungal infection and fungal-related mortality.²⁵ A study by Menichetti et al. of 820 patients receiving prophylaxis with oral fluconazole versus oral amphotericin showed no difference in efficacy, but better tolerability of oral fluconazole.²⁶ The same group performed a placebo-controlled trial of itraconazole oral solution and found that itraconazole reduced proven and suspected deep fungal infection and candidemia.²⁷ Concerns have been raised, however, about the increasing incidence of colonization with *C. glabrata* and *C. krusei* in patients receiving fluconazole prophylaxis.²⁸

Several trials have assessed lipid formulations of amphotericin B. Prentice et al. conducted two multicenter trials (one in adults and one in children) comparing conventional versus liposomal amphotericin in patients with fever and neutropenia.²⁹ Liposomal amphotericin was associated with fewer side effects, and defervescence occurred in 64% of those on 3 mg/kg/day liposomal amphotericin as opposed to 49% of those on conventional amphotericin ($p = 0.03$).²⁹ Mattiuzzi et al. compared liposomal amphotericin B versus the combination of fluconazole and itraconazole prophylaxis.³⁰ Efficacy was similar, but liposomal amphotericin was associated with more increases in serum creatinine and bilirubin.³⁰ Wingard et al. compared liposomal amphotericin with ABLC and found similar efficacy, but fewer infusion-related reactions with liposomal amphotericin.³¹ Walsh et al. (NIAID Mycoses Study Group) compared liposomal amphotericin B with conventional amphotericin B in a study of 687 patients.³² Resolution of fever, survival, and rates of discontinuation of the study drug were similar in both groups, but there were fewer proven breakthrough fungal infections in the liposomal amphotericin group as well as less infusion-related toxicity and nephrotoxicity.³²

Walsh et al. also compared voriconazole with liposomal amphotericin B in a randomized trial of 837 patients with persistent fever and neutropenia.³³ The overall success rate was similar; however, there were fewer breakthrough fungal infections, less nephrotoxicity, and fewer infusion-related reactions with voriconazole.³³

Given the number of randomized trials comparing antifungal medications, several meta-analyses have been performed. Gotzsche and Johansen in 2002 analyzed 30 trials in which antifungal therapy had been compared with placebo or no treatment.³⁴ Antifungal treatment with amphotericin B, itraconazole, or fluconazole decreased the incidence of invasive fungal infection. A meta-analysis of 38 trials from 2002 by Bow et al. showed that antifungal prophylaxis reduced the use of parenteral antifungal therapy, and superficial and deep fungal infections. For the overall population, mortality was not reduced, but it was reduced in the subgroups with prolonged neutropenia and who had received hematopoietic stem cell transplantation.³⁵ Glasmacher et al. analyzed 13 randomized trials of itraconazole prophylaxis and concluded that itraconazole solution (not capsules) reduced the incidence of invasive fungal infections, invasive yeast infections, and mortality from fungal infections but not overall mortality.³⁶

There is still no consensus on the optimal antifungal agent to use, or whether to start this agent before fever occurs. The 2002 IDSA guidelines state that amphotericin B has usually been the drug of choice.¹ Lipid formulations of amphotericin B can be used as alternatives, with similar efficacy, less toxicity, and higher cost. Fluconazole is an acceptable alternative at institutions at which invasive mold infections and *C. krusei* infections are uncommon. Voriconazole and caspofungin are increasingly used, and newer antifungal agents are still being developed.

MANAGEMENT OF ANTIMICROBIAL TOXICITY

Renal dysfunction

When multiple antimicrobial agents are administered, the risk of drug toxicity increases. Renal dysfunction may result from fluid shifts, hypotension, chemotherapy, other medications, or sepsis. Aminoglycosides and amphotericin B are particularly likely to cause nephrotoxicity. Less commonly, vancomycin, or occasionally beta-lactams (via interstitial nephritis), can be nephrotoxic. When the creatinine rises, there are several possibilities for alteration of the regimen. If an aminoglycoside is being used in combination with a beta-lactam, it may be replaced with a quinolone or aztreonam, unless cultures dictate otherwise. Amphotericin B may be replaced by a lipid formulation of amphotericin. i.v. itraconazole and voriconazole are prepared in a cyclodextrin vehicle, which cannot be used in renal dysfunction, so these may have to be changed to oral therapy or to other antifungals.

Rash

Drug-associated dermatitis is common in the febrile neutropenic patient, and drug fever may occur with or without rash. Antibiotic-associated rashes are frequently diffuse and maculopapular or confluent, but occasionally appear as palpable purpura, and sometimes progress to desquamation. Consideration should be given to changing antibiotics when a rash occurs, particularly beta-lactams and vancomycin, or less commonly quinolones or azoles. Rashes due to aminoglycosides or amphotericin are uncommon. Drug rashes may progress for several days after discontinuation.

Discontinuation of vancomycin is prudent if the treated patient develops a rash, as some vancomycin reactions can become severe. If needed to treat a methicillin-resistant Gram-positive infection, another agent, such as clindamycin, daptomycin, or quinupristin-dalfopristin may be substituted. If a beta-lactam agent is discontinued due to rash, consideration should be given to avoiding related drugs, such as cephalosporins or carbapenems.

Clostridium difficile colitis

Diarrhea is common in the neutropenic patient, with common causes including chemotherapy-induced mucositis and antibiotics. Only a fraction of these cases reflect *C. difficile* colitis, but this can be clinically severe, especially when ileus and abdominal distention develop. Bacteremias due to enteric flora are more likely to occur from disruption of colonic mucosa. As febrile neutropenic patients require ongoing antibiotic therapy, treatment of *C. difficile* colitis is challenging. In addition to therapy with oral metronidazole (or oral vancomycin in the patient who has failed metronidazole), it may be helpful to change the antibiotic regimen to omit clindamycin or cephalosporins. If the patient is unable to take oral medication or has severe ileus, i.v. metronidazole is preferred.

OTHER TOPICS IN ANTIMICROBIAL THERAPY

Pneumocystis prophylaxis

The use of prophylaxis for *Pneumocystis jiroveci* (formerly *P. carinii*) pneumonia (PCP) has been most extensively studied in children with acute lymphoblastic leukemia, who have an overall 21% risk of PCP without prophylaxis, and in whom risk depends on the intensity of maintenance therapy.³⁷ PCP occurs in other leukemic patients as well. Prophylaxis with thrice weekly trimethoprim-sulfamethoxazole (TMP-SMX) is highly effective.³⁷ Whereas the IDSA guidelines do not recommend TMP-SMX prophylaxis for all neutropenic patients, they do recommend such prophylaxis for all patients at high risk for PCP, whether neutropenic or not, including leukemic patients receiving steroid therapy.¹ In addition, any patient with a prior episode of PCP should receive long-term secondary prophylaxis.

Antiviral therapy

Although CMV infection is a common occurrence in the allogeneic HSCT recipient, it is uncommonly seen in the nontransplanted leukemic patient unless the patient also has some defect in cellular immunity. Therefore, anti-CMV therapy is not generally a part of the empiric regimen in febrile neutropenia. It is, however, appropriate to perform diagnostic tests for CMV in a patient with persistent unexplained fever or pulmonary infiltrates.

HSV reactivation may occur in the setting of chemotherapy and neutropenia, and acyclovir prophylaxis is commonly used to prevent oral mucosal and perineal HSV in that setting.

Respiratory viruses, such as influenza, parainfluenza, RSV, and adenovirus, can be devastating. Where such illness is suspected, rapid isolation of the patient is crucial for prevention of nosocomial transmission. Under certain outbreak circumstances, it may be appropriate for a whole ward to receive antiinfluenza prophylaxis (e.g., with oseltamivir). As immunocompromised patients may have a suboptimal antibody response to yearly influenza vaccination (though they should still receive it), *all* health care workers and family members in contact with neutropenic patients should be strongly advised to be vaccinated against influenza, using the injected vaccine (rather than the inhaled vaccine, which is live).

Previous infections

When assessing a patient who has had previous significant infections, previous microbiologic data may be helpful. For example, a previous catheter-related bacteremia with a *Pseudomonas* resistant to ceftazidime, even though fully treated, might make the clinician choose something other than ceftazidime monotherapy for this patient's next episode of neutropenic fever.

Similarly, knowing the details of past invasive fungal infections, and verification that these were treated with an appropriate length of therapy and radiographic resolution, is crucial.

Hypogammaglobulinemia

In addition to the immune defect conferred by neutropenia, certain patients may also have humoral immune defects that contribute to infection risk. Hypogammaglobulinemia is most frequently seen in patients with CLL and in the early phase after allogeneic bone marrow transplant. Low immunoglobulin levels (IgG below 400 mg/dl) predispose to recurrent and severe bacterial infections; immunoglobulin replacement can be helpful.

INFECTION CONTROL

Space does not permit a detailed discussion of infection control issues, but highlights will be briefly outlined. The reader is referred to monographs from the

Centers for Disease Control and Prevention, Infectious Diseases Society of America, and American Society of Blood and Marrow Transplantation,³⁸ as well as other reviews,³⁹ for more details.

HAND HYGIENE

Although numerous infection control measures have been proposed to protect neutropenic patients, the most universal agreement concerns the importance of hand hygiene. The importance of health care workers' washing their hands thoroughly before and after patient contact cannot be overemphasized, yet compliance is surprisingly incomplete. Recently, antimicrobial hand rubs have been introduced as an alternative to traditional handwashing, and appear to be effective.³⁹

AIR AND VENTILATION MANAGEMENT

Laminar air-flow rooms and/or high-efficiency particulate air (HEPA) filtration have been advocated as measures to reduce the concentration of potential airborne pathogens, particularly fungal spores. The efficacy of such measures is most established for high-risk patients, such as those with prolonged neutropenia and/or HSCT transplantation. The importance of such measures for patients with lower risk, shorter duration neutropenia is less well established.³⁹

When hospital construction is taking place, it is prudent to take all preventive measures possible to prevent exposure of vulnerable patients to increased fungal spores. These measures may include masks when patients leave the floor, protective barriers, air surveillance, or even moving an entire ward during phases of construction. When outbreaks of unexpected fungal

infection occur, air and ventilation issues in the unit in question should be thoroughly examined.³⁹

RESPIRATORY ISOLATION AND OTHER SPECIAL PRECAUTIONS

As discussed above, patients with suspected respiratory virus should be placed in isolation rooms with negative airflow to reduce the possibility of airborne spread of these viruses to other patients. Visitors with any symptoms of respiratory infection should not be allowed to visit the oncology ward. Mild illness in a visitor could result in devastating infection in one or more patients.

Documented or suspected tuberculosis or primary varicella (chickenpox) also require respiratory isolation. Hospitals vary in their infection control measures for resistant pathogens such as MRSA, VRE, and multiresistant Gram-negative bacteria.

OTHER POTENTIAL NOSOCOMIAL EXPOSURES

One of the best-known pathogens to be transmitted through hospital water sources is *Legionella*.⁴⁰ Hospitals vary in their *Legionella* incidence, and infection control and surveillance measures differ from one institution to another. Copper-silver ionization systems have been described as the most effective way to control potential sources.⁴⁰

Hospital visitors should not be permitted to visit if they have any fever or respiratory illness. Visitors should wash their hands before and after leaving the patient's room. In outbreak settings such as respiratory viruses in the community, it may be prudent to restrict visitation to immediate family members.

Chapter 35

AUTOLOGOUS STEM CELL TRANSPLANTATION FOR LEUKEMIA

Alexander E. Perl, Selina M. Luger, and Edward A. Stadtmauer

AUTOLOGOUS STEM CELL TRANSPLANTATION: INTRODUCTION AND HISTORY

INTRODUCTION

If high-dose therapy (HDT) and autologous stem cell transplant (ASCT) are to be successful as a curative therapy for leukemia, then one or more of the following must be true:

1. HDT overcomes drug resistance, and therefore eliminates minimal and otherwise undetectable leukemic burden in the patient that could potentially lead to relapse.
2. The processing and purging of stem cells eliminates contaminating leukemia cells from the graft, thereby resulting in cure, once HDT has been administered.
3. There is some not-well-understood difference between high-dose chemotherapy (HDCT) and conventional dose therapy that stimulates the host immune system to eradicate minimal residual leukemia cells in a form of adoptive immunotherapy.

Numerous phase III trials have compared standard, dose-intensive chemotherapy for acute leukemia to ASCT. Limitations of the studies' designs and/or execution has, however, left many questions at present unanswered, making the precise utility of ASCT in the treatment of leukemia still a point of great debate.

HISTORY

The potential for cryopreservation of human cells was first realized in the late 1940s,¹ when viability of spermatozoa following long-term, ultra-low temperature storage in glycerol was initially reported. Approximately one decade later, dimethylsulfoxide (DMSO) was also shown to be an effective cryopreserving agent.²

Following successes in the development of myeloablative chemotherapy, attempts to provide the clinical benefits of myeloablative therapy to patients who lacked histocompatible marrow donors were undertaken. The first report of autologous stem cell transplantation for acute myeloid leukemia (AML) was published in the late 1970s by Gorin et al.³ This patient with AML had had marrow collected and cryopreserved at first remission that was thawed and reinfused following a myeloablative regimen at the time of first relapse. Fefer et al. reported a series of patients with refractory AML who underwent syngeneic donor transplants, and also demonstrated long-term relapse-free survival (RFS).⁴ A number of reports followed, utilizing first remission marrow for hematopoietic rescue after HDT for refractory AML, all demonstrating high response rates, but few cures. With these promising reports of activity, the procedure was moved earlier into the course of disease, at first or subsequent remission.

AUTOLOGOUS STEM CELL TRANSPLANTATION FOR ACUTE MYELOGENOUS LEUKEMIA

RATIONALE

Increased dose and dose intensity of post-remission therapy have been shown to clearly improve outcome in AML. In 1988, Cassileth et al. demonstrated that low-dose cytosine arabinoside (Ara-C) maintenance CT was superior to no post-remission therapy in first remission AML.⁵ Indeed, all patients who did not receive further therapy relapsed, with a median time to progression of only 4 months. Subsequent studies established a dose response effect of post-remission cytarabine among patients under the age of 60, ultimately leading to 4-year continuous complete

Table 35.1 Factors that affect relapse risk following autologous transplantation for leukemia

• Age
• Karyotype
• Minimal residual disease status at time of harvest
• Disease status at time of transplant (initial remission, second remission, etc.)
• Time from achievement of remission to transplant
• Post-remission chemotherapy prior to harvest (in AML)
• Presence of FLT3-ITD (in AML)

FLT3-ITD: *fms*-like tyrosine kinase 3-internal tandem duplication mutation.

remissions in more than 40% of patients treated with the most dose-intensive regimens.⁶ These data strongly suggested that increasing intensity of post-remission therapy was a critical strategy to achieve cure of AML. SCT was the logical progression of this idea: administering myeloablative doses of CT, hopefully toxic enough to leukemic cells that hematopoietic stem cell (HSC) replacement was necessary for marrow recovery.

PROGNOSTIC FACTORS

A number of patient characteristics have now been identified as prognostic factors in the treatment of AML (Table 35.1). Interpretation of clinical trial results must take into account these different prognostic subtypes. Factors that have consistently been found to predict poor therapeutic outcome with standard CT include old age, high white blood cell (WBC) count at diagnosis, AML arising from an antecedent stem cell disorder (e.g., myelodysplasia), therapy-related leukemia, extramedullary disease, more than one cycle of induction chemotherapy to achieve complete remission (CR), MDR-1 expression by flow cytometry, poor-risk cytogenetics (including abnormalities of chromosomes 3q, 5q, 7, 11q23, or complex karyotype), internal tandem duplications of the FLT3 receptor tyrosine kinase, or the presence of minimal residual disease at completion of consolidation CT (Table 35.2).^{7–11} Favorable prognostic factors include the lack of the above characteristics. In addition, these include cytogenetic abnormalities, such as the 15;17 translocation in acute promyelocytic leukemia, or transcriptional repression of the core binding factor complex associated with 8;21 translocation or inversion of chromosome 16.⁹

In general, patients with secondary or therapy-related AML, myelodysplasia, and residual cytogenetic abnormalities are rarely treated with ASCT. All other subgroups have been considered appropriate for clinical trials.

METHODS OF SCT

Myeloablative regimens

A number of myeloablative regimens have been used for SCT in AML. The two most common were derived

Table 35.2 Risk stratification of acute myeloid leukemia

<i>Favorable</i>	
Age <60	
WBC <100,000	
De novo leukemia	
t(15;17); t(8;21); inv16 (or t(16;16))	
absence of high risk cytogenetic abnormalities or FLT3-ITD	
<i>Unfavorable</i>	
Age >60	
WBC >100,000	
Antecedent hematologic condition (e.g., myelodysplasia) or prior chemotherapy/radiation	
Deletions/monosomies of chromosome 3, 5, 7, or complex karyotype (≥3 per SWOG or ≥5 per MRC), t6;9, 11q23 rearranged

by the pioneering work in AML by the Seattle and Johns Hopkins groups. To this day, total body irradiation (TBI) and cyclophosphamide (Cy) or the busulfan (Bu) and Cy, are the most common regimens utilized. Traditional Bu/Cy consists of 1 mg/kg oral Bu given every 6 h for 16 total doses (16 mg/kg), followed by 2–4 days Cy for a total of 120–200 mg/kg. Most centers utilize the Bu/Cy (2) regimen, as comparison between it and Bu/Cy (4) has shown reduced toxicity for BuCy (2) without an impact on efficacy. Recently, Bu dosing has been guided and adjusted pharmacokinetically by measuring area under the curve (AUC) to correct for erratic GI absorption and first-pass hepatic metabolism. Maintenance of steady-state Bu levels within a narrow range seems to reduce toxicity, particularly hepatic veno-occlusive disease. More recently, an intravenous formulation of busulfan has become available, with the benefit of far more predictable pharmacokinetics, minimal patient to patient variability, and potentially less toxicity. The most common radiation-containing preparative regimen for autografting is 120 mg/kg Cy with six fractionated doses of 200 cGy. No definitive data suggest a clear benefit of a radiation-containing regimen over a CT regimen.

Stem cell source

Pluripotent HSCs can be derived from bone marrow (BM) via numerous percutaneous aspirations or by leukapheresis of cells circulating in the blood following growth factor stimulation or recent chemotherapy, or both. Blood-derived stem cells appear to consistently shorten the time to neutrophil and platelet recovery, compared to BM. Peripheral blood cells have all but replaced bone marrow in general practice due to ease of collection, superior engraftment, and equiv-

absence of relapse risk and survival from comparison studies between the two approaches.¹²

Stem cell in vitro purging

As stated at the outset of this chapter, due to the nature of harvesting stem cells in a marrow disorder such as leukemia, one can expect tumor contamination of grafts. A number of approaches to reduce tumor burden among harvested grafts have been undertaken to reduce the likelihood of relapse following ASCT. Such relapses can be expected to arise from one of the two sources: harvested cells in the autograft, or unharvested, drug-resistant clones that survive the preparative regimen. A combination of the two etiologies is likely. Studies of relapses after syngeneic transplantation demonstrate relapse rates of more than 50%, demonstrating that the myeloablative regimen itself may be a greater source of therapeutic failure than inability to achieve a tumor-free graft at the time of reinfusion.¹³ The corollary to the syngeneic data, however, shows that residual leukemia is frequently present at the time of harvesting. It is therefore not surprising that grafts should have a high risk of tumor contamination, and that—even with improvements in myeloablative regimens—this may contribute to relapse.

Contamination of autografts at the time of harvesting occurs frequently and is readily confirmed by immunophenotype, clonogenic assay, or PCR. Experiments in which harvested marrow was transfected with a retroviral construct containing the neomycin-resistance gene were found to show incorporation of the marker gene in a subset of leukemia cells at the time of relapse. This suggests that a component of the relapse was indeed caused by leukemia cells from the reinfused harvest product.¹⁴ Purging of the graft therefore makes intuitive sense to minimize the risk of reinfusion of clonogenic leukemia cells.

Purging of marrow is accomplished by chemical, immunologic, or physical means. Chemotherapeutic agents such as the prodrugs 4-hydroperoxycyclophosphamide (4-HC) or mafosfamide are particularly toxic to committed progenitors and leukemic blasts, but spare the earliest hematopoietic elements. These stem cells express relatively high levels of the detoxifying enzyme aldehyde dehydrogenase, decreasing intracellular generation of active metabolites such as phosphoramine mustard and limiting stem cell injury from either agent.¹⁵ Regardless of this fact, purging with cytotoxic agents lowers stem cell dose. In combination with the slow self-renewal rates of early progenitors, it is not surprising that engraftment is typically delayed following purging with cytotoxic agents, and this may be associated with increased bleeding or risk of infection.

Numerous studies have demonstrated that purging can decrease the degree of leukemic burden in the autograft, and that this is associated with a lower relapse rate.^{16,17} There are no prospective randomized

trials to examine whether purging is associated with improved survival as compared to unmanipulated autografts. The largest study investigating the benefits of purging in AML is a retrospective analysis of nearly 300 autologous transplants from the Autologous Blood and Marrow Registry.¹⁸ In all of these cases, transplantation occurred within 6 months of complete remission, minimizing the bias of delay prior to transplantation that confounds numerous studies of purging. A multivariate analysis of this data showed purging with 4-HC was associated with an improved leukemia-free survival (56% vs 31% in first CR; 29% vs 10% in second CR, respectively) and overall survival (62% vs 40% in first CR; 46% vs 17% in second CR, respectively), with comparable transplant-related morbidity and mortality. Significant differences were noted between the two groups in terms of time to engraftment, with a median time to ANC >500 of 40 days in the purged group and 30 days in those receiving unpurged transplants. Differences in regimen-related toxicities, as well as some disparities in baseline characteristics of the patients receiving each type of transplant may have contributed to the study's findings. However, the overall survival of 46% among purged transplants beyond the first remission deserves note, as this survival is more typical of the survival plateau among historical studies of unpurged transplants in first remission. Indeed, there are few, if any large series of unpurged transplants that significantly exceed this level, regardless of disease status.

A number of monoclonal antibodies have been employed to purge contaminating early hematopoietic cells, such as anti-CD33 and CD14, along with immunomagnetic beads or complement fixation.¹⁹⁻²² Other methods that have been used include density-gradient centrifugation, elutriation, hyperthermia, and cytokines, such as interleukin-2.²³ Like the effect of chemotherapeutic purging, molecular and immunologic purging of autografts, even when associated with reduction in leukemic burden, lowers stem cell count. Numerous retrospective and phase II studies have shown that graft manipulation delays engraftment. Attempts to use myeloid growth factors, such as granulocyte or granulocyte-macrophage stimulating factors have not been pursued to determine if these agents can minimize some of this toxicity. Alternatively, amifostine has been examined as a cytoprotective agent, to allow for the sparing of normal hematopoietic stem cells in the graft.²⁴

Despite a sound rationale and both laboratory and clinical evidence for the feasibility and efficacy of autograft purging, the benefit of purging remains speculative. The labor-intensive procedure adds substantial cost to transplant, as well as the potential for increased transplant-related morbidity from delayed engraftment. This has kept the practice from widespread acceptance. From available literature, patients that seem to benefit the most from the practice are those

who are beyond the first remission at the time of transplant. However, this is a heterogeneous group and this complicates analysis of data from various centers and purging agents. It is also unclear if there would be a benefit of purging marrow obtained in second remission above that of using stem cells harvested and stored early in the course of disease (i.e., as soon as feasible once in first remission). In the absence of randomized data, the practice of autograft purging for leukemia remains investigational at present.

Stem cell in vivo purging

Treatment with chemotherapy, antibodies, or molecularly targeted agents prior to stem cell harvest provides an ability to perform graft purging in vivo. Given that relapse following initial remission is universal among patients with acute leukemia, some form of post-remission therapy appears necessary to ensure a purified stem cell harvest. Chemotherapy purging with high dose cytarabine (HDAC)-containing regimens are most commonly used to this end, an approach pioneered at the City of Hope.²⁵ The number of post-remission cycles needed for adequate purging is unanswered. Additional cytoreduction from multiple cycles of chemotherapy may produce a "cleaner" harvest, but whatever benefit is achieved is counterbalanced against increased regimen-related toxicity, as well as a decreased ability to adequately collect cells with each cycle delivered. For this reason, most centers harvest cells following 1–2 cycles of HDAC-based chemotherapy. The University of California, San Francisco group developed a feasible, two-step approach to autologous transplant based on this work.²⁶ This center used a single consolidation cycle of HDAC plus infusional etoposide, followed by peripheral stem cell harvest at GCSF-supported recovery. This approach provided more than 5×10^6 CD34+ cells/kg at collection for more than 99% of patients so treated. Ninety-one percent of these patients were subsequently able to receive the intended stem cell transplant. With a median follow-up of over 5 years, a disease-free survival of 55% in 133 patients transplanted with unpurged cells was observed, with a DFS of 74% among those with favorable cytogenetics.²⁷

In addition to intensive chemotherapy, a newer agent that is potentially suitable for in-vivo purging is gemtuzumab ozogamicin. Gemtuzumab is an antibody directed against CD33 that is linked to an anthracycline-like toxin, calicheamicin. The agent produces complete responses in approximately one-third of patients treated at relapse, and is associated with a favorable toxicity profile compared to reinduction chemotherapy. However, a number of patients re-induced with gemtuzumab developed hepatic veno-occlusive disease during subsequent allogeneic transplant.²⁸ This has tempered enthusiasm for this agent in relapsed patients who are expected to proceed to transplant once in remission. The drug, however,

may not be associated with this toxicity if administered during remission, particularly since lower doses may provide adequate in vivo purging of minimal disease following stem cell harvest. This approach is currently being assessed in cooperative group trials.

CLINICAL RESULTS OF AUTOLOGOUS TRANSPLANTATION FOR ACUTE MYELOID LEUKEMIA

Phase II trials in AML

Numerous phase II trials have demonstrated the efficacy of ASCT as a consolidation therapy for AML in remission. Trials in second and subsequent remission generally demonstrate a 20–30% long-term RFS; studies in first remission show less uniform results, ranging from 34% to 70% long-term RFS. This likely depends largely upon quality of pre-transplant in vivo purging with chemotherapy and pre-treatment cytogenetics. Given that some studies suggest dramatic efficacy (RFS of up to 70%), caution must be used in interpreting these data. Additional factors that might influence how these results are interpreted include the duration between initial remission and transplant, baseline differences among patients likely to enter innovative trials (generally healthier and younger than historical controls), and variations in induction, consolidation, and preparative therapies. Lastly, most relapses following ASCT occur within first two years, and therefore adequate follow up prior to publication is necessary to avoid premature conclusions of efficacy.

Phase III trials in AML

There have been four large, prospective, randomized trials comparing the outcome of newly diagnosed patients with AML treated with post-remission intensive consolidation chemotherapy versus autologous versus allogeneic transplant and a fifth comparing auto to allo-BMT (Table 35.3). In all cases, allogeneic transplant was not based upon randomization, but on availability of a human leukocyte antigen (HLA)-matched sibling donor. Randomization of remaining patients to either chemotherapy or autologous transplantation was performed. With the exception of the US intergroup study, the other four studies used unpurged marrows as a stem cell source and none used growth factor support following marrow reinfusion. All studies present their results by intention-to-treat analysis.

The AML-8A EORTC-GIMEMA (European Organization for the Research and Treatment of Cancer-Gruppo Italiano Maligne dell'Adulto) trial included 941 eligible and evaluable children and younger adults with newly diagnosed AML.²⁹ Median age was 33 years (range 11–59). All patients received infusional ara-C at 200 mg/m² for 7 days plus daunorubicin 45 mg/m² by bolus on days 1–3. Those in remission after 1–2 cycles received a single course of intensive consolidation, consisting of intermediate dose cytarabine (500–1000 mg/m² q12h on days 1–4) with amsacrine. Seventeen

ABMT: autologous bone marrow transplant; alloBMT: allogeneic bone marrow transplant; DA: daunorubicin, ara-C; IA: idarubicin, ara-C; RA: rubidazole, ara-C; MiDAC: mitoxantrone, intermediate dose ara-C; HDAC: high dose ara-C; ASCT: autologous stem cell transplant.

^a NR not reported by intention-to-treat. The toxic death rate for patients who actually underwent autologous transplant, intensive chemotherapy, and allogeneic transplant on this study were 6.5%, 3%, and 22%, respectively. Unlike patients assigned allogeneic BMT, patients treated with either intensive chemotherapy or autologous transplant also underwent an additional cycle of intensive chemotherapy, associated with a 2.5% mortality rate.

percent of patients received T-cell depleted grafts using elutriation. Those assigned to autologous transplant received at least 1×10^8 nucleated cells/kg, without graft manipulation or purging. Patients assigned to intensive consolidation chemotherapy received a second intensive chemotherapy cycle consisting of high dose ara-C (2 gm/m² q12h on days 1–4) with daunorubicin (45 mg/m² on days 5–7).

Of the 941 patients enrolled, the complete remission rate was 66% (623 patients). Due to early relapses, toxic death, non-lethal toxicity, or refusal of assigned therapy, 201 patients received no further therapy than induction or the single post-remission course of intensive chemotherapy. Of the 422 patients who completed intensive consolidation and proceeded to further therapy, approximately one-third (168) of these patients were found to be eligible for allo-BMT. The number of patients randomized to autologous transplant was 128 and 126 to intensive chemotherapy. Seventy-nine patients (19%) did not receive the intended post-remission therapy for aforementioned reasons; these patients were roughly equally distributed among the three groups. Ultimately, 144 patients

received an allograft, 95 patients received an autograft, and 104 patients received a second cycle of intensive chemotherapy.

With the obvious exception of age due to the established cutoff in the allo-BMT arm, baseline characteristics were well matched among the treatment arms, including cytogenetic risk groups, FAB classification, number of cycles needed to achieve CR, and initial WBC count at diagnosis. Time to hematopoietic recovery was significantly longer in the autologous group. The time from documented remission to initiation of assigned therapy was significantly longer in the autologous and allogeneic arms (14 and 15 months, respectively) than in the chemotherapy arm (10 months, $p < 0.0001$). This delay may have accounted for the decrease in early relapses in the chemotherapy group (5 vs 12 and 18 in the autologous and allogeneic arms, respectively). This difference in timing of therapy may have selected for high-risk disease among those in the CT group, since patients destined to ultimately relapse may have been more likely to have received their assigned therapy prior to this event due to treatment delay in the other arms. Accordingly, this might

underestimate the treatment effect of their post-consolidation therapy.

The 4-year RFS estimates were 55%, 48%, and 30% for allotransplant, autotransplant, and chemotherapy, respectively. These differences in estimated RFS between the two transplant arms were non-significant. However, the survival estimates of either were significantly better than that of CT ($p = 0.05$). Death in first remission was most likely in those treated with allo-BMT. Interestingly, the 4-year OS was not statistically significantly different in any arm, with rates of 59%, 56%, and 46% for allotransplant, autotransplant, and CT, respectively ($p = 0.43$). A high rate of salvage was seen among patients treated with consolidation CT who relapsed. Of these patients, 62% (36/58) achieved a second remission and nearly two-thirds (22/36) of those achieving a second remission were subsequently treated with an autologous transplant. While relapses among those transplanted in first remission were less frequent, the salvage rate in the autologous and allogeneic arms was inferior, at 38% (11/29) and 40% (8/20), although the authors did not report whether this finding was of statistical significance. Second transplants were rarely performed (two in each treatment arm).

Following these results, the EORTC/GIMEMA abandoned the use of intensive post-remission chemotherapy and designed their next study (AML-10) to compare the benefit of autologous BMT/PSCT with that of allo-BMT in younger patients.³⁰ To minimize bias, this study also attempted to place transplant in as early a point in post-remission therapy as possible and analyzed the data on the basis of allogeneic donor versus no donor. Patients in the age group of 15–45 years with newly diagnosed AML were treated with infusional ara-C (100 mg/m² d1-7) and three doses of an anthracycline on days 1, 3, and 5. Patients in CR were treated with one cycle of intermediate dose ara-C (500 mg/m² q12h d1-6) and those without a histocompatible sibling underwent either bone marrow or peripheral blood harvest of stem cells. The intended conditioning regimen for all patients was Bu/Cy (2), although many patients received Cy/TBI. Approximately one quarter of patients assigned to allo-BMT received T-cell depletion. Autologous grafts were unmanipulated.

A total of 1136 patients were eligible for study entry. Of these patients, 822 (74%) entered a CR following induction and 734 received further therapy and were eligible for analysis. Of these, 293 had HLA-matched siblings and were designated “donor” and the remaining 441 were considered to have “no donor”. The two groups were well balanced for age, FAB subtype, number of induction cycles. Cytogenetics were unavailable in approximately 40% of patients in each group, but their outcome paralleled the group for which cytogenetics was known. For those with a known karyotype, the two groups were well matched except for highest risk cytogenetics (abnormal 3q, 5, 7, 11q23, t(6;9),

t(9;22), or complex karyotype), which were seen in 14% patients in the no-donor group but 24% in the donor group (no p value provided). 69% of patients who had a donor identified actually received an allogeneic transplant and 56% of those lacking a donor received an autograft. The median follow-up was 4 years; during this time, 293 relapses occurred and 66 patients died in CR1. The 4-year DFS was improved among those patients with a donor versus no donor (52% vs 42%, respectively, $p = 0.044$), although 9 months of follow-up was needed before the survival curves showed this difference. Despite this decrease in relapse risk among those with donors, no statistically significant difference in overall survival was noted (58% vs 51% for donor vs no donor, respectively, $p = 0.18$).

The French Cooperative, Groupes Ouest Est Leucémies Aigues Myeloblastiques (GOELAM), trial³¹ was designed to compare the outcome of patients treated with two cycles of intensive post-remission therapy with that of one cycle of intensive chemotherapy followed by autologous transplantation. This study enrolled patients from the age group of 15 to 50 in remission following either rubidazole or idarubicin plus infusional ara-C for 1–2 cycles. Those under 40 years of age with an HLA-identical sibling received an allogeneic transplant. Most of these patients were treated with one cycle of post-remission amsacrine and standard dose ara-C (100 mg/m² SQ) while awaiting allogeneic transplant. The remaining patients on the study received one cycle of intensive chemotherapy using high dose ara-C (3 gm/m² q12 h d1-4) and idarubicin or rubidazole. These patients were randomized either to receive a subsequent autologous transplant or a second cycle of intensive chemotherapy using etoposide and amsacrine. Unmanipulated bone marrow was harvested following the first intensive consolidation cycle and contained at least 1×10^8 nucleated cells/kg. The conditioning regimens for the autologous transplant arm was Bu/Cy (4) in all patients. Those receiving an allogeneic transplant were predominantly conditioned with Cy/TBI, although about one-fourth of patients received Bu/Cy. No T-cell depletion was performed and most patients received cyclosporine plus methotrexate as immunosuppression and GVHD prophylaxis. The median follow-up was 62 months.

The median age of enrolled patients was 36 years. Of the 504 enrolled and evaluable patients, 367 (73%) achieved a CR, with no statistical difference in the success or toxicity of the two induction regimens. Of the patients in CR, 88 were assigned to allo-BMT and 73 actually received the intended therapy. Of the remaining patients eligible for randomization, only 164 were able to be randomized, with 86 assigned auto-SCT and 78 assigned CT. The large patient drop out prior to randomization was due to early relapse, poor hematologic reconstitution, infections, toxic death, patient refusal, or protocol violations. The time from initial remission to intended therapy was shortest in those who

received allogeneic transplants (68 days), followed by CT (91 days) and autologous transplant (109 days). Baseline characteristics in terms of cytogenetic groups, FAB classification, presenting WBC, or number of cycles required for initial CR were well matched between groups, with the exception of the cytogenetic risk profile of the group assigned allo-BMT, which had a statistically significant lower percentage of patients with intermediate or unfavorable risk karyotypes (17% vs 47% in CT arm, $p = 0.001$). The 4-year RFS and OS were 44% and 52.5% for allo-BMT, 44% and 55% for ABMT, and 40% and 54.5% for CT, with all comparisons among groups not statistically significant. The time to hematopoietic recovery was similar for the ABMT and CT groups, except for that of time-to-platelet recovery, which was significantly longer in the transplant group (110 vs 19 days), likely again related to the relatively low stem cell dose.

The UK Medical Research Council AML 10 trial³² asked a very different question from the previously described studies. It examined whether autologous or allogeneic transplant improved outcome in patients who had otherwise completed a full course of intensive post-remission chemotherapy. In this study, newly diagnosed children and young adults (age less than 56 years) were randomly assigned to either daunorubicin, ara-C, and etoposide (ADE) or daunorubicin, ara-C, and thioguanine (DAT) for two cycles, with those in CR proceeding to one cycle of standard-dose ara-C (200 mg/m² CI d1-5) based consolidation. Patients with HLA-identical siblings were eligible to receive an allogeneic BMT following an additional cycle of intermediate dose ara-C (1 gm/m² d1-3) plus mitoxantrone (MiDAC). The remainder underwent bone marrow harvest of at least 1×10^8 nucleated cells followed by MiDAC consolidation. Following this cycle, patients were randomized to receive either an unpurged autologous transplant or no further therapy. If patients relapsed in the observation group, reinduction was attempted and those salvaged were consolidated with autologous cells from the prior harvest. The myeloablative preparative regimen was Cy/TBI for both allogeneic and autologous transplants and patients received immunosuppression and GVHD prophylaxis based upon institutional preferences.

Of the 1857 patients enrolled on this trial, 81% (1509) entered CR. Number of patients in CR found to have HLA-matched sibling donors was 370, leaving 1131 patients eligible for randomization. However, the majority (620) of these patients were not randomized, with most choosing not to receive treatment after the fourth cycle of chemotherapy (481), and some choosing autologous transplant (79). Only 25% of those initially entering remission (381) were randomized to either autologous BMT ($n = 190$) or no further therapy ($n = 191$) following four cycles of chemotherapy. Of the patients randomized to autologous transplant, 126 received the intended therapy (66%). The median

bone marrow harvest dose was 2.18×10^8 mononuclear cells/kg. Patients randomized to autologous BMT showed a significant reduction in relapse risk as compared to those assigned no further therapy (37% vs 58%, $p = 0.0007$). There was no evidence for a weighted risk reduction based on age or cytogenetic risk group. Relapse following autologous transplant was associated with a notably poorer risk of achieving a second CR than among patients who had received no further therapy (34% vs 59%). No difference in survival was seen between autologous transplant and those who received no further therapy (57% vs 45%, $p = 0.2$). Most relapses in the auto-BMT group occurred within 2 years, while there was an increase in relapses after 2 years in remission among those who received no further therapy. When survival past 2 years was analyzed separately, a statistically significant benefit for autologous BMT was seen. A subsequent analysis based upon allogeneic donor versus no-donor status showed a statistically significant decrease in relapse risk at 7 years based on the presence of a donor (36% vs 52%, $p = 0.0001$), but only a trend toward improved survival (56% vs 50%, $p = 0.1$) was noted.

In addition to the small number of patients who were eligible for randomization, a criticism of this study is that the total post-remission dose of ara-C is relatively low in comparison to other randomized studies of consolidation therapy. Patients treated with MACE and MiDAC received a total of 4 gm/m² of ara-C. By contrast, those treated on the EORTC/GIMEMA study received a total of 20 gm/m², patients on the GOELAM trial received 24 gm/m², those on the US intergroup study received 36 gm/m²,³³ and, finally, those treated on the initial CALGB study that established the benefits of dose escalating post-remission ara-C received an impressive 72 gm/m² over their four consolidation cycles.⁶ The UK MRC-AML10 is the only study of the four phase III trials comparing intensive chemotherapy with autologous or allogeneic transplant to show a significant survival benefit of autologous transplant compared with intensive chemotherapy. In this context, one must question if the post-remission therapeutic intensity of the chemotherapy arm was adequate to draw any firm conclusions regarding its efficacy.

The Eastern Cooperative Oncology Group-led North American Intergroup trial³³ enrolled patients with newly diagnosed AML between the age groups of 16 and 55. Subjects received induction therapy with 1–2 cycles of idarubicin and infusional ara-C (3+7) followed by intensification with identical agents (2+5). Patients with HLA-compatible siblings were assigned to allo-BMT using Bu/Cy (4) conditioning and all others were randomized to receive either a single cycle of high dose ara-C (3 gm/m² q12 h d1-6) or ABMT using Bu/Cy (4) conditioning and perfosfamide (4-HC, 4-hydroperoxycyclophosphamide) purging. The CR rate for the 740 evaluable patients enrolled was 70% (518).

Of these enrolled patients 120 were assigned to allo-BMT; 116 and 120 patients were randomized to ABMT and HDAC consolidation, respectively. Ultimately 105, 63, and 99 patients went on to receive their assigned allotransplant, autotransplant, or HDAC consolidation, respectively. With a median follow-up of 4 years, DFS was not significantly different at 43%, 37%, and 35%, respectively. OS was slightly better in the HDAC arm, at 54%, than either the allo- or auto-BMT arms at 46% and 47%, respectively ($p = 0.05$). The 100-day mortality after post-remission therapy was 3% in the HDAC arm, 14% in the auto-BMT arm, and 21% in the allo-BMT arm. The median time-to-platelet recovery was 64 days in the autoBMT arm versus 24 days in the alloBMT arm. Subsequent studies by the same cooperative group using unpurged peripheral blood stem cells have shown comparable efficacy with transplant-related mortality of 0% ($n = 32$), suggesting that the use of bone marrow source and purging may have accounted for some of the surprisingly high mortality rate in this arm.³⁴

Correlation of cytogenetic risk group with response to autologous transplant in AML

A benefit of the five randomized comparisons of post-remission therapy was the enrollment and categorization of more than 4000 patients with AML in the US, UK, and Western Europe. Several publications have reinforced the concept that pre-treatment karyotype is among the strongest predictors of outcome for newly diagnosed patients. Classifications of favorable, indeterminate/intermediate, and poor-risk (see Methods of SCT) were applied fairly uniformly to the various studies. Regardless of the differences in treatment algorithms on the individual trials, the three risk groups showed remarkably similar long-term outcome from study to study, validating this prognostic model. Subgroup analyses of the various treatment arms ensued to determine if a particular post-remission approach (CT, ABMT, or alloBMT) was best suited to particular risk groups.

The MRC-AML 10, US-intergroup, and EORTC/GIMEMA AML-10 studies all included detailed analyses based upon cytogenetic risk groups.³⁰⁻³⁶ In both the US intergroup and EORTC/GIMEMA study, patients with poor-risk cytogenetics had a dismal leukemia-free and overall survival when treated with intensive chemotherapy or autoBMT. When analyzed on a donor versus non-donor basis, the difference in overall survival was improved among those with donors, and this met statistical significance in both studies ($p = 0.043$ and $p = 0.035$, respectively). By contrast, the MRC study showed no statistically significant benefit to any arm. Patients with indeterminate/intermediate cytogenetic risk showed no consistent benefit to any post-remission strategy in any of the studies. The results in the favorable cytogenetics group varied most from study to study. In each study, however, the allograft arm had an inferior overall survival, and this met statistical significance in the MRC

study. In the US intergroup study, autografted patients in the favorable risk cytogenetics group had a superior survival to those treated with chemotherapy or allografting. However, this study had a surprisingly poor outcome of those in the favorable risk category who were treated with high dose ara-C consolidation. Indeed, in comparison to historical controls⁹ or even to patients in the study with indeterminate/intermediate risk cytogenetics, the favorable risk group had notably inferior disease free and overall survival.

The benefit of autologous BMT for acute promyelocytic leukemia is well established by several trials. FAB M3 disease was allowed on all of the randomized phase III studies listed above except for the EORTC/GIMEMA AML10, which began accrual following the widespread availability of all-trans retinoic acid in induction regimens. Given the superb results of ATRA-based chemotherapy regimens (OS of approximately 70%), it is felt that historical results of autologous transplant or allogeneic transplant in CR1 do not improve upon this performance. Given the increased toxicity associated with these regimens, transplantation in CR1 is not justified. Most patients with M3 AML do not receive transplantation unless they relapse and subsequently achieve a second remission with reinduction chemotherapy. Several studies have looked at the outcome of transplants for second remission APL, and the outcome of autologous transplant in this setting is excellent. Meloni et al. showed that achieving a molecular remission by RT-PCR for PML-RARa fusion was a strong predictor of survival following unpurged autograft in CR2. Although the group studied was small, the difference in relapse rate among those with RT-PCR negative harvests (1/9) as compared to those with detectable minimal residual disease harvests (7/7) was impressive.³⁷ A larger, retrospective report of the European Acute Promyelocytic Group³⁸ documented the outcome of patients with relapsed APL who underwent successful salvage. Patients who subsequently underwent autologous transplant had a superior overall survival compared to those who received an allogeneic transplant or chemotherapy alone (60 vs 52 vs 40%, respectively, $p = 0.04$). A potential limitation of these data is the absence of arsenic for salvage, which is currently considered the standard of care and might obviate the need for subsequent transplantation.

Autologous BMT for AML: Conclusions

Adult patients with AML in first CR currently have three effective post-remission therapies. Five large, randomized trials have failed to establish clear superiority of one approach over another, although available data suggest that patients with high risk cytogenetics may be best benefited by allografting, when feasible. Autologous transplant for AML in first complete remission seems to provide comparable leukemia-free and overall survival to allogeneic transplant for patients with standard or favorable risk cytogenetics. In comparison

to intensive chemotherapy, autologous transplant may provide superior initial antileukemic therapy, particularly among those with favorable cytogenetics, but has not clearly been shown to offer a survival benefit. This is likely due to the high salvage rate among those treated with intensive chemotherapy, many of whom may receive subsequent myeloablative therapy in second remission. Quality of life scores among patients treated with autologous transplant are typically superior to those of patients who underwent allogeneic transplant but inferior to those of patients treated with intensive chemotherapy, particularly regarding impaired fertility and libido.³⁹ The choice of post-remission therapy remains largely an individual one, based on cytogenetics and other risk stratification, availability of histocompatible sibling donors, as well as physician and patient preference.

The benefits of ABMT for patients with AML in second and subsequent remissions are clear, particularly for those without HLA-compatible donors and patients with acute promyelocytic leukemia, given the low likelihood of conventional chemotherapy to be curative. Because of the efficacy of all-trans retinoic acid plus anthracycline-based chemotherapy at inducing remission and preventing relapse with comparably low toxicity, autologous transplant should no longer be offered to patients with acute promyelocytic leukemia in first CR. However, ABMT in second remission should be considered the standard of care for patients without RT-PCR evidence of PML-RAR fusion. There remains a strong need for innovative phase I and phase II trials to develop novel therapies in AML.

AUTOLOGOUS STEM CELL TRANSPLANTATION FOR ACUTE LYMPHOBLASTIC LEUKEMIA

RATIONALE

Acute lymphoblastic leukemia (ALL) is an uncommon disease in adults. It is initially very responsive to chemotherapy and the vast majority enters remission. However, relapse is common and the ultimate long-term survival rate hovers at approximately 20–30%. Poor prognostic factors include very young or old age, high WBC count at diagnosis, the presence of the Philadelphia chromosome (Ph⁺), and slow initial response to therapy (Table 35.4).⁴⁰

The chance for long-term RFS after relapse without transplant is very limited. It seems paramount to adequately achieve initial leukemic control due to low response rate to salvage and lack of durability of subsequent remissions, regardless of consolidation strategy.

PURGING

In vitro HSC purging is well studied in ALL, due to the well-known antigens that characterize this disease and the ability to raise monoclonal antibodies (mAbs)

Table 35.4 Risk stratification of acute lymphoblastic leukemia

<i>High risk</i>
Time to CR >4 wks
t(9;22) (BCR-ABL) or t(4;11), t(1;19), +8, -7
WBC >100,000 (for precursor-B ALL)
Age >30
<i>Favorable risk</i>
Time to CR <4 weeks
No high risk cytogenetics
Precursor-T ALL or precursor-B ALL with WBC <30,000
Age <30

against these antigens, mAbs against anti-CD 9, 10, 19, 20 have been most commonly used in B-cell ALL⁴¹ and anti-CD5, and anti-CD7 for T-cell ALL.⁴² Similar antibodies have been combined with immunotoxins or magnetic beads. 4-HC has also been used as a purging agent. In vitro laboratory studies demonstrate significant reduction in contaminating tumor cells, but, as with other purging techniques, there has not been substantial clinical evidence to demonstrate the efficacy of this procedure. Most recently, CD34 selection columns have been used to positively screen and select pluripotent HSCs and to passively purge pure contaminating leukemia cells. The limited degree of selection of these devices, and the possibility of CD34 expression on leukemic blasts, make this approach less promising. In vivo purging with mobilizing chemotherapy prior to blood stem cell collection is also under investigation in ALL.

The development of imatinib is increasing interest in autografting in Ph⁺ ALL. The drug is being investigated as an in vivo purging agent, as well as post-autograft maintenance therapy. Already, several groups—notably MD Anderson and the German Multicenter ALL cooperative group—have reported feasibility of incorporating imatinib into standard regimens such as Hyper-CVAD⁴³ and BFM-style inductions. In the latter group, greater molecular responses at the time of stem cell harvest were noted when imatinib was started within two weeks of initiation of chemotherapy and no planned treatment breaks occur up to the time of stem cell mobilization.⁴⁴ The ECOG/MRC ALL study has recently amended its treatment protocol to incorporate 4 weeks of imatinib as in vivo purging prior to stem cell harvest, as well as maintenance post transplant for all Ph⁺ patients. As is true with the agent in CML, longer follow-up of clinical trials is necessary to see if the often impressive early hematologic and cytogenetic responses to imatinib are paired with clinically meaningful outcomes such as improved LFS and OS.

There are case reports showing successful use of rituximab for CD20+ ALL as in vivo purging but no large series or trials to support its use.^{45,46} Unfortunately, the

antigen is only rarely expressed among precursor B-ALL, making its use in autologous transplant only suitable to a minority of patients. Due to frequent expression in Burkitt (FAB L3 ALL) leukemia, it may be an attractive choice in the small number of patients with this disease who require autografting.

A final antibody that may ultimately prove relevant as an *in vitro* purging agent is the anti-CD52 mAb (Campath 1H). CD-52 is expressed in the majority of pre-B ALL, and alemtuzumab is well tolerated as an injectible chemotherapy in the treatment of B-cell malignancies. The drug is already being used as an immunomodulatory agent in allogeneic transplantation due to its *in vivo* T-cell depletion ability without the typical side effects of reduced stem cell dose from graft manipulation. Whether the drug will develop a role in autologous transplantation remains to be seen, but it has been employed successfully in small series.²²

HIGH DOSE REGIMENS

Common regimens for ALL include cytoxan and TBI, with or without the addition of etoposide. Traditionally, the TBI is fractionated, sometimes with an increased dose of 1200–1400 cGy, particularly in the pediatric population. No one regimen has been demonstrated to be superior to another. Rapid engraftment is typically seen.

CLINICAL RESULTS OF PHASE II TRIALS OF AUTOLOGOUS TRANSPLANTATION FOR ACUTE LYMPHOBLASTIC LEUKEMIA

Numerous small phase II trials have been conducted of ABMT for ALL, in first or second remission, or with refractory disease. OS has generally ranged between 5% and 20% for relapsed leukemia and 2-year DFS was 30–60%, when transplant is conducted in first CR. Interpretation of these trials suffers from the likely selection bias inherent in phase II trials and the varying pre-transplant regimens and prognostic factors for the patients studied.

CLINICAL RESULTS OF PHASE III TRIALS OF AUTOLOGOUS TRANSPLANTATION FOR ACUTE LYMPHOBLASTIC LEUKEMIA

The Leucemie Aigues Lymphoblastiques de l'Adulte (LALA) 94 trial⁴⁷ was a follow-up to the LALA 87 trial, which randomized patients with newly diagnosed ALL in remission to standard chemotherapy, autologous transplant, or allogeneic transplant. This study showed no difference in outcome between post-remission therapies in ALL among standard risk disease, but clear superiority of allogeneic transplant among those with high-risk disease.⁴⁸ Autologous transplant showed a trend toward improved outcome in comparison to standard chemotherapy, but was inferior to alloBMT among high risk patients. The LALA 94 trial further examined the role of intensified consolidation and risk-directed post-remission therapy in a large

multicenter trial. Following a standard, four-drug induction, patients were stratified into one of four risk categories. Those with standard risk ALL (defined by WBC < 30K, time to CR < 4 weeks, absence of high risk cytogenetics, absence of CNS disease at presentation, and typical immunophenotype with absent myeloid markers) were randomized to either standard or intensive consolidation followed by 2 years of consolidation/maintenance. High risk patients (albeit Ph⁻ and without CNS disease) all received intensive consolidation and those who lacked histocompatible donors were randomized to receive either an autologous transplant or standard consolidation/maintenance. High risk patients with HLA-matched siblings received an allogeneic BMT. All Ph⁺ patients received intensive consolidation and were assigned to allogeneic or autologous transplant, depending on availability of an HLA-matched donor (sibling or unrelated). Lastly, patients with CNS disease received triple intrathecal therapy, whole brain radiation, and intensive consolidation followed by either allogeneic or autologous transplant, depending on donor status. All transplants used Cy/TBI conditioning, except for patients who were Ph⁺, who also received high dose etoposide. Autografts were unpurged except in rare cases.

Over 8 years, the LALA94 study enrolled 1000 patients, of which 922 were evaluable; 771 (84%) achieved CR; 706 received subsequent therapy and were risk-stratified. Of the high risk patients, 82 had a sibling donor and were assigned to transplant. The remaining 129 were randomized to chemotherapy versus autologous transplant. Of those randomized to autograft, 87% actually received the intended therapy. Seventy-eight Ph⁺ patients were assigned to allo-BMT, while 65 had no donor. 18 patients with CNS disease had matched-family donors, while 30 were assigned to autograft. In all three risk groups where autologous transplant and/or standard chemotherapy was compared to allo-BMT there was a statistically superior DFS, 3-year survival, and 5-year survival favoring the allogeneic arm. In the comparison between autologous transplant and standard consolidation among high risk patients, there was a trend among autografted patients toward improved median LFS (15 vs 11 months, $p = 0.08$), 3-year survival (39 vs 24%, no p value given), and 5-year survival (25 vs 15%, no p value given). A notable difference in the two groups was the pattern of relapse, specifically the absence of late relapses among those autografted. By contrast, the chemotherapy-treated group had a continuous pattern of relapse over time.

The largest prospective, randomized trial to assess the utility of post-remission strategies in ALL is the ECOG 2993/MRC UKALL XII study, which randomizes newly diagnosed patients with ALL to either standard chemotherapy or an autologous PSC transplant. Patients under age 55 with an HLA-matched sibling are

given an allo-BMT and those with Ph⁺ disease may receive a matched, unrelated donor transplant. The conditioning regimen for all transplants is TBI/VP16. The study uses a two-month, modified BFM induction followed by high dose methotrexate and asparaginase intensification. After intensification, patients receive either a transplant or four cycles of consolidation followed by 18 months of maintenance therapy. Interim results have been presented in an abstract form.⁴⁹ To date, over 1500 patients have been enrolled for this study worldwide, including more than 550 patients who received transplants as consolidation therapy. The CR rate is 93% among those with Ph⁻ disease and 84% in the Ph⁺ subgroup. The trial shows substantial improvement in the 5-year OS among those treated with allogeneic transplant as compared to autograft (55% vs 39%, $p < 0.05$). The effect was robust regardless of age, donor source (sibling or unrelated), or cytogenetics. No comparative data among the randomized arms have been disclosed to date as the study continues to accrue patients. The survival of patients after relapse was dismal, with only 13 patients (6%) alive at 5 years after relapse, regardless of subsequent therapy.

CONCLUSIONS

The results of the ECOG 2993/MRC UKALL XII may ultimately define a role for autologous transplant in the management of adult ALL. At present, there is no clear group for which it should be considered a standard of care. Available data recommend allogeneic transplant in CR1 for all patients with ALL, though the data seem to be more robust among high risk patients. Outside clinical trials, autologous transplantation should be reserved for patients with poor prognostic factors in first remission who are not candidates for allogeneic SCT, or patients in second and subsequent remission.

AUTOLOGOUS SCT FOR CHRONIC MYELOGENOUS LEUKEMIA

HISTORY

CML has traditionally been the most common indication for allogeneic transplantation and the curative potential of allo-BMT in this disease is well established. The majority of preparative regimens used for leukemia were developed to treat this disease. It was also the model for adoptive immunotherapy in the form of graft-versus-tumor that established the practice of donor lymphocyte infusion. The development of imatinib has substantially decreased the number of patients who are treated with stem cell transplants, but it remains the standard bearer for patients treated with curative intent.

Autologous transplant plays a less established role in CML management than allogeneic BMT. However, given the lack of potential histocompatible donors for

many patients, as well as the tendency for the disease to present after the age of 50 years, autologous transplant has enjoyed a fair amount of interest in terms of offering the potential benefits of myeloablative therapy to more patients with CML. This is particularly true for advanced phase disease, for which there are no effective therapies outside of transplant. The initial reports of autologous transplant in CML used stem cells frozen from chronic phase to rescue patients treated with myeloablative chemotherapy at a time of blast crisis. A second chronic phase ensued in many patients, but relapses typically occurred in less than 1 year.⁵⁰ Due to persistence of leukemia following autologous transplantation, attempts using a number of in vitro purging agents ensued, none of which consistently provided protection against relapse. Ultimately the development of imatinib may have rekindled interest in harvesting of PCR negative stem cells for use in future because of imatinib failure. Given the low toxicity of the drug, however, there is little interest in autologous transplant as initial therapy.

RATIONALE

CML derives from disordered proliferation of a Ph⁺ clone that arises from an early hematopoietic stem cell. Marrows of patients with CML may contain chimerism between malignant Ph⁺ and non-malignant Ph⁻ cells. The results of chemotherapy, interferon, or imatinib to induce cytogenetic responses, as well as the ability to grow CFU of Ph⁻ cells from cultured CML marrow, demonstrates this point. Collecting stem cells purified for Ph⁻ clones has been the elusive goal of studies of autologous transplant for CML. To this end, a number of purging approaches have been investigated. However, data regarding syngeneic transplantation show a high relapse rate and suggest that graft versus leukemia may be equivalent to—if not more important than—myeloablation and infusion of a tumor-free graft.¹³

PHASE I AND II TRIALS OF ABMT IN CHRONIC MYELOGENOUS LEUKEMIA

Most autologous transplant trials in CML consist of small series of patients at single institutions (Table 35.5). There are no randomized data to compare the merits of autologous transplant against any other therapy for CML. By far, most series instead attempt to define a novel method of isolating Ph⁺ cells for harvest, typically via purging of Ph⁺ clones. Among the agents used in attempts to purge Ph⁻ cells in vitro have been chemicals such as 4-HC,⁵¹ mafosfamide,⁵² interferon gamma.⁵³ Other approaches included differentiation agents, such as GM-CSF⁵⁴ or extended culture to purify for Ph⁻ clones. In small series, all of these approaches were seen to have transient significant activity, frequently leading to engraftment with complete cytogenetic responses. However, relapse across these studies, was near universal, typically after only a

few months of remission. It is unclear if survival among treated patients would exceed that expected by the natural history of this chronic disease.

Autografts for CML have been one of the first places that gene-directed therapy with antisense oligodeoxynucleotides (AS-ODN) have been employed. Two pilot studies deserve note. Not surprisingly, AS-ODN directed against BCR-ABL were the first target to be tested in CML. Eight patients in transformation to advanced disease were subjected to autologous transplantation using marrow that had had antisense against BCR-ABL incubating for 24–72 hours prior to cryopreservation. Two patients had a complete cytogenetic response by FISH. The remainder had minimal or no response. Toxicity was negligible. Another oligodeoxynucleotide target protein has been the c-myb proto-oncogene,⁵⁵ which is felt to play an essential role in both hematopoiesis and leukemogenesis. Because leukemia cells show enhanced reliance upon myb's ability to transactivate a number of important growth regulatory genes important in CML, myb inhibition is an attractive therapeutic target in this disease. Twenty-four patients underwent bone marrow harvest with incubation of their marrow for either 24 or 72 hours in AS-ODN targeted against c-myb. After conditioning with busulfan with or without cytoxan, the purged marrow cells were reinfused. Myb and RNA transcript numbers decreased appreciably in approximately half of patients. Two patients achieved a complete cytogenetic response and three more had major cytogenetic responses. However, unlike the AS-ODN targeted against BCR-ABL, significant delayed engraftment was seen among all those treated with 72-hour incubation, requiring back up marrow infusion in a number of patients.

Imatinib has been utilized both prior to harvesting and following autologous transplantation.^{56,57} Given its impressive success in upfront CML therapy, the number of autologous stem cell transplants that have been performed for this disease has plummeted.

However, imatinib has only transient activity in advanced phase disease.⁵⁸ A role for imatinib in combination with autografting may ultimately be established among patients initially presenting with advanced phase disease who are either poor candidates for allogeneic transplant or lack suitable donors. Several groups have shown that Ph⁻ stem cell collection is feasible among patients treated with complete cytogenetic responses to imatinib who are mobilized with GCSF.⁵⁹

Because approximately one quarter of patients treated with imatinib will achieve more than 3 log reduction or even molecular clearance of BCR-ABL, these patients could be considered ideal candidates for harvesting of stem cells, either for immediate use or during disease progression period on imatinib. At present, one remaining question is: for whom would this approach be warranted? Patients with negative quantitative PCR studies for BCR-ABL would initially seem to be attractive candidates, since these patients are most likely to be able to mobilize BCR-ABL negative harvests as measured by PCR. Yet disease progression models consider such patients to be at the lowest risk of progression, with current estimates ranging as low as less than 1% risk of progression/year.⁶⁰ Those for whom disease control is suboptimal and progression is probable are unlikely to produce uncontaminated grafts even with imatinib.

CONCLUSION

Allogeneic transplant remains the only proven cure for CML and should be strongly considered in young, highly motivated patients with HLA-identical siblings. Current disease models also suggest that survival is extended by imatinib, and therefore an initial therapeutic trial of the agent is also reasonable. Autologous BMT is rarely performed for CML due to the predictability of response to imatinib and the low level of toxicity. As data regarding imatinib resistance have come to prominence, novel approaches to treat resistant

disease are sought. Here it is possible that autologous transplant may return to prominence as the cohort currently being treated with imatinib ages and resistance becomes more common over time. A growing number of second-generation *abl* kinase inhibitors have been developed to treat this looming threat.

Given the lack of durable responses in most ABMT series, it is unlikely that autologous transplant will gain much prominence in the future of this disease unless more effective purging or adoptive immunotherapy is able to be incorporated into autologous regimens.

Chapter 36

ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION FOR THE ACUTE LEUKEMIAS IN ADULTS

Corey Cutler and Joseph H. Antin

INTRODUCTION

Acute lymphoblastic leukemia (ALL) is an uncommon malignancy in adults, with an incidence rate of 0.3–0.8 cases/10⁵ individuals between the ages of 20 and 50. In comparison, acute myeloid leukemia (AML) occurs in 1.2–2.4/10⁵ individuals between the ages of 20 and 50.¹ Nevertheless, AML and ALL represent the two most common indications for allogeneic stem cell transplantation worldwide, as reported to the International Bone Marrow Transplant Registry in 2002, accounting for over 7000 reported transplants worldwide.²

Modest advances in the therapy for ALL and AML have been made in the last decade; but despite these advances, long-term outcomes for these diseases, particularly in adults, remain poor, as less than half of these patients achieve a durable remission.^{3,4} This chapter discusses the established and emerging role of allogeneic stem cell transplantation as therapy for the acute leukemias.

ALLOGENEIC STEM CELL TRANSPLANTATION FOR ALL

TRANSPLANTATION IN FIRST COMPLETE REMISSION

ALL has a relatively poor prognosis in adults with long-term survival in only 30–40% of newly diagnosed individuals.⁵ Traditional risk factors defining “high-risk” disease include advanced age, very elevated WBC at presentation, immunophenotype (Pro-B cell ALL), the presence of adverse cytogenetic changes (i.e., t(9:22) and t(4:11)), and a delay in the time to achieve a first remission.⁵ Newer prognostic factors include the presence of minimal residual disease detected by sensitive molecular techniques and gene-expression profile

hierarchical clustering and expression analysis.⁴ As outcome in high-risk disease is significantly worse than for standard risk disease (most notably for adverse cytogenetic changes), many analyses on cohorts of high-risk patients transplanted in first remission have been performed.

Single center data on transplantation for ALL are extremely heterogeneous. One report of an experience treating 39 adults with high-risk features in first remission, with a uniform conditioning regimen of total body irradiation and etoposide, yielded a relapse rate of only 15%, with an event-free survival of 64% at 10 years.⁶ However, a review of 99 patients from six trials, all with Ph+ ALL transplanted in first remission using fully matched, sibling or unrelated donors demonstrated disease-free survival of 0–86%.⁷ Numerous other single-arm studies have reported similarly heterogeneous outcomes.⁸

True randomized evidence supporting the role of allogeneic transplantation for ALL in first complete remission is lacking. An attempt to address this question has been addressed with studies of biologic assignment, where patients with histocompatible donors are assigned to allogeneic transplantation, while those patients without suitable donors are randomized to autologous transplantation or conventional chemotherapy. Table 36.1 summarizes the results from the published comparative trials. The GOELAM used a biologic assignment strategy and assigned allogeneic transplantation or consolidative chemotherapy followed by autologous transplantation to 156 patients younger than 50 years, all with high-risk ALL. Transplant-related mortality was only 15% and at 6 years, disease-free survival was greater in the allogeneic transplant arm (75 vs 46%, $p = 0.0027$; Figure 36.1).¹⁰ The LALA group used a similar strategy and assigned allogeneic transplant to Ph+ patients with a sibling donor and compared outcomes

Table 36.1 Trials of biologic randomization in ALL, since 1990

Trial, (year of publication)	Entry criteria and methodology	Comparison	N	Survival	Relapse	Survival by risk	Comments
EORTC ALL-3, (2004) ⁹	Age 15–50 Standard and high –risk Ph- Biologic randomization 2nd randomization for no donor group	AlloBMT vs AutoBMT + chemotherapy	68 116	6 yr DFS 38.2% 36.8% $p = 0.69$	OS 41.2% 38.8% $p = 0.95$	38.2% 56.3% $p = 0.01$	No differences when stratified by risk Only 69% of AlloBMT group underwent transplantation. Figure 36.1 (a) Overall survival and (b) Relapse from the GOELAL02 trial

with a group that received autologous and unrelated donor transplantation. Overall survival was 37% in the transplant arm in comparison with 12% in the chemotherapy cohort.¹² The prior LALA randomized trial also demonstrated an advantage to transplant in first remission among high-risk patients.¹⁴ Preliminary results from the MRC UKALL/ECOG co-operative study suggest that even for standard risk ALL, allogeneic transplant in first remission may be beneficial (54 vs 34% 5 year OS, $p = 0.04$).¹³ In contrast, recent studies published by the EORTC⁹ and Gupta et al.,¹¹ demonstrated that transplantation in first remission did not increase survival in either high-risk or standard risk cohorts. Interestingly, all of the trials found similar outcomes in patients receiving autologous SCT and chemotherapy, suggesting that autologous transplantation does not improve survival in ALL.

All of the biologic assignment studies have agreed that the relapse rate after allogeneic transplantation is lower than after autologous transplantation or consolidative chemotherapy. However, transplant-related morbidity and mortality offsets survival gains through reduction in relapse rates. Nonetheless, the results of these large studies have made allogeneic transplantation from an HLA-matched sibling the therapy of choice for patients with high-risk ALL in first remission.

There has been reluctance to offer unrelated donor stem cell transplantation in first remission, even to patients with high-risk ALL, because of anticipated higher rates of treatment-related mortality when unrelated donors are used. However, with high resolution HLA typing and improvements in immunosuppression and antibiotic management, morbidity and mortality after unrelated transplantation for ALL is not greatly increased in comparison with related donor transplantation. Therefore there is now interest in offering unrelated donor transplantation in first remission to patients without suitable related donors in whom transplant is indicated. A retrospective review conducted through the National Marrow Donor Program evaluated matched, or

single-antigen mismatched, unrelated transplantation for high-risk ALL in first remission.²⁰ In this study, overall survival at 4 years was 32%, which is similar to the sibling transplantation results reported above. In another retrospective study comparing outcomes for patients in first remission and beyond who underwent transplantation, no difference in outcome for patients receiving related and unrelated donor transplants was noted (42 vs 45% 5 year DFS).²¹ Similarly, a retrospective cohort analysis suggested that outcomes after matched, unrelated transplant in first remission were similar to, or better than, outcomes after autologous transplantation (51 vs 44% 3 year OS).²²

For patients with standard risk leukemia, the biologic assignment studies do not conclusively support routine transplantation at this time, although the results of the MRC UKALL/ECOG study are promising. While biologic assignment and intention-to-treat analysis are the most appropriate methodology for policy development on the issue of the role of transplant in first remission,²³ for the individual patient, the results of these studies may be inappropriate to help guide therapy. Reported very rarely, as-treated analyses are more helpful in the situation in deciding on the role of transplantation, once a remission has been attained, a suitable donor is identified, and the patient is deemed to be a suitable transplant candidate. Two other factors need to be considered for patients with standard risk ALL. With the widespread use of intensive and continuous chemotherapy regimens as primary therapy for ALL, it is possible that the achievement of second remission after relapse will become less likely, as tumors may develop resistance to chemotherapy. This may actually worsen outcomes for transplantation for relapsed disease²⁴ and make a strategy of salvage transplant for relapsed disease less likely to be successful. Second, the morbidity and mortality after transplantation while in remission continues to decline. Taken together, a strategy to maximize long-term survival among standard-risk ALL patients may include allogeneic transplantation from an HLA-identical sibling in first remission.

TRANSPLANTATION FOR ADVANCED ALL

Allogeneic transplantation is the therapy of choice in relapsed ALL, as durable remissions with chemotherapy alone are rare in adults. Transplantation in untreated first relapse and second remission yield roughly equivalent results; however, long-term remission rates are significantly lower when compared to transplantation in first remission. In a retrospective analysis of 182 adults with ALL, 5 year overall survival after transplantation in second or greater remission ($n = 46$) and relapse ($n = 95$) were 23% and 9%, respectively, in comparison with 43% for patients transplanted in first remission.²⁵ In a retrospective review of 147 patients transplanted for advanced ALL (the majority with matched, related donors), overall survival was less than 10% among 79 patients with a pre-B phenotype.²⁶

Only a minority of patients with advanced ALL will have suitable matched, related donors. Since the outcome of relapsed or refractory ALL is so poor with chemotherapy alone, unrelated or alternative donor transplantation is warranted in this setting. In a study of 63 patients in second or greater remission or with refractory ALL, overall survival was 17% for patients in remission and 5% for patients with refractory disease;²⁰ however, survival for patients in second remission was greater (36% at 5 years) in another study facilitated by the NMDP that included patients of all risk types transplanted in second remission.²⁷ In this study, unrelated transplantation was not statistically better than autologous transplantation in second remission (36 vs 27%, $p = 0.11$), but a Cox multivariable regression analysis demonstrated an improvement in long-term survival in patients receiving allogeneic transplantation who survived 6 months after transplantation. Again, lower relapse rates after allogeneic transplantation were offset by the mortality of the transplant procedure itself. In a matched-pair analysis of matched, unrelated donor transplantation in comparison with autologous transplantation, the EBMT demonstrated similar survival outcomes (39 vs 31%, $p = 0.19$).²⁸

In summary, transplantation for advanced ALL should be performed whenever feasible. Despite trends toward improved outcomes with unrelated donor transplantation over autologous transplantation, no single comparative trial has demonstrated convincing evidence of superiority. Since outcomes after unrelated allogeneic transplantation have been improving as HLA matching techniques improve, it is likely that allogeneic transplantation, rather than autologous transplantation, will become the strategy of choice to reduce relapse with advanced disease.

ALLOGENEIC TRANSPLANTATION IN COMBINATION WITH IMATINIB

Imatinib mesylate (formerly known as STI-571, Gleevec,TM Novartis AG) is a potent, reversible inhibitor of bcr/abl tyrosine kinase activity.²⁹ When

added to induction chemotherapy, this drug has been shown to increase remission rates among Ph+ ALL patients.^{30,31} Similarly, this drug may be effective for relapsed Ph+ ALL.³² By increasing remission rates among newly diagnosed Ph+ ALL patients, the long-term success of allogeneic transplantation may be improved, as disease status at the time of transplantation is a powerful predictor of long-term survival.²⁵ Furthermore, imatinib use may increase the window of opportunity for patients with newly diagnosed or relapsed disease to find suitable allogeneic donors by prolonging remission time. Imatinib has been given to newly diagnosed, refractory or relapsed patients prior to allogeneic transplantation.³³⁻³⁶ At this time, all that can be concluded from this experience is that imatinib therapy prior to transplantation does not impair engraftment of transplanted hematopoietic progenitor cells.³³ Since the number of patients reported at this time is limited, estimates of the long-term impact of imatinib use prior to transplantation are difficult to predict. Whether empiric imatinib after transplantation will be effective as a preventative strategy against relapse is also unpredictable.

NONMYELOABLATIVE TRANSPLANTATION

Transplantation with nonmyeloablative or reduced-intensity conditioning regimens eliminates much of the morbidity and mortality associated with high-dose transplantation.^{37,38} As such, this approach has been used widely in older individuals, in individuals with comorbid illnesses, and in those who have undergone prior high-dose therapy approaches. Without high-dose chemoradiotherapy, this approach to transplantation relies exclusively on the development of a potent graft-versus-leukemia (GVL) reaction. While GVL reactions are prominent in some hematologic malignancies, they may be less pronounced in aggressive lymphoid malignancies, such as ALL. However, after ablative transplantation, the presence of GVHD has been shown to be protective against relapse, invoking the power of a potent GVL response.^{26,39-41}

No single study has prospectively accrued sufficient subjects to make reliable conclusions on the role of nonmyeloablative transplant for ALL; however, investigators from four large trials⁴²⁻⁴⁶ have pooled their results and reported outcomes on 27 patients.⁴⁷ The median age of the patients was 50 years, and most had advanced disease (only four were in first remission while 12 were chemorefractory or in relapse at the time of transplant) or adverse cytogenetic features (Philadelphia chromosome in 11). In this study, multiple conditioning regimens, GVHD prophylaxis regimens, stem cell donor types, and stem cell sources were used. Despite this, donor-derived hematopoiesis occurred in all patients, with a 63% incidence of Grade II-IV acute GVHD and a 72% rate of chronic GVHD among evaluable patients. Treatment-related mortality was 23%. Eight of 27 patients are alive without disease at a median of

816 days from transplantation (range 381–1375 days), which is considered a promising result, given the otherwise poor prognosis of these patients without transplantation. In this study, a correlation between the incidence of acute GVHD and protection from relapse was noted (hazard rate for relapse prevention 3.3, $p = 0.05$), invoking an active GVL reaction.

A more uniform cohort of 22 high-risk ALL patients enrolled in a multicenter German trial has been reported.⁴⁸ The majority of these patients received a fludarabine-busulfan conditioning regimen followed by an infusion of peripheral blood stem cells (PBSC) from matched related (13), unrelated (8), and mismatched related (1) donors. Despite similar rates of acute GVHD as reported in the pooled analysis, the overall survival in this cohort was 18% at a median follow-up of 16.5 months for survivors (range 5–30 months). In summary, at the present time, there remains insufficient data to routinely recommend nonmyeloablative transplant outside of a clinical trial.

OTHER ISSUES IN TRANSPLANTATION FOR ALL

Stem cell source and preparative regimen

There is no preparative regimen that yields superior results when used prior to transplant for ALL. Many centers employ regimens that include etoposide; however, this agent has not been shown to improve transplant outcomes among adults. The IBMTR has analyzed the outcomes in 298 patients who received HLA-matched sibling transplants for ALL in first or second remission. Long-term survival was superior in patients who received ≥ 13 Gy of TBI, but no differences were noted when cyclophosphamide and etoposide use were compared.⁴⁹ Regarding stem cell source, no randomized trial has directly compared PBSC with bone marrow for ALL transplantation because of the rarity of this disease and large sample size that a clinical trial would need to demonstrate differences. While superior disease-free survival has been demonstrated with PBSC transplantation over stem cell transplantation using HLA-identical sibling donors, particularly with advanced malignancies, subgroup analyses in ALL are too small to demonstrate differences.⁵⁰ A single retrospective analysis of 102 ALL patients who received an unrelated stem cell transplant demonstrated inferior survival among PBSC patients despite no differences in grade II–IV acute GVHD or chronic GVHD incidence.⁵¹ In this study, PBSC patients were less likely to receive TBI as conditioning ($p = 0.06$), which may have influenced outcome.⁴⁹ Although used infrequently, umbilical cord transplantation has been attempted in adults with advanced ALL. The advantage of cord blood transplantation is the rapid access to stem cells and the potential for less GVHD than with other unrelated stem cell products. Too few transplants for ALL have been performed to make conclusive comments on the role of cord blood transplanta-

tion; however, the relative lack of GVHD could be associated with a high risk of relapse.

Therapy of relapse: DLI and imatinib

ALL in relapse after transplantation is rarely salvaged by donor lymphocyte infusion. This observation is consistent but confusing, since there does appear to be a measurable GVL response in primary transplantation. Less than 20% of patients will achieve a remission to DLI alone^{52,53}; however, this number may be increased with concomitant chemotherapy. Despite this, remissions are rarely durable. Imatinib has been used as therapy for relapse after transplantation of ALL⁵⁴; however, the majority of the reported experience in relapsed Ph+ malignancies is in chronic myeloid leukemia (CML)^{55,56} or the lymphoblastic phase of CML.^{57,58} The combination of imatinib and DLI may prove to an important therapeutic modality for relapsed ALL. Attempts at second transplantation have been made with reasonable success, with long-term survival in up to 30% of patients.⁵⁹

ALLOGENEIC STEM CELL TRANSPLANTATION FOR AML

TRANSPLANTATION IN FIRST COMPLETE REMISSION

There have been at least 12 prospective trials that have used a biologic randomization strategy to assign allogeneic stem cell transplant or consolidative chemotherapy (with or without autologous stem cell transplantation) for patients with AML in first remission (Table 36.2). Several recurring themes have emerged as a result of this vast experience involving over 3600 patients. First, it is clear that a profound GVL effect exists, as relapse rates after allogeneic transplantation are uniformly lower after allogeneic transplant in comparison with nonallogeneic postremission strategies. Second, allogeneic transplantation continues to be a risky medical procedure, as mortality while in remission is markedly higher in the allogeneic transplant arms of the prospective trials. Third, the risks of reduced relapse rates but higher treatment-related mortality have led to modest gains in disease-free and overall survival in the more recent comparative trials of allogeneic stem cell transplantation.

The decision to undertake allogeneic stem cell transplantation while in first complete remission is usually based on risk stratification according to cytogenetics.⁷⁴ The greatest controversy on the role of transplantation for AML in first complete remission has focused on the group of patients with intermediate risk cytogenetics, where long-term remissions without transplantation occur in less than 40% of affected individuals. The EORTC/GIMEMA AML-10 trial compared 293 patients with AML in first remission with an HLA-identical sibling to 441 patients in whom a suitable HLA-matched family member donor was not available.⁶² Subjects

Figure 36.2 Disease-free survival from ORTC/GIMEMA AML-10 trial

without a suitable stem cell donor were assigned to autologous stem cell transplantation, although only 56% of these subjects underwent the procedure. Up to 40% of the patients in both arms had no cytogenetic information available, but approximately 35% of the remaining patients were classified as having intermediate risk cytogenetics. Overall, the 4 year disease-free survival in the transplant group, in an intent-to-treat fashion, was superior to the nontransplant group (52.2 vs 42.2%, $p = 0.044$; Figure 36.2); however, in subgroup analysis, the intermediate risk group alone did not show a trend toward improved survival. The favorable differences in outcome were more prominent in the younger age groups, suggesting that the combination of a relative decrease in treatment-related mortality associated with young age and the gains in relapse prevention was sufficient to generate a clinical benefit. The prior EORTC/GIMEMA AML 8A trial was unable to demonstrate a difference between allogeneic and autologous transplantation strategies, although in this trial, both forms of transplantation were superior to chemotherapy alone as postremission consolidation therapy.⁶⁶

The MRC AML 10 trial compared the outcomes of 419 patients in remission and assigned to allogeneic transplant on the basis of an available HLA-identical sibling with 868 patients with no sibling donor, all of whom were assigned autologous transplantation.⁶⁴ Disease-free survival was prolonged in the transplantation group in comparison with the nontransplant cohort (50 vs 42% at 7 years, $p = 0.001$; Figure 36.3). Overall survival was marginally, but not statistically, better (56 vs 50%, $p = 0.1$). Although this trial was designed to decide whether allogeneic transplantation was superior to autologous transplantation, only 23% of the no-donor arm actually underwent autologous transplantation, making the interpretation of these results questionable. Nonetheless, in the intermediate-risk subgroup, allogeneic transplantation was associ-

ated with an improvement in disease-free survival (50 vs 39%, $p = 0.004$; Figure 36.3) and overall survival (54 vs 44%, $p = 0.02$).⁶⁴

For patients with intermediate cytogenetic risk AML in first complete remission, consolidation with allogeneic transplantation is superior antileukemic therapy in comparison with chemotherapy or autologous transplantation. While no trial has focused uniquely on patients with intermediate risk cytogenetics, this group represented the majority of patients studied in most of the trials, and as such, the best estimate of the effect in this majority subgroup is the overall effect of the trial, as long as significant heterogeneity among the subgroups is absent.⁷⁵ The three largest trials demonstrated a reduction in relapse rates after allogeneic transplant of 21–26% and an absolute improvement in disease-free or overall survival of 8–13%.^{62,64,66,67} Many other trials have been performed that addressed this question (Table 36.2), and three additional small trials have been able to demonstrate the statistical superiority of allogeneic transplantation over consolidation chemotherapy or autologous transplantation,^{70,72,73} while the other trials were too small and underpowered to demonstrate differences,^{60,63,71} or no differences were noted.^{68,69}

The favorable cytogenetic changes in AML (t(8;21), t(15;17), inv(16), t(16;16), and del(16q)) comprise a distinct minority of favorable-outcome adult AML cases. Only a few trials have accrued sufficient numbers of favorable-risk subjects to properly examine the role of transplantation for AML with favorable cytogenetics. The SWOG/ECOG Intergroup trial included 121 patients with favorable cytogenetics, 84% of whom achieved a complete remission to induction chemotherapy and were subsequently assigned to allogeneic stem cell transplant if an HLA-identical sibling was available ($n = 19$) or randomized to autologous transplantation ($n = 26$) or chemotherapy ($n = 22$).^{68,76} Thirty one additional patients were

Figure 36.3 Disease-free survival from the MRC AML-10 subgroup analyses

not treated on study. The outcome of allogeneic transplantation and autologous transplantation (5 year OS 63% and 71%, respectively) was superior to the result for chemotherapy alone (5 year OS 35%), which is significantly lower than in other reported series of favorable risk AML.^{74,77,78} The EORTC/GIMEMA trial, which studied 123 patients with favorable risk cytogenetic profiles did not demonstrate a difference in outcomes among patients (68.1 vs 73.9% 4 year DFS)⁶² although patients with favorable cytogenetic changes benefited most from transplantation.⁷⁶ Nonetheless, consolidative chemotherapy remains the most commonly applied consolidation strategy for favorable-risk patients.

Patients with unfavorable cytogenetics have a very poor prognosis, despite similar rates of remission after induction chemotherapy compared with other AML cytogenetic risk groups. For this reason, transplantation in first remission is widely accepted as standard therapy, wherever a suitable donor is identified. The

biologic assignment studies have confirmed that allogeneic transplantation is a superior therapy in comparison with consolidative chemotherapy or autologous transplantation. The EORTC/GIMEMA trial even suggested that with an increasingly unfavorable prognosis prior to transplantation, the greater the benefits that can be achieved with transplant therapy.⁶² The prognosis of unfavorable cytogenetic risk AML is poor enough that unrelated allogeneic stem cell transplantation is generally undertaken in first remission, when a suitable HLA-matched sibling donor is unavailable. Since matched, related transplantation is not yet the accepted standard for either intermediate or favorable cytogenetic risk AML in first remission, unrelated donor transplantation cannot be routinely recommended.

TRANSPLANTATION FOR ADVANCED AML

Once relapsed, AML carries a poor prognosis, with very few long-term remissions induced by chemotherapy

Table 36.2 Trials of biologic assignment in AML, since 1990

Trial (year of publication)	Entry criteria and methodology	Comparison	N	Survival	Relapse	Survival by risk	Comments
CETLAM (2004) ⁶⁰	Age ≤50 Intermediate, adverse cytogenetics Biologic randomization	AlloSCT vs AutoSCT	28 36	4 yr OS 48% 60% p = NS			Uniform induction, consolidation chemotherapy regimen PBSC and BM used, T depleted in majority Multiple GVHD regimens As treated analyses presented

alone.⁷⁹ Patients with favorable prognostic features, including a longer duration of first remission^{79,80} and favorable cytogenetic features at presentation,⁸¹ have more favorable outcomes. The CALGB tested autologous transplantation in a cohort of 50 individuals with AML in second remission. With a short follow-up, 25% of patients remain in remission.⁸² While other small series exist, because of short follow-up, autologous transplantation cannot be routinely recommended for patients in second or subsequent remission. Allogeneic stem cell transplantation is the recommended therapy for second or subsequent remission AML. The French Bone Marrow Transplant Group (SFGM) retrospectively reviewed the outcomes in 310 patients with relapsed AML who underwent transplantation. The 5-year probability of survival was 35% in patients who underwent transplant in second or subsequent complete remission. This was significantly better than the outcomes for patients transplanted in untreated or refractory relapse (14% and 11%, respectively).⁸³ Overall, patients with sibling donors fared better than patients with unrelated donors ($p = 0.001$), mainly due to differences in transplant-related mortality. While transplantation in untreated relapse is certainly feasible,⁸⁴ recent analyses suggest that reinduction chemotherapy may have some value, if only to help determine prognosis with transplantation.

Despite anthracycline-based induction chemotherapy, up to 30% of patients with newly diagnosed AML will not achieve a complete remission. The long-term prognosis for these patients with primary refractory AML is extraordinarily grim, with essentially no long-term survivors in the absence of allogeneic stem cell therapy. Salvage transplantation can result in long-term remissions in approximately 10–30% of individuals when family members or unrelated volunteers are used as donors.^{83,85–87} In this setting, the use of unrelated donors and adverse cytogenetics negatively impact long-term survival.⁸⁶ The timing and number of chemotherapy cycles prior to transplantation for refractory AML is likely critical, as patients exposed to multiple rounds of chemotherapy and infectious complications of prolonged neutropenia have a higher incidence of transplant-related morbidity and mortality. Achieving a remission after primary induction failure does not appear to influence long-term outcome⁸⁶ and so multiple attempts to induce a remission are likely detrimental.

NONMYELOABLATIVE TRANSPLANTATION

Similar to the situation in ALL, nonmyeloablative transplantation for AML has been shown to reduce transplant-related morbidity and mortality, mainly by reducing the incidence of serious complications in the immediate posttransplant period. Here as well, the GVL reaction is an important component of therapy. The Spanish Group for Hematopoietic Transplantation

demonstrated a significant improvement in outcome for patients who developed grade II–IV acute GVHD in comparison with patients who experienced no GVHD after nonmyeloablative transplantation (13 vs 58% disease progression at 1 year, $p = 0.008$).⁸⁸

The use of transplantation for patients with AML in first remission has been demonstrated to be safe. Feinstein *et al.* transplanted 18 patients with AML in first remission and demonstrated that nonrelapse mortality was only 17% at 1 year. The majority of treatment failures in this cohort were related to disease relapse, which was responsible for 70% of the deaths in this trial.⁸⁹ Nonmyeloablative transplantation has been used as consolidation therapy for patients in second remission, for relapsed disease after failed autologous transplantation or prior high-dose allogeneic stem cell transplantation and for patients with refractory leukemia. In these settings, the most important predictors of long-term outcome include cytogenetics and remission status at the time of transplantation.

To explore the utility of nonmyeloablative transplantation in a cohort of individuals traditionally considered eligible for ablative transplantation approaches, Ruiz-Arguelles *et al.* transplanted 24 young patients (median age 35 years) with AML, using nonmyeloablative conditioning.⁹⁰ The median survival of this cohort exceeds 7 years and has not been reached and progression-free survival at 2 years is 66%. Transplant-related toxicity was very minor, and the majority of transplants occurred in an outpatient setting. Similarly, Alyea *et al.* compared the results of ablative and nonmyeloablative conditioning in a cohort of individuals above the age of 50, the majority of whom had AML. No differences in outcome were noted; however, interestingly, it appeared that patients <50 years did better with ablative regimens.⁹¹ While results from larger series need to confirm these findings, the combination of reduced treatment-related morbidity and mortality with an active GVL effect may make nonmyeloablative transplantation the therapy of choice for individuals in first remission with either intermediate or unfavorable cytogenetic risks, but is not recommended routinely at this time.

THERAPY OF RELAPSE AFTER TRANSPLANTATION

Relapse after allogeneic transplantation for AML is not uncommon and represents a difficult challenge to the clinician. Rates of response to donor lymphocyte infusions (DLI) are roughly the same for AML as for ALL and occur in roughly 15–40% of cases.^{52,92,93} Most of these responses are short-lived and are often associated with either acute or chronic GVHD. To be effective most DLI must be performed in remission.

For patients who do not respond to DLI, the option of a second allogeneic transplant exists. Using a second, matched related donor, 3 year leukemia-free survival among 125 patients with relapsed AML after a

first matched, related transplant was 27%.⁵⁹ The majority of these patients received allografts from the same donor, and the majority had myeloablative conditioning regimens. Factors that predicted survival included the length of remission from initial transplant, remission status at the time of second transplant, and the age of the recipient.⁵⁹ Similar findings were reported from three European studies⁹⁴⁻⁹⁶, although the transplant-related mortality in the French study was 68%.⁹⁶ In this study, chronic GVHD was associated with a more favorable outcome (hazard rate 3.2 for overall survival, $p = 0.0005$), suggesting that GVL is required for favorable long-term outcome.⁹⁶ These outcomes are only observed if the transplant takes place more than a year after the first transplant. Attempts at transplantation within 1 year are associated with increased transplant-related mortality. The use of unrelated donors to harness more potent GVL effects⁹⁷ and the use of nonmyeloablative conditioning to reduce transplant-related mortality have been attempted as well.⁹⁸

SPECIAL TOPICS IN TRANSPLANTATION FOR AML

Stem cell source

As in ALL, trials have prospectively enrolled patients to determine if outcomes using PBSC are superior, equivalent, or inferior to stem cell transplantation. The Stem Cell Trialists group demonstrated in an individual-patient meta-analysis that for all hematologic malignancies, disease-free outcomes were slightly superior for PBSC transplantation, although this was not seen in the AML subgroup. In a large retrospective IBMTR review, outcome for patients with AML in first remission was no different for PBSCT in comparison with BMT (1 year DFS 70% vs 61%, $p = 0.25$); however, patients in second remission benefited significantly with PBSCT (1 year DFS 77% vs 57%, $p = 0.003$).⁹⁹ This is in contrast to a large EBMT survey where no differences were noted,¹⁰⁰ and a second EBMT survey where CD34⁺ rich stem cell transplantation was associated with improved outcome for patients with AML in first remission.¹⁰¹

The use of umbilical cord transplantation has been explored for patients with AML, and until recently was considered outside a clinical trial only when a sibling or suitable unrelated donor was not available. Two recent trials have recently demonstrated that although there are differences in rates of GVHD and time to engraftment with cord blood transplantation, long-term outcomes are similar to unrelated stem cell transplantation.^{102,103} Whether cord blood transplantation is equivalent to unrelated PBSC transplantation is unknown.

Transplantation for secondary AML

Therapy-related AML or AML arising from a myelodysplastic syndrome (collectively, secondary AML, sAML)

is considered incurable with standard chemotherapeutic approaches. Secondary AML is often associated with adverse cytogenetic features including loss of part or all of chromosome 7, loss of chromosome 5q, translocations involving *MLL* gene at 11q23, or a complex karyotype with multiple cytogenetic aberrations. As in de novo AML, these cytogenetic changes are associated with poor prognosis¹⁰⁴ and wherever possible a suitable allogeneic donor should be identified once secondary AML is diagnosed.^{105,106} Since many patients with sAML are of advanced age, the less toxic approaches of autologous and nonmyeloablative stem cell transplantation have been used with varying degrees of success. The EBMT reported outcomes in 173 patients with MDS or secondary AML who underwent autologous transplantation. The risk of relapse was 55%, which was higher than for allogeneic stem cell recipients.¹⁰⁷ There are currently no long-term studies supporting the use of autologous transplantation for sAML. Allogeneic transplantation is the preferred therapeutic modality, leading to long-term remission in approximately 20–30%, when ablative conditioning is utilized.^{105,108}

Acute promyelocytic leukemia

Acute promyelocytic leukemia (APL), associated with the t(15;17) translocation has the most favorable prognosis of the AMLs, with long-term remission rates of approximately 80% with ATRA-based induction strategies.¹⁰⁹ Nonetheless, relapses occur and frequently involve the CNS.¹¹⁰ Fortunately, reinduction with arsenic-based regimens is often successful at inducing second remissions.¹¹¹ As consolidative therapy for APL in second remission, both autologous and allogeneic transplant approaches have been attempted. Meloni et al. demonstrated the value of PCR testing for minimal residual disease in a series of patients who underwent autologous transplantation for APL in second clinical remission. Patients with detectable translocations between the *PML* and *RAR* α genes all relapsed, while the in patients without minimal residual disease by PCR relapsed rarely.¹¹² In a series of patients with APL in second clinical remission who received allogeneic stem cell transplants from HLA-identical siblings, long-term disease-free survival was 46%.¹¹³ Sustained remissions were noted even in patients with persistent minimal residual disease prior to transplantation. This suggests that an active GVL effect can cure APL, when autologous transplantation is not indicated. While autologous or allogeneic transplantation are generally only indicated for patients with APL in first remission when standard therapy cannot be administered, patients in second remission benefit from autologous transplantation, when minimal residual disease is undetectable or allogeneic transplantation when minimal residual disease persists.

Chapter 37

TRANSPLANTATION IN CHRONIC LEUKEMIA

Thomas S. Lin and Edward A. Copelan

CHRONIC MYELOGENOUS LEUKEMIA

Allogeneic stem cell transplantation is the only proven curative treatment for chronic myelogenous leukemia (CML). More allogeneic transplants have been performed for CML and more cures achieved than for any other disease. Paradoxically, while the results of transplantation in CML appear to be improving over the last several years, the number of allogeneic transplants for CML has decreased over the same period. This decrease has occurred as an increasing proportion of patients are placed on imatinib mesylate (Gleevec) as initial treatment and as a result of the effectiveness of this agent.

Important questions remain regarding the appropriate timing of allogeneic transplantation in the treatment of CML. First, which patients should undergo transplantation shortly after diagnosis? Secondly, when should patients who initially receive treatment with imatinib to be considered for transplantation? Although most clinicians are familiar with recent clinical studies with imatinib, many are less knowledgeable about the results of recent transplant studies. The following section details the current status of transplantation in CML.

MYELOABLATIVE ALLOGENEIC TRANSPLANTATION IN CML

Texts and review articles commonly provide a wide range of survival and mortality rates in patients with CML who undergo allogeneic transplantation.¹⁻⁵ The lower range of survival and higher range of mortality rates generally quoted are derived from studies of patients who underwent transplantation 20 or more years ago.⁶⁻¹¹ Results have improved with time.⁶⁻¹²

Allogeneic transplantation using myeloablative regimens works through two different mechanisms. The myeloablative regimen eradicates nearly all malignant cells in most patients. A retrospective analysis of iden-

tical twins with CML demonstrated a 3-year probability of leukemia-free survival of 59%, compared to 61% for HLA-identical sibling transplants.¹⁴ Although the 3-year probability of treatment-related mortality was only 3% for the twins, their risk of relapse was 40% at three years, compared to 7% for a cohort of HLA-identical sibling transplants. The fact that some patients with CML are cured by syngeneic transplants demonstrates that myeloablative therapy alone can eradicate all malignant cells in some patients. The higher relapse rate indicates a role for allogeneic cells in complete eradication of disease. Lower relapse rates in patients who undergo unrelated transplants and in those who develop graft-versus-host disease¹⁵⁻¹⁷ further support the importance of the allogeneic effect. The sustained elimination of Ph⁺ cells following infusion of donor lymphocytes, in patients who relapse following transplantation, is clear demonstration of the potency of the allogeneic affect.¹⁸⁻²⁰

MATCHED SIBLING TRANSPLANTS

Five-year estimates of leukemia-free survival following myeloablative transplantation using sibling donors do not precisely reflect rates of long-term disease-free survival in chronic phase CML. Extended follow-up demonstrates that deaths from chronic GVHD and relapses occur beyond 5 years.^{21,22} However, donor lymphocyte infusion (DLI) results in sustained leukemia-free survival in a substantial proportion of patients who relapse following transplantation, and who would be considered treatment failures by conventional analysis. "Current DFS"²³ more accurately assesses long-term results of allogeneic transplantation by appropriately recognizing patients who achieve sustained remission following DLI. With current approaches, including the use of DLI, approximately two-thirds of patients with chronic phase CML can be cured by myeloablative transplantation. Twenty-five to 30% of patients die from complications of transplantation, and 5% of relapsed disease.

Figure 37.1 Outcomes after transplantation using a targeted BU/CY regimen. Estimates of survival, DFS, and relapse at 3 years after transplantation are 86%, 78%, and 8%, respectively

Along with improvements in supportive care, modifications in preparative regimens may play an important role in improving results. Although busulfan has not been proven statistically superior to total body irradiation (TBI) as preparation for allogeneic transplantation, some studies report lower rates of transplant-related mortality and relapse, and higher rates of leukemia-free survival using busulfan.²⁴⁻²⁶ Continued refinement of busulfan-based regimens, including the use of intravenous busulfan^{27,28} and/or pharmacological targeting¹³ of busulfan, appears to improve results. Radich et al. reported that 78% of patients transplanted in Seattle have sustained leukemia-free survival using dose adjustment of busulfan to ensure “targeted” concentrations¹³ (Figure 37.1).

MYELOABLATIVE TRANSPLANTATION FROM UNRELATED DONORS

The outcomes in patients receiving unrelated transplants have improved more rapidly than have outcomes in patients with sibling donors. More sophisticated techniques for determining HLA compatibility and better understanding of the relative importance of matching of specific HLA antigens are largely responsible. Leukemia-free survival rates with well-matched unrelated donors in patients 40 years and younger, undergoing transplantation within a year of diagnosis, appear to be similar to those obtained with related donors.²⁹⁻³¹ Yet, patients without histocompatible sibling donors are rarely considered for transplantation early in the course of disease. Although identification of donors and procurement of stem cells can not be accomplished as quickly as for sibling donors, preliminary studies can be used to estimate the likelihood of finding a fully matched donor. In most cases, donor stem cells can be obtained expeditiously. Appropriate patients without sibling donors should be offered this potential therapy.

PROGNOSTIC FACTORS IN ALLOGENEIC TRANSPLANTATION

Identification of significant prognostic factors represents an important advance in transplantation in CML. In some situations, an understanding of these factors, such as the interval between diagnosis and transplantation, provides an opportunity to optimize results. In others it permits a more accurate assessment of outcome. Prognostic factors can also identify patients who would be at high risk for complications of transplantation, and for whom a transplant is not an appropriate therapy.

AGE

Older age is perceived by many to be among the most important adverse factors in transplantation. For allogeneic transplantation in general, the adverse influence of older age largely results from the favorable outcome of pediatric compared to adult patients.^{32,33} Differences between younger and older adults are less dramatic.

Studies using TBI in the preparative regimen for transplantation in CML have demonstrated a significant adverse influence of advancing age.^{34,35} The Seattle program described a significant adverse affect of age in CML using TBI, but not in patients who receive busulfan^{13,36,37} (Figure 37.2). Others have similarly failed to identify age as a significant independent prognostic factor in patients who receive busulfan.^{38,39} Results from Ohio State have demonstrated that the influence of age is attributable to other factors, including interval from diagnosis to transplantation, which is generally longer in older patients.³⁹

INTERVAL FROM DIAGNOSIS TO TRANSPLANTATION

The incidence of transplant-related mortality increases and leukemia-free survival decreases with prolongation of the interval from diagnosis to transplantation.

Figure 37.2 Effect of age on survival. There are no statistically significant differences in survival of patients aged younger than 40 years, 40 to 50 years, and older than 50 years ($p = 0.55$)

Although most studies have suggested a threshold at 1 or 2 years, at which point patients transplanted beyond this cutoff fare significantly worse, analysis of data from Ohio State demonstrates that interval is a continuous variable. Patients undergoing transplantation less than 3 months following diagnosis had 5 years of leukemia-free survival in excess of 90% (Figure 37.3).³⁹ Data from Seattle indicate favorable outcomes in patients who undergo transplantation fewer than 6 months from diagnosis.⁴⁰

The higher rate of transplant-related mortality associated with prolonged intervals between diagnosis and transplantation likely results from subclinical toxicities due to therapy. Prior busulfan⁴¹ and interferon therapy^{42,43} are associated with more regimen-related toxicity than hydroxyurea. The adverse influence of interferon is not seen with short-term treatment (<6 months)⁴⁴ or when therapy is discontinued at

least 3 months prior to transplantation.⁴⁵ Preliminary results of transplantation in patients who took imatinib have not generally indicated an adverse influence, but data suggesting a possible adverse affect have been presented.⁴⁶

PHASE OF DISEASE

The prior discussion refers to patients with chronic phase disease. Patients with accelerated or blastic phase disease have substantially worse outcomes with allogeneic transplantation. Approximately one in three patients with accelerated phase disease is cured by allogeneic transplantation.^{1-6,47} Higher rates of success have been reported in some studies; however, the use of different definitions of accelerated phase disease complicates interpretation of these data. Only one in ten patients with blastic phase disease is cured by transplantation.^{1-7,47}

Figure 37.3 The probability of event-free survival for patients with chronic phase chronic myelogenous leukemia undergoing allogeneic transplantation less than 3 months, 3 months to a year, or more than a year

Figure 37.4 No deaths occurred beyond 12 years in any group. Among low-risk patients, 12 in the matched group and four in the mismatched group have follow-up beyond 12 years and are indicated as censored observation at 12 years

DONOR SOURCE

Unrelated transplantation is perceived by many clinicians to be substantially more dangerous than transplantation using sibling donors. Although overall sustained LFS is roughly 10% lower using unrelated donors, according to international registry data, results in selected patients closely resemble those achievable with siblings. Patients aged 50 years or younger, with well-matched donors, who undergo transplantation within a year of diagnosis, have sustained survival rates of approximately 70%.²⁹

The difference in outcome between siblings and matched unrelated donors is closely related to the degree of HLA incompatibility between donor and recipient (Figure 37.4). Patients with chronic phase CML within 2 years of diagnosis, mismatched at a single HLA-A, B, C, DRB1, or DQB1 allele have a significantly worse outcome than their counterparts with no mismatch. A single mismatch of an HLA-C allele or antigen, an occurrence largely unrecognized historically because of the failure to prospectively match donor-recipient pairs at this site, confers a significantly increased risk of mortality.⁴⁹

Multiple mismatches further increase transplant risk. Those involving HLA-DQB increase mortality compared to those not involving HLA-DQB.⁴⁹ These findings emphasize the necessity of performance of and appropriate analysis of molecular typing of HLA alleles for donor selection.

MARROW VERSUS PERIPHERAL BLOOD

The use of peripheral blood cells have been associated with more rapid engraftment and less severe regimen-related toxicities, compared to marrow, in several studies.⁵⁰⁻⁵⁴ An increased incidence of chronic GVHD with peripheral blood cells has offset

this advantage, and most studies indicate similar overall outcomes.

APPROACH TO PATIENTS

The Gratwohl score estimates transplant outcome using age, disease, stage, interval from diagnosis to transplant, type of donor, and donor-recipient genders.³⁵ IBMTR data have confirmed the value of this model.⁵⁵

Newly diagnosed patients should be provided with extensive information on imatinib and on transplantation. Most patients who understand well the two approaches will determine their own initial treatment. Physicians must be certain that patients are well informed. Many do not understand the significant influence of treatment delay on transplant outcome, the ease with which the potential for unrelated donor matches can be determined, nor even that molecular evidence of disease is present in patients who respond well to imatinib.

For patients who receive imatinib as initial therapy, response to treatment is predictive of outcome. Patients who achieve a major cytogenetic remission have a prolonged survival. Those who achieve complete cytogenetic remission enjoy the greatest survival advantage.^{56,57} Quantitative assays demonstrate that patients who achieve complete cytogenetic remission with imatinib are more than twice as likely as those achieving complete remission with interferon plus cytarabine to have 3 log reductions in Bcr-Abl transcript levels.⁵⁸ All patients who achieve this level of reduction are free from progression at 2 years.^{58,59} These patients should continue imatinib until they demonstrate progressive disease.

At many centers, patients who fail to achieve substantial reductions in Bcr-Abl positive cells within

3–4 months, or a cytogenetic remission by 6 months, are considered for allogeneic transplantation without further delay. For patients who achieve cytogenetic remission, but later have progressive increase in the proportion of Bcr-Abl positive cells, transplantation is similarly considered without delay.

MANAGING RELAPSE

Relapse of CML occurs in approximately 10% of patients who undergo myeloablative allogeneic transplantation for chronic phase disease, and in more than 50% of patients with blastic phase disease. Higher relapse rates occur in identical twins and in T-cell depleted transplants, and lower relapse rates occur in patients developing GVHD. These data led to the use of donor lymphocyte infusions to treat patients who relapsed following allogeneic transplantation.^{19,20} A majority of patients who recur achieve sustained molecular remissions with appropriately administered DLI. Escalating dose schedules of DLI reduce the frequency of GVHD and marrow aplasia, and improve the effectiveness of this procedure.²⁰

Molecular testing for Bcr-Abl transcripts can be used to identify patients who are likely to relapse. Detection of Bcr-Abl transcripts 6 to 12 months following transplantation is highly predictive of subsequent relapse, whereas detection less than 3 months or more than 18 months from transplantation is less predictive.

Quantification of Bcr-Abl offers more reliable prediction of hematologic relapse. Patients with persistently high levels of transcripts or with increasing Bcr-Abl transcripts are highly likely to relapse.

REDUCED-INTENSITY STEM CELL TRANSPLANTATION

The desire to reduce transplant-related mortality, the effectiveness of donor lymphocyte infusions, and evidence in canine models that low doses of TBI provide sufficient immunosuppression to permit engraftment of histocompatible donor hematopoietic cells^{60,61} led to the development and application of reduced intensity regimens in CML.^{62–64} Although treatment was initially restricted to patients whose age or co-morbidities placed them at high risk for complications, present studies are designed to evaluate their effectiveness in a broader range of patients.

Reduced-intensity regimens result in less acute toxicity and reduced regimen-related morbidity and mortality.^{62–66} However, the incidence of severe GVHD may be similar to that seen with myeloablative regimens.^{65–67} Graft rejection^{68,69} and relapse occur more frequently,^{65,66,68–70} while infectious complications occur at a similar rate.^{66,68,71} These regimens permit allogeneic transplantation of individuals who would

not be considered good candidates for myeloablative transplantation. Their widespread application requires further investigation.

AUTOLOGOUS TRANSPLANTATION

Autografting using Ph-negative stem cells harvested during recovery from induction chemotherapy may result in short-term cytogenetic remission and prolonged survival modestly.^{72,73} However, Ph-positive hematopoiesis generally recurs quickly.

Several ongoing studies collect mobilized stem cells from patients who are not candidates for allogeneic transplantation and who achieve cytogenetic remissions with imatinib. When patients progress, autotransplantation is carried out. Such studies require sufficient accrual and follow-up to render meaningful results.⁷⁴

SUMMARY

Multiple areas of controversy surround the appropriate timing of transplantation in individuals with CML. Although the discussion focuses on transplantation as initial therapy, timing of transplantation in patients who first receive imatinib is equally important and more frequently encountered.

Age and the availability of a sibling donor are the two variables most commonly used to determine candidacy for transplantation as initial therapy. Older age does not appear to be a significant adverse factor for allogeneic transplantation when busulfan-based preparative regimens are used. Results with well-matched unrelated donors are similar to those achieved with sibling donors. The ability to assess preliminary results, estimate the probability of finding a suitable donor, and perform allogeneic transplantation quickly, has made early transplantation with unrelated donors a reasonable possibility in a sizable number of patients.

In patients who receive imatinib as initial treatment, monitoring Bcr-Abl transcript levels or, at the least, monitoring of marrow cytogenetics to evaluate initial response and early evidence of progression are vital to provide appropriate care. The effectiveness of reduced-intensity transplants, particularly in patients with progressive disease, has not been firmly established. Reduced-intensity transplantation and autografting should be performed only on appropriate clinical trials.

CHRONIC LYMPHOCYTIC LEUKEMIA

Chronic lymphocytic leukemia (CLL), the most common leukemia in the Western hemisphere, remains incurable with standard therapies. The increasing use

of genetic risk stratification factors, such as cytogenetic abnormalities,⁰⁰⁻⁰⁰ zeta-associated protein 70 (ZAP-70),⁰⁰⁻⁰⁰ and immunoglobulin heavy chain variable region (IgVH) mutational status⁰⁰⁻⁰⁰ allows physicians to identify high-risk patients who likely will fare poorly with standard chemotherapy. CLL patients with unmutated IgVH have a much poorer prognosis than patients with mutated CLL⁰⁰⁻⁰⁰ and comprise a target population for whom SCT should be considered. However, despite considerable interest in the use of SCT for CLL, the long-term survival benefit of SCT remains unclear in this disease. Autologous SCT has failed to demonstrate a durable long-term survival benefit, whereas myeloablative allogeneic SCT is associated with significant treatment-related mortality (TRM). Non-myeloablative allogeneic SCT has demonstrated promise, but long-term follow-up is lacking. The role of SCT in CLL has been extensively reviewed⁰⁰⁻⁰⁰; therefore, this section will focus on selected topics.

AUTOLOGOUS SCT

Studies of autologous SCT in CLL have produced mixed results, due to patient selection and the variable use of purging techniques. Disease-free survival (DFS) has ranged from 25% to 69%, with similar discrepancies in overall survival (OS).⁰⁰⁻⁰⁰ Until recently, the best results (63–69% 4-year DFS, 85–94% 4-year OS) were achieved using purged SCT in patients with relatively early disease.⁰⁰⁻⁰⁰ However, a British MRC study recently reported that autologous SCT using unpurged stem cells achieved 5-year DFS and OS rates of 78% and 52%, respectively, in 65 patients.⁰⁰⁻⁰⁰ Sixteen of 20 evaluable patients achieved molecular remission by PCR examination of IgVH gene rearrangement. The benefit of stem cell purging has not been demonstrated by randomized studies, and this recent British study showed that excellent results can be obtained without purging.⁰⁰⁻⁰⁰ Therefore, the use of stem cell purging should remain experimental.

The utility of autologous SCT in high-risk patients with unmutated IgVH has been examined. A retrospective German study of 58 CLL patients (20 mutated, 38 unmutated) showed that unmutated IgVH remained an adverse prognostic factor despite autologous SCT.⁰⁰⁻⁰⁰ Median time to clinical relapse was 37 months in the unmutated group, whereas only one mutated patient relapsed 4 years post-SCT; the 2-year probability of relapse was 19% and 0%, respectively, for unmutated and mutated patients. Nonetheless, unmutated patients still enjoyed a 2-year OS of 89%. A similar study examined 325 consecutive CLL patients enrolled on clinical studies at the University of Heidelberg.⁰⁰⁻⁰⁰ Forty-four patients who underwent autologous SCT were matched with 44 similar patients who received chemotherapy without SCT. Unmutated IgVH was

seen in 66% of both cohorts. Median survival from diagnosis for unmutated patients was 139 months for SCT, versus 73 months for chemotherapy, with a hazard ratio (HR) of 0.31 ($p = 0.02$). These studies demonstrate that, while patients with genetic risk factors, such as unmutated IgVH, still do poorly compared to good- or intermediate-risk patients who undergo autologous SCT, autologous SCT still confers benefit onto high-risk CLL patients. Thus, an autologous SCT as part of a clinical trial should be considered for poor-risk CLL patients who are unable to undergo allogeneic SCT.

Despite the promising results of these studies, the utility of autologous SCT in CLL is limited by several factors. Firstly, patients with CLL often have significant marrow and blood involvement that may result in contamination of the stem cell product despite cytoreductive therapy.⁰⁰⁻⁰⁰ Secondly, the predominant chemotherapeutic agent in CLL, fludarabine, is profoundly myelosuppressive and may hamper collection of an adequate number of autologous stem cells. For example, peripheral stem cell mobilization was unsuccessful in 33% of patients in the MRC study.⁰⁰⁻⁰⁰ Thirdly, the high-dose conditioning regimens used in autologous SCT are associated with a significant risk of secondary myelodysplasia (MDS) or AML; 8% of patients in the MRC study developed MDS/AML.⁰⁰⁻⁰⁰ Finally, extensive studies in follicle center lymphoma⁰⁰⁻⁰⁰ and multiple myeloma⁰⁰⁻⁰⁰ have not demonstrated that autologous SCT is curative in hematologic malignancies that are incurable with standard chemotherapy. In particular, this last factor has dampened enthusiasm for further studies of autologous SCT for CLL, particularly for patients who have an HLA-identical sibling donor. Given the limitations of autologous SCT, the major focus of clinical research in SCT for CLL has shifted to allogeneic SCT.

MYELOABLATIVE ALLOGENEIC SCT

Allogeneic SCT offers several theoretical advantages over autologous SCT in CLL. First, contamination of the stem cell source and inadequate stem cell collection are not obstacles for allogeneic SCT. Secondly, the use of an allogeneic donor allows for an immunological graft-versus-leukemia (GVL) effect. Although GVL is not as pronounced in allogeneic SCT for CLL as it is for CML, studies have demonstrated that this immunological effect is still important.⁰⁰⁻⁰⁰ Limited data suggest that TBI-containing conditioning regimens are superior to busulphan and cytotan (BuCy) in CLL. A small study of 25 patients by the Seattle group revealed a 100-day TRM of 57% for BuCy ($n = 7$), compared to 17% for TBI regimens ($n = 18$). Five-year actuarial survival was 56% for 14 patients transplanted with TBI regimens from 1992 to 1999.⁰⁰⁻⁰⁰ An MD

Anderson study of Cy/TBI in 28 CLL patients observed a 100-day TRM of 11%. Five-year PFS and OS were 78% and 78%, respectively, for chemo-sensitive patients, compared to 26% and 31% for refractory patients.⁰⁰⁻⁰⁰ Thus, TBI-containing myeloablative regimens offer the potential of long-term survival with acceptable TRM. Although results are superior for chemo-sensitive patients, myeloablative allogeneic SCT benefits a substantial minority of refractory patients.

Although prospective studies of myeloablative allogeneic SCT for CLL have been limited by small sample size and inadequate follow-up, large, retrospective multi-center registry analyses have examined the use of allogeneic SCT in large numbers of CLL patients.⁰⁰⁻⁰⁰ A retrospective EBMT study of 135 patients showed a 54% 3-year OS and 40% 100-day TRM.⁰⁰⁻⁰⁰ Similar findings were reported by the IBMTR, with a 45% 3-year OS and 30% 100-day TRM in 242 patients.⁰⁰⁻⁰⁰ Although patients in these analyses were relatively young (median age 45 and 47), with a median of only two prior therapies, the high TRM may be explained in part by the late stage of the disease in many of these patients. Median time from diagnosis to SCT was 41 and 46 months in the two studies, respectively,⁰⁰⁻⁰⁰ and 37% of patients in the EBMT study were chemo-refractory entering transplant.⁰⁰⁻⁰⁰ Although there are no randomized studies, a retrospective comparison showed a 3-year DFS of 57% for allogeneic SCT, versus 24% for purged autologous SCT.⁰⁰⁻⁰⁰

Thus, myeloablative allogeneic SCT may offer superior DFS in CLL, compared to autologous SCT. Although 3-year DFS after allogeneic SCT is approximately 50%,⁰⁰⁻⁰⁰ longer follow-up is needed to determine if this disease remission proves durable over time. However, the advantage in markedly decreased relapse rates with allogeneic SCT is offset by a higher TRM,⁰⁰⁻⁰⁰ decreasing enthusiasm for this treatment modality in CLL, which is often an indolent disease. Limited data indicate that Bu/Cy may be particularly toxic in this population; in contrast, TBI regimens appear to induce acceptable TRM.⁰⁰⁻⁰⁰ In order to preserve the immunological GVL effect while reducing TRM, the focus of clinical SCT research in CLL has turned to non-myeloablative allogeneic SCT in recent years (discussed below). However, the ability of myeloablative allogeneic SCT to achieve DFS in a significant minority of chemo-refractory patients indicates that a full allogeneic SCT should be considered for this group of patients. Cy/TBI or a similar TBI regimen should be considered for any CLL patient undergoing full alloeneic SCT.

NON-MYELOABLATIVE ALLOGENEIC SCT

The major focus of clinical transplant research in CLL has shifted to non-myeloablative allogeneic SCT. Ideally, the GVL effect of allogeneic SCT can be har-

nessed, while reducing TRM from acute GVHD, acute infection and organ toxicity associated with myeloablative SCT. Although many reports of non-myeloablative SCT have included CLL with other indolent lymphoproliferative diseases, such as follicle center lymphoma, several studies have specifically examined CLL.⁰⁰⁻⁰⁰ Fludarabine, busulfan, and ATG were administered to 30 German CLL patients; the stem cell source was a matched related ($n = 15$) or unrelated ($n = 15$) donor.⁰⁰⁻⁰⁰ Grade 2–4 acute GVHD was observed in 56% patients, while 75% developed chronic GVHD.⁰⁰⁻⁰⁰ Responses were seen in 93% patients, with 40% achieving CR. Of note, it took up to 2 years for patients to achieve CR, suggesting a GVL effect. All patients achieved a molecular CR by PCR, but only six patients were in continued molecular CR after a median follow-up of two years. Two-year TRM, PFS, and OS were 15%, 67%, and 72%, respectively.⁰⁰⁻⁰⁰

The EBMT retrospectively examined 77 CLL patients who received a variety of non-myeloablative conditioning regimens, followed by allogeneic SCT.⁰⁰⁻⁰⁰ Median follow-up was 18 months. Complete chimerism and best response were achieved a median of 3 months post-SCT. One-year TRM was 18%, and the 2-year probability of relapse was 31%. Two-year DFS and OS were 56% and 72%, respectively. Nineteen patients received donor lymphocyte infusion (DLI) for relapse or incomplete donor chimerism, but only seven responded to DLI (37%). Unfortunately, the interpretation of this study was compromised by the heterogeneity of conditioning regimens, and the use of ATG or Campath-1H for T-cell depletion in 40% of patients.

A recent, small German study indicated that non-myeloablative allogeneic SCT may be superior to autologous SCT in obtaining clinical and molecular remissions in high-risk CLL patients with unmutated IgVH, due to a GVL effect. Seven of nine patients (78%) became negative by PCR for allele-specific IgVH after day + 100 post-SCT; attainment of molecular CR occurred after DLI or development of chronic GVHD. In contrast, only six of 26 control CLL patients (23%) achieved a PCR-negative state after autologous SCT.⁰⁰⁻⁰⁰ Thus, an immunological GVL effect appears to be important in CLL and may confer a long-term survival advantage for allogeneic over autologous SCT, given sufficient time. Finally, the MD Anderson administered fludarabine and cyclophosphamide to 17 patients, 10 of whom also received rituximab, followed by allogeneic SCT.⁰⁰⁻⁰⁰ Ten patients subsequently received DLI for persistent CLL; 7 achieved a CR, and 2 a PR. Of the 17 patients, 12 achieved a CR and 4 a PR, for an overall response rate of 94%. Interestingly, OS was 100% for patients who received rituximab with conditioning, compared to 14% for patients who did not. Although these results were intriguing, this was a small study, and it is unclear how rituximab may augment or facilitate the GVL effect of allogeneic SCT in CLL.

SUMMARY

Despite advances in chemotherapy for CLL, this disease remains incurable by standard therapies. Thus, SCT should be considered, especially for younger patients and patients with high-risk genetic features who likely will do poorly with chemotherapy. Non-myeloablative allogeneic SCT is the most promising transplant modality in CLL, and is the focus of most clinical transplant studies in CLL. Short-term DFS of 50–75% has been obtained with acceptable TRM, and molecular responses have been obtained with the onset of GVHD or the therapeutic use of DLI. However, long-term follow-up is lacking, and it is unclear

whether the DFS observed during 2 years will prove durable over time. Myeloablative allogeneic SCTs should be considered for patients with bulky or refractory disease; a TBI-containing regimen should be used to reduce TRM. Finally, autologous SCT should be considered for high-risk CLL patients who do not have an allogeneic option. Although autologous SCT has not proven curative in CLL, it still confers a survival advantage on patients with unmutated IgVH. However, it is necessary to limit the number of prior therapies, particularly fludarabine-based regimens, given that insufficient stem cells are collected from a third or more of CLL patients being considered for autologous SCT.

MYELODYSPLASTIC SYNDROMES

Chapter **38**

MYELODYSPLASTIC SYNDROMES: MOLECULAR BIOLOGY, PATHOLOGY, AND CYTOGENETICS

Rami Komrokji and John M Bennett

INTRODUCTION

The myelodysplastic syndrome (MDS) is a heterogeneous group of clonal neoplastic stem cell disorders. The disease is characterized clinically by bone marrow failure with peripheral cytopenias and a tendency to progress to acute myeloid leukemia (AML). Pathologically, dysplastic morphologic features in the peripheral blood and bone marrow gives the disease its misnomer as myelodysplastic syndrome, although it is truly neoplastic.¹

The recognition and classification of MDS have evolved over the years as we learn more about the disease. The description of refractory anemia early in the past century was followed by the observation of progression to leukemia. MDS was then recognized as a primary bone marrow failure disorder. The French-American-British classification (FAB) and its revision addressed the heterogeneity in the subtypes and noted the variability in progression to AML.^{2,3} The new World Health Organization (WHO) classification refined the FAB classification in an attempt to better predict outcome by using more homogenous and distinct subgroups.⁴

MDS is predominantly a disease of the older adults, probably reflecting the requirement of multiple and prolonged leukemogens for the disease to develop. MDS may be more common than chronic lymphocytic

leukemia (CLL). The estimated incidence is 4/100,000 US citizens per year and it increases with age.⁵ Majority of patients will succumb to the disease, more so because of infections and their complications rather than AML evolution.⁶ Only one third of patients will eventually progress to AML, a process that may result from accumulating further DNA damage, as well as from clonal evolution.

PATHOGENESIS MODEL

The occurrence of MDS is best viewed in the framework of a multi-hit theory. Hereditary and multiple environmental factors result in a neoplastic stem cell clone.⁷ The MDS clone is characterized by altered gene functions; the gene alterations result either from single-gene mutations, chromosomal abnormalities (mostly deletions), or gene silencing. Many of those altered genes are suppressor genes that function in a recessive manner. Various gene alterations of MDS clone result in an intrinsic increase in the susceptibility of the clone to apoptosis. MDS clone is also recognized by the immune system leading, in some cases, to clonal T-cell proliferation that leads to release of various cytokines, including TNF alpha.⁸⁻¹⁰ The cytokines cause the apoptosis of the MDS clone and of normal hematopoietic cells.¹¹ This

intrinsic and immune-mediated susceptibility to apoptosis are the hallmarks of early MDS pathogenesis, explaining the clinical findings of peripheral cytopenias despite a hypercellular bone marrow.¹²

EVIDENCE OF CLONALITY

The neoplastic MDS clone arises from a pluripotent stem cell. The evidence of clonality was originally demonstrated through G6PD mosaicism.¹³ Subsequently, cytogenetic studies revealed two clones with and without trisomy eight in patients with sideroblastic anemia.¹⁴ Clonality is also supported by restriction fragment length polymorphisms (RFLPs) of X-chromosome genes and by the use of fluorescence in-situ hybridization (FISH).¹⁵ The assay is based on differences in X chromosome inactivation patterns between normal and neoplastic tissues of female patients. In a polyclonal cell population, the maternal X chromosome is active in half the cells and inactive in the other half, while in a monoclonal cell population, the maternal X chromosome is either active or inactive in all the cells. This difference in the pattern of X chromosome inactivation between normal and neoplastic cell populations can be demonstrated, in females heterozygous for a particular RFLP, by a Southern blot analysis using X-linked DNA probes with restriction enzymes capable of differentially cleaving the material from the paternal X chromosome on one hand, and the active from the inactive X chromosome on the other. Several studies have also shown evidence of clonality in lymphoid lineages as well, suggesting that the MDS clone arises from early pluripotent stem cells capable of myeloid and lymphoid differentiation.^{16,17} Karyotypic evolution and complex karyotypic changes may occur with progression of MDS and transformation to AML.

GENE ALTERATIONS

Loss or gain of gene function can result from single-gene mutations, chromosomal translocations (unbalanced or balanced), and epigenetic alterations, such as silencing of gene expression by hypermethylation. The net result is either gain of an oncogene function or loss of tumor-suppressor gene function. Tumor-suppressor gene function in a recessive fashion that requires loss of both alleles.¹⁸ Haploinsufficiency (loss of a single gene copy) can result in reduction of the gene products and a predisposition to malignancies.¹⁹

The RAS gene family is the most studied in MDS. Ten to forty percent of patients with MDS have RAS mutations. The most common mutation is a single base change at codon 12 of the N-RAS family. The resultant mutated N-RAS protein retains an active GTP form, promoting continuous signaling to the nucleus. N-RAS mutations carry a higher risk of AML transformation and portend a worse prognosis.

Other gene mutations described in MDS include P53 tumor suppression gene (5–10% of cases);²⁰ FLT3 oncogene receptor tyrosine kinase (5% of cases);²¹ P15 ink4b, a tumor suppressor gene that is transcriptionally repressed through promoter silencing by hypermethylation (can be present in up to 50% of high-grade MDS).²² The abnormality is seen with the 7q- syndrome and is associated with shorter survival.²³ Microsatellite instability (MSI) resulting from defective mismatch repair genes (MMR) has been described particularly in therapy related MDS (t-MDS).²⁴ Table 38.1 lists a few of the described genes that are altered in MDS.

Certain co-existing gene mutations may increase the individual susceptibility to develop MDS; the NQO1 gene mutation increases the risk for t-MDS in both the homozygotic and heterozygotic states. NQO1 is a quinone oxidoreductase required for detoxifying benzene derivatives.^{25,26}

Table 38.1 Altered genes in MDS

Gene	Abnormality	Significance in MDS	Function
BCL-2	Overexpression	High risk MDS	Anti-apoptosis
CSF1R/FMS	Mutation	High risk MDS	Encodes macrophage CSF
GCSFR	Mutation	Congenital neutropenia and progression to MDS/AML	Encodes G-CSF receptor
FLT 3	Internal tandem duplication	High risk MDS, progression to AML	Encodes tyrosine kinase receptor
MDR1	Expressed	Drug resistance	Transmembrane efflux pump
MPL	Overexpressed	High risk MDS	Encodes thrombopoietin receptor
NF1	Mutation	Pediatric MDS	Tumor suppressor gene
NRAS	Mutation	Early MDS	Cell signaling pathway
P15 ink4b	Hypermethylation	High risk MDS	Cycline-dependent kinase inhibitor
P53	Mutation	Early and high risk MDS, poor prognosis	Arrests cell cycle to allow DNA damage repair
Telomerase	Increase activity	High risk MDS	Maintain telomere length

MICROARRAY ANALYSIS IN MDS

The introduction of microarray analysis revolutionized the analysis of gene profiles. Not only can thousands of genes be analyzed together, but the technique also identifies gene profiles, “molecular signatures” that can help refine the disease, categorize its subtypes, better predict outcomes, and hopefully tailor therapies.

Microarray analysis studies in MDS identified new important genes, profiles that may help distinguish MDS from AML, as well as low risk from high risk MDS. In one study, investigators were able to discriminate between healthy control bone marrow samples and samples from MDS patients using the expression profile of 11 selected genes representing different gene classes. The gene expression profile was also able to discriminate between low risk and high risk MDS. The retinoic acid induced gene (RAI3), radiation-inducible immediate early response gene (IEX1), and the stress-induced phosphoprotein 1 (STIP1) gene were among the genes down-regulated in low risk MDS reflecting that the CD34 MDS, stem cells may lack the defensive proteins and thus be more susceptible to damage.²⁷ In another study, researchers were able to distinguish between AML blasts and MDS blasts by using gene profiles. Delta-like gene (Dlk), Tec gene, and inositol 1,4,5-triphosphate receptor type 1 gene were among those highly specific for MDS. The Dlk 1 gene, for example, may be an important gene in cell proliferation and may allow stromal cells to support stem cells.²⁸ Gene sets identified for early stage MDS included the PIASy gene (PIAS family are a group of signaling proteins), which functions as a tumor-suppressor gene. As MDS progresses and transforms to AML, those gene expressions are decreased.²⁹

CYTOGENETICS

Chromosomal abnormalities are described in 40–70% of all MDS cases.³⁰ Chromosomal abnormalities usually consist of an unbalanced loss, deletion, or translocation. It may be surprising to find a normal karyotype in 30–60% of a clonal disease; however, this could be explained by technical failures, as well as karyotypic evolution over time. A normal karyotype does, however, carry a better prognosis, similar to the 5q- syndrome, 20q-, or loss of chromosome Y. A complex karyotype is defined as the presence of three or more different cytogenetic abnormalities. It occurs in 10–20% of primary MDS and in up to 90% of therapy-related MDS.³¹ More cytogenetic abnormalities occur in high risk MDS and therapy related MDS. The reported frequency of cytogenetic abnormalities under the new WHO classification are: refractory anemia 25%; refractory anemia with ring sideroblasts 10%; refractory

Table 38.2 Cytogenetic abnormalities in MDS

Cytogenetic abnormality	Primary MDS	Therapy-related MDS
All over	40–70%	80–90%
-5/ del (5q)	10–20%	90% -5 or -7
-7/ del (7q)	5–10%	
+8	10%	10%
-Y	10%	
17 p-	7%	
del(20q)	5%	
t(11q23)	5–6%	3%
Complex karyotype	10–20%	90%

cytopenia with multi-lineage dysplasia 50%; and refractory anemia with excess blasts type I & II 30–50%.³² Cytogenetic abnormalities do not correlate with WHO subtypes, except for the 5q- syndrome, which represents a separate entity, and isodenticent X chromosome associated with ring sideroblasts.³¹

LOSS OF CHROMOSOME 5/del(5q)

Loss of chromosome 5 or interstitial deletion of its long arm is one of the most common chromosomal abnormalities described in primary and therapy-related MDS (see Table 38.2). This abnormality is associated with previous exposure to carcinogens, including benzene, alkylating agents, and radiation.³³ This -5/del(5q) abnormality is distinguished from the 5q- syndrome. The 5q- syndrome is associated with a macrocytic anemia and often thrombocytosis. It occurs more commonly in upper middle age females, and carries the best prognosis of MDS subtypes. The deletion in the 5q- syndrome breakpoint, which involves band 5q33, contains a different myeloid tumor-suppressor gene from the 5q31 band that is commonly involved in -5/del (5q).³¹

LOSS OF CHROMOSOME 7/Del(7q)

Monosomy 7 or deletion of the long arm of chromosome 7 is well described in therapy-related MDS and primary MDS (see Table 38.2). The breakpoint 7q22 is more commonly associated with MDS cases. A monosomy 7 syndrome entity is described in the pediatric literature, and is common in juvenile myelomonocytic leukemia (JMML). Interestingly, -7/del(7q) is the most common abnormality described in patients with hereditary predispositions to MDS, such as Fanconi anemia.^{31,34}

Loss of 7q is associated with AML1 gene mutations. Monosomy 7 or deletion of the long arm of chromosome 7 is associated with a poor outcome in children and adults.

TRISOMY 8

Trisomy 8 is described in different hematological malignancies including MDS. Its significance is not well understood.^{31,34}

LOSS OF Y CHROMOSOME

Loss of chromosome Y is described in patients with hematological and non-hematological diseases, and by itself does not represent diagnostic evidence of a hematological process.³⁵ Once present, however, in MDS it may carry a favorable prognosis.

LOSS OF THE SHORT ARM OF CHROMOSOME 17

17p syndrome is associated morphologically with the classical pseudo-Pelger-Huët hypolobulation. The p53 gene is located on 17p13.1 and is often involved in this syndrome.³¹

DELETION OF THE LONG ARM OF CHROMOSOME 20

Del (20q) carries a favorable prognosis as an isolated abnormality. It is more often seen in early MDS. Prominent erythrocytic and megakaryocytic dysplasia is often seen. Mature granulocytes from the peripheral blood may lack the abnormality, suggesting an increased propensity for apoptosis in the clone carrying this abnormality.^{31,34} Isochromosome 20q with loss of interstitial material i (20q-) was described recently in six MDS patients out of a registry of 998. This was seen more commonly in older patients, whose MDS behaved different clinically from the 20q-syndrome, with its rapid progression and shorter survival. The i (20q-) could represent a further evolution of the 20q karyotype, thus predicting disease progression.³⁶

11q23 SYNDROME

Translocations involving 11q23 are classically described in therapy-related MDS secondary to topoisomerase II class drugs.^{37,38} The MLL (mixed lineage leukemia) gene is located on 11q23, and in acute leukemia usually portends a poor prognosis. The exact involvement of the MLL gene in primary MDS is not well defined.³⁴

OTHER CHROMOSOMAL ABNORMALITIES

t(5;12)(q33;p13) occurs in 2–3% of CMML cases. The translocation results in a fusion oncogene TEL/PDGFR. TEL is a transcription factor gene located on chromosome 12p13.1. It is involved in angiogenesis and hematopoiesis. TEL fuses to the transmembrane and cytoplasmic domains of PDGFR, replacing the ligand-binding site, and leads to autoactivation of the PDGFR.^{39,40} CMML patients with this translocation may benefit from therapy with imatinib mesylate as well as other tyrosine kinase inhibitors.^{40–42} Other translocations reported in CMML includes: t(5;17)(q33;p13) (Rabaptin-5/PDGFR),⁴³ t(5;7)(q33;p11.2) (HIP1/PDGFR),⁴⁴ and t(5;10)(q33;q21) (H4-D10S170/PDGFR).⁴³ Cytogenetic abnormalities are seen in 20–30% of CMML cases.⁴⁵

t(3,21) is described in t-MDS/AML. EAP (Epstein-Barr virus small RNAs associated protein) at 3q26 fuses

to the RUNX1 gene (AML gene) on 21q22 leading to truncation of RUNX1 and loss of its function. Two other genes described on 3q26 include EVI1 (ecotropic virus infection site) and MDS/EVI1 (MDS associated sequences). The MDS/EVI1 gene fuses to RUNX1, leading to a different EVI1 protein.³¹ Patients with MDS who have EVI1 abnormalities may benefit from therapy with arsenic trioxide.

The Philadelphia chromosome t(9,22) has been described in MDS. Ph+MDS patients had a median survival of 13 months in one review.⁴⁶ Translocations seen in AML, such as t(8,21) or inv(16), have also been described in MDS.

CYTOGENETICS AND PROGNOSIS OVERVIEW

The international prognostic scoring system (IPSS) is one of the best available systems to predict prognosis and AML evolution in MDS. The IPSS was developed by the international MDS risk analysis workshop. Data were pooled from seven previous studies that used independent risk-based prognostic systems. In a multivariate analysis age, gender, cytogenetics, cytopenias, and bone marrow blasts were significant independent prognostic variables.⁴⁷

According to cytogenetics, patients were placed into three categories: a good prognosis group with normal cytogenetics, –Y, del(5q), and del(20q); a poor prognosis group, including patients with three or more cytogenetic anomalies or chromosome 7 anomalies; and other anomalies, classified in the intermediate group. The median survival in years for good, intermediate, and poor prognosis groups were 3.8, 2.4, and 0.8 years, respectively. The time to 25% AML evolution was 5.6, 1.6, and 0.9 years, respectively.^{47,48}

APOPTOSIS IN MDS

Apoptosis may carry the explanation for the paradoxical observation of peripheral cytopenias and a normo- or hypercellular bone marrow in MDS.^{49,12} Evidence of apoptosis in MDS is supported by various techniques. Apoptosis was first observed by electron microscopic examination of the bone marrow in MDS patients. Evidence of apoptosis was also shown by biochemical techniques, in situ methods, and flow cytometric studies.¹²

Apoptosis seems to be greater in the early stages of MDS and decreases as MDS progresses and transforms to AML. Flow cytometric studies revealed that the proportion of CD34+ cells in G1-DNA phase is higher in early MDS. Also, the ratio of c-Myc (a pro-apoptotic gene) to BCL 2 (an anti-apoptotic gene) decreases as MDS progresses to AML.⁵⁰ It is controversial whether apoptosis is restricted to CD34+ progenitors, or whether it also includes mature cells.¹²

Several mechanisms can explain the observation of excessive apoptosis in MDS. The MDS clone itself may

carry an intrinsic liability for apoptosis due to altered gene functions and expression; however, there is a lack of correlation between cytogenetic abnormalities and apoptosis, suggesting that the phenomenon is not only restricted to the MDS clone.^{51,52} Increased apoptosis in MDS could also be secondary to inhibitory cytokines (mainly TNF- α) that can induce apoptosis and may affect both the MDS clone and normal cells.^{53,54} Increased expression of FAS ligand (CD 95 cell surface protein) in MDS bone marrow cells could also be one of the mechanisms contributing to apoptosis.⁵⁵ Other potential mechanisms include cell cycle abnormalities and mitochondrial abnormalities leading to increased apoptosis. Mutations of mitochondrial DNA may also impair iron metabolism, contributing to sideroblastic anemia.¹²

MICROENVIRONMENT IN MDS

The hematopoietic microenvironment refers to the fibroblasts, adipose cells, macrophages, endothelial cells, and the supportive matrix of the bone marrow.⁵⁶ Though still somewhat controversial, there is growing evidence that abnormalities of the supporting stroma affect its ability to effectively support normal hematopoiesis in MDS.⁵⁶⁻⁵⁹

Using *in vitro* studies, abnormalities of the hematopoietic microenvironment in patients with MDS were demonstrated.⁶⁰ Adherent cell layers were developed in long-term bone marrow cultures (LTMC) from MDS patients and normal marrows. The adherent cell layer consisted of a mixture of cells, mostly fibroblasts and macrophages. Morphologically, the adherent cell layer appeared to be normal in MDS, however, it produced more IL-6 and TNF compared to normal bone marrow. The adherent cell layers were then separated into macrophage, and fibroblast-enriched cell layers, both of which demonstrated increased apoptosis. The macrophage-enriched cell layer produced significantly higher TNF- α , while the fibroblast-enriched layer produced significantly higher IL-6 than normal marrows. A dysfunctional stroma may also contribute to the pathogenesis of MDS. Reports of donor cell leukemia or MDS after allogeneic stem cell transplant may represent supporting evidence for the role of the microenvironment and stroma in disease pathogenesis.⁶¹

PATHOLOGY

Pathological dysplastic features are the hallmark of MDS. The diagnosis of MDS requires careful examination of the peripheral blood, bone marrow aspirate, and core biopsy. MDS is a diagnosis of exclusion, and no single dysplastic or morphological feature is pathognomonic. The pathological examination should provide information regarding the presence of dysplasia, the cell

lines involved, the percentage of bone marrow blasts, and the presence and percentage of ring sideroblasts.

The French-American-British (FAB) system served as the gold standard classification for MDS for more than 20 years.^{2,3} The new WHO classification was built on the FAB classification system with further attempts to refine the classification.⁴ Table (38.3) summarizes the WHO subtypes and the required criteria for the diagnosis of each. Briefly, the major changes in the WHO classification include the introduction of multi-lineage dysplasia (defined as more than 10% dysplastic progeny of two or more cell lines and less than 5% blasts) and preservation of the subtypes refractory anemia and refractory anemia with ring sideroblasts to uni-lineage dysplasia and less than 10% dysplasia in either the myeloid or the megakaryocytic cell lines. Refractory anemia with excess blasts is subdivided into type I (5-9% blasts) and type II (10-19%) blasts. Refractory anemia with excess blasts in transformation is eliminated and the threshold for diagnosis of AML is lowered to 20% blasts instead of 30% blasts. Chronic myelomonocytic leukemia is moved to a separate category (myelodysplastic/myeloproliferative disorders) along with atypical chronic myelogenous leukemia (CML) and JMML. Finally, the 5q- syndrome is recognized as a distinct entity due to its unique clinical presentation and favorable outcome.^{32,62,48}

The recommendations for the diagnosis of MDS are the same in the WHO and FAB classifications.³² Peripheral blood and a bone marrow aspirate and biopsy should be examined. Cytogenetics should be tested when feasible. The standard stains (Romanowsky, hematoxylin and eosin) should be done, in addition to the Prussian blue stain for iron and the reticulin stain for fibrosis. Silver stains may reveal sideroblasts in cases of iron deficiency anemia.⁶³ To determine the percentage of blasts, a 500-cell differential should be performed on the bone marrow and a 200-cell differentiation on the peripheral blood.

The dysplastic features in the bone marrow and peripheral blood include:

Dyserythropoietic features: In the bone marrow these include multinuclearity, nuclear fragments, megakaryoblastoid changes, cytoplasmic abnormalities, and increased erythroblasts (Figure 38.1(a) and (b)). In the peripheral blood manifestations may include poikilocytosis, anisocytosis, nucleated red blood cells, and basophilic stippling.

Dysgranulopoietic features: These include hypolobulation, nuclear sticks, ring-shaped nuclei, and hypogranulation. The classical pseudo-Pelger-Huët neutrophils should be seen in more than 10% of the peripheral neutrophils (Figure 38.1(a)).

Dysmegakaryocytopoietic features: These include micromegakaryocytes, large mononuclear forms, and multiple small nuclei (Figure 38.1(c)).

Abnormal sideroblasts: These are defined by five or more iron granules. When the granules encircle one third or more of the nucleus in iron stained smears, the term

Table 38.3 The WHO classification of MDS and required criteria for diagnosis

Category	Percentage of MDS cases	Peripheral blood	Bone marrow
Refractory anemia (RA)	5–10%	Anemia <1% blasts < 1×10^9 monocytes	Erythroid dysplasia < 10 % myeloid or megakaryocytic dysplasia < 5% blasts < 15% sideroblasts
Refractory anemia with ring sideroblasts (RARS)	10–15%	Anemia < 1% blasts < 1×10^9 monocytes	Erythroid dysplasia < 10 % myeloid or megakaryocytic dysplasia < 5% blasts > 15% sideroblasts
Refractory cytopenia with multilineage dysplasia (RCMD)	24%	Bi-or pancytopenia < 1% blasts < 1×10^9 monocytes	Dysplasia in > 10% of the cells in two or more cell lines < 5% blasts in BM < 15% sideroblasts
Refractory anemia with multilineage dysplasia and ring sideroblasts (RCMD-RS)	15%	Bi-or pancytopenia < 1% blasts < 1×10^9 monocytes	Dysplasia in > 10% of the cells in two or more cell lines < 5% blasts in BM > 15% sideroblasts
Refractory anemia with excess blasts type I and II (RAEB-1 & RAEB II)	40%	Cytopenia Type I: 1–5% blasts Type II: 6–19% blasts	Uni or multilineage dysplasia Type I 5–9% blasts Type II 10–19% blasts
5q syndrome	?	Normal or elevated platelets < 5% blasts	Normal or increased megakaryocytes < 5% blasts
MDS unclassified (MDS-U)	?	Cytopenia < 1% blasts	Unilineage dyplasia of myeloid or megakaryocytic line < 5% blasts

“ringed sideroblast” is applied (Figure 38.1(d)). Ring sideroblast MDS subtypes have more than 15% ring sideroblasts and less than 5% blasts.

In addition to the aspirate, the bone marrow biopsy may give helpful information. A bone marrow biopsy allows for a better assessment of cellularity. MDS bone marrow is typically normo or hypercellular;⁶⁴ however, hypoplastic MDS, an entity that resembles aplastic anemia, could be challenging to differentiate from aplastic anemia or hypocellular AML.⁶⁵ A bone marrow biopsy can also help assess the degree of fibrosis, as in 50% of MDS cases some degree of fibrosis may be seen on reticulin stains.^{66,67} Dysmegakaryocytes may be easier to identify on a bone marrow biopsy. Finally, identification of abnormal localization of immature precursors (ALIP) may carry a poor prognosis. ALIP are defined as the presence of three or more foci of immature cells—myeloblasts or promyelocytes—displaced from the paratrabeular area to the intertrabeular areas.⁶⁸

Cytochemical and immunocytochemical stains could be an adjunct in the diagnosis of MDS in identifying its subtypes. Peroxidase and Sudan Black stains are helpful in distinguishing the myeloid origin of the blasts, though peroxidase can decrease over the course of MDS.⁶⁹ Esterase and double esterase stain can help distinguish dysplastic granulocytes from early monocytes.⁷⁰ Staining megakaryocytes for GP IIb/IIIa using alkaline phosphatase anti-alkaline phosphatase (APAAP)

can help distinguish small dysplastic megakaryocytes that could be mistaken for lymphocytes.⁷¹ Flow cytometry can detect immunophenotypic abnormalities in cases when combined morphology and cytogenetics are nondiagnostic.⁷² Immunophenotypic myeloid dysplasia features include hypogranular neutrophils based on orthogonal scatter, CD64 negativity, and low CD11b, CD16, and CD13 expression. Erythroid immunophenotypic dysplasia includes decreased CD71 (transferrin receptor) expression on glycoprotein A+ precursors. Megakaryocytic lineage dysplasia is, however, difficult to recognize currently immunophenotypically.

SUMMARY

The myelodysplastic syndromes are heterogeneous clonal stem cell disorders characterized by dysplastic pathological features, clinical peripheral cytopenias, and a tendency to progress to AML.

The pathogenesis of MDS includes clonal gene function alterations due to single-gene alteration, chromosomal abnormalities or epigenetic phenomenon. Apoptosis can explain the paradoxical observation of peripheral cytopenias and normo- or hypercellular bone marrow. Different mechanisms, such as abnormal cytokines production and intrinsic clonal susceptibility lead to excessive apoptosis. Alterations in the

Figure 38.1 Bone marrow: (a) megaloblastoid erythroid precursor, pseudo-Pelger-Huët neutrophils (bilobed and hypogranular), and a myeloblast with Auer rods; (b) dysplastic erythroid precursors, bi-nucleated erythroid precursor, and a myeloblast; (c) mononuclear and micromegakaryocytes; (d) Prussian blue stain of the bone marrow showing a ring sideroblast

immune system and bone marrow microenvironment clearly contribute to the development of MDS.

Pathologically, dysplasia is the hallmark of the disease. A careful pathological exam of the peripheral blood and bone marrow aspirate, and biopsy is necessary for diagnosis and better classification. MDS remains a diagnosis of exclusion. Cytogenetic testing using conventional analysis as well as molecular methods, such as fluorescence in-situ hybridization should be done when feasible. The clinician should use the information from pathologic examination and cyto-

netic testing to better classify the disease, predict the prognosis, and hopefully tailor the treatment.

In the future, we will continue to explore the molecular biology and different pathogenetic aspects of the disease to develop a better understanding and to translate the basic science findings into targeted therapies. The new WHO classification may allow us to classify the disease into more homogenous classes, to develop treatments for those subtypes, and to continue refining the classification, as we understand the biology and behavior of the disease.

Chapter 39

CLINICAL FEATURES AND MAKING THE DIAGNOSIS OF MYELODYSPLASTIC SYNDROMES

Lewis R. Silverman

CLINICAL FEATURES

PHYSICAL: SIGNS, SYMPTOMS, AND EXAM

Although the myelodysplastic syndromes (MDS) have occasionally been described in children and adolescents, they are primarily encountered in adults in their sixth decade or older.^{1,2} In most reports, the median age is over 65 and there appears to be a male predominance.^{2,3} The clinical and laboratory presentation, although nonspecific in most patients, is dominated by and often reflects the fact that MDS derives from a defect involving a multipotent hematopoietic stem cell affecting one or more cell lineages.

Symptoms relate primarily to the peripheral blood cytopenias, with those attributable to anemia being most common. These may produce signs and symptoms on their own, or exacerbate those attributable to other pre-existing comorbid conditions. Most patients present for medical evaluation because of complaints relating to these symptoms. These include weakness, fatigue, dyspnea, poor exercise tolerance, angina pectoris, pallor, and signs of cardiac failure relating to the degree of anemia. Signs and symptoms in association with neutropenia and thrombocytopenia are encountered less frequently. These include bacterial infections involving the lungs, kidneys, bladder, and skin; easy bruising, ecchymosis, petechiae, epistaxis, gingival bleeding, and hematuria. Patients with severe thrombocytopenia (i.e., platelets $<20 \times 10^9/L$) may manifest life threatening gastrointestinal, pulmonary, gynecologic, or neurologic hemorrhage.

Physical findings are also nonspecific. The exam will often reveal signs relating to the underlying cytopenias. Hepatic and/or splenic enlargement are reported in 10–40% of patients and are most commonly found in chronic myelomonocytic leukemia (CMML). Lymphadenopathy and skin infiltration are uncommon,^{4–9} although the appearance of leukemia cutis in patients with MDS may herald the transformation to acute leukemia by weeks or months. Identification of leukemia cutis may also signal the development of a more

aggressive clinical course, and in one study appeared to be associated with a poor prognosis.¹⁰ Similar to patients with AML, patients with MDS develop Sweet's syndrome (neutrophilic dermatosis).^{11,12} Other skin findings include vasculitis and pyoderma gangrenosum.^{12,13}

LABORATORY

Hematologic laboratory findings demonstrate peripheral blood cytopenias in one or more cell lines associated with dysmorphic features. These reflect dysmaturation of one or more of the cell lines and are detailed in Table 39.1. These maturational defects may be identified not only in the lines with diminished production but may also be seen in the lines where bone marrow production is still conserved. The bone marrow is most often hypercellular and features morphologic abnormalities involving one, two, or all of the cell lineages (Table 39.1 and Figures 39.1 and 39.2). The dysmorphic features are critical to establish the diagnosis, and both the French–American–British (FAB) and World Health Organization (WHO) classification systems are based primarily on these findings (see Chapter 38). A diagnosis without maturational abnormalities in at least one cell line would be difficult to support.

Histologic examination of bone marrow trephine biopsies by Tricot and colleagues have pointed to abnormalities of the microenvironment.¹⁴ They noted the presence of clusters of immature precursor cells in the central intertrabecular region of the marrow, rather than along the endosteal surfaces. They cited this as evidence of abnormal localization of immature precursors (ALIP).^{14,15} ALIP was detected even before bone marrow smears revealed an excess of blasts. In a series of 40 patients, the presence of ALIP correlated significantly with shortened survival and was associated with an increased risk of transformation to AML. These findings were independent of the FAB subtype and were detected even in patients with refractory

Table 39.1 Morphologic and functional cellular abnormalities

<i>Erythrocytes</i>	<i>Enzymes</i>
<i>Morphology</i>	Increased hexokinase
Anisocytosis	decreased pyruvate kinase
Poikilocytosis	decreased 2,3 diphosphoglycerate mutase
Oval macrocytes	decreased phosphofructokinase
Microcytes	increased adenosine deaminase
Basophilic stippling	increased pyruvate kinase
Howell–Jolly bodies	<i>Leukocytes</i>
Circulating nucleated red cells	<i>Function</i>
Ringed sideroblasts	Increased leukocyte alkaline phosphatase
Increased stainable iron	Decreased myeloperoxidase
Megaloblastoid maturation*	Increased muramidase (CMML)
Multinucleated precursors*	Loss of granule membrane glycoproteins
Nuclear fragmentation*	Inappropriate surface antigens
Nuclear budding*	Decreased adhesion
Karyohehexis*	Defective chemotaxis
Defective hemoglobinization*	Deficient phagocytosis
<i>Leukocytes</i>	Impaired bacteriocidal activity
<i>Morphology</i>	<i>Megakaryocytes</i>
Pseudo Pelger-Huet Cells	<i>Function</i>
Monocytosis	Defective platelet aggregation
Defective granule formation (hypogranulation)	Deficiency in thromboxane A ₂
Megaloblastoid maturation	Bernard–Soulier-like defect
Auer rods	<i>Immune Deficiencies</i>
Abnormal chromatin clumping	Decreased T-cell IL-2 receptors
Abnormal nuclear bridging	Decreased IL-2 production
Increased myeloblasts	Decreased NK activity
<i>Megakaryocytes</i>	Decreased NK response to gamma inteferon
<i>Morphology</i>	Decreased gamma interferon production
Circulating megakaryocyte fragments	Decreased response to mitogens
Giant platelets	Decreased T ₄ cells
Micromegakaryocytes*	Immunoglobulin abnormalities
Hypolobulated nuclei*	Autoantibodies
Hyperlobulated nuclei*	Autoimmune phenomenon
Large mononuclear forms*	Impaired self-recognition
<i>Erythrocytes</i>	
<i>Function</i>	
Decrease or loss of blood group antigens	
Increased fetal hemoglobin	
Aberrant globin chain synthesis	
Disordered ferrokinetics	

CMML, Chronic myelomonocytic leukemia

*Bone marrow findings

**Figure 39.1** Bone marrow smear with marked erythroid poiesis and binucleated erythroid progenitors**Figure 39.2** Bone marrow smear with increased myeloblasts

anemia. Care must be applied to differentiate true ALIP from pseudo-ALIP. In the latter case, the clusters of cells are either of erythroid or megakaryocytic origin and do not convey the same prognostic information compared to the former, where the immature cells are of myeloid origin. The determination of the immature precursor phenotype by immunohistochemical methods may be helpful in distinguishing pseudo and true ALIP, and thus permit identification of specific MDS subgroups with a poor prognosis.¹⁶ ALIP is not, however, specific to patients with MDS, and therefore not useful as a diagnostic tool.¹⁶

Functional abnormalities can occur in all three cell lines and range in severity from minor laboratory defects to those impairments associated with major clinical manifestations. These functional defects may exacerbate underlying existing cytopenias (i.e., anemia, neutropenia, and thrombocytopenia) or may produce a functionally deficient state even when peripheral blood counts remain in the normal range. Thus, patients with normal neutrophil counts may still experience recurrent bacterial infections reflecting functional neutropenia. Erythroid enzyme defects, aberrant expression of red cell surface antigens, and abnormalities of hemoglobin production and iron metabolism have all been described. Some of the changes in enzyme activity, such as those that occur with pyruvate kinase, may affect red cell survival.^{17,18} Impaired activity of A and H transferase and galactosyltransferase has resulted in changes in blood types.^{19,20} Hemoglobin production is affected with increased fetal hemoglobin, aberrant globin chain synthesis, and disordered ferrokinetics.^{21,22} Acquired alpha-thalassemia has been described secondary to a deletion of the alpha-globin chain cluster or an inactivating mutation of the transcriptional factor ATRX, resulting in down-regulation of the alpha-globin chain synthesis.²³

The myeloid series often reveals leukopenia with immature forms and increased numbers of large unstained cells. Neutropenia is more commonly found in patients with refractory anemia with excess blasts (RAEB) and RAEB-T than in patients with refractory anemia (RA) and refractory anemia with ringed sideroblasts (RARS).⁸ Leukocytosis most often accompanies CMML, and by definition requires an absolute monocytosis ($>1 \times 10^9/L$) for diagnosis. Monocytosis may, however, also be present in the other MDS subtypes.⁸ Cytoplasmic abnormalities result in cells with hypogranule or defective granule formation, Auer rods, or abnormal azurophilic granules. Histochemical studies reveal cells with increased or decreased levels of leukocyte alkaline phosphatase, decreased myeloperoxidase staining, and loss of granule membrane glycoproteins.^{24–28} Surface antigen analysis has shown loss of lineage-specific antigens, with persistent or increased expression of inappropriate antigens and lineage infidelity.^{29–32} In some instances, the abnormal persistence of antigens or an increased proportion of cells express-

ing those antigens was associated with an increased risk of leukemic transformation and shortened survival. Abnormal expression of an activated surface phenotype on monocytes has been demonstrated in patients within all FAB subtypes, while expression of activated surface antigens on granulocytes was almost exclusively seen in patients with excess blasts.³³ Impaired granulocyte function includes impaired respiratory burst, deficit in chemotaxis and superoxide release, as well as a defect in neutrophil stimulation signaling.^{33,34} Nuclear abnormalities such as pseudo Pelger-Huet cells and functional abnormalities are further outlined in Table 39.1.³⁵

Megakaryocytes can be decreased and their morphology is often bizarre (Table 39.1). Patients with RAEB and RAEB-T more commonly have thrombocytopenia, decreased megakaryocytes, and greater degrees of dysmegakaryopoiesis.⁸ Megakaryocyte fragments and giant thrombocytes may circulate in the peripheral blood. Hemorrhagic symptoms in these patients may be due to thrombocytopenia and functionally defective platelets. Dysfunction can result from defective platelet aggregation, deficiencies in thromboxane A2 activity, or the development of a Bernard-Soulier-type platelet defect. This latter defect has developed from a deficiency in the membrane glycoprotein GP 1b-IX complex.^{36,37}

A small percentage of patients present with hypoplastic bone marrows and cytopenias which morphologically may be difficult to distinguish from aplastic anemia.³⁸ Cytogenetic analysis with or without interphase FISH may be helpful in establishing a diagnosis.

The relationship of MDS to abnormalities of the immune system is of particular interest given the broad range of abnormalities described. There is a decrease in the number of T-cell interleukin-2 (IL-2) receptors, as well as IL-2 production. The latter is due in part to a failure of immunoregulatory B cells.³⁹ Natural Killer (NK) cell activity and responsiveness to alpha-interferon is decreased, as is alpha-interferon production, while total numbers of NK cells are variable.³⁹ There are decreases in the number of T cells, responsiveness to mitogenic stimulation, the total number of cells, and the T4/T8 ratio.^{31,40,41} The latter is due predominantly to a decrease in T4 cells. Overexpression of HLA-DR15 may occur in some patients, and may be a useful predictive factor for response to immunotherapeutic interventions.⁴²

Immunoglobulin abnormalities manifest as autoantibodies or a positive direct Coombs' test.^{43,44} The relationship of the disease to the immune abnormalities is poorly understood. A general dysregulation of the immune system is prevalent in many patients. Many patients will present with evidence of associated autoimmune disorders.¹³ This may include polyserositis with frank, nonspecific inflammatory pericarditis and pleuritis with significant effusions,¹³ or it may be

associated with other autoimmune diseases, such as Crohn's and Behcet's disease.^{45,46} Additional autoimmune mediated conditions associated with MDS include relapsing polychondritis, arthritis, polyneuropathy, hemolytic anemia, and immune thrombocytopenia. Recent reports have also described glomerulonephritis and nephrotic syndrome.^{47,48} In some cases, increased serum lysozyme (muramidase) in patients with CMML may be the inciting nephrotoxic agent. Although the pathophysiologic relationship of these autoimmune phenomemas and MDS is uncertain, it appears that the prognostic factors relating to MDS are the primary determinants for outcome, rather than the autoimmune disease.⁴⁹ Consistent with this is the finding of altered antibody repertoires of self-reactive IgM and IgG in MDS patients, indicating a disturbance in self-recognition mechanisms.⁵⁰ Whether some abnormalities relate in part to the number of red cell transfusions, or whether they are reversible with effective treatment, is unknown. Given the nature of the defect in a multipotent stem cell with the potential to differentiate along multiple pathways,⁵¹ the dysregulation of T and B cells is not surprising. A report of 20 patients with nontherapy-related MDS and concurrent lymphoid or plasmacytic malignant neoplasms provides further evidence to the multipotency of the stem cell affected, and to the derivative generalized immune dysregulation.^{8,43}

ESTABLISHING A DIAGNOSIS

The diagnosis of MDS in most patients is readily established with standardized testing, which should include history and physical examination, complete blood count, and review of the peripheral blood smear. The findings of cytopenias in the absence of explanation from biochemical, vitamin deficiency, hemorrhage, toxin/drug, or infectious etiology should lead to a bone marrow aspirate and biopsy with routine cytogenetic evaluation. The diagnosis of MDS is based primarily on morphologic criteria demonstrating dysmorphic features in the peripheral blood and bone marrow precursors (described above and Table 39.1). Although some of the classification systems include cytogenetic information (IE:WHO), they are based primarily on bone marrow and peripheral blood morphology. A diagnosis of MDS cannot be definitively established without examination of a bone marrow aspirate. Peripheral blood smears may be suggestive, but not conclusive. Some in the hematologic community believe a bone marrow smear alone is adequate for diagnosis. In some instances a smear is sufficient, however, a bone marrow biopsy provides complimentary information on cellularity, infiltrative disease, megakaryocyte morphology, and fibrosis that is often important in completing the evaluation and is informative for thera-

peutic decisions. Analysis of the marrow population, using flow cytometric analysis has become standard for the diagnosis and subtyping in patients with acute leukemia. It is more routinely being applied to establish a diagnosis of MDS, as well. Abnormal populations and skewed antigen expression can be identified.⁵²⁻⁵⁸ However, comparative studies of bone marrow morphology and flow cytometry results have not been conducted, and thus one cannot be certain if used alone whether flow cytometry results can reliably establish a diagnosis and classification of MDS. Accurate classification according to FAB or WHO criteria must be based, at least in part, on bone marrow morphology. Thus, flow cytometry should be viewed as a complementary examination, but not sufficient to establish the diagnosis and classification.

DIAGNOSTIC DILEMMAS

Certain patients with MDS may present with unusual or uncharacteristic features and represent a diagnostic challenge. These cases usually represent a small but difficult subset of patients in which to confidently establish the diagnosis. Patients may present with isolated thrombocytopenia that may antedate the diagnosis of MDS by months or years.⁵⁹ The bone marrow may reveal increased megakaryocytes, and an antiplatelet antibody may be identified in the serum. However, as noted above, this may be seen in conjunction with MDS, and may not represent a true case of immune thrombocytopenic purpura (ITP). Often, treatments typically used for ITP are ineffective. In these patients, careful examination of peripheral blood and bone marrow morphology may reveal the correct diagnosis. As in other patients in whom establishment of a diagnosis may be problematic, cytogenetic analysis may be helpful in leading to the correct diagnosis of MDS. Finding a cytogenetic abnormality frequently associated with MDS can often lead to the appropriate diagnosis. This applies both to these patients and to others described below.

Some patients with MDS present with features also suggestive of a myeloproliferative disorder (MPD), representing an "overlap syndrome."^{60,61} In these patients, cytopenias may present simultaneously with elevated white blood cell or platelet counts. In some patients, an increased leukocyte count may be accompanied by a monocytosis. Under current classification systems, some of these patients will be clearly defined as having an MPD, while others are still categorized as having MDS depending on the upper limit of the WBC count permitted in the classification system (see Chapter 38). Others may have myelofibrosis with or without marked splenomegaly and peripheral blood cytopenias,^{59,61-63} yet also have dysplastic features suggesting MDS. These patients are more difficult to classify. Those with

myelofibrosis with markedly enlarged spleens and a leukoerythroblastic peripheral smear are more likely to have classical myelofibrosis with myeloid metaplasia, while patients without significant splenomegaly and/or the peripheral leukoerythroblastic picture may be considered to have primary MDS with fibrosis.

The hypoplastic MDS variant is often indistinguishable from aplastic anemia, and may have many features in common.^{53,64–67} Those patients with increased expression of HLA-DR15 and the paroxysmal nocturnal hemoglobinuria (PNH) phenotype (decreased expression of CD59), whether having MDS or aplastic anemia, may respond to immunomodulatory treatments. Cytogenetic abnormalities, if present, involving chromosomes frequently abnormal in MDS may suggest the diagnosis of MDS, but does not completely exclude aplastic anemia.⁶⁸

Finally, there are patients who present with severe pancytopenia and bone marrow findings that are nondiagnostic (i.e., minimal if any dysmorphic changes, no increase in myeloblasts) and without any cytogenetic abnormalities. Some of these patients

may have MDS and only with continued observation and testing will a diagnosis be unequivocally established. Others may have been exposed to a bone marrow insult (toxin, infectious agent, etc.), which may never be identified, but which may permit eventual complete or partial marrow recovery over months or years. In these latter individuals, in the absence of clear diagnostic evidence, patience, continued observation, and supportive care may be the best approach pending a declarative diagnosis. One other consideration for these patients would be an immune-mediated injury to hematopoietic stem cells. The differential in these patients includes large granular lymphocytic leukemia, where T-cell receptor and immunoglobulin gene rearrangement studies may be informative.⁶⁹

Thus, MDS represents a disease with protean clinical and laboratory features. In the majority, with the appropriate evaluation, a diagnosis can be readily established, permitting accurate classification and appropriate therapeutic decisions.

Chapter 40

TREATMENT APPROACH TO EARLY MYELOYDYSPLASTIC SYNDROMES

Virginia M. Klimek and Stephen D. Nimer

INTRODUCTION

Developing a standard treatment algorithm for patients with myelodysplastic syndrome (MDS) is difficult, due to the tremendous heterogeneity of the disease and the limited, variably toxic available therapies. In this chapter, we attempt to place into context the currently available treatment options for patients with MDS, focusing on supportive care and low-intensity therapies. In our summary, we propose a treatment approach to MDS, based on specific clinical presentations.

MDS patients can be classified according to the French–American–British (FAB) classification system,¹ the World Health Organization classification system,² and most recently, the International Prognostic Scoring System (IPSS)³, which integrate a variety of clinical features. These systems do not take into account the biological basis of this set of diseases, which remain ill-defined. The development of targeted therapies for leukemia and related diseases is dependent on identifying genetic lesions that are critical for the growth of the malignant cell or for monoclonal antibody-based therapy, and on identifying cell surface markers that are abundantly expressed on the target cell. No such critical genetic lesions or cell surface markers have been identified for the vast majority of MDS patients; their identification has been hampered by the lack of an animal model of MDS and by difficulties in isolating “MDS-initiating cells” in the laboratory. Thus, other than the use of imatinib for rare chronic myelomonocytic leukemia (CMML) patients with t(5;12), i.e., TEL-PDGFR β -positive CMML, targeted therapies cannot yet be applied to MDS.

The few recurrent genetic abnormalities identified in MDS patients, such as point mutations in the *AML1* gene, the t(3;5) that generates the NPM-MLF1 fusion protein, or the t(3;21) (which generates an AML1-EVI-1 fusion), are infrequent. While del(5q), del(7q), del(20q), and trisomy 8 are the most frequent cytogenetic

abnormalities found in MDS, the gene(s) affected by these abnormalities have still not been determined. Given the absence of identified genetic abnormalities in MDS hematopoietic cells and the heterogeneity of the disease, studies have also focused on defining the bone marrow milieu that supports or sustains the MDS process. Overactive macrophage function (with increased cytokine secretion), changes in microvessel density, and abnormalities in the maintenance of telomeres have been observed in some MDS patients. Immunologic abnormalities have also been identified in patients with MDS, and these abnormalities (especially those also found in aplastic anemia (AA) patients) have provided the rationale for the testing of immunomodulatory treatments.

Recent discoveries, such as the lack of circulating natural killer T cells in these patients, may provide additional therapeutic options in the future, although some cellular abnormalities may simply represent “down-stream” effects of the impaired hematopoiesis found in MDS, and may not provide insight into new therapies. Similarly, the excess production of inhibitory cytokines by macrophages (and other bone marrow cells) that can suppress hematopoiesis has led to testing of a variety of forms of anticytokine therapy. Though thus far largely unsuccessful, such approaches may be used more effectively in the future. A thorough discussion of the novel therapies being applied to subsets of MDS patients will be covered in Chapter X.

SUPPORTIVE CARE

Many patients with MDS require close monitoring only during the early phase of their disease. However, once patients become symptomatic from cytopenias, the timely use of supportive care measures can impact significantly on their quality of life (QOL). Supportive care measures generally consist of packed red blood cell (PRBC) transfusions to treat or prevent the symptoms

and physiologic consequences of anemia, antibiotics to treat or prevent infection, and platelet transfusions to prevent or treat bleeding.

The “optimal” hemoglobin concentration for anemic, transfusion-dependent MDS patients has never been defined. Nonetheless, a commonly used threshold for PRBC transfusions has been a hemoglobin level of less than 8.0 g/dL. This may be too low for many patients, as studies in patients with cancer and chemotherapy-induced anemia suggest that a hemoglobin level of 11.0–12.0 g/dL may provide optimal symptom relief.⁴ During the routine care of MDS patients, this level may be difficult to achieve or maintain because of the frequency and amount of blood required and the poorer response of MDS bone marrow to erythropoietic agents. Therefore, the threshold for individual MDS patients will vary depending on the patient’s age, conditioning, level of activity, and the presence or absence of cardiopulmonary disease. QOL studies should aid in defining the benefit of maintaining higher hemoglobin levels in MDS patients.

Platelet transfusions are used to prevent or treat bleeding due to severe thrombocytopenia or platelet dysfunction. Assuming normal platelet function, prophylactic transfusions are generally reserved for patients with a platelet count of $<10,000/\mu\text{L}$. Patients with evidence of significant platelet dysfunction should be evaluated on a case-by-case basis. Otherwise, thrombocytopenic MDS patients who are not bleeding can be observed if they have no other risk factors for significant bleeding. For patients undergoing active therapy for MDS, it may be desirable to maintain a platelet count of $>20,000/\mu\text{L}$ during periods of reversible, treatment-related myelosuppression. A diagnosis of immune-mediated thrombocytopenia (ITP) should be considered in thrombocytopenic patients, as ITP and other autoimmune phenomas are associated with MDS.⁵ Potent thrombopoietic agents, however, are not currently available. Interleukin-11 has been tested in thrombocytopenic MDS patients, but its safety and efficacy has not been established. A variety of thrombopoietin “mimics” are currently being evaluated, with some activity being seen in thrombocytopenic patients.

Supportive care for MDS patients includes managing infectious complications from neutropenia. Fever or signs of infection should be assessed promptly in neutropenic patients and treated with antibiotics. During brief periods of neutropenia, antibiotic prophylaxis may be appropriate. Granulocyte transfusions may improve survival in patients with transient neutropenia and severe bacterial or fungal infections that are not responding to appropriate antibiotics. However, their efficacy in patients with unremitting neutropenia is not established. Other supportive care measures include vaccinating MDS patients (and their close contacts) against influenza, and considering the use of pneumococcal vaccines.

Chronic PRBC transfusion therapy can result in iron overload, and prevention of hemochromatosis should be considered in patients with stable disease. Liver biopsy is the gold standard for assessing iron overload, but it may not be feasible in some patients because of thrombocytopenia or other medical concerns. Superconducting quantum interference device imaging can quantitate hepatic iron deposition, but this technology is available at few sites throughout the world. MRI of the liver or heart can be used to document iron overload,⁶ and despite its limitations, serial serum ferritin levels can also be used to estimate systemic iron burden. Patients with chronically elevated ferritin levels (1500–2500 ng/mL or greater), and those who have received 25–50 units of PRBCs, should be considered for iron chelation therapy with subcutaneous desferrioxamine.^{7,8} Unfortunately, because of the cost, discomfort, and time involved in its administration, desferrioxamine therapy is frequently refused or administered irregularly by MDS patients. Oral chelating agents are being evaluated in Europe (deferiprone) and in the United States (ICL670), primarily in patients with thalassemia. If shown to be effective and safe in MDS, oral chelating agents may be used with or instead of desferrioxamine in the future.

Other risks of transfusion therapy include acute transfusion reactions, alloimmunization, transfusion-associated graft-versus-host disease, and rarely, the transmission of infectious diseases, such as HIV, hepatitis viruses, or even more rarely West Nile virus.^{9,10} These risks, as well as iron overload, can be lessened with the judicious use of transfusions. Irradiated blood products should be used for patients with MDS undergoing intensive therapy or ablative transplant conditioning to prevent transfusion-associated graft-versus-host disease. Furthermore, leukocyte depletion of RBC and platelet transfusions can reduce the incidence of human leukocyte antigen (HLA) alloimmunization, transmission of viral infections, and transfusion reactions.

LOW-INTENSITY THERAPY

Low-intensity therapies include hematopoietic growth factors (such as recombinant erythropoietin), immunosuppressive therapy (IST), hypomethylating agents (5-azacytidine and decitabine, though only in specific subsets of early MDS patients), and antiangiogenic/immunomodulatory agents (such as thalidomide or lenalidomide). They may be administered as standard care, when appropriate, or in the context of a clinical trial. For patients with IPSS low or intermediate-1 risk disease, these treatments may be used before or concomitant with supportive care measures, or when supportive care measures are no longer effective or interfere significantly with a patient’s QOL (e.g., due to frequent transfusions, infections). Low-intensity

therapy may also be used for higher risk patients who are elderly or have significant comorbid conditions that prevent them from receiving higher intensity therapies, or at times used in preparation for such high-intensity treatment.

GROWTH FACTORS

Following the Food and Drug Administration (FDA) approval of recombinant human erythropoietin (rHuEPO) therapy for treating anemia in hemodialysis patients, rHuEPO was given to patients with anemia, including those with MDS, in a variety of clinical trials.

These studies are summarized in Table 40.1. A meta-analysis of 17 early, small studies in anemic MDS patients revealed an overall erythroid response rate of 16%, generally at rHuEPO doses >150 U/kg three times per week.¹¹ Predictors for a response (a rise in hemoglobin ≥ 2.0 g/dL or becoming PRBC transfusion independent) included a low serum-erythropoietin level, nontransfusion-dependent anemia, and a diagnosis of refractory anemia (RA) or refractory anemia with excess blasts (RAEB). Patients with low erythropoietin levels and few or no transfusion requirements had a response rate >50%. High doses of erythropoietin are

Table 40.1 Larger trials of rHuEPO (alone or with rHuG-CSF or rHuGM-CSF) to treat anemia in MDS patients

Reference	Trial design	Number of patients	Overall erythroid response rate	Erythroid response		Response correlates
				Major	Minor	
11	Phase II Meta-analysis EPO	205	16%	ND	ND	EPO <200 U/L; no prior PRBC transfusions
(Rose, Abels et al. 1995)	Phase II EPO	115 (100 evaluable)	28%	ND	ND	RA; EPO <100 U/L
(Terpos, Mougou et al. 2002)	Phase II EPO	292 (281 evaluable)	18% at 12 weeks 45% at 26 weeks	8% at 12 weeks 27% at 26 weeks	10% at 12 weeks 18% at 26 weeks	EPO <150 U/L; IPSS good risk cytogenetics
15	Phase III, EPO vs. Placebo	87 (75 evaluable -38 on EPO arm)	37% (vs. 11%, $P = 0.007$)	13% (vs. 0%)	24% (vs. 11%)	RA; EPO <200 U/L; no prior PRBC transfusions
(Negrin, Stein et al. 1996)	Phase II, EPO + G-CSF	55	48%	32%	16%	Low EPO level
(Hellstrom-Lindberg, Ahlgren et al. 1998)	Phase II, EPO + G-CSF	56 (47 evaluable)	38%	21%	17%	EPO level <500 U/L; ≤ 2 u PRBC/mos.
(Remacha, Arrizabalaga et al. 1999)	Phase II, EPO + G-CSF	32	50%	38%	13%	Predictive model (Hellstrom-Lindberg, Negrin et al. 1997)
(Mantovani, Lentini et al. 2000)	Phase II, EPO + G-CSF	33 (28 evaluable at 12 weeks)	61% at 12 weeks 80% at 26 weeks	43% at 12 weeks -56% at 36 weeks	18% at 12 weeks -25% at 36 weeks	Higher pre-tx HGB level
(Hellstrom-Lindberg, Gulbrandsen et al. 2003)	Phase II, EPO + G-CSF	63 (53 evaluable)	42%	28%	13%	Predictive model (Hellstrom-Lindberg, Negrin et al. 1997)
(Casadevall, Durieux et al. 2004)	EPO + G-CSF vs. supp. care	60 (24 evaluable in treatment arm)	42% vs. 0% ($p = 0.01$)	2/24; 8/24	8/24; 7/24	RA and RARS
(Thompson, Gilliland et al. 2000)	EPO + GM-CSF	45	9%	ND	ND	EPO <500 U/L

EPO, recombinant erythropoietin; G-CSF, recombinant granulocyte colony-stimulating factor; GM-CSF, recombinant granulocyte-macrophage colony-stimulating factor; PRBC, packed red blood cell transfusions; RA, refractory anemia; RARS, refractory anemia with ringed sideroblasts; Hgb, hemoglobin (g/dL); ND, not determined.

needed to grow BFU-E and CFU-E from MDS bone marrows,¹² and inappropriately low serum-erythropoietin levels are seen in only approximately one third of patients with MDS^{13,14}; perhaps these features account for the low clinical response rates seen. In the only randomized, placebo-controlled, phase III rHuEPO trial, 87 MDS patients with a Hgb <9.0 g/dL were treated with rHuEPO at a dose of 150 U/kg/day for 8 weeks. An overall response rate of 36.8% was detected.¹⁵ Patients with RA or refractory anemia with ringed sideroblasts (RARS) were the most responsive, and nontransfused patients fared better than those that had been transfused. Although rHuEPO can improve hematocrit levels in relatively low-risk patients with low erythropoietin levels and low transfusion requirements, its impact on survival and QOL is not well characterized. Also, most patients in these clinic trials received rHuEPO three or more times per week. This frequent self-injection schedule may be too cumbersome or uncomfortable for most patients, and it is unknown whether similar results can be achieved in a routine outpatient setting.

rHuEPO is well tolerated in patients with anemia, and although some cases of pure red cell aplasia have been associated with rHuEPO, these episodes appeared to be related to packaging and storage problems with a specific rHuEPO formulation (used primarily in Europe) that may have increased the immunogenicity of the drug.¹⁶ As transfusion therapy can be associated with short-term and long-term complications, the use of rHuEPO in responding anemic MDS patients has major advantages over transfusion therapy.

Granulocyte colony-stimulating factor (G-CSF) (and Granulocyte-macrophage colony-stimulating factor (GM-CSF) to a lesser extent) increase peripheral blood neutrophil counts in MDS patients,¹⁷ but neither has proven beneficial for long-term use. The lack of clinical benefit for G-CSF was demonstrated in a randomized clinical trial, which showed that prophylactic G-CSF did not decrease the incidence of infections or improve survival compared to standard supportive care.¹⁸ A randomized trial of GM-CSF likewise showed no significant benefit.¹⁹ Nonetheless, MDS patients may benefit from the short-term use of G-CSF, particularly during an infection-prone period (e.g., perioperatively), during the transient neutropenia which follows induction chemotherapy, or in the setting of antibiotic-resistant infection. As G-CSF and GM-CSF can rarely exacerbate thrombocytopenia,^{18,20} these agents should be used with caution in severely thrombocytopenic patients.

In vivo and in vitro synergy on erythropoiesis has been demonstrated for rHuEPO and G-CSF. Erythroid response rates of 38–50% have been reported when these agents are combined^{21,22} and responses have been lost and restored with the withdrawal and reinitiation of G-CSF, supporting their synergism.²³ Having RARS (where the response rate is 50%)^{21,23,24} or

low pretreatment erythropoietin levels (≤ 500 U/L) and PRBC transfusion dependence of less than 2 units/month is predictive of an erythroid response to combined rHuEPO/G-CSF.²⁵ A randomized trial comparing G-CSF plus rHuEPO to supportive care showed that despite improvements in hematocrit and transfusion requirements, QOL parameters did not significantly improve, although the study showing this was likely underpowered to detect QOL differences.²⁶ No change in survival has been reported with this treatment; thus, its use should still be largely investigational. Because of its toxicity and low response rate, the combination of GM-CSF and rHuEPO is not recommended for MDS patients.²⁷

IMMUNOMODULATORY DRUGS

Both immunomodulatory therapy and IST have been tried in patients with MDS. Thalidomide is an immunomodulatory agent with numerous cytokine-altering and antiangiogenic effects.^{28,29} On the basis of its significant clinical activity in multiple myeloma,³⁰ thalidomide has been given to MDS patients in attempts to favorably modify the bone marrow cytokine milieu and possibly impair angiogenesis. Thalidomide appears to have mostly erythropoietic activity in MDS, but it is not well tolerated. In one phase II thalidomide study, 51 of 83 patients were able to complete 12 weeks of thalidomide therapy, and 15 had an erythroid response³¹ using the International Working Group response criteria. While 11 patients (13%) had a major erythroid response (a hemoglobin rise of >2 gm/dL or loss of transfusion dependence), 32 patients (38%) were removed from the study or they withdrew their consent because of excessive toxicity, progression of disease, or other medical problems. Similar results have been obtained in other trials of thalidomide in MDS, as summarized in Table 40.2. Although anemia may be significantly improved, myelosuppression is often seen, and it is difficult to predict who will respond to thalidomide. While a North American phase III trial comparing thalidomide to supportive care has been completed, its outcome has not yet been reported.

Another “immunomodulatory” agent, CC-5013 (lenalidomide), appears to have greater erythropoietic activity than does thalidomide in PRBC transfusion-dependent MDS patients. A phase I/II clinical trial of lenalidomide in MDS patients was presented at the 2003 American Society of Hematology Annual Meeting. The 33 enrolled patients had primarily low-risk MDS by IPSS score (88% were in the Low/Int-1 group) and all had significant anemia (Hgb level <9g/dL or transfusion dependent). The overall erythroid response rate was 64%, with a 58% major erythroid response rate.³² Many patients had received, but had not responded to, thalidomide or rHuEPO therapy. The median increase in hemoglobin level was 4.4 g/dL in responding patients, and the time to treatment failure was 19–71+

Table 40.2 Phase II trials of thalidomide for the treatment of anemia in MDS

Reference	Number of patients	MDS subtype treated	Daily dose (mg)	ITT erythroid response rate	Drop out rate (for toxicity, POD, other)
(Raza, Meyer et al. 2001)	83	FAB-RA-36 RARS-13 RAEB-24 RAEBt-6 CMMoL-4 IPSS-Low-21 Int-1-37 Int-2-12 High-13	100–400	19% (n = 15)	42% (n = 35)

(Strupp, Germing et al. 2002)	34	FAB-R-16 RARS-6 RAEB-4 RAEBt-5 CMMoL-3 IPSS-low-4 Int-1-4 Int-2-9 High-7	100–500	56% (n = 19)	32% (n = 11)

IWG, international working group; IPSS, International Prognostic Scoring System; WHO, World Health Organization; CR, complete remission; PR, partial remission; ITT, intent to treat; POD, progression of disease; RA, refractory anemia; RARS, refractory anemia with ringed sideroblasts; RAEB, refractory anemia with excess blasts.

weeks (median not reached). In addition, lenalidomide induced major cytogenetic responses, including reversion to a normal karyotype in 10 patients. Response rates were highest in the RA subtype (82%), the IPSS Low/Int-1 risk groups (71%), in patients who never received rHuEPO (100%), and in patients with the 5q– cytogenetic abnormality (91% or 10/11 patients). Lenalidomide was well tolerated, with dose-dependent myelosuppression (neutropenia, thrombocytopenia) being the most common adverse event. Results from two recently completed, multicenter phase II trials, evaluating lenalidomide for 5q– patients and for non-5q– MDS patients, will likely be reported in 2005. The apparent sensitivity of patients with the 5q– cytogenetic anomaly to lenalidomide is unexplained, as is the mechanism of action of lenalidomide or thalidomide.

ATG AND CYCLOSPORINE

While ISTs, such as antithymocyte globulin (ATG) and cyclosporine, have remarkably altered the clinical course of patients with AA, these drugs have been of limited benefit in MDS patients. While patients with AA can be cured with IST, the response to IST in MDS patients is neither curative nor sustained beyond a year in most cases.³³ In one study, 16 of 42 patients with RA, RARS, or RAEB who were treated with 4 days

of ATG became transfusion independent. The highest response rate was seen in RA patients (61%), whereas none of the patients with RARS responded.³⁴ Most responding patients had hypocellular marrows, and responses to ATG in both MDS and AA patients seems to be associated with expression of the HLA DR15,³⁵ even though patients with other HLA types also respond. Predictive models can help determine which factors in MDS patients are more likely to predict for response to ATG therapy, such as having RA, normal cytogenetics, pancytopenia, or a hypocellular bone marrow. Cyclosporine alone has also produced responses in MDS patients.^{36,37}

OTHER THERAPIES: AMIFOSTINE OR ARSENIC TRIOXIDE

Amifostine, an organic thiophosphate with antioxidant activity, was evaluated in the mid to late 1990s in MDS patients. Hematologic improvements were seen in 84% (5/18 patients) in the first amifostine trial,³⁸ but this response rate could not be confirmed in subsequent small phase II studies.^{39–41} In general, responses were brief, and some responses were lost by the time the subsequent cycle of amifostine was due to be administered. Combinations of amifostine with other agents have also shown only modest activity.⁴²

Arsenic trioxide, an FDA-approved treatment for acute promyelocytic leukemia, has also shown modest activity in MDS patients. Hematologic improvements were seen in two small early clinical trials,^{43,44} and several patients had major erythroid responses with loss of transfusion dependence. Myelosuppression and other toxicities were generally mild to moderate and manageable, included grade 3 and 4 myelosuppression. In a study of arsenic trioxide and thalidomide, trilineage hematologic responses were seen in 2/28 patients, both of whom carried the *inv(3)(q21q26.2)* cytogenetic abnormality.⁴⁵ As our knowledge grows, the use of therapies without widespread efficacy in specific subsets of MDS patients (such as those with *inv(3)(q21)*, if these results are confirmed by others) may be useful.

DIFFERENTIATING AGENTS

The maturation block evident in patients with MDS has provided a rationale for more than a decade of treatments with “differentiation-inducing” agents. However, none of the clinical trials with such agents have provided clear evidence of a differentiating effect, despite the demonstration of *in vitro* differentiation effects on leukemia cell lines. The agents studied include retinoids, vitamin D₃ analogs, cytarabine (at one time thought to induce differentiation at low doses), phenylbutyrate, and hexamethylene bisacetamide. Overall, the results have been generally disappointing.⁴⁶ Low-dose cytarabine continues to be used for some MDS patients, perhaps based on a randomized study comparing low-dose cytarabine to supportive care, in which a 35% hematologic response was seen. However, in that study cytarabine did not improve survival or delay progression to acute myelocytic leukemia (AML).⁴⁷ *cis*-Retinoic acid was also shown to be no better than supportive care in another randomized trial.⁴⁸ A more recent trial reported hematologic improvement in 11/19 patients with the newer vitamin D₃ analog, calcitriol.⁴⁹

DEMETHYLATING AGENTS

DNA methylation is a normal mechanism of gene expression regulation, and abnormal DNA methylation patterns that can interfere with the expression of genes used for growth, differentiation, and survival are seen in MDS. It has been known for some time that hypomethylating drugs can promote *in vitro* cellular differentiation,⁵⁰ and that this occurs at doses much lower than those needed for maximal cytotoxic effect. The clinical trials using the DNA demethylating agents 5-azacytidine (azacitidine, Vidaza) and 5-aza-2'-deoxycytidine began decades ago, prior to a full understanding of their demethylating effects. As a result, they were initially studied as cytidine analogs, using a classic phase I design to determine their maximally tolerated dose in leukemia patients. Subsequent trials in MDS patients used lower, more tolerable doses, with

the goal of inducing differentiation and minimizing toxicity, which manifested itself primarily as myelosuppression in the earlier, high-dose trials.

Low-dose 5-azacytidine was first used to treat MDS by the Cancer and Leukemia Group B (CALGB) in the 1980s. Small studies evaluated 5-azacytidine at a dose of 75 mg/m²/day by either continuous intravenous infusion or subcutaneous injection for 7 days each month and found a 49% or 50% response rate, respectively; both showed a complete remission (CR) rate of 12%.^{51,52} In a subsequent, multicenter, randomized, phase III trial, 191 patients with MDS of all subtypes were randomized to receive either 5-azacytidine given subcutaneously at a dose of 75 mg/m²/day for 7 days per month with supportive care, or supportive care alone.⁵³ Patients on the supportive care arm were permitted to crossover to the 5-azacytidine arm after 4 months for worsening disease or persistent severe cytopenias. The overall response rate (CR + PR) on the 5-azacytidine arm was 23% (7% CR), with a median response duration of 15 months and a median time on treatment of 9.1 months. Hematologic improvement was seen in 37% of the patients. Responses were seen in all MDS subtypes, with a median time to best response of 93 days. Moreover, the median time to AML transformation or death was longer for patients randomized to receive 5-azacytidine (21 months) than those in the supportive care arm (12 months). A non-significant difference in median survival was detected (20 months vs. 14 months, *p* = 0.10), but a 6-month landmark analysis (to eliminate the confounding effect of the 49 crossover patients) detected an improvement in survival (18 months vs. 11 months, *p* = 0.03). Treatment with 5-azacytidine was also associated with significant improvements in QOL parameters, including fatigue, dyspnea, and psychological well-being.⁵⁴ 5-Azacytidine was approved by the FDA in May 2004 for all MDS subtypes based on this data, but treatment for the RA or RARS patients was approved only for those with moderate to severe neutropenia (ANC <1000/μL), thrombocytopenia (< 50,000/μL), or transfusion-dependent anemia.

The FDA approval of 5-azacytidine represents the first agent approved for treating patients with MDSs. The CALGB study of 5-azacytidine took many years to complete and report, and a confirmatory phase III study is underway comparing 5-azacytidine to several conventional therapies (supportive care, low-dose cytarabine, or intensive, AML-like therapies). The recent approval of 5-azacytidine in the United States suggests that this trial will primarily enroll patients in Europe. As the IPSS was not devised when the first phase III 5-azacytidine trial was started, this trial may better define which MDS patients have the highest likelihood of responding to 5-azacytidine.

Three large phase II studies of low-dose 5-aza-2'-deoxycytidine (decitabine) have been conducted in Europe, and the results recently summarized. Of 169

MDS patients treated with intravenous doses of 45–50 mg/m²/day for 3 days every 6 weeks (either 50 mg/m²/day by continuous i.v. infusion over 3 days, or 15 mg/m² every 8 h for 3 days for a total of 9 doses), 20% had a CR, 10% had a partial remission (PR), and the overall response rate was 49% (including hematologic improvement).⁵⁵ An early (after one cycle) and often dramatic rise in the platelet count was frequently seen, and was predictive of a subsequent tri-lineage response.⁵⁶ On the basis of these positive results, a multicenter, phase III study was opened in the United States and Canada, which completed accrual in 2003. A total of 160 patients were randomized to receive decitabine 15 mg/m² every 8 h over 3 days (total 45 mg/m²/day) plus supportive care, or supportive care alone, with no crossover allowed. Data from this trial was reported at the 2004 annual American Society of Hematology meeting with benefit seen in the IPSS high-risk and Int-2 risk patients, but not the Int-1 risk patients.⁵⁷ Among the key questions are whether decitabine and 5-azacytidine work equally well in the same types of patients, or whether some MDS patients would benefit more from one versus the other drug. In the absence of FDA approval of decitabine, however, such questions are not yet clinically relevant. An oral formulation of decitabine is in preclinical trials, and new hypomethylating agents (e.g., zebularine)⁵⁸ may also make their way into clinical trials.

These agents appear to induce hypomethylation by irreversibly binding and “trapping” DNA methyltransferases so that the next round of DNA replication produces a demethylated base at a site that was previously methylated. Although it is clear that these

agents have clinical activity in MDS, demethylation of specific genes (e.g., the CDK inhibitors p15, p16, p21) has not been definitively correlated with clinical responses. Therefore, the specific mechanism by which hypomethylation induces responses in MDS remains unclear. Identifying biological correlates of clinical responses will help define the mechanism of action of these agents, and will identify predictors of hematologic responses in this heterogeneous disease. A common side effect of low-dose decitabine and 5-azacytidine is some degree of myelosuppression, which suggests that even at lower doses, cytotoxicity may be important for the clinical responses seen in MDS.

Future studies with the demethylating agents 5-azacytidine and decitabine will hopefully improve our understanding of how these drugs improve the cytopenias and bone marrow function in MDS. These agents will also be combined with other therapies in an attempt to improve the CR rate and duration, which may include maintenance therapy. Attractive combinations include the use of hypomethylating agents with other drugs that also have an impact on gene regulation, such as all-*trans* retinoic acid (ATRA), vitamin D analogs, or histone deacetylase inhibitors such as SAHA, depsipeptide, phenylbutyrate, or valproic acid. Mouse models are finally being developed for MDS (e.g., see Ref. 4) and they may prove useful for such preclinical studies.

NOVEL AGENTS AND COMBINATIONS

Improvements in our understanding of the pathobiology of MDS will help to generate new therapeutic approaches. As new agents are developed, some will be appropriate for low-risk patients, and given the

Table 40.3 Clinical trials of hypomethylating agents in MDS

GR, complete remission, PR, partial remission.

paucity of available treatments for MDS, patients should be referred for appropriate clinical trials whenever possible. Low-intensity therapies, such as histone deacetylase inhibitors, farnesyl transferase inhibitors, and tyrosine kinase inhibitors, are being tested in advanced MDS and AML, but may be evaluated in lower risk MDS as well. In Chapter X, such novel approaches to treating MDS will be discussed in detail.

HIGH-INTENSITY THERAPY: CHEMOTHERAPY OR STEM CELL TRANSPLANTATION

Intensive chemotherapy treatment for MDS has generally produced complete remission rates of 40–50%, which is lower than the response rates seen in the younger patients with de novo AML. Furthermore, remission durations are generally brief (5–15 months), and given the treatment-related mortality of ~25–50% and the time required to recover to baseline function for survivors of such therapy, the use of AML-like therapies has been limited. Although some patients have achieved complete hematologic and cytogenetic remissions, no survival benefit has yet been shown for intensive chemotherapy. Several new combinations have been studied for advanced MDS, which include the topoisomerase I inhibitor topotecan.^{59,60} These combinations are unlikely to produce a significant improvement in survival unless followed by allogeneic stem cell transplants. In general, these treatments should be reserved for higher risk patients enrolled in clinical trials, given the uncertain risk-benefit ratio.

Allogeneic stem cell transplant is the only potentially curable treatment for MDS. Although it appears that the associated short-term and long-term risks of transplant are generally acceptable for high-risk MDS patients, the optimal timing for transplanting patients

with low-risk disease is not established. Furthermore, it is not clear how pretransplant therapies or the degree of pretransplant cyto-reduction impacts on the disease-free survival of MDS patients.

TREATMENT OPTIONS—OVERVIEW

The choice of therapy, and the decision to undergo treatment, must be tailored to the individual patient. In general, the factors that govern these decisions include patient age, performance status, and medical comorbidities, as well as the patient's risk-aversion profile and the severity of the disease at presentation. MDSs are not curable without stem cell transplantation. However, the combination of advanced age and limited donor availability renders the vast majority of patients with MDS ineligible for such therapy. Intensive antileukemic chemotherapy may alter the natural history of MDS in some patients, but candidates for this therapy must be selected carefully to avoid excessive risk in this aging, medically vulnerable population.

Although supportive care remains a mainstay of treatment for many patients with low-risk, largely asymptomatic disease, the ability to impact the natural history of this disease in symptomatic (and possibly asymptomatic) patients now and in the future is exciting. Given the current state of the field, and paucity of curable options, patients with MDS should be treated on clinical protocols, if at all possible.

COMPREHENSIVE TREATMENT STRATEGY FOR MDS

The clinical problems that MDS patients experience can be broken down into three basic categories. While anemia is the major problem for some patients, others have potentially life-threatening neutropenia or thrombocytopenia. Patients in both categories may be at high risk for developing AML. These scenarios are discussed below.

- Anemia only:** These patients often have relatively good-risk disease, and are most suitable for low-intensity approaches or supportive care alone. rHuEPO should be tried for patients with symptomatic anemia; it works best in those with little or no transfusion requirements and relatively low serum erythropoietin levels. The doses required are higher than those used to treat chemotherapy-associated anemia. Patients with RARS, in particular, may benefit from combining G-CSF with rHuEPO, as there appears to be synergistic effects on erythropoiesis. Lenalidomide has shown significant activity in transfusion-dependent patients with a del(5q) cytogenetic abnormality, and also in those with a normal karyotype. Thalidomide has modest stimula-

Table 40.4 Treatment strategy for patients with MDS

Three clinical issues to consider if predominant problem is

- (1) anemia: Consider rHuEPO +/- G-CSF, 5-azacytidine, ATG, (ce-5013 if FDA-approved), or Thalidomide (in a clinical trial);
- (2) severe neutropenia or thrombocytopenia: Consider stem cell transplantation early. Alternatively (or pretransplant), consider 5-azacytidine (or decitabine, if available), ATG, or AML-like regimens;
- (3) points 1 or 2 and/or increased blasts (at risk for leukemic progression): Consider Stem cell transplant, 5-azacytidine (or possibly decitabine).

Considerations for stem cell transplant candidates: patients with fewest precent blasts do best; not known if pre-stem cell transplant treatment is of benefit.

tory activity on red blood cell production, but its activity seems inferior to lenalidomide. 5-Azacytidine has received FDA approval for RBC-transfusion-dependent patients. Although it has greater side effects than rHuEPO, its use may forestall the development of iron overload and thus may benefit certain high-risk patient subsets. Heavily transfused patients are appropriate candidates for investigational therapies and in rare instances, even stem cell transplantation. The timing for such treatment should be determined in consultation with a transplant physician.

2. *Neutropenia/thrombocytopenia*: Patients with mild to moderate, uncomplicated neutropenia and/or thrombocytopenia can often be observed; however, such patients should be evaluated on an individual basis. Patients with life-threatening neutropenia or thrombocytopenia warrant active treatment and not simply supportive care (such as platelet transfusions and antibiotics), even though some such patients may be assigned to a “low-risk” IPSS subcategory. 5-Azacytidine can induce trilineage responses and along with decitabine (an investigational agent in phase III testing) can induce rapid and impressive improvements in peripheral blood counts. Patients with severe cytopenias (even without an increase in bone marrow (BM) blasts) should be considered for allogeneic stem cell transplantation before they have life-threatening infectious or bleeding complications. Whether patients with cytopenias and no increase in BM blasts will have superior outcomes with reduced intensity stem cell transplantation is not known, but hopefully will be addressed in future clinical trials. Patients with severe cytopenias who are not eligible for a stem cell transplant should receive a series of

low- or high-intensity therapies (e.g., AML-like treatment regimens) in clinical trials whenever possible.

3. *Patients at great risk for progressing to AML*: Patients with increased BM blasts and/or poor risk cytogenetics have a high likelihood of transforming to AML, and AML arising in a patient with MDS has an extremely poor prognosis. Thus, allogeneic stem cell transplant should be considered for such poor prognosis MDS patients as soon as possible. Many MDS patients will not be suitable transplant candidates based on their performance status, other complicating medical problems, age, or lack of a suitable donor. Improvements in unrelated donor transplantation may provide more hope for these patients in the future. A major risk for these patients post-stem cell transplant is disease relapse. Whether using 5-azacytidine, or standard AML induction therapy, to reduce the BM blast count prior to transplantation will improve transplant outcomes, is not known. It is a vitally important question to address. Patients who are not eligible for a stem cell transplant should be treated with 5-azacytidine, or with investigational therapy in the setting of a clinical trial.

Chapter 41

APLASTIC ANEMIA AND STEM CELL FAILURE

Jaroslav P. Maciejewski

INTRODUCTION

HISTORY

Dramatic disappearance of the marrow and profound cytopenia seemingly occurring without prodromal signs have stimulated the research of generations of physicians and scientists since the initial descriptions of aplastic anemia (AA) in the last decades of the nineteenth century. The almost inevitable fatal outcome of severe AA made it a subject of research by renowned hematologists. Later, its illustrative features allowed insights into stem cell function, regulation of blood cell production, and the role of immune system in the regulation of hematopoiesis. Research into the causes of AA has led to the description of cellular elements of blood, and later to the introduction of stem cell transplantation as a means of replacing a defective stem cell compartment. Today, the longer survival of patients with AA uncovers new instructive aspects of the disease and provides new therapeutic challenges. These aspects include the evolution of clonal diseases, such as myelodysplastic syndromes (MDS) and paroxysmal nocturnal hemoglobinuria (PNH).

EPIDEMIOLOGY AND DEMOGRAPHICS

AA can occur at any age, but the peak incidence is in early adulthood. It is not clear whether the often described second peak in the sixth to seventh decades of life may be a result of the diagnostic overlap of AA and MDS that affects older individuals and can mimic AA, especially if the marrow is hypocellular.¹⁻³ The incidence of AA in the United States and Europe is comparable at around 4/10⁶ individuals.⁴⁻⁶ In East Asia, the incidence of AA appears to be significantly higher, an early observation made by Dr Dameshek. This endemic occurrence of AA in the Far East led to many theories as to how this disease relates to PNH, also more prevalent in this part of the world, and to the search for geographically related epidemiologic factors, such as endemic pathogens. The extensive epidemiologic studies performed in Thailand did not yield specific clues, but disproved speculations as to

the role of hepatitis viruses in the etiology of classic idiopathic AA.⁷ AA has been described in Africa and India, where it may be also more prevalent than in the West, but exact epidemiologic studies are not available. In the United States, AA does not appear to show an ethnic predilection.

PATHOPHYSIOLOGY

STEM CELL FAILURE IN AA

Direct and indirect stem cell injury

Iatrogenic bone marrow failure induced by chemotherapeutic drugs or radiation is perhaps the best example of a direct injury to hematopoietic stem cells. While stem cells, due to their dormant nature, may be more resistant to certain cytotoxic drugs, clearly a dose-response relationship with the degree of stem cell damage can be established. Noniatrogenic direct stem cell injury is less well characterized. If a putative inciting agent directly destroys stem cells, causing a permanent depletion, the clinical presentation of cytopenia may be delayed, precluding recognition of the causative agent. Regardless of the mechanism, direct stem cell damage is most likely random and can become obvious when certain critically low stem cell numbers are reached. None of these viral agents has been directly implicated in the pathogenesis of idiopathic AA. In the case of drugs and chemical agents most notoriously implicated in the pathogenesis of AA, the direct toxicity as a mechanism of injury is also in question. However, the most compelling evidence exists that the mechanisms of stem cell damage in AA are indirectly mediated by the cells of the immune system (see below).⁸⁻¹⁰

Quantitative defect

Theoretically, failed blood cell production in AA could be attributed to a defect restricted to the progenitor cell compartment and/or involve a stem cell. Low numbers of hematopoietic progenitors, as measured by colony assays or by flow cytometry, have been a consistent

finding in AA.¹¹⁻¹⁶ Both the more committed as well as the immature (CD34⁺c-kit⁻ or CD34⁺CD38⁻) progenitor cells are depleted.¹⁵ Hematopoietic progenitor cells from AA show decreased sensitivity to trophic signals,¹³ and colony formation by AA bone marrow cells remains unresponsive *in vitro* and *in vivo*, even to high levels of circulating hematopoietic growth factors present in most patients.¹⁷⁻¹⁹ Unlike in murine models, measurement of more immature progenitor and stem cells is not easily accomplished in humans.

The hematopoietic recovery following successful immunosuppression demonstrates that some stem cells must be spared from the pathologic process. Serial studies were conducted to determine the numbers of stem cells during the course of disease; a profound defect in the numbers may persist for a long time upon hematopoietic recovery, e.g., following successful immunosuppression.^{20,21} In most patients, a residual numeric defect may be permanent despite a full recovery of the blood counts. Complete reconstitution of the numbers may be found only in a minority of patients who sustained a complete remission.²⁰ Nevertheless, serial studies suggested that at least partial recovery of stem cells is possible, and a highly depleted stem cell pool can sustain seemingly normal blood cell counts (Figure 41.1).

Qualitative defect

In multiple studies stromal function has been found to be unaffected in AA.²²⁻²⁴ The defect of the stem

cells, rather than that of supporting stroma, has been elegantly demonstrated in experiments in which CD34⁺ cells from AA patients showed poor growth on allogeneic normal stromal layers, while normal CD34⁺ cells planted on the stroma derived from AA patients showed normal growth properties.^{19,22} Clinically, stem cell transplantation is a highly successful therapy in AA, but stromal elements remain of host origin following transplantation.²⁵ Damage to the stem cell compartment in acquired AA is likely the main cause for the quantitative defect by all measures used to quantitate early hematopoietic cells. The number of colony-forming cells or long-term culture-initiating cells (LTC-IC) assayed from purified CD34⁺ population derived from AA patients is lower than that observed with normal CD34⁺ cells.^{12,21,26} A decreased proportion of cycling cells has also been described in AA,¹¹ suggesting that a blockade in cell cycling may precede apoptosis.^{27,28} Alternatively, quiescent cells are resistant to apoptotic stimuli, and cycling cells may be selectively inhibited or killed, effectively turning off all active stem cells.

Apoptosis, telomere shortening, and genetic damage

In AA, an abundance of trophic signals and a relative lack of efficacy of hematopoietic growth factors argue against their deficiency as a mechanism of apoptosis.¹⁷ However, an increased apoptotic fraction within CD34⁺

Figure 41.1 Fate of hematopoietic stem cell compartment in aplastic anemia. Under normal circumstances, within the stem cell compartment, a certain number of cycling stem cells maintain supplies of committed progenitor cells that produce mature blood cells. In immune-mediated aplastic anemia, all stages of hematopoietic development are affected but the decrease of the stem cell numbers is the essential lesion, explaining involvement of all blood cell lineages. After successful treatment (e.g., with immunosuppression), removal of inhibitory stimuli may allow the remaining stem cells to compensate their numeric deficiency with increased production of committed progenitor cells, and, as a result, normal or seminormal blood cell counts can be maintained (right portion). However, a limited regeneration of stem cells may be possible (either within the compartment itself or through recruitment from the more pluripotent pool) and the normal blood cell production is restored (left)

cell populations derived from AA has been demonstrated.²⁹⁻³¹ In addition to proapoptotic cytokines and growth factors withdrawal, apoptosis in AA may be mediated by nitric oxide or oxygen radicals secreted by CD34⁺ cells in paracrine fashion.^{32,33}

Frequent evolution of clonal disease^{34,35} suggests that the process leading to the depletion of stem cells may promote acquisition of stem cell damage, and the expansion of the dysplastic clone may be the result of a clonal escape, possibly due to a different susceptibility to depletion mechanisms between normal and mutated stem cells. It is also possible that the depletion of normal stem cells may more likely facilitate the recruitment of a preexisting defective (under normal circumstances quiescent) stem cell (known as the oligoclonality theory). Alternatively, some of the proposed proapoptotic signals may serve as potential DNA-damaging agents. The putative mechanisms may involve generation of reactive oxygen and nitrogen species capable of damaging the DNA.

In true stem cells, self-renewal does not result in telomere shortening, but upon recruitment and commitment the telomere length progressively declines with each division.³⁶⁻³⁸ In general, shorter telomeres, measured by various methods, were reported in AA.³⁸⁻⁴⁰ While patients with chronic moderate AA showed short telomeres, in acute severe cytopenia, shortening of the telomeres may not be evident due to the blocking of stem cell cycling. Upon recovery, due to the recruitment of new stem cells, telomeres of the progeny may provide longer measurements again, or, if the stem cell number operating at a given time is small (and normal cell counts maintained), telomere shortening may be more pronounced. In general, once a critical telomere length is reached, chromosomes may become unstable. Such a mechanism could explain the evolution of clonal karyotypic defects in AA, but shortened chromosomes were not consistently found in AA patients who evolved into myelodysplasia.

CLASSIFICATION OF AA BASED ON ETIOLOGY AND PATHOPHYSIOLOGIC MECHANISMS

AA may have diverse causes that allow for clinically useful classification (Table 41.1). While iatrogenic AA is uncommon, it can be easily recognized. The most common is the idiopathic form of AA, and most parts of this chapter deal with this classical AA entity. Congenital bone marrow failure syndromes can evolve to AA; they will not be discussed in detail here.

Drug- and chemical-induced AA

Drugs and chemicals have been implicated as etiologic agents in AA for many decades. Benzene has served as a model chemical implicated in AA.⁴¹⁻⁴³ Intermittent exposure may be at least or even more toxic than chronic exposure. The mechanism of benzene toxicity is not entirely clear, and several metabolites may be

Table 41.1 Classification of aplastic anemia by etiology

involved. Consequently, genetic polymorphisms of the catabolic pathways may constitute predisposition factors for the development of benzene toxicity. In addition to direct toxicity comparable to that of some cytotoxic agents, other mechanisms, including stromal damage or even immune mediated effects, can be involved. Other aromatic hydrocarbons are also cited as causes of AA. Similarly, pesticides and insecticides have often been reported as causes of AA, but the rigorous systematic epidemiologic studies are scarce or showed mixed results. Overall, the proportion or cases attributable to specific pesticides or aromatic hydrocarbons is relatively small, especially given the ubiquitous nature of these chemicals in the modern world.

Medical drugs have been frequently implicated as causes of AA.⁶ Cytotoxic agents may serve as a prototype, and a patient's medical history should make a diagnosis obvious. Of importance are drugs used for treatment of unrelated disorders. Chloramphenicol and AA as well as aminopyridine and agranulocytosis are the best examples of agents recognized to be associated with an increased risk of disease.⁴⁴⁻⁴⁶ In general, drug reactions can be classified into dose-related effects and idiosyncratic reactions, in which occurrence is rare and not dose dependent. The list of drugs that have been implicated in causing AA is long, but all of them can account only for a fraction of cases (around 15%). The most comprehensive epidemiologic study performed in Europe identified agents that were associated with the occurrence of AA, but for most of the cases the stratified risk estimate was relatively low. The highest risk was found for some nonsteroidal anti-inflammatory drugs (NSAIDs) (piroxicam), gold, antithyroid agents, and allopurinol. Even for chloramphenicol, notoriously implicated in AA (at the peak of its usage 30% of all cases), the increase in the risk is modest (13-fold, or about 1/20,000). In general, agranulocytosis and mild pancytopenia are more common drug reactions than severe AA. The list of commonly implicated agents is provided in Table 41.2.

Table 41.2 Drugs most commonly implicated in aplastic anemia

Dose-dependent marrow cytopenia
Chemotherapy
Drug that may cause idiosyncratic association but low probability
Chloramphenicol
NSAID
Anticonvulsants (e.g., carbamazepine)
Antithyroid
Gold, D-penicillinamine
Sulfonamides
Carbonic anhydrase inhibitors
Very rare associations
Antibiotics
Allopurinol
Psychotropic (e.g., phenothiazines)
Cardiovascular drugs
Lithium
Sedatives (e.g., chlorpromazine)

Radiation

Bone marrow aplasia is a well-known toxicity of ionizing radiation. Myeloablation using γ -radiation is used therapeutically as a conditioning regimen for stem cell transplantation. The bone marrow is affected directly by γ -rays, and secondarily by α - and β -particles. Certain cell types, such as lymphocytes, are very sensitive and are killed directly, while hematopoietic progenitors require cell division for severe damage; thus, mitotically active cells are most sensitive. The onset and severity of pancytopenia is dose dependent. However, the regeneration capacity of the irradiated marrow is remarkable, likely due to the presence of quiescent, more resistant stem cells. While the exact LD50 dose is not precisely known in humans, 1.5–2 Gy of whole body radiation can induce marrow aplasia. The dose of 4.5 Gy (Shields–Warren number) has been estimated to constitute the LD50.^{11,47} The estimation of marrow toxicity is hampered by the toxicity to other organ systems that may limit survival. At doses at LD50, bone marrow toxicity limits survival.

Viruses

In many respects, clinical and pathophysiologic features of AA suggest a possible infectious etiology. Most commonly, viruses have been implicated. Over the years, many of the suggested agents have been excluded as etiologic factors. The search for AA agents has been extensive. Hepatitis B and A were proven not to be the causative agent for typical AA. Similarly, cytomegalovirus (CMV), although certainly capable of producing bone marrow suppression under certain clinical circumstances, such as following stem cell transplantation, is not responsible for idiopathic AA. Certain serologic CMV types have been implicated in transplantation-refractory AA, but these studies have not found application to explain typical AA.^{48–50} A series of cases clearly

attributable to Epstein–Barr virus (EBV) has been described, but again, EBV is a rare cause of AA.⁵¹ The best evidence for a viral etiology exists in a specific hepatitis/AA syndrome, in which severe AA follows with a 3–6 months latency. So far, a specific agent of this non-A, non-B, non-C hepatitis has not been found.⁵²

Immune-mediated bone marrow failure in AA

That AA is an immune-mediated disease has been concluded from the successes of immunosuppressive (IS) therapy. Despite progress in laboratory investigations, most experimental evidence supporting an autoimmune attack in AA remains indirect, and this clinical observation provides the strongest evidence for an autoimmune pathophysiology of this disease. The inciting events for the immune reaction in AA include viral infections that, through molecular mimicry, lead to the breach of tolerance toward antigens residing on hematopoietic stem cells. In addition, cross-reactive antigens could also be generated by chemical modification or conjugation with drugs. Finally, neoantigens created by transcription of mutated fused genes may induce an immune reaction with effector cells that are unable to selectively kill abnormal cells, and mediate depletion of normal elements as well (Figure 41.2).

Experimental evidence supports an immunologic mechanism in AA (for review see^{8–10}) (Figure 41.3). A role for T cells in AA was first suggested by coculture and depletion experiments, in which inhibition of hematopoietic colony formation was associated with this lymphocyte population.^{53,54} Later, an inverted CD4/CD8 ratio,²⁷ activated cytotoxic lymphocytes (CTL) as detected by the expression of HLA-DR⁵⁵ and CD25,⁵⁶ and skewing of the variable β -chain (V β) repertoire of the T-cell receptor (TCR) were found, consistent with expansion of autoimmune T-cell clones.^{57–65}

The damage to the stem cells can be mediated by a variety of mechanisms, including direct cell-mediated killing by CTL as well as cytokine-transduced inhibition (Figure 41.2). In addition to interferon γ (IFN γ) and tumor necrosis factor α (TNF α), Fas ligand or TNF-related inhibitory ligand (TRAIL) appears to play an important role as effector cytokines in the hematopoietic inhibition in AA.^{29,66–68} Such mechanisms may be restricted not only to the original targets, but also may include bystander cells. Ultimately, these factors may result in apoptosis of stem cells.

Genetic predisposition and congenital AA

Several rare congenital syndromes can present as AA or evolve to a clinical picture consistent with AA. Defect in the DNA repair machinery may lead to stem cell damage, but the pathophysiologic mechanism leading to pancytopenia is not clear. In some studies, immune mechanisms such as excessive production of TNF α have been implicated.^{41,42} Fanconi anemia is the most common differential diagnostic consideration that should be excluded in all children and younger

Figure 41.2 Immune mechanisms in AA. APC: antigen presenting cell; HSC: hematopoietic stem cells

patients. Due to the variable presentation of Fanconi anemia, patients may show initially normal counts, and AA evolves progressively. Dysmorphic features and short stature may not be obvious. Dyskeratosis congenita is another congenital syndrome that may present with pancytopenia. Classically, leukoplakia and nail abnormalities are present.

CLINICAL FEATURES OF AA

PRESENTATION

Most patients with AA present with symptoms of anemia or bleeding due to deficient red blood cell and platelet production. Infection associated with low neutrophil numbers is not a common initial presentation. Often, AA is uncovered incidentally; patients may remain asymptomatic for a long time due to the latent onset of anemia. Consequently, the latency period and the onset of the disease are difficult to determine. In some cases, when AA is discovered early, a follow-up blood examination will reveal progressive worsening of cytopenia.

DEFINITION, DIAGNOSIS, AND DIFFERENTIAL DIAGNOSIS

Definitions and classification

According to the useful definition of the AA Working Party, AA is defined by bone marrow cellularity (usually <10%) and a decrease in two out of three blood lineages. Cytopenia secondary to other hematologic diseases and systemic conditions has to be excluded. The issue of the requirement of normal cytogenetics is a subject of some controversy, especially that in a proportion of patients, cytogenetic analysis may not be informative. Most experts believe that the presence of karyotypic abnormalities at presentation is consistent

with the diagnosis of MDS, excluding idiopathic AA. According to the severity classification proposed by Camitta⁶⁹ (Table 41.3), patients with moderately depressed counts have an excellent prognosis even if untreated, while those with severely affected blood counts have poor survival in the absence of therapy.

Differential diagnosis

A large number of conditions may mimic AA in all or some of its aspects and features, and depending on the clinical circumstances, some alternate diagnoses have to be excluded (Figure 41.4). Several systemic diseases can present with an aplastic bone marrow; bone marrow biopsies can be hypocellular in up to 10% of patients with MDS.¹⁻³ In addition, marrow aplasia can be encountered in hairy cell leukemia, or be iatrogenic. Discrimination of AA and MDS may be particularly challenging if hypocellularity precludes proper morphologic evaluation and cytogenetic examination is not informative. Clues may be provided by presence of micromegakaryocytes, myeloid dysplasia, and residual blasts.

Table 41.3 Classification of aplastic anemia by severity

Aplastic anemia	
Severe aplastic anemia	Moderate aplastic anemia
Bone marrow cellularity, 10% Depression of at least two out of three hematopoietic lineages: ANC, 500/uL Transfusion dependence with absolute reticulocyte count (ARC), 60,000/uL Platelets count	Decreased bone marrow cellularity Depression of at least two out of three hematopoietic lineages not fulfilling the severity criteria as specified in the right column

Figure 41.3 Bone marrow finding in AA. (a) Peripheral blood smear from a patient with aplastic anemia demonstrates severe pancytopenia with normocytic to slightly macrocytic anemia, neutropenia, and thrombocytopenia (peripheral blood, Wright–Giemsa stain, original magnification $\times 100$). (b) Bone marrow touch imprints may be helpful in excluding mimics of aplastic anemia, such as hairy cell leukemia, which can result in a dry tap. This low-power image of a touch imprint reflects the overall hypocellularity encountered in aplastic anemia (bone marrow biopsy touch imprint, Wright–Giemsa stain, original magnification $\times 10$). (c) Bone marrow biopsy in aplastic anemia illustrates severe panhypoplasia with only rare scattered lymphocytes and plasma cells (bone marrow core biopsy, hematoxylin–eosin stain, original magnification $\times 40$). (d) Because marrow cellularity may vary geographically within the biopsy, with the area immediately subjacent to the cortex often being hypocellular, it is essential to obtain an adequately sized core biopsy when evaluating for possible aplastic anemia (bone marrow core biopsy, hematoxylin–eosin stain, original magnification $\times 10$). (e) Hypocellular MDS can mimic aplastic anemia. In this biopsy, mature myeloid elements are reduced, and the presence of occasional mononuclear cells consistent with blasts (arrow) can be a subtle feature. Marrow aspirate smear (inset) showed 9% myeloid blasts with dysplastic changes in erythroid precursors (bone marrow core biopsy, hematoxylin–eosin stain, original magnification $\times 40$; inset: bone marrow aspirate, Wright–Giemsa stain, original magnification $\times 100$) (courtesy of Dr. Karl Theil, Cleveland Clinic)

Diagnostic procedures

Diagnostic procedures include blood counts and a differential, and a bone marrow aspiration and biopsy (Figure 41.5). A reticulocyte count should always be obtained to assess severity and establish that anemia is related to the deficient marrow red blood cell production. The marrow exam should include cytogenetic evaluation. The presence of even small numbers of blasts strongly questions the correctness of the AA diagnosis. The residual erythropoiesis may be mega-

loblastic; overt dysplasia of the myeloid series should not be seen in typical AA. Megakaryocytes are most typically absent or severely decreased in number. Routine flow cytometry of blood is not indicated, but may be helpful in excluding T-cell lymphoproliferative syndromes and B-cell malignancies, especially hairy cell leukemia. Due to a common association and possible prognostic considerations, the presence of PNH should be investigated by flow cytometry on both red blood cells and granulocytes, which provide

Figure 41.4 Differential diagnosis of idiopathic aplastic anemia and pancytopenia

a much more sensitive and, unlike erythrocytes, transfusion-independent assessment of the size of the PNH clone. In younger patients, Fanconi anemia should be excluded by diaminobenzidine (DAB) testing. Splenomegaly and lymphadenopathy are atypi-

cal and always herald the presence of an alternative diagnosis or additional disorder.

DISTINCT CLINICAL ENTITIES

AA/paroxysmal nocturnal hemoglobinuria syndrome
Recent studies using a sensitive flow cytometric method have demonstrated that a glycosyl phosphatidyl inositol (GPI) deficient clone can be present in up to 1/3 of all patients with AA at presentation.^{70,71} While in most of these patients PNH clones are tiny in size, in a significant minority of patients significantly expanded GPI-deficient PNH clones are present. These patients, unlike those with a primary hemolytic form of PNH, may have hypocellular bone marrow and low reticulocyte count. It has been hypothesized that the autoimmune attack responsible for the stem cell depletion in AA generates permissive conditions under which an otherwise dormant PNH clone can evolve.^{72,73} The finding of a large proportion of PNH cells may be a significant feature, as administration of antithymocyte globulin (ATG) may be associated with a precipitation of a major hemolytic episode.

AA/hepatitis syndrome

AA/hepatitis syndrome has been described as a rare but instructive variant of this disease clearly pointing to a viral etiology of some cases of AA.^{52,74} Despite extensive laboratory investigation, such a virus has not been

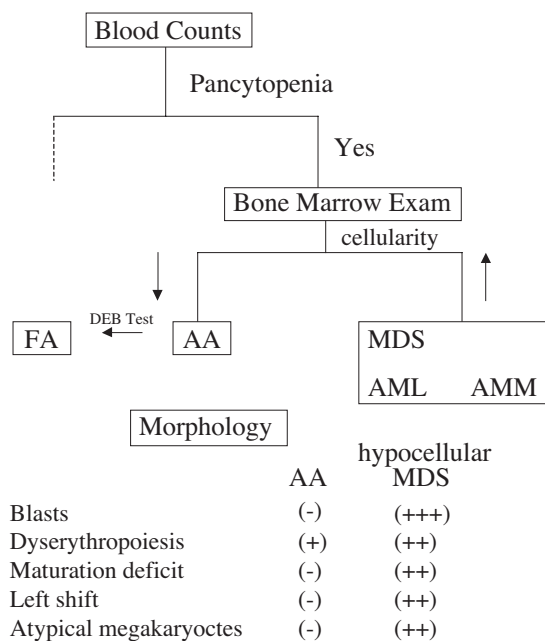

Figure 41.5 Diagnostic algorithm in aplastic anemia

found. It appears that the often fulminant hepatitis initiating the disease is caused by a non-A, non-B, non-C hepatitis virus. The hepatitis is associated with jaundice and an often pronounced rise in transaminases. It can result in fulminant liver failure. In patients who survive the hepatic phase, transaminases, decrease and a latency period characterized by a period of a relative well-being follows. After a variable time period (often several months), pancytopenia develops with a clinical picture typical of severe AA. ATG therapy is effective and can often result in a complete remission. The time course of the syndrome is highly suggestive of virally induced hepatitis, which upon clearance of virus results in induction of cross-reactive T-cell response directed against hematopoietic stem cells.

Chronic moderate AA

In contrast to severe AA, AA with moderately depressed counts has a favorable prognosis and often does not require therapy. The definition of moderate AA is difficult, as it may represent a transition stage of severe AA. A sufficient observation period (>3 months) with chronically and not progressively depressed counts makes the diagnosis of moderate AA. Over time the blood counts may decline, with evolution to a severe AA. It remains unclear whether moderate AA represents a separate entity, a number of nosologic entities such as unrecognized congenital bone marrow failure syndromes or a stage/variant of typical AA.

AA in pregnancy

Pregnancy seems to predispose to AA, but this issue remains controversial. In fact, one of the first cases of AA documented in the early writings on this disease was a young pregnant woman.⁷⁵ The mechanism that triggers AA in pregnancy remains unclear, but AA often resolves with the termination of pregnancy and can recur during subsequent pregnancies. Even if the initial presentation of AA was not associated with pregnancy, women with a recent history of successfully treated AA should be counseled to not get pregnant. Successful pregnancies have been described, and in the majority of case series most of the women had good outcomes.⁷⁶ The therapy of pregnancy-associated AA depends on the gestational age of the fetus. The pregnancy of a woman with severe AA may be terminated if it is close to term. Earlier in pregnancy, supportive measures are most commonly used. ATG has also been administered to women with severely depressed counts, especially low absolute neutrophil count (ANC). Overall, the prognosis for the mother and baby is good.

affected by this disease. The most common IS regimens combine equine ATG (at 40 mg/kg/day for 4 days) with cyclosporine A (CsA) (12–15 mg/kg in a divided dose b.i.d.) given for at least 3 months, but usually for 6 months (Figure 41.6). Steroids are usually added to counteract the serum sickness intrinsic to ATG therapy. Rabbit ATG (3.5 mg/kg/d × 5d) is likely as effective as horse ATG, but its efficacy has not been compared in a randomized trial.⁷⁷ The response rate to horse ATG ranges from 70 to 80%, with a 5-year survival of 80–90%.^{12,78–81} ATG appears to be superior to CsA,^{82,83} and the combination of ATG and CsA provides better results than ATG alone or CsA alone.^{84,85} Intense immunosuppression with ATG/CsA has also been administered with good success in elderly patients.⁸⁶ The addition of granulocyte colony-stimulating factor (G-CSF) may improve neutropenia, but does not increase survival.⁸⁷ Patients who respond have excellent survival, while those who are refractory have less favorable survival, with counts at 3 months post-ATG therapy having a good correlation with long-term prognosis. Most patients who are destined to respond do so by that time, and subsequent improvement may occur in additional one fourth of patients. Newer IS regimens may employ other agents, such as mycophenolate mofetil and, in the context of CsA toxicity, Dacluzimab Zenapax [anti-IL-2 receptor (CD25) monoclonal antibody], but the efficacy of these agents is not known. Refractory patients may be retreated with multiple courses of ATG. Repeated ATG may result in salvage of a significant proportion of patients. In one study of patients refractory to horse ATG, rabbit ATG resulted in a 50% response rate and excellent long-term survival.⁷⁷ No good prognostic factors are available with regard to the response to ATG, with the exception of the presence of HLA-DR15 alleles and the PNH clone, both of which correlate with good responsiveness to immunosuppression.⁸⁸

High-dose cyclophosphamide has been advocated as an effective first-line therapy alternative to ATG.⁸⁹ High response rates were reported to be associated with prevention of relapse, and also with clonal disease. However, prolonged cytopenia has resulted in an excessive toxicity related to neutropenic complications in a randomized trial between ATG/CsA and cyclophosphamide/CsA, resulting in a termination of the study.^{90,91} Long-term follow-up of patients treated with cyclophosphamide showed that relapse and clonal disease can occur after this type of therapy.^{91,92} It seems that high-dose cyclophosphamide does not constitute advancement over ATG/CsA, and should be used only in selected cases or in the context of clinical trials.

THERAPY

IMMUNOSUPPRESSIVE THERAPY

IS therapy remains the most important primary treatment modality for the major portion of patients

OTHER THERAPIES

Hematopoietic growth factors

Hematopoietic growth factors should not be used in the primary setting. Some patients will show an improvement of neutropenia with G-CSF, but severe

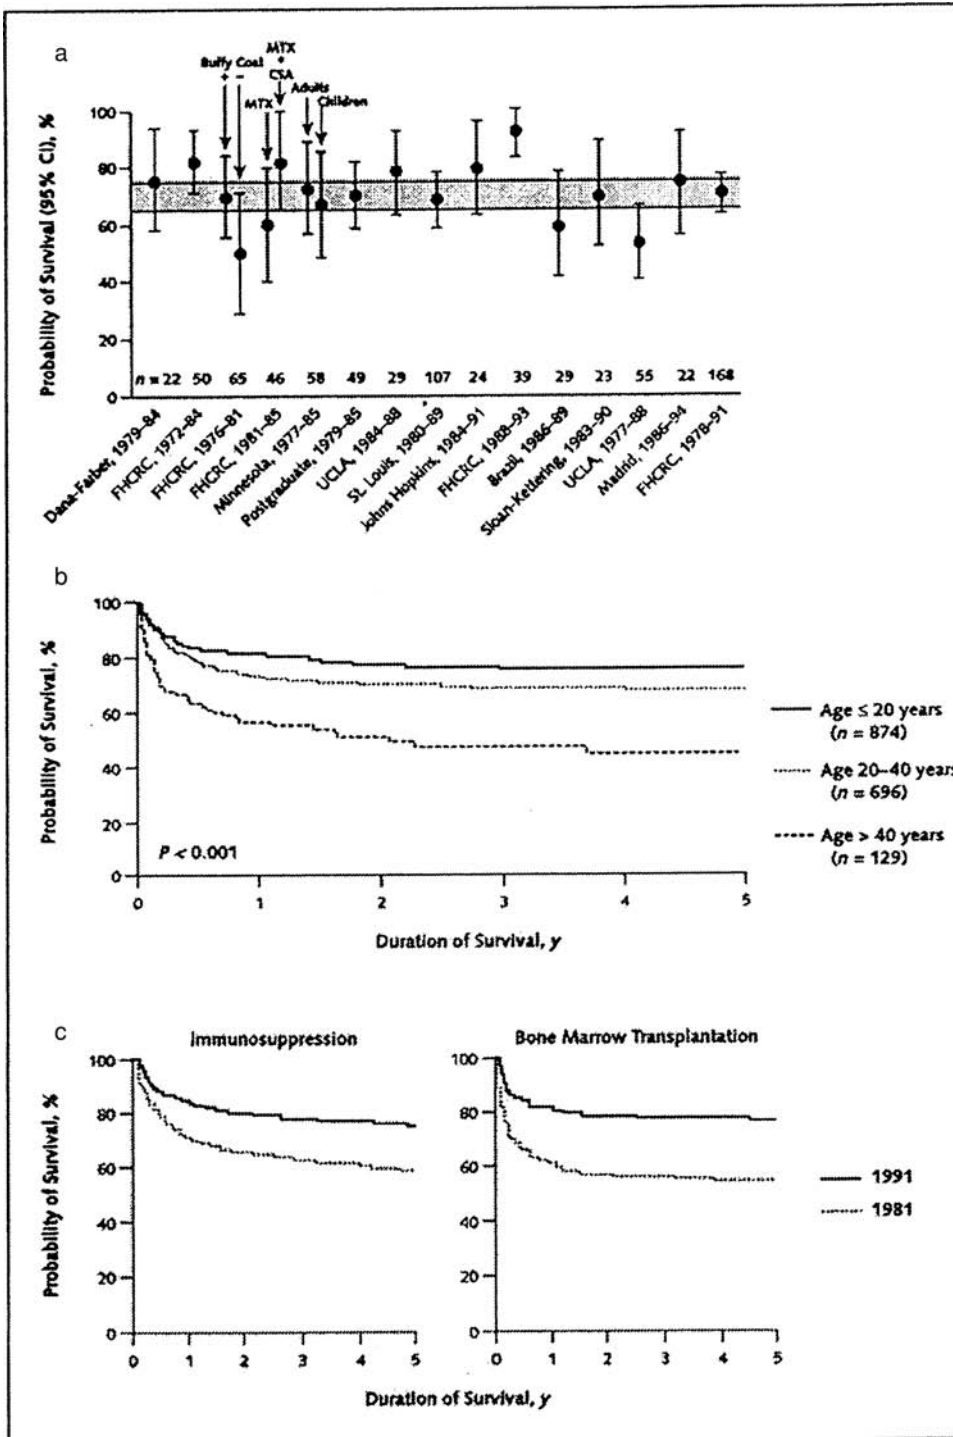

Figure 41.6 Results of immunosuppression and stem cell transplantation in aplastic anemia. (a) Allogeneic stem cell transplantation. Data are presented from individual hospital series in peer-reviewed publications from 1991 to 1997. The shaded area represents the 5-year probability of survival (with the same confidence intervals) of patients reported to the International Bone Marrow Transplant Registry (IBMTR) during this period. (b) The continuing influence of age on survival, as reflected in IBMTR data. (c) Comparative probability of survival after immunosuppression and stem cell transplantation. The data are for patients reported to the Working Party on Severe Aplastic Anemia of The European Group for Blood and Marrow Transplantation in the 1980s and 1990s. CSA = cyclosporine; FHCRC = Fred Hutchinson Cancer Research Center; MTX = methotrexate; UCLA = University of California, Los Angeles (Adapted with permission from Ref. 9)

neutropenia due to a typical AA is mostly refractory. In combination with an ATG/CsA regimen, G-CSF can improve neutropenia (neutrophil response), and response to this therapy constitutes an early positive prognostic factor with respect to future response.⁸⁷ However, no survival advantage has been reported.⁸⁷ Dose escalation does not appear to be beneficial.⁹³

Anabolic steroids

Anabolic steroids have been widely used as therapy of AA, prior to the advent of IS therapy.^{94,95} Currently,

androgens are mostly used as a salvage therapy for refractory patients. Historically, response rates to androgens were clearly observed, and were reported to be 30–60%. The androgens in current use include oxymethalone and danazol. Danazol has a relatively low virilizing potential.

STEM CELL TRANSPLANTATION

AA was the first disease treated successfully with stem cell transplantation. The most common conditioning regimen was established early and includes

cyclophosphamide and ATG. For graft-versus-host disease (GvHD) prophylaxis, methotrexate, together with CsA, appears to produce better results than CsA alone.⁹⁶ Improvement in the general care and treatment of GvHD rendered stem cell transplantation a much safer procedure and made transplantation a curative treatment option for more patients.

MATCHED SIBLING DONOR TRANSPLANTATION

Allogeneic transplantation is available to only a minority of patients (around 30%). With the general improvement in the outcomes of stem cell transplantation, the overall survival (OS) for matched sibling donor transplantation has been as good as 85–90% (Figure 41.6).^{96,97} Even better results were reported in children, in whom stem cell transplantation appears to be more effective in improving survival than does immunosuppression,⁹⁸ making this procedure a treatment of choice for children with severe AA and a matched sibling donor. However, the typical decrease in the OS is observed with increasing age of the recipient, making the therapeutic decision for older patients a challenge. Children and young adults with a matched sibling donor should be offered stem cell transplantation as a first therapeutic option.

UNRELATED ALLOGENIC STEM CELL TRANSPLANTATION

The survival rates in patients who undergo a matched unrelated stem cell transplantation of approximately 35% are by far less impressive than those performed from matched sibling donors.⁹⁷ In one report from 1996, the OS was around 54%.⁹⁹ Various methods, including modified conditioning regimens and T-cell depletion, have been used to improve results,^{100,101} but relatively little progress has been made in comparison to matched sibling donor transplantation.⁹⁷ Most deaths occur due to GvHD, graft failure, and opportunistic infections. More recent results, and those obtained in children, are more favorable.^{102,103}

COMPLICATIONS AND LONG-TERM PROGNOSIS

In general, patients successfully treated with immunosuppression have an excellent prognosis, while nonresponders who cannot undergo stem cell transplantation have a poor survival. In recent years, the survival of chronically pancytopenic patients improved, likely due to advances in supportive care. Conversion of severe AA into moderate disease appears to be sufficient to significantly improve the long-term prognosis. The most common complications of AA include relapse and evolution of clonal disease. These complications occur in patients treated with immunosuppression. Recipients of allogeneic grafts show a different set of long-term com-

plications, including cataracts, thyroid disorders, and secondary cancers.¹⁰⁰

RELAPSE

The relapse rate following IS therapy may be substantial. For ATG/CsA, it may be as high as 35% in 7 years.^{12,81} In general, relapse has a good prognosis and survival of relapsed patients is not significantly shortened.⁸¹ Patients with falling blood counts can receive a trial of CsA. If unsuccessful in rescuing the counts, a repeated course of ATG should be given. The response rates are likely comparable to those seen in the initial course of ATG. In some instances, rabbit ATG can be used instead of horse ATG, but it is unclear whether this measure helps to avoid more dramatic allergic reactions. High-dose cyclophosphamide (see above) has been suggested to prevent subsequent relapses.

EVOLUTION OF CLONAL DISEASE

With the introduction of IS therapy, the survival of AA patients who are not treated with stem cell transplantation has improved significantly.⁹ With long-term systematic observation, evolution of AA to other hematologic diseases has been frequently recognized as a serious late complication. Historically, the development of PNH was considered the most common clonal complication of AA. Although the appearance of PNH clones is often already observed at first presentation of bone marrow failure,^{70,71} manifest PNH develops in a much smaller but significant proportion of patients. MDS is another common clonal disease occurring in the context of AA.

EVOLUTION OF MDS

Theories of MDS evolution in the context of the pathophysiology of AA

A fundamental question in the evolution of clonal disease in AA is whether its pathophysiology is intrinsic to the natural history of AA, and now only observed, as patients survive longer, due to effective therapies. Alternatively, clonal evolution may be secondary to the treatment of AA, as a complication of IS therapy, or more recently, due to chronic growth factor administration. Theoretically, inhibition of immune surveillance could lead to the uncontrolled outgrowth of abnormal clones. However, MDS has occurred in AA treated with androgens only,^{104,105} arguing against the theory that the clonal evolution to MDS is a consequence of immunosuppression. In addition, patients with primary MDS have been treated with IS agents and no acceleration of the disease has been observed.^{36,106,107} While prolonged G-CSF treatment was linked by Japanese investigators to the evolution of monosomy 7,^{105,108–110} there was no increased risk observed in a randomized study of ATG and CsA with and without G-CSF¹¹¹ or in the analysis of the European Group for Blood and Marrow Transplantation (EBMT)

data.¹¹² In a National Institutes of Health (NIH) study,³⁴ many of the AA patients who developed cytogenetic abnormalities received hematopoietic growth factors, mainly as support or as salvage therapy after unsuccessful immunosuppression, and refractory disease itself may be the underlying risk factor for clonal evolution.

Diagnosis of evolution, its frequency, and timing

The relationship between AA, a disease dominated by an immune pathophysiology similar to other organ-specific autoimmune diseases, and MDS, usually viewed as a premalignant process, remains unclear in many clinical and pathophysiologic aspects. Aberrant differentiation of hematopoietic precursor cells, increased numbers of myeloblasts, and marrow hypercellularity are all characteristic of MDS, but persistent bone marrow hypocellularity in AA may preclude reliable morphologic analysis. Clinical similarities between MDS and AA are most obvious in the hypocellular form of dysplasia, and clinical distinction is often not possible.

The development of MDS in the setting of diagnosed AA has been described in several studies, but these vary significantly in their design, and especially in case definition,^{12,109,113–118} exemplifying diverse views with respect to the criteria required for the diagnosis of both MDS and AA. In historical studies of AA, patients with abnormal cytogenetics and hypoplastic marrows at presentation were often included,^{119–122} and in some institutions, abnormal cytogenetic studies are compatible with a primary diagnosis of AA.^{104,122–124}

Most commonly, abnormal cytogenetics was felt to exclude a diagnosis of AA, regardless of marrow morphology; in a series from the NIH involving 122 patients treated with intensive immunosuppression consisting of ATG and CsA, all patients showed a normal karyotype at presentation, and 14 subsequently developed karyotypic abnormalities, with a risk of about 21% at 10 years. Only two patients were diagnosed as having a late MDS by marrow morphology alone, with normal chromosomes.¹¹⁹ In an early study from Seattle, an abnormal karyotype was reported in 7 of 183 AA patients, but only 3 of these developed after immunosuppression.¹⁰⁴ The differences in the diagnostic criteria are also obvious, such as in a recent analysis by the EBMT AA Working Party, in which karyotypic abnormalities occurred in 23 of 170 patients, but in 4 cases chromosomal changes were present at first diagnosis¹¹⁹ and would be classified as MDS at other institutions. Similarly, in a recent British series of 13 patients with AA and abnormal cytogenetics, only 2 presented with normal karyotype and later developed an abnormality.¹²³ In a study of 159 children with AA from Japan, the authors identified 6 patients with the diagnosis of “AA with cytogenetic abnormalities.”¹²² In another cohort compiled of 100 patients from the GITMO (Gruppo Italiano Trapianto di Midollo Osseo) and EBMT study involving anti lym-

phocyte globulin (ALG), CsA, prednisone, and G-CSF, during a median follow-up of 1424 days, 11 patients developed cytogenetic abnormalities.¹²⁵ In the interval of 11 years, 8% of patients enrolled in the randomized ATG +/- CsA study developed MDS or AML.¹²⁶

The evolution of an abnormal karyotype has also been reported in children. In a series of 114 pediatric patients from Europe, 7 developed chromosomal abnormalities but the aberrant clone was retrospectively found in 2 at presentation,¹²⁷ decreasing the true evolution rate in this study to 5/114. Among 40 Japanese pediatric patients treated with G-CSF and CsA, 11 showed clonal evolution, mainly to monosomy 7.¹⁰⁹ Recently, the same group reported on the development of MDS or AML in 5 of 41 children treated with immunosuppression for their hepatitis-associated AA.¹²⁸

After clonal evolution, marrow morphology was characterized by a predominance of hypercellularity (41%) and patchy biopsy cellularity (27%), while continued hypocellularity was found in 1/3 of the patients. Frank dysplasia, including changes in megakaryocyte morphology, was found in 15 of 29 patients, and a left shift in myeloid differentiation was observed in 12. However, in 9 of 29 patients, there were no morphologic changes suggestive of MDS.³⁴ While the entity of AA with cytogenetic abnormalities may exist, the new appearance of a karyotypically abnormal clone in the course of AA warrants the change of current diagnosis of AA to MDS. In a recent NIH analysis, patients with AA were followed with periodic cytogenetic analyses of marrows, and evolution of abnormal karyotypes was identified in 29 patients (a total of 189 patients were analyzed), allowing for the estimation of the evolution rate of 14% in 5 years and 20% in 10 years, respectively.³⁴ While the detection of a new cytogenetic abnormality is a stringent diagnostic sign, it may not reflect the total rate of MDS evolution in AA. In primary MDS, the proportion of patients with a normal karyotype is 40–60%, and by analogy, it is possible that also in post-AA, MDS can evolve without overt chromosomal damage.

Risk factors

As various types of MDS and clonal abnormalities may have different underlying pathophysiologies, it may be difficult to identify specific risk factors for progression to clonal disease. For example, monosomy 7 appears to evolve in primary refractory patients or those with incomplete responses to immunosuppression, while trisomy 8 was observed in patients whose counts improved adequately.³⁴ A similar clinical observation was made for the 13q- abnormality.¹²⁹ In another study, a similar distribution of clonal evolution between responders and nonresponders and monosomy 7 was observed in both groups of patients.¹²⁷

Chromosomal abnormalities

The most commonly found cytogenetic abnormalities following AA were aberrations of chromosome 7 and trisomy 8. For example, in a study from Seattle, monosomy 7 was found in three and trisomy 8 in two of seven patients with karyotypic abnormalities¹⁰⁴ and, in a Dutch series, in three of five AA patients who evolved to MDS.¹¹⁴ In a recent report from Japan, a series of 9 patients with 13q- following otherwise typical AA was reported¹²⁹; in the NIH experience, 13q- was also reported in several of the 29 patients who developed an abnormal karyotype after AA.³⁴ In agreement with the Japanese report, both patients showed stable counts and a good response to immunosuppression. In a study of children in Japan, monosomy 7 occurred at the highest frequency,¹³⁰ and in children reported from Germany and Austria, monosomy 7 was present in two of seven patients, while trisomy 8 was encountered once.¹²⁷ In a long-term update of the NIH ATG/CsA trial, aberrations of chromosome 7 were present in 10 and trisomy 8 in 2 out of 13 patients.⁸¹ All other abnormalities appear to occur more randomly, and given the overall low number of patients reported, it is difficult to establish individual frequencies.

There are no predictive factors to identify patients at risk for the clonal evolution of myelodysplasia. In retrospect, blood counts of patients at the time of the cytogenetic evolution to trisomy 8 were significantly higher than those of patients with monosomy 7. Additionally, even after evolution to trisomy 8, sustained improved blood counts were often dependent upon continued CsA administration. Patients with monosomy 7 and those with complex karyotypes usually (but not always) had a poor response to immunosuppression and persistent pancytopenia.³⁴

Although the appearance of a cytogenetic abnormality in a patient with AA is strong evidence of clonal evolution to MDS, in some studies a high proportion of apparently transient chromosomal changes would diminish the diagnostic and prognostic implications of new cytogenetic findings. Conversion to a normal karyotype is not a frequent event, and may also be a function of the frequency of marrow examinations. In our previously published study,³⁴ such an event was observed in only 2 of 29 patients, but since publication of this report another patient reverted (unpublished observation). It is likely that abnormal clones may be recruited and contribute to blood production for limited periods of time.

Prognosis

MDS, evolving from AA, and primary MDS differ in the distribution of specific cytogenetic abnormalities. In primary MDS, aberration of chromosome 5 is generally cited as the most frequent abnormality, present in 10–37% of all patients,^{131–136} but this chromosome is only rarely affected in AA patients. 20q- and -Y also are more often abnormal in primary MDS in compar-

son to AA.^{131,133} Conversely, monosomy 7, most prominent in the late evolution of MDS from AA, occurs in a minority of primary MDS (6.5–11%).^{12,131,134–138} Trisomy 8 appears to have a comparable incidence among cytogenetic abnormalities evolving from AA and in primary MDS (6–20%)^{131–138}.

Clearly, the diagnosis of MDS in the course of AA has prognostic significance. Most obvious modifiers include the presence of blasts, a hypercellular bone marrow, certain types of defects, and recurrence or persistence of profound cytopenia, all constituting unfavorable prognostic markers. For example, in one report, AA patients who developed secondary chromosomal abnormalities had a mortality rate of about 27% with a mean follow-up after evolution of 29 months (from the initial diagnosis, the total observation interval was 70 months). All but two deaths were related to AML.³⁴ Response to immunosuppression in patients with aplasia and abnormal karyotypes may be as high as 50%,¹²² and certain karyotypic abnormalities (trisomy 8, 13q-) may favorably respond to immunosuppression. While the low numbers of patients reported preclude generalization, no individual abnormality predicted unresponsiveness. However, certain types of chromosomal defects are less likely to benefit from immunosuppression, including monosomy 7, complex karyotypes or 5q- syndrome. A stem cell transplantation may be the only therapeutic option for patients affected.

EVOLUTION OF PAROXYSMAL NOCTURNAL HEMOGLOBINURIA

Theories of PNH evolution in the context of AA

The mechanisms of the selective advantage of the PNH clone has been the subject of intense research, but no conclusive results have been obtained. The simplest model to explain how the PIG-A mutation accounts for the ability of the PNH clone to expand predicts that PIG-A mutant cells enjoy an intrinsic growth advantage. Surprisingly, clinical observation and much experimental data do not support this hypothesis.⁷³ Most obviously, PNH does not behave like leukemia. PNH stem cells are capable of producing mature cells of all lineages and respond to many physiologic stimuli. PNH progenitor and stem cells do not accumulate. In some patients, the proportion of PNH cells remains stable for years,⁷⁰ suggesting that GPI-deficient and normal hematopoiesis may coexist and that PNH cells do not simply displace normal cells. The presence of PNH cells in normal adults is also difficult to reconcile with this model, given the rarity of this disease. The differential susceptibility to apoptosis of PNH cells has been reported by several groups,^{56,139,140} but their results have not been confirmed by others.^{141,142} Appropriate controls with primary cells are difficult in such experiments, while cell lines may not reflect the situation *in vitro*.

Clinical features

A PNH clone can be present in a significant proportion of patients with AA at presentation, but most patients harbor small clones without clinical significance. The presence of PNH clones constitutes a positive prognostic factor for the response to immunosuppression. The behavior of the PNH clone in the course of the disease and following therapy is erratic. In some patients, the clonal size does not change, while a clinical PNH can

evolve in up to 10% of AA patients over the period of 10 years. Currently, there are no good predictive factors, and most of the current data are derived from an older cohort of patients. It remains unclear whether AA patients who developed PNH did have minor PNH clones detectable at presentation, or whether their PNH developed truly de novo. PNH can be a disabling chronic complication of AA and is associated with hemolysis, transfusion dependence, and thrombotic complications.

Chapter **42****ALLOGENEIC STEM CELL
TRANSPLANTATION FOR
MYELOYDYSPLASTIC SYNDROME
AND APLASTIC ANEMIA***Vikram Mathews and John F. DiPersio***ALLOGENEIC STEM CELL
TRANSPLANTATION FOR
MYELOYDYSPLASTIC SYNDROMES****INTRODUCTION**

Myelodysplastic syndrome (MDS) is a heterogeneous group of clonal hematopoietic disorders characterized by ineffective hematopoiesis, marrow dysplasia, and variable rates of transformation to acute myeloid leukemia predominantly affecting older patients (mean age 69 years).¹ With the aging of the population and increased awareness, the incidence and prevalence of MDS has been steadily increasing over the last 20 years.² In the United States, the estimated incidence of MDS is between 3.5 and 12.6 per 100,000 new.³ MDS is associated with several subtypes diagnosed each year. The older FAB classification⁴ of MDS has been replaced by the WHO classification.⁵ The diagnostic subtypes have a significant bearing both for treatment and on prognosis. The blast percentage, the cytogenetic findings, and number of cytopenias at diagnosis are important in prognostication. Together these parameters have been used to generate a scoring system termed the International Prognostic Scoring System (IPSS).⁶ The IPSS has a bearing not only in the overall prognosis of a patient with a diagnosis of MDS, but is also a useful predictor of transplantation outcomes.^{7,8} In spite of there being significant progress in the understanding of the pathophysiology of MDS, which has translated into novel therapeutic interventions, allogeneic stem cell transplantation (SCT) still remains the only therapy that has curative potential in this condition. This was first demonstrated as early as 1984.⁹ The epidemiology, molecular biology, pathology, and clinical features have been addressed in detail in Chapters 41–43.

ALLOGENEIC SCT IN MDS

Various therapeutic options exist for the management of a newly diagnosed patient with MDS. In addition to the subtype and IPSS score at diagnosis, the age and performance status of the patient are important determinants of feasible therapeutic options. In spite of significant improvements in supportive care and the increasing therapeutic options that are available (Chapter 44 and 48), an allogeneic SCT remains the only option that has curative potential, leading to the recommendation that all patients who are eligible for a transplant procedure and have an available donor should be considered for this procedure.¹⁰ However, in reality this therapeutic option is limited to a small fraction of patients with this diagnosis, as the majority of patients are over 65 years, with additional comorbidities and poor performance status. Even when other adverse factors are not present, this group of older patients is perceived as being unable to tolerate a standard myeloablative conditioning regimen.

Since MDS has significant variability in the natural history and response to therapy, no single therapeutic algorithm can be applied to this group of patients; rather, therapy has to be tailored to the individual patient. For patients eligible to undergo an allogeneic SCT, the factors that have a bearing on transplant outcome have to be weighed against the risks involved. In this chapter we look at some of these factors and provide a broad overview of the role of an allogeneic SCT in the management of MDS.

EFFECT OF AGE ON OUTCOME

Intuitively, older patients should do poorly following an allogeneic SCT. Most studies have shown that recipient age is an important prognostic factor for nonrelapse mortality (NRM).¹¹ In a majority of the large trials using a myeloablative regimen with related^{7,12–14} and

unrelated donors,^{12,15–17} this holds true. However, in one large study by Deeg et al.⁸ that used targeted busulfan levels in a myeloablative conditioning regimen, in a multivariate analysis, there was no significant effect of age (up to 66 years) on relapse-free survival (RFS). The data on the use of nonmyeloablative transplants for older patients is still evolving and could potentially improve the outcome of older patients undergoing an allogeneic SCT.

EFFECT OF IPSS SCORE ON OUTCOME

IPSS scores have been shown to have a bearing on the outcome following an allogeneic SCT.^{7,8} In the more recent publication by Deeg et al.,⁸ the 3-year RFS was 80% for patients with low-risk MDS (IPSS score 0), which progressively decreased with increasing scores to 29% among patients with an IPSS score higher than 2 (Figure 42.1). Earlier studies had shown a similar correlation with cytogenetic risk groups and posttransplant outcomes in patients with MDS. Nevill et al.¹⁸ showed a 7-year event-free survival of 51%, 40%, and 6% in the good-, intermediate-, and poor-risk cytogenetic risk groups, respectively. Since the IPSS score includes additional parameters of percentage of blasts in the bone marrow and number of cytopenias at diagnosis,

which are important independent adverse factors,¹⁴ it is likely to be a more robust system to predict outcome following an allogeneic SCT.

IPSS score also has an important bearing on decision making with regards to proceeding with an allogeneic stem cell transplant. In the low-risk group with a median survival of 11.8 years in patients younger than 60 years,⁶ one would opt for supportive care or a nonintensive low-risk therapy rather than subject such an individual to the risk of treatment-related mortality (TRM) following an allogeneic SCT. On the other hand, a patient with an IPSS score >2, who has a median survival of a few months⁶, is a candidate for an allogeneic SCT provided a donor is available and his or her performance status permits the procedure to be done.

EFFECT OF TIME TO TRANSPLANT FROM DIAGNOSIS

While an allogeneic SCT is the only curative therapeutic option in the management of MDS, it is also associated with the highest TRM. NRM caused by infections, graft-versus-host disease (GVHD), and organ toxicity in large series of patients undergoing an allogeneic SCT varies from 30–54%.^{16,18,19} It would not be appropriate to expose low-risk MDS patients to these risks. However, MDS is for the most part a continuously evolving disease process with an inexorable progression to acute leukemia, and an allogeneic SCT done in a more advanced stage of the disease process is associated with significantly worse outcomes.^{7,8} The optimal time has been a matter of controversy, especially for the low- and intermediate-risk MDS. A recent publication by Cutler et al.²⁰ attempted to address this issue by applying a statistical technique called a Markov model to predict long-term outcomes under conditions of uncertainty. In patients with low- or intermediate-risk MDS, delayed transplantation by a fixed time interval (2–2.5 years) and prior to leukemia transformation maximized overall survival. This survival advantage was even more prominent in patients younger than 40 years in this risk group. For intermediate 2 and the high-risk group, immediate transplantation improved overall survival.

ROLE OF INDUCTION CHEMOTHERAPY PRIOR TO AN ALLOGENEIC SCT

The majority of published studies have shown that patients in remission or with a lower percentage of bone marrow blasts have a lower relapse rate and an improved outcome. In the European Group for Blood and Marrow Transplantation (EBMT) series, outcomes were significantly better for patients in first remission compared to the patients with active disease at the time of transplant.¹² Other groups have failed to demonstrate this benefit of remission induction prior to an allogeneic SCT,^{8,14,21,22} suggesting that it would be preferable to take patients with high-risk MDS directly to an allogeneic SCT if they were eligible for this procedure. These studies are limited by being

single center small retrospective analyses of heterogeneous groups of patients. The data from some studies addressing this issue are summarized in Table 42.1. The study by Copelan et al. suggests that the outcome in patients receiving induction therapy is in fact worse than those taken to transplant directly as a result of increased regimen related toxicity (RRT) compared to the group taken directly to a transplant.²² This issue needs to be further evaluated, especially in the setting of newer, less toxic remission induction agents, preferably as a prospective study. On the basis of the available data, it would be reasonable to take patients with a low percentage of bone marrow blasts directly to transplant, while patients with a bone marrow blast percentage closer to that of a diagnosis of acute myelocytic leukemia would probably benefit from induction therapy prior to a transplant. These recommendations must also be based on the age, motivations, and comorbidities of the patient.

CONDITIONING REGIMENS FOR ALLOGENEIC SCT IN MDS

Standard myeloablative conditioning regimens (both total body irradiation (TBI) based and non-TBI based) are associated with significant RRT, and contribute to NRM. As the majority of patients with a diagnosis of MDS are above the age of 60 years, they are less likely to tolerate these regimens. New nonmyeloablative regimens are being explored with the hope of being able to offer an allogeneic SCT, its graft-versus-leukemia effect, and the potential for cure to this older population.

Myeloablative conditioning regimens

In the 1980s, using a cyclophosphamide/TBI (Cy/TBI) ablative regimen resulted in a disease-free survival of 30–40% in patients with high-risk MDS.²³ In an effort to study if further intensification of the conditioning regimen would improve the outcome, busulfan was added to this regimen and compared with historical controls using Cy/TBI alone. The results showed that there was a decrease in relapse risk, but no significant

difference in survival with significantly more NRM (68% vs 36%).²⁴ From these early studies it appears that further intensification of the conditioning regimen is not a solution to improve the outcome in this disease. In the setting of unrelated matched donor transplants it has been shown that use of non-TBI-based conditioning regimens (Bu/Cy) is associated with improved outcomes both in the low- and high-risk MDS groups.¹⁶ Overall, there has been a move toward the use of non-TBI-based conditioning regimens for allogeneic SCT in MDS. Oral busulfan with pharmacologic targeting and intravenous busulfan reduce the incidence of RRT and NRM and improve transplant outcomes.^{16,25,26} Recent data published by Deeg et al. using targeted busulfan levels with cyclophosphamide have shown promising results even in an older patient population with low- and high-risk MDS.⁸ The data from some of the largest series using myeloablative regimens are summarized in Table 42.2.

Nonmyeloablative conditioning regimens

In view of the older age group of patients with a diagnosis of MDS and the inability of a significant proportion of these patients to receive a standard myeloablative conditioning regimen, in the 1990s reduced intensity conditioning (RIC) or non-myeloablative conditioning regimens for an allogeneic SCT were actively pursued. It was hoped that this approach would reduce the RRT and NRM in this population. The most commonly used RIC regimen is a combination of fludarabine with either melphalan or low-dose TBI. Results from some of the largest series published^{27–32} are summarized in Table 42.3. In a majority of these studies, the NRM was lower with myeloablative regimens but was associated with higher relapse rates, which was especially noted in the EBMT study.³⁰ More recently a publication from the MD Anderson Cancer Center showed a similar correlation with an increased risk of relapse in the group receiving a less intensive conditioning regimen when comparing two

Table 42.2 Summary of data from some large series of patients with MDS who underwent a related matched, sibling allogeneic SCT using a myeloablative conditioning regimen

DFS – diseasefree survival; NRM – nonrelapse mortality; NS – not stated; OS – overall survival; TBI – total body irradiation.

reduced intensity regimens,³¹ suggesting that more intensive conditioning may be required. There are a number of ongoing clinical trials addressing this issue, and the optimal regimen remains to be defined.

PERIPHERAL BLOOD VERSUS BONE MARROW AS A SOURCE OF STEM CELLS

The use of G-CSF mobilized peripheral blood stem cells (PBSCs) has been associated with improved outcome compared to marrow. A retrospective analysis of the EBMT data of 234 patients with a diagnosis of MDS undergoing an HLA identical sibling transplant showed an improved 2-year survival of 50% with PBSC versus 39% with bone marrow and also reduced TRM and relapses.³³ Similar reduced relapse risk and improved overall outcome was also noted in the studies published by Deeg et al.⁸ and Canizo et al.³⁴

ROLE OF ALTERNATE DONOR SOURCES

A related HLA-identical sibling is the ideal donor for an allogeneic stem cell transplant. Unfortunately only 25–30% of patients are likely to have an HLA-identical sibling. In this older population, an HLA-matched sibling may not be eligible as a donor because of age and comorbidities. Alternative donor sources include a

matched unrelated donor (MUD), matched or mismatched cord blood, or a haploidentical donor. Analysis of MUD transplants under the auspices of the National Marrow Donor Program (NMDP) shows comparable results to that of an HLA identical related transplant.¹⁶ The data with cord blood transplants is preliminary, but it has the potential to be a significant alternative source, especially with mismatched cord blood.^{35,36} There is insufficient data with haploidentical transplants in this condition to recommend it outside of a clinical trial.

CONCLUSION

An allogeneic stem cell transplant remains the only therapy with a curative potential in the management of a patient with a diagnosis of MDS. However, the risks associated with an allogeneic transplant in this older population have to be weighed against the benefits. Statistical models predict that delaying an allogeneic stem cell transplant for patients in the low-risk MDS group is associated with maximal life expectancy. Myeloablative regimens are associated with a lower risk of relapse in patients with high-risk MDS. Recent data using myeloablative regimens with targeted buslfan levels hold promise in both reducing the RRT

and the risk of relapse. Preliminary data with non-myeloablative regimens show a definite reduction in NRM, though the high risk of relapse is of some concern, especially in patients in the high-risk group of MDS. Ongoing clinical trials may help identify an optimal nonmyeloablative regimen. Cytokine mobilized PBSC transplants appear to be superior to marrow transplants in this setting. Published data suggest that outcomes with MUD stem cell transplant are comparable to that with an HLA-identical related donor. Preliminary data with mismatched cord blood transplants are exciting, but remain to be validated.

ALLOGENEIC SCT FOR APLASTIC ANEMIA

INTRODUCTION

Acquired aplastic anemia (AA) is a rare but potentially fatal bone marrow failure syndrome characterized by pancytopenia. It can be acquired secondary to exposure to radiation, drugs, chemicals, and infections, or as part of an autoimmune disorder. However, most commonly it is idiopathic in origin. Inherited disorders such as Fanconi anemia, dyskeratosis congenital, and Shwachman's syndrome as well as acquired disorders such as paroxysmal nocturnal hemoglobinuria can lead to AA, and are not discussed in this chapter.

AA can present with varying severity. The International AA Study Group has established criteria for the diagnosis of severe aplastic anemia (SAA).³⁷ For the diagnosis of SAA, the bone marrow cellularity should be less than 25% of expected and two out of the following three criteria should be present (1) ANC $<0.5 \times 10^9/\text{lt}$; (2) platelets $<20 \times 10^9/\text{lt}$; and (3) reticulocytes $<1\%$. Very severe aplastic anemia (VSAA) is defined as for SAA but with an ANC $<0.2 \times 10^9/\text{lt}$. Patients not fulfilling criteria for SAA or VSAA have nonsevere AA.

Allogeneic stem cell transplant is a curative option in patients with this diagnosis. It is reserved for the treatment of patients with SAA or VSAA. It can also be considered for patients with nonsevere AA who have failed immunosuppressive therapy. An approach to the treatment of patients with a diagnosis of AA is outlined in Chapter 45.

EFFECT OF AGE ON OUTCOME

Long-term survival for patients with AA undergoing an HLA-identical sibling transplant varies from 75% to 90%.³⁸⁻⁴¹ In most studies, patient age has a significant bearing on the outcome following an allogeneic stem cell transplant. There is some controversy as to the upper age limit at which an HLA-identical related allogeneic SCT would be offered as an initial therapy, with most recommendations putting the upper age limit as 40 years⁴²; the study by Bacigalupo et al. showed that the outcomes were significantly worse for those older than 30 years.⁴¹ Following failure of standard immunosuppressive therapy this option could be offered to all patients who have a donor and have no other contraindication to undergo an allogeneic SCT.

CONDITIONING REGIMEN

Currently, the combination of cyclophosphamide and antithymocyte globulin (ATG) is considered the best conditioning regimen for patients with a diagnosis of AA undergoing an HLA-identical related transplant.^{38,40,43,44} In a majority of studies, use of irradiation was associated with lower rejection rates but significantly higher TRM. A recent retrospective analysis by Ades et al. illustrates this⁴⁰ (Figure 42.2). In the setting of alternate donors, such as MUD SCT, the optimal regimen remains to be defined. A publication by Deeg et al. suggests that cyclophosphamide with ATG may not be sufficient in this setting.⁴⁵ The same group used escalating doses of TBI with cyclophosphamide

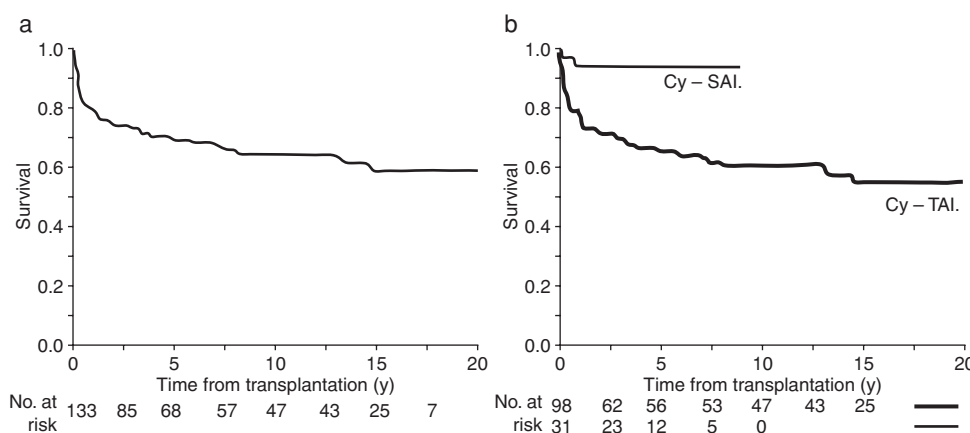

Figure 42.2 Overall survival. (a) Overall survival of 133 patients who underwent transplantation at the Hospital St. Louis (median follow-up of 13.6 years). (b) Overall survival according to the conditioning regimen with cyclophosphamide plus either antithymocyte globulin (Cy-ATG) or thoracoabdominal irradiation (Cy-TAI). (Reprinted from Ref. 40, used with permission.)

and ATG and concluded that the addition of 2-Gy TBI to cyclophosphamide and ATG was associated with the best result of 67% survival at 2 years.⁴⁶ Use of Fludarabine-based and other RIC, both in the setting of related and alternate donors, remains to be evaluated in large studies.

CYTOKINE MOBILIZED PBSC VERSUS BONE MARROW

In the setting of AA, there are no randomized control trials that have studied the benefit or disadvantages of one over the other source of stem cells. As with other allogeneic SCT, cytokine mobilized PBSC transplants are associated with faster engraftment, yet it is unclear if this translates to a superior outcome. Marsh et al. report that in personal communications the retrospective analysis of both European Blood and Marrow Transplant Group and the International Blood and Marrow Transplant Registry have shown significantly worse survival with PBSC versus bone marrow transplants (60% vs. 75%).⁴⁷ In the setting of transplanting

patients with SAA who have received multiple transfusions prior to their transplant, it has been reported that the use of PBSC improves the outcome.⁴⁸

ALTERNATIVE DONOR SCT

MUD transplants

Using the NMDP, around 70% of Caucasian patients are likely to find an HLA-matched donor; for other ethnic groups the chances are much lower. Retrospective analysis of the NMDP data reported a 2-year survival of 29% for 31 patients with SAA.⁴⁹ Better results were published from the Milwaukee group and the Fred Hutchinson Cancer Center Group, with 2-year survivals of 58% and 67%, respectively, using a more intensive conditioning regimen.^{46,50} MUD transplants as first-line therapy remain experimental, and are associated with high morbidity and mortality. Guidelines from a group of experts suggest that it be reserved for patients who have failed two courses of immunosuppressive therapy.⁵¹

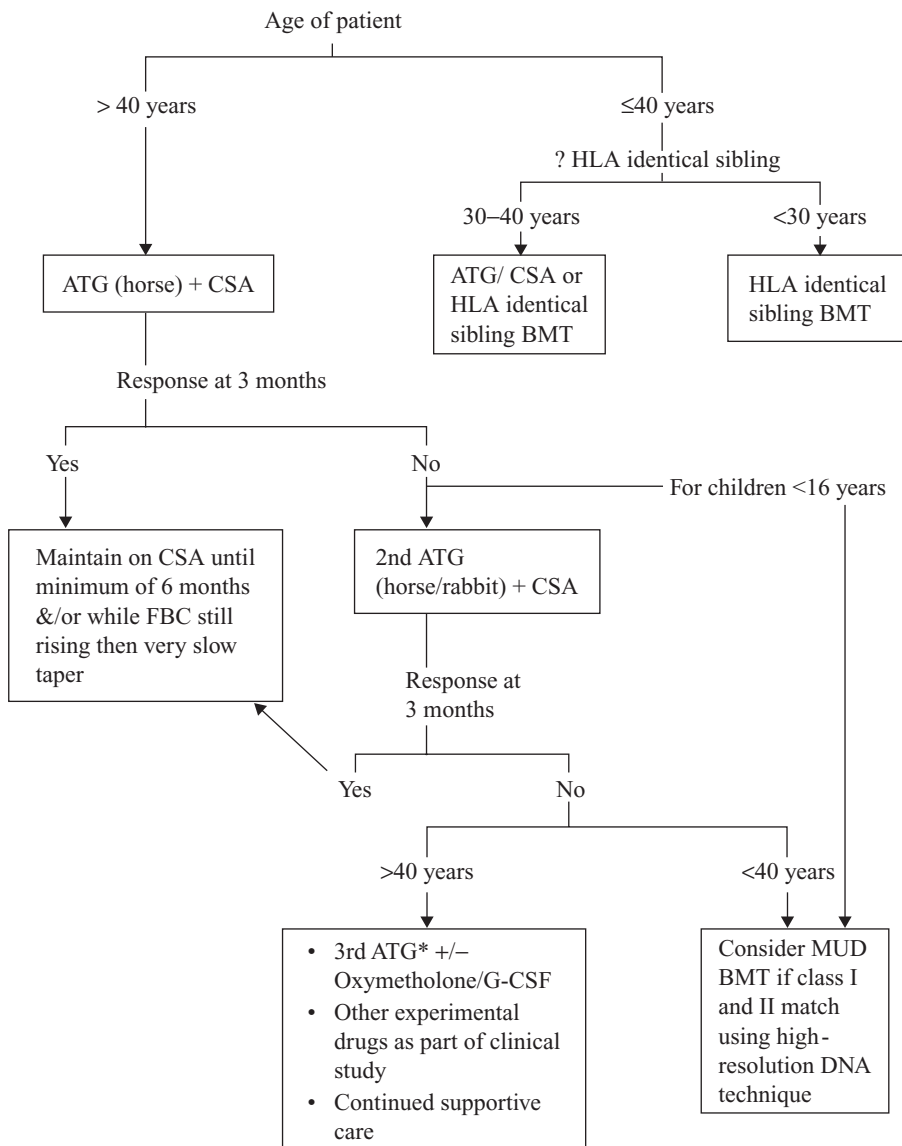

Figure 42.3 Algorithm for appropriate management of a patient with severe aplastic anemia (SAA) or very severe aplastic anemia (VSAA). BMT, bone marrow transplantation; G-CSF, granulocyte colony-stimulating factor; MUD, matched unrelated donor transplantation. (Reprinted from Ref. 42, used with permission.)

Partially matched family donor

The chance of having a one antigen mismatched family donor is 5–7% in North America and Europe.⁴⁷ Usually these transplants are done as a last resort in patients who have been clinically deteriorating with a poor performance status. The results in this setting have been dismal, with a high mortality from graft failure, GVHD, and infection.^{52,53}

Other donors

There is insufficient data with cord blood and haploidentical donors to recommend this as a standard approach for patients with SAA. Umbilical cord blood has been used in a small number of patients.^{54,55} Its use is limited to small recipients because of the low number of stem cell progenitors. Recent recommendations suggest that it be considered for patients who have failed immunosuppressive therapy and are eligible for an allogeneic SCT.⁵¹

CONCLUSION

An allogeneic SCT is a curative therapeutic option for patients with a diagnosis of SAA or VSAA. All patients below the age of 40 years who have an HLA-identical

related donor should be considered for this procedure as first-line therapy. In this group of patients the outcome of an allogeneic SCT is superior to that of immunosuppressive therapy, with a 75–90% chance of long-term survival. In addition, unlike with immunosuppressive therapy, there is a much lower risk of late relapses and development of clonal disorders. Conditioning regimens for patients undergoing an HLA-identical related donor should preferably be free of irradiation, and it appears that cyclophosphamide combined with ATG is optimal in this setting. Preliminary retrospective analyses suggest that for HLA-identical related transplants for AA, the use of PBSC is associated with a worse outcome compared to bone marrow. Alternate donors should not be considered for front-line therapy and should be limited to patients who have failed immunosuppressive therapy. For alternate donor transplants, the use of cyclophosphamide with ATG as a conditioning regimen is probably inadequate and further intensification is justified to reduce the risk of graft rejection and improve outcomes. Figure 42.3 outlines an algorithm that could be used to decide on the appropriate management of a patient with SAA or VSAA.

Chapter 43

DEFINITION OF RESPONSE, PROGNOSIS, AND FOLLOW-UP OF MYELODYSPLASTIC SYNDROMES

Miguel A. Sanz and Guillermo F. Sanz

INTRODUCTION

The myelodysplastic syndromes (MDS) have heterogeneous clinical characteristics, morphologic features, cytogenetics, and clinical outcomes that can make management of patients with these disorders difficult. This clinical and prognostic heterogeneity can complicate the planning of therapy. The different therapeutic goals for patients with MDS vary according to age, performance status, the severity of cytopenia and its associated complications, risk of progression to acute myeloid leukemia (AML), and other factors, such as socioeconomic status.

The clinical objectives may differ according to the patient's age or other factors. For example, older patients or those with poor physical health might be unable to withstand aggressive treatment compared to younger patients in better health who can more easily overcome the complications associated with high-intensity therapies. Similarly, the therapeutic goals also differ depending on the patient's risk of progressing to AML. In general, the main objectives for low-risk patients are to improve cytopenias and their associated complications, and quality of life (QOL); in contrast, the main goal for high-risk patients, especially younger patients, is to achieve complete remission (CR) and then to eradicate the malignant clone through chemotherapy and possibly stem cell transplantation.

Because a variety of strategies can be used to treat patients with MDS according to prognosis and chance of a cure, and because the goals of treatment may vary, physicians should evaluate the responses in the context of these goals. Therefore, a consensus should be reached on the use of reliable MDS prognostic classification schemes and on standardized response criteria when designing clinical trials and evaluating different treatment options.

This chapter reviews the state of the art on the assessment of responses to treatment, prognosis, and follow-up of patients with MDS.

RESPONSE CRITERIA

In the past, the treatment for the vast majority of patients with MDS consisted of supportive care to mitigate cytopenia-related complications, which involved mainly red blood cell (RBC) transfusions and growth factor use to avoid symptomatic anemia. Only patients who progressed to AML were treated more aggressively, usually with chemotherapy similar to that used to treat AML; these patients were then assessed using the same criteria as those to assess the response to therapy for patients with AML.

The algorithm used to treat patients with MDS has become much more complex recently for several reasons. First, reliable prognostic classification systems have been developed to best determine the natural history of MDS (discussed further below) and to identify different prognostic subgroups. Second, several therapies have been developed that influence outcome and QOL in each identifiable prognostic subgroup. Third, the responses are now evaluated according to the goals of each therapeutic approach. Thus, clinicians and investigators encounter greater variability in the definitions of the responses to MDS than in the past, making it difficult to interpret and compare results between clinical trials.

To resolve this variability in the response criteria, an international working group of investigators with expertise in MDS has achieved a consensus to establish standardized response criteria for clinical trials involving patients with MDS¹⁻³ (Table 43.1). This working group looked for clinically relevant, practical, and

Table 43.1 Measurement of response/treatment effect in MDS**ALTERING DISEASE NATURAL HISTORY****1. Complete remission (CR)**

Bone marrow evaluation: Repeat bone marrow showing less than 5% myeloblasts with normal maturation of all cell lines, with no evidence for dysplasia.^a When erythroid precursors constitute less than 50% of bone marrow nucleated cells, the percentage of blasts is based on all nucleated cells; when there are 50% or more erythroid cells, the percentage blasts should be based on the nonerythroid cells.

Peripheral blood evaluation (absolute values must last at least 2 months)^b:

Hemoglobin greater than 11 g/dL (untransfused, patient not on erythropoietin)

Neutrophils 1500/mm³ or more (not on a myeloid growth factor)

Platelets 100 000/mm³ or more (not on a thrombopoietic agent)

Blasts, 0%

No dysplasia^a

2. Partial remission (PR) (absolute values must last at least 2 months):

All the CR criteria (if abnormal before treatment), except:

Bone marrow evaluation: Blasts decreased by 50% or more over pretreatment, or a less advanced MDS FAB classification than pretreatment. Cellularity and morphology are not relevant.

3. Stable disease

Failure to achieve at least a PR, but with no evidence of progression for at least 2 months.

4. Failure

Death during treatment or disease progression characterized by worsening of cytopenias, increase in the percentage bone marrow blasts, or progression to an MDS FAB subtype more advanced than pretreatment.

5. Relapse after CR or RR—one or more of the following:

a) Return to pretreatment bone marrow blast percentage

b) Decrement of 50% or greater from maximum remission/response levels in granulocytes or platelets

c) Reduction in hemoglobin concentration by at least 2g/dL or transfusion dependence^c

6. Disease progression

a) For patients with less than 5% blasts: a 50% or more increase in blasts to more than 5% blasts

b) For patients with 5–10% blasts: a 50% or more increase to more than 10% blasts

c) for patients with 10–20% blasts: a 50% or more increase to more than 20% blasts

d) For patients with 20–30% blasts: a 50% or more increase to more than 30% blasts

e) One or more of the following: 50% or greater decrement from maximum remission/response levels in granulocytes or platelets, reduction in hemoglobin concentration by at least 2 g/dL, or transfusion dependence^c

7. Disease transformation

Transformation to AML (30% or more blasts)

8. Survival and progression-free survival (see Table 43.2)**CYTOGENETIC RESPONSE**

(Requires 20 analyzable metaphases using conventional cytogenetic techniques.)

Major: No detectable cytogenetic abnormality, if preexisting abnormality was present.

Minor: 50% or more reduction in abnormal metaphases.

Fluorescent in situ hybridization may be used as a supplement to follow a specifically defined cytogenetic abnormality.

QUALITY OF LIFE

Measured by an instrument such as the FACT Questionnaire.

Clinically useful improvement in specific domains:

Physical

Functional

Emotional

Social

Spiritual

HEMATOLOGIC IMPROVEMENT (HI)

(Improvements must last at least 2 months in the absence of ongoing cytotoxic therapy.)^b

Hematologic improvement should be described by the number of individual, positively affected cell lines (e.g. HI-E; HI-E + HI-N; HI-E + HI-P + HI-N).

1. Erythroid response (HI-E)

Major response: For patients with pretreatment hemoglobin less than 11 g/dL, greater than 2 g/dL increase in hemoglobin; for RBC transfusion-dependent patients, transfusion independence.

Minor response: For patients with a pretreatment hemoglobin less than 11 g/dL, 1–2 g/dL increase in hemoglobin; for RBC transfusion-dependent patients, 50% decrease in transfusion requirements.

2. Platelet response (HI-P)

Major response: For patients with a pretreatment platelet count less than 100 000/mm³, an absolute increase of 30 000/mm³ or more; for platelet transfusion-dependent patients, stabilization of platelet count and platelet transfusion independence.

Minor response: For patients with a pretreatment platelet count less than 100 000/mm³, a 50% or more increase in platelet count with a net increase greater than 10 000/mm³ but less than 30 000/mm³.

3. Neutrophil response (HI-N)

Major response: For absolute neutrophil count (ANC) less than 1500/mm³ before therapy, at least a 100% increase, or an absolute increase of more than 500/mm³, whichever is greater.

Minor response: for ANC less than 1500/mm³ before therapy, ANC increase of at least 100%, but absolute increase less than 500/mm³.

4. Progression/relapse after HI: One or more of the following: a 50% or greater decrement from maximum response levels in granulocytes or platelets, a reduction in hemoglobin concentration by at least 2 g/dL, or transfusion dependence.^c

For a designated response (CR, PR, HI), all relevant response criteria must be noted on at least two successive determinations at least 1 week apart after an appropriate period following therapy (e.g., 1 month or longer).

^aThe presence of mild megaloblastoid changes may be permitted if they are thought to be consistent with treatment effect. However, persistence of pretreatment abnormalities (e.g., pseudo-Pelger-Huet cells, ringed sideroblasts, dysplastic megakaryocytes) is not consistent with CR.

^bIn some circumstances, protocol therapy may require the initiation of further treatment (e.g., consolidation, maintenance) before the 2-month period. Such patients can be included in the response category into which they fit at the time the therapy is started.

^cIn the absence of another explanation such as acute infection, gastrointestinal bleeding, hemolysis and so on.

Adapted from Cheson BD, Bennett JM, Kantarjian H, et al.: Report of an international working group to standardize response criteria for myelodysplastic syndroms. *Blood* 96:3671–3674, 2000; used with permission.

reproducible definitions of responses that could be used easily by investigators and clinicians from different institutions. The working group defined the response categories to best evaluate the major therapeutic goals of therapy in MDS: (1) controlling symptoms resulting from cytopenia; (2) improving QOL, including minimizing the toxicity of therapy; and (3) altering the natural history of the disease by improving overall survival or decreasing progression to AML.

PROGNOSIS OF MDS

As stated previously, the clinical and prognostic heterogeneity of MDS confers an additional difficulty when planning therapy. Some patients experience prolonged survival and remain symptom-free for many years, whereas others die within a few weeks or months after diagnosis. Overall, the median survival is nearly 19 months and the risk of AML evolution is 35% at 5 years.^{3a} Most patients die as a consequence of cytopenia-associated complications, in the presence or absence of AML transformation. However a significant number of patients die of causes unrelated to the disorder. Although the French–American–British (FAB) classification⁴ has been relatively effective in categorizing MDS patients, it has some limitations in the clinical setting. These limitations include the wide range of marrow blast percentages in patients classified as having refractory anemia (RA) with excess blasts (RAEB) or chronic myelomonocytic leukemia, the failure to consider some important biologic determinants such as marrow cytogenetics, and the degree and number of cytopenias. These well-accepted problems in categorizing patients with MDS have led to the development of many additional risk-based stratification systems, which are reviewed critically in this chapter.

PROGNOSTIC FACTORS

Studies on prognostic factors in MDS have identified several patient and disease characteristics that are highly associated with survival or leukemic transformation, or both (Table 43.2). Although a number of characteristics may influence the prognosis of MDS, the percentage of bone marrow (BM) blasts, cytogenetic pattern, and number and extent of cytopenias are currently considered the most powerful prognostic factors in these disorders.^{3a,5,6}

BM blasts

Increased BM blast percentage has generally been associated with poorer prognosis for survival and with leukemic transformation in MDS patients. A Spanish group showed,⁷ and others have confirmed,^{8,9} that adding an extra cutoff point of 10% to the generally accepted 5 and 20% FAB criteria clearly improved the prognostic value of this variable.

Cytogenetics

Several series have reported the prognostic impact on survival and leukemic risk of several types of marrow chromosomal abnormalities, although only recently has this variable been shown to have independent prognostic value.^{8–11} Sequential cytogenetic studies are valuable tools during follow-up.^{12,13} The appearance of chromosomal abnormalities in a patient with a previously normal karyotype or the emergence of additional aberrations is associated with disease progression and shorter survival. This finding may be of particular value in patients with RA and RA with ringed sideroblasts (RARS). However, it should be stressed that chromosomal stability does not preclude the development of AML. In fact, the majority of MDS patients do not show chromosomal changes at the time of acute leukemic transformation.^{3a,13}

Table 43.2 Prognostic factors identified in patients with MDS

Characteristic	Unfavorable value
Clinical	
Age	Advanced (60 years)
Sex	Male
Systemic symptoms	Presence
Etiology	Therapy related
Hematologic	
In peripheral blood	
Platelets	Lower counts
Hemoglobin	Lower level
Neutrophils	Neutropenia
Leukocytes	Leukopenia or leukocytosis
Blasts	Presence
In bone marrow	
Blasts	Higher percentage
Micromegakaryocytes	Presence
Basophilia/eosinophilia	Higher percentage
Dysplasia	Multilineal (2/3 lines) ^a
Marrow biopsy findings	
Cellularity	Increased
ALIP ^b	Presence
Dysmegakaryopoiesis	Severe
Fibrosis	Presence
FAB classification	RAEB, RAEBT ^c
Biochemical parameters	
LDH	Increased
β-2-microglobulin	Increased
Cytogenetics^d	Complex (>2 abnormalities) Monosomy 7/del(7q)
Molecular genetics	
N-RAS mutation	Presence
p53 deletion	Presence
FMS mutation	Presence
p15 methylation	Presence
WT1 expression	Higher
VEGFR-1 expression	Higher
Marrow culture studies	
Number of colonies	Lower
Number of clusters	Higher
Colony-to-cluster ratio	Low
Leukemic pattern	Presence
Immunophenotype	
CD34-positive cells	Higher proportion
Immature-to-mature cell ratio	Increased
CD7-positive blasts in marrow	Higher percentage
Marrow apoptosis	Increased

^a As defined by the WHO classification.

^b ALIP denotes abnormal localization of immature precursors.

^c RAEBT denotes refractory anemia with excess blasts in transformation.

^d Favorable categories are normal karyotype, and del(5q), del(20q), and -Y as single abnormalities.

Cytopenias

Of various peripheral blood cell counts, platelet counts and hemoglobin level have a greater prognostic weight than neutrophil counts.⁷ Several studies have demonstrated that the greater the severity and the higher the number of cytopenias, the worse the survival and the higher the risk of leukemic evolution.^{7,9}

Other characteristics

Other variables with prognostic value, but of lesser importance, include age (which reflects a poorer tolerance to cytopenia-associated complications and the impact of other comorbid conditions associated with older age rather than a more aggressive clinical course)^{7,9}; FAB classification⁷; gender (worse prognosis for male patients, which may be explained to some extent by the greater life expectancy of women in industrialized countries)⁷; percentage of blasts in peripheral blood⁷; presence of immature myeloid precursors and nucleated RBCs in peripheral blood⁷; degree of multilineage dysplasia in RA and RARS (as in the recent World Health Organization [WHO] proposals of classification of MDS¹⁴)¹⁵⁻²¹; marrow basophilia or eosinophilia,²² serum lactate dehydrogenase (LDH) level (which may provide an indirect measure of ineffective hematopoiesis and leukemic burden)²³; and some BM biopsy findings, such as abnormal location of immature myeloid precursors (ALIP), hypercellularity, and fibrosis.^{5,6,24} Other characteristics, such as serum β-2-microglobulin level,²⁵ in vitro growth pattern of granulocyte-macrophage progenitors,²⁶ plasma soluble interleukin 2 receptor level,²⁷ plasma levels of soluble vascular endothelial growth factor receptor 1,²⁸ and magnetic resonance imaging pattern²⁹ have been also implicated in MDS prognosis. Several flow cytometry parameters have been shown to influence the outcome of disease,³⁰ including the expression of CD7, CD10, and CD15 by BM blasts,³¹ and the number of CD34-positive cells in the peripheral blood.³² A prognostic scoring system based exclusively on flow cytometry data has been reported to predict the outcome after allogeneic stem cell transplantation.³³

The recent progress in understanding the biology of MDS has led to studies of new prognostic parameters to predict outcome. A greater degree of apoptosis in the BM, as measured by different techniques, has been associated with longer survival and time to develop AML.³⁴⁻⁴⁵ Mutations of *ras*, *fms*, and *p53* genes, which reflect genomic instability, occur more frequently in patients with poor prognosis and are associated with shorter survival and a higher risk of leukemia.^{46,47} The level of expression of WT1, measured by real-time quantitative polymerase chain reaction (PCR), has a strong direct relationship with the percentage of blasts in the BM and the presence of chromosomal abnormalities.⁴⁸ Telomere stability, another marker of genomic instability, is frequently

impaired in high-risk MDS. Patients with shortened terminal restriction fragments, measured by the PCR-based twin reversed arterial perfusion assay, have a significantly lower hemoglobin level, higher percentage of BM blasts, higher incidence of cytogenetic abnormalities, and a higher risk of leukemic transformation.³⁷ The incidence of inactivation by methylation of the *p15* gene is higher in patients with $\geq 10\%$ BM blasts and increases with progression to AML.^{49,50} Preliminary evidence suggests that gene profiling could also have prognostic value in MDS patients.^{51,52} Information on the prognostic relevance of these new biological factors, however, is still scarce. Further studies that include a larger number of cases and multivariate analyses are needed before this evidence can be accepted and used in the clinical management of patients.

PROGNOSTIC SCORING SYSTEMS

Research on prognostic factors has led to the development of several scoring systems, some of which incorporate cytogenetic factors.^{3a,5,6}

Scoring systems without karyotype analyses

Table 43.3 shows the main prognostic scoring systems proposed for MDS that do not include cytogenetic factors. The Bournemouth score was the first proposed scoring system. Patients were assigned to one of three risk groups based on the number of cytopenias present and the proportion of blasts in the BM.⁵³ The main criticism of this system is the emphasis on blood cytopenias in relation to the proportion of blasts in the BM.⁷ The scoring system proposed by the Spanish group uses the proportion of BM blasts, platelet count, and age.⁷ This system is easy to use and has been demonstrated to predict survival in

other series, including untreated patients and patients treated with granulocyte colony-stimulating factor or AML-type chemotherapy.^{6,55,56} The Goasguen score uses only two cytopenias (hemoglobin and platelets) and blasts in the BM,⁵⁴ and the Düsseldorf score includes these same variables and the serum LDH concentration.²³

Scoring systems with karyotype analyses

Table 43.4 shows the main prognostic scoring systems proposed for MDS that include cytogenetic factors. The Lille group was the first to incorporate cytogenetics in a prognostic score of MDS,⁸ though only cases with complex abnormalities were considered as a high-risk group. An International MDS Risk Analysis Workshop was convened to improve the clinical and prognostic utility of scoring systems, to better define the cytogenetic risk categories, and to develop a consensus prognostic risk-based analysis system. This workshop published the International Prognostic Scoring System (IPSS) in 1997.⁹ The IPSS includes the proportion of blasts in the BM, cytogenetics, and number of cytopenias. Combining the risk scores for these three major variables allows patients to be stratified into four distinctive risk groups according to both survival and AML evolution; the risk scores are low (0 points), intermediate-1 (0.5–1.0 points), intermediate-2 (1.5–2.0 points), and high (≥ 2.5 points). The overall median survival was 5.7, 3.5, 1.2, and 0.4 years for low-, intermediate-1-, intermediate-2-, and high-risk patients, respectively (Figure 43.1). The time taken for 25% of the patients in each of the four risk groups to evolve toward acute leukemia was 9.4, 3.3, 1.1, and 0.2 years, respectively. Survival of low-risk patients was strongly related to age, with median survival times of 11.8 years in patients ≤ 60 years of age, 4.8 years in

Table 43.3 Prognostic scoring systems without karyotype analyses for patients with MDS

Scoring system	0	1	2	Risk group	Score
Bournemouth⁵³					
Hemoglobin (g/dL)	>10	≤ 10		Low	0 or 1
Neutrophils ($\times 10^9/L$)	>2.5 and ≤ 16	≤ 2.5 and >16		Intermediate	2 or 3
Platelets ($\times 10^9/L$)	≥ 100	<100		High	4

Age (years)	≤ 60	>60		High	4 or 5
Goasguen⁵⁴					
Hemoglobin (g/dL)	>10	≤ 10		Low	0
Platelets ($\times 10^9/L$)	>100	≤ 100		Intermediate	1 or 2
Marrow blasts (%)	<5	≥ 5		High	3
Düsseldorf²³					
Marrow blasts (%)	<5	≥ 5		low (A)	0
Platelets ($\times 10^9/L$)	>100	≤ 100		Intermediate (B)	1 or 2
Hemoglobin (g/dL)	>9	≤ 9		High (C)	3 or 4
LDH (U/L)	≤ 200	>200			

Table 43.4 Main prognostic scoring systems with karyotype analyses for patients with MDS

Scoring system	Points					Risk group	Score
	0	0.5	1	1.5	2		
Lille^{8a}							
Marrow blasts (%)	<5		5–10		11–30	Low	0
Karyotype ^b	Good		poor			Intermediate	1 or 2
Platelets ($\times 10^9/L$)	>75		<75			High	3 or 4
IPSS⁹							
Marrow blasts (%)	<5	5–10		11–20	21–30	Low	0
Karyotype ^c	Good	Intermediate	Poor			Intermediate-1	0.5–1
Cytopenias ^d	0 or 1	2 or 3				Intermediate-2	1.5–2
						High	2.5–3.5

^a For leukemic risk, only blasts in BM and karyotype are considered.

^b Good, normal, single abnormalities; poor, complex (≥ 2) abnormalities.

^c Good, normal, del(5q) only, del(20q) only, -Y only; intermediate, +8, single miscellaneous, double abnormalities; poor, very complex (>2) abnormalities, chromosome 7 abnormalities.

^d Cytopenias, hemoglobin <10 g/dL, platelets $<100 \times 10^9/L$, neutrophils $<1.8 \times 10^9/L$

patients of 61–70 years, and 3.9 years in patients >70 years of age.⁹

Scoring systems, particularly the IPSS, are useful for defining the outcome and for designing and accurately analyzing therapeutic trials in patients with MDS. The IPSS has proven its value in several series of untreated

patients,^{10,57–60} and in series of patients treated with intensive chemotherapy⁶¹ or stem cell transplantation.⁶² Because of its clinical value and simplicity, the IPSS has gained universal acceptance and is now used to decide the most appropriate therapy in an individual patient and to design clinical trials in patients with MDS.

International MDS Risk Classification

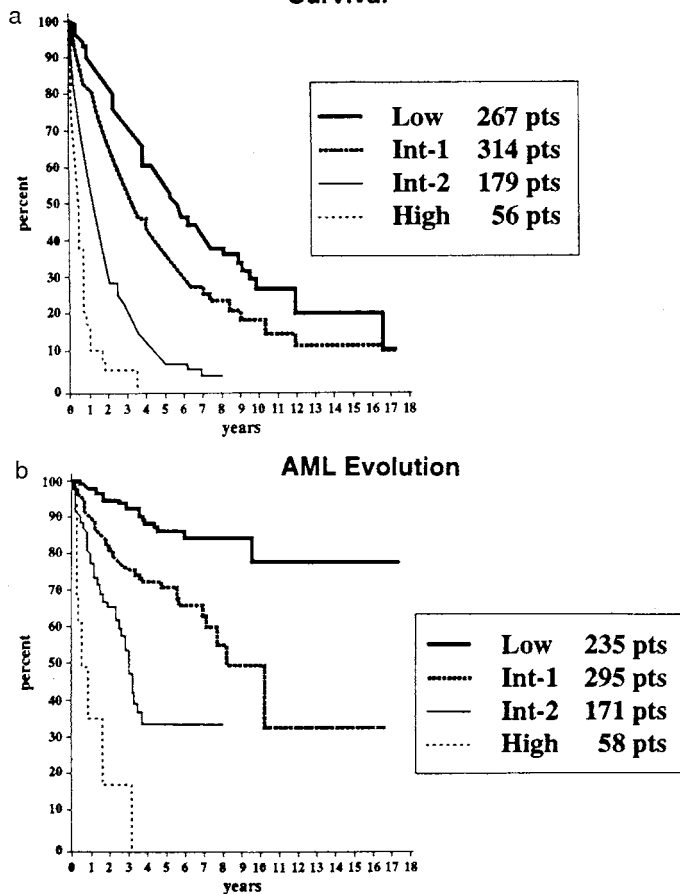

Figure 43.1 Survival (a) and freedom from AML evolution (b) of MDS patients related to their classification by the IPSS for MDS: low, intermediate-1, (Int-1), Int-2, and high (Kaplan-Meier curves). (Adapted from Greenberg P, Cox C, LeBeau MM, et al.: International scoring system for evaluating prognosis in myelodysplastic syndromes. *Blood* 89:2079–2088, 1997; used with permission)

FOLLOW-UP

The clinical and analytical follow-up of patients with MDS depends primarily on their individual prognosis, based on the IPSS scoring system, and the approach chosen for their treatment. Physicians should also consider that the therapy of patients with MDS is always investigational, as no therapy outside of stem cell transplantation is curative. Whenever possible, patients should be included in well-designed clinical trials aimed at evaluating new therapeutic interventions and conducted according to the standards of good clinical practice. In all cases, follow-up evaluations must include serial physical examination; blood analyses, including whole blood counts, and blood biochemistry; and BM aspirates and biopsies. A careful morphologic review of peripheral blood and BM slides is mandatory to evaluate the cellularity, the percentage of blast cells, and the presence and degree of dysplasia of the different hematopoietic cell lines, which may signal the progression to a more advanced morphologic MDS subtype or the occurrence of AML transformation.

Periodic cytogenetic studies are also required to assess the appearance of new chromosomal abnormali-

ties and the evolution of the malignant clone. In addition to conventional cytogenetics, the use of fluorescence in situ hybridization techniques is strongly recommended, because these highly sensitive tests can detect hidden chromosomal aberrations that influence the outcome.⁶³ For this purpose, the use of probes for ruling out numerical and/or structural abnormalities of chromosomes 5, 7, 8, 11 and 20 should be considered. As stated previously, the frequency of invasive techniques should depend on the prognosis, type of therapy, and good clinical judgment. Performing a BM aspirate and biopsy annually seems appropriate for low-risk patients with stable blood cell counts who are not enrolled in a clinical trial. In all instances, a sudden deterioration of cytopenias or the appearance or increase of blasts in the blood should prompt a complete BM evaluation. For patients included in clinical trials, the timing of BM examinations will be determined by the trial specifications. Obviously, in patients undergoing intensive chemotherapy, BM aspirates with or without a core biopsy should be performed after each cycle of treatment. The international consensus criteria for evaluating responses must be strictly adhered to in all cases.

Chapter 44

TREATMENT OF RELAPSED OR REFRACTORY MYELOYDYSPLASTIC SYNDROMES AND NEW FRONTIERS IN MYELOYDYSPLASTIC SYNDROME THERAPY

Huma Qawi, Naomi Galili, and Azra Raza

INTRODUCTION

Myelodysplastic syndrome (MDS) is not a single disease, but rather a group of disorders affecting the bone marrow. Therefore, no single approach is likely to be of universal benefit to all patients. In fact, one way to consider the complexity of MDS is to think of it as being to the bone marrow what pneumonia is to the lungs—the response of an organ to a variety of assaults, such as aging, toxic exposure, infections, and autoimmunity. Among infections of the lungs alone, pneumonia could be the result of a variety of possible pathogens, including bacteria, viruses, tuberculous, or fungal agents. Similarly, MDS is the response of the bone marrow to a variety of unknown insults and cannot be treated as a single disease. Until recently, there was no approved treatment for MDS, but as of May 2004, 5-azacytidine (a methyltransferase inhibitor) has been approved by the Food and Drug Administration (FDA) in the United States for use in all subtypes of MDS. Most patients who will then fall in the category of relapsed or refractory disease will include those who have received some sort of supportive care (SC) in the form of transfusions or growth factors, and most likely, a trial of 5-azacytidine. Subsequent treatment options would depend upon the type of MDS and general condition of this predominantly elderly group of patients. For those with high-risk disease, the danger comes from a rapid transformation toward acute leukemia, while for those with low-risk disease, it is the deepening profundity of cytopenias, which pose a potentially lethal threat of bleeding or infection. This chapter will outline the new types of treatments that have emerged to treat these patients and summarize some of the clinical responses already seen in preliminary clinical trials.

HIGH-RISK MDS

High-risk MDS, for this discussion, refers to patients belonging to the intermediate-2 (int-2) or high-risk International Prognostic Scoring System (IPSS) categories. As blast cells in these patients are continuously increasing and the probability of transforming into acute myeloid leukemia (AML) is high, therapeutic intervention is essential. Chemotherapeutic agents have traditionally been used, especially busulfan, VP-16, topotecan, and low-dose cytosine arabinoside alone or in combination.¹ More recently, a better understanding of the molecular mechanisms underlying the evolution of malignancy has produced new classes of drugs that have proved to be quite successful. These drugs, in addition to DNA methyltransferase inhibitors, include histone deacetylase (HDAC) inhibitors, farnesyl transferase inhibitors (FTIs), tyrosine kinase inhibitors (TKIs), and arsenic trioxide (ATO). The cellular targets of these drugs are varied and include, either singly or in combination, the chromatin structure of the MDS cell, cytoplasmic regulatory proteins that are essential for cell proliferation, survival, and cell death, and cellular receptors that respond to cytokines of the bone marrow microenvironment.

DNA METHYLTRANSFERASE INHIBITORS

Gene silencing due to hypermethylation is the most common epigenetic modification in human malignancies.² Unlike genetic changes involving mutations or deletions, this modification is potentially reversible, making it attractive as a therapeutic target. Hypermethylation of the chromatin is caused by an increase in DNA methyltransferase I activity; this enzyme covalently links a methyl group to the 5-position of cytosine of CpG residues typically found in gene promoter regions (CpG

islands). Normally, unmethylated CpG islands are protected from hypermethylation. This protection is lost in neoplastic cells due to the increase in DNA methyltransferase activity. The methylated promoters bind specific proteins, which then recruit transcriptional corepressors. These complexes lead to transcriptional silencing through chromatin remodeling. DNA hypermethylation of promoter regions of tumor suppressor genes leads, ultimately, to uncontrolled cell proliferation. Several of the DNA methyltransferase inhibitors are S-phase specific, making inhibitors of these agents the logical agents for cancer therapy. In the late 1960s, 5-azacytidine (Aza-C) was developed as an antitumor agent for the treatment of AML.³ Aza-C, an analog of cytosine, is incorporated into the DNA but, unlike cytosine, cannot be methylated at position 5. In addition, Aza-C binds directly to and inhibits methyltransferase. The drug also exerts cytotoxic and cell-differentiating properties by unknown mechanisms. Most recently, as described below, Aza-C has received attention as a therapeutic agent for MDS, leading to the recent full FDA approval for Aza-C on May 19, 2004, for MDS patients of all subtypes. This is the very first agent to be fully approved by the FDA for the treatment of MDS.

The pivotal phase III study for Aza-C was a randomized controlled Cancer and Leukemia Group B (CALGB) trial carried out in 191 patients with MDS of all subtypes.⁴ Half of the patients received Aza-C 75 mg/m² subcutaneously for 7 days every 4 weeks for a minimum of 16 weeks, and half received only SC. A 60% overall response was found in patients on the treatment arm (7% complete response (CR), 16% partial response (PR), and 37% with hematologic improvement (HI)), with trilineage responses in 23% of patients. Only 5% of those on the observation arm showed hematologic improvement ($P < 0.001$). Furthermore, when a subset of 49 patients from the observation arm crossed over to the treatment arm, a 47% response was achieved, once again with 10% achieving a CR, 4% a PR, and 33% with clinical improvement. The median duration of response was 15 months, but the most striking observation in this study was the significantly longer median time to transformation to acute leukemia and longer median survival in patients receiving treatment: 21 months, versus 12 months for the observation-only patients. Patients initially treated with Aza-C showed a median survival of 18 months in comparison to 14 months for the early crossover arm, and 11 months for those crossed over after 6 months or not crossed over at all.

Aza-C is a pro-drug for 5-aza-2'-deoxycytidine (decitabine, DAC), a pyrimidine nucleoside analog that has completed a phase III clinical trial. Aza-C is first converted to DAC before incorporation into DNA. It then binds and irreversibly inhibits DNA methyltransferase. DAC is a strong inhibitor of DNA methylation, and like Aza-C has been used for the treatment of high-risk MDS. In a phase II trial by Wijermans et al., 66 MDS patients received DAC 45 mg/m²/day every 8 h for 3 days every 6 weeks, for a maximum of 6 cycles.⁵

The overall response rate was 49%, with a 64% response rate in those with an IPSS high-risk score. There were 34 CRs, with a median response duration of 31 weeks. However, there was an 8% toxic death rate, with a delayed onset of cytopenias. In a subsequent study using the same drug regime, 16 out of 50 patients with clonal cytogenetic abnormalities developed normal karyotypes after treatment with DAC,⁶ responses lasting for a median of 7.5 months. This study also noted correlation of cytogenetic responses to survival.

Saba et al. have recently shown responses and better tolerance in a phase III multicenter trial of 170 MDS patients treated with DAC.⁷ DAC was administered at 15 mg every 8 h for 3 days every 6 weeks. The response rate by International Working Group (IWG) criteria was 35% (10% CR, 15% PR, and 10% HI) for DAC versus 0% for SC ($P < 0.001$). Time to response was 100 days, and the median duration was estimated at >9 months. There were no significant differences in mortality rates on treatment, and no treatment-related deaths. As expected, grade III-IV toxicity (mainly hematologic) occurred more in DAC patients than in SC patients. Most patients tolerated the treatment well; discontinuation due to toxicity as primary reason was reported in 9% of DAC patients.

The correlation between methylation status and clinical response, however, is not yet clear. The suppressor genes *p15* and *p16* inhibit cyclin-dependent kinases and are frequently hypermethylated in hematologic neoplasias, including AML and MDS. Bone marrow mononuclear cells from patients with high-risk MDS were examined for *p15*/INK-4B and *p16* methylation status during treatment with DAC.⁸ Hypermethylation of the 5' *p15* region was detected in 15 of 23 (65%) patient samples examined. After treatment, 9 of 12 patient samples showed a decrease in methylation, which was associated with clinical responses in these patients. However, response to the drug was also seen in patients without hypermethylation. Thus, DAC may work by multiple mechanisms, and direct clinical correlation to methylation status cannot be assumed at this time.

More recently, a phase I trial of prolonged exposure to lower doses of DAC was conducted in 50 patients, mostly with AML/MDS.⁹ Patients were given four different doses of DAC: 5 mg, 10 mg, 15 mg, and 20 mg/m²/day i.v. over 1 h for 10 days. All doses were well tolerated and responses were noted even in the lowest doses. There was a 65% response rate at the 15 mg/m² dose with no increase in response after dose escalation or prolongation to 15 and 20 days. In this study, there was no correlation noted between *p15* methylation at baseline or after therapy and response to DAC. Hence, DAC appears to be an effective therapy for MDS with manageable toxicity, and its role in light of the recent FDA approval for Aza-C remains to be determined.

HISTONE DEACETYLASE INHIBITORS

Chromatin remodeling is part of the epigenetic changes seen during neoplastic transformation. While promoter hypermethylation is associated with silencing of tumor

suppressor genes, it is not the only modification that controls chromatin condensation and promoter activity. Posttranslational modifications, such as acetylation, methylation, and phosphorylation of histone proteins comprising the chromatin nucleosomes, are responsible for formation of complexes that control gene expression. Typically, acetylation of the lysine residues in the histone “tail” by acetyltransferases (HAT) leads to “open” transcriptionally active chromatin, whereas deacetylation, dependent on histone deacetylases (HDAC), leads to “closed” inactive chromatin. HDAC activity is associated with promoter methylation, and it is the combination of both that contributes to promoter inactivation.¹⁰ As therapeutic reactivation of tumor suppressor genes has gained the attention of drug companies, multiple HDAC inhibitors have been investigated. Since HDAC inhibitors are often cell-cycle and tissue specific, these agents have been found to exert pleiotropic effects.

Butyrate is an acetylating agent that has been used to induce expression of fetal hemoglobin in sickle cell anemia and thalassemia, but proved unsuccessful for the treatment of AML in phase II trials.¹¹ Sodium phenylbutyrate (PB), a derivative thought to be deliverable in oral form, has been shown to induce histone acetylation, p21 expression, G1 cell-cycle arrest, and apoptosis *in vitro*.¹² In a trial conducted by Gore et al.,¹³ PB was given for 7/28 or 21/28 days to MDS and AML patients, with improvement in thrombocytopenia and neutropenia seen in a small number of patients. A dose-limiting toxicity of reversible encephalopathy was due to accumulation of phenylacetate. Currently, oral forms of PB are being investigated. Valproic acid, an oral antiepileptic agent, SAHA (suberoylanilide hydroxamic acid), and FK 228 (with FDA approval for cutaneous T-cell lymphoma) are newer HDAC inhibitors currently undergoing clinical trials.

As chromatin remodeling involves a balance between CpG methylation and histone modification, a phase I trial of sequential administration of Aza-C and PB was initiated in MDS. The dose de-escalation trial of varying doses of Aza-C followed by a 7-day continuous infusion of PB was well tolerated, with significant clinical responses.¹⁴ Additional studies combining DAC with valproic acid are underway, with monitoring of methylation, acetylation, and gene re-expression.

FARNESYL TRANSFERASE INHIBITORS (FTIs)

The family of Ras proteins are components of multiple cellular pathways essential for cell proliferation, growth, and survival. Addition of the carbon farnesyl group to these cytoplasmic proteins allows them to be transported to the cell membrane, where they are integral to signal transduction pathways. The enzyme farnesyl transferase mediates the farnesylation process. Ras mutations are found in <20% of MDS patients, but are more common in chronic myelomonocytic leukemia (CMML). Ras, however, may be activated by other proteins that similarly require farnesylation, and therefore its expression

may be controlled by multiple mechanisms. Small molecules that can selectively and competitively inhibit farnesyl transferase (FTIs) have been developed for clinical use, and two, tipifarnib (R115777) and lonafarnib (SCH66336), have been studied in high-risk MDS.

A phase I trial of R115777 in 21 MDS patients of all subtypes, reported by Kurzrock et al.,¹⁵ established the maximum tolerated dose of 600 mg b.i.d. Of note, only two of the six responders had Ras mutations, and no correlation between Ras mutation status and response was detected in this initial study. In a phase II trial by the same group,¹⁶ 28 MDS patients were given R115777 600 mg twice a day, 4 weeks on, 2 weeks off, to increase exposure to the drug. There were two complete responses, both of which did not possess a Ras mutation. Eleven of 27 patients discontinued treatment due to toxicity, with more than 60% of patients experiencing myelosuppression, fatigue, and nausea. The phase II study therefore concluded that lower doses should be used in future trials. A separate phase II study done in patients with poor-risk AML or MDS using 600 mg b.i.d. every 4–6 weeks yielded responses in 12 of 30 patients (2 CRs and 8 PRs), with stabilization of disease in 12 patients.¹⁷

List et al. conducted a phase I study of continuous dosing of lonafarnib (SCH66336) in advanced CML, MDS, CMML, or AML.¹⁸ Twenty-nine percent of patients showed clinical improvement, and dose-limiting toxicity was diarrhea and hypokalemia at 300 mg b.i.d. In a phase II trial by Feldman et al.,¹⁹ 67 MDS patients with RAEB/RAEB-T or CMML were given lonafarnib 200 mg b.i.d. and a 29% response was seen. There were two complete responses, and 10 patients showed hematologic improvement. In this study, 26% of patients discontinued therapy due to grade III and IV toxicities. Current phase III trials are being conducted with lower doses of single-agent FTIs for longer periods of time, which may be useful for previously untreated patients and those with minimal residual disease. There is limited data to suggest a synergistic effect with chemotherapy,²⁰ but identifying specific molecular targets within the cell cycle may lead to useful combinations of FTIs and chemotherapeutic agents, each affecting a different stage of the cycle.

TYROSINE KINASE RECEPTOR INHIBITORS (TKI)

These agents inhibit signaling pathways activated by ligand binding to vascular endothelial growth factor (VEGF) receptors (VEGFRs) and other type III receptors, including c-kit, Flt-3, platelet-derived growth factor receptor β (PDGFR β), and basic fibroblast growth factor (bFGF). By selectively mimicking ATP, these molecules impair autophosphorylation of the tyrosine kinase domain of the receptor (RTK). SU5416 is a small, lipophilic, highly protein-bound, synthetic RTK inhibitor of VEGFR-2. SU5416 binds to the ATP domain on the kinase, affecting VEGF-dependent cell proliferation. In a human colon cancer xenograft model, this molecule inhibits tumor metastases, microvessel formation, and proliferation. Like other

RTKs, SU5416 also targets c-kit (expressed in AML blasts in 60–80% patients) and Flt-3 (mutated in about 30% of AML patients), prompting clinical studies for the treatment of AML and MDS.

A multicenter phase II study was conducted in patients with refractory AML ($n = 33$) or MDS ($n = 22$), all of whom received 145 mg/m² of SU5416 twice weekly i.v. for a median of 9 weeks.²¹ Eleven patients could not complete 4 weeks of therapy (mainly due to disease progression). Three patients had a partial response and one had a hematologic response. Phase I and II studies are ongoing with SU11248 and two other RTKs, PTK/ZK and AG13736, alone or in combination with chemotherapy.^{22–24}

Imatinib mesylate (Gleevec)

The first FDA-approved and best known TKI, imatinib mesylate, has been shown to be potent for the inhibition of the BCR/ABL tyrosine kinase in chronic myeloid leukemia (CML). Like other RTKs, imatinib also inhibits two other tyrosine kinases, PDGFR and c-kit, at similar concentrations. A small percentage of CMMoL patients express PDGFR fusion genes involving four partner genes. This is now a distinct phenotype classified by the World Health Organization (WHO) as CMMoL-Eos, with reciprocal translocations on chromosome 5q33. Imatinib interacts with the ATP-binding pocket of PDGFR β kinase associated with the translocation [e.g., t(5;12)(q33;p13)], much like its interaction with BCR/ABL in CML.

Four patients with CMMoL harboring a t(5;12), three of whom had the associated fusion gene *ETV6/PDGFR β* , were treated with imatinib.²⁵ Hematologic responses were achieved within 4 weeks of starting treatment, and normal counts were maintained for up to 1 year. Even more impressive was the disappearance of the translocation t(5;12) by 12 weeks in three patients and by 36 weeks in the fourth patient.

Raza et al. treated 16 CMMoL patients lacking translocations of the *PDGFR β* gene with imatinib. No responses were seen,²⁶ further confirming the specificity of the drug for this target. Another phase II study of 18 MDS, CMMoL, and AML patients, all lacking the fusion gene, showed no responses.²⁷ Although c-kit is expressed in over 80% of AML and MDS patients and imatinib is thought to inhibit c-kit, in this study no responses were achieved. These results were also seen in some solid tumors, where imatinib has failed to show any significant responses as monotherapy, despite the expression of c-kit.

PROTEOSOME INHIBITORS (PS-341, BORTEZOMIB)

Proteasomes are enzymes that mediate many critical cellular regulatory signals by degradation of the regulatory proteins or their inhibitors and, therefore, are potential therapeutic targets for cancer. Activity of several proteins shown to be overexpressed in MDS, such as nuclear factor κ B (NF- κ B), AP1, and E2F1, is partly dependent upon the 26S proteasome that can be selectively inhibited by bortezomib (formerly PS-341). This agent has been approved in 2003 for use in patients

with relapsed multiple myeloma, and is currently being investigated in MDS trials.

Thirty-two patients with MDS were treated with bortezomib at Rush University Medical Center.²⁸ All patients were treated at 1.5 mg/m² once weekly for 4 weeks followed by a 2-week recovery. Twenty patients received at least two cycles; five patients (25%) had stable disease and seven (35%) showed a partial response. Further studies in MDS with bortezomib are awaited.

DNA TOPOISOMERASE I INHIBITOR:

TOPOTECAN (HYCAMTIN)

Topotecan binds to DNA topoisomerase I and stabilizes the complex formed between topoisomerase I and DNA, which leads to DNA strand breakage and cell death. This agent has been successfully used as a single-agent treatment and in combination for patients with AML and MDS. The noncumulative and reversible nature of its hematologic cytotoxicity is attractive for induction therapy.

The activity of single-agent topotecan was evaluated by Beran et al. in 60 patients with MDS or CMMoL.²⁹ The dose used was 2 mg/m² by continuous infusion for 5 days every 4–6 weeks for 2 courses, and then at 1–2 mg/m² for 5 days every 4–8 weeks for a maximum of 12 courses. Thirty-one percent of patients achieved a CR, including 8/11 with cytogenetic remissions. Those with no previous treatments had higher CRs (43%), but overall there were significant toxicities. These included severe mucositis and diarrhea, febrile neutropenia in 85%, and 47% patients had documented infections, with a mortality rate of 20% in the first 4 weeks. The median survival was 10.5 months, with a median remission duration of 7.5 months.

The same group used a combined regimen of topotecan at a lower dose (1.25 mg/m²) with cytarabine (1.0 mg/m²) in patients with MDS and CMMoL.³⁰ Fifty-six percent of patients had complete responses overall, with up to 72% CR in those with poor-prognosis karyotypes and secondary MDS. This regimen was much better tolerated, with fewer hematologic and nonhematologic toxicities. Lower response rates (33% CR and 38% PR) with topotecan and cytarabine have been reported in more recent trials.³¹ Forty-five MDS patients were treated at Rush University in Chicago, in a phase II trial using a combination of topotecan and thalidomide.³² Topotecan 2.0 mg/m² was given for 5 days every 21 days for three to five cycles, with thalidomide starting at 100 mg/day (maximum dose 300 mg) for a year. This lower dose of topotecan was well tolerated; only four patients discontinued therapy due to toxicity, and three patients died of infection/progressive disease. Of 38 evaluable patients, 20% had HI and 29% had stable disease. Responses were seen in all subtypes, and one third of patients showed a >50% reduction in bone marrow blasts.

ARSENIC TRIOXIDE

Arsenic trioxide (ATO), the active ingredient in Fowler's solution, has been used to lower white blood

cell counts since 1878. It remained in use until the advent of radiation therapy and the use of modern chemotherapeutic drugs. The drug re-emerged as an antileukemia agent in the 1990s, with the report from Chinese investigators that remissions of up to 90% were seen in patients with acute promyelocytic leukemia (APL).³³ The FDA approved ATO for use in relapsed/refractory APL in September 2001.

ATO has a wide spectrum of biologic activity, which makes it an ideal drug to use in the treatment of MDS. ATO binds to proteins with available sulfhydryl groups, causing disruption of the membrane potential of the mitochondria, releasing cytochrome c with subsequent activation of caspase effectors, and initiation of apoptosis. ATO has antiangiogenic properties, resulting in suppression of VEGF synthesis from myeloid cells, as well as significant antiproliferative activity, in part related to modulating cytokine release and interfering with cell-cycle progression. In addition, ATO can promote histone acetylation through activation of the mitogen-activated protein kinase (MAPK) signaling pathway, and can promote differentiation by modulating gene expression. It is also known to inhibit DNA methyltransferase, an important epigenetic target, as discussed above.

List et al. conducted a phase II study in which 53 MDS patients (median age 69) with both low/int-1 and int-2/high-risk groups received ATO 0.25 mg/kg, Monday to Friday for two consecutive weeks every 28 days. Response was evaluated every 8 weeks.³⁴ Hematologic responses were observed in 7 of 28 evaluable patients (25%). Responses were maintained for 2 months and often noted after 8–22 weeks after starting treatment. Immunosuppression was the primary adverse effect, although a small number of patients suffered from cardiac and pulmonary toxicities.

Similar results were reported by another group, who treated MDS patients on a slightly different regimen.³⁵ Here, ATO was given as a 1-h i.v. infusion, with a loading dose of 0.30 mg/kg/day for 5 days, and maintenance with 0.25 mg/kg/day twice weekly for 15 weeks or more. Patients were evaluated at 8 weeks. Eighty-one patients were enrolled with a median age of 67 years, of all IPSS groups. Hematologic responses, mostly erythroid, were achieved in 13 of 50 evaluable patients. There was a 5/19 (26%) response in low-risk and 8/31 (26%) response in high-risk patients. Once again, responses were seen after 6–22 weeks. Forty-four patients had stable disease for up to 6 months while on study.

Combinations of ATO with other agents

Combining ATO with the antiangiogenic agent thalidomide, Raza et al. has recently shown that several MDS patients harboring an *inv(3)(q21q26.2)* abnormality achieved trilineage responses.³⁶ This suggested that perhaps a gene(s) on chromosome 3 may be interacting with ATO to inhibit clonal proliferation. The human *EVI-1* gene, located at chromosome 3q25-q28, has been shown to inhibit transcription of *GATA-1*

target genes and impair responsiveness of erythroid precursors to erythropoietin.³⁶ This suggested that perhaps *EVI-1* deregulation has a role in the pathogenesis of MDS and/or response to this therapeutic regime. *EVI-1* was found to be abnormally expressed in five patients, with three out of five patients responding especially well to therapy.³⁷ Accordingly, *EVI-1* expression may be a useful preselection criterion for therapy with ATO +/- thalidomide.)

LOW-RISK MDS
